In an SC lossless integrator, the output referred noise density component due to the OTA is frequency limited by the GB product of the OTA. In order to avoid misunderstandings, in this section f_u (the unity-gain frequency of the OTA in hertz) is used instead of ω_u (in radians per second). Since f_u must be higher than the clock frequency, high-frequency noise is folded back into the integrator baseband. In the case of the SC integrator and assuming that the flicker noise is not folded back, the output referred spectral noise density becomes

$$V_{oeq1}^2 = \left(v_{eq1/f}^2 + 4KTR_{eqth}\left(1 + \frac{2f_u}{f_c}\right)\right)|1 + H(z)|^2 \tag{17.38}$$

where the folding factor is equal to f_u/f_c, f_c is the clock frequency and $H(z)$ is the z-domain transfer function of the integrator. The factor $2f_u/f_c$ is the result of both positive and negative folding. Typically, the frequency range of the signal to be processed is around and below the unity-gain frequency of the integrator, therefore $|H(z)| > 1$ and Equation 17.38 can be approximated as

$$V_{oeq1}^2 = \left(v_{eq1/f}^2 + 4kTR_{eqth}\left(1 + \frac{2f_u}{f_c}\right)\right)|H(z)|^2 \tag{17.39}$$

17.4.6 Noise due to the Switches

In SC networks, the switches are implemented with single or complementary MOS transistors. These transistors are biased in the cutoff and ohmic region for open and close operations, respectively. In cutoff region, the drain-source resistance of the MOS transistor is very high, then the noise contribution of the

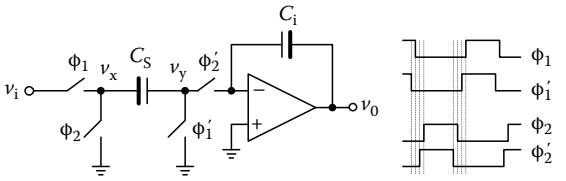

FIGURE 17.12 Typical switched-capacitor lossless integrator.

switch is confined to very low frequencies and it can be considered as dc offset. When the switch is in the on state, the transistor is biased in linear region and its spectral noise distribution is characterized by Equation 17.30. This noise contribution is the most fundamental limit for the signal-to-noise ratio of SC networks. The effects of these noise sources are better appreciated if an SC integrator is considered.

Let us consider the SC integrator of Figure 17.12 and assume that $\phi_1 = \phi_1'$ and $\phi_2 = \phi_2'$. The spectral noise density of the ϕ_1-driven switches are low-pass filtered by the on resistance of the switches R_{on} and the sampling capacitor C_s. The cutoff frequency of this continuous-time filter is given by $f_{on} = 1/(2\pi R_{on} C_s)$. Typically, f_{on} is higher than the clock frequency, therefore, the high-frequency noise is folded back into the baseband of the integrator when the SC integrator samples it. Taking into account the folding effects, the spectral noise density component of the switch-capacitor combination becomes

$$v_{eq2}^2 = 4kTR_{on}\left(1 + \frac{2f_{on}}{f_c}\right) \tag{17.40}$$

with R_{on} the switch resistance. Considering that the noise bandwidth is given by $2\pi f_{on} = 1/R_{on}C_S$, then the integrated noise level yields:

$$v_{eq-integrated}^2 = \frac{kT}{C_S}\left(1 + \frac{2f_{on}}{f_c}\right) \tag{17.41}$$

For the noise induced by the ϕ_2 driven switches, the situation is slightly different, but for practical purposes the same equation is used. According to Equation 17.41, the integrated noise power is inversely proportional to C_S. Therefore, for low-noise applications it is desirable to design the integrators with large capacitors. However, the costs for the noise reduction are larger silicon area and higher power consumption. This last result is because the slew rate of the OTA is inversely proportional to the load capacitance and in order to maintain the specifications it is necessary to increase the current drive capability of the OTA. Clearly, there is a trade-off between noise level, silicon area, and power consumption.

17.4.7 Clock Feedthrough

Another factor that limits the accuracy of SC networks is the charge induced by the clocking of the switches. These charges are induced by the gate-source capacitance, the gate-drain capacitance, and the charge stored in the channel. Furthermore, some of these charges are input signal dependent and introduce distortion in the circuit. Although these errors cannot be canceled, there are some techniques that reduce these effects.

The analysis of the clock feedthrough is not straightforward because it depends on the order of the clock phases, the relative delay of the clock phases, as well as the speed of the clock transition [13]. For instance, let us consider in Figure 17.12 the case when ϕ_1 goes down before ϕ_1'. This situation is shown in Figure 17.13a.

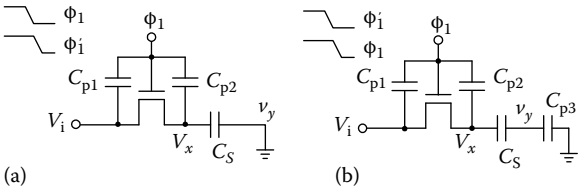

FIGURE 17.13 Charge induced due to the clocks. (a) If ϕ_1 goes down before ϕ_1' and (b) If ϕ_1' goes down before ϕ_1.

While C_{p1} is connected between two low-impedance nodes, C_{p2} is connected between ϕ_1, a low-impedance node, and v_x. For $\phi_1 > v_i + V_T$ the transistor is on and the current injected by C_{p2} is absorbed by the drain-source resistance; then v_x remains at a voltage equal to v_i. When the transistor is turned off, $\phi_1 < v_i + V_T$, charge conservation at node v_x leads to

$$v_x = v_i + \frac{C_{p2}}{C_S + C_{p2}}(\text{VSS} - v_i - V_T) \tag{17.42}$$

where VSS is the low level of ϕ_1 and ϕ_2. During the next clock phase, the charge of C_S is injected to C_i. Thus, C_{p2} induces a charge error proportional to $v_i C_{p2}/(C_S + C_{p2})$. In addition, an offset voltage proportional to VSS – V_T is also generated. Because the threshold voltage V_T is a nonlinear function of v_i, an additional error in the transfer function and harmonic distortion components appear at the output of the integrator. The same effect occurs when the clock phases ϕ_2 and ϕ_2' have a similar sequence.

Let us consider the case when ϕ_1' is opened before ϕ_1; the situation is shown in the Figure 17.13b. Before the transistors turn off, $v_x = v_i$ and $v_y = 0$. When the transistor is turned off, $\phi_1 < v_i + V_T$, the charge is recombined between C_S, C_{p2}, and C_{p3}. After the charge redistribution, the charge injected into C_{p3} is approximately given by

$$\Delta Q_{C_{p3}} = \frac{C_{p2}C_{p3}}{C_{p2} + C_{p3}}(\text{VSS} - v_i - V_T) \tag{17.43}$$

Notice that the current feedthrough generated by C_{p2} flows through both capacitors C_S and C_{p3}, hence $\Delta Q_{C_{p3}} = -\Delta Q_{C_s}$. During the next clock phase, both capacitors C_S and C_{p3} transfer the ideal charge $C_S v_i + \Delta Q_{C_s}$ and $\Delta Q_{C_{p3}}$, making the clock feedthrough induced error close to zero. The conclusion is that if the clock phase ϕ_1' is a bit delayed than ϕ_1 the clock-induced error is further reduced. This is also true for the clock phases ϕ_2 and ϕ_2'.

In Figure 17.12, the right-hand switch also introduces clock feedthrough, but unlike the clock feedthrough previously analyzed, this is input signal independent. When the clock phase ϕ_2 goes down, the gate-source overlap capacitor extracts from the summing node the following charge:

$$\Delta Q = C_{GS}(\text{VSS} - V_T) \tag{17.44}$$

In this case, V_T does not introduce distortion because v_y is almost at zero voltage for both clock phases. The main effect of this charge is to introduce an offset voltage. The same analysis reveals that the bottom right-hand switch introduces similar offset voltage. From the previous analysis it can be seen that using minimum transistors dimension can reduce the clock feedthrough. This implies minimum parasitic capacitors and minimum induced charge from the channel. If possible, the clock phases should be arranged for minimum clock feedthrough. The use of extra dummy switches driven by the complementary clock phase may alleviate the clock feedthrough issue, but its effectiveness must be carefully evaluated by postlayout simulations.

17.4.8 Channel Mobile Charge

Charge injection also occurs due to the mobile charge in the channel. If the transistor is biased in linear region, the channel mobile charge can be approximated by

$$Q_{ch} = C_{GS}(V_{GS} - V_T) \tag{17.45}$$

where C_{GC} is the gate-channel capacitor; see Figure 17.14.

When the switch is turned off this charge is released and part of it goes to the sampling capacitor. Fortunately, the previously discussed early clock phase technique for the reduction of clock feedthrough also reduces the effects of the channel mobile charge injection. The mobile charge injected to the sampling capacitor is a function of several parameters, e.g., input signal, falling rate of the clock, overlap capacitors, gate capacitor, threshold voltage, integrating capacitor, and the supply voltages.

The effects of the channel mobile charges are severe when the ϕ_1-driven transistor is opened before the ϕ_1'-driven transistor. In this case, the situation is similar to that shown in Figure 17.13a, in which one terminal of C_S is still grounded. While ϕ_1 is higher than $v_i + V_T$ the channel resistance is small and v_i absorbs most of the channel-released charge. For $\phi_1 < v_i + V_T$, the channel resistance increases further and a substantial amount of charge released by the channel will flow through C_S, introducing a charge error. If the clock phases are arranged as shown in Figure 17.13b, most of the charge released by the channel returns back to v_i. The main reason is because the equivalent capacitor seen at the right-hand side of the transistor is nearly equal to C_{p3}, if C_{p2} is neglected, making this a high-impedance node. Because this parasitic capacitor is smaller than the sampling capacitor, a small amount of extracted (or injected) charge will produce a huge variation on v_y, see Figure 17.13b, pushing back most of the mobile charges. Equation 17.45 shows that the mobile charge is a function of V_{GS} ($=V_{clock} - V_{in}$ for the sampling switch), hence the part of the charge injected into the sampling capacitor is signal dependent. This issue can be alleviated if the clock is correlated with the incoming signal such that VGS is maintained constant using charge pumps circuits; the technique proposed in Ref. [14] implements this concept.

17.4.9 Dynamic Range

The dynamic range is defined as the ratio of the maximum signal that the circuit can drive without significant distortion to the noise level. The maximum distortion tolerated by the circuit depends on the application, but −60 dB is commonly used. Since the linearity of the capacitor is good enough and if the harmonic distortion components introduced by the OTA input stage are small, the major limitation for

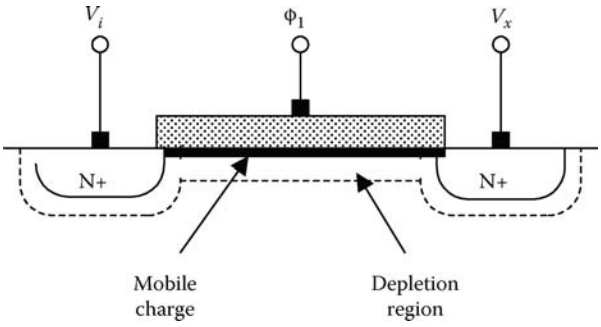

FIGURE 17.14 Cross section of the MOS transistor showing the mobile charge.

the linearity is determined by the output stage of the OTA. For the folded cascode OTA of Figure 17.11 this limit is

$$v_{\text{omax}} \cong V_{\text{R2}} + V_{\text{TP3}} \tag{17.46}$$

If the reference voltage V_{R2} is maximized, Equation 17.46 yields

$$V_{\text{omax}} \cong V_{\text{DD}} - 2V_{\text{DSATP}} \tag{17.47}$$

A similar expression can be obtained for the lowest limit. Assuming a symmetrical single-side output stage, from Equation 17.47, the maximum rms value of the OTA output voltage is given by

$$v_{\text{oRMS}} \cong \frac{V_{\text{DD}} - 2V_{\text{DSATP}}}{\sqrt{2}} \tag{17.48}$$

If the in-band noise, integrated up to $\omega = 1/R_{\text{int}}C_{\text{I}}$, is considered and if the most important term of Equation 17.41 is retained, the dynamic range of the single-ended SC integrator becomes

$$\text{DR} \cong \frac{(V_{\text{DD}} - 2V_{\text{DSATP}})}{\sqrt{2}\sqrt{2kT/C_{\text{S}}}} = \frac{(V_{\text{DD}} - 2V_{\text{DSATP}})}{2\sqrt{kT}}\sqrt{C_{\text{S}}} \tag{17.49a}$$

For this equation, the alias effects have been neglected and only the noise contribution of the switches driven by ϕ_1 and ϕ_2 are considered. At room temperature, this equation is reduced to the following expression:

$$\text{DR} \cong 7.9 \times 10^9 \sqrt{C_{\text{S}}}(V_{\text{DD}} - 2V_{\text{DSATP}}) \tag{17.49b}$$

According to this result, the dynamic range of the SC integrator is reduced when the power supplies are scaled down and minimum capacitors are employed. Clearly, there is a trade-off between power consumption, silicon area, and dynamic range. As an example, for the case of $C_{\text{S}} = 1.0$ pF and supply voltages of ± 1.5 V and $V_{\text{DSATP}} = 0.25$ V, the dynamic range of a single integrator is around 78 dB. For low-frequency applications, however, the dynamic range is lower due to the low-frequency flicker noise component. This is a very optimistic result since neither the op-amp noise not aliasing effects nor other noise sources were considered.

17.5 Design Considerations for Low-Voltage Switched-Capacitor Circuits

For the typical digital supply voltages, 0−5 V, SCs achieve dynamic ranges of the order of 80–100 dB. As long as the power supplies are reduced, the swing of the signal decreases and the switch resistance increases further. Both effects reduce the dynamic range of the SC networks. A discussion of these topics follows.

17.5.1 Low-Voltage Operational Amplifiers

The design techniques for low-voltage low-power amplifiers for SC circuits have been addressed by several authors [4,7–9,11–13]. The implementation of op-amps for low-voltage applications does not seem to be a fundamental limitation as long as the transistor threshold voltage is smaller than $(V_{\text{DD}} - V_{\text{SS}})/2$. This limitation will become clear in the design example presented in this section.

The design of the operational amplifier is strongly dependent on the application. For high-frequency circuits, the folded cascode op-amp is suitable, but the cascode transistors limit the swing of the signals at the output stage. If large output voltage swing is needed, complementary stages are desirable. To illustrate the design trade-offs involved in the design of a low-voltage OTA, let us consider the folded cascode OTA of Figure 17.11. For low-voltage applications and small signals, the transistors have to be biased with very low V_{DSAT} $(=V_{GS} - V_T)$.

For the case of supply voltages limited to ± 0.75 V and $V_T = 0.5$ V, $V_{DSAT1} + V_{DSAT6}$ must be lower than 0.25 V, otherwise the transistor M_6 goes to the triode region. For large signals, however, the variations of the input signal produce variations at the source voltage of M_1. It is well known that linear range of the differential pair is of the order of $\pm 1.4\ V_{DSAT1}$. Hence, if the noninverting input of the OTA is connected to the common-mode level V_{CM}, for proper operation of the OTA input stage (see Figure 17.11) it is desirable to satisfy

$$V_{CM} - V_T - \text{VSS} > 1.4V_{DSAT1} + V_{DSAT6} \tag{17.50}$$

It has to be taken into account that the threshold voltage of M_1 increases if an N-well process is used, due to the body effects. In critical applications, PMOS transistors fabricated in a different well with their source tied to their own well can be used. Equation 17.50 shows that it is beneficial to select a proper common-mode level V_{CM} to extend the linear range of the amplifier input stage, especially for low-voltage applications.

The dimensioning of the transistors and the bias conditions are directly related to the application. For instance, if the SC integrator must slew 1 V into 4 μs and the load capacitor is of the order of 10 pF, the OTA output current must be equal to or higher than 2.5 μA. Typically, for the folded cascode OTA the dc current of both output and input stages are the same. Therefore, the bias current for M_1, M_3, M_4, and M_5 can be equal to 2.5 μA. The bias current for M_2 and M_6 is 5 μA. If $V_{GS1} - V_{T1}$ is fixed at 100 mV the dimensions of M_1 can be computed according to the required small signal transconductance. Similarly, the dimension of the other transistors can be calculated, most of them designed to maximize the output swing and dc gain. A very important issue in the design of low-voltage amplifiers is the reference voltage. In the folded cascode of Figure 17.11, the values of the reference voltages V_{R1} and V_{R2} must be optimized for maximum output swing. OTA design techniques are fully covered in Refs. [11] and [13].

17.5.2 Analog Switches

For low-voltage applications, the highest voltage that can be processed is limited by the analog switches rather than by the op-amps. For a single NMOS transistor, the switch resistance is approximately given by

$$R_{DS} = \frac{1}{\mu_n C_{OX} \frac{W}{L}(V_{GS} - V_T)} \tag{17.51}$$

where μ_n and C_{OX} are technological parameters. According to Equation 17.51, the switch resistance increases further when V_{GS} approaches to V_T. This effect is shown in Figure 17.15 for the case $V_{DD} = -V_{SS} = 0.75$ V and $V_T = 0.5$ V. From this figure, the switch resistance is higher than 300 kΩ for input signals of 0.2 V. However, for a drain-source voltage higher than $V_{GS} - V_T$ the transistor saturates and does not behave as a switch anymore. This limitation clearly reduces further the dynamic range of the SC circuits.

A solution for this drawback is to generate the clocks from higher voltage supplies. A simplified diagram of a voltage doubler is depicted in Figure 17.16a. During the clock phase ϕ_1, the capacitor C_1 is charged to V_{DD} and during the next clock phase its negative plate is connected to V_{DD}. Hence, at the

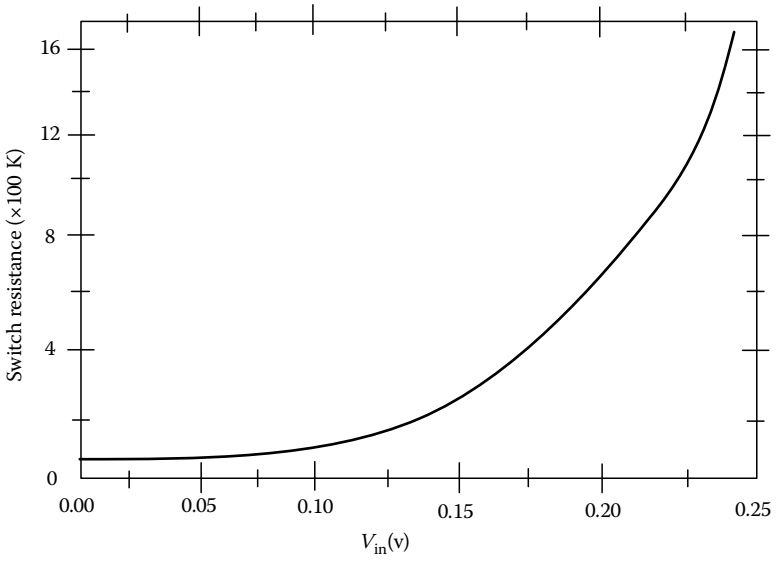

FIGURE 17.15 Typical switch resistance for an NMOS transistor.

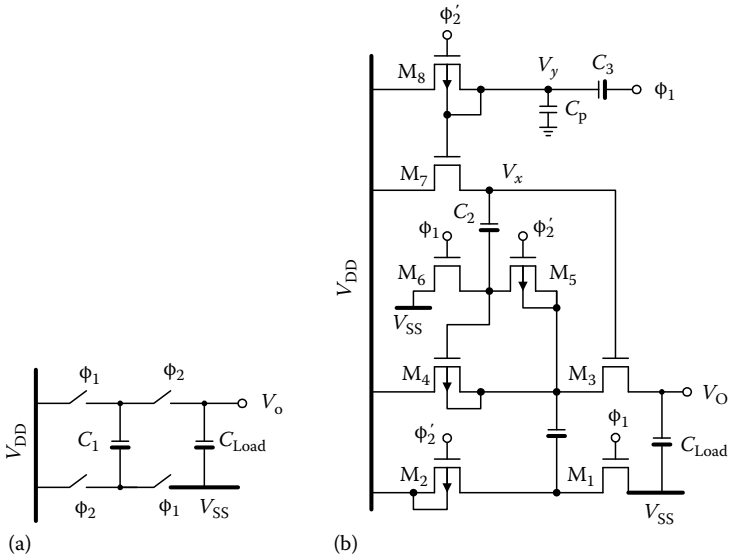

FIGURE 17.16 Voltage doubler. (a) Simplified diagram and (b) transistor level diagram.

beginning of ϕ_2, the voltage at the top plate of C_1 is equal to $2V_{DD} - V_{SS}$. After several clock cycles, if C_{LOAD} is not further discharged, the charge is recombined leading to an output voltage equal to $2V_{DD} - V_{SS}$. A practical implementation for an N-well process is shown in Figure 17.16b.

In this circuit, the transistors M_1, M_2, M_3, and M_4 behave as the switches S_1, S_2, S_3, and S_4 respectively, of Figure 17.16a. While for M_1 and M_2 the normal clocks are used, special clock phases are generated for M_3 and M_4 because they drive higher voltages. The circuit operates as follows.

During ϕ_1, M_8 is opened because ϕ_2' is high. The voltage at node v_y is higher than V_{DD} because the capacitors C_3 and C_p were charged to V_{DD} during the previous clock phase ϕ_2 and, when ϕ_1 goes up, charge is injected to the node through the capacitor C_3. Since v_y is higher than V_{DD}, M_7 is turned on. The bottom plate of C_2 is connected to V_{SS} by M_6 and C_2 is charged to $V_{DD}-V_{SS}$.

During ϕ_2, the refresh clock phase, the bottom plate of C_1 is connected to V_{DD} by the PMOS transistor M_2. Note that if an NMOS transistor is employed, the voltage at the bottom plate of C_1 is equal to $V_{DD}-V_T$, resulting in lower output voltage. During ϕ_2 if C_1 is not discharged, the voltage at its top plate is $2V_{DD} - V_{SS}$. The voltage at node v_x becomes close to $3V_{DD}-2V_{SS}$ volts, turning M_3 on and enabling the charge recombination of C_1 and C_{LOAD}. As a result, after several clock periods, the output voltage v_o becomes equal to $2V_{DD}-V_{SS}$. To avoid discharges the gate of M_4 is connected to the bottom plate of C_2. Thus, M_4 is turned off during the refresh phase. An efficient solution using boosted clock switches is described in Ref. [14]. Another technique using switched op-amps, described in Ref. [15], have been also successfully used.

17.6 Fully Differential Filters

An important issue when designing a high-frequency filter is the proper selection of the clock phases for the switches. It is desirable that the input to each integrator is as close as possible to a step function, and to minimize the loading capacitors during the integration clock phase. Making the OTAs to perform the hold and integrate functions at alternate phases ensure this. Unfortunately this approach cannot be implemented in the conventional single-ended topologies unless an additional inverter is added to the loop. Two backward integrators with a half-delay in each and by crossing the outputs of the fully differential integrators in order to have an odd number of inversions in the loops is one of the best configurations for high-frequency applications as depicted in Figure 17.17. The first op-amp may process the information

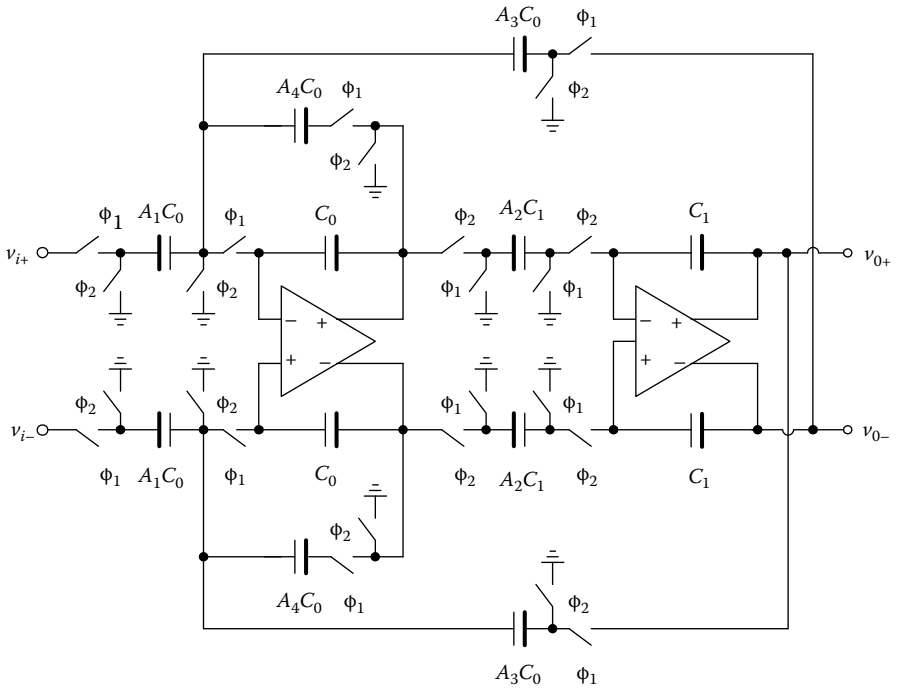

FIGURE 17.17 Fully decoupled, fully differential biquadratic filter.

during ϕ_1 and hold it during ϕ_2 while the second op-amp do the same functions during the complementary clock phases. In general, having the differential outputs available makes the system more flexible and gives several advantages while designing high-performance analog signal processors.

Fully differential amplifiers are widely used technique to reduce the effect of charge injection, clock feedthrough, and better rejection to common-mode signals such as substrate and power supply noise and an improved dynamic range when compared to single-ended circuits. As long as the noise present at the output of the amplifier is present in both outputs of the amplifier with the same amplitude and same phase, it will be rejected by the differential nature of the following stage. In addition, an additional loop that operates on the common-mode signals presents low output impedance for these signals, it fix the operating point of the differential outputs at the desired level and further minimizes the common-mode output fluctuations up to the unity-gain frequency of the loop. Their disadvantage comes from the fact that they require a common-mode feedback (CMFB) circuit.

The fully differential version of the folded cascode amplifier is depicted in Figure 17.18a. It requires the same amount of power as the single-ended version shown in Figure 17.11. Since the current mirror present in the single-ended amplifier for the conversion of the fully differential current of the differential pair into single-ended output is eliminated, the fully differential amplifier has a single internal pole located at the source terminal of M_3. Since several parasitic poles and phantom zeros are eliminated, the fully differential amplifier has inherently better phase margin than its single-ended counterpart. The circuit is fully symmetric and any noise injected through M_0 is evenly split by the differential pair and will appear at the two outputs as a pure common-mode signal. The common-mode noise present at the transistors M_1 is further attenuated by the small sensitivity of the differential pair to common-mode

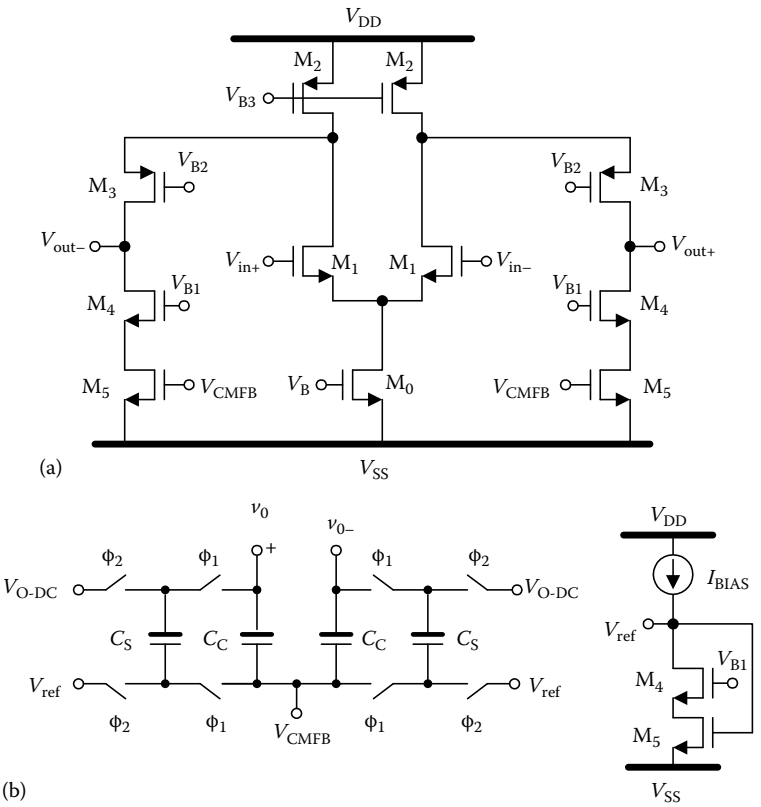

FIGURE 17.18 (a) Fully differential folded cascode amplifier and (b) switched-capacitor based CMFB circuit.

signals; the small common-mode current resulting at the drain of M_1 will be reflected at the output as a common-mode signal. Similarly, any V_{DD} noise generates a current noise through M_2 that appears as a common-mode noise at both outputs of the amplifier; notice that to minimize these components V_{B3} must be further attached to V_{DD}. V_{SS} noise generates current that appears at the output as common-mode noise, as well thanks to the differential nature of the topology. The gate voltage of transistors M_5 is used to accommodate the control of the CMFB loop; V_{B3} can also be used for that purpose.

The CMFB is a block that extracts the common-mode signal present at both outputs and compares its dc value with a reference voltage in a loop with enough gain for the common-mode signals. If the loop has enough gain, the error between the detected common-mode signal and the reference voltage is minimized forcing the common-mode output signals (DC operating point of each amplifier output) to be at the reference level. Several CMFB circuits have been proposed in the literature [4,11,12] but for SC applications it has been preferred to use SC-based CMFB (SC–CMFB) circuits [4] since they do not consume significant power and have better linearity when compared to their continuous-time counterpart. The CMFB circuits consist of a common-mode voltage detector (output is proportional to $\frac{v_{out+}+v_{out-}}{2}$ and a circuit that generates the common-mode error after comparing the common-mode output voltage and a proper and stable reference voltage. The efficient SC detector, shown in Figure 17.18b, uses two SC resistors (C_C and switches) that detect the common-mode output voltage and compare it with $V_{O\text{-}DC}$ [4,9,13]. Using conventional charge redistribution analysis and ignoring the effect of C_C, the voltage at node V_{CMFB} during ϕ_1 is given by

$$V_{CMFB} = \left(\frac{v_{out+} + v_{out-}}{2} - V_{O-DC}\right) + V_{ref} \tag{17.52}$$

The circuit makes the comparison of the common-mode output voltage and the desired output DC level $V_{O\text{-}DC}$. A remarkable advantage of this circuit is that in addition to the desired comparison, it translates the ideal voltage V_{ref} needed at the gate of M_5 to generate the DC current in transistors M_5. In steady state, V_{CMFB} will be very close to V_{ref}. Equation 17.52 is also valid for the common-mode noise; in the absence of noise in V_{ref} and $V_{O\text{-}DC}$, the common-mode output noise is compared with zero and for the frequencies where the CMFB loop is high, it is suppressed, thanks to the feedback. Hence it is desirable not only to have large low-frequency gain but wide-band CMFB loop to reject high-frequency noise as well.

Since the SC resistors and the parasitic capacitors generate a relatively low-frequency pole at V_{CMFB} node, the capacitors C_S are added to introduce a compensating zero that helps with the stabilization of the CMFB loop. One of the drawbacks of this topology is that the common detector loads significantly the output of the amplifier, reducing its unity-gain frequency and slew rate. The value of C_S is typically one-quarter to one-tenth of C_C. To prevent significant offset voltages due to charge injection from the switches, C_S is commonly chosen to be greater than 200 fF. Therefore, the capacitive loading on the amplifier due to the CMFB can go from 1 pF to 2 pF in most designs. As demonstrated in Ref. [16] this SC–CMFB suffers of poor rejection to the supply noise used as reference for the common-mode loop. This can be partially alleviated by combining passive common-mode detector and active signal comparator at the expenses of additional power consumption or using continuous-time CMFB systems.

17.7 Design Examples

17.7.1 Biquadratic Filter

In this section, a second-order bandpass filter (BPF) is designed. The specifications for this biquad are

Center frequency 1.6 kHz
Quality factor 16
Peak gain 10 dB
Clock frequency 8 KHz

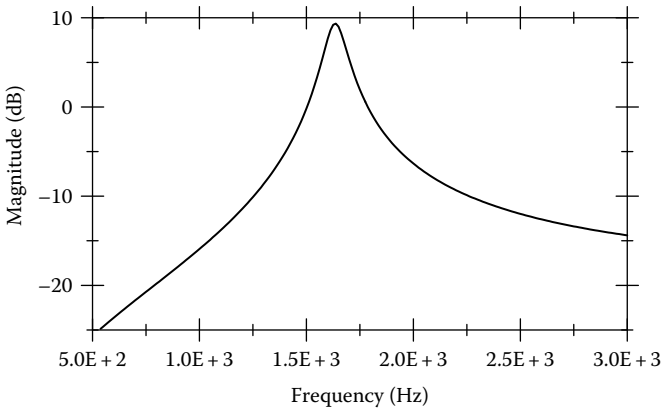

FIGURE 17.19 Frequency response of the second-order bandpass filter.

A transfer function in the z-domain that realizes this filter is given by the following expression:

$$H(z) = \frac{0.1953(z-1)z}{z^2 + 0.5455z + 0.9229} \tag{17.53}$$

The equivalent $H(s)$ is obtained and then mapped into the z-domain using the LDI transformation. This transfer function can be implemented by using the biquads presented in Section 17.2. For the biquad of Figure 17.10, and employing $A_1 = A_4 = A_7 = 0$, the circuit behaves as a BPF. Equating the terms of Equation 17.53 with the terms of Equation 17.19, the following equations are obtained:

$$\begin{aligned} A_6 &= \frac{1}{0.9229} - 1 \\ A_5 &= \frac{0.1953}{0.9229} \\ A_2A_3 &= 2 + A_6 - \frac{0.5455}{0.9229} \end{aligned} \tag{17.54}$$

Solving these equations, the following values are obtained: $A_6 = 0.0835$, $A_5 = 0.2116$, and $A_2A_3 = 1.4924$. A typical design procedure employs $A_2 = 1$. For this case, after node scaling the total capacitance is of the order of 32 unit capacitances. The frequency response of the filters is shown in Figure 17.19.

17.7.2 Sixth-Order Bandpass Ladder Filter

In this section, the design procedure for a sixth-order BPF based on an RLC prototype is considered. The ladder filters are very attractive because of their low passband sensitivity to tolerances in the filter components. Let us consider the following specifications:

Center frequency 100 kHz
Bandwidth 2.5 kHz
Passband ripple $<$0.5 dB
Clock frequency 2 MHz

The design starts with an RLC low-pass prototype, see Figure 17.20.

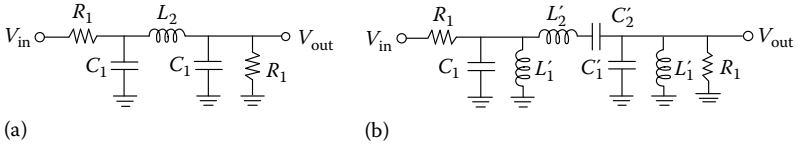

FIGURE 17.20 RLC prototypes. (a) Third-order low-pass filter and (b) sixth-order bandpass filter.

The values of the components for a prototype with 1 rad/s passband frequency can be obtained from tables or computed from well-known expressions. For this example, the passive components are $R_1 = 1\ \Omega$, $C_1 = 1.5963$ F, and $L_2 = 1.0967$ H. Using the low-pass to bandpass transformation, the capacitor C_1 is transformed into a parallel of a capacitor and an inductor. The values of the resulting components are

$$C_1' = \frac{C_1}{BW}$$
$$L_1' = \frac{1}{\omega_0^2 C'} \tag{17.55}$$

where ω_o and BW are the center frequency in radians per second and the filter bandwidth in radians per second, respectively. The inductor L_2 is transformed in a series of an inductor and a capacitor whose values become

$$L_2' = \frac{L_2}{\text{BW}}$$
$$C_2' = \frac{1}{\omega_0^2 L_2'} \tag{17.56}$$

The bandpass prototype is shown in Figure 17.20b. Before making the denormalizations it is desirable to transform the passive prototype to an active implementation. The grounded LC tank circuit can be simulated by the RC active implementation shown in Figure 17.21.

The value of the simulated inductance is

$$L_1' = R_1^2 C_1' \tag{17.57}$$

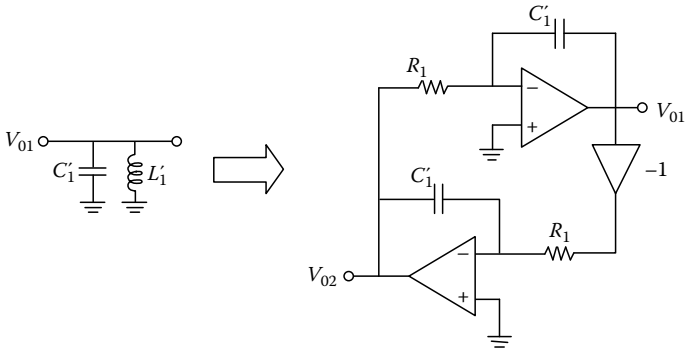

FIGURE 17.21 RC active implementation of a grounded LC tank circuit.

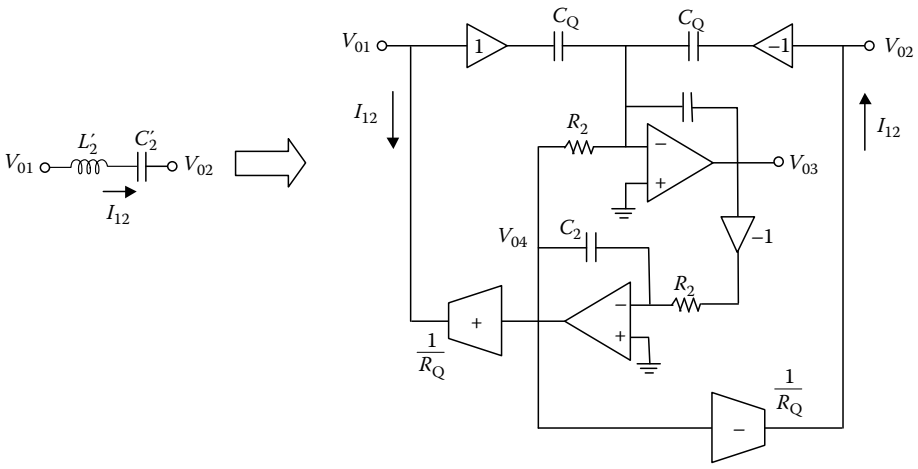

FIGURE 17.22 RC active implementation of a floating LC tank circuit.

It is important to note that the output of the active-RC circuit is a low-impedance node. Therefore, the inverting input of the op-amps must be used for current injection. Similarly, the circuit shown in Figure 17.22 can simulate a floating resonator. Obviously, this is an expensive implementation but typically several active elements can be shared in the final design. Using typical circuit analysis techniques it can be shown that i_{12} for the passive LC tank is related to the components by the following expression:

$$i_{12} = \frac{sC_2'}{1 + s^2 L_2' C_2'}(v_{o1} - v_{o2}) \tag{17.58}$$

and for the active implementation

$$i_{12} = \frac{\left(\frac{R_2}{R_Q} C_Q\right)s}{1 + s^2 R_2^2 C_2^2}(v_{o1} - v_{o2}) \tag{17.59}$$

Comparing Equations 17.57 and 17.58, the active and passive implementations are equivalents if the following constraints are satisfied:

$$C_2' = \frac{R_2}{R_Q} C_Q \tag{17.60}$$

$$L_2' C_2' = R_2^2 C_2^2 \tag{17.61}$$

Obviously, the resistors R_2 can be replaced by SC equivalents. Using these building blocks, the implementation of the sixth-order BPF is straightforward. The sixth-order SC BPF is shown in Figure 17.23. The implementation of the $L_1' C_1'$ tank circuit is straightforward from Figure 17.21. The resonant frequency of the SC resonator is determined by the capacitors θC_1. The node voltage v_{o1} is taken at the output of the first op-amp. The input resistor is implemented by the capacitor C_R and its associated switches. In Figure 17.23, the resonator associated with v_{o3} and v_{o4} and the capacitors C_Q implement the $L_2' C_2'$ floating tank circuit. The final step of the design is to compute the values of the components. A simplified design follows, but more detailed procedures are presented in Refs. [1,2,6].

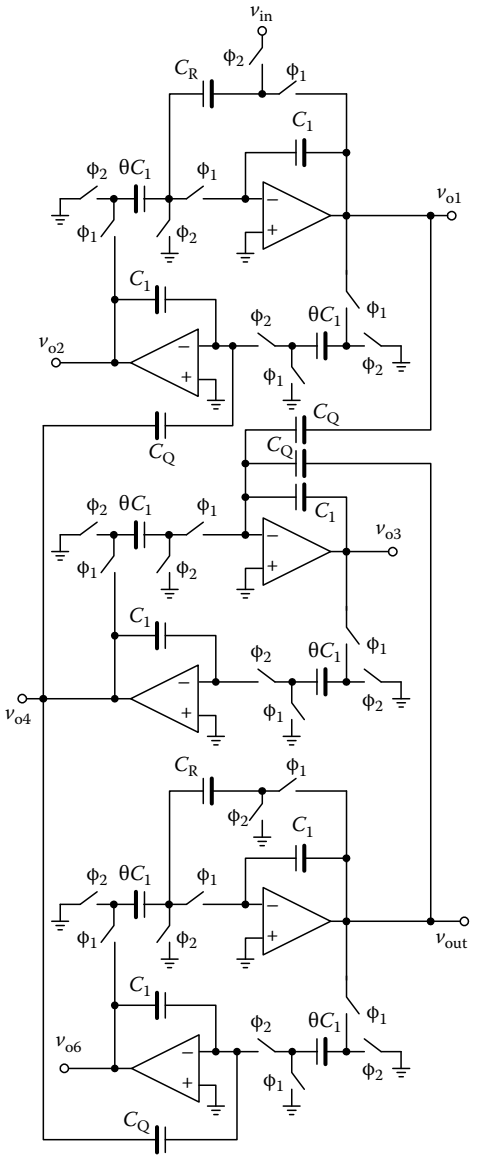

FIGURE 17.23 Sixth-order bandpass ladder filter.

The loops of the SC filter implementation are of the lossless discrete integrator (LDI) type and the resistors are of the serial type. Hence, if an LDI prewarping scheme is used the analog center frequency of the filter should be mapped to the desired value, mainly for high-Q filters wherein the interaction between resonators is very small. Since the resistors are not LDI, a distortion in the quality factor of the filter sections occurs, thus increasing the passband ripple. The LDI transformation relates the analog and discrete frequencies by the following expression [1,6]:

$$\omega_{\text{analog}} = 2f_c \sin\left(\frac{\omega_{\text{discrete}}}{2f_c}\right) \tag{17.62}$$

Applying the LDI transformation to the center frequency of the filter, the predistorted center frequency is equal to 99,056 kHz. Using this prewarped frequency and Equations 17.54 through 17.61, the following component values are obtained:

$$R_1 = 1\ \Omega$$
$$C_1' = 1.01623 \times 10^{-4}\ \text{F}$$
$$L_1' = 2.51316 \times 10^{-8}\ \text{H}$$
$$C_2' = 3.65803 \times 10^{-8}\ \text{F}$$
$$L_2' = 6.98181 \times 10^{-5}\ \text{H}$$

In addition, the continuous-time and SC resistors are approximately related by the following expression:

$$C_{\text{eq}} \cong \frac{1}{f_c R_{\text{cont}}} \tag{17.63}$$

In the SC filter, the transconductor $1/R_Q$ is implemented by C_Q/C_1R. Hence, the final values of the capacitors are

$C_R = 0.0738$ pF
$C_1 = 15.000$ pF
$\theta C_1 = 4.6900$ pF
$C_Q = 0.2833$ pF

While the filter center frequency of this design is accurate, the passband ripple is increased to around 0.8 dB instead of 0.5 dB. This is because the resistors used in the terminals of the filter are not implemented as LDI resistors. However, this effect can be partially corrected adjusting the resonant frequency of the second loop. If θC_1 is equal to 4.685 pF for the second resonator, the ripple is decreased to around 0.55 dB. The results for this case are shown in Figure 17.24.

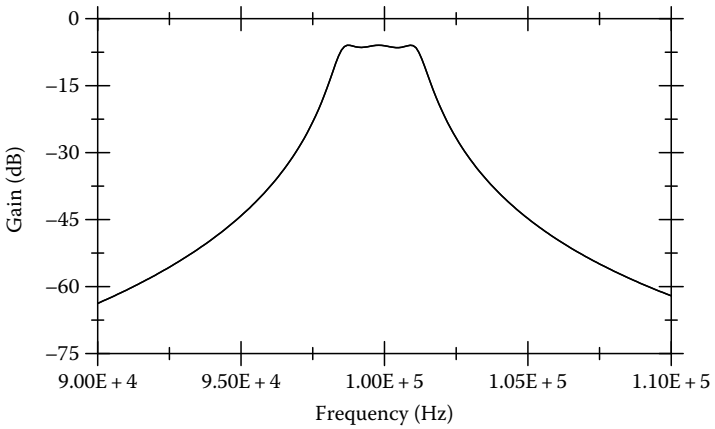

FIGURE 17.24 Frequency response for the sixth-order bandpass filter.

17.7.3 Programmable Switched-Capacitor Filter

In most of the programmable filters, the important parameters are the resonant frequencies, the pole-quality factor, and sometimes, the peak gain. Thus, programmable low-pass, bandpass, high-pass, and bump equalizers are typically designed. Nevertheless, in some applications it is more important to control the gain at the frequency bands instead of that at the resonant frequency, the quality factor, or the peak gain. A typical approach for the implementation of these systems is to employ a parallel of a low-pass, bandpass, and a high-pass filter with programmable peak gain. For a second-order system, the implementation of this approach needs at least six operational amplifiers, three capacitor banks, and the implementation of six poles. Therefore, the number of switches, the power dissipation, and the silicon area needed for these structures are considerable. Another approach follows in this section.

In order to independently control the low-, medium-, and high-frequency bands it is required to realize the following transfer function:

$$H(s) = \frac{K_1 s^2 + K_2 \mathrm{BW} s + K_3 \omega_o^2}{s^2 + \mathrm{BW} s + \omega_o^2} \tag{17.64}$$

where BW and ω_o are the bandwidth and the frequency of the poles, respectively. The control of the frequency bands is carried out by the parameters K_1, K_2, and K_3. From Equation 17.64 it is clear that the dc gain and the high-frequency gain are equal to K_3 and K_1, respectively. A disadvantage of this expression is the lack of good control in the medium frequencies. If K_1 is equal to K_3, the filter gain at the resonant frequency depends on K_2. However, for the general case it is affected by the parameters K_1 and K_3. In addition, the shape of the transfer function is not well behaved for moderate- and high-Q applications. The behavior of the transfer function is improved if the following equation is employed:

$$H(s) = K_1 \left(\frac{s^2 + K_2 K_3 \mathrm{BW} s + K_3 \omega_o^2}{s^2 + K_1 \mathrm{BW} s + K_1 \omega_o^2} \right) \tag{17.65}$$

For low and high frequencies the behavior of this equation is similar to that of Equation 17.64. At medium frequencies the behavior of the transfer function is better controlled by the parameter K_2 than

for the case of Equation 17.64. For the medium-frequency band, the gain is related to the product K_2K_3 instead of the absolute value of K_2. Therefore, the effect of parameter K_2 on the transfer function is related to K_3.

A block diagram representation of Equation 17.65 is presented in Figure 17.25. In this figure, the filter bandwidth BW is equal to ω_o/Q, with Q equal to the quality factor of the filter. The control parameters are the gain factors K_1, K_2, and K_3. The implementation of this block diagram can be carried out by using various techniques, e.g., OTA-C, MOSFET-C, or SC. An SC implementation is shown in Figure 17.26. For high-sampling rate $2\pi f_c \gg \omega_o$, the capacitors θC_I are related with the pole frequency by the equation $\theta = \omega_o T$. The capacitor banks control the gain of the three frequency bands. For the computation of the total capacitance, the capacitors can be associated in the following groups: the first group (K_3C_1, C_1), second group (θC_2, K_2C_2/Q, C_2), and third group ($\theta C_3/Q$, θC_3, C_3/K_1, C_3).

The versatility of the topology is shown in Figure 17.27. For these results, the following design parameters have been employed: clock frequency = 128 kHz, $\omega_o = 6.2832 * 350$ rad/s, and $Q = 0.5$. For Figure 17.26, the parameter K_3 is equal to 10, fixing the low-frequency gain at 20 dB. The medium-frequency band is controlled by the parameter K_2, which corresponds to the values 0.5 (attenuation of 6 dB), 1 (0 dB attenuation), and 2 (gain of 6 dB). The high-frequency gain is controlled by the parameter K_1, which corresponds to the values 1, 2.5, 5, and 10, giving a high-frequency gain of 0, 8, 14, and 20 dB, respectively.

17.7.4 Switched-Capacitor Filters with Reduced Area

Most of the high-performance filters, sigma–delta modulators, and data converters are based on SC techniques [11,13]. Several architectures for narrow-band applications have been reported; many of them use several paths to relax the OTA specifications. In this approach two biquadratic filters connected in parallel running at $f_s/2$ each but acting in complementary clock phases lead to filters working at twice the clock speed. Gain-compensated single-stage OTAs and double sampling techniques are also available for the design of efficient narrow-band (highly selective) filters.

For high-Q filters, the scenario is even more complex because large capacitive spreads (proportional to Q) are required. Area efficient high-Q filters require special design strategies such as judiciously use of partial positive feedback and use of slower clocks in critical filter building blocks. The use of slower clocks allows us to reduce the capacitive spread as well. The resistance of an SC resistor driven by periodic clocks is approximately given by T/C $(=1/f_sC)$. If the signal is sampled once every N-periods, the equivalent resistance increases by a factor of N [17]. The basic idea of this approach is shown in Figure 17.28 for the case $N = 4$; the frequency of the clock phases ϕ_{11} and ϕ_{22} is $f_s/4$. Each time A_2C_0 is activated, small amount of charge is taken by the capacitor controlling the losses of the lossy integrator.

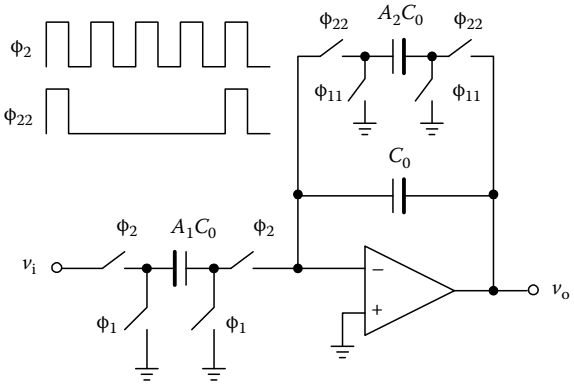

FIGURE 17.28 SC lossy integrator using a slower clock to reduce capacitor area.

If this technique is used for high-Q applications ($A_2 \ll 1$), those losses generate some spurious tones as well, but usually they are very small [17–18]. This approach results in lower capacitance spread without sacrificing sensitivity of critical filter parameters to component variations. The combination of several design techniques results in significant reduction in the total capacitance savings both silicon area and power consumption [18]. As a consequence of the use of slower clocks, additional alias components appear at integer multiples of f_s/N that may limit the filter's performance and increase the requirements on the antialias filter that precedes the SC network. It is critical to estimate the amount of alias components when using these techniques.

17.7.5 Spectrum Analyzer Using Switched-Capacitor Techniques

The growth in complexity and number of functions that can be integrated on a single chip have increased rapidly in the last years, making the testing a difficult task. Even though the majority of these systems are mainly digital, the analog section is always an important part of such mixed-mode architectures. Testing in analog circuits faces many problems; e.g., sweeping frequency and amplitude, measurement of magnitudes, and phase for a number of frequencies. Spectrum and network analyzers are routinely used for the characterization of mixed-mode systems. A cheap on-chip spectrum analyzer has been developed in Ref. [19]. Due to the flexibility of SC techniques, a gracious synchronization is ensured between the frequency of the input stimuli f_{in} and the center frequency of the circuits that perform the measurements, controlled by clocks ϕ_1 and ϕ_2.

A conceptual schematic diagram of the base-band SC network analyzer is shown in Figure 17.29. It consists of a digital frequency synthesizer, an SC sinewave generator, two VGAs, an SC BPF, and an analog-to-digital converter. The frequency synthesizer generates the master clock used as the sinusoidal generator sampling frequency as well as the nonoverlapping clock phases for the SC blocks. The sinewave generator, based on SC techniques, delivers a sinusoidal signal with a frequency of 1/16 of the master clock frequency. The amplitude of the signal coming from the sinusoidal generator is adjustable to provide the proper level to the stimuli. The output of the device under test (DUT) is bandpass filtered and conditioned by the second VGA to accommodate it to the proper input range of the ADC. The narrowband SC filter is a key building block of the spectrum-vector analyzer, its function is twofold: one, it can be centered at the center frequency f_0 to obtain the DUT transfer function; second, to select the proper frequency component (f_0, $2f_0$, $3f_0$,) for harmonic distortion characterization. The main advantage of this system is its inherent synchronization between the sinewave input signal and center frequency of the BPF.

The sinewave generator is based on SC circuits, with an oscillating frequency equal to $f_s/16$, where f_s is the clock frequency generated by the digital frequency synthesizer. Figure 17.30 shows the schematic diagram of a flexible sinewave generator using an SC circuit. It consists of a programmable gain amplifier whose preset gain stages correspond to the values of an ideal sampled and held sinewave. The SC circuit has four different gain stages, which generate a sinusoidal output with 16 steps per period generated from four capacitors and two reference voltages. The switch *PZ* sets the zero of the sinusoidal waveform.

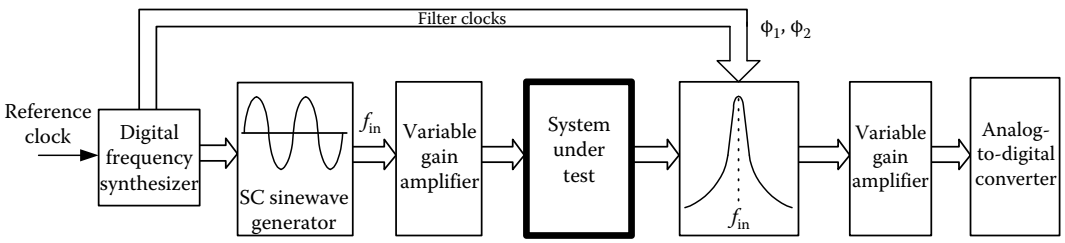

FIGURE 17.29 On-chip spectrum/vector analyzer block diagram using switched-capacitor techniques.

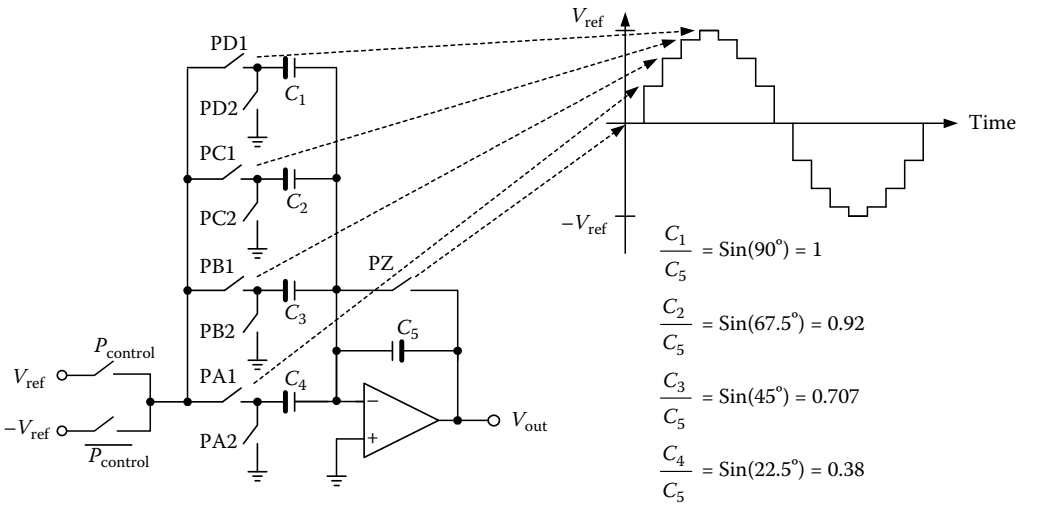

FIGURE 17.30 SC amplifier used to generate the discrete sinewave with low distortion.

The switches PA1 through PD1 are closed sequentially with each clock cycle to generate the first quarter-period of the sinusoidal waveform. Once the maximum value is obtained, the switches close in the opposite direction (from PD1 to PA1) in order to generate the second quarter-period. In the second zero crossing, $P_{control}$ switches from V_{ref} to $-V_{ref}$ so the lower half of the signal is generated. The capacitors are weighted such that the ideal values of a discrete sinewave signal are generated. The advantage of this implementation against direct digital synthesizers lies in the simplicity of the digital logic required to generate the required clock phases, resulting in a very compact implementation. The reset switch PZ also eliminates the accumulation of offset voltages. Since the peak value of the discrete sinewave signal is determined by V_{ref}, making it programmable allows obtaining an amplitude programmable sinewave generator. A modification of the structure allows generating the sinewave signal using a single reference voltage. Figure 17.31 shows the sinewave generator output for three different reference voltages: ±200 mV, ±100 mV, and ±50 mV. The oscillating frequency is 1 kHz, and the clock frequency is 16 MHz. The measured HD3 of this block is in the order of −51 dB for an input signal of 200 mV_{peak}.

17.7.6 Programmable Switched-Capacitor Oscillator

Sinewave oscillators are essential parts in many electronic systems and in a host of applications. Integrating the oscillator with the other circuit blocks on a single chip makes it easy and reliable to implement several applications including built-in testing. Among the various types of oscillator, a BPF-based oscillator is an attractive and practical implementation due to its many advantages such as the programmability of the oscillation frequency by means of changing the center frequency (f_0) of the BPF, and the fact that the oscillation amplitude can be controlled with the help of a comparator. In base-band applications, BPF can be implemented with conventional SC design techniques that are preferred because of its accuracy, simple implementation, and reduced sensitivity to process and temperature variations. A block diagram of a BPF-based SC oscillator is shown in Figure 17.32 [20].

For highly linear oscillator, conventional approaches to minimize the frequency harmonics of the SC BPF-based oscillator requires a high-quality-factor (Q-factor) BPF, which involves high capacitor spread and, hence, leads to large silicon area. Also, improving the linearity by increasing Q-factor is not that efficient considering the fact that the nth-order harmonic distortion (HD_n) can be approximated as

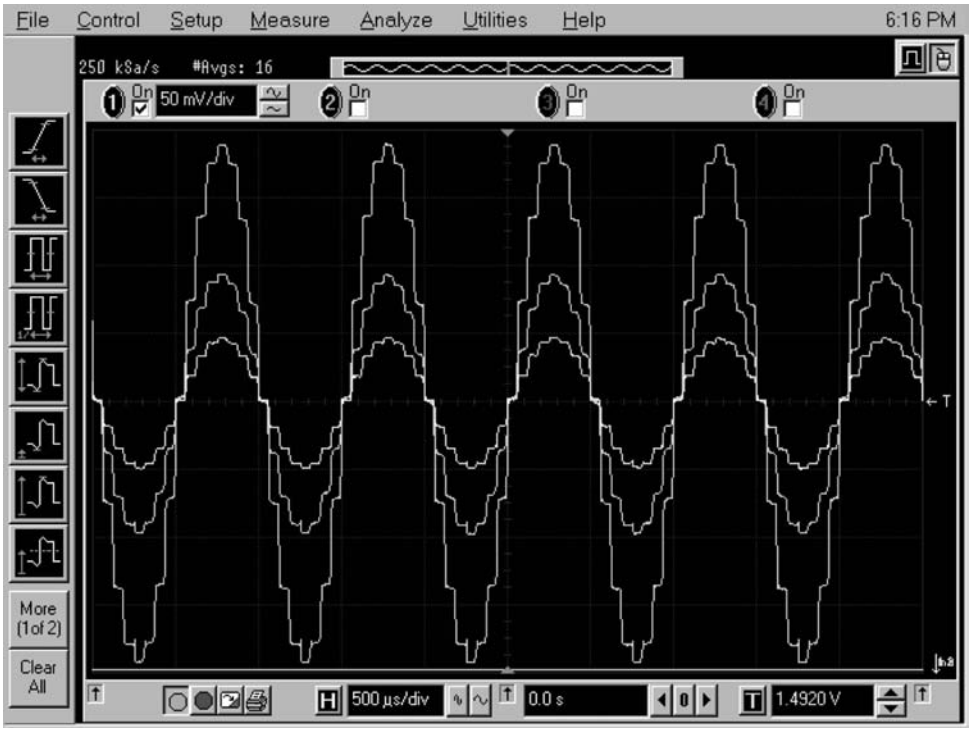

FIGURE 17.31 Measured output signal of the sinewave generator.

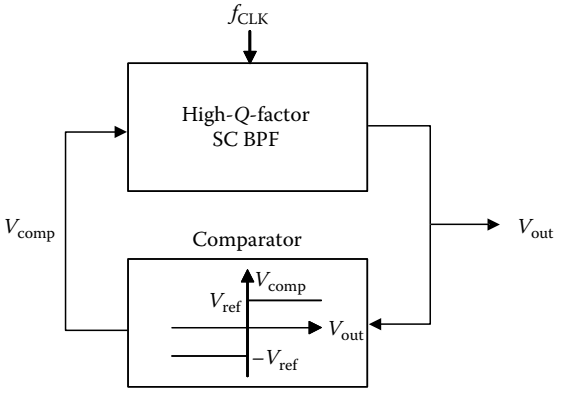

FIGURE 17.32 Block diagram of conventional BPF-based SC oscillator.

$1/(n^2Q)$, where Q is a Q-factor of BPF in second-order BPF-based oscillator. If HD3 of -60 dB is needed, then the required Q-factor becomes more than 100 that may not be practical for an IC realization.

The linearity can be significantly improved without requiring a high-Q-factor BPF if a technique based on nonlinear shaping of the frequency spectrum is used. For this purpose, a comparator must exhibit multilevel outputs. The four-level square wave with a certain condition (as depicted for $f(t)$ in Figure 17.33) rejects the third-order harmonic component. Implementation of a multilevel comparator

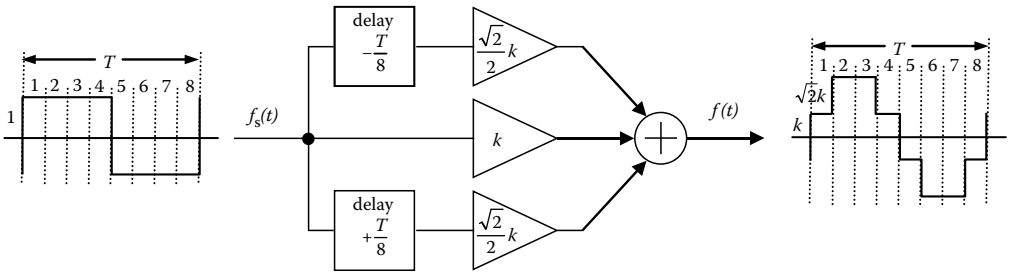

FIGURE 17.33 Conceptual diagram of a four-level quasi-sinusoidal wave generator.

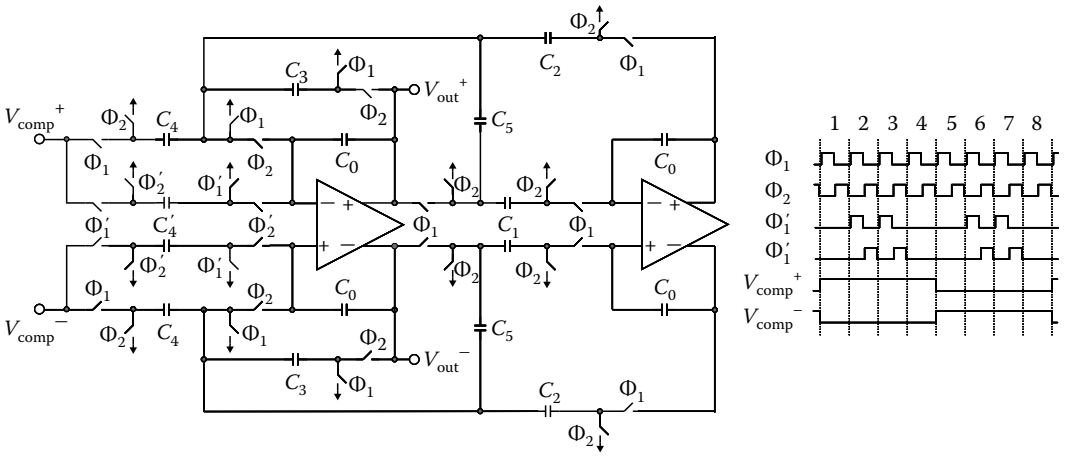

FIGURE 17.34 SC BPF implementation with an embedded FIR filter.

can be explained as adding finite-impulse-response (FIR) filter to a conventional comparator as shown in Figure 17.33. In this figure, $f_s(t)$ is an output of a conventional comparator and $f(t)$ is an output of FIR filter. A transfer function of an FIR filter in discrete-time domain, assuming that $T/8$ is one sampling period, can be expressed

$$H(z) = \frac{F(z)}{F_s(z)} = \frac{k}{\sqrt{2}} z(1 + \sqrt{2}z^{-1} + z^{-2}) \tag{17.66}$$

Equation 17.66 shows zeros at $z = 0$, $e^{\pm j3\pi/4}$. Note that $z = e^{\pm j3\pi/4}$ corresponds to the third-order harmonic frequency since $8/T$ is used for a sampling frequency. FIR filter can be easily embedded into SC BPF with the minimum cost, because BPF readily has an adder and a multiplier at its input. Figure 17.34 shows the BPF with the embedded FIR filter. In Figure 17.34, C_4' should be $\sqrt{2}$ C_4 for the cancellation of third-order harmonic, and all other capacitors should be determined by the requirements as of a conventional BPF.

The SC BPF-based oscillator was fabricated using CMOS 0.35 μm technology. BPF has a center frequency of $f_0 = 10$ MHz, a Q-factor of 10, and a master clock frequency of $f_C = 80$ MHz. The measured frequency spectrums for both oscillators are shown in Figure 17.35. Over −54 dB of HD3 for the SC BPF-based with FIR filter is achieved, which is 20 dB smaller than the conventional oscillator. HD3 improvement of the proposed oscillator is mainly determined by the accuracy of the multiplying factor

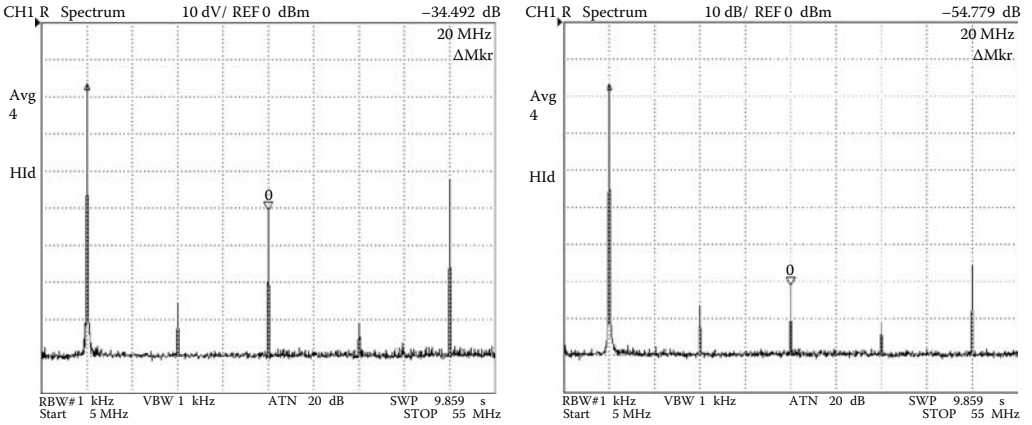

FIGURE 17.35 Measured frequency spectrum of the SC oscillators.

($\sqrt{2}$ in this case). In practical implementation, the ratio of 4:3 (=1.33) can be used for approximation of $\sqrt{2}$ (=1.4142), which limits the amount of harmonic cancellation. The implementation of the FIR filter requires minimum additional area (10% of the total area).

18.1 Properties of FIR Filters

M.H. Er

18.1.1 Linear Phase Property

The finite-impulse response (FIR) filter is characterized by a unit-sample response that has a finite duration. One of the advantages of FIR filters compared to their infinite-impulse response (IIR) counterparts is that FIR filters can be designed with exactly linear phase. Linear phase response is important for applications where phase distortion due to n onlinear phase can degrade performance, such as in data transmission and television applications.

A FIR causal filter can be characterized by the transfer function [1]

$$H(z) = \sum_{n=0}^{N-1} h(nT) z^{-n} \tag{18.1}$$

where

$h(nT)$ is the impulse response of the filter
N is the filter length
T is the sampling interval

Using the relationship that

$$H(z) = \frac{Y(z)}{X(z)} \tag{18.2}$$

the difference equation of a FIR filter can be obtained by taking the inverse Z-transform of Equation 18.1, that is

$$y(iT) = \sum_{n=0}^{N-1} h(nT)X(iT - nT) \tag{18.3}$$

which says that the current output of a FIR causal filter is the weighted sum of the current and past inputs. The weighting coefficients are given by the impulse response of the filter.

From Equation 18.1, the frequency response can be obtained by replacing $z = e^{j\omega T}$ as

$$H(e^{j\omega T}) = \sum_{n=0}^{N-1} h(nT)e^{-j\omega nT} = M(\omega)e^{j\phi(\omega)} \tag{18.4}$$

where $M(\omega)$ and $\phi(\omega)$ are the magnitude and phase responses, respectively, defined as

$$M(\omega) = \left|H(e^{j\omega T})\right| \tag{18.5a}$$

$$\phi(\omega) = \arg\ H(e^{j\omega T}) \tag{18.5b}$$

The phase delay and group (time) delay functions of a filter are defined as

$$\tau_p = -\frac{\phi(\omega)}{\omega} \tag{18.6}$$

and

$$\tau_g = -\frac{d\phi(\omega)}{d\omega} \tag{18.7}$$

respectively. Filters for which τ_p and τ_g are independent of frequency are referred to as constant time delay or linear phase filters. Hence, the phase response of a linear phase filter is given by

$$\phi(\omega) = -\tau\omega, \quad -\pi < \omega < \pi \tag{18.8}$$

where τ is a constant phase delay in samples.

From Equations 18.4, 18.5b and 18.8, the phase response can be expressed as

$$\phi(\omega) = -\tau\omega = \tan^{-1}\frac{-\sum_{n=0}^{N-1} h(nT)\sin(\omega nT)}{\sum_{n=0}^{N-1} h(nT)\cos(\omega nT)} \tag{18.9}$$

Consequently,

$$\tan(\omega\tau) = \frac{\sum_{n=0}^{N-1} h(nT)\sin(\omega nT)}{\sum_{n=0}^{N-1} h(nT)\cos(\omega nT)} \tag{18.10}$$

Using the definition $\tan(\omega\tau) = \sin(\omega\tau)/\cos(\omega\tau)$, Equation 18.10 can be reexpressed as

$$\sum_{n=0}^{N-1} h(nT)\sin(\omega\tau - \omega nT) = 0 \tag{18.11}$$

It can be shown [1] that a solution to Equation 18.11 is given by

$$\tau = \frac{(N-1)T}{2} \tag{18.12}$$

and

$$h(nT) = h[(N-1-n)T], \quad 0 \le n \le N-1 \tag{18.13}$$

Hence, FIR filters can be designed to have constant phase and group delays if the conditions of Equations 18.12 and 18.13 are satisfied. The symmetry property of Equation 18.13 can also lead to efficient filter realizations.

In applications where only constant group delay is needed, the phase response can have the form

$$\phi(\omega) = \phi_0 - \tau\omega \tag{18.14}$$

where ϕ_0 is a constant. With $\phi_0 = \pm\pi/2$, it can be shown [1] that the impulse response is of the form

$$h(nT) = -h[(N-1-n)T], \quad 0 \le n \le N-1 \tag{18.15}$$

In this case, the impulse response exhibits antisymmetrical property.

18.1.2 Frequency Response of Linear Phase FIR Filters

The frequency response of a causal linear phase FIR filter can be simplified to some simple forms using Equations 18.13 and 18.15 and the values of N as follows:

(1) *Symmetric impulse response and N = odd.* In this case,

$$H(e^{j\omega T}) = \sum_{n=0}^{(N-3)/2} h(nT)e^{-j\omega nT} + h\left[\frac{(N-1)T}{2}\right]e^{-j\omega(N-1)T/2} + \sum_{n=(N+1)/2}^{N-1} h(nT)e^{-j\omega nT} \tag{18.16}$$

Using Equation 18.13, letting $m = N-1-n$ and changing the limits of summation, and finally letting $m = n$, the last summation in Equation 18.16 can be reexpressed as

$$\sum_{n=(N+1)/2}^{N-1} h(nT)e^{-j\omega nT} = \sum_{n=0}^{(N-3)/2} h(nT)e^{-j\omega(N-1-n)T} \tag{18.17}$$

Substituting Equation 18.17 into Equation 18.16, one obtains

$$H(e^{j\omega T}) = \sum_{n=0}^{(N-3)/2} h(nT)\left[e^{-j\omega nT} + e^{-j\omega(N-1-n)T}\right] + h\left[\frac{(N-1)T}{2}\right] e^{-j\omega(N-1)T/2} \tag{18.18}$$

Factoring $e^{-j\omega(N-1)T/2}$ in Equation 18.18 and letting $k = (N-1)/2 - n$, Equation 18.18 can be reexpressed as

$$H(e^{j\omega T}) = e^{-j\omega(N-1)T/2}\left\{\sum_{k=1}^{(N-1)/2} h\left[\left(\frac{N-1}{2} - k\right)T\right](e^{j\omega kT} + e^{-j\omega kT}) + h\left[\frac{(N-1)T}{2}\right]\right\} \tag{18.19}$$

Using the property that $e^{j\theta} + e^{-j\theta} = 2\cos\theta$, Equation 18.19 can be simplified to the form

$$H(e^{j\omega T}) = e^{-j\omega(N-1)T/2}\left\{\sum_{k=1}^{(N-1)2} 2h\left[\left(\frac{N-1}{2} - k\right)T\right]\cos(\omega kT) + h\left[\frac{(N-1)T}{2}\right]\right\} \tag{18.20}$$

Letting $a(o) = h[(N-1)T/2]$ and $a(k) = 2h[((N-1)/2 - k)T]$, Equation 18.20 can be simplified further to

$$H(e^{j\omega T}) = e^{-j\omega(N-1)T/2}\left[\sum_{k=0}^{(N-1)/2} a(k)\cos(\omega kT)\right] \tag{18.21}$$

(2) *Symmetric impulse response and N = even*. For this case, the frequency response takes the form

$$H(e^{j\omega T}) = e^{-j\omega(N-1)T/2}\left\{\sum_{k=0}^{N/2-1} 2h(kT)\cos\left[\omega\left(\frac{N}{2} - k - \frac{1}{2}\right)T\right]\right\} \tag{18.22}$$

Letting $b(k) = 2h[N/2 - k)T]$, $k = 1, 2, \ldots, N/2$, Equation 18.22 can be expressed as

$$H(e^{j\omega T}) = e^{-j\omega(N-1)T/2}\left\{\sum_{k=1}^{N/2} b(k)\cos\left[\omega\left(k - \frac{1}{2}\right)T\right]\right\} \tag{18.23}$$

An interesting feature of this frequency response is that $H(e^{j\omega T})$ is always equal to zero for $\omega = \pi$, independent of $b(k)$. This implies that high-pass filter characteristics cannot be realized with this type of filter.

(3) *Antisymmetric impulse response and N = odd*. For this case, the derivation of the frequency response is the same as that in (1) except that the cosine summations are replaced by the sine summations multiplied by j because of Equation 18.15. Hence, the frequency response is given by

$$H(e^{j\omega T}) = je^{-j\omega(N-1)T/2}\left\{\sum_{k=1}^{(N-1)/2} 2h\left[\left(\frac{N-1}{2} - k\right)T\right]\sin(\omega kT) + h\left[\frac{(N-1)T}{2}\right]\right\} \tag{18.24}$$

It should be noted that for odd values of N, Equation 18.15 requires that $h[(N-1)T/2] = 0$. Letting $c(k) = 2h[((N-1)/2 - k)T]$, $k = 1, 2, \ldots, (N-1)/2$, Equation 18.24 becomes

TABLE 18.1 Frequency Response of Linear Phase FIR Filters

$h(nT)$	N	$H(e^{j\omega T})$
Symmetrical	Odd	$e^{-j\omega(N-1)T/2}\sum_{k=0}^{(N-1)/2} a(k)\cos(\omega kT)$
	Even	$e^{-j\omega(N-1)T/2}\sum_{k=1}^{N/2} b(k)\cos\left[\omega\left(k-\frac{1}{2}\right)T\right]$
Antisymmetrical	Odd	$je^{-j\omega(N-1)T/2}\sum_{k=1}^{(N-1)/2} c(k)\sin(\omega kT)$
	Even	$je^{-j\omega(N-1)T/2}\sum_{k=1}^{N/2} d(k)\sin\left[\omega\left(k-\frac{1}{2}\right)T\right]$

Where $a(o)=h\left[\frac{(N-1)T}{2}\right]$, $a(k)=c(k)=2h\left[\left(\frac{N-1}{2}-k\right)T\right]$, $b(k)=d(k)=2h\left[\left(\frac{N}{2}-k\right)T\right]$.

$$H(e^{j\omega T})=je^{-j\omega(N-1)T/2}\left\{\sum_{k=1}^{(N-1)/2} c(k)\sin(\omega kT)\right\} \tag{18.25}$$

A notable feature of this frequency response is that at frequencies $\omega=0$ and $\omega=\pi$, the frequency response is always zero, independent of $c(k)$.

(4) *Antisymmetric impulse response and N = even*. For this case, the frequency response is the same as that in (2) except the cosine summations become sine summations multiplied by j as follows:

$$H(e^{j\omega T})=je^{-j\omega(N-1)T/2}\left\{\sum_{k=0}^{N/2-1} 2h(kT)\sin\left[\omega\left(\frac{N}{2}-k-\frac{1}{2}\right)T\right]\right\} \tag{18.26}$$

Letting $d(k)=2h[N/2-k)T]$, $k=1, 2, \ldots, N/2$, Equation 18.26 becomes

$$H(e^{j\omega T})=je^{-j\omega(N-1)T/2}\left\{\sum_{k=1}^{N/2} d(k)\sin\left[\omega\left(k-\frac{1}{2}\right)T\right]\right\} \tag{18.27}$$

In this case, the frequency response is zero at $\omega=0$, independent of $d(k)$.

In summary, the frequency responses of the four possible types of FIR filters with linear phase are given in Table 18.1.

18.1.3 Locations of Zeros of Linear Phase FIR Filters

The symmetric and antisymmetric conditions of the impulse response given by Equations 18.13 and 18.15 impose certain constraints on the zeros of the transfer function $H(z)$ [2]. For the case where N is an odd value, $H(z)$ can be written as

$$H(z)=z^{-(N-1)/2}\sum_{k=0}^{(N-1)/2}\frac{a(k)}{2}(z^k\pm z^{-k}) \tag{18.28}$$

where the $\pm$ sign corresponds to symmetry and antisymmetry in the impulse response respectively, and $a(o)$ and $a(k)$ are defined in Table 18.1.

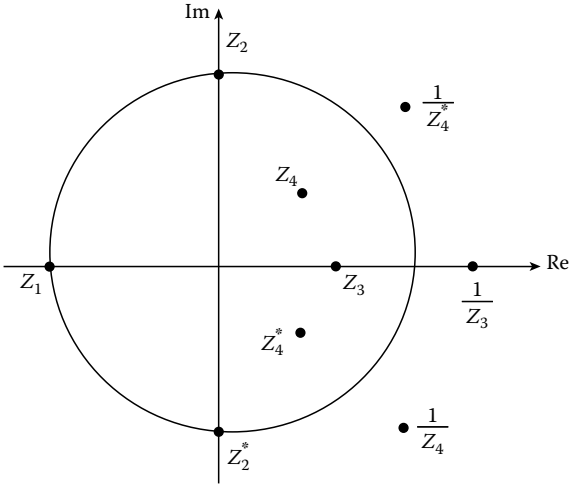

FIGURE 18.1 Typical zero positions of linear phase filters.

Substituting z^{-1} for z in Equation 18.28, one obtains

$$H(z^{-1}) = z^{(N-1)/2} \sum_{k=0}^{(N-1)/2} \frac{a(k)}{2}(z^{-k} \pm z^{k}) \tag{18.29}$$

It follows from Equations 18.28 and 18.29 that

$$H(z^{-1}) = \pm z^{(N-1)} H(z) \tag{18.30}$$

Equation 18.30 shows that $H(z)$ and $H(z^{-1})$ are identical to within a delay of $(N-1)$ samples and a multiplier of ± 1. Thus, the zeros of $H(z^{-1})$ are identical to the zeros of $H(z)$. Therefore, if $z_i = r_i e^{j\phi i}$ is a zero of $H(z)$, then $z_i^{-1} = (1/r_i)e^{-j\phi i}$ must also be a zero of $H(z)$. This has the following implications on the zero locations:

1. If $r_i = 1$ and $\phi_i = 0$ or π, then the zeros lie at either $z = +1$ or $z = -1$. In these cases, the zero is its own complex conjugate.
2. If $r_i = 1$ and $\phi_i \neq 0$ or π, then the zeros of $H(z)$ that are on the unit circle are also zeros of $H(z^{-1})$ that are on the unit circle. Hence, the zeros occur in complex conjugate pairs on the unit circle.
3. If $r_i \neq 1$ and $\phi_i = 0$ or π, then the zeros are real and occur in reciprocal pairs on the unit circle.
4. If $r_i \neq 1$ and $\phi_i \neq 0$ or π, then the zeros occur in quadruplets with complex conjugate reciprocal pairs off the unit circle.

Figure 18.1 shows the possible types of zeros for linear phase FIR filters.

18.2 Windowing Techniques

M.H. Er

Windowing is one of the earliest techniques for designing FIR filters [3,4]. The technique is simple because the filter coefficients can be obtained in closed form without the need for solving complex optimization problems as in some other sophisticated FIR design techniques. Hence, the design time is very short and the technique remains an attractive tool for FIR filter design.

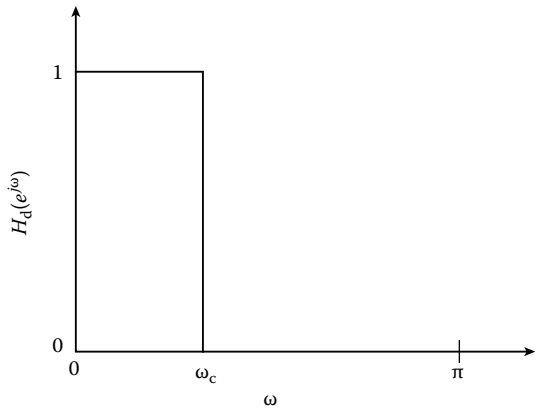

FIGURE 18.2 An ideal low-pass filter specification.

To understand the windowing technique, first consider the process of obtaining a finite-length impulse response by truncating an infinite-duration impulse response sequence. Suppose $H_d(e^{j\omega T})$ is an ideal desired low-pass response with cutoff frequency ω_c. As the frequency response of an FIR filter is a periodic function, it can be expressed as a Fourier series as

$$H_d(e^{j\omega T}) = \sum_{n=-\infty}^{\infty} h_d(nT)e^{-j\omega nT} \tag{18.31}$$

where

$$h_d(nT) = \frac{T}{2\pi}\int_{-\pi/T}^{\pi/T} H_d(e^{j\omega T})e^{j\omega nT}d\omega \tag{18.32}$$

In general, $H_d(e^{j\omega T})$ is piecewise constant with a certain passband and stopband and with discontinuities at the boundaries between bands. Hence, the impulse sequence $h_d(nT)$ is of infinite duration. For example, for the ideal low-pass response shown in Figure 18.2, the corresponding impulse response sequence is given by

$$h_d(nT) = \frac{\omega_c T}{\pi}\left(\frac{\sin \omega_c nT}{\omega_c nT}\right), \quad -\infty \le n \le \infty \tag{18.33}$$

It is clear that Equation 18.33 is a noncausal IIR filter. Also it is unstable and therefore unrealizable.

The rectangular window. One way to obtain a finite-duration causal impulse response is to simply truncate $h_d(nT)$ and introduce sufficient delay to obtain a causal impulse response, i.e., define

$$h(nT) = \begin{cases} h'_d(nT) & 0 \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{18.34}$$

where $h'_d(nT)$ is a delay version of $h_d(nT)$.

This can be represented as the product of the desired impulse response and a finite-duration window $w_r(nT)$, i.e.,

$$h(nT) = h'_d(nT)w_r(nT) \tag{18.35}$$

where $w_r(nT)$ is the rectangular window function defined as

$$w_r(nT) = \begin{cases} 1 & 0 \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{18.36}$$

Let $\theta = \omega T$ and using the fact that multiplication of two discrete-time sequences corresponds to a convolution of their Fourier transforms. Hence,

$$H(e^{j\omega}) = \frac{1}{2\pi}\int_{-\pi}^{\pi} H'_{\mathrm{d}}(e^{j\theta})W_{\mathrm{r}}(e^{j(\omega-\theta)})\mathrm{d}\theta \tag{18.37}$$

where $W_{\mathrm{r}}(e^{j\theta})$ is the spectrum of the rectangular window.

Since the two functions in the integral are periodic, a circular convolution results and the limits of integration are taken over one period. Thus the frequency response $H(e^{j\omega})$ will be a "smeared" version of the desired response $H'_{\mathrm{d}}(e^{j\omega})$ and the discontinuities in the desired frequency response become transition bands of $H(e^{j\omega})$. To understand this, it is instructive to examine the frequency response for the causal rectangular window, that is,

$$\begin{aligned} W_{\mathrm{r}}(e^{j\omega T}) &= \sum_{n=0}^{N-1} e^{-j\omega nT} \\ &= e^{-j\omega(N-1)T/2}\frac{\sin(\omega NT/2)}{\sin(\omega T/2)} \end{aligned} \tag{18.38}$$

The spectrum $W_{\mathrm{r}}(e^{j\omega T})$ for $N = 31$ is shown in Figure 18.3. The spectrum $W_{\mathrm{r}}(e^{j\omega T})$ has two features that are worth noting, the mainlobe width and the sidelobe amplitude. The mainlobe width is defined as the distance between the two points closest to $\omega = 0$, where $W_{\mathrm{r}}(e^{j\omega T})$ is zero. For a rectangular window, the mainlobe width is equal to $4\pi/N$. The maximum sidelobe amplitude for $W_{\mathrm{r}}(e^{j\omega T})$ is equal to approximately -13 dB relative to the maximum value at $\omega = 0$.

Figure 18.4 shows the log–magnitude response of applying a 31-point rectangular window to approximate an ideal low-pass filter with a cutoff frequency equal to $\pi/4$. It can be seen that the sharp transition in the ideal response at $\omega = \omega_{\mathrm{c}}$ has been converted into a gradual transition. Also, in the passband a series of overshoots and undershoots occur, and in the stopband, where the desired response is zero, the FIR filter has a nonzero response. These are the results of the convolution between $W_{\mathrm{r}}(e^{j\omega T})$ and $H_{\mathrm{d}}(e^{j\omega T})$. The mainlobe of $W_{\mathrm{r}}(e^{j\omega T})$ causes the smearing of the desired response and the sidelobes of $W_{\mathrm{r}}(e^{j\omega T})$ appear as overshoots and undershoots to the desired response. It is interesting to note that there will

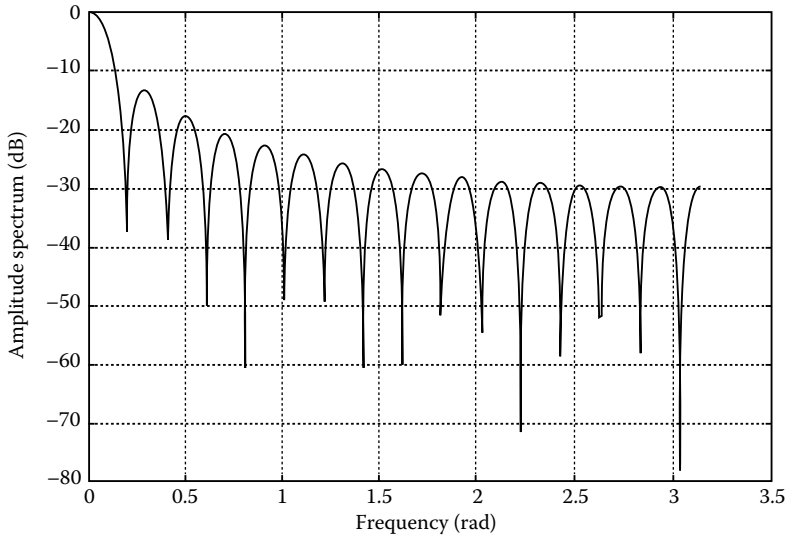

FIGURE 18.3 Fourier transform of the rectangular window.

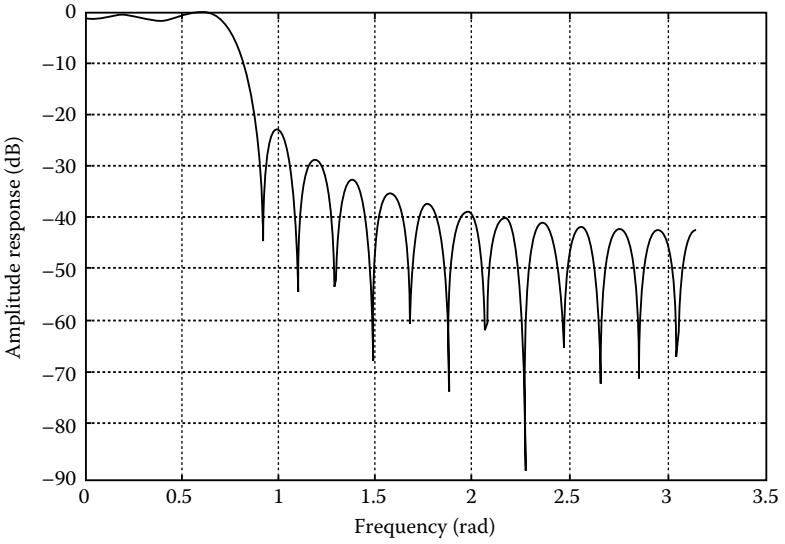

FIGURE 18.4 Magnitude response of low-pass FIR filter design using a 31-point rectangular window.

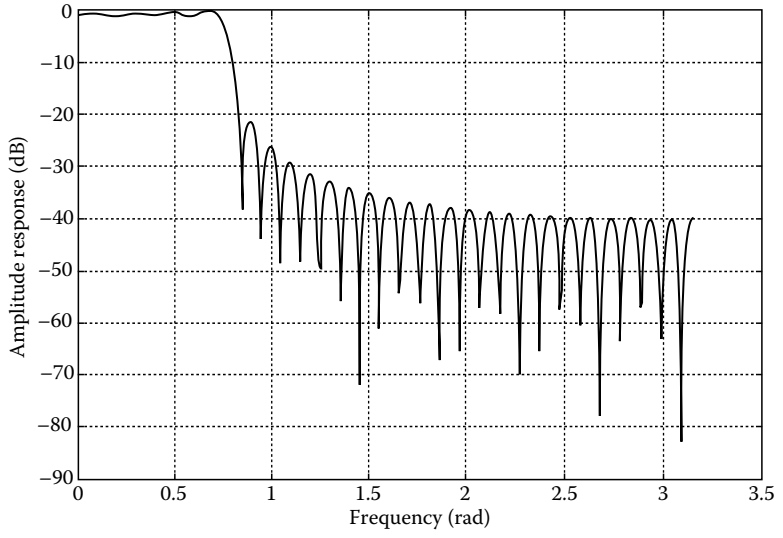

FIGURE 18.5 Magnitude response of low-pass FIR filter design using a 61-point rectangular window.

always be oscillations in the function $H(e^{j\omega T})$ in the vicinity of the steep transitions in $H'_{\mathrm{d}}(e^{j\omega T})$, no matter how large the value of N as shown in Figure 18.5 for $N = 61$. This result is known as the Gibbs phenomenon [2] in the theory of Fourier series.

To reduce the oscillations in $H(e^{j\omega T})$, other window functions having spectra exhibiting smaller sidelobes must be used. To understand how the form of windows should be selected, it is observed that the sidelobes of the rectangular window represent the high-frequency components and are due to the sharp transitions from one to zero at the edges of the window. Therefore, the amplitudes of these sidelobes can be reduced by replacing the sharp transitions by more gradual ones. Some of the most frequently used window functions are described below.

The Bartlett window. The Bartlett window, also known as the triangular window, is defined as

$$w_t(nT) = \begin{cases} \frac{2n}{N-1} & 0 \le n \le \frac{N-1}{2} \\ 2 - \frac{2n}{N-1} & \frac{N-1}{2} \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{18.39}$$

The spectrum $W_t(e^{j\omega T})$ is shown in Figure 18.6. As expected, the sidelobe level is smaller than that of the rectangular window, being reduced from -13 to -25 dB relative to the maximum. However, the mainlobe width is now $8\pi/N$, twice that of the rectangular window. Hence, there is a trade-off between mainlobe width and sidelobe level.

Figure 18.7 illustrates the FIR low-pass magnitude response obtained by using the Bartlett window. Comparing Figure 18.7 to Figure 18.4, it is observed that the Bartlett window produces a smoother magnitude response.

The Hanning window. The Hanning window, also known as the raised-cosine window, is given by

$$w_c(nT) = \begin{cases} \frac{1}{2}\left[1 - \cos\left(\frac{2\pi n}{N-1}\right)\right] & 0 \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{18.40}$$

The amplitude spectrum of this window is shown in Figure 18.8 for $N = 31$. The magnitude of the first sidelobe level is -31 dB, down with respect to the peak value at $\omega = 0$. Comparing to the triangular window, there is an improvement of 6 dB. Since the mainlobe widths of both windows are the same, the Hanning window is preferred over the triangular one.

The amplitude response of the FIR low-pass filter with $\omega_c = \pi/4$ produced by applying the Hanning window with $N = 31$ is shown in Figure 18.9. The largest peak in the stopband is now reduced to -44 dB relative to the passband level.

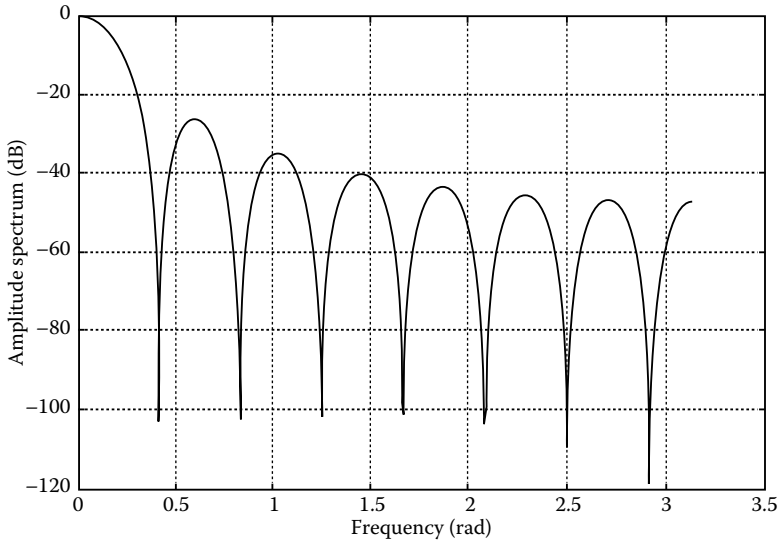

FIGURE 18.6 Fourier transform of the Bartlett window.

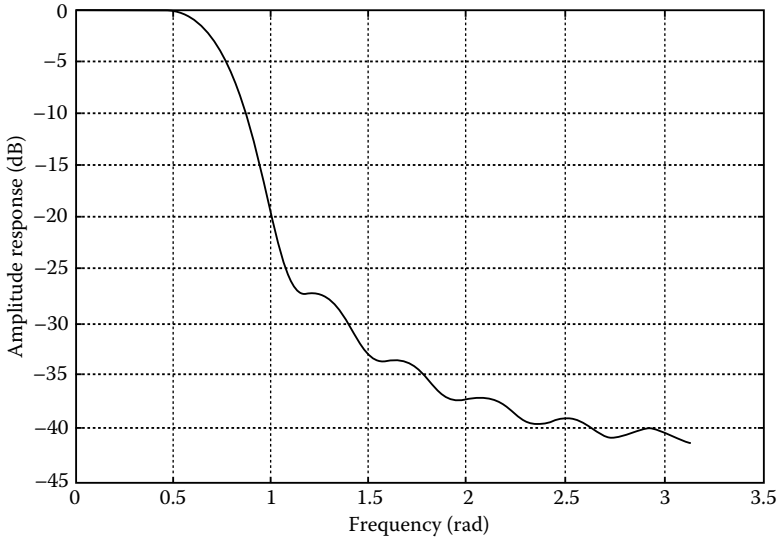

FIGURE 18.7 Magnitude response of low-pass FIR filter design using a 31-point Bartlett window.

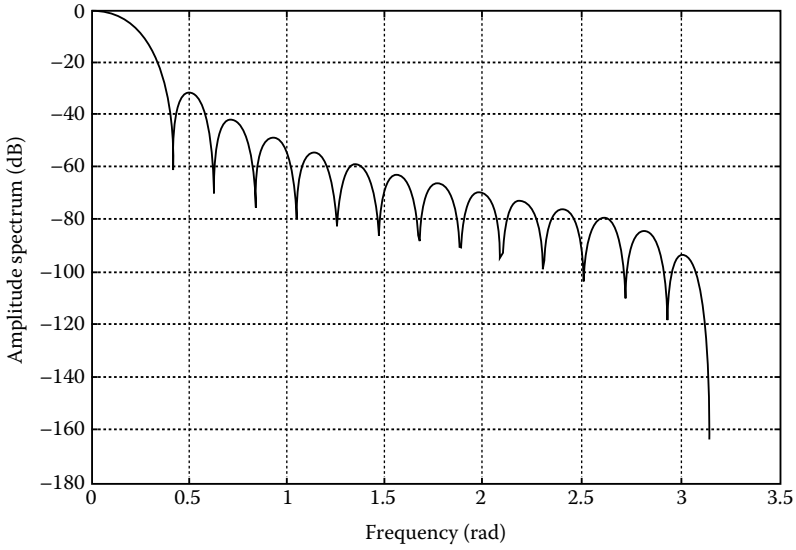

FIGURE 18.8 Fourier transform of the Hanning window.

The Hamming window. The Hamming window is given by

$$w_{\mathrm{h}}(nT) = \begin{cases} 0.54 - 0.46\cos\left(\frac{2\pi n}{N-1}\right) & 0 \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{18.41}$$

Figure 18.10 shows the amplitude spectrum of the Hamming window, The magnitude of the highest sidelobe is about −41 dB, a reduction of 10 dB relative to the Hanning window. This reduction is achieved at the expense of higher sidelobes at the higher frequencies.

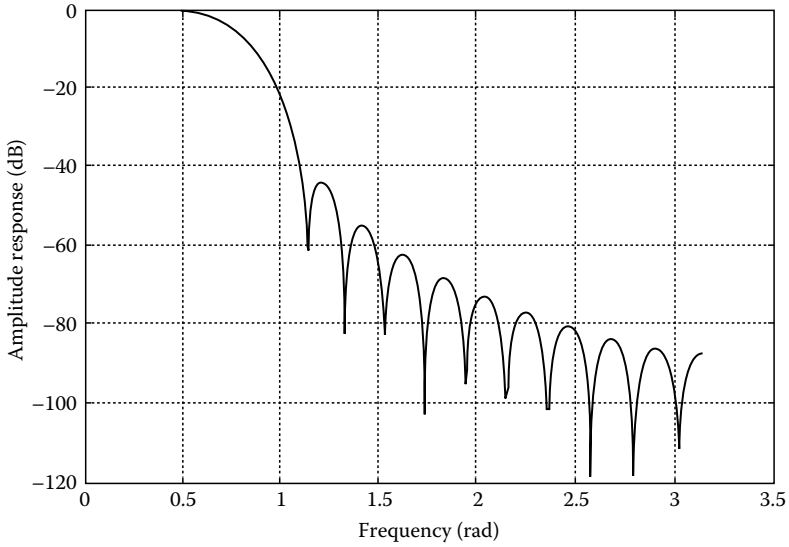

FIGURE 18.9 Magnitude response of low-pass FIR filter design using a 31-point Hanning window.

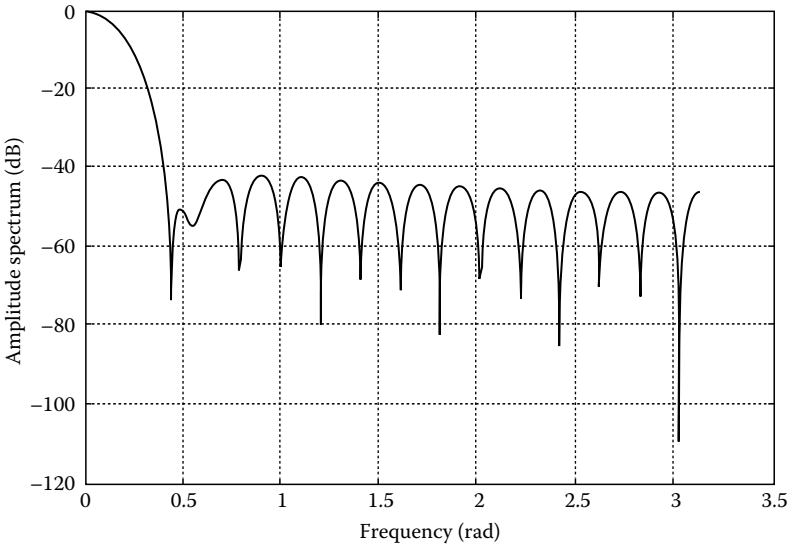

FIGURE 18.10 Fourier transform of the Hamming window.

Figure 18.11 illustrates the amplitude response of the FIR low-pass filter with $\omega_c = \pi/4$ obtained by applying the Hamming window for $N = 31$. The first sidelobe peak is -51 dB, a -7 dB improvement with respect to that using the Hanning window. However, it is noted that as frequency increases, the stopband attenuation does not increase as much as that produced by using the Hanning window.

The Blackman window. The Blackman window is given by

$$w_b(nT) = \begin{cases} 0.42 - 0.5\cos\left(\frac{2\pi n}{N-1}\right) + 0.08\cos\left(\frac{4\pi n}{N-1}\right) & 0 \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{18.42}$$

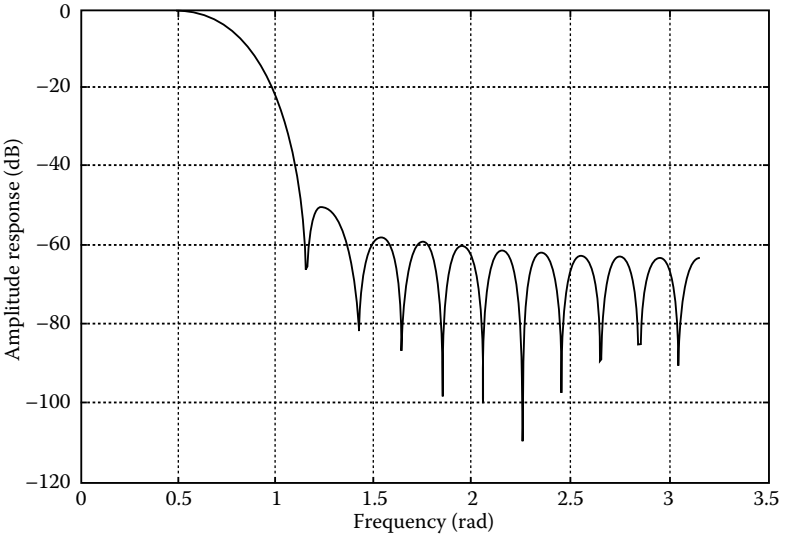

FIGURE 18.11 Magnitude response of low-pass FIR filter design using a 31-point Hamming window.

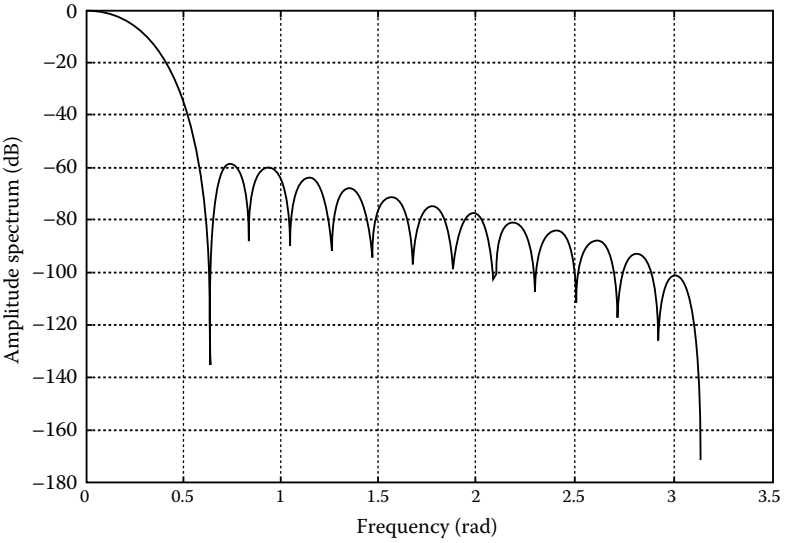

FIGURE 18.12 Fourier transform of the Blackman window.

The amplitude response of the Blackman window is shown in Figure 18.12. It can be seen that it has the highest sidelobe level, down −57 dB from the mainlobe peak. However, the mainlobe width has increased to $12\pi/N$.

The amplitude response of the FIR low-pass filter obtained when applying the Blackman window is shown in Figure 18.13. The minimum attenuation in the stopband is about −74 dB, but it occurs for $\omega > \pi/2$.

The Kaiser window. For the foregoing windows, the width of the mainlobe is inversely proportional to N. However, the minimum stopband attenuation is independent of the window length and is a function of

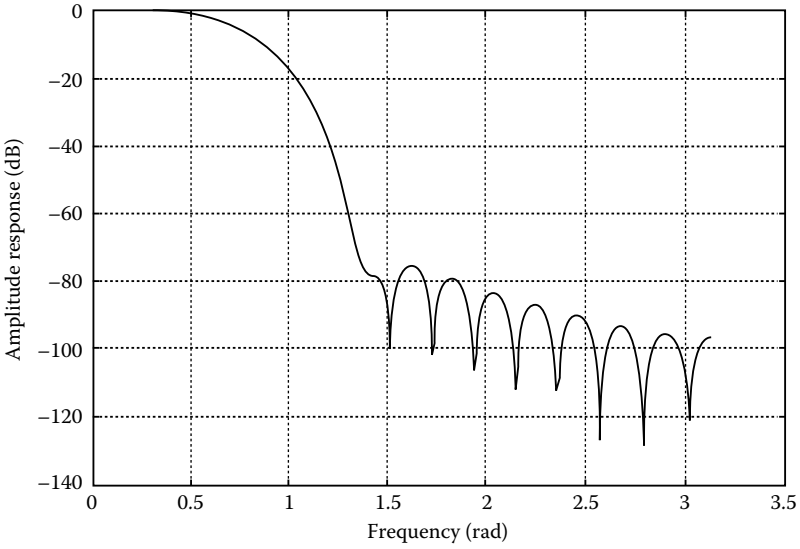

FIGURE 18.13 Magnitude response of low-pass FIR filter design using a 31-point Blackman window.

the selected window. Hence, to meet a desired stopband attenuation, the designer is forced to select a window that meets the design specifications. It is worth noting that windows with low sidelobe levels have broader mainlobe widths, hence requiring an increase in the order of the filter N to achieve the desired transition width.

In 1974, Kaiser [4] introduced a new window, now known as the Kaiser window, based on discrete-time approximations of the prolate spheroidal wave functions. This window has a variable parameter β, which can be varied to control the sidelobe level with respect to the mainlobe peak. As in other windows,

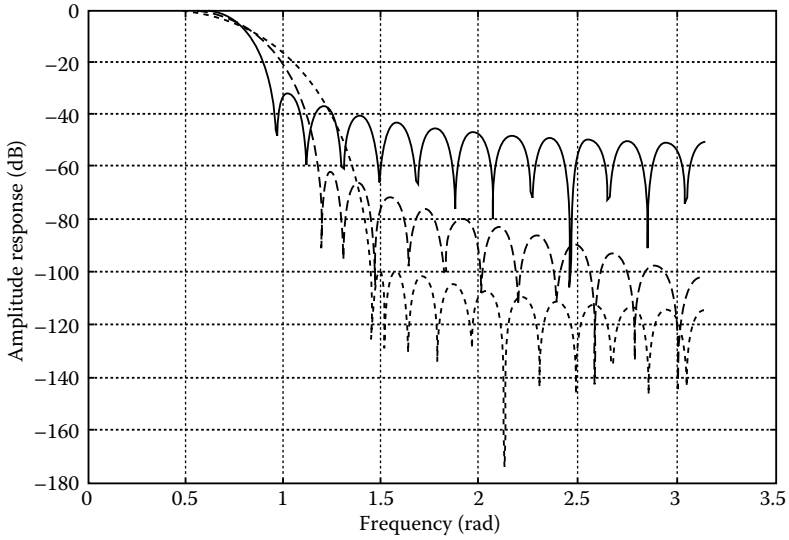

FIGURE 18.14 Magnitude responses of low-pass FIR filter design using a 31-point Kaiser window with $\beta = 1$ (solid line), $\beta = 6$ (dash line), and $\beta = 10$ (dotted line).

TABLE 18.2 Spectral Properties of N-Point Windows

Window	Mainlobe Width	Peak Amplitude of Sidelobe (dB)
Rectangular	$4\pi/N$	−13
Bartlett	$8\pi/N$	−25
Hanning	$8\pi/N$	−31
Hamming	$8\pi/N$	−41
Blackman	$12\pi/N$	−57

the mainlobe width can be adjusted by changing the length of the window, which in turn adjusts the transition width of the filter. Therefore, FIR filters can be efficiently designed using the Kaiser window.

The Kaiser windows are defined by

$$w_k(nT) = \begin{cases} \dfrac{I_0\left(2\beta\sqrt{\frac{n}{N-1}-\left(\frac{n}{N-1}\right)^2}\right)}{I_0(\beta)} & 0 \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{18.43}$$

where $I_0(x)$ is the modified zeroth-order Bessel function of the first kind. Kaiser has shown that these windows are nearly optimum in the sense of having the largest energy in the mainlobe for a given peak sidelobe amplitude.

To give an impression of the results that can be obtained by using Kaiser windows, Figure 18.14 shows the amplitude responses of an FIR low-pass filter design with $N = 31$ and $\omega_c = \pi/4$ and with $\beta = 1$, $\beta = 6$, and $\beta = 10$. As the value of β increases, the stopband attenuation of the low-pass filter increases and the transition band widens. Proper choice of N then leads to the final design.

The windows discussed above are compared in terms of their mainlobe width and the maximum sidelobe level in Table 18.2.

18.3 Design of FIR Filters by Optimization

Andreas Antoniou

18.3.1 Equiripple FIR Filters

The design of FIR filters can be accomplished either through noniterative or iterative methods. Noniterative methods entail the use of a small set of closed-form formulas and are, as a consequence, simple to apply. A frequently used method of this class is through the use of the Fourier series in conjunction

with window functions. Iterative methods are based on the application of optimization techniques. These are characterized by a substantial increase in the computational complexity, but often lead to designs that are optimal in some respect.

This section deals with an iterative method for the design of FIR filters known as the *weighted-Chebyshev* method. In this approach, an error function is formulated for the desired filter in terms of a linear combination of cosine functions and is then minimized by using a very efficient multivariable optimization algorithm known as the *Remez exchange algorithm*. When convergence is achieved, the error function becomes equiripple, as in other Chebyshev solutions. The amplitude of the error in different frequency bands of interest is controlled by applying weighting to the error function.

The weighted-Chebyshev method is very flexible and can be used to obtain optimal solutions for most types of FIR filters, e.g., digital differentiators, Hilbert transformers, and low-pass, high-pass, bandpass, bandstop, and multiband filters with piecewise-constant amplitude responses. Furthermore, it can be used to design filters with arbitrary amplitude responses. Consequently, it is widely used. In common with other optimization methods, the weighted-Chebyshev method requires a large amount of computation; however, as the cost of computation is becoming progressively cheaper with time, this disadvantage is not a serious one.

The underlying principles of the weighted-Chebyshev method were proposed during the early 1970s [1–3] and a series of developments soon after [4–8] led to the well-known computer program of McClellan et al. [9]. Some more recent enhancements to the method are reported in Refs. [10,11]. A detailed treatment of the subject can be found in Ref. [12].

18.3.2 Problem Formulation

An FIR filter with a symmetrical impulse response and odd length N can be represented by the transfer function

$$H(z) = \sum_{n=0}^{N-1} h(nT)z^{-n}$$

If we assume a sampling rate $\omega_s = 2\pi$, we have $T = 2\pi/\omega_s = 1$ s, and hence the frequency response of the filter can be expressed as

$$H(e^{j\omega T}) = e^{-jc\omega}P_c(\omega)$$

where

$$P_c(\omega) = \sum_{k=0}^{c} a_k \cos k\omega \tag{18.44}$$

with

$$\begin{aligned} a_0 &= h(c) \\ a_k &= 2h(c-k) \quad \text{for } k = 1, 2, \ldots, c \\ c &= (N-1)/2 \end{aligned}$$

For a desired frequency response $e^{-jc\omega}D(\omega)$ and a specified weighting function $W(\omega)$, an error function $E(\omega)$ can be constructed as

$$E(\omega) = W(\omega)[D(\omega) - P_c(\omega)] \tag{18.45}$$

If it were possible to minimize the magnitude of the above error such that

$$|E(\omega)| \leq \delta_p$$

with respect to some compact subset of the frequency interval $[0, \pi]$, say Ω, a filter would be obtained in which

$$|E_0(\omega)| = |D(\omega) - P_c(\omega)| \leq \frac{\delta_p}{|W(\omega)|} \quad \text{for } \omega \in \Omega \tag{18.46}$$

In an equiripple filter, the magnitude of the error oscillates uniformly between zero and some maximum in each passband and stopband. In a low-pass equiripple filter, the amplitude response assumes the form depicted in Figure 18.15, where δ_p and δ_a are the amplitudes of the passband and stopband ripples, and ω_p and ω_a are the passband and stopband edges, respectively. Hence, we require

$$D(\omega) = \begin{cases} 1 & \text{for } 0 \leq \omega \leq \omega_p \\ 0 & \text{for } \omega_a \leq \omega \leq \pi \end{cases}$$

with

$$|E_0(\omega)| \leq \begin{cases} \delta_p & \text{for } 0 \leq \omega \leq \omega_p \\ \delta_a & \text{for } \omega_a \leq \omega \leq \pi \end{cases} \tag{18.47}$$

Therefore, from Equations 18.46 and 18.47 we deduce

$$W(\omega) = \begin{cases} 1 & \text{for } 0 \leq \omega \leq \omega_p \\ \delta_p/\delta_a & \text{for } \omega_a \leq \omega \leq \pi \end{cases}$$

Similarly, for high-pass filters, we obtain

$$D(\omega) = \begin{cases} 0 & \text{for } 0 \leq \omega \leq \omega_a \\ 1 & \text{for } \omega_p \leq \omega \leq \pi \end{cases}$$

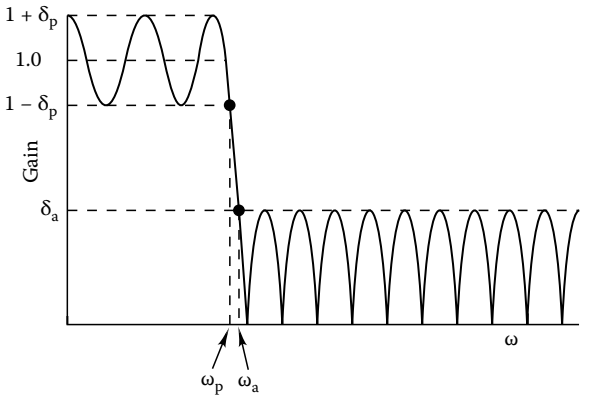

FIGURE 18.15 Amplitude response of equiripple low-pass filter. (Reproduced from Antoniou, A. *Digital Filters: Analysis, Design, and Applications*, McGraw-Hill, New York, 1993. With permission.)

and

$$W(\omega) = \begin{cases} \delta_p/\delta_a & \text{for } 0 \le \omega \le \omega_a \\ 1 & \text{for } \omega_p \le \omega \le \pi \end{cases}$$

Bandpass and bandstop filters. The above formulation can be easily extended to other types of filters. For bandpass filters, we have

$$D(\omega) = \begin{cases} 0 & \text{for } 0 \le \omega \le \omega_{a1} \\ 1 & \text{for } \omega_{p1} \le \omega \le \omega_{p2} \\ 0 & \text{for } \omega_{a2} \le \omega \le \pi \end{cases}$$

and

$$W(\omega) = \begin{cases} \delta_p/\delta_a & \text{for } 0 \le \omega \le \omega_{a1} \\ 1 & \text{for } \omega_{p1} \le \omega \le \omega_{p2} \\ \delta_p/\delta_a & \text{for } \omega_{a2} \le \omega \le \pi \end{cases}$$

where δ_p and δ_a are the amplitudes of the passband and stopband ripples, respectively, ω_{p1} and ω_{p2} are the passband edges, and ω_{a1} and ω_{a2} are the stopband edges, as depicted in Figure 18.16. On the other hand, for bandstop filters

$$D(\omega) = \begin{cases} 1 & \text{for } 0 \le \omega \le \omega_{p1} \\ 0 & \text{for } \omega_{a1} \le \omega \le \omega_{a2} \\ 1 & \text{for } \omega_{p2} \le \omega \le \pi \end{cases}$$

and

$$W(\omega) = \begin{cases} 1 & \text{for } 0 \le \omega \le \omega_{p1} \\ \delta_p/\delta_a & \text{for } \omega_{a1} \le \omega \le \omega_{a2} \\ 1 & \text{for } \omega_{p2} \le \omega \le \pi \end{cases}$$

The alternation theorem. An effective approach for the design of equiripple filters is to solve the minimax problem

$$\underset{x}{\text{minimize}}\left\{\max_{\omega}|E(\omega)|\right\} \tag{18.48}$$

where

$$x = [\,a_0 \quad a_1 \quad \cdots \quad a_c\,]^{\mathrm{T}}$$

is a column vector whose elements are the coefficients of the transfer function of the filter, which happen to be the values of the impulse response. The solution of this problem exists by virtue of the so-called alternation theorem [13], which is as follows.

THEOREM 18.1

If $P_c(\omega)$ is a linear combination of $r = c + 1$ cosine functions of the form

$$P_c(\omega) = \sum_{k=0}^{c} a_k \cos k\omega$$

then a necessary and sufficient condition that $P_c(\omega)$ be the unique, best, weighted-Chebyshev approximation to a continuous function $D(\omega)$ on Ω, where Ω is a compact subset of the frequency interval $[0, \pi]$, is that the weighted error function $E(\omega)$ exhibit at least $r + 1$ extremal frequencies in Ω, i.e., there must exist at least $r + 1$ points $\hat{\omega}$ in Ω such that

$$\begin{aligned} &\hat{\omega}_0 < \hat{\omega}_1 < \cdots < \hat{\omega}_r \\ &E(\hat{\omega}_i) = -E(\hat{\omega}_{i+1}) \quad \text{for } i = 0,\ 1,\ \ldots,\ r-1 \end{aligned}$$

and

$$|E(\hat{\omega}_i)| = \max_{\omega\in\Omega}|E(\omega)| \quad \text{for } i = 0,\ 1,\ \ldots,\ r$$

From the alternation theorem and Equation 18.45 we can write

$$E(\hat{\omega}_i) = W(\hat{\omega}_i)[D(\hat{\omega}_i) - P_c(\hat{\omega}_i)] = (-1)^i\delta \tag{18.49}$$

for $i = 0, 1, \ldots, r$, where δ is a constant. This system of equations can be put in matrix form as

$$\begin{bmatrix} 1 & \cos\hat{\omega}_0 & \cos 2\hat{\omega}_0 & \cdots & \cos c\hat{\omega}_0 & \frac{1}{W(\hat{\omega}_0)} \\ 1 & \cos\hat{\omega}_1 & \cos 2\hat{\omega}_1 & \cdots & \cos c\hat{\omega}_1 & \frac{-1}{W(\hat{\omega}_1)} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & \cos\hat{\omega}_r & \cos 2\hat{\omega}_r & \cdots & \cos c\hat{\omega}_r & \frac{(-1)^r}{W(\hat{\omega}_r)} \end{bmatrix} \begin{bmatrix} a_0 \\ a_1 \\ \vdots \\ a_c \\ \delta \end{bmatrix} = \begin{bmatrix} D(\hat{\omega}_0) \\ D(\hat{\omega}_1) \\ \vdots \\ D(\hat{\omega}_r) \end{bmatrix} \tag{18.50}$$

If the extremal frequencies (or extremals for short) were known, coefficients a_k and, in turn, the frequency response of the filter could be computed using Equation 18.44. The solution of this system exists since the above $(r+1)\times(r+1)$ matrix is nonsingular [13].

18.3.2.1 Remez Exchange Algorithm

The Remez exchange algorithm is an *iterative multivariable* algorithm, which is naturally suited for the solution of the minimax problem stated in Equation 18.48. It is based on the second optimization method of Remez [14] and involves the following basic steps.

ALGORITHM 18.1: Basic Remez Exchange Algorithm

---

1. Initialize extremals $\hat{\omega}_0, \hat{\omega}_1, \ldots, \hat{\omega}_r$ ensuring that an extremal is assigned at each band edge.
2. Locate the frequencies $\hat{\omega}_0, \hat{\omega}_1, \ldots, \hat{\omega}_\rho$ at which $|E(\omega)|$ is maximum and $|E(\hat{\omega}_i)| \geq \delta$. These frequencies are *potential* extremals for the next iteration.
3. Compute the convergence parameter

$$Q = \frac{\max\left|E(\hat{\omega}_i)\right| - \min\left|E(\hat{\omega}_i)\right|}{\max\left|E(\hat{\omega}_i)\right|}$$

   where $i = 0, 1, \ldots, \rho$.
4. Reject $\rho - r$ *superfluous* potential extremals $\hat{\omega}_i$ according to an appropriate rejection criterion and renumber the remaining $\hat{\omega}_i$ sequentially; then set $\hat{\omega}_i = \hat{\omega}_i$ for $i = 0, 1, \ldots, r$.
5. If $Q > \varepsilon$, where ε is a convergence tolerance (say $\varepsilon = 0.01$), repeat from step 2; otherwise continue to step 6.
6. Compute $P_c(\omega)$ using the last set of extremals; then deduce $h(n)$, the impulse response of the required filter, and stop.

The amount of computation required by the algorithm tends to depend quite heavily on the initialization scheme used in step 1, on the search method used for the location of the maxima of the error function in step 2, and on the criterion used to reject superfluous frequencies $\hat{\omega}_i$ in step 4.

Initialization of extremals. The simplest scheme for the initialization of extremals $\hat{\omega}_i$ for $i = 0, 1, \ldots, r$ is to assume that they are uniformly spaced in the frequency bands of interest. If there are J distinct bands in the required filter of widths $B_1, B_2, \ldots, B_J$ and extremals are to be located at the left-hand and right-hand band edges of each band, the sum of these bandwidths should be divided into $r + 1 - J$ intervals. Thus the average interval between adjacent extremals is

$$W_0 = \frac{1}{r + 1 - J} \sum_{j=1}^{J} B_j$$

Since the quantities B_j/W_0 need not be integers, the use of W_0 for the generation of the extremals will almost always result in a fractional interval in each band. This problem can be avoided by rounding the number of intervals B_j/W_0 to the nearest integer and then readjusting the frequency interval for the corresponding band accordingly. This can be achieved by letting the number of intervals in bands j and J be

$$m_j = \text{Int}\left(\frac{B_j}{W_0} + 0.5\right) \quad \text{for } j = 1, 2, \ldots, J - 1$$

and

$$m_J = r - \sum_{j=1}^{J-1} (m_j + 1)$$

respectively, and then recalculating the frequency intervals for the various bands as

$$W_j = \frac{B_j}{m_j} \quad \text{for } j = 1, 2, \ldots, J$$

A more sophisticated initialization scheme, which was found to give good results, is described in Ref. [15].

Location of maxima of the error function. The frequencies, $\hat{\omega}_i$, which *must include maxima at band edges if* $|E(\hat{\omega}_i)| \geq |\delta|$, can be located by simply evaluating $|E(\omega)|$ over a dense set of frequencies. A reasonable number of frequency points that yield sufficient accuracy in the determination of the frequencies $\hat{\omega}_i$ are $8(N+1)$. This corresponds to about 16 frequency points per ripple of $|E(\omega)|$. A suitable frequency interval for the jth band is $w_j = W_j/S$ with $S = 16$.

The above *exhaustive* search can be implemented in terms of Algorithm 18.2 below, where ω_{Lj} and ω_{Rj} are the left-hand and right-hand edges in band j; W_j is the interval between adjacent extremals and m_j is the number of intervals W_j in band j; w_j is the interval between successive samples of $|E(\omega)|$ in interval W_j and S is the number of intervals w_j in each interval W_j; N_j is the total number of intervals w_j in band j; and J is the number of bands.

ALGORITHM 18.2: Exhaustive Step-by-Step Search

1. Set $N_j = m_j S$, $w_j = B_j/N_j$, and $e = 0$.
2. For each of bands $1, 2, \ldots, j, \ldots, J$ do the following. For each of frequencies $\omega_{1j} = \omega_{Lj}$, $\omega_{2j} = \omega_{Lj} + \omega_j, \ldots, \omega_{ij} = \omega_{LJ} + (i-1)\omega_j, \ldots, \omega_{(N_j+1)j} = \omega_{Rj}$, set $\hat{\omega}_e = \omega_{ij}$ and $e = e + 1$ provided that $|E(\omega_{ij})| \geq |\delta|$ and one of the following conditions holds:
   (a) Case $\omega_{ij} = \omega_{Lj}$: if $|E(\omega_{ij})|$ is maximum at $\omega_{ij} = \omega_{Lj}$ (i.e., $|E(\omega_{Lj})| > |E(\omega_{Lj} + \varepsilon)|$)
   (b) Case $\omega_{Lj} < \omega_{ij} < \omega_{Rj}$: if $|E(\omega)|$ is maximum at $\omega = \omega_{ij}$ (i.e., $|E(\omega_{ij} - \omega_j)| < |E(\omega_{ij})| > |E(\omega_{ij} + \omega_j)|$)
   (c) Case $\omega_{ij} = \omega_{Rj}$: if $|E(\omega_{ij})|$ is maximum at $\omega_{ij} = \omega_{Rj}$ (i.e., $|E(\omega_{Rj})| > |E(\omega_{Rj} - \varepsilon)|$)

The parameter ε in steps 2(a) and 2(c) is a small positive constant and a value $10^{-2} w_j$ yields satisfactory results.

In practice, $|E(\omega)|$ is maximum at an interior left-hand band edge* if its first derivative at the band edge is negative, and a mirror-image situation applies at an interior right-hand band edge. In such cases, $|E(\omega)|$ has a zero immediately to the right or left of the band edge and the inequality in step 2(a) or 2(c) may sometimes fail to identify a maximum. However, the problem can be avoided by using the inequality $|E(\omega_{Lj} - \varepsilon)| > |E(\omega_{Lj})|$ in step 2(a) and $|E(\omega_{Rj})| < |E(\omega_{Rj} + \varepsilon)|$ in step 2(c) for interior band edges.

In rare circumstances, a maximum of $|E(\omega)|$ may occur between a band edge and the first sample point. Such a maximum may be missed by Algorithm 18.2, but the problem can be easily identified since the number of potential extremals will then be less than the minimum. The remedy is to check the number of potential extremals at the end of each iteration and if it is found to be less than $r + 1$, the density of sample points, i.e., S is doubled and the iteration is repeated. If the problem persists, the process is repeated until the required number of potential extremals is obtained. If a value of S equal to or less than 256 does not resolve the problem, the loss of potential extremals is most likely due to some other reason.

An important precaution in the implementation of the preceding search method is to ensure that extremals belong to the dense set of frequency points to avoid numerical ill-conditioning in the computation of $E(\omega)$ (see Equations 18.49 and 18.51). In addition, the condition $|E(\omega_{ij})| \leq |\delta|$ should

* An interior band edge is one in the range $0 < \omega < \pi$, i.e., not at $\omega = 0$ or π.

be replaced by $|E(\omega_{ij})| > |\delta| - \varepsilon_1$, where ε_1 is a small positive constant, say 10^{-6}, to ensure that no maxima are missed owing to roundoff errors.

The search method is very reliable and its use in Algorithm 18.1 leads to a *robust* algorithm since the entire frequency axis is searched using a dense set of frequency points. Its disadvantage is that it requires a considerable amount of computation and is, therefore, inefficient.

A more efficient version of Algorithm 18.2 is obtained by maintaining all the interior band edges as extremals throughout the optimization independently of the behavior of the error function at the band edges. However, the algorithm obtained tends to be somewhat less robust, i.e., it tends to fail more frequently than Algorithm 18.2.

Computation of $|E(\omega)|$ *and* $P_c(\omega)$. In steps 2 and 6 of the basic Remez algorithm (Algorithm 18.1), $|E(\omega)|$ and $P_c(\omega)$ need to be evaluated. This can be done by determining coefficients a_k by inverting the matrix in Equation 18.50. However, this approach is inefficient and may be subject to numerical ill-conditioning, in particular, if δ is small and N is large. An alternative and more efficient approach is to deduce δ analytically and then interpolate $P_c(\omega)$ on the r frequency points using the *barycentric* form of the *Lagrange interpolation* formula. The necessary formulation is as follows.

Parameter δ can be deduced as

$$\delta = \frac{\sum_{k=0}^{r} \alpha_k D(\hat{\omega}_k)}{\sum_{k=0}^{r} \frac{(-1)^k \alpha_k}{W(\hat{\omega}_k)}}$$

and $P_c(\omega)$ is given by

$$P_c(\omega) = \begin{cases} C_k & \text{for } \omega = \hat{\omega}_0, \hat{\omega}_1, \ldots, \hat{\omega}_{r-1} \\ \frac{\sum_{k=0}^{r-1} \frac{\beta_k C_k}{x - x_k}}{\sum_{k=0}^{r-1} \frac{\beta_k}{x - x_k}} & \text{otherwise} \end{cases} \tag{18.51}$$

where

$$\alpha_k = \prod_{i=0, i\neq k}^{r} \frac{1}{x_k - x_i}$$

$$C_k = D(\hat{\omega}_k) - (-1)^k \frac{\delta}{W(\hat{\omega}_k)}$$

$$\beta_k = \prod_{i=0, i\neq k}^{r-1} \frac{1}{x_k - x_i}$$

with

$$x = \cos\omega \quad \text{and} \quad x_i = \cos\hat{\omega}_i \quad \text{for } i = 0, 1, 2, \ldots, r$$

In step 2 of the Remez algorithm, $|E(\omega)|$ often needs to be evaluated at a frequency that was an extremal during the previous iteration. For these cases, the magnitude of the error function is simply $|\delta|$ according to Equation 18.49, and need not be evaluated. This would reduce the amount of computation to some extent.

An alternative formulation that simplifies the implementation of the Remez exchange algorithm can be found in Ref. [12].

Rejection of superfluous potential extremals. The solution of Equation 18.50 can be obtained only if *precisely* $r+1$ extremals are available. By differentiating $E(\omega)$, one can show that in a filter with one frequency band of interest (e.g., a digital differentiator) the number of maxima in $|E(\omega)|$ (potential extremals in step 2 of Algorithm 18.1) can be as high as $r+1$. In the weighted-Chebyshev method, band edges at which $|E(\omega)|$ is maximum or $|E(\omega)| \geq |\delta|$ are treated as potential extremals (see Algorithm 18.2). Therefore, whenever the number of frequency bands is increased by one, the number of potential extremals is increased by 2, i.e., for a filter with J bands there can be as many as $r+2J-1$ frequencies $\hat{\omega}_i$ and a maximum of $2J-2$ superfluous $\hat{\omega}_i$ may occur. This problem is overcome by rejecting $\rho - r$ of the potential extremals $\hat{\omega}_i$, if $\rho > r$, in step 4 of the algorithm.

A simple rejection scheme is to reject the $\rho - r$ frequencies $\hat{\omega}_i$ that yield the lowest $|E(\hat{\omega}_i)|$ and then renumber the remaining $\hat{\omega}_i$ from 0 to r [8]. This strategy is based on the well-known fact that the magnitude of the error in a given band is inversely related to the density of extremals in that band, i.e., a low density of extremals results in a large error and a high density results in a small error. Conversely, a low band error is indicative of a high density of extremals, and rejecting superfluous $\hat{\omega}_i$ in such a band is the appropriate course of action.

A problem with the scheme just described is that whenever a frequency remains an extremal in two successive iterations, $|E(\omega)|$ assumes the value of $|\delta|$ in the second iteration by virtue of Equation 18.49. In practice, there are almost always several frequencies that remain extremals from one iteration to the next, and the value of $|E(\omega)|$ at these frequencies will be the same. Consequently, the rejection of potential extremals on the basis of the magnitude of the error can become arbitrary and may lead to the rejection of potential extremals in bands where the density of extremals is low. This tends to increase the number of iterations, and it may even prevent the algorithm from converging on occasion. This problem can to some extent be alleviated by rejecting only potential extremals that are not band edges.

An alternative rejection scheme based on the aforementioned strategy, which gives excellent results for two-band and three-band filters, involves ranking the frequency bands in the order of lowest average band error, dropping the band with the highest average error from the list, and then rejecting potential extremals, one per band, in a cyclic manner starting with the band with the lowest average error [11]. The steps involved are as follows.

ALGORITHM 18.3: Rejection of Superfluous Potential Externals

1. Compute the average band errors

$$E_j = \frac{1}{\nu_j} \sum_{\hat{\omega}_i \in \Omega_j} \left| E(\hat{\omega}_i) \right| \quad \text{for } j = 1, 2, \ldots, J$$

   where Ω_j is the set of potential externals in band j given by

$$\Omega_j = \left\{ \hat{\omega}_j : \omega_{\mathrm{L}j} \leq \hat{\omega}_j \leq \omega_{\mathrm{R}j} \right\}$$

   ν_j is the number of potential externals in band j, and J is the number of bands.
2. Rank the J bands in the order of lowest average error and let $l_1, l_2, \ldots, l_{\mathrm{J}}$ be the ranked list obtained, i.e., l_1 and l_{J} are the bands with the lowest and highest average errors, respectively.
3. Reject one $\hat{\omega}_i$ in each of bands $l_1, l_2, \ldots, l_{\mathrm{J}-1}, l_1, l_2, \ldots, l_1$ until $\rho - r$ superfluous $\hat{\omega}_i$ are rejected. In each case, reject the $\hat{\omega}_i$, other than a band edge, that yields the lowest $|E(\hat{\omega}_i)|$ in the band.

For example, if $J = 3$, $\rho - r = 3$, and the average errors for bands 1, 2, and 3 are, respectively, 0.05, 0.08, and 0.02, then $\hat{\omega}_i$ are rejected in bands 3, 1, and 3. Note that potential extremals are not rejected in band 2, which is the band of highest average error.

Computation of impulse response. The impulse response in step 6 of Algorithm 18.1 can be determined by noting that function $P_c(\omega)$ is the frequency response of a noncausal version of the required filter. The impulse response of this filter, represented by $h_0(n)$ for $-c \leq n \leq c$, can be determined by computing $P_c(k\Omega)$ for $k = 0, 1, 2, \ldots, c$, where $\Omega = 2\pi/N$, and then using the *inverse discrete Fourier transform*. It can be shown that

$$h_0(n) = h_0(-n) = \frac{1}{N}\left[P_c(0) + \sum_{k=1}^{c} 2P_c(k\Omega)\cos\left(\frac{2\pi kn}{N}\right)\right]$$

for $n = 0, 1, 2, \ldots, c$. Therefore, the impulse response of the required causal filter is given by

$$h(n) = h_0(n - c)$$

for $n = 0, 1, 2, \ldots, N - 1$.

18.3.2.2 Improved Search Methods

For a filter of length N, with the number of intervals w_j in each internal W_j equal to S, the exhaustive step-by-step search described (Algorithm 18.2) requires about $S \times (N + 1)/2$ function evaluations, where each function evaluation entails $N - 1$ additions, $(N + 1)/2$ multiplications, and $(N + 1)/2$ divisions (see Equation 18.51).

A Remez optimization usually requires 4 to 8 iterations for low-pass or high-pass filters, 4 to 10 iterations for bandpass filters, and 4 to 12 iterations for bandstop filters. Further, if prescribed specifications are to be achieved and the appropriate value of N is unknown, typically two to four Remez optimizations have to be performed.* Thus, if $N = 101$, $S = 16$, number of Remez optimizations $= 4$, iterations per optimization $= 6$, the design would entail 24 iterations, 19,200 function evaluations, 1.92×10^6 additions, 0.979×10^6 multiplications, and 0.979×10^6 divisions. This is in addition to the computation required for the evaluation of δ and coefficients α_k, C_k, and β_k once per iteration. In effect, the amount of computation required to complete a design is quite substantial.

The bulk of the computation in Algorithm 18.2 is carried out to locate the maxima of $|E(\omega)|$ and the large amount of computation is a consequence of the exhaustive character of the search. Therefore, any attempt to reduce the computational complexity of the Remez exchange algorithm must of necessity involve a more efficient search for the maxima of $|E(\omega)|$.

The error function in the weighted-Chebyshev method is well behaved in practice, and is normally unimodal between successive zeros, as can be seen in Figures 18.15 and 18.16. Hence, the maxima of $|E(\omega)|$ can be located through more sophisticated search methods that utilize gradient information. Two such methods are the so-called *selective step-by-step search* and *cubic-interpolation search* reported in Refs. [10,11]. Collectively, the two search methods can reduce the amount of computation to about one-fifth the amount required by the exhaustive search.

Selective step-by-step search. The underlying principle in the development of the selective step-by-step search is that normally there is strict alternation between the maxima and the zeros of $|E(\omega)|$. In a given iteration, the maxima of $|E(\omega)|$ are either old maxima from the previous iteration that have moved or new maxima introduced at band edges. New interior maxima may also arise, in theory, but such occurrences are quite rare in practice.

* See Section 18.3.2.3.

The selective step-by-step search involves three distinct parts as follows:

(1) Maxima that correspond to previous maxima are located by searching in the neighborhoods of the most recent set of extremals in a step-by-step fashion using the first derivative of $|E(\omega)|$. If the first derivative is positive at an extremal, the search is carried out to the right of the extremal; otherwise, the search is carried out to the left of the extremal.
(2) New maxima at band edges can be located by noting the circumstances under which new maxima can arise. These are as follows:
   a. To the right of $\omega = 0$ (first band), if there is an extremal and $|E(\omega)|$ has a minimum at $\omega = 0$
   b. To the left of $\omega = \pi$ (last band), if there is an extremal and $|E(\omega)|$ has a minimum at $\omega = \pi$
   c. At $\omega = 0$, if there is no extremal at $\omega = 0$
   d. At $\omega = \pi$, if there is no extremal at $\omega = \pi$
   e. To the right of an interior left-hand edge
   f. To the left of an interior right-hand edge
   g. At $\omega = \omega_{Lj}$, if there is no extremal at $\omega = \omega_{Lj}$
   h. At $\omega = \omega_{Rj}$, if there is no extremal at $\omega = \omega_{Rj}$
(3) New interior maxima, which cannot be located by the checks in (1) and (2) can be found by noting the presence of large gaps in the set of potential extremals identified in (1) and (2). If the difference between two consecutive potential extremals exceeds 1.5 to 2 times the initial interval between extremals (i.e., W_j), then the interval is checked for additional maxima.

If a selective step-by-step search based on the above principles is used in Algorithm 18.1, then at the start of the optimization the distance between a typical extremal $\hat{\omega}_i$ and the nearby maximum point $\hat{\omega}_i$ will be less than half the period of the corresponding ripple of $|E(\omega)|$, owing to the relative symmetry of the ripples of the error function. In effect, during the first iteration less than half of the combined width of the different bands needs to be searched. Thus the number of function evaluations required would be reduced from about 16 to less than 8 per extremal in practice. This will reduce the number of function evaluations by more than 50% relative to that required by the exhaustive search of Algorithm 18.1 without degrading the accuracy of the optimization in any way. As the optimization progresses and the solution is approached, extremal $\hat{\omega}_i$ and maximum point $\hat{\omega}_i$ tend to coincide and, therefore, the cumulative length of the frequency range that has to be searched is progressively reduced, thereby resulting in further economies in the number of function evaluations. In the last iteration, only two or three function evaluations are needed (including derivatives) per ripple. As a result, the total number of function evaluations can be reduced by 65%–70% relative to that required by the exhaustive search [10,11].

Cubic-interpolation search. The maxima in item (1) of the above method can also be found through the use of one stage of polynomial interpolation. Either quadratic or cubic interpolation can be used. In these methods, a polynomial approximation is obtained for the magnitude of the error function in the neighborhood of a given extremal and the location of the maximum is determined by finding the point at which the first derivative is zero. Although cubic interpolation entails a more complicated formulation than quadratic interpolation, it leads to improved accuracy, which tends to translate into improved efficiency.

Several choices are possible in setting up a cubic-interpolation search for the problem at hand. One that was found to work well in practice entails evaluating $|E(\omega)|$ at three frequency points and its derivative at one point. Choosing the extremal itself as one of the points reduces the computation further since the value of $|E(\omega)|$ is known to be $|\delta|$ from the previous iteration. Thus this scheme entails three function evaluations per extremal.

The computational complexity of the cubic-interpolation search described remains constant from iteration to iteration since the number of function evaluations required to perform an interpolation is constant. At the start of the optimization, the cubic-interpolation search is more efficient than the selective step-by-step search. However, as the solution is approached the number of function evaluations

required by the selective search is progressively reduced, as was stated earlier, and at some point the selective search becomes more efficient. A prudent strategy under the circumstances is to use the cubic-interpolation search at the start of the optimization and switch over to the selective step-by-step search when some suitable criterion is satisfied. Extensive experimentation has shown that computational advantage can be gained by using the cubic-interpolation search if parameter Q (see Algorithm 18.1) is greater than about 0.65 and the selective search otherwise. The use of the cubic-interpolation search along with the selective step-by-step search of the preceding section can reduce the number of function evaluations by 70%–85% relative to that required by the exhaustive search [10,11].

More information, including the necessary formulation as well as a practical and efficient implementation of the Remez exchange algorithm in terms of the above search methods, can be found in Ref. [12].

Example 18.1

The Remez algorithm was used with (1) the exhaustive search, (2) the selective step-by-step search, and (3) the selective search in conjunction with the cubic-interpolation search to design an FIR equiripple high-pass filter satisfying the following specifications:

Filter length N: 23
Passband edge $\boldsymbol{\omega}_p$: 2.0 rad/s
Stopband edge $\boldsymbol{\omega}_a$: 1.0 rad/s
Ratio $\boldsymbol{\delta}_p/\boldsymbol{\delta}_a$: 15.0
Sampling frequency $\boldsymbol{\omega}_s$: $2\boldsymbol{\pi}$ rad/s

The progress of the design is illustrated in Table 18.3. As can be seen, the exhaustive and selective search methods required six iterations each, whereas the selective search in conjunction with cubic interpolation required seven iterations. However, the number of function evaluations (evaluations of $P_c(\boldsymbol{\omega})$ using Equation 18.51 plus evaluations of its first or second derivative) decreased from 1013 in the first method to 350 in the second method to 259 in the third method. In the Remez algorithm, approximately 80%–90% of the computational effort involves function evaluations. In effect, relative to that required by the exhaustive search, the use of the selective step-by-step search reduced the amount of computation by about 65.4%, and the use of the selective step-by-step search in conjunction with the cubic-interpolation search reduced the amount of computation by about 74.4%.

The three methods resulted in approximately the same impulse responses, as can be seen in Table 18.4, and the passband ripple and minimum stopband attenuation obtained in each case were 0.043 and 75.7 dB, respectively. The amplitude response of the filter is illustrated in Figure 18.17.

Example 18.2

In this example, the Remez algorithm was used with (1) the exhaustive search, (2) the selective step-by-step search, and (3) the selective step-by-step search in conjunction with the cubic-interpolation search to design an FIR equiripple bandstop filter satisfying the following specifications:

Filter length N: 29
Lower passband edge ω_{p1}: 0.8 rad/s
Upper passband edge ω_{p2}: 2.1 rad/s
Lower stopband edge ω_{a1}: 1.1 rad/s
Upper stopband edge ω_{a2}: 1.8 rad/s
Ratio δ_{p1}/δ_a: 5.0
Ratio δ_{p1}/δ_{p2}: 2.0
Sampling frequency ω_s: 2π rad/s

The progress of the design is illustrated in Table 18.5. In this example, each of the three methods required four iterations. The number of function evaluations decreased from 804 in the first method to 190 in the second method to 131 in the third method. In effect, the use of the selective step-by-step search reduced the amount of computation by about 76.4%, and the use of the

selective step-by-step search in conjunction with the cubic-interpolation search reduced the amount of computation by about 83.7%, relative to that required by the exhaustive search.

The three methods resulted in approximately the same impulse responses, as can be seen in Table 18.6. The amplitude response of the filter is illustrated in Figure 18.18; the passband ripples obtained for the two passbands were 1.78 and 0.89 dB, respectively, and the minimum stopband attenuation was 33.79 dB.

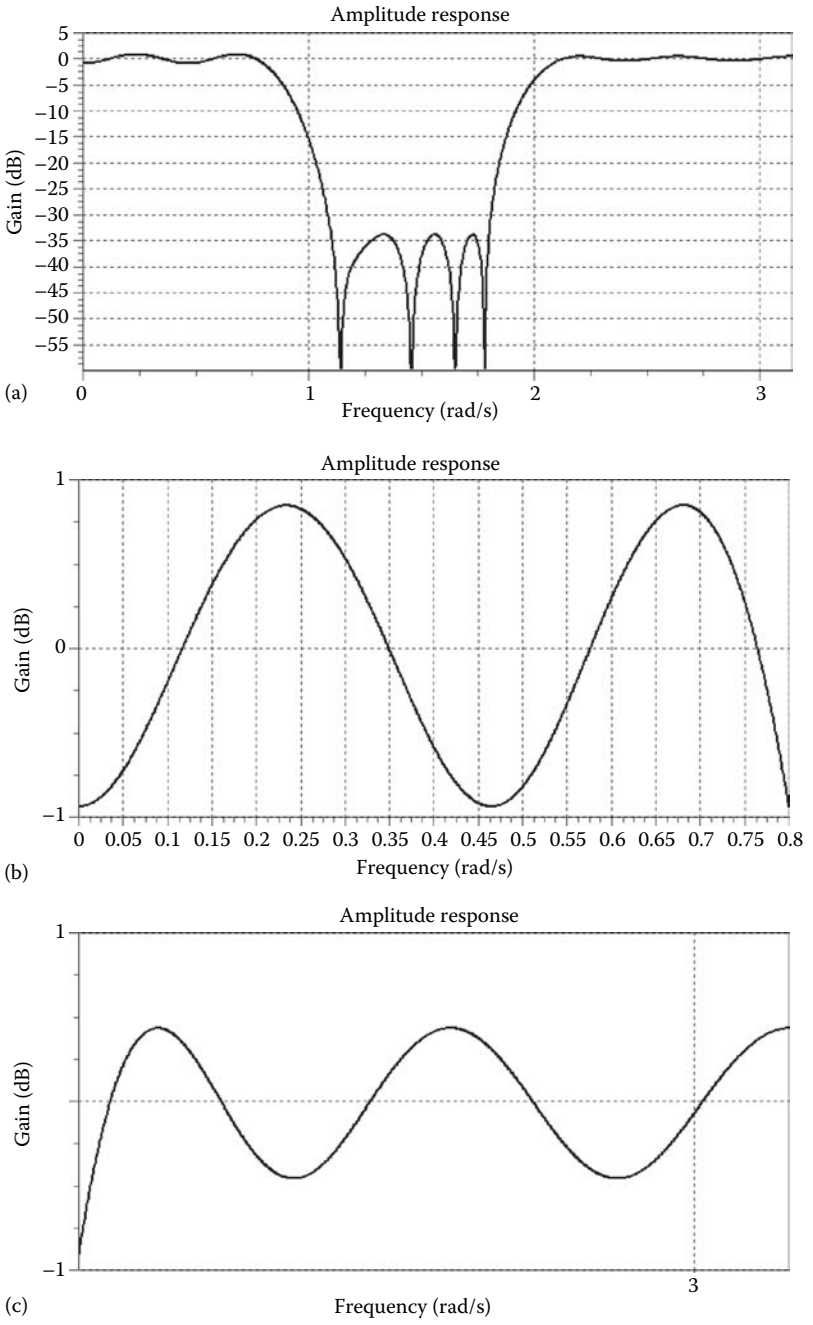

FIGURE 18.18 Amplitude response of equiripple bandstop filter (Example 18.2): (a) baseband, (b) lower passband, and (c) upper passband.

18.3.2.3 Prescribed Specifications

Given a filter length N, a set of passband and stopband edges, and a ratio δ_p/δ_a, an FIR filter with approximately piecewise-constant amplitude-response specifications can be readily designed. While the filter obtained will have passband and stopband edges at the correct locations and the ratio δ_p/δ_a will be as required, the amplitudes of the passband and stopband ripples are highly unlikely to be precisely as specified. An acceptable design can be obtained by predicting the value of N on the basis of the required specifications and then designing filters for increasing or decreasing values of N until the lowest value of N that satisfies the specifications is found.

A reasonably accurate *empirical* formula for the prediction of N for the case of low-pass and high-pass filters, due to Hermann et al. [16], is

$$N = \text{Int}\left[\frac{(D - FB^2)}{B} + 1.5\right] \tag{18.52}$$

where

$$\begin{aligned} B &= \left|\omega_a - \omega_p\right|/2\pi \\ D &= \left[0.005309(\log\delta_p)^2 + 0.07114\log\delta_p - 0.4761\right]\log\delta_a \\ &\quad - \left[0.00266(\log\delta_p)^2 + 0.5941\log\delta_p + 0.4278\right] \\ F &= 0.51244(\log\delta_p - \log\delta_a) + 11.012 \end{aligned}$$

Interestingly this formula can also be used to predict the filter length in the design of bandpass, bandstop, and multiband filters in general. In these filters, a value of N is computed for each transition band between a passband and stopband or a stopband and passband using Equation 18.52 and the largest value of N so obtained is taken to be the predicted filter length. *Prescribed specifications* can be achieved by using the following design algorithm.

ALGORITHM 18.4: Design of Filters Satisfying Prescribed Specifications

1. Compute N using Equation 18.52; if N is even, set $N = N + 1$.
2. Design a filter of length N and determine the minimum value of δ, say $\breve{\delta}$.
   A. If $\breve{\delta} > \delta_p$, then do the following:
      i. Set $N = N + 2$, design a filter of length N, and find $\breve{\delta}$.
      ii. If $\breve{\delta} \leq \delta_p$, then go to step 3; else, go to step 2(A)(i).
   B. If $\breve{\delta} < \delta_p$, then do the following:
      i. Set $N = N - 2$, design a filter of length N, and find $\breve{\delta}$.
      ii. If $\breve{\delta} > \delta_p$ then go to step 4; else, go to step 2(B)(i).
3. Use the last set of extremals and the corresponding value of N to obtain the impulse response of the required filter and stop.
4. Use the last but one set of extremals and the corresponding value of N to obtain the impulse response of the required filter and stop.

Example 18.3

Algorithm 18.4 was used to design an FIR equiripple bandpass filter that would satisfy the following specifications:

Odd filter length
Maximum passband ripple A_p: 0.5 dB
Minimum stopband attenuation A_{a1}: 50.0 dB
Minimum stopband attenuation A_{a2}: 30.0 dB
Lower passband edge ω_{p1}: 1.2 rad/s
Upper passband edge ω_{p2}: 1.8 rad/s
Lower stopband edge ω_{a1}: 0.9 rad/s
Upper stopband edge ω_{a2}: 2.1 rad/s
Sampling frequency ω_s: 2π rad/s

The progress of the design is illustrated in Table 18.7. As can be seen, a filter of length 41 was initially predicted, which was found to have a passband ripple of 0.47 dB, a minimum stopband attenuation of 50.4 in the lower stopband, and 30.4 dB in the upper stopband, i.e., the required specifications were satisfied. Then a filter length of 39 was tried and found to violate the specifications. Hence the first design is the required filter. The impulse response is given in Table 18.8. The corresponding amplitude response is depicted in Figure 18.19.

18.3.2.4 Generalization

There are four types of constant-delay FIR filters. The impulse response can be *symmetrical* or *antisymmetrical*, and the filter length can be *odd* or *even*. In the preceding sections, we considered the design of filters with symmetrical impulse response and odd length. In this section, we show that the Remez algorithm can also be applied for the design of other types of filters.

Antisymmetrical impulse response and odd filter length. Assuming that $\omega_s = 2\pi$, the frequency response of an FIR filter with *antisymmetrical* impulse and *odd* length can be expressed as

$$H(e^{j\omega T}) = e^{-jc\omega} jP'_c(\omega)$$

10	3.860990×10^{-2}	—	—

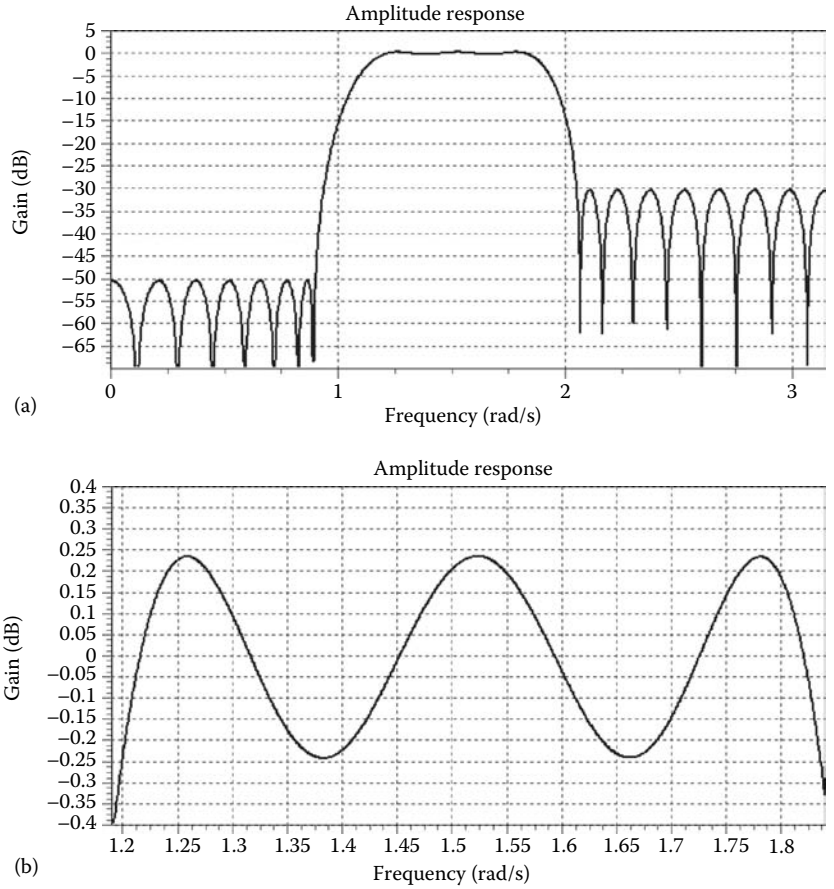

FIGURE 18.19 Amplitude response of equiripple bandpass filter (Example 18.3): (a) baseband and (b) passband.

where

$$\begin{aligned} P_c'(\omega) &= \sum_{k=1}^{c} a_k \sin k\omega \\ a_k &= 2h(c-k) \quad \text{for } k = 1, 2, \ldots, c \\ c &= (N-1)/2 \end{aligned} \tag{18.53}$$

A filter with a desired frequency response $e^{-jc\omega}\, jD(\omega)$ can be designed by constructing the error function

$$E(\omega) = W(\omega)[D(\omega) - P_c'(\omega)] \tag{18.54}$$

and then minimizing $|E(\omega)|$ with respect to some compact subset of the frequency interval $[0, \pi]$. From Equation 18.53, $P_c'(\omega)$ can be expressed as [6]

$$P_c'(\omega) = (\sin \omega)\ P_{c-1}(\omega) \tag{18.55}$$

where

$$P_{c-1}(\omega) = \sum_{k=0}^{c-1} \tilde{c}_k \cos k\omega$$

and

$$\begin{aligned} a_1 &= \tilde{c}_0 - \frac{1}{2}\tilde{c}_2 \\ a_k &= \frac{1}{2}(\tilde{c}_{k-1} - \tilde{c}_{k+1}) \quad \text{for } k = 2, 3, \ldots, c-2 \\ a_{c-1} &= \frac{1}{2}\tilde{c}_{c-2} \\ a_c &= \frac{1}{2}\tilde{c}_{c-1} \end{aligned}$$

Hence Equation 18.54 can be put in the form

$$E(\omega) = \tilde{W}(\omega)[\tilde{D}(\omega) - \tilde{P}(\omega)] \tag{18.56}$$

where

$$\begin{aligned} \tilde{W}(\omega) &= Q(\omega)W(\omega) \\ \tilde{D}(\omega) &= D(\omega)/Q(\omega) \\ \tilde{P}(\omega) &= P_{c-1}(\omega) \\ Q(\omega) &= \sin\omega \end{aligned}$$

Evidently, Equation 18.56 is of the same form as Equation 18.45, and upon proceeding as in Section 18.3.2, one can obtain the system of equations

$$\begin{bmatrix} 1 & \cos\hat{\omega}_0 & \cos 2\hat{\omega}_0 & \cdots & \cos(c-1)\hat{\omega}_0 & \frac{1}{W(\hat{\omega}_0)} \\ 1 & \cos\hat{\omega}_1 & \cos 2\hat{\omega}_1 & \cdots & \cos(c-1)\hat{\omega}_1 & \frac{-1}{W(\hat{\omega}_1)} \\ \vdots & \vdots & \vdots & & \vdots & \vdots \\ 1 & \cos\hat{\omega}_r & \cos 2\hat{\omega}_r & \cdots & \cos(c-1)\hat{\omega}_r & \frac{(-1)^r}{W(\hat{\omega}_r)} \end{bmatrix} \begin{bmatrix} a_0 \\ a_1 \\ \vdots \\ a_{c-1} \\ \delta \end{bmatrix} = \begin{bmatrix} \tilde{D}(\hat{\omega}_0) \\ \tilde{D}(\hat{\omega}_1) \\ \vdots \\ \tilde{D}(\hat{\omega}_r) \end{bmatrix}$$

where $r = c$ is the number of cosine functions in $P_{c-1}(\omega)$. The above system is the same as that in Equation 18.50 except that the number of extremals has been reduced from $c+2$ to $c+1$; therefore, the application of the Remez algorithm follows the methodology detailed in Sections 18.3.2 and 18.3.2.1 formulation and the Remez exchange algorithm.

The use of Algorithm 18.1 yields the optimum $P_{c-1}(\omega)$ and from Equation 18.55, the cosine function $P'_c(\omega)$ can be formed. Now $jP'_c(\omega)$ is the frequency response of a noncausal version of the required filter. The impulse response of this filter can be obtained as

$$h_0(n) = -h_0(-n) = -\frac{1}{N}\left[\sum_{k=1}^{c} 2P'_c(k\Omega)\ \sin\left(\frac{2\pi kn}{N}\right)\right]$$

for $n = 0, 1, 2, \ldots, c$, where $\Omega = 2\pi/N$, by using the inverse discrete Fourier transform. The impulse response of the corresponding causal filter is given by

$$h(n) = h_0(n-c)$$

for $n = 0, 1, 2, \ldots, N-1$.

The Remez algorithm can also be applied for the design of filters with symmetrical or antisymmetrical impulse response and even N. However, these filters are used less frequently. The reader is referred to Refs. [6,12] for more details.

18.3.2.5 Digital Differentiators

The Remez algorithm can be easily applied for the design of *equiripple digital differentiators*. The ideal frequency response of a causal differentiator is of the form $e^{-jc\omega}\, jD(\omega)$ where

$$D(\omega) = \omega \quad \text{for } 0 < |\omega| < \pi \tag{18.57}$$

and

$$c = (N-1)/2$$

Since the frequency response is antisymmetrical, differentiators can be designed in terms of filters with antisymmetrical impulse response of either odd or even length.

Problem formulation. Assuming odd filter length, Equations 18.54 and 18.57 give the error function

$$E(\omega) = W(\omega)\left[\omega - P'_c(\omega)\right] \quad \text{for } 0 < \omega \le \omega_p$$

where ω_p is the required bandwidth. Equiripple absolute or relative error may be required, depending on the application at hand. Hence, $W(\omega)$ can be chosen to be either unity or $1/\omega$. In the latter case, which is the more meaningful of the two in practice, $E(\omega)$ can be expressed as

$$E(\omega) = 1 - \frac{1}{\omega} P'_c(\omega) \quad \text{for } 0 < \omega \le \omega_p$$

and from Equation 18.55

$$E(\omega) = 1 - \frac{\sin\omega}{\omega} P_{c-1}(\omega) \quad \text{for } 0 < \omega \le \omega_p \tag{18.58}$$

Therefore, the error function can be expressed as in Equation 18.56 with

$$\tilde{W}(\omega) = \frac{1}{\tilde{D}(\omega)} = \frac{\sin\omega}{\omega}$$
$$\tilde{P}(\omega) = P_{c-1}(\omega)$$

Prescribed specifications. A digital differentiator is fully specified by the constraint

$$|E(\omega)| \le \delta_p \quad \text{for } 0 < \omega \le \omega_p$$

where

δ_p is the maximum passband error
ω_p is the bandwidth of the differentiator

The differentiator length N that will just satisfy the required specifications is not normally known *a priori* and, although it may be determined on a hit-or-miss basis, a large number of designs may need to be carried out. In filters with approximately piecewise-constant amplitude responses, N can be predicted using the empirical formula of Equation 18.52. In the case of differentiators, N can be predicted by noting

a useful property of digital differentiators. If δ and δ_1 are the maximum passband errors in differentiators of lengths N and N_1, respectively, then the quantity $\ln(\delta/\delta_1)$ is *approximately linear* with respect to $N - N_1$ for a wide range of values of N_1 and ω_p. Assuming linearity, we can show that [17]

$$N = N_1 + \frac{\ln(\delta/\delta_1)}{\ln(\delta_2/\delta_1)}(N_2 - N_1) \tag{18.59}$$

where δ_2 is the maximum passband error in a differentiator of length N_2.

By designing two low-order differentiators, a fairly accurate prediction of the required value of N can be obtained by using Equation 18.59. Once a filter order is predicted a series of differentiators can be designed with increasing or decreasing N until a design that just satisfies the specifications is obtained.

Example 18.4

The selective step-by-step search with cubic interpolation was used in Algorithm 18.4 to design a digital differentiator that should satisfy the following specifications:

Odd differentiator length
Bandwidth ω_p: 2.75 rad/s
Maximum passband ripple δ_p: 1.0×10^{-5}
Sampling frequency ω_s: 2π rad/s

The progress of the design is illustrated in Table 18.9. First, differentiators of lengths 21 and 23 were designed and the required N to satisfy the specifications was predicted to be 55 using Equation 18.59. This differentiator length was found to satisfy the specifications, and a design for length 53 was then carried out. The second design was found to violate the specifications and hence the first design is the required differentiator. The impulse response of this differentiator is given in Table 18.10. The amplitude response and passband relative error of the differentiator are plotted in Figure 18.20a and b.

18.3.2.6 Arbitrary Amplitude Responses

Very frequently FIR filters are required whose amplitude responses cannot be described by analytical functions. For example, in the design of two-dimensional filters through the singular-value decomposition [18,19], the required two-dimensional filter is obtained by designing a set of one-dimensional digital filters whose amplitude responses turn out to have arbitrary shapes. In these applications, the desired amplitude response $D(\omega)$ is specified in terms of a table that lists a prescribed set of frequencies and the corresponding values of the required filter gain. Filters of this class can be readily designed by employing some interpolation scheme that can be used to evaluate $D(\omega)$ and its first derivative with respect to ω at any ω. A suitable scheme is to fit a set of third-order polynomials to the prescribed amplitude response.

18.3.2.7 Multiband Filters

The algorithms presented in the previous sections can also be used to design *multiband* filters. While there is no theoretical upper limit on the number of bands, in practice, the design tends to become more and more difficult as the number of bands is increased. The reason is that the difference between the number of possible maxima in the error function and the number of extremals increases linearly

with the number of bands, e.g., if the number of bands is 8, then the difference is 14. As a consequence, the number of potential extremals that need to be rejected is large and the available rejection techniques become inefficient. The end result is that the number of iterations is increased quite significantly, and convergence is slow and sometimes impossible.

In mathematical terms, the above difficulty is attributed to the fact that, in the weighted-Chebyshev methods considered here, the approximating polynomial becomes seriously *underdetermined* if the number of bands exceeds three. The problem can be overcome by using the generalized Remez method described in Ref. [15]. This approach was found to yield better results for filters with more than four or five bands.

18.4 Design of Computationally Efficient FIR Filters Using Periodic Subfilters as Building Blocks

Tapio Saramäki

For many digital signal processing applications, FIR filters are preferred over their IIR counterparts as the former can be designed with exactly linear phase and they are free of stability problems and limit cycle oscillations. The major drawback of FIR filters is that they require, especially in applications demanding narrow transition bands, considerably more arithmetic operations and hardware components than do comparable IIR filters. Ignoring the correction term for very low-order filters, the minimum order of an optimum linear-phase low-pass FIR filter can be approximated [1] by

$$N \approx \Phi(\delta_p, \delta_s)/(\omega_s - \omega_p) \tag{18.60a}$$

where

$$\begin{aligned}\Phi(\delta_p, \delta_s) = {} & 2\pi\left[0.005309(\log_{10}\delta_p)^2 + 0.07114\log_{10}\delta_p - 0.4761\right]\log_{10}\delta_s \\ & - 2\pi\left[0.00266(\log_{10}\delta_p)^2 + 0.5941\log_{10}\delta_p + 0.4278\right]\end{aligned} \tag{18.60b}$$

Here, ω_p and ω_s are the passband and stopband edge angles, whereas δ_p and δ_s are the passband and stopband ripple magnitudes. From the above estimate, it is seen that as the transition bandwidth $\omega_s - \omega_p$ is made smaller, the required filter order increases inversely proportionally to it. Since the direct-form implementation exploiting the coefficient symmetry requires approximately $N/2$ multipliers, this kind of implementation becomes very costly if the transition bandwidth is small.

The cost of implementation of a narrow transition-band FIR filter can be significantly reduced by using multiplier-efficient realizations, fast convolution algorithms, or multirate filtering. This section considers those multiplier-efficient realizations that use as basic building blocks the transfer functions obtained by replacing each unit delay in a conventional transfer function by multiple delays. We concentrate on the synthesis techniques described in Refs. [2–4,6,8–10].

18.4.1 Frequency-Response Masking Approach

A very elegant approach to significantly reducing the implementation cost of an FIR filter has been proposed by Lim [3]. In this approach, the overall transfer function is constructed as

$$H(z) = F(z^L)G_1(z) + \left[z^{-LN_F/2} - F(z^L)\right]G_2(z) \tag{18.61a}$$

where

$$F(z^L) = \sum_{n=0}^{N_F} f(n)z^{-nL}, \quad f(N_F - n) = f(n) \tag{18.61b}$$

$$G_1(z) = z^{-M_1}\sum_{n=0}^{N_1} g_1(n)z^{-n}, \quad g_1(N_1 - n) = g_1(n) \tag{18.61c}$$

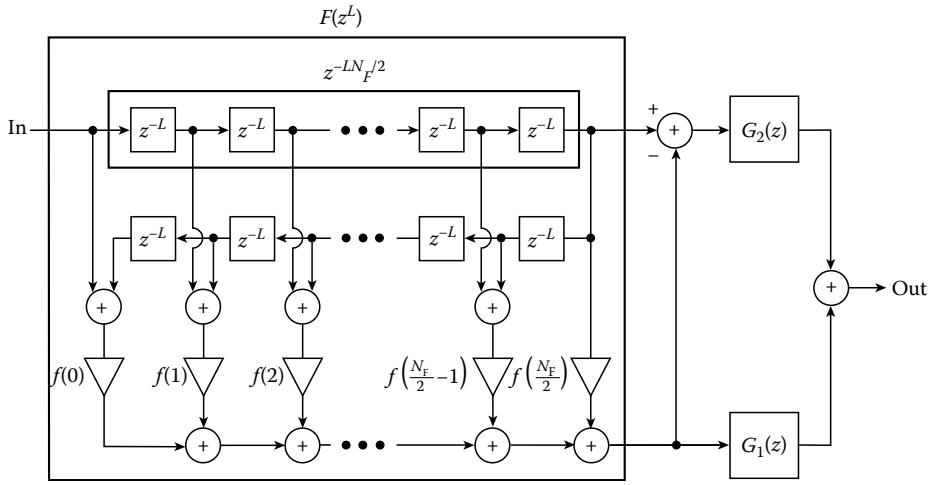

FIGURE 18.21 Efficient implementation for a filter synthesized using the frequency-response masking approach.

and

$$G_2(z) = z^{-M_2}\sum_{n=0}^{N_2} g_2(n)z^{-n}, \quad g_2(N_2 - n) = g_2(n) \tag{18.61d}$$

Here, N_F is even, whereas both N_1 and N_2 are either even or odd. For $N_1 \leq N_2$, $M_1 = 0$ and $M_2 = (N_1 - N_2)/2$, whereas for $N_1 < N_2$, $M_1 = (N_2 - N_1)/2$ and $M_2 = 0$. These selections guarantee that the delays of both of the terms of $H(z)$ are equal. An efficient implementation for the overall filter is depicted in Figure 18.21, where the delay term $z^{-LN_F/2}$ is shared with $F(z^L)$. Also, $G_1(z)$ and $G_2(z)$ can share their delays if a transposed direct-form implementation (exploiting the coefficient symmetry) is used.

The frequency response of the overall filter can be written as

$$H(e^{j\omega}) = H(\omega)e^{-j(LN_F + \max[N_1, N_2])\omega/2} \tag{18.62}$$

where $H(\omega)$ denotes the *zero-phase frequency response* of $H(z)$ and can be expressed as

$$H(\omega) = H_1(\omega) + H_2(\omega) \tag{18.63a}$$

where

$$H_1(\omega) = F(L\omega)G_1(\omega) \tag{18.63b}$$

and

$$H_2(\omega) = [1 - F(L\omega)]G_2(\omega) \tag{18.63c}$$

with

$$F(\omega) = f(N_F/2) + 2\sum_{n=1}^{N_F/2} f(N_F/2 - n)\cos n\omega \tag{18.63d}$$

and

$$G_k(\omega) = \begin{cases} g_k(N_k/2) + 2\sum_{n=1}^{N_k/2} g_k(N_k/2 - n)\cos n\omega & N_k \text{ even} \\ 2\sum_{n=0}^{(N_k-1)/2} g_k[(N_k-1)/2 - n]\cos[(n+1/2)\omega] & N_k \text{ odd} \end{cases} \tag{18.63e}$$

for $k = 1, 2$.

The efficiency as well as the synthesis of $H(z)$ are based on the properties of the pair of transfer functions $F(z^L)$ and $z^{-LN_F/2} - F(z^L)$, which can be generated from the pair of *prototype* transfer functions

$$F(z) = \sum_{n=0}^{N_F} f(n) z^{-n} \tag{18.64}$$

and $z^{-N_F/2} - F(z)$ by replacing z^{-1} by z^{-L}, that is, by substituting for each unit delay L unit delays. The order of the resulting filters is increased to LN_F, but since only every Lth impulse response value is nonzero, the filter complexity (number of adders and multipliers) remains the same. The above prototype pair forms a *complementary* filter pair since their zero-phase frequency responses, $F(\omega)$ and $1 - F(\omega)$ with $F(\omega)$ given by Equation 18.63d, add up to unity. Figure 18.22a illustrates the relations between these responses in the case where $F(z)$ and $z^{-N_F/2} - F(z)$ is a low-pass–high-pass filter pair with edges at θ and ϕ.

The substitution $z^{-L} \rightarrow z^{-1}$ preserves the complementary property resulting in the *periodic* responses $F(L\omega)$ and $1 - F(L\omega)$, which are frequency-axis compressed versions of the prototype responses such that the interval $[0, L\pi]$ is shrunk onto $[0, \pi]$ (see Figure 18.22b). Since the periodicity of the prototype responses is 2π, the periodicity of the resulting responses is $2\pi/L$ and they contain several passband and stopband regions in the interval $[0, \pi]$.

For a low-pass filter $H(z)$, one of the transition bands provided by $F(z^L)$ or $z^{-LN_F/2} - F(z^L)$ is used as that of the overall filter. In the first case, denoted by Case A, the edges are given by (Figure 18.23)

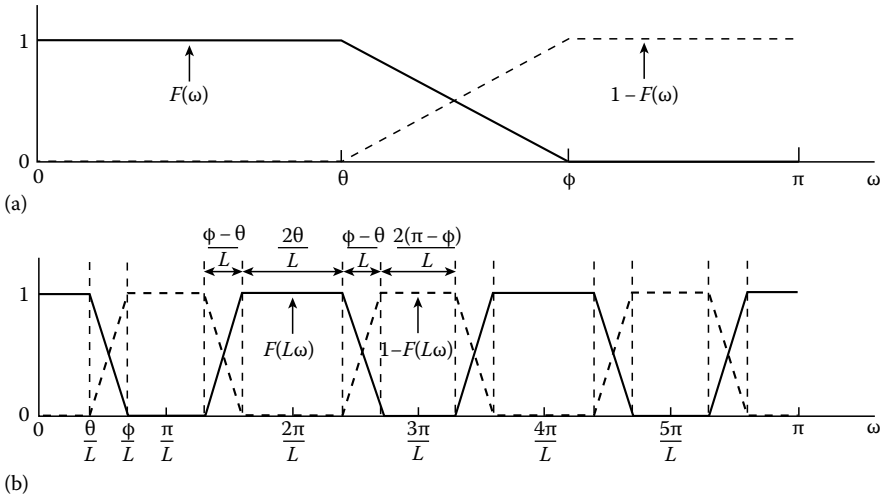

FIGURE 18.22 Generation of a complementary periodic filter pair by starting with a low-pass–high-pass complementary pair. (a) Prototype filter responses $F(\omega)$ and $1 - F(\omega)$. (b) Periodic responses $F(L\omega)$ and $1 - F(L\omega)$ for $L = 6$.

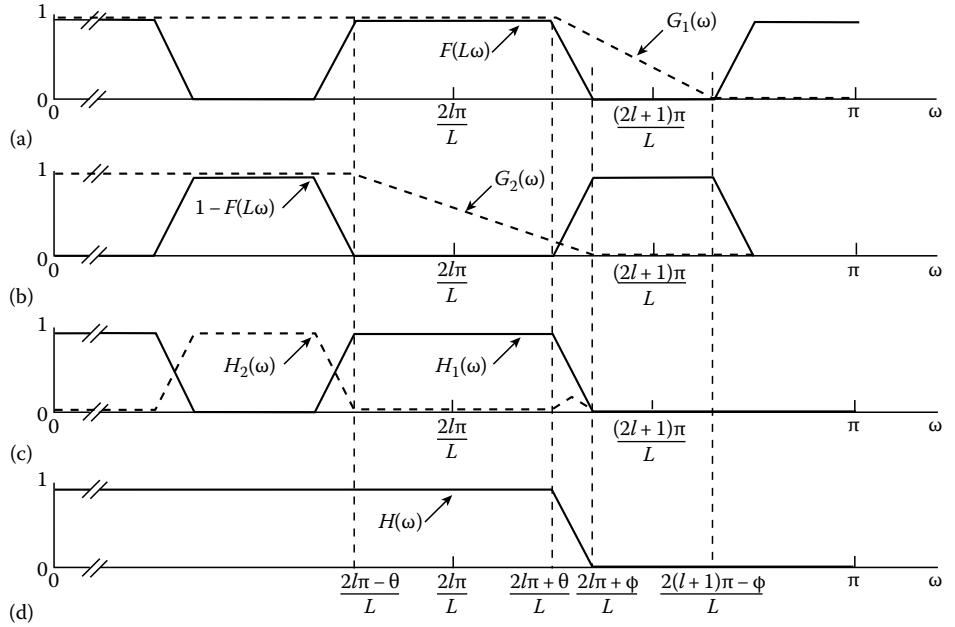

FIGURE 18.23 Case A design of a low-pass filter using the frequency-response masking technique.

$$\omega_p = (2l\pi + \theta)/L \quad \text{and} \quad \omega_s = (2l\pi + \phi)/L \tag{18.65}$$

where l is a fixed integer, and in the second case, referred to as Case B, by (Figure 18.24)

$$\omega_p = (2l\pi - \phi)/L \quad \text{and} \quad \omega_s = (2l\pi - \theta)/L \tag{18.66}$$

The widths of these transition bands are $(\phi - \theta)/L$, which is only $1/L$th of that of the prototype filters. Since the filter order is roughly inversely proportional to the transition bandwidth, this means that the arithmetic complexity of the periodic transfer functions to provide one of the transition bands is only $1/L$th of that of a conventional nonperiodic filter. Note that the orders of both the periodic filters and the corresponding nonperiodic filters are approximately the same, but the conventional filter does not contain zero-valued impulse response samples.

In order to exploit the attractive properties of the periodic transfer functions, the two low-order masking filters $G_1(z)$ and $G_2(z)$ are designed such that the subresponses $H_1(\omega)$ and $H_2(\omega)$ as given by Equations 18.63b and c approximate in the passband $F(L\omega)$ and $1 - F(L\omega)$, respectively, so that their sum approximates unity, as is desired. In the filter stopband, the role of the masking filters is to attenuate the extra unwanted passbands and transition bands of the periodic responses. In Case A, this is achieved by selecting the edges of $G_1(z)$ and $G_2(z)$ as (see Figure 18.23)

$$\omega_p^{(G_1)} = \omega_p = [2l\pi + \theta]/L \quad \text{and} \quad \omega_s^{(G_1)} = [2(l+1)\pi - \phi]/L \tag{18.67a}$$

$$\omega_p^{(G_2)} = [2l\pi - \theta]/L \quad \text{and} \quad \omega_s^{(G_2)} = \omega_s = [2l\pi + \phi]/L \tag{18.67b}$$

Since $F(L\omega) \approx 0$ on $[\omega_s, \omega_s^{(G1)}]$,the stopband region of $G_1(z)$ can start at $\omega = \omega_s{}^{(G1)}$, instead of $\omega = \omega_s$. Similarly, since $H_1(\omega) \approx F(L\omega) \approx 1$ and $[1 - F(L\omega)] \approx 0$ on $[\omega_p^{(G2)}, \omega_p]$, the passband region of $G_2(z)$ can start at $\omega = \omega_p{}^{(G2)}$, instead of $\omega = \omega_p$.

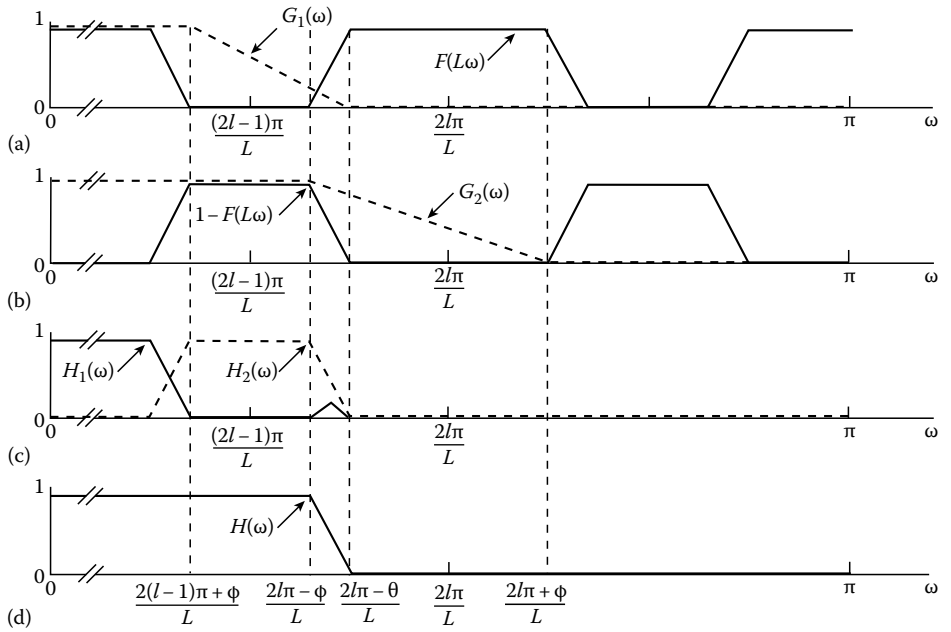

FIGURE 18.24 Case B design of a low-pass filter using the frequency-response masking technique.

For Case B designs, the required edges of the two masking filters, $G_1(z)$ and $G_2(z)$ are (see Figure 18.24)

$$\omega_p^{(G_1)} = [2(l-1)\pi + \phi]/L \quad \text{and} \quad \omega_s^{(G_1)} = \omega_s = [2l\pi - \theta]/L \tag{18.68a}$$

$$\omega_p^{(G_2)} = \omega_p = [2l\pi - \phi]/L \quad \text{and} \quad \omega_s^{(G_2)} = [2l\pi + \theta]/L \tag{18.68b}$$

The effects of the ripples of the subresponses on the ripples of the overall response $H(\omega)$ have been studied carefully in Ref. [3]. Based on these observations, the design of $H(z)$ with passband and stopband ripples of δ_p and δ_s can be accomplished for both Case A and Case B in the following two steps:

1. Design $G_k(z)$ for $k = 1, 2$ using either the Remez algorithm or linear programming such that $G_k(\omega)$ approximates unity on $[0, \omega_p^{(Gk)}]$ with tolerance $0.85\delta_p \cdots 0.9\delta_p$ and zero on $[\omega_s^{(Gk)}, \pi]$ with tolerance $0.85\delta_s \cdots 0.9\delta_s$.
2. Design $F(L\omega)$ such that the overall response $H(\omega)$ approximates unity on

$$\Omega_p^{(F)} = \begin{cases} \left[\omega_p^{(G_2)}, \omega_p\right] = [[2l\pi - \theta]/L, [2l\pi + \theta]/L] & \text{for Case A} \\ \left[\omega_p^{(G_1)}, \omega_p\right] = [[2(l-1)\pi + \phi]/L, [2l\pi - \phi]/L] & \text{for Case B} \end{cases} \tag{18.69a}$$

with tolerance δ_p and approximates zero on

$$\Omega_s^{(F)} = \begin{cases} \left[\omega_s, \omega_s^{(G_1)}\right] = [[2l\pi + \phi]/L, [2(l+1)\pi - \phi]/L] & \text{for Case A} \\ \left[\omega_s, \omega_s^{(G_2)}\right] = [[2l\pi - \theta]/L, [2l\pi + \theta]/L] & \text{for Case B} \end{cases} \tag{18.69b}$$

with tolerance δ_s.

TABLE 18.11 Error Function for Designing $F(\omega)$ Using the Remez Algorithm

$$E_F(\omega) = W_F(\omega)\,[F(\omega) - D_F(\omega)],$$

where

$$D_F(\omega) = [u(\omega) + l(\omega)]/2,\ W_F(\omega) = 2/[u(\omega) - l(\omega)]$$

with

$$u(\omega) = \min(\Psi_1(\omega) + \psi_1(\omega),\ \Psi_2(\omega) + \psi_2(\omega))$$

$$l(\omega) = \max(\Psi_1(\omega) - \psi_1(\omega),\ \Psi_2(\omega) - \psi_2(\omega))$$

$$\Psi_k(\omega) = \frac{D_H[h_k(\omega)] - G_2[h_k(\omega)]}{G_1[h_k(\omega)] - G_2[h_k(\omega)]},\quad k = 1,\ 2$$

$$\psi_k(\omega) = \frac{1/W_H[h_k(\omega)]}{|G_1[h_k(\omega)] - G_2[h_k(\omega)]|},\quad k = 1,\ 2$$

and

$$h_1(\omega) = (2l\pi + \omega)/L,\quad h_2(\omega) = \begin{cases} (2l\pi - \omega)/L & \text{for } \omega \in [0,\ \theta] \\ [2(l+1)\pi - \omega]/L & \text{for } \omega \in [\phi,\ \pi] \end{cases}$$

for Case A and

$$h_1(\omega) = (2l\pi - \omega)/L,\quad h_2(\omega) = \begin{cases} (2l\pi + \omega)/L & \text{for } \omega \in [0,\ \theta] \\ [2(l-1)\pi + \omega]/L & \text{for } \omega \in [\phi,\ \pi] \end{cases}$$

for Case B

The design of $F(L\omega)$ can be performed conveniently using linear programming [3]. Another, computationally more efficient, alternative is to use the Remez algorithm [10]. Its use is based on the fact that

$$|E_{\mathrm{H}}(\omega)| \le 1 \text{ for } \omega \in \Omega_{\mathrm{p}}^{(\mathrm{F})} \cup \Omega_{\mathrm{s}}^{(F)} \tag{18.70a}$$

where

$$E_{\mathrm{H}}(\omega) = W_{\mathrm{H}}(\omega)[H(\omega) - D_{\mathrm{H}}(\omega)] \tag{18.70b}$$

is satisfied when $F(\omega)$ is designed such that the maximum absolute value of the error function given in Table 18.11 becomes less than or equal to unity on $[0,\ \theta] \cup [\phi,\ \pi]$.

For step 2 of the above algorithm, $D_{\mathrm{H}}(\omega) = 1$ and $W_{\mathrm{H}}(\omega) = 1/\delta_{\mathrm{p}}$ on $\Omega_{\mathrm{p}}^{(F)}$, whereas $D_{\mathrm{H}}(\omega) = 0$ and $W_{\mathrm{H}}(\omega) = 1/\delta_s$ on $\Omega_{\mathrm{s}}^{(F)}$, giving for $k = 1,\ 2$

$$D_{\mathrm{H}}[h_k(\omega)] = \begin{cases} 1 & \text{for } \omega \in [0,\ \theta] \\ 0 & \text{for } \omega \in [\phi,\ \pi] \end{cases} \quad \text{and} \quad W_{\mathrm{H}}[h_k(\omega)] = \begin{cases} 1/\delta_{\mathrm{p}} & \text{for } \omega \in [0,\ \theta] \\ 1/\delta_{\mathrm{s}} & \text{for } \omega \in [\phi,\ \pi] \end{cases} \tag{18.71a}$$

for Case A and

$$D_{\mathrm{H}}[h_k(\omega)] = \begin{cases} 1 & \text{for } \omega \in [0,\ \theta] \\ 0 & \text{for } \omega \in [\phi,\ \pi] \end{cases} \quad \text{and} \quad W_{\mathrm{H}}[h_k(\omega)] = \begin{cases} 1/\delta_{\mathrm{s}} & \text{for } \omega \in [0,\ \theta] \\ 1/\delta_{\mathrm{p}} & \text{for } \omega \in [\phi,\ \pi] \end{cases} \tag{18.71b}$$

for Case B. Even though the resulting error function looks very complicated, it is straightforward to use the subroutines EFF and WATE in the Remez algorithm described in Ref. [5] for optimally designing $F(z)$.

The order of $G_1(z)$ can be considerably reduced by allowing larger ripples on those regions of $G_1(z)$ where $F(L\omega)$ has one of its stopbands. As a rule of thumb, the ripples on these regions can be selected to be 10 times larger [3]. Similarly, the order $G_2(z)$ can be decreased by allowing (ten times) larger ripples on those regions where $F(L\omega)$ has one of its passbands.

In practical filter synthesis problems, ω_p and ω_s are given and l, L, θ, and ϕ must be determined. To ensure that Equation 18.65 yields a desired solution with $0 \le \theta < \phi \le \pi$, it is required that (see Figure 18.23)

$$\frac{2l\pi}{L} \le \omega_p \quad \text{and} \quad \omega_s \le \frac{(2l+1)\pi}{L} \tag{18.72a}$$

for some positive integer l, giving

$$l = \lfloor L\omega_p/(2\pi) \rfloor, \quad \theta = L\omega_p - 2l\pi, \quad \text{and} \quad \phi = L\omega_s - 2l\pi \tag{18.72b}$$

where $\lfloor x \rfloor$ stands for the largest integer that is smaller than or equal to x. Similarly, to ensure that Equation 18.66 yields a desired solution with $0 \le \theta < \phi \le \pi$, it is required that (see Figure 18.23)

$$\frac{(2l-1)\pi}{L} \le \omega_p \quad \text{and} \quad \omega_s \le \frac{2l\pi}{L} \tag{18.73a}$$

for some positive integer l, giving

$$l = \lceil L\omega_s/(2\pi) \rceil, \quad \theta = 2l\pi - L\omega_s, \quad \text{and} \quad \phi = 2l\pi - L\omega_p \tag{18.73b}$$

where $\lfloor x \rfloor$ stands for the smallest integer that is larger than or equal to x. For any set of ω_p, ω_s, and L, either Equation 18.72b or Equation 18.73b (not both) will yield the desired θ and ϕ, provided that L is not too large. If $\theta = 0$ or $\phi = \pi$, then the resulting specifications for $F(\omega)$ are meaningless and the corresponding value of L cannot be used.

The remaining problem is to determine L to minimize the number of multipliers, which is $N_P/2 + 1 + 1\lfloor (N_1+2)/2 \rfloor + \lfloor (N_2+2)/2 \rfloor$ or $N_F + N_1 + N_2 + 3$ depending on whether the symmetries in the filter coefficients are exploited or not. Hence, in both cases, a good measure of the filter complexity is the sum of the orders of the subfilters. Instead of determining the actual minimum filter orders for various values of L, the computational workload can be significantly reduced based on the use of the estimation formula given by Equations 18.60a and b. Since the widths of transition bands of $F(z)$, $G_1(z)$, and $G_2(z)$ are $\phi - \theta$, $(2\pi - \phi - \theta)/L$ and $(\phi + \theta)/L$, respectively, good estimates for the corresponding filter orders are

$$N_F \approx \frac{\Phi(\delta_p, \delta_s)}{\phi - \theta}, \quad N_1 \approx \frac{L\Phi(\delta_p, \delta_s)}{2\pi - \phi - \theta}, \quad \text{and} \quad N_2 \approx \frac{L\Phi(\delta_p, \delta_s)}{\phi + \theta} \tag{18.74}$$

For the optimum nonperiodic direct-form design, the transition bandwidth is $\omega_s - \omega_p = (\phi - \theta)/L$, giving

$$N_{opt} \approx \frac{L\Phi(\delta_p, \delta_s)}{\phi - \theta} \tag{18.75}$$

The sum of the subfilter orders can be expressed in terms of N_{opt} as follows:

$$N_{ove} = N_{opt}\left[\frac{1}{L} + \frac{\phi - \theta}{2\pi - \phi - \theta} + \frac{\phi - \theta}{\phi + \theta}\right] \tag{18.76}$$

The smallest values of N_{ove} are typically obtained at those values of L for which $\theta + \phi \approx \pi$ and, correspondingly, $2\pi - \theta - \phi \approx \pi$. In this case, $N_1 \approx N_2$ and Equation 18.76 reduces, after substituting $\phi - \theta = L(\omega_s - \omega_p)$, to

$$N_{ove} = N_{opt}\left[\frac{1}{L} + 2L(\omega_s - \omega_p)/\pi\right] \tag{18.77}$$

At these values of L, N_F decreases and $N_1 \approx N_2$ increases inversely proportionally to L with the minimum of N_{ove} given by

$$N_{ove} = 2N_{opt}\sqrt{\frac{2(\omega_s - \omega_p)}{\pi}} \tag{18.78}$$

taking place at

$$L_{opt} = 1\Big/\sqrt{\frac{2(\omega_s - \omega_p)}{\pi}} \tag{18.79}$$

If for $L = L_{opt}$, $\theta + \phi$ is not approximately equal to π, then L minimizing the filter complexity can be found in the near vicinity of L_{opt}. The following example illustrates the use of the above estimation formulas.

Example 18.1

Consider the specifications: $\omega_p = 0.4\pi$, $\omega_s = 0.402\pi$, $\delta_p = 0.01$, and $\delta_s = 0.001$. For the optimum conventional direct-form design, $N_{opt} = 2541$, requiring 1271 multipliers when the coefficient symmetry is exploited. Equation 18.79 gives $L_{opt} = 16$. Table 18.12 shows, for the admissible values of L in the vicinity of this value, l, θ, ϕ, the estimated orders for the subfilters, and the sum of the subfilter orders as well as whether the overall filter is a Case A or Case B design. For N_F, the minimum even order larger than or equal to the estimated order is used, whereas N_2 is forced to be even (odd) if N_1 is even (odd).

Also with the estimated filter orders of Table 18.12, $L = 16$ gives the best result. The actual filter orders are $N_F = 162$, $N_1 = 70$, $N_2 = 98$. The responses of the subfilters as well as that of the overall design are depicted in Figure 18.25. The overall number of multipliers and adders for this design are 168 and 330, respectively, which are 13 percent of those required by an equivalent conventional direct-form design (1271 and 2541). The overall filter order is 2690, which is only 6 percent higher than that of the direct-form design (2541).

18.4.2 Multistage Frequency-Response Masking Approach

If the order of $F(z)$ is too high, its complexity can be reduced by implementing it using the frequency-response masking technique. Extending this to an arbitrary number of stages results in the multistage frequency-response masking approach [3,4], where $H(z)$ is generated iteratively as

$$H(z) \equiv F^{(0)}(z) = F^{(1)}(z^{L_1})G_1^{(1)}(z) + \left[z^{-L_1 N_F^{(1)}/2} - F^{(1)}(z^{L_1})\right] G_2^{(1)}(z) \tag{18.80a}$$

$$F^{(1)}(z) = F^{(2)}(z^{L_2})G_1^{(2)}(z) + \left[z^{-L_2 N_F^{(2)}/2} - F^{(2)}(z^{L_2})\right] G_2^{(2)}(z) \tag{18.80b}$$

$$\vdots$$

$$F^{(R-1)}(z) = F^{(R)}\left(z^{L_R}\right)G_1^{(R)}(z) + \left[z^{-L_R N_F^{(R)}/2} - F^{(R)}\left(z^{L_R}\right)\right] G_2^{(R)}(z) \tag{18.80c}$$

TABLE 18.13 Implementation Form for the Transfer Function in the Multistage Frequency-Response Masking Approach

$$H(z) \equiv F^{(0)}(z^{\hat{L}_0}) = F^{(1)}(z^{\hat{L}_1})G_1^{(1)}(z^{\hat{L}_0}) + [z^{-M_1} - F^{(1)}(z^{\hat{L}_1})]G_2^{(1)}(z^{\hat{L}_0})$$

$$F^{(1)}(z^{\hat{L}_1}) = F^{(2)}(z^{\hat{L}_2})G_1^{(2)}(z^{\hat{L}_1}) + [z^{-M_2} - F^{(2)}(z^{\hat{L}_2})]G_2^{(2)}(z^{\hat{L}_1})$$

$$\vdots$$

$$F^{(R-1)}(z^{\hat{L}_{R-1}}) = F^{(R)}(z^{\hat{L}_R})G_1^{(R)}(z^{\hat{L}_{R-1}}) + [z^{-M_R} - F^{(R)}(z^{\hat{L}_R})]G_2^{(R)}(z^{\hat{L}_{R-1}}),$$

where

$$\hat{L}_0 = 1,\ \hat{L}_r = \prod_{k=1}^{r} L_k, \quad r = 1, 2, \cdots, R$$

$$M_R = \hat{L}_R N_F^{(R)}/2, \quad M_{R-r} = M_{R-r+1} + m_{R-r}, \quad r = 1, 2, \cdots, R-1$$

$$m_{R-r} = \hat{L}_{R-r}\ \max\left\{N_1^{(R-r+1)}, N_2^{(R-r+1)}\right\}/2, \quad r = 1, 2, \cdots, R-1$$

$N_F^{(R)}$ is the order of $F^{(R)}(z)$

$N_1^{(r)}$ and $N_2^{(r)}$ are the orders of $G_1^{(r)}(z)$ and $G_2^{(r)}(z)$, respectively

Here, the $G_1^{(r)}(z)$'s and $G_2^{(r)}(z)$'s for $r = 1, 2, \ldots, R$ as well as $F^{(R)}(z)$ are the filters to be designed. For implementation purposes, $H(z)$ can be expressed in the form shown in Table 18.13. Figure 18.26 shows an efficient implementation for a three-stage filter, where the delay terms z^{-M3}, z^{-m2}, and z^{-m1}, can be shared with $F^{(3)}(z^{L_3})$. In order to obtain a desired overall solution, the orders of the $G_1^{(r)}(z)$'s and $G_2^{(r)}(z)$'s for $r = 2, 3, \ldots, R$, denoted by $N_1^{(r)}$ and $N_2^{(r)}$ in Table 18.13, have to be even.

Given the filter specifications and the L_r's for $r = 1, 2, \ldots, R$, the $G_1^{(r)}(z)$'s and $G_2^{(r)}(z)$'s as well as $F^{(R)}(z)$ can be synthesized in the following steps:

1. Set $r = 1$, $L = L_1$, and

$$D_H(\omega) = \begin{cases} 1 & \text{for } \omega \in [0, \omega_p] \\ 0 & \text{for } \omega \in [\omega_s, \pi] \end{cases}, \quad W_H(\omega) = \begin{cases} 1/\delta_p & \text{for } \omega \in [0, \omega_p] \\ 1/\delta_s & \text{for } \omega \in [\omega_s, \pi] \end{cases} \tag{18.81}$$

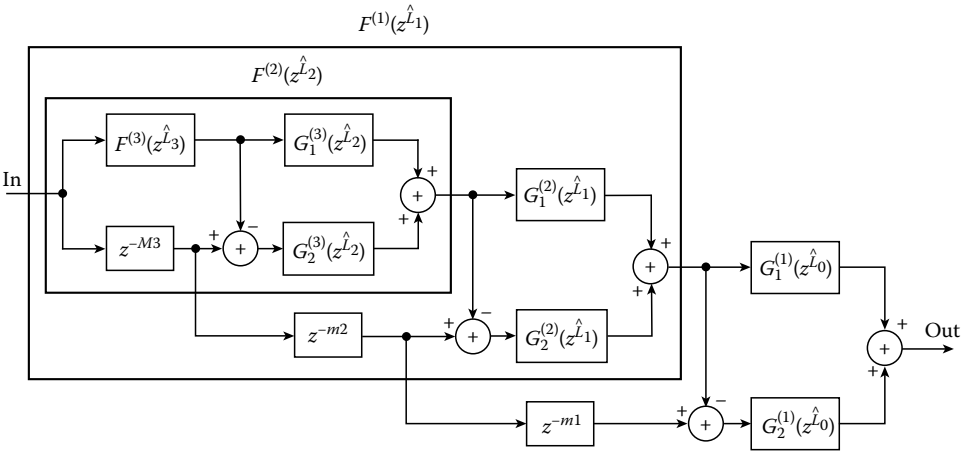

FIGURE 18.26 An implementation for a filter synthesized using the three-stage frequency-response masking approach.

2. Determine whether $F^{(r-1)}(z)$ is a Case A or Case B design as well as θ, ϕ, and l for $F^{(r)}(z)$ according to Equation 18.72b or Equation 18.73b. Also, determine $\omega_p^{(Gk)}$ and $\omega_s^{(Gk)}$ for $k = 1, 2$ from Equations 18.67a and b or Equations 18.68a and b.
3. Design $G_k^{(r)}(z)$ for $k = 1, 2$, using either the Remez algorithm or linear programming, in such a way that

$$\max_{\omega \in \left[0,\ \omega_p^{(G_k)}\right] \cup \left[\omega_s^{(G_k)},\ \pi\right]} \left| W_H(\omega)\left[G_k^{(r)}(\omega) - D_H(\omega)\right]\right| \leq 0.9 \tag{18.82}$$

4. Determine $W_F(\omega)$ and $D_F(\omega)$ from Table 18.11.
5. If $r = R$, then go to the next step. Otherwise, set $r = r + 1$, $L = L_r$, $W_H(\omega) = W_F(\omega)$, $D_H(\omega) = D_F(\omega)$, $\omega_p = \theta$, $\omega_s = \phi$, and go to step 2.
6. Design $F^{(R)}(z)$, using either the Remez algorithm or linear programming, in such a way that

$$\max_{\omega \in [0,\theta] \cup [\phi,\pi]} \left| W_F(\omega)\left[F^{(R)}(\omega) - D_F(\omega)\right]\right| \leq 1 \tag{18.83}$$

In the above algorithm, $G_1^{(1)}(z)$ and $G_2^{(1)}(z)$ are determined like in the one-stage frequency-response masking technique. The remaining filter part as given by Equation 18.80b has then to be designed such that the maximum absolute value of the error function given in Table 18.11 becomes less than or equal to unity on $[0, \theta] \cup [\phi, \pi]$. Using the substitutions $\omega_p = \theta$ and $\omega_s = \phi$, the synthesis problem for $F^{(1)}(z)$ becomes the same as for the overall filter with the only exception that the desired function $D_F(\omega)$ and the weighting function $W_F(\omega)$ are not constants in the passband and stopband regions. Therefore, the following $G_1^{(r)}(z)$'s and $G_2^{(r)}(z)$'s can be designed in the same manner. Finally, $F^{(R)}(z)$ is determined at step 6 like $F(z)$ in one-stage designs.

Given the filter specifications, the remaining problem is to select R as well as the L_r's to minimize the filter complexity. This problem has been considered in Ref. [4]. Assuming that for all the selected L_r's, $\theta + \phi \approx \pi$, the sum of the estimated orders of $F^{(R)}(z)$ and the $G_1^{(r)}(z)$'s and $G_2^{(r)}(z)$'s becomes

$$N_{ove}(R) = \left[1 \Big/ \prod_{r=1}^{R} L_r + [2(\omega_s - \omega_p)/\pi] \sum_{r=1}^{R} L_r\right] N_{opt} \tag{18.84}$$

The minimum of $N_{ove}(R)$ taking place at

$$L_1 = L_2 = \cdots = L_R = L_{opt}(R) = \left[\frac{2(\omega_s - \omega_p)}{\pi}\right]^{-1/(R+1)} \tag{18.85}$$

is

$$N_{ove}(R) = (R+1)\left[\frac{(2\omega_s - \omega_p)}{\pi}\right]^{R/(R+1)} N_{opt} \tag{18.86}$$

The derivation of the above formula is based on the assumption that the orders of all the $G_1^{(r)}(z)$'s and $G_2^{(r)}(z)$'s for $r = 1, 2, \ldots, R$ are equal, which is seldom true. Therefore, in order to minimize the overall filter complexity, the values of the L_r's should be varied in the vicinity of $L_{opt}(R)$. Given ω_p, ω_s, and R, good values for the L_r's can be obtained by the following procedure:

1. Set $r = 1$.
2. Determine $L = L_{opt}(R + 1 - r)$ from Equation 18.85.
3. For values of $\tilde{L}_r$ in the vicinity of L determine $\theta(\tilde{L}_r)$ and $\phi(\tilde{L}_r)$.

4. If $r = R$, then go to step 7. Otherwise, go to the next step.
5. Determine $L_r = \tilde{L}_r$ minimizing

$$(R+1-r)\left[\frac{2[\phi(\tilde{L}_r)-\theta(\tilde{L}_r)]}{\pi}\right]^{(R-r)/(R+1-r)}+\frac{\phi(\tilde{L}_r)-\theta(\tilde{L}_r)}{\theta(\tilde{L}_r)+\phi(\tilde{L}_r)}+\frac{\phi(\tilde{L}_r)-\theta(\tilde{L}_r)}{2\pi-\theta(\tilde{L}_r)-\phi(\tilde{L}_r)} \tag{18.87}$$

6. Set $r = r+1$, $\omega_p = \theta(L_r)$, $\omega_s = \phi(L_r)$, and go to step 2.
7. Determine $L_R = \tilde{L}_r$ minimizing

$$\frac{1}{\tilde{L}_R}+\frac{\phi(\tilde{L}_R)-\theta(\tilde{L}_R)}{\theta(\tilde{L}_R)+\phi(\tilde{L}_R)}+\frac{\phi(\tilde{L}_R)-\theta(\tilde{L}_R)}{2\pi-\theta(\tilde{L}_R)-\phi(\tilde{L}_R)} \tag{18.88}$$

At the first step in this procedure, L_1 is determined to minimize the estimated overall complexity of $G_1^{(1)}(z)$, $G_2^{(1)}(z)$, and the remaining $F_1^{(1)}(z)$, which is given by Equation 18.87 as a fraction of N_{opt}. Compared to Equation 18.76 for the one-stage design, $1/\tilde{L}_r$ is replaced in Equation 18.87 by the first term. This term estimates the complexity of $F_1^{(1)}(z)$ based on the use of Equation 18.86 with $\omega_p = \theta(\tilde{L}_r)$ and $\omega_s = \phi(\tilde{L}_r)$ and the fact that it is an $R-1$ stage design. Also, L_2 is redetermined based on the same assumptions and the process is continued in the same manner. Finally, L_R is determined to minimize the sum of the estimated orders of $G_1^{(R)}(z)$, $G_2^{(R)}(z)$, and $F^{(R)}(z)$ like in the one-stage design (cf. Equation 18.76).

Example 18.2

Consider the specifications of Example 18.1. For a two-stage design, the above procedure gives $L_1 = L_2 = 6$. For these values, $F^{(0)}(z) + H(z)$ and $F^{(1)}(z)$ are Case A designs ($l = 1$) with $\theta = 0.4\pi$ and $\phi = 0.412\pi$; and $\theta = 0.4\pi$ and $\phi = 0.472\pi$, respectively. The minimum orders of $G_1^{(1)}(z)$, $G_2^{(1)}(z)$, $G_1^{(2)}(z)$, $G_2^{(2)}(z)$, and $F^{(2)}(z)$ are 26, 40, 28, 36, and 74, respectively. Compared with the conventional direct-form FIR filter of order 2541, the number of multipliers and adders required by this design (107 and 204) are only 8 percent at the expense of a 15 percent increase in the overall filter order (to 2920). For a three-stage design, we get $L_1 = L_2 = L_3 = 4$. In this case, $F^{(0)}(z)$, $F^{(1)}(z)$, and $F^{(2)}(z)$ are Case B designs ($l = 1$) with $\theta = 0.392\pi$ and $\phi = 0.4\pi$; $\theta = 0.4\pi$ and $\phi = 0.432\pi$; and $\theta = 0.272\pi$ and $\phi = 0.4\pi$, respectively. The minimum orders of $G_1^{(1)}(z)$, $G_2^{(1)}(z)$, $G_1^{(2)}(z)$, $G_2^{(2)}(z)$, $G_1^{(3)}(z)$, $G_2^{(3)}(z)$, and $F^{(3)}(z)$ are 16, 28, 18, 24, 16, 32, and 40, respectively. The number of multipliers and adders (94 and 174) are only 7 percent of those required by the direct-form equivalent at the expense of a 26 percent increase in the overall filter order (to 3196). The amplitude responses of the resulting two-stage and three-stage designs are depicted in Figure 18.27.

18.4.3 Design of Narrowband Filters

Another general approach for designing multiplier-efficient FIR filters has been proposed by Jing and Fam [2]. This design technique is based on iteratively using the fact that there exist efficient implementation forms for filters with $\omega_s < \pi/2$ and for filters with $\omega_p > \pi/2$. A filter with $\omega_s < \pi/2$ is called a *narrowband* filter while that with $\omega_p > \pi/2$ is called a *wideband* filter. This section considers the design of narrowband filters, whereas Section 18.4.4 is devoted to the design of wideband filters. Finally, these techniques are combined, resulting in the Jing–Fam approach.

When the stopband edge of $H(z)$ is less than $\pi/2$, the first transition band of $F(z^L)$ can be used as that of $H(z)$ (Figure 18.28), that is,

$$\omega_p = \theta/L \quad \text{and} \quad \omega_s = \phi/L \tag{18.89}$$

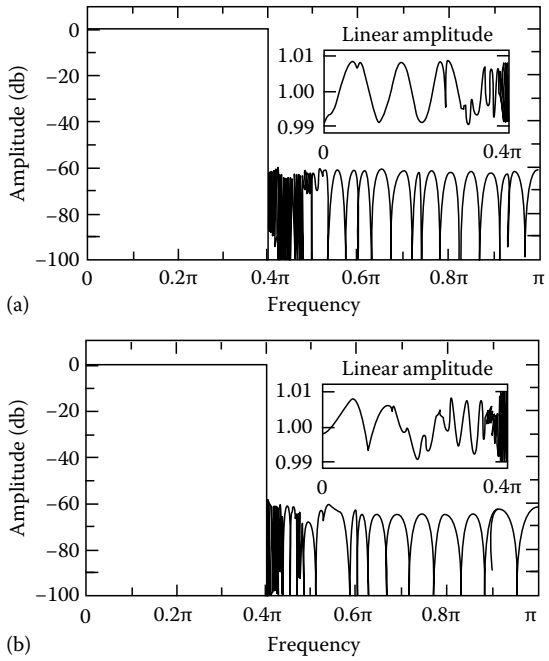

FIGURE 18.27 Amplitude responses for filters synthesized using the multistage frequency-response masking approach. (a) Two-stage filter. (b) Three-stage filter.

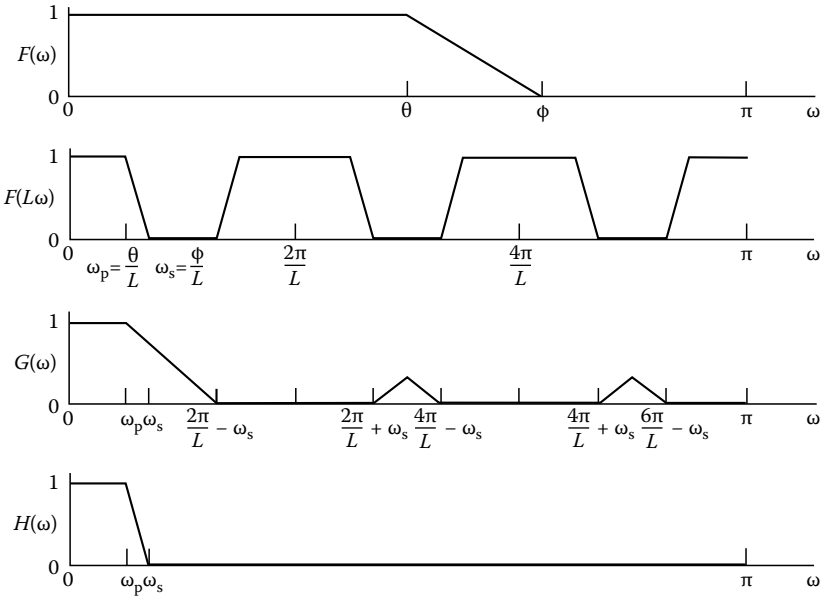

FIGURE 18.28 Synthesis of a narrowband filter as a cascade of a periodic and a nonperiodic filter.

In this case, the overall transfer function can be written in the following simplified form [6,8]:

$$H(z) = F(z^L)G(z) \tag{18.90}$$

where the orders of both $F(z)$ and $G(z)$ can be freely selected to be either even or odd. As shown in Figure 18.28, the role of $G(z)$ is to provide the desired attenuation on those regions where $F(z^L)$ has extra unwanted passband and transition band regions, that is, on

$$\Omega_s(L, \omega_s) = \bigcup_{k=1}^{\lfloor L/2 \rfloor} \left[k\frac{2\pi}{L} - \omega_s,\ \min\left(k\frac{2\pi}{L} + \omega_s, \pi \right) \right] \tag{18.91}$$

There exist two ways of designing the subfilters $F(z^L)$ and $G(z)$. In the first case, they are determined, by means of the Remez algorithm, to satisfy

$$1 - \delta_p^{(F)} \le F(\omega) \le 1 + \delta_p^{(F)} \quad \text{for } \omega \in [0,\ L\omega_p] \tag{18.92a}$$

$$-\delta_s \le F(\omega) \le \delta_s \quad \text{for } \omega \in [L\omega_s,\ \pi] \tag{18.92b}$$

$$1 - \delta_p^{(G)} \le G(\omega) \le 1 + \delta_p^{(G)} \quad \text{for } \omega \in [0,\ \omega_p] \tag{18.92c}$$

$$-\delta_s \le G(\omega) \le \delta_s \quad \text{for } \omega \in \Omega_s(L,\ \omega_s) \tag{18.92d}$$

where

$$\delta_p^{(G)} + \delta_p^{(F)} = \delta_p \tag{18.92e}$$

The ripples $\delta_p^{(F)}$ and $\delta_p^{(G)}$ can be selected, e.g., to be half the overall ripple δ_p. In the above specifications, both $F(z^L)$ and $G(z)$ have $[0,\ \omega_p]$ as a passband region.

Another approach, leading to a considerable reduction in the order of $G(z)$, is to design simultaneously $F(\omega)$ to satisfy

$$1 - \delta_p \le F(\omega)G(\omega/L) \le 1 + \delta_p \quad \text{for } \omega \in [0,\ L\omega_p] \tag{18.93a}$$

$$-\delta_s \le F(\omega)G(\omega/L) \le \delta_s \quad \text{for } \omega \in [L\omega_s,\ \pi] \tag{18.93b}$$

and $G(\omega)$ to satisfy

$$G(0) = 1 \tag{18.94a}$$

$$-\delta_s | le F(L\omega)G(\omega) \le \delta_s \quad \text{for } \omega \ \in\ \Omega_s(L,\ \omega_s) \tag{18.94b}$$

The desired overall solution can be obtained by iteratively determining, by means of the Remez algorithm, $F(z)$ to meet the criteria of Equations 18.93a and b and $G(z)$ to meet the criteria of Equations 18.94a and b. Typically, only three to five designs of both of the subfilters are required to arrive at a solution that does not change if further iterations are used. For more details, see Ref. [8] or [10]. Figure 18.29 shows typical responses for $G(z)$ and $F(z^L)$ and for the overall optimized design. As seen in this figure, $G(z)$ has all its zeros on the unit circle concentrating on providing the desired attenuation for the overall response on $\Omega_s(L, \omega_s)$, whereas $F(z^L)$ makes the overall response equiripple in the passband and in the stopband portion $[\omega_s,\ \pi/L]$.

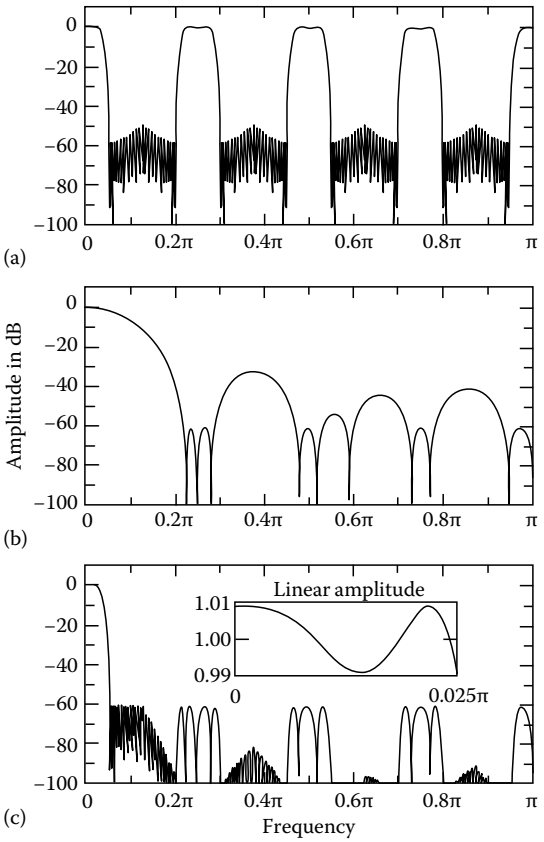

FIGURE 18.29 Typical amplitude responses for a filter of the form $H(z) = F(z^L)G(z)$. $L = 8$, $\omega_p = 0.025\pi$, $\omega_s = 0.05\pi$, $\delta_p = 0.01$, and $\delta_s = 0.001$. (a) $F(z^L)$ of order 26 in z^L. (b) $G(z)$ of order 19. (c) Overall filter.

For the order of $F(z)$, a good estimate is

$$N_F \approx \frac{\Phi(\delta_p, \delta_s)/L}{\omega_s - \omega_p} \tag{18.95}$$

so that it is $1/L$th of that of an optimum conventional nonperiodic filter meeting the given overall criteria. The order of $G(z)$, in turn, can be estimated accurately by [10]

$$N_G = \cosh^{-1}(1/\delta_s)\left[\frac{1}{X\left(\omega_p, \frac{2\pi}{L} - \frac{\omega_p + 2\omega_s}{3}\right)} + \frac{L/2}{X\left(\frac{L\omega_p}{2}, \pi - \frac{L(\omega_p + 2\omega_s)}{6}\right)}\right] \tag{18.96a}$$

where

$$X(\omega_1, \omega_2) = \cosh^{-1}[(2\cos\omega_1 - \cos\omega_2 + 1)/(1 + \cos\omega_2)] \tag{18.96b}$$

The minimization of the number of multipliers, $[(N_F + 2)/2] + [(N_G + 2)/2]$, with respect to L can be performed conveniently by evaluating the sum of the above estimated orders for the admissible values of L,

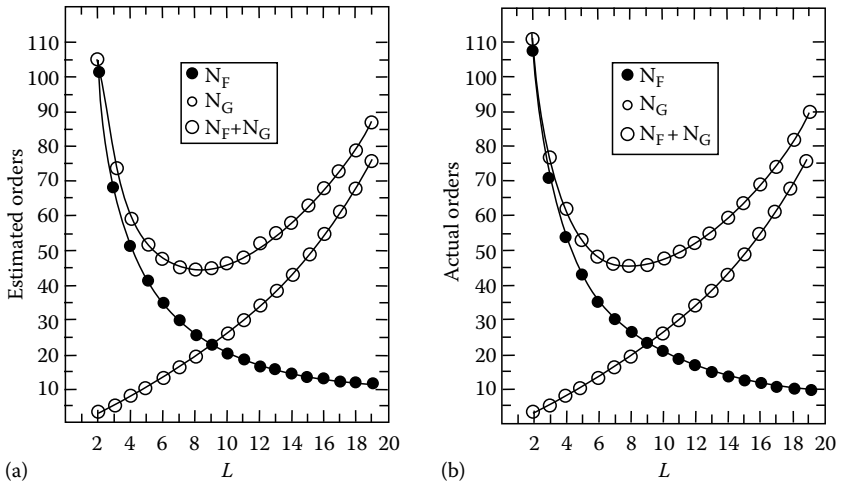

FIGURE 18.30 Estimated and actual subfilter orders as well as the sum of the subfilter orders vs. L in a typical narrowband case.

$2 \leq L < \pi/\omega_s$. The upper limit is a consequence of the fact that the stopband edge angle of $F(z)$, $\phi = L\omega_s$, must be less than π. The following example illustrates the minimization of the filter complexity.

Example 18.3

The narrowband specifications are $\omega_p = 0.025\pi$, $\omega_s = 0.05\pi$, $\delta_p = 0.01$, and $\delta_s = 0.001$. Figure 18.30a shows the estimated N_F, N_G, and $N_F + N_G$ as functions of L, whereas Figure 18.30b shows the corresponding actual minimum orders. It is seen that the estimated orders are so close to the actual ones that the minimization of the filter complexity can be accomplished based on the use of the above estimation formulas. It is also observed that $N_F + N_G$ is a unimodal function of L. With the estimates, $L = 8$ gives the best result. The estimated orders are $N_F = 25$ and $N_G = 19$, whereas the actual orders are $N_F = 26$ and $N_G = 19$. The amplitude responses for the subfilters and for the overall filter are depicted in Figure 18.29. This design requires 24 multipliers and 45 adders. The minimum order of a conventional direct-form design is 216, requiring 109 multipliers and 216 adders. The price paid for these 80% reductions in the filter complexity is a 5 percent increase in the overall filter order (from 216 to 227).

In the cases where L can be factored into the product

$$L = \prod_{r=1}^{R} L_r \tag{18.97}$$

where the L_r's are integers, further savings in the filter complexity can be achieved by designing $G(z)$ in the following multistage form [8]:

$$G(z) = G_1(z)G_2(z^{L_1})G_3(z^{L_1 L_2}) \cdots G_R(z^{L_1 L_2 \cdots L_{R-1}}) \tag{18.98}$$

Another alternative to reduce the number of adders and multipliers is to use special structures for implementing $G(z)$ [8–10].

18.4.4 Design of Wideband Filters

The synthesis of a wideband filter $H(z)$ can be converted into the design of a narrowband filter based on the following fact. If $\hat{H}(z)$ of even order $2M$ is a low-pass design with the following edges and ripples:

$$\hat{\omega}_p = \pi - \omega_s, \quad \hat{\omega}_s = \pi - \omega_p, \quad \hat{\delta}_p = \delta_s, \quad \hat{\delta}_s = \delta_p \tag{18.99}$$

then

$$H(z) = z^{-M} - (-1)^M \hat{H}(-z) \tag{18.100}$$

is a low-pass filter having the passband and stopband edge angles at ω_p and ω_s and the passband and stopband ripples of δ_p and δ_s. Hence, if ω_p and ω_s of $H(z)$ are larger than $\pi/2$, then $\hat{\omega}_p$ and $\hat{\omega}_s$ of $\hat{H}(z)$ are smaller than $\pi/2$ [10]. This enables us to design $\hat{H}(z)$ in the form

$$\hat{H}(z) = F(z^L)G(z) \tag{18.101}$$

using the techniques of Section 18.4.3, yielding

$$H(z) = z^{-M} - (-1)^M F\left[(-z)^L\right] G(-z) \tag{18.102a}$$

where

$$M = (LN_F + N_G)/2 \tag{18.102b}$$

is half the order of $F(z^L)G(z)$. For implementation purposes, $H(z)$ is expressed as

$$H(z) = z^{-M} - \hat{F}(z^L)\hat{G}(z), \quad \hat{F}(z^L) = (-1)^M F[(-z)^L], \quad \hat{G}(z) = G(-z) \tag{18.103}$$

An implementation of this transfer function is shown in Figure 18.31, where the delay term z^{-M} can be shared with $\hat{F}(z^L)$. To avoid half-sample delays, the order of $\hat{F}(z^L)\hat{G}(z)$ has to be even.

Example 18.4

The wideband specifications are $\omega_p = 0.95\pi$, $\omega_s = 0.975\pi$, $\delta_p = 0.001$, and $\delta_s = 0.01$. From Equation 18.99, the specifications of $\hat{H}(z)$ become $\omega_p = 0.025\pi$, $\hat{\omega}_5 = 0.05\pi$, $\hat{\delta}_p = 0.01$, and $\hat{\delta}_s = 0.001$. These are the narrowband specifications of Example 18.3. The desired wideband design is thus obtained by using the subfilters $F(z^L)$ and $G(z)$ of Figure 18.29 ($L = 8$, $N_F = 26$, and $N_G = 19$). However, the overall order is odd (227). A solution with even order is achieved by increasing the order of $G(z)$ by one ($N_G = 20$). Figure 18.32 shows the amplitude response of the resulting filter, requiring 25 multipliers, 46 adders, and 228 delay elements. The corresponding numbers for a conventional direct-form equivalent of order 216 are 109, 216, and 216, respectively.

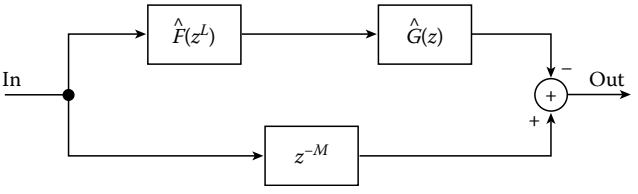

FIGURE 18.31 Implementation for a wideband filter in the form $H(z) = z^{-M} - (-1)^M F[(-z^L)G(-z)$. $\hat{F}(z^L) = (-1)^M \cdot F[(-z)^L]$ and $\hat{G}(z) = G(-z)$.

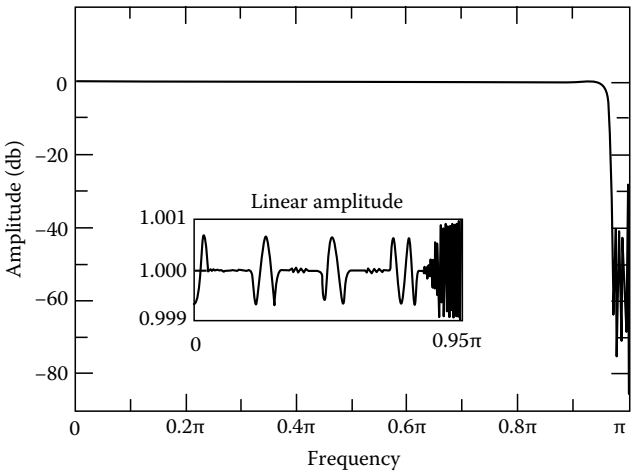

FIGURE 18.32 Amplitude response for a wideband filter implemented as shown in Figure 18.38.

18.4.5 Generalized Designs

The Jing–Fam approach [2] is based on iteratively using the facts that a narrowband filter can be implemented effectively as $H(z) = F(z^L)G(z)$ and a wideband filter in the form of Equations 18.102a and b. In this approach, a narrowband filter is generated [9] as

$$H(z) \equiv \hat{H}_1(z) = G_1(z)F_1(z^{L_1}) \tag{18.104a}$$

where

$$F_1(z) = z^{-M_1} - (-1)^{M_1}\hat{H}_2(-z) \quad \hat{H}_2(z) = G_2(z)F_2(z^{L_2}) \tag{18.104b}$$

$$F_2(z) = z^{-M_2} - (-1)^{M_2}\hat{H}_3(-z) \quad \hat{H}_3(z) = G_3(z)F_3(z^{L_3}) \tag{18.104c}$$

$$\vdots$$

$$F_{R-2}(z) = z^{-M_{R-2}} - (-1)^{M_{R-2}}\hat{H}_{R-1}(-z) \quad \hat{H}_{R-1}(z) = G_{R-1}(z)F_{R-1}(z^{L_{R-1}}) \tag{18.104d}$$

$$F_{R-1}(z) = z^{-M_{R-1}} - (-1)^{M_{R-1}}\hat{H}_R(-z) \quad \hat{H}_R(z) = G_R(z) \tag{18.104e}$$

with M_r for $r = 1, 2, \ldots, R-1$ being half the order of $\hat{H}_{r+1}(z)$. Here, the basic idea is to convert iteratively the design of the narrowband overall filter into the designs of narrowband transfer function $\hat{H}_r(z)$ for $r = 2, 3, \ldots, R$ until the transition bandwidth of the remaining $\tilde{H}_r(z) = G_R(z)$ becomes large enough and, correspondingly, its complexity (the number of multipliers) is low enough. The desired conversion is performed by properly selecting the L_r's and designing the lower-order filters $G_r(z)$ for $r = 1, 2, \ldots, R-1$.

In order to determine the conditions for the L_r's as well as the design criteria for the $G_r(z)$'s, we consider the rth iteration, where

$$\hat{H}_r(z) = G_r(z)F_r(z^{L_r}) \tag{18.105a}$$

with

$$F_r(z) = z^{-M_r} - (-1)^{M_r}\hat{H}_{r+1}(-z) \tag{18.105b}$$

Let the ripples of $\hat{H}_r(z)$ be $\hat{\delta}_p^{(r)}$ and $\hat{\delta}_s^{(r)}$ and the edges be located at $\omega_p^{(r)} < \pi/2$ and $\omega_s^{(r)} < \pi/2$. Since $F_r(z)$ is implemented in the form of Equation 18.105b, it cannot alone take care of shaping the passband response of $\hat{H}_r(z)$. Therefore, the simultaneous criteria for $G_r(z)$ and $F_r(z)$ are stated according to Equations 18.92a through e so that the passband and stopband regions of $G_r(z)$ are, respectively, $[0,\omega_p^{(r)}]$ and $\Omega_s L_r \omega_s^{(r)})$ with $\Omega_s(L, \omega_s)$ given by Equation 18.91. L_r has to be determined such that the edges of $F_r(z)$, $L_{r\omega p}^{(r)}$ and $L_{r\omega s}^{(r)}$, become larger than $\pi/2$ and, correspondingly, the edges of $\hat{H}_{r+1}(z)$, $\omega_p^{(r+1)} = \pi - L_{r\omega s}^{(r)}$ and $\omega_s^{(r+1)} = \pi - L_{r\omega p}^{(r)}$, become less than $\pi/2$.

In the case of the specifications of Equations 18.92a through e, the stopband ripple of $G_r(z)$, denoted for later use by $\delta_s^{(r)}$, and that of $F_r(z)$ are equal to $\hat{\delta}_s^{(r)}$, whereas the sum of the passband ripples is equal to $\hat{\delta}_p^{(r)}$. Denoting by $\hat{\delta}_p^{(r)}$ the passband ripple selected for $G_r(z)$, the corresponding ripple of $F_r(z)$ is $\hat{\delta}_p^{(r)} - \delta_p^{(r)}$. Since $F_r(z)$ and $\hat{H}_{(r+1)}(z)$ interchange the ripples, the ripple requirements for $\hat{H}_{r+1}(z)$ are $\hat{\delta}_p^{(r+1)} = \hat{\delta}_s^{(r)}$ and $\hat{\delta}_s^{(r+1)} = \hat{\delta}_p^{(r)} - \delta_p^{(r)}$.

The criteria for the $G_r(z)$'s for $r = 1, 2, \ldots, R$ can thus be stated as

$$1 - \delta_p^{(r)} \le G_r(\omega) \le 1 + \delta_p^{(r)} \quad \text{for } \omega \in [0, \omega_p^{(r)}] \tag{18.106a}$$

$$-\delta_s^{(r)} \le G_r(\omega) \le \delta_s^{(r)} \quad \text{for } \omega \in \Omega_s^{(r)} \tag{18.106b}$$

where

$$\Omega_s^{(r)} = \begin{cases} \bigcup_{k=1}^{\lfloor L_r/2 \rfloor} \left[k\frac{2\pi}{L_r} - \omega_s^{(r)},\ \min\left(k\frac{2\pi}{L_r} + \omega_s^{(r)},\ \pi \right) \right] & \text{for } r < R \\ \left[\omega_s^{(R)},\ \pi \right] & \text{for } r = R \end{cases} \tag{18.106c}$$

Here, the $\omega_p^{(r)}$'s and $\omega_s^{(r)}$'s for $R = 2, 3, \ldots, R$ are determined iteratively as

$$\omega_p^{(r)} = \pi - L_{r-1}\omega_s^{(r-1)}, \quad \omega_s^{(r)} = \pi - L_{r-1}\omega_p^{(r-1)} \tag{18.106d}$$

where $\omega_p^{(1)} = \omega_p$ and $\omega_s^{(1)} = \omega_s$ are the edges of the overall design, and the $\delta_s^{(r)}$'s as

$$\delta_s^{(r)} = \begin{cases} \delta_p - \sum_{\substack{k=1 \\ k \text{ odd}}}^{r-1} \delta_p^{(k)} & \text{for } r \text{ even} \\ \delta_s - \sum_{\substack{k=2 \\ k \text{ even}}}^{r-1} \delta_p^{(k)} & \text{for } r \text{ odd} \end{cases} \tag{18.106e}$$

where δ_p and δ_s are the ripple values of the overall filter and $\delta_p^{(r)}$ is the passband ripple selected for $G_r(z)$. In order for the overall filter to meet the given ripple requirements, $\delta_s^{(R)}$ and the $\delta_p^{(r)}$'s have to satisfy for R even

$$\sum_{\substack{k=2 \\ k \text{ even}}}^{R} \delta_p^{(k)} = \delta_s, \quad \delta_s^{(R)} + \sum_{\substack{k=1 \\ k \text{ odd}}}^{R-1} \delta_p^{(k)} = \delta_p \tag{18.107a}$$

or for R odd

$$\sum_{\substack{k=1 \\ k \text{ odd}}}^{R} \delta_p^{(k)} = \delta_p, \quad \delta_s^{(R)} + \sum_{\substack{k=2 \\ k \text{ even}}}^{R-1} \delta_p^{(k)} = \delta_s \tag{18.107b}$$

In the above, the L_r's have to be determined such that the $\omega_s^{(r)}$'s for $r < R$ become smaller than $\pi/2$. It is also desired that for the last filter stage $G_R(z)$, $\omega_s^{(R)}$ is smaller than $\pi/2$.

If $2\pi/L_r - \omega_s^{(r)} < \pi/2$ for $r < R$ or $\omega_s^{(R)} < \pi/2$, then the arithmetic complexity of $G_r(z)$ can be reduced by designing it, using the techniques of previous sections, in the form

$$G_r(z) = G_r^{(1)}(z^{K_r})G_r^{(2)}(z) \tag{18.108}$$

It is preferred to design the subfilters of $G_r(z)$ in such a way that the passband shaping is done entirely by $G_r^{(1)}(z^{K_r})$. The number of multipliers in the $G_r(z)$'s for $r = 1, 2, \ldots, R-1$ can be reduced by the experimentally observed fact that the overall filter still meets the given criteria when the stopband regions of these filters are decreased by using in Equation 18.106c the substitution

$$\left(2\omega_s^{(r)} + \omega_p^{(r)}\right)/3 \mapsto \omega_s^{(r)} \tag{18.109}$$

After some manipulations, $H(z)$ as given by Equation 18.104a through e and Equation 18.106 can be rewritten in the explicit form shown in Table 18.14. If $G_r(z)$ is a single-stage design, then $G_r^{(1)}(z^{K_r}) + 1$. In order to obtain the desired overall solution, the overall order of $G_r(z)$ for $r \geq 2$, denoted by N_r in Table 18.14, has to be even. Realizations for the overall transfer function are given in Figure 18.33, where

$$m_r = \hat{M}_r - \hat{M}_{r+1} = \frac{1}{2}\hat{L}_r N_r, \quad r = 2, 3, \ldots, R-1, \quad m_R = \hat{M}_R \tag{18.110}$$

The structure of Figure 18.33b is preferred since the delay terms z^{-m_r} can be shared with $H_R^{(1)}(z^{K_R\hat{L}_R})$ or, if this filter stage is not present, with $H_R^{(2)}(z^{K_R\hat{L}_R})$. This is because the overall order of this filter stage is usually larger than the sum of the m_r's.

If the edges ω_p and ω_s of the overall filter are larger than $\pi/2$, then we set $H(z) + F_1(z)$ in Equation 18.104a. In this case, $\delta_p^{(1)} + 0$, $L_1 + 1$, and $G_1(z)$,, $\omega_p^{(1)}$ and $\omega_s^{(1)}$ are absent. Furthermore, $\omega_p^{(2)} = \pi - \omega_s$, and $\omega_s^{(2)} = \pi - \omega_p$, and $H_1(z)$ is absent in Figure 18.33 and in Table 18.14.

TABLE 18.14 Explicit Form for the Transfer Function in the Jing–Fam Approach

$$H(z) = H_1(z^{\hat{L}_1})\Big\{I_2 z^{-\hat{M}_2} + H_2(z^{\hat{L}_2})\Big[I_3 z^{-\hat{M}_3} + H_3(z^{\hat{L}_3})(\cdots)$$
$$\Big\{I_{R-1}z^{-\hat{M}_{R-1}} + H_{R-1}(z^{\hat{L}_{R-1}})\Big[I_R z^{-\hat{M}_R} + H_R(z^{\hat{L}_R})\Big]\Big\}\ldots\Big)\Big]\},$$

where

$$H_r(z^{\hat{L}_r}) = H_r^{(1)}(z^{K_r\hat{L}_r})H_r^{(2)}(z^{\hat{L}_r})$$

$$H_r^{(1)}(z) = G_r^{(1)}\left(J_r^{(1)}z\right), \quad H_r^{(2)}(z) = S_r G_r^{(2)}\left(J_r^{(2)}z\right)$$

$$S_1 = 1, \quad S_r = -(-1)^{\hat{M}_r/\hat{L}_r}, \quad r = 2, 3, \ldots, R$$

$$J_1^{(2)} = 1, \quad J_2^{(2)} = -1, \quad J_r^{(2)} = -\left[J_{r-1}^{(2)}\right]^{\hat{L}_{r-1}}, \quad r = 3, 4, \ldots, R$$

$$J_r^{(1)} = \left[J_r^{(2)}\right]^{K_r}$$

$$\hat{L}_1 = 1, \quad \hat{L}_r = \prod_{k=1}^{r-1} L_k, \quad r = 2, 3, \ldots, R$$

$$\hat{M}_R = \tfrac{1}{2}\hat{L}_R N_R, \quad \hat{M}_{R-r} = \hat{M}_{R-r+1} + \tfrac{1}{2}\hat{L}_{R-r}N_{R-r}, \quad r = 1, 2, \ldots, R-2$$

$$I_2 = 1, \quad I_r = \left[J_{r-1}^{(2)}\right]^{\hat{M}_r/\hat{L}_{r-1}}, \quad r = 3, 4, \ldots, R$$

$$N_r = K_r N_r^{(1)} + N_r^{(2)}$$

$N_r^{(1)}$ and $N_r^{(2)}$ are the orders of $G_r^{(1)}(z)$ and $G_r^{(2)}(z)$, respectively

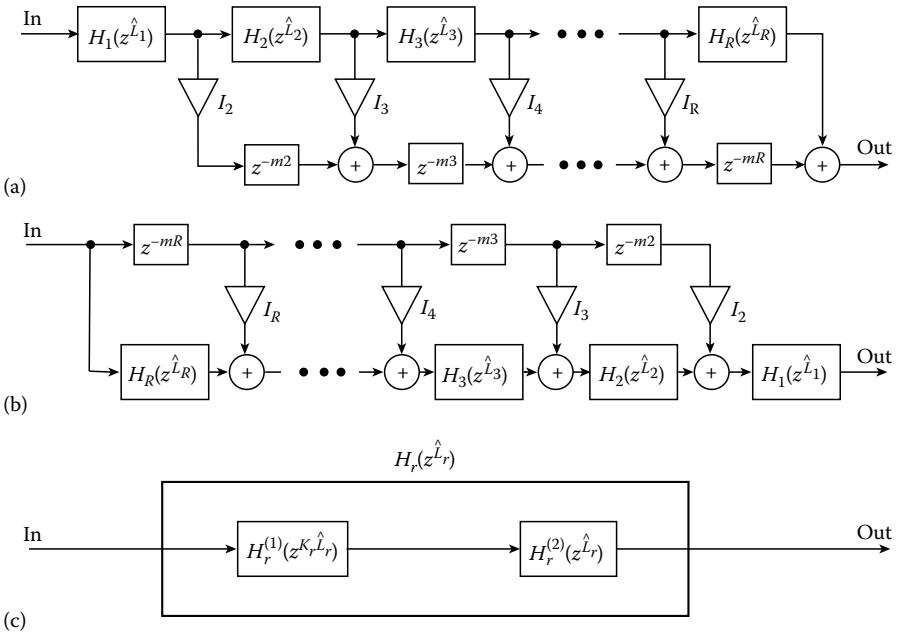

FIGURE 18.33 Implementations for a filter synthesized using the Jing–Fam approach. (a) Basic structure. (b) Transposed structure. (c) Structure for the subfilter $H_r(z^{O_{L_r}})$.

The remaining problem is to select R, the L_r's, the K_r's, and the ripple values such that the filter complexity is minimized. The following example illustrates this.

Example 18.5

Consider the specifications of Example 18.1, that is, $\boldsymbol{\omega}_p = 0.4\boldsymbol{\pi}$, $\boldsymbol{\omega}_s = 0.402\boldsymbol{\pi}$, $\boldsymbol{\delta}_p = 0.01$, and $\boldsymbol{\delta}_s = 0.001$. In this case, the only alternative is to select $L_1 = 2$. The resulting passband and stopband regions for $G_1(z)$ are (the substitution of Equation 18.109 is used)

$$\boldsymbol{\Omega}_p^{(1)} = [0,\ 0.4\boldsymbol{\pi}] \quad \text{and} \quad \boldsymbol{\Omega}_s^{(1)} = [0.5987\boldsymbol{\pi},\ \boldsymbol{\pi}]$$

For $\hat{H}_2(z)$, the edges become $\boldsymbol{\omega}_p^{(2)} = \boldsymbol{\pi} - L_{1\boldsymbol{\omega}s} = 0.196\boldsymbol{\pi}$ and $\boldsymbol{\omega}_s^{(2)} = \boldsymbol{\pi} - L_{1\boldsymbol{\omega}p} = 0.2\boldsymbol{\pi}$. For L_2, there are two alternatives to make the edges of $\hat{H}_3(z)$, $\boldsymbol{\omega}_p^{(3)} = \boldsymbol{\pi} - L_{2\boldsymbol{\omega}s}^{(2)}$ and $\boldsymbol{\omega}_s^{(3)} = \boldsymbol{\pi} - L_{2\boldsymbol{\omega}p}^{(2)}$, less than $\boldsymbol{\pi}/2$. These are $L_2 = 3$ and $L_2 = 4$. For $R = 5$ stages, there are the following four alternatives to make all the $\boldsymbol{\omega}_s^{(r)}$'s smaller than $\boldsymbol{\pi}/2$:

$$\begin{aligned}
&L_1 = 2, \quad L_2 = 4, \quad L_3 = 3, \quad L_4 = 2\\
&L_1 = 2, \quad L_2 = 4, \quad L_3 = 4, \quad L_4 = 4\\
&L_1 = 2, \quad L_2 = 3, \quad L_3 = 2, \quad L_4 = 4\\
&L_1 = 2, \quad L_2 = 3, \quad L_3 = 2, \quad L_4 = 3
\end{aligned}$$

Among these alternatives, the first one results in an overall filter with the minimum complexity. In this case, the edges of $\hat{H}_3(z)$, $\hat{H}_4(z)$, and $\hat{H}_5(z)+G_5(z)$ become as shown in Table 18.15. The corresponding passband and stopband regions for $G_2(z)$, $G_3(z)$, $G_4(z)$, and $G_5(z)$ are

I_r	—	1	1	-1	1
S_r	1	1	-1	1	-1
m_r	—	70	120	312	1920

$$\Omega_p^{(2)} = [0,\ 0.196\pi], \quad \Omega_s^{(2)} = [0.3013\pi,\ 0.6987\pi] \cup [0.8013\pi,\ \pi]$$
$$\Omega_p^{(3)} = [0,\ 0.2\pi], \quad \Omega_s^{(3)} = [0.4560\pi,\ 0.8773\pi]$$
$$\Omega_p^{(4)} = [0,\ 0.352\pi], \quad \Omega_s^{(4)} = [0.616\pi,\ \pi]$$
$$\Omega_p^{(5)} = [0,\ 0.2\pi], \quad \Omega_s^{(5)} = [0.296\pi,\ \pi]$$

What remains is to determine the ripple requirements. From Equation 18.107b, it follows for $R=5$, $\delta_p^{(1)} + \delta_p^{(3)} + \delta_p^{(5)} = \delta_p$ and $\delta_p^{(2)} + \delta_p^{(4)} + \delta_p^{(6)} = \delta_s$. By simply selecting the ripple values in these summations to be equal, the required ripples for the $G_r(z)$'s become as shown in Table 18.15.

The first and fourth subfilter are single-stage filters since their stopband edges are larger than $\pi/2$, whereas the remaining three filters are two-stage designs. The parameters describing the overall filter are shown in Table 18.15, whereas Figure 18.34a depicts the response of this filter. The number of multipliers and the order of this design are 78 and 4875, whereas the corresponding numbers for the direct-form equivalent are 1271 and 2541. The number of multipliers required by the proposed design is thus only 6 percent of that of the direct-form filter. Since the complexity of $H_5(z^{\hat{L}_5})$ is similar to those of the earlier filter stages, $R=5$ is a good selection in this example.

The overall filter order as well as the number of multipliers can be decreased by selecting smaller ripple values for the first stages, thereby allowing larger ripples for the last stages. Proper selections for the ripple requirements and filter orders are shown in Table 18.16. The first four filters have been optimized such that their passband variations are minimized. The first criteria are met by a half-band filter of order 34, having the passband and stopband edges at 0.4013π and 0.5987π. Since every second impulse response coefficient of this filter is zero-valued except for the central coefficient with an easily

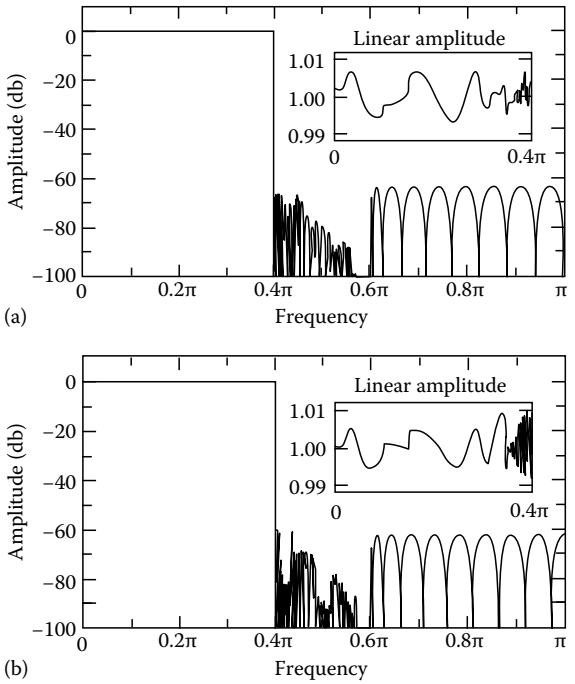

FIGURE 18.34 Amplitude responses for filters synthesized using the Jin–Fam approach.

implementable value of 1/2, this filter requires only nine multipliers. For the last stage, K_5 is reduced to 2 to decrease the overall filter order. The order of the resulting overall filter [see Figure 18.34b] is 3914, which is 54 percent higher than that of the direct-form equivalent. The number of multipliers is reduced to 70.

The Jing–Fam approach cannot be applied directly for synthesizing filters whose edges are very close to $\pi/2$. This problem can, however, be overcome by slightly changing the sampling rate or, if this is not possible, by shifting the edges by a factor 3/2 by using decimation by this factor at the filter input and interpolation by the same factor at the filter output [2]. One attractive feature of the Jing–Fam approach is that it can be combined with multirate filtering to reduce the filter complexity even further [7].

When comparing the above designs with the filters synthesized using the multistage frequency-response masking technique (Example 18.2), it is observed that the above designs require slightly fewer multipliers at the expense of an increased overall filter order. Both of these general approaches are applicable to those specifications that are not very narrowband or very wideband. For most very narrowband and wideband cases, filters synthesized in the simplified forms $H(z) = F(z^L)G(z)$ and $H(z) = z^{-M} - (-1)^M F[(-z)^L]G(-z)$, respectively, give the best results (see Examples 18.3 and 18.4).

19.1 Properties of IIR Filters

Sawasd Tantaratana

19.1.1 System Function and Impulse Response

A digital filter with impulse response having infinite length (i.e., its values outside a finite interval cannot all be zero) is termed infinite impulse response (IIR) filter. The most important class of IIR filters can be described by the difference equation

$$\begin{aligned} y(n) = {} & b_0 x(n) + b_1 x(n-1) + \cdots + b_M x(n-M) \\ & - a_1 y(n-1) - a_2 y(n-2) - \cdots - a_N y(n-N) \end{aligned} \tag{19.1}$$

where
$x(n)$ is the input
$y(n)$ is the output of the filter
$\{a_1, a_2, \ldots, a_N\}$ and $\{b_0, b_1, \ldots, b_M\}$ are constant coefficients

We assume that $a_N \neq 0$. The impulse response is the output of the system when it is driven by a unit impulse at $n = 0$, with the system being initially at rest, i.e., the output being zero prior to applying the input. We denote the impulse response by $h(n)$. With $x(0) = 1, x(n) = 0$ for $n \neq 0$, and $y(n) = 0$ for

$n < 0$, we can compute $h(n)$, $n \geq 0$, from Equation 19.1 in a recursive manner. Taking the z-transform of Equation 19.1, we obtain the system function

$$H(z) = \frac{Y(z)}{X(z)} = \frac{b_0 + b_1 z^{-1} + \cdots + b_M z^{-M}}{1 + a_1 z^{-1} + \cdots + a_N z^{-N}} \tag{19.2}$$

where N is the order of the filter. The system function and the impulse response are related through the z-transform and its inverse, i.e.,

$$H(z) = \sum_{n=-\infty}^{\infty} h(n) z^{-1} \quad h(n) = \frac{1}{2\pi j} \oint_C H(z) z^{n-1} \mathrm{d}z \tag{19.3}$$

where C is a closed counterclockwise contour in the region of convergence. See Chapter 5 of *Fundamentals of Circuits and Filters* for a discussion of z-transform. We assume that $M \leq N$. Otherwise, the system function can be written as

$$H(z) = \left[c_0 + c_1 z^{-1} + \cdots + c_{M-N} z^{-(M-N)}\right] + \left[\frac{b_0' + b_1' z^{-1} + \cdots + b_M' z^{-M}}{1 + a_1 z^{-1} + \cdots + a_N z^{-N}}\right] \tag{19.4}$$

which is a finite impulse response (FIR) filter in parallel with an IIR filter, or as

$$H(z) = \left[c_0' + c_1' z^{-1} + \cdots + c_{M-N}' z^{-(M-N)}\right] \left[\frac{b_0'' + b_1'' z^{-1} + \cdots + b_M'' z^{-M}}{1 + a_1 z^{-1} + \cdots + a_N z^{-N}}\right] \tag{19.5}$$

which is an FIR filter in cascade with an IIR filter. FIR filters are covered in Chapter 18. This chapter covers IIR filters.

For ease of implementation, it is desirable that the coefficients $\{a_1, a_2, \ldots, a_N\}$ and $\{b_0, b_1, \ldots, b_M\}$ be real numbers (as opposed to complex numbers), which is another assumption that we make, unless specified otherwise.

19.1.2 Causality (Physical Realizability)

A causal (physically realizable) filter is one whose output value does not depend on the future input values. A noncausal filter cannot be realized in real time since some future inputs are needed in computing the current output value. The difference equation in Equation 19.1 can represent a causal system or a noncausal system. If the output $y(n)$ is calculated, for an increasing value of n, from $x(n), x(n-1), \ldots, x(n-M)$, $y(n-1), \ldots, y(n-N)$, according to the right-hand side of Equation 19.1 then the difference equation represents a causal system. On the other hand, we can rewrite Equation 19.1 as

$$\begin{aligned} y(n-N) = &\frac{1}{a_N}[b_0 x(n) + b_1 x(n-1) + \cdots + b_M x(n-M) \\ &- y(n) - a_1 y(n-1) - \cdots - a_{N-1} y(n-N+1)] \end{aligned} \tag{19.6}$$

If the system calculates $y(n-N)$, for a decreasing due of n, using the right-hand side of Equation 19.6, then the system is noncausal since $y(n-N)$ depends on $x(n), \ldots, x(n-M)$, which are future input values. We shall assume that the IIR filter represented by Equation 19.1 is causal. It follows from this assumption that $h(n) = 0$ for $n < 0$ and that the convergence region of $H(z)$ is of the form: $|z| > r_0$, where r_0, is a nonnegative constant.

Noncausal filters are useful in practical application where the output need not be calculated in real time or where the variable n does not represent time, such as in image processing where n is a spatial variable. Generally, a noncausal filter can be modified to be causal by adding sufficient delay at the output.

19.1.3 Poles and Zeros

Rewriting Equation 19.2 we have

$$H(z) = z^{N-M} \frac{b_0 z^M + b_1 z^{M-1} + \cdots + b_{M-1} z + b_M}{z^N + a_1 z^{N-1} + \cdots + a_{N-1} z^{-N}} \tag{19.7}$$

Assuming $b_0, b_M \neq 0$, then there are N poles given by the roots of the denominator polynomial and M zeros given by the roots of the numerator polynomial. In addition, there are $N - M$ zeros at the origin on the complex plane. The locations of the poles and zeros can be plotted on the complex z plane. Denoting the poles by $p_1, p_2, \ldots, p_N$, and the nonzero zeros by $q_1, q_2, \ldots, q_M$, we can write

$$H(z) = b_0 z^{N-M} \frac{(z - q_1)(z - q_2) \cdots (z - q_M)}{(z - p_1)(z - p_2) \cdots (z - p_N)} \tag{19.8}$$

Since we assume that the coefficients $\{a_1, a_2, \ldots, a_N\}$ and $\{b_0, b_1, \ldots, b_M\}$ are each complex-valued pole (i.e., pole off the real axis on the z plane), there must be another pole that is the complex conjugate of the first. Similarly, complex-valued zeros must exist in complex–conjugate pairs. The combination of a complex–conjugate pole pair (or zero pair) yields a second-order polynomial with real coefficients. Real-valued pole (or zero) can appear single in Equation 19.8.

It is clear from Equation 19.8 that knowing all the pole and zero locations, we can write the system function to within a constant factor. Since the constant factor is only a gain, which can be adjusted as desired, specifying the locations of the poles and zeros essentially specifies the system function of the IIR filter.

19.1.4 Stability

A causal IIR filter is stable (in the sense that a bounded input gives rise to a bounded output) if all the poles lie inside the unit circle. If there are one or more simple poles on the unit circle (and all the others lie inside the unit circle), then the filter is marginally stable, giving a sustained oscillation. If there are multiple poles (more than one pole at the same location) on the unit circle or if there is at least one pole outside the unit circle, a slight input will give rise to an output with increasing magnitude. For most practical filters, all the poles are designed to lie inside the unit circle. In some special systems (such as oscillators), poles are placed on the unit circle to obtain the desired result.

Given the system function in the form of Equation 19.2 or Equation 19.7, the stability can be verified by finding all the poles of the filters and checking to see if all of them are inside the unit circle. Equivalently, stability can be verified directly from the coefficients $\{a_i\}$, using the Schür-Cohn algorithm [1]. For a second-order system, if the coefficient a_1, and a_2, lie inside the triangle in Figure 19.1, then the system is stable.

19.1.5 Frequency Response

The frequency response of the IIR filter is the due of the system function evaluated on the unit circle on the complex plane, i.e., with $z = e^{j2\pi f}$, where f varies from 0 to 1, or from $-1/2$ to $1/2$. The variable f represents the digital frequency. For simplicity, we write $H(f)$ for $H(z)|_{z=\exp(j2\pi f)}$. Therefore,

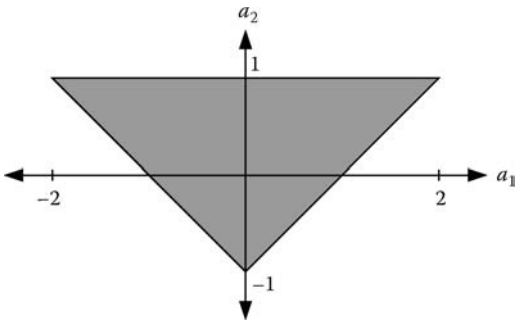

FIGURE 19.1 Region for the coefficients a_1 and a_2 that yield a stable second-order IIR filter.

$$H(f) = b_0 e^{j2\pi(M-N)f} \frac{(e^{j2\pi f} - q_1)(e^{j2\pi f} - q_2)\cdots(e^{j2\pi f} - q_M)}{(e^{j2\pi f} - p_1)(e^{j2\pi f} - p_2)\cdots(e^{j2\pi f} - p_N)} \tag{19.9}$$

$H(f)$ is generally a complex function of f, consisting of the real part $H_R(f)$ and the imaginary part $H_I(f)$. It can also be expressed in terms of the magnitude $|H(f)|$ and the phase $\theta(f)$

$$H(f) = H_R(f) + jH_I(f) = |H(f)|e^{j\theta(f)} \tag{19.10}$$

From Equation 19.9 we see that the magnitude response $|H(f)|$ equals the product of the magnitudes of the individual factors in the numerator, divided by the product of the magnitudes of the individual factors in the denominator. The magnitude square can be written as

$$|H(f)|^2 = H(f)H^*(f) = [H_R(f)]^2 + [H_I(f)]^2 \tag{19.11}$$

Since $H^*(f) = H^*(1/z^*)|_{z=\exp(j2\pi f)}$ and $H^*(1/z^*) = H(z^{-1})$ when all the coefficients of $H(z)$ are real, we have

$$|H(f)|^2 = H(z) \cdot H(z^{-1})|_{z=\exp(j2\pi f)} \tag{19.12}$$

Using Equation 19.12, the magnitude square can be put in the form

$$|H(f)|^2 = \frac{\sum_{k=0}^{M} \tilde{b}_k \cos(2\pi k f)}{\sum_{k=0}^{N} \tilde{a}_k \cos(2\pi k f)} \tag{19.13}$$

where the coefficients are given by

$$\begin{aligned} \tilde{b}_0 &= \sum_{j=0}^{M} b_j^2 \quad \tilde{b}_k = 2\sum_{j=k}^{M} b_j b_{j-k} \quad k = 1, \ldots, M \\ \tilde{a}_0 &= \sum_{j=0}^{N} a_j^2 \quad \tilde{a}_k = 2\sum_{j=k}^{N} a_j a_{j-k} \quad k = 1, \ldots, N \end{aligned} \tag{19.14}$$

with the understanding that $a_0 = 1$. Given $\{\tilde{b}_0, \tilde{b}_1, \ldots, \tilde{b}_M\}$ we can find $\{b_0, b_1, \ldots, b_M\}$ and vice versa. Similarly, $\{\tilde{a}_1, \tilde{a}_2, \ldots, \tilde{a}_N\}$ and $\{a_1, a_2, \ldots, a_N\}$ can be computed from each other. The form in Equation 19.13 is useful in computer-aided design of IIR filters using linear programming [2].

We see from Equation 19.9 that the phase response $\theta(f)$ equals the sum of the phases of the individual factors in the numerator minus the sum of the phases of the individual factors in the denominator. The phase can be written in terms of the real and imaginary parts of $H(f)$ as

$$\theta(f) = \arctan\left[\frac{H_{\mathrm{I}}(f)}{H_{\mathrm{R}}(f)}\right] \tag{19.15}$$

A filter having linear phase in a frequency band (e.g., in the passband) means that there is no phase distortion in that band.

The group delay is defined as

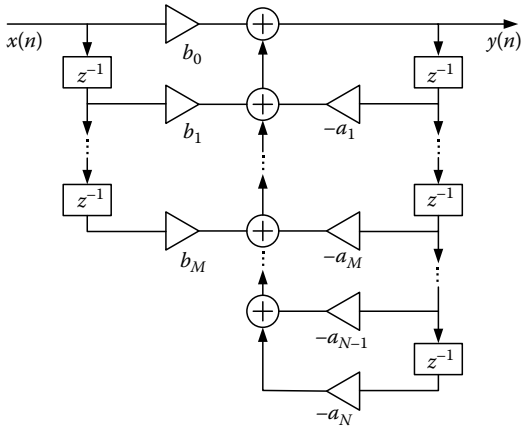
$$\tau(f) = -\frac{1}{2\pi}\frac{\mathrm{d}}{\mathrm{d}f}\theta(f) \tag{19.16}$$

The group delay corresponds to the delay, from the input to the output, of the envelope of a narrowband signal [3]. A linear phase gives rise to a constant group delay. Nonlinearity in the phase appears as deviation of the group delay from a constant value.

The magnitude response of IIR filter does not change, except for a constant factor, if a zero is replaced by the reciprocal of its complex conjugate, i.e., if $(z - q)$ is replaced with $(z - 1/q^*)$. This can be seen as follows. Letting $\tilde{H}(z)$ be the system function without the factor $(z - q)$, we have

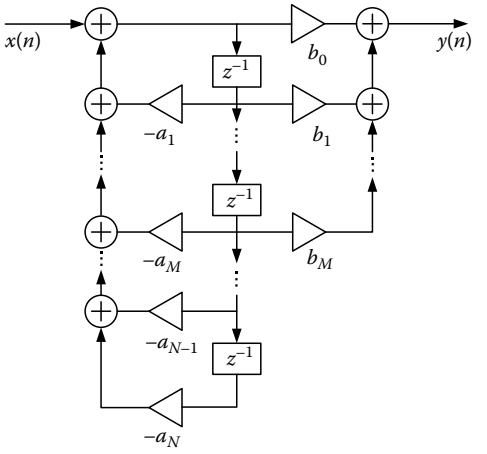
$$\begin{aligned}
|H(f)|^2 &= H(z)H^*(1/z^*)|_{z=\exp(j2\pi f)} \\
&= \hat{H}(z)\hat{H}^*(1/z^*)\frac{(z-q)(z^{-1}-q^*)}{(z-1/q^*)(z^{-1}-1/q)}\bigg|_{z=\exp(2j\pi f)} \\
&= |q|^2
\end{aligned}$$

Similarly, replacing the pole at p with a pole at $1/p^*$ will not alter the magnitude of the response except for a constant factor. This property is useful in changing an unstable IIR filter to a stable one without altering the magnitude response.



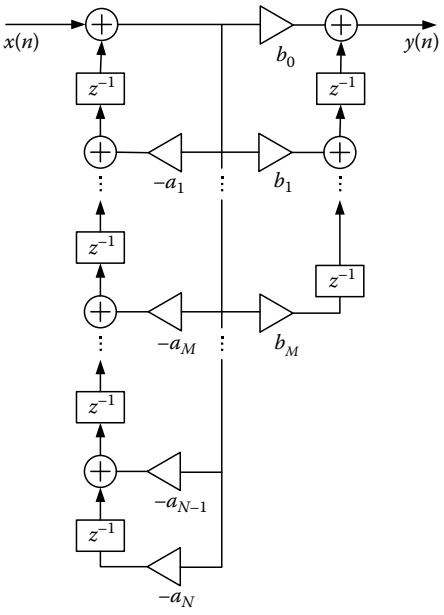
Compared to an FIR filter, an IIR filter requires a much lower order to achieve the same requirement of the magnitude response. However, the phase of a stable casual IIR filter cannot be made linear. This is the major reason not to use an IIR filter in applications where linear phase is essential. Nevertheless, using phase compensation such as allpass filters (see Section 19.1.8), the phase of an IIR filter can be adjusted close to linear. This process increases the order of the overall system, however. Note that if causality is not required, then a linear-phase IIR filter can be obtained using a time-reversal filter [2].

19.1.6 Realizations

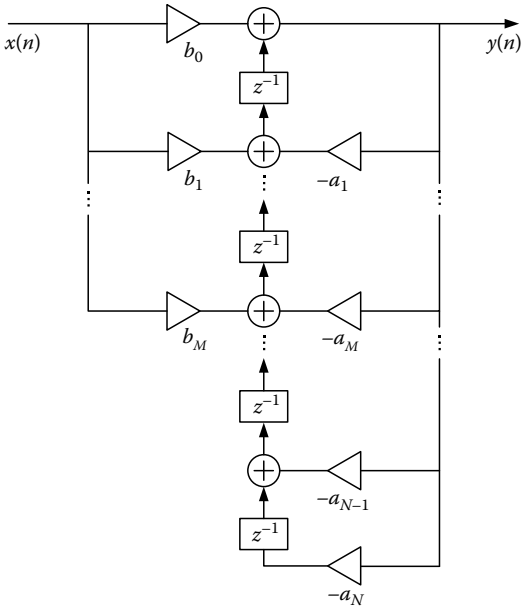


A realization of an IIR filter according to Equation 19.1 is shown in Figure 19.2a, which is called Direct Form I. By rearranging the structure, we can obtain Direct Form II, as shown in Figure 19.2b. Through transposition, we can obtain Transposed Direct Form I and Transposed Direct Form II as shown in Figure 19.2c and d.

The system function can be put in the form



$$H(z) = \prod_{i=1}^{K}\frac{b_{i0} + b_{i1}z^{-1} + b_{i2}z^{-2}}{1 + a_{i1}z^{-1} + a_{i2}z^{-2}} \tag{19.17}$$



(a) Direct form I

(b) Direct form II

(c) Transposed direct form I

(d) Transposed direct form II

FIGURE 19.2 Direct form realizations of IIR filters.

by factoring the numerators and denominators into second-order factors, or in the form

$$H(z) = \frac{b_N}{a_N} + \sum_{i=1}^{K} \frac{b_{i0} + b_{i1} z^{-1}}{1 + a_{i1} z^{-1} + a_{i2} z^{-2}} \tag{19.18}$$

by partial fraction expansion. The value of K is $N/2$ when N is even and is $(N+1)/2$ when N is odd. When N is odd, one of a_{i2} must be zero, as well as one of b_{i2}, in Equation 19.17 and one of b_{i1} in Equation 19.18. All the coefficients in Equations 19.17 and 19.18 are real numbers. According to Equation 19.17, the IIR filter can be realized by K second-order IIR filters in cascade, as shown in Figure 19.3a. According

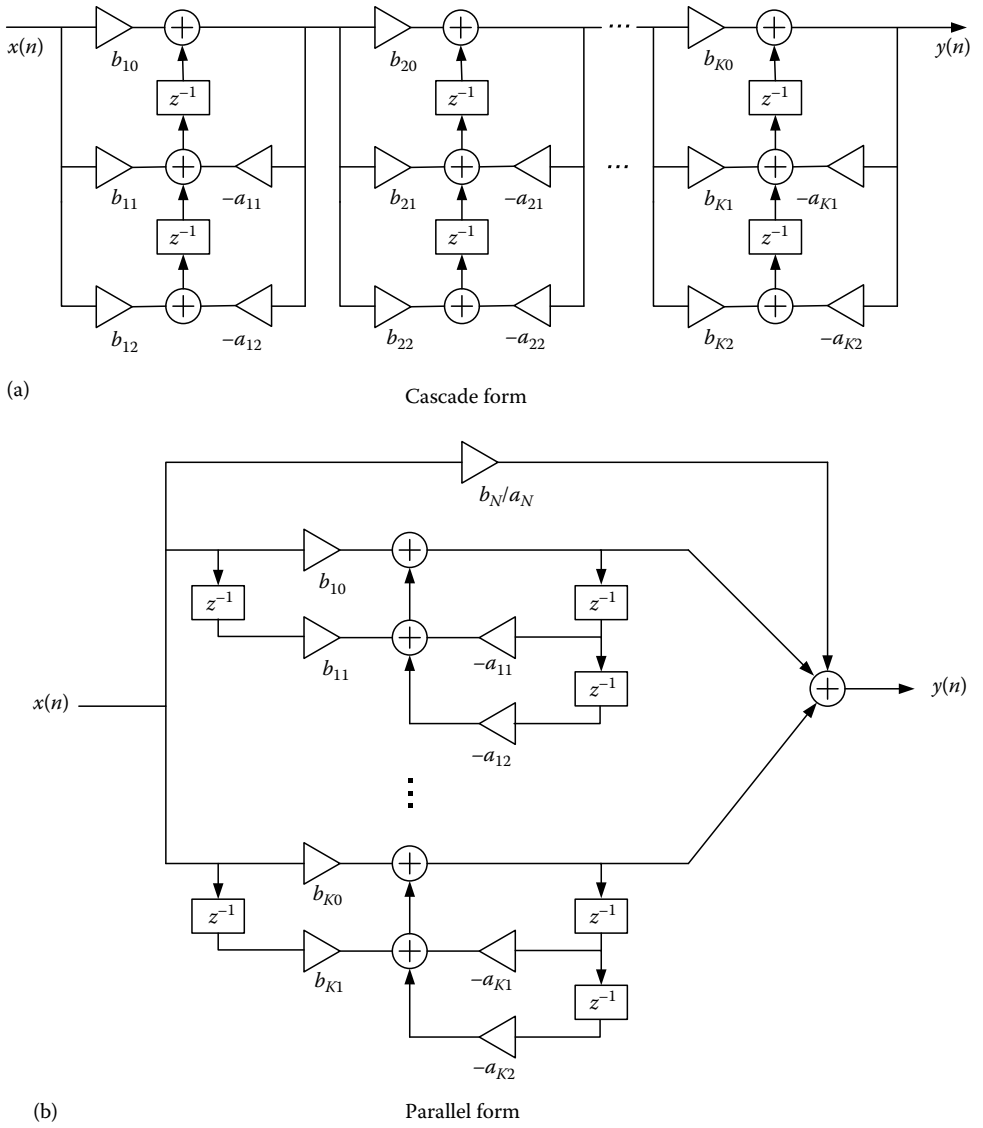


FIGURE 19.3 Cascade (a) and parallel (b) realizations of IIR filters.

to Equation 19.18, the IIR filter is realized by K second-order IIR filters and one scaler (i.e., b_N/a_N) in parallel, as depicted in Figure 19.3b. Each second-order subsystem can use any of the structures given in Figure 19.2.

There are many other realizations for IIR filters, such as state-space structures [4], wave structures, and lattice structures (Section 19.3).

Actual implementation of IIR filters requires that the signals and the coefficients be represented in a finite number of bits (or digits). Quantization of the coefficients to a finite number of bits essentially changes the filter coefficients, hence the frequency response changes. Coefficient quantization of a stable IIR filter may yield an unstable filter. For example, consider a second-order IIR filter with $a_1 = 1.26$ and $a_2 = 0.3$, which correspond to pole locations of -0.9413 and -0.3187, respectively. Suppose that we quantize these coefficients to two bits after the decimal point, yielding a quantized a_1 of 1.01 in binary or

1.25 and a quantized a_2 of 0.01 in binary or 0.25. This pair corresponds to pole locations at -1.0 and -0.25, respectively. Since one pole is on the unit circle, the IIR filter with quantized coefficients produces an oscillation. In this example, the quantization is equivalent to moving a point inside the triangle in Figure 19.1 to a point on the edge of the triangle. Different realizations are affected differently by coefficient quantization. Chapter 20 investigates coefficient quantization and roundoff noise in detail.

19.1.7 Minimum Phase

An IIR filter is a minimum-phase filter if all the zeros and poles are inside the unit circle. A minimum-phase filter introduces the smallest group delay among all filters that have the same magnitude response. A minimum-phase IIR filter can be constructed from a nonminimum-phase filter by replacing each zero (or pole) outside the unit circle with a zero (or pole) that is the reciprocal of its complex conjugate, as illustrated in Figure 19.4. This process moves all zeros and poles outside the unit circle to the inside. The magnitude response does not change, except for a constant factor, which is easily adjusted. Given an IIR filter $H(z)$ with input $x(n)$ and output $y(n)$, the inverse filter $1/H(z)$ can reconstruct $x(n)$ from $y(n)$ by feeding $y(n)$ to the input of $1/H(z)$. Assuming that both the filter and the inverse filter are causal, both of them can be stable only if $H(z)$ is a minimum-phase filter.

19.1.8 Allpass Filters

An allpass filter has a magnitude response of unity (or constant). An Nth-order IIR allpass filter with real coefficients has a system function given by

$$H(z) = z^{-N}\frac{D(z)}{D(z^{-1})} = z^{-N}\frac{a_N z^N + \cdots + a_2 z^2 + a_1 z + 1}{1 + a_1 z^{-1} + a_2 z^{-2} + \cdots + a_N z^{-N}} \tag{19.19}$$

$$= z^{-N}\frac{(1 - p_1 z)(1 - p_2 z)\cdots(1 - p_N z)}{(1 - p_1 z^{-1})(1 - p_2 z^{-1})\cdots(1 - p_N z^{-1})} \tag{19.20}$$

Since $H(z)(z^{-1}) = 1$, it follows that $|H(f)|^2 = 1$. The factor z^{-N} is included so that the filter is causal. Equation 19.20 implies that zeros and poles come in reciprocal pairs: if there is a pole at $z = p$, then there is a zero at $z = 1/p$, as illustrated in Figure 19.5.

Since the coefficients are real, poles and zeros off the real axis must exist in quadruplets: poles at p and p^* and zeros at $1/p$ and $1/p^*$, where $|p| < 1$ for stability. For poles and zeros on the real axis, they exist in reciprocal pairs: pole at p and zero at $1/p$, where p is real and $|p| < 1$ for stability. Since the numerator and the denominator in (19.19) share the same set of coefficients, we need only N multiplications in

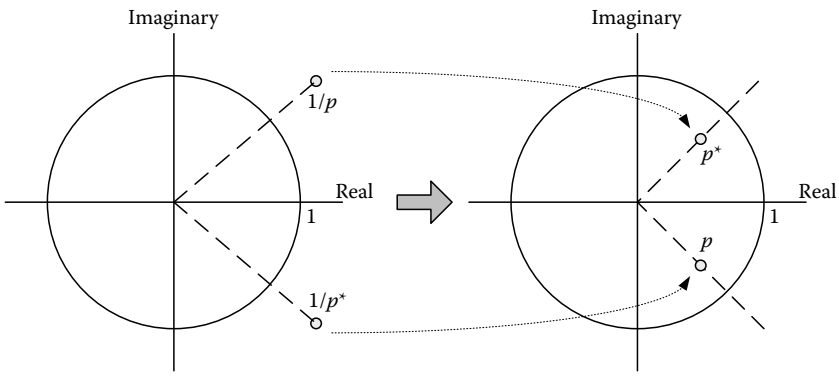

FIGURE 19.4 Changing a zero location to obtain a minimum-phase filter.

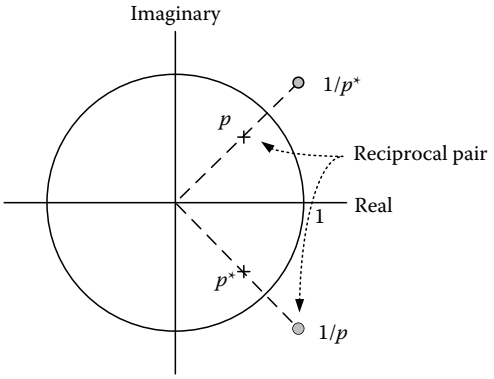

FIGURE 19.5 Pole-zero reciprocal pair in an allpass IIR filter.

realizing an *N*th-order allpass filter. The system function in Equation 19.19 can be written as the product (or sum) of first- and second-order allpass filters. The system function and the phase response of a first-order allpass filter is given by

$$H(z) = \frac{a_1 z + 1}{z + a_1} \tag{19.21}$$

$$\theta(f) = \arctan\left[\frac{(a_1^2 - 1)\sin(\omega)}{2a_1 + (a_1^2 + 1)\cos(\omega)}\right] \tag{19.22}$$

where $\omega = 2\pi f$. For a second-order allpass filter, these are

$$H(z) = \frac{a_2 z^2 + a_1 z + 1}{z^2 + a_1 z + a_2} \tag{19.23}$$

$$\theta(f) = \arctan\left[\frac{2a_1(a_2 - 1)\sin(\omega) + (a_2^2 - 1)\sin(2\omega)}{2a_2 + a_1^2 + 2a_1(a_2 + 1)\cos(\omega) + (a_2^2 + 1)\cos(2\omega)}\right] \tag{19.24}$$

The group delay $\tau(f)$ of an allpass filter is always ≥ 0. The output signal energy of an allpass filter is the same as the input signal energy, i.e., $\sum_{n=-\infty}^{\infty} |y(n)|^2 = \sum_{n=-\infty}^{\infty} |x(n)|^2$, which means that the allpass filter is a lossless system. Note that if we attempt to find a minimum-phase filter from a stable allpass filter, by moving all the zeros inside the unit circle, all poles and zeros would cancel out, yielding the trivial filter with a system function of unity.

A more general form of Equation 19.19, allowing the coefficients to be complex, is *N*th-order allpass filer with system function

$$H(z) = z^{-N}\frac{D^*(z^*)}{D(z^{-1})} = z^{-N}\frac{a_N^* + \cdots + a_2^* z^2 + a_1^* z + 1}{1 + a_1 z^{-1} + a_2 z^{-2} + \cdots + a_N z^{-N}} \tag{19.25}$$

$$= z^{-N}\frac{(1 - p_1^* z)(1 - p_2^* z)\cdots(1 - p_N^* z)}{(1 - p_1 z^{-1})(1 - p_2 z^{-1})\cdots(1 - p_N z^{-1})} \tag{19.26}$$

Therefore, for a pole at $z = p$ there is a zero at $z = 1/p^*$, i.e., poles and zeros exist in reciprocal–conjugate pairs.

Allpass filters have been used as building blocks for various applications [5]. Particularly, an allpass filter can be designed to approximate a desired phase response. Therefore, an allpass filter in cascade with an IIR filter can be used to compensate the nonlinear phase of the IIR filter. Such a cascade filter has

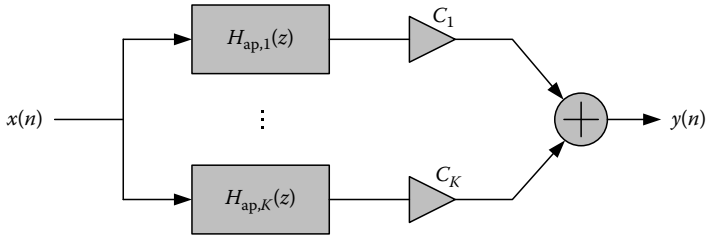

FIGURE 19.6 Block diagram of an IIR filter, using allpass filters.

system function of the form $H(z) = H_{IIR}(z)H_{ap}(z)$, where $H_{IIR}(z)$ is an IIR filter satisfying some magnitude response and $H_{ap}(z)$ is an allpass filter that compensates for the nonlinearity of the phase response of $H_{IIR}(z)$. Allpass filters in parallel connection can be used to approximate a desired magnitude response. For this, the system function is in the form $H(z) = \sum_{i=1}^{K} c_i H_{ap,i}(z)$, where $H_{ap,i}(z)$ is an allpass filter and c_i is a coefficient. A block diagram is shown in Figure 19.6.

19.2 Design of IIR Filters

Sawasd Tantaratana, Chalie Charoenlarpnopparut, and Phakphoom Boonyanant

19.2.1 Introduction

A filter is generally designed to satisfy a frequency response specification. IIR filter design normally focuses on satisfying a magnitude response specification. If the phase response is essential, it is usually satisfied by a phase compensation filter, such as an allpass filter (see Section 19.1.8). We will adopt a magnitude specification that is normalized so that the maximum magnitude is 1. The magnitude square in the passband must be at least $1/(1+\varepsilon^2)$ and at most 1; while it must be no larger than δ^2 in the stopband, where ε and δ are normally small. The passband edge is denoted by f_p and the stopband edge by f_s. Figure 19.7a shows such a specification for a low-pass filter (LPF). The region between the passband and the stopband is the transition band. There is no constraint on the response in the transition band. Another specification that is often used is shown in Figure 19.7b using δ_1, and δ_2, to specify the acceptable magnitude. Given δ_1, and δ_2, they can be converted to ε and δ using $\varepsilon = 2\delta_1^{0.5}/(1-\delta_1)$ and $\delta = \delta_2/(1+\delta_1)$. The magnitude is often specified in decibels, which is $20\log_{10}|H(f)|$. Specifications for other types of filters (high-pass, bandpass, and bandstop) are similar.

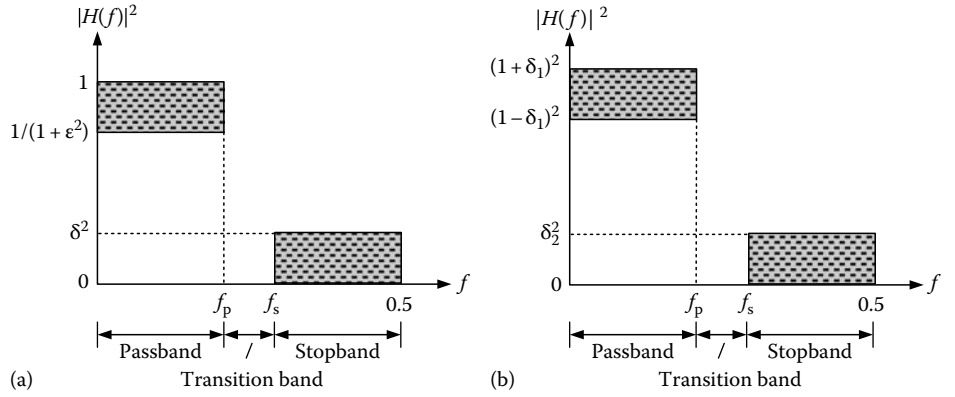

FIGURE 19.7 Specifications for a digital LPF. (a) Specification using ε and δ; (b) specification using δ_1 and δ_2.

We can classify various IIR filter design methods into three categories: the design using analog prototype filter, the design using digital frequency transformation, and computer-aided design. In the first category, an analog filter is designed to the (analog) specification and the analog filter transfer function is transformed to digital system function using some kind of transformation. The second category assumes that a digital LPF can be designed. The desired digital filter is obtained from the digital LPF by a digital frequency transformation. The last category uses some algorithm to choose the coefficients so that the response is as close (in some sense) as possible to the desired filter. Design methods in the first two categories are simple to do, requiring only a handheld calculator. Computer-aided design requires some computer programming, but it can be used to design nonstandard filters.

19.2.2 Analog Filters

Here, we describe four basic types of analog LPFs that can be used as prototype for designing IIR filters. For each type, we give the transfer function, its magnitude response, and the order N needed to satisfy the (analog) specification. We will use $H_a(s)$ for the transfer function of an analog filter, where s is the variable in the Laplace transform. Each of these filters have all its poles on the left-half s plane, so that it is stable. We will use the variable λ to represent the analog frequency in radians/second. The frequency response $H_a(\lambda)$ is the transfer function evaluated at $s = j\lambda$. The analog LPF specification is given by

$$\begin{aligned}(1+\varepsilon^2)^{-1} \le |H_a(\lambda)|^2 \le 1 \quad &\text{for } 0 \le (\lambda/2\pi) \le (\lambda_p/2\pi) \\ 0 \le |H_a(\lambda)|^2 \le \delta^2 \quad &\text{for } (\lambda_s/2\pi) \le (\lambda/2\pi) \le \infty\end{aligned} \tag{19.27}$$

where λ_p and λ_s are the passband edge and stopband edge, respectively. The specification is sketched in Figure 19.8.

19.2.2.1 Butterworth Filters

The transfer function of an Nth-order Butterworth filter is given by

$$H_a(s) = \begin{cases} \displaystyle\prod_{i=1}^{N/2} \frac{1}{(s/\lambda_c)^2 - 2\mathrm{Re}(s_i)(s/\lambda_c)+1} & N = \text{even} \\ \dfrac{1}{(s/\lambda_c)+1} \displaystyle\prod_{i=1}^{(N-1)/2} \frac{1}{(s/\lambda_c)^2 - \mathrm{Re}(s_i)(s/\lambda_c)+1} & N = \text{odd} \end{cases} \tag{19.28}$$

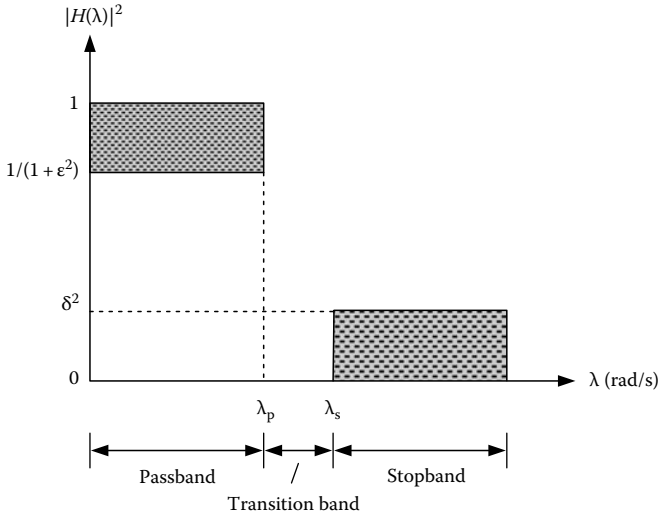

FIGURE 19.8 Specification for an analog LPF.

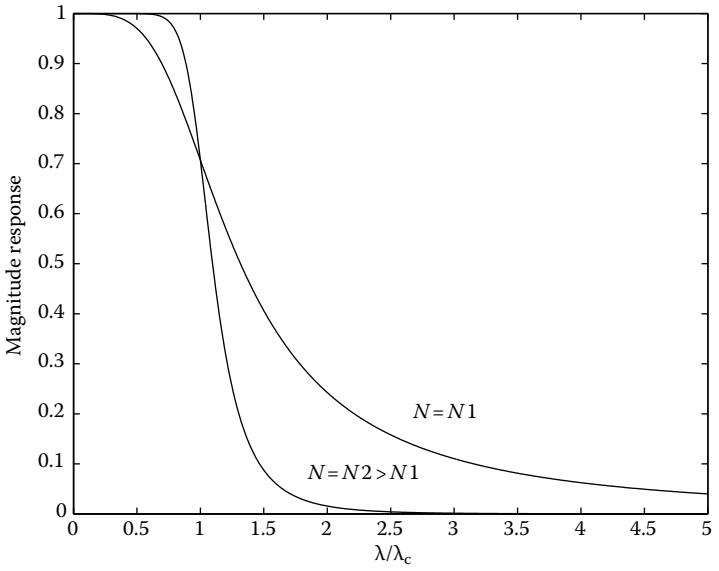

FIGURE 19.9 Magnitude responses of Butterworth filters.

where $\lambda_p \le \lambda_c \le \lambda_s$ and $s_i = \exp\{j[1 + (2i-1)/N]\pi/2\}$. The magnitude response square is

$$|H_a(\lambda)|^2 = \frac{1}{1 + (\lambda/\lambda_c)^{2N}} \tag{19.29}$$

Figure 19.9 shows the magnitude response $|H_a(\lambda)|$, with $\lambda_c = 1$. Note that a Butterworth filter is an all-pole (no zero) filter, with the poles being at $s = \lambda_c s_i$ and $s = \lambda_c s_i^*, i = 1, \ldots, N/2$ if N is even or $i = 1, \ldots, (N-1)/2$ if N is odd, where x^* denotes the complex conjugate of x. When N is odd, there

TABLE 19.1 Factorized, Normalized, Butterworth Polynomial $B_N(s)$

3	$(s+1)(s^2+s+1)$
4	$(s^2+\sqrt{2-\sqrt{2}}s+1)(s^2+\sqrt{2+\sqrt{2}}s+1)$
5	$(s+1)\left(s^2+\left(\frac{\sqrt{5}-1}{2}\right)s+1\right)\left(s^2+\left(\frac{\sqrt{5}+1}{2}\right)s+1\right)$
6	$\left(s^2+\left(\frac{\sqrt{3}-1}{\sqrt{2}}\right)s+1\right)(s^2+\sqrt{2}s+1)\left(s^2+\left(\frac{\sqrt{3}+1}{\sqrt{2}}\right)s+1\right)$
7	$(s+1)(s^2+0.4450s+1)(s^2+1.2470s+1)(s^2+1.8019s+1)$
8	$(s^2+0.3902s+1)(s^2+1.1111s+1)(s^2+1.6629s+1)(s^2+1.9616s+1)$
9	$(s+1)^2(s^2+0.3473s+1)(s^2+1.5321s+1)(s^2+1.8794s+1)$
10	$(s^2+0.3219s+1)(s^2+0.9080s+1)(s^2+1.4142s+1)(s^2+1.7820s+1)(s^2+1.9754s+1)$

is another pole at $s=-\lambda_c$. All N poles are on the left-half s plane, located on the circle with radius λ_c. Therefore, the filter in Equation 19.28 is stable.

To satisfy the specification in Equation 19.27, the filter order can be calculated from

$$N = \text{integer} \geq \frac{\log\left[\varepsilon/(\delta^{-2}-1)^{1/2}\right]}{\log\left[\lambda_p/\lambda_s\right]} \tag{19.30}$$

The value of λ_c can be chosen as any value in the following range:

$$\lambda_p \varepsilon^{-1/N} \leq \lambda_c \leq \lambda_s(\delta^{-2}-1)^{-1/(2N)} \tag{19.31}$$

If we choose $\lambda_c = \lambda_p\varepsilon^{-1/N}$, then the magnitude response square passes through $1/(1+\varepsilon^2)$ at $\lambda=\lambda_p$. If we choose $\lambda_c = \lambda_s(\delta^{-2}-1)^{-1/(2N)}$, then the magnitude response square passes through δ^2 at $\lambda=\lambda_s$. If λ_c is between these two values, then the magnitude square will be $\geq 1/(1+\varepsilon^2)$ at $\lambda=\lambda_p$ and $\leq \delta^2$ at $\lambda=\lambda_s$.

For the sake of convenience, the transfer function of the Nth-order Butterworth filter with $\lambda_c=1$ can be found by

$$H_a(s) = \frac{1}{B_N(s)}$$

where $B_N(s)$ is the normalized Butterworth polynomial of order N shown in Table 19.1. For other values of λ_c', the transfer function can be computed similarly by analog–analog frequency transformation, i.e., replacing s in $H_a(s)$ with s/λ_c'.

19.2.2.2 Chebyshev Filters (Type-I Chebyshev Filters)

A Chebyshev filter is also an all-pole filter. The Nth-order Chebyshev filter has a transfer function given by

$$H_a(s) = C\prod_{i=1}^{N}\frac{1}{(s-p_i)} \tag{19.32}$$

where

$$C = \begin{cases} -\prod_{i=1}^{N} p_i & N \text{ is odd} \\ (1+\varepsilon^2)^{-1/2} \prod_{i=1}^{N} p_i & N \text{ is even} \end{cases} \tag{19.33}$$

$$p_i = -\lambda_p \sinh(\phi) \sin\left(\frac{2i-1}{2N}\pi\right) + j\lambda_p \cosh(\phi) \cos\left(\frac{2i-1}{2N}\pi\right) \tag{19.34}$$

$$\phi = \frac{1}{N} \ln\left[\frac{1+(1+\varepsilon^2)^{1/2}}{\varepsilon}\right] \tag{19.35}$$

The value of C normalizes the magnitude so that the maximum magnitude is 1. Note that C is always a positive constant. The poles are on the left-half s plane, lying on an ellipse centered at the origin with a minor radius of $\lambda_p \sinh(\phi)$ and major radius of $\lambda_p \cosh(\phi)$. Except for one pole when N is odd, all the poles have a complex–conjugate pair. Specifically, $p_i = p^*_{N-i+1}, i = 1, 2, \cdots, N/2$ or $(N-1)/2$. Combining each complex–conjugate pair in Equation 19.32 yields a second-order factor with real coefficients. The magnitude response can be computed from Equations 19.33 through 19.35 with $s = j\lambda$. Its square can also be written as

$$|H_a(\lambda)|^2 = \frac{1}{1+\varepsilon^2 T_N^2(\lambda/\lambda_p)} \tag{19.36}$$

where $T_N(x)$ is the Nth degree Chebyshev polynomial of the first kind, which is shown in Table 19.2 and also given recursively by

$$\begin{aligned} T_0(x) &= 1 \quad T_1(x) = x \\ T_{n+1}(x) &= 2xT^n(x) - T_{n-1}(x) \quad n \geq 1 \end{aligned} \tag{19.37}$$

Notice that $T_N^2(\pm 1) = 1$. Therefore, we have from Equation 19.36 that the magnitude square passes through $1/(1+\varepsilon^2)$ at $\lambda = \lambda_p$, i.e., $|H_a(\lambda_p)|^2 = 1/(1+\varepsilon^2)$. Note also that $T_N(0) = (-1)^{N/2}$ for even N and it is 0 for odd N. Therefore, $|H_a(0)|^2$ equals $1/(1+\varepsilon^2)$ for even N and it equals 1 for odd N. Figure 19.10 shows some examples of magnitude response square.

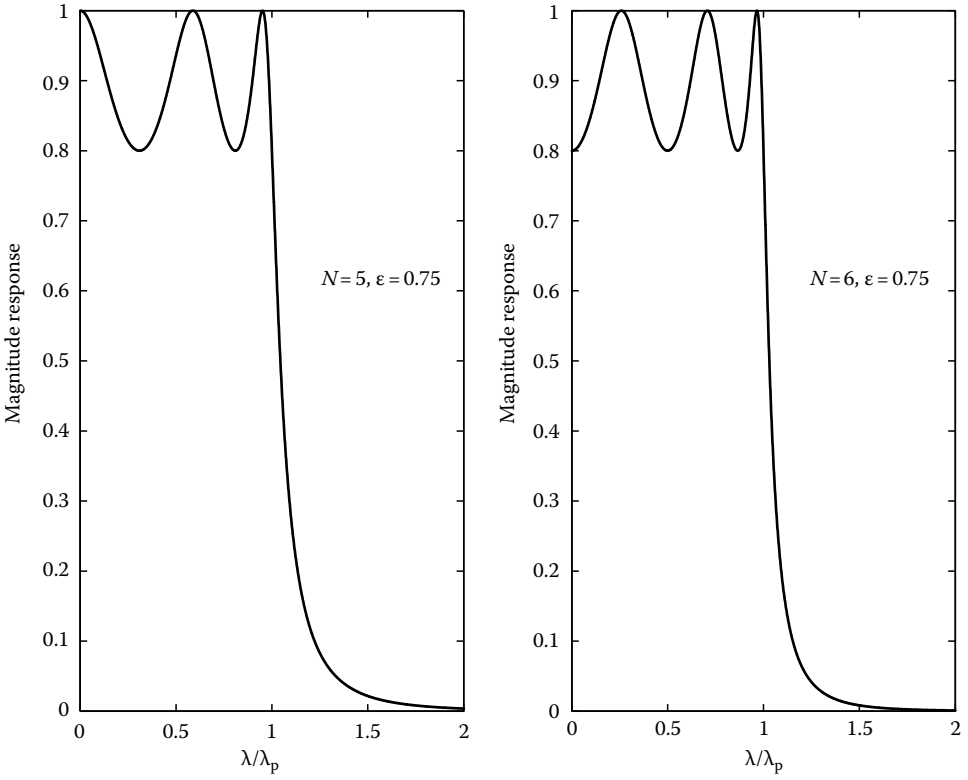

FIGURE 19.10 Magnitude responses of Chebyshev filters.

The filter order required to satisfy the specification in Equation 19.27 is

$$N \geq \frac{\cosh^{-1}\left[(\delta^{-2}-1)^{1/2}/\varepsilon\right]}{\cosh^{-1}(\lambda_s/\lambda_p)} = \frac{\log\{[(\delta^{-2}-1)^{1/2}/\varepsilon] + [(\delta^{-2}-1)/\varepsilon^2 - 1]^{1/2}\}}{\log\{(\lambda_s/\lambda_p) + [(\lambda_s/\lambda_p)^2 - 1]^{1/2}\}} \tag{19.38}$$

which can be computed knowing ε, δ, λ_p, and λ_s.

Table 19.3 shows the normalized Chebyshev polynomials $C_N(s)$ for different values of N and passband ripples. The transfer function of a unity dc gain, unity cutoff frequency Chebyshev Type-I filter is given by

$$H_a(s) = \frac{1}{C_N(s)}$$

19.2.2.3 Inverse Chebyshev Filters (Type-II Chebyshev Filters)

Notice from Figure 19.10 that the Chebyshev filter has magnitude response containing equiripples in the passband. The equiripples can be arranged to go inside the stopband, for which case we obtain inverse Chebyshev filters. The magnitude response square of the inverse Chebyshev filter is

TABLE 19.3 Normalized Chebyshev Polynomials $C_N(s)$ for Passband Ripple = 0.5, 1, and 3 dB

6	$22.6005s^6 + 12.8981s^5 + 37.5813s^4 + 15.6082s^3 + 15.8000s^2 + 3.6936s + 1$

$$|H_a(\lambda)|^2 = \frac{1}{1 + \frac{(\delta^{-2}-1)}{T_N^2(\lambda_s/\lambda)}} \tag{19.39}$$

Since $T_N^2(\pm 1) = 1$, Equation 19.39 gives $|H_a(\lambda_s)|^2 = \delta^2$. Figure 19.11 depicts some examples of Equation 19.38. Note that $|H_a(\infty)|$ equals 0 if N is odd and it equals δ if N is even.

The transfer function giving rise to Equation 19.39 is given by

$$H_a(s) = \begin{cases} C\prod_{i=1}^{N} \frac{(s-q_i)}{(s-p_i)} & N = \text{even} \\ \frac{C}{(s-p_{(N+1)/2})} \prod_{i=1, i\neq(N+1)/2}^{N} \frac{(s-q_i)}{(s-p_i)} & N = \text{odd} \end{cases} \tag{19.40}$$

where

$$C = \begin{cases} \prod_{i=1}^{N} \frac{p_i}{q_i} & N \text{ is even} \\ -p_{(N+1)/2} \prod_{i=1, i\neq(N+1)/2}^{N} \frac{p_i}{q_i} & N \text{ is odd} \end{cases} \tag{19.41}$$

$$p_i = \frac{\lambda_s}{\alpha_i^2 + \beta_i^2}(\alpha_i - j\beta_i) \quad q_i = j\frac{\lambda_s}{\cos\left(\frac{2i-1}{2N}\pi\right)} \tag{19.42}$$

$$\phi = \frac{1}{N}\cosh^{-1}(\delta^{-1}) = \frac{1}{N}\ln[\delta^{-1} + (\delta^{-2} - 1)^{1/2}] \tag{19.43}$$

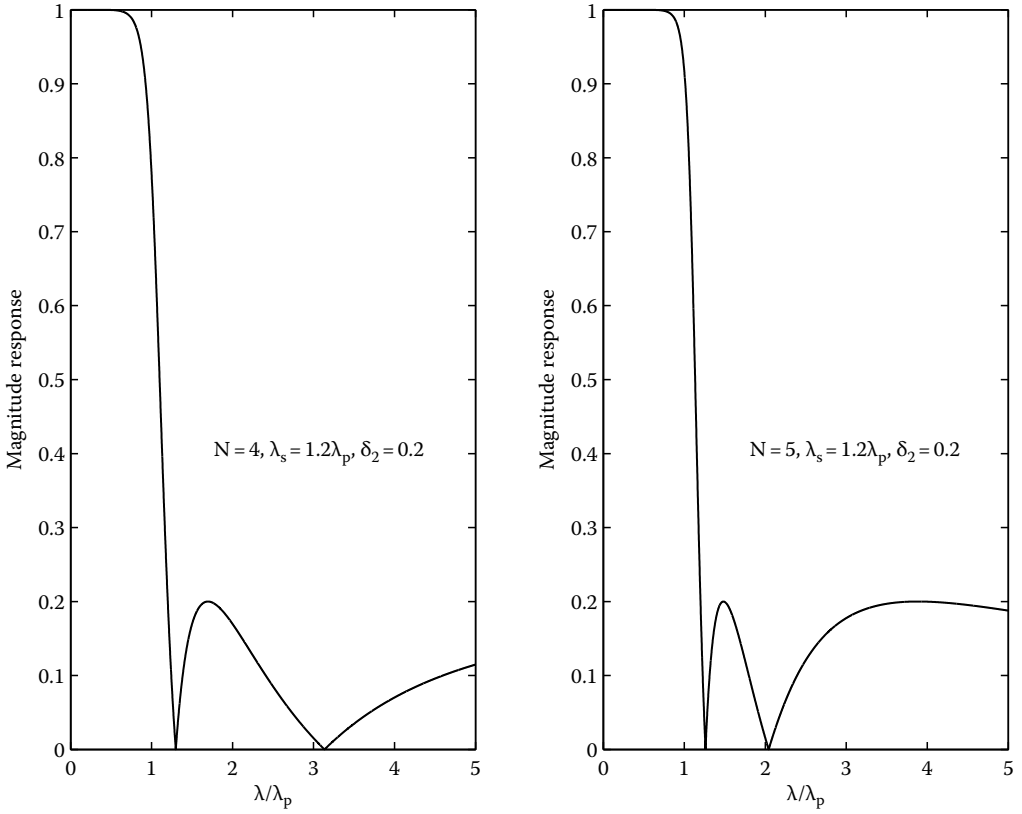

FIGURE 19.11 Magnitude responses of inverse Chebyshev filters.

Note that the zeros are on the imaginary axis on the *s* plane. The filter order N required to satisfy the specification in Equation 19.27 is the same as the order for the Chebyshev filter, given by Equation 19.38.

Another form for the inverse Chebyshev filter has magnitude response square given by

$$|H_a(\lambda)|^2 = \frac{1}{1 + \varepsilon^2 \frac{T_N^2(\lambda_s/\lambda_p)}{T_N^2(\lambda_s/\lambda)}} \tag{19.44}$$

which passes through $1/(1+\varepsilon^2)$ at $\lambda = \lambda_p$. For further details of this form see Ref. [1].

19.2.2.4 Elliptic Filters (Cauer Filters)

Elliptic filters have equiripples in both the passband and the stopband. We summarize the magnitude response and the transfer function of an elliptic filter as follows. Detail of derivation can be found in Refs. [2,3].

The magnitude response square is given by

$$|H_a(\lambda)|^2 = \frac{1}{1 + \varepsilon^2 R_N^2(\lambda)} \tag{19.45}$$

where $R_N(\lambda)$ is the Chebyshev rational function given by

$$R_N(\lambda) = \begin{cases} \frac{(\delta^{-2}-1)^{1/4}}{\varepsilon^{1/2}} \lambda \prod_{i=1}^{(N-1)/2} \frac{\lambda^2 - \lambda_r \mathrm{sn}^2\left[\frac{2iK(\lambda_r)}{N}, \lambda_r\right]}{\lambda^2 \lambda_r \mathrm{sn}^2\left[\frac{2iK(\lambda_r)}{N}, \lambda_r\right] - 1} & N = \text{odd} \\ \frac{(\delta^{-2}-1)^{1/4}}{\varepsilon^{1/2}} \lambda \prod_{i=1}^{(N-1)/2} \frac{\lambda^2 - \lambda_r \mathrm{sn}^2\left[\frac{(2i-1)K(\lambda_r)}{N}, \lambda_r\right]}{\lambda^2 \lambda_r \mathrm{sn}^2\left[\frac{(2i-1(\lambda_r)}{N}, \lambda_r\right] - 1} & N = \text{even} \end{cases} \tag{19.46}$$

Here, $\lambda_r = \lambda_p/\lambda_s, K(t)$ is the complete elliptic integral of the first kind given by

$$K(t) = \int_0^{\pi/2} \frac{d\theta}{(1 - t^2 \sin^2 \theta)^{1/2}} = \int_0^1 \frac{dx}{[(1-x^2)(1-t^2x^2)]^{1/2}} \tag{19.47}$$

The Jacobian elliptic sine function $\mathrm{sn}[u, t]$ is defined as

$$\mathrm{sn}[u, t] = \sin\phi \quad \text{if } u = \int_0^{\phi} \frac{d\theta}{(1 - t^2 \sin^2 \theta)^{1/2}} \tag{19.48}$$

The integral

$$F(\phi, t) = \int_0^{\phi} \frac{d\theta}{(1 - t^2 \sin^2 \theta)^{1/2}} = \int_0^{\sin\phi} \frac{dx}{[(1-x^2)(1-t^2x^2)]^{1/2}} \tag{19.49}$$

is called the elliptic integral of the first kind. Note that $K(t) = F(\pi/2, t)$.

The transfer function corresponding to the magnitude response in Equation 19.45 is

$$H_a(s) = \begin{cases} \frac{C}{(s+p_0)} \prod_{i=1}^{(N-1)/2} \frac{(s^2+B_i)}{(s^2+A_{i1}s+A_{i2})} & N \text{ odd} \\ C \prod_{i=1}^{N/2} \frac{(s^2+B_i)}{(s^2+A_{i1}s+A_{i2})} & N \text{ even} \end{cases} \tag{19.50}$$

$$C = \begin{cases} p_0 \prod_{i=1}^{(N-1)/2} \frac{A_{i2}}{B_i} & N \text{ odd} \\ \frac{1}{(1+\varepsilon^2)^{1/2}} \prod_{i=1}^{N/2} \frac{A_{i2}}{B_i} & N \text{ even} \end{cases} \tag{19.51}$$

The pole p_0 and the coefficients B_i, A_{i1} are calculated as follows:

$$\lambda_r = \frac{\lambda_p}{\lambda_s} \quad \lambda_c = \sqrt{\lambda_p \lambda_s} \quad \alpha = 0.5 \frac{1 - (1 - \lambda_r^2)^{1/4}}{1 + (1 - \lambda_r^2)^{1/4}} \tag{19.52}$$

$$\beta = e^{-\pi K[(1-\lambda_r^2)^{1/2}]/K(\lambda_r)} \approx \alpha + 2\alpha^5 + 15\alpha^9 + 150\alpha^{13} \tag{19.53}$$

$$\gamma = \frac{1}{2N} \ln\left[\frac{(1+\varepsilon^2)^{1/2} + 1}{(1+\varepsilon^2)^{1/2} - 1}\right] \tag{19.54}$$

$$\sigma = \left| \frac{2\beta^{1/4} \prod_{k=0}^{\infty} (-1)^k \beta^{k(k+1)} \sinh[(2k+1)\gamma]}{1 + 2\prod_{k=1}^{\infty} (-1)^k \beta^{k^2} \cosh[2k\gamma]} \right| \tag{19.55}$$

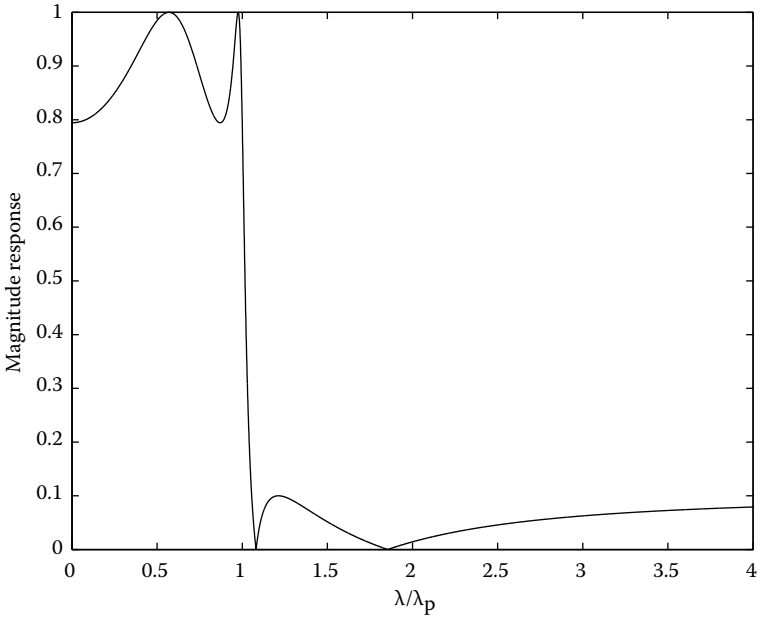

FIGURE 19.12 Magnitude response of elliptic filter.

$$\zeta = (1 + \lambda_r \sigma^2)\left(1 + \frac{\sigma^2}{\lambda_r}\right) \quad \eta = \begin{cases} i & N \text{ odd} \\ i - 0.5 & N \text{ even} \end{cases} \tag{19.56}$$

$$\psi_i = \frac{2\beta^{1/4} \sum_{k=0}^{\infty} (-1)^k \beta^{k(k+1)} \sin\left[(2k+1)\pi\eta/N\right]}{1 + 2\sum_{k=1}^{\infty} (-1)^k \beta^{k^2} \cos\left[2k\pi\eta/N\right]} \tag{19.57}$$

$$\mu_i = \left[(1 - \lambda_r \psi_i^2)\left(1 - \frac{\psi_i^2}{\lambda_r}\right)\right]^{1/2} \tag{19.58}$$

$$p_0 = \lambda_c \sigma \quad B_i = \frac{\lambda_c^2}{\psi_i^2} \quad A_{i1} = \frac{2\lambda_c \sigma \mu_i}{1 + \sigma^2 \psi_i^2} \quad A_{i2} = \lambda_c^2 \frac{\sigma^2 \mu_i^2 + \zeta \psi_i^2}{\left[1 + \sigma^2 \psi_i^2\right]^2} \tag{19.59}$$

The infinite summations above converge very quickly, so that only a few terms are needed in actual calculation. A simple program can be written to compute the values in Equations 19.52 through 19.59.

The filter order required to satisfy Equation 19.27 is calculated from

$$N \geq \frac{1}{\log(\beta)} \log\left[\frac{\varepsilon^2}{16(\sigma^{-2} - 1)}\right] \tag{19.60}$$

where β is given by Equation 19.53. An example of the magnitude response is plotted in Figure 19.12. We see that there are ripples in both the passband and the stopband.

19.2.2.5 Comparison

In comparing the filters given above, the Butterworth filter requires the highest order and the elliptic filter requires the smallest order to satisfy the same passband and stopband specifications. The Butterworth filter and the inverse Chebyshev filter have nicer (closer to linear) phase characteristics in the passband

than Chebyshev and elliptic filters. The magnitude responses of the Butterworth and Chebyshev filters decrease monotonically in the stopband to zero, which reduces the aliasing caused by some analog-to-digital transformation.

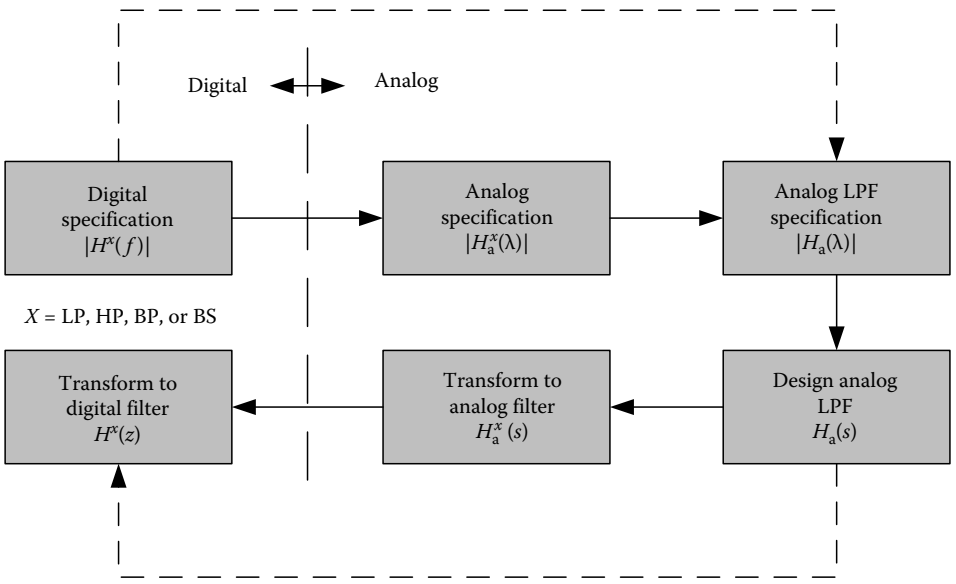
19.2.3 Design Using Analog Prototype Filters

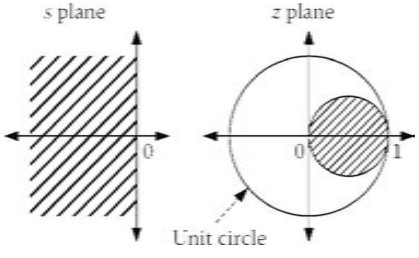
In this subsection, we consider designing IIR filters using analog prototype filters. This method is suitable for designing the standard types of filters: low-pass filter (LPF), high-pass filter (HPF), bandpass filter (BPF), and bandstop filter (BSF). The basic idea is to transform the digital specification to analog specification, design an analog flter, and then transform the analog filter transfer function to digital filter system function. Several types of transformation have been studied.

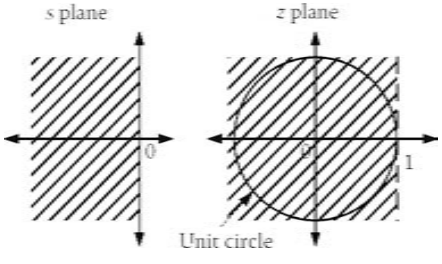
The design steps are outlined in Figure 19.13. Given the desired magnitude response $|H^x(f)|$ of digital LPF, HPF, BPF, or BSF, it is transformed to analog magnitude specification (of the corresponding type: LPF, HPF, BPF, or BSF) $|H_a^x(\lambda)|$. The analog magnitude specification is then transformed to analog LPF magnitude specification $|H_a(\lambda)|$. We then design an analog prototype filter as discussed in Section 19.2.2, obtaining analog LPF transfer function $H_a(s)$. Next, the analog LPF transfer function is transformed to analog transfer function $H_a^x(s)$ of the desired type (LPF, HPF, BPF, or BSF), followed by a transformation to digital filter system function $H^x(z)$. By combining the appropriate steps, we can obtain transformations to go directly from $|H^x(f)|$ to $|H_a(\lambda)|$ and directly from $H_a(s)$ to $H(z)$, as indicated by the dotted lines in Figure 19.13. Note that for designing digital LPF, the middle steps involving $|H_a^x(\lambda)|$ and $H_a^x(s)$ are not applicable.

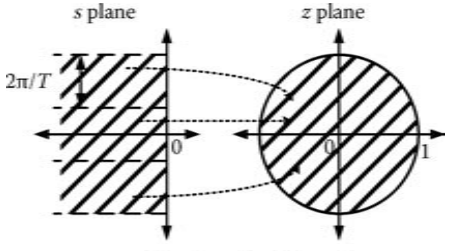
19.2.3.1 Transformations

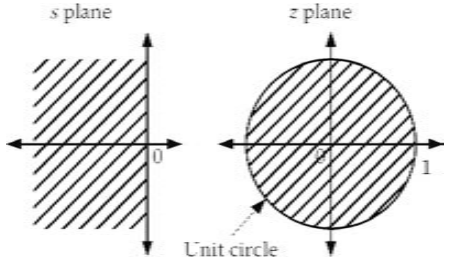
There are several types of transformations. They arise from approximating continuous-time signals and systems by discrete-time signals and system. Table 19.4 shows several transformations, with their advantages and disadvantages. The constant T is the sampling interval. The resulting mapping is used for transforming $H_a(s)$ to $H(z)$. For example, in the backward difference approximation we obtain $H(z)$ by replacing the variable s with $(1 - z^{-1})/T$ in $H_a(s)$, i.e., $H(z) = H_a(s)|_{s=1-z^{-1}/T}$. The bilinear











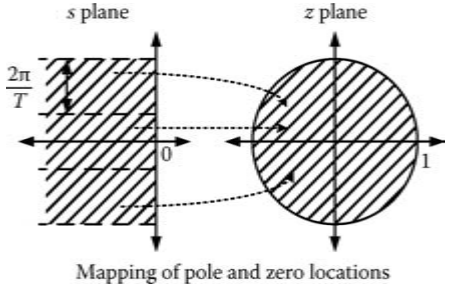


FIGURE 19.13 Diagram outlining the steps involved in designing IIR filter using analog prototype filter.

TABLE 19.4 Various Types of Analog-to-Digital Transformation

Type of Transformation	Principle	Resulting Mapping	Advantages	Disadvantages
Backward difference approximation	$\frac{dy}{dt} \approx \frac{y(n) - y(n-1)}{T}$	$s = \frac{1 - z^{-1}}{T}$, $z = \frac{1}{1 - sT}$ 	Stable analog filter yields stable digital filter	Left-half s plane is not mapped onto unit circle on z plane. Pole locations will be in the circle centered at 0.5 with radius 0.5 on the z plane
Forward difference approximation	$\frac{dy}{dt} \approx \frac{y(n+1) - y(n)}{T}$	$s = \frac{z - 1}{T}$, $z = 1 + sT$ 		Stable analog filler does not yield stable digital filter Left-half s plane is not mapped onto unit circle on z plane
Impulse invariant method	Sample the analog impulse response: $h(n) = h_a(nT)$	Transform $H_a(s) = \sum_{i=1}^{N} \frac{b_i}{s - p_i}$ to $H(z) = \sum_{i=1}^{N} \frac{b_i}{[1 - z^{-1} \exp(p_i T)]}$	Preserve shape of impulse response Stable analog filter yields stable digital filter The analog frequency and digital frequency are linearly related, $\lambda T = 2\pi f, -0.5 \le f \le 0.5$	Aliasing in the frequency domain (due to many-to-one mapping from s to z plane) $T \cdot H(f) = \sum_{k=-\infty}^{\infty} H_a\left(2\pi \frac{f + k}{T}\right)$

(*continued*)

TABLE 19.4 (continued) Various Types of Analog-to-Digital Transformation

Type of Transformation	Principle	Resulting Mapping	Advantages	Disadvantages
		 Mapping of pole locations		
Bilinear transformation	Approximation $y(t) = \int_{t-T}^{t} y'(\tau)d\tau + y(t-T)$ by $y(n) = \frac{T}{2}[y'(n) + y'(n-1) + y(n-1)]$	$s = \frac{2}{T}\left(\frac{1-z^{-1}}{1+z^{-1}}\right), \quad z = \frac{(2/T)+s}{(2/T)-s}$ 	Stable analog filter yields stable digital filter Left-half s plane is mapped onto unit circle z plane, on a one-to-one mapping	Frequency warping nonlinear relation between analog frequency and digital frequency
Matched z transformation	Map zero on s plane directly to pole and zero on z plane	Transform $H_a(s) = \sum_{i=1}^{N} \frac{s-q_i}{s-p_i}$ to $H(z) = \sum_{i=1}^{N} \frac{[1-z^{-1}\exp(q_i T)]}{[1-z^{-1}\exp(p_i T)]}$  Mapping of pole and zero locations	Stable analog filter yields stable digital filter	Aliasing in the frequency domain (due to many-to-one mapping from s to z plane)

transformation is the best all-around method, followed by the impulse invariant method. Therefore, we describe these two transformations in more detail.

19.2.3.1.1 Bilinear Transformations

Using this transformation, the analog filter is converted to digital filter by replacing s in the analog filter transfer function with $(2/T)(1 - z^{-1})/(1 + z^{-1})$, i.e.,

$$H(z) = H_a(s)|_{s=(2/T)(1-z^{-1})/(1+z^{-1})} \tag{19.61}$$

From the mapping, we can show as follows that the imaginary axis on the s plane is mapped to the unit circle on the z plane. Letting $s = j\lambda$, we have

$$\begin{aligned} z &= \frac{(2/T) + s}{(2/T) - s} = \frac{(2/T) + j\lambda}{(2/T) - j\lambda} \\ &= \frac{\sqrt{(2/T)^2 + (\lambda)^2}\, e^{j \arctan(\lambda/(2/T))}}{\sqrt{(2/T)^2 + (\lambda)^2}\, e^{j \arctan(-\lambda/(2/T))}} \end{aligned} \tag{19.62}$$

which is the unit circle on the z plane as λ goes from $-\infty$ to ∞. Writing $z = e^{j2\pi f}$ in Equation 19.62, we obtain the relation between the analog frequency λ and the digital frequency f:

$$f = \frac{1}{\pi} \arctan\left(\frac{\lambda T}{2}\right) \quad \lambda = \frac{2}{T} \tan(\pi f) \tag{19.63}$$

which is plotted in Figure 19.14. Equation 19.63 is used for converting digital specification to analog specification, i.e., $\lambda_s = (2/T)\tan(\pi f_s)$ and $\lambda_p = (2/T)\tan(\pi f_p)$. In a complete design process, starting from the digital specification and ending at the digital filter system function, as outlined in Figure 19.13, the sampling interval T is canceled out in the process. Hence, it has no effect and any convenient value (such as 1 or 2) can be used.

19.2.3.1.2 Impulse Invariance Method

This method approximates the analog filter impulse response $h_a(t)$ by its samples separated by T seconds. The result is the impulse response $h(n)$ of the digital filter, i.e., $h(n) = h_a(nT)$. From this relation, it can be shown that

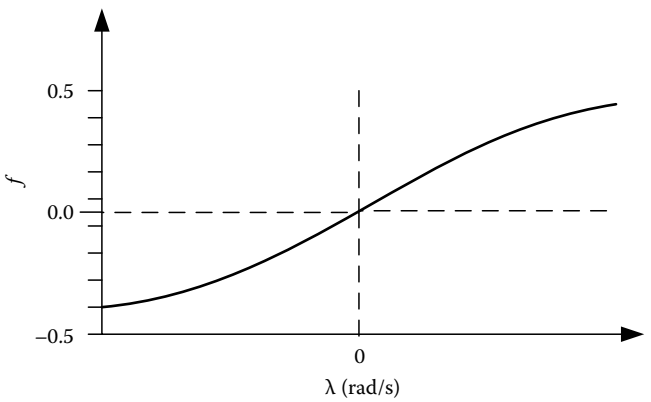

FIGURE 19.14 Relation between λ and f for bilinear transformation.

$$H(f) = \frac{1}{T}\sum_{k=-\infty}^{\infty} H_a(\lambda)\Big|_{\lambda=2\pi(f+k)/T} = \frac{1}{T}\sum_{k=-\infty}^{\infty} H_a\left(2\pi\frac{f+k}{T}\right) \tag{19.64}$$

The analog and digital frequencies are related by

$$f = \frac{\lambda T}{\pi}, \quad |f| \le 0.5 \tag{19.65}$$

From Equation 19.64, the digital filter frequency response is the sum of shifted versions of the analog filter frequency response. There is aliasing if $H_a(\lambda)$ is not zero for $|\lambda/2\pi| > 1/(2T)$. Therefore, the analog filter used in this method should have a frequency response that goes to zero quickly as λ goes to ∞. Because of the aliasing, this method cannot be used for designing a HPF. Writing the analog filter transfer function in the form

$$H_a(s) = \sum_{i=1}^{N} \frac{b_i}{(s-p_i)} \tag{19.66}$$

it follows that the analog impulse response is given by $h_a(t) = \sum_{i=1}^{N} b_i e^{p_i t}$ and the digital filter can be obtained as

$$\begin{aligned} H(z) &= \sum_{n=0}^{\infty} h(n)z^{-n} = \sum_{n=0}^{\infty} h(nT)z^{-n} \\ &= \sum_{i=1}^{N} b_i \sum_{n=0}^{\infty} (e^{p_i T}z^{-1})^n = \sum_{i=1}^{N} \frac{b_i}{1-e^{p_i T}z^{-1}} \end{aligned} \tag{19.67}$$

Therefore, an analog filter transfer function $H_a(s) = \sum_{i=1}^{N} b_i/(s-p_i)$ gets transformed to a digital filter system function $H(z) = \sum_{i=1}^{N} b_i/(1-e^{p_i T}z^{-1})$, as shown in Table 19.4. Similar to the bilinear transformation, in a complete design process the choice of T has no effect (except for the final magnitude scaling factor).

19.2.3.2 Low-Pass Filters

We give one example in designing an LPF using the impulse invariant method and one example using the bilinear transformation. In this example, suppose that we wish to design a digital filter using an analog Butterworth prototype filter. The digital filter specification is

$$\begin{aligned} &20\log|H(f)| \ge -2\,\text{dB} \quad \text{for } 0 \le f \le 0.11 \\ &20\log|H(f)| \le -10\,\text{dB} \quad \text{for } 0.2 \le f \le 0.5 \end{aligned}$$

where the log is of base 10. Therefore, we have $\varepsilon = 0.7648$, $\delta = 0.3162$, $f_p = 0.11$, and $f_s = 0.2$. Let us use the impulse invariant method. Therefore, the analog passband edge and stopband edge are $\lambda_p = 0.22\pi/T$ and $\lambda_s = 0.4\pi/T$, respectively. We use the same ripple requirements: $\varepsilon = 0.7648$ and $\delta = 0.3162$. Using these values, a Butterworth filter order is calculated from Equation 19.30, yielding $N \ge 2.3$. So, we choose $N = 3$. With $\lambda_c = \lambda_p \varepsilon^{-1/N} = 0.2406\pi/T$, we find the analog filter transfer function to be

$$\begin{aligned} H_a(s) &= \frac{\lambda_c^3}{(s+\lambda_c)(s^2+\lambda_c s+\lambda_c^2)} \\ &= \lambda_c\left[\frac{1}{s+\lambda_c} + \frac{-0.5-j0.5/\sqrt{3}}{s+0.5(1-j\sqrt{3})\lambda_c} + \frac{-0.5+j0.5/\sqrt{3}}{s+0.5(1+j\sqrt{3})\lambda_c}\right] \\ &= \frac{0.7559}{T}\left[\frac{1}{s+0.7559/T} + \frac{-0.5-j0.5/\sqrt{3}}{s+0.3779(1-j\sqrt{3})/T} + \frac{-0.5+j0.5/\sqrt{3}}{s+0.3779(1+j\sqrt{3})/T}\right] \end{aligned}$$

Using Equations 19.66 and 19.67 we obtain the digital filter system function:

$$H(z) = \frac{0.7559}{T}\left[\frac{1}{1-e^{-0.7559}z^{-1}} + \frac{-0.5-j0.5/\sqrt{3}}{1-e^{-0.3779(1-j\sqrt{3})}z^{-1}} + \frac{-0.5+j0.5/\sqrt{3}}{1-e^{-0.3779(1-j\sqrt{3})}z^{-1}}\right]$$
$$= \frac{0.7559}{T}\left[\frac{1}{1-0.4696z^{-1}} - \frac{1-0.7846z^{-1}}{1-1.0873z^{-1}+0.4696z^{-2}}\right]$$

Due to aliasing, the maximum value of the resulting magnitude response (which is at $f = 0$ or $z = 1$) is no longer equal to 1, although the analog filter has maximum magnitude (at $\lambda = 0$ or $s = 0$) of 1. Note that the choice of T affects only the scaling factor, which is only a constant gain factor. If we adjust the system function so that the maximum magnitude is 1, that is, $|H(f)| = 1$, we have

$$H(z) = \frac{0.7565}{T}\left[\frac{1}{1-0.4696z^{-1}} - \frac{1-0.7846z^{-1}}{1-1.0873z^{-1}+0.4696z^{-2}}\right]$$

The magnitude response in decibels and the phase response in degrees are plotted in Figure 19.15. From the result, $|H(f)| = -1.97$ dB at $f = 0.11$ and $|H(f)| = -13.42$ dB at $f = 0.2$; both satisfy the desired specification. The aliasing in this example is small enough that the resulting response still meets the specification. It is possible that the aliasing is large enough that the designed filter does not meet the specification. To compensate for the unknown aliasing, we may want to use smaller ε and δ in designing the analog prototype filter.

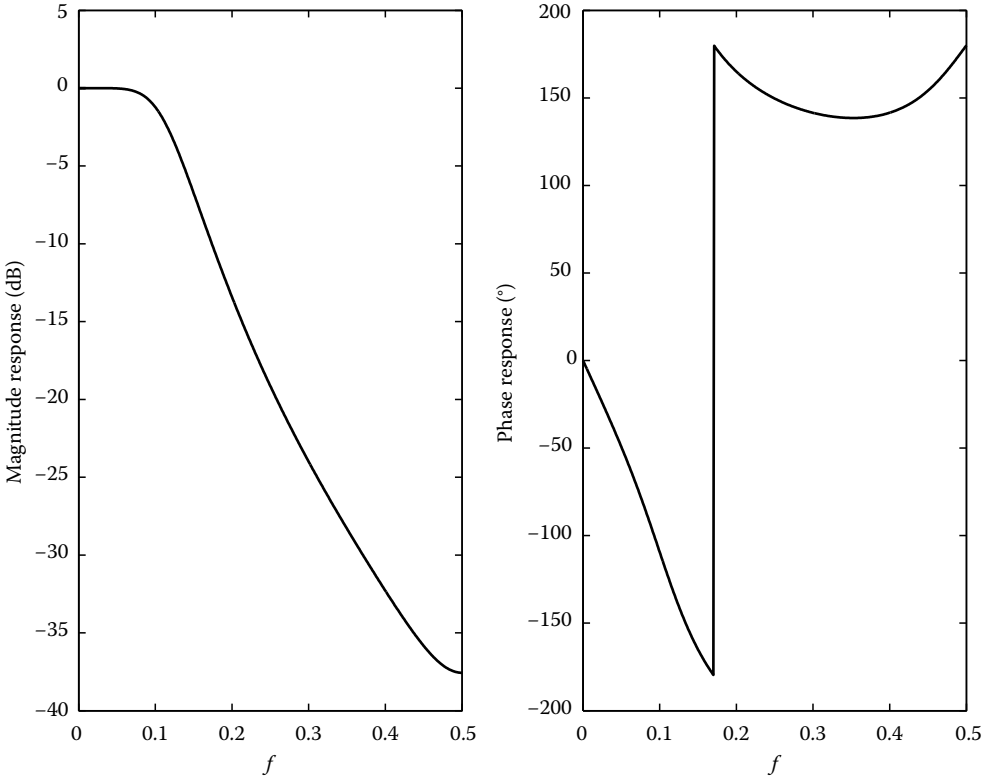

FIGURE 19.15 Frequency response of the LPF designed using impulse invariant method.

In this next example, we demonstrate the design method using bilinear transformation, with an analog elliptic prototype filter. Let the desired filter specification be

$$|H(f)|^2 \geq 0.8 \text{ (or } -0.97\,\text{dB)} \quad \text{for } 0 \leq f \leq 0.1125$$
$$|H(f)|^2 \leq 2.5 \times 10^{-5} \text{ (or } -46.02\,\text{dB)} \quad \text{for } 0.15 \leq f \leq 0.5$$

which means $\varepsilon = 0.5$, $\delta = 0.005$, $f_p = 0.1125$, and $f_s = 0.15$. For bilinear transformation, we calculate the analog passband and stopband edges as $\lambda_p = (2/T)\tan(\pi f_p) = 0.7378/T$ and $\lambda_s = (2/T)\tan(\pi f_s) = 1.0190/T$, respectively. Therefore, $\lambda_p/\lambda_s = 0.7240$. From Equation 19.60, we obtain the order $N \geq 4.8$. So, we use $N = 5$. The analog elliptic filter transfer function is calculated from Equations 19.50 through 19.59 to be

$$H_a(s) = \frac{7.8726 \times 10^{-3}\left[\left(\frac{sT}{2}\right)^2 + 0.6006\right]\left[\left(\frac{sT}{2}\right)^2 + 0.2782\right]}{\left[\left(\frac{sT}{2}\right) + 0.1311\right]\left[\left(\frac{sT}{2}\right)^2 + 0.1689\left(\frac{sT}{2}\right) + 0.0739\right]\left[\left(\frac{sT}{2}\right)^2 - 0.0457\left(\frac{sT}{2}\right) + 0.1358\right]}$$

To convert to digital filter system function, we replace s with $(2/T)(1 - z^{-1})/(1 + z^{-1})$. Equivalently, we replace $sT/2$ with $(1 - z^{-1})/(1 + z^{-1})$, yielding

$$H(z) = \frac{1.0511 \times 10^{-2}(1 + z^{-1})(1 - 0.4991Z^{-1} + z^{-2})(1 - 1.1294z^{-1} + z^{-2})}{(1 - 0.7682z^{-1})(1 - 1.4903z^{-1} + 0.7282z^{-2})(1 - 1.5855z^{-1} + 1.0838z^{-2})}$$

Note that the choice of T has no effect on the resulting system function. The magnitude response in decibels and the phase response are plotted in Figure 19.16, which satisfies the desired magnitude specification. Note the equiripples in both the passband and the stopband.

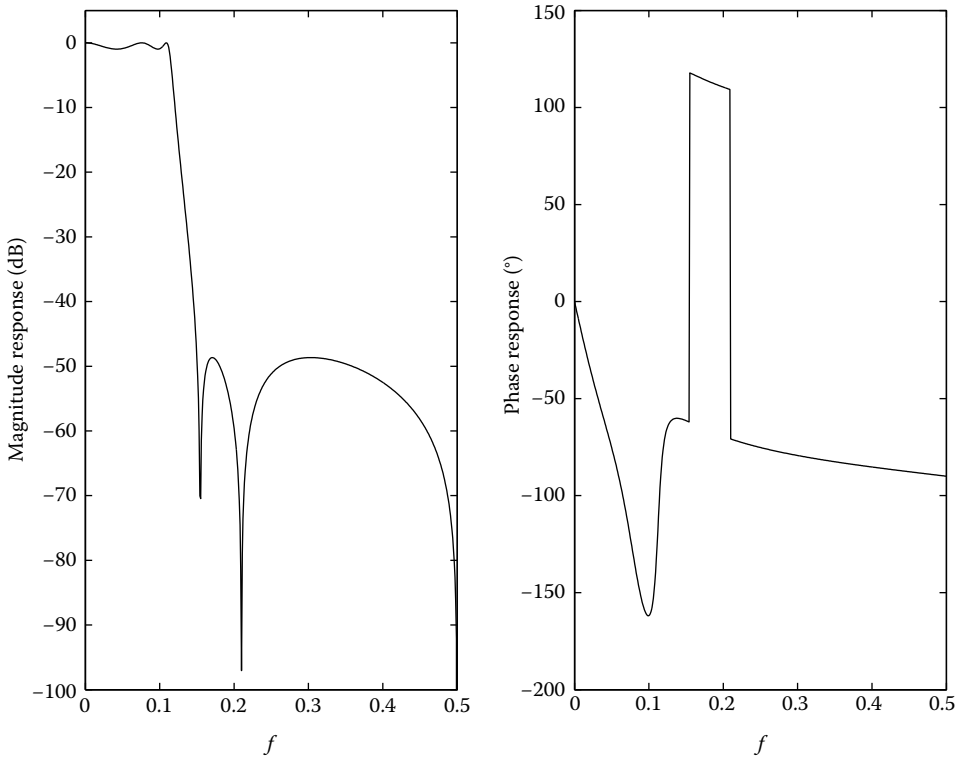

FIGURE 19.16 Frequency response of the LPF designed using bilinear transformation.

19.2.3.3 High-Pass Filters

As mentioned above, the impulse invariant method is not suitable for HPFs due to aliasing. Therefore, we only discuss the bilinear transformation. In addition to the procedure used with designing an LPF, we need to transform the analog high-pass specification to analog low-pass specification and transform the resulting analog LPF to analog HPF. There is a simple transformation for this job: replacing s in the analog LPF transfer function with $1/s$. In terms of the frequency, $j\lambda$ becomes $1/j\lambda = j(-1/\lambda)$, i.e., a low frequency is changed to a (negative) high frequency. Therefore, an analog LPF becomes an analog HPF. When combined with the bilinear transformation, this process gives the transformation

$$s = \frac{T}{2}\frac{(1+z^{-1})}{(1-z^{-1})} \quad \text{or} \quad z = \frac{s+(T/2)}{s-(T/2)} \tag{19.68}$$

Writing $s = j\lambda$, we can show that $z = \exp\{j[2\arctan(2\lambda/T) - \pi]\}$. With $z = \exp(j2\pi f)$, we have

$$\lambda = \frac{T}{2}\tan[\pi(f+0.5)] \tag{19.69}$$

To write f in terms of λ, we can show that, after adjusting the range of f to $[-1/2, 1/2]$,

$$f = \begin{cases} -\frac{1}{2} + \frac{1}{\pi}\arctan(2\lambda/T) & \lambda > 0 \\ +\frac{1}{2} + \frac{1}{\pi}\arctan(2\lambda/T) & \lambda < 0 \end{cases} \tag{19.70}$$

Equations 19.69 and 19.70 give the relation between the digital frequency and the analog frequency, corresponding to the transformation in Equation 19.68. This relation is plotted in Figure 19.17, from which we see that a low digital frequency corresponds to a high analog frequency and vice versa.

We can summarize the design steps as follows. Given a digital HPF specification as in Figure 19.18, it is converted to an analog LPF specification using Equation 19.70 to obtain the passband and stopband edges λ_p and λ_s, from f_p and f_s, respectively. With λ_p, λ_s, ε, and δ, we design the low-pass analog prototype filter. Let the transfer function be $H_a(s)$. This transfer function is then converted to digital HPF system function by replacing s with $(T/2)(1+z^{-1})/(1-z^{-1})$.

Note that this corresponds to the procedure in Figure 19.13, with the bypass of the "analog specification" block and the "transform to analog filter" block, as indicated by the dotted lines in Figure 19.13.

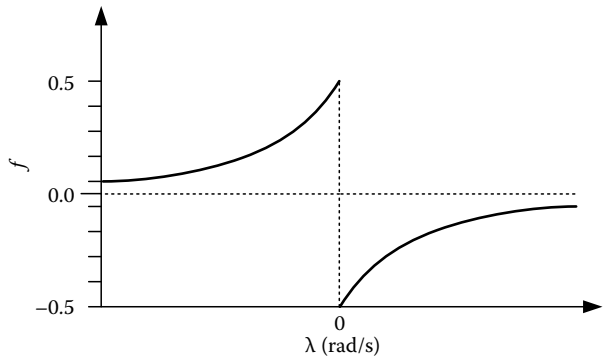

FIGURE 19.17 The relation for designing an HPF.

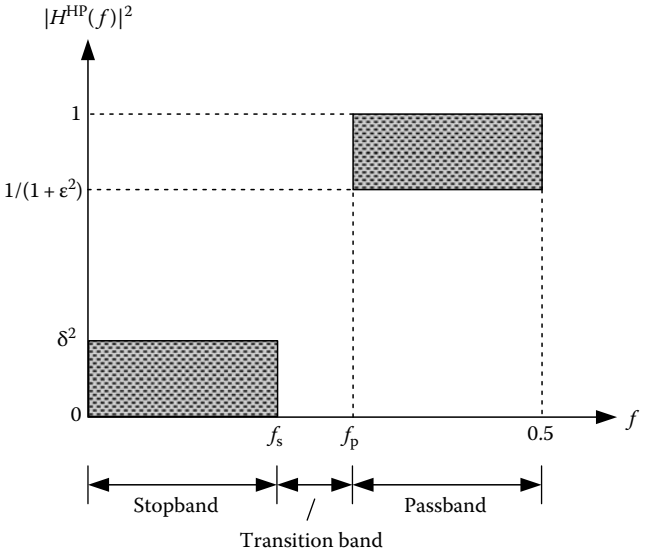

FIGURE 19.18 Digital HPF specification.

As an example, consider designing a digital HPF with the following specification:

$$|H^{HP}(f)|^2 \geq 0.8 \text{ (or } -0.97\,\text{dB)} \quad \text{for } 0.4 \leq f \leq 0.5$$
$$|H^{HP}(f)|^2 \leq 2.5 \times 10^{-5} \text{ (or } -46.02\,\text{dB)} \quad \text{for } 0 \leq f \leq 0.3$$

Since T does not affect the result, we let $T = 2$ for convenience. We calculate the analog LPF passband and stopband edges as $\lambda_p = \tan[\pi(0.5 + f_p)] = -0.3249$ rad/s and $\lambda_s = \tan[\pi(0.5 + f_s)] = -0.7265$ rad/s. Since the magnitude response is in symmetry with respect to $\lambda = 0$, we use $\lambda_p = 0.3249$ rad/s and $\lambda_s = 0.7265$ rad/s. Therefore, $\lambda_s/\lambda_p = 2.2361$. Suppose that we choose the inverse Chebyshev filter as the analog prototype filter. From Equation 19.37, we obtain the order $N \geq 4.6$. So, we use $N = 5$. From Equation 19.40, the low-pass analog inverse Chebyshev filter transfer function is

$$H_a(s) = \frac{1.8160 \times 10^{-2}(s^2 + 0.5835)(s^2 + 1.5276)}{(s + 0.4822)(s^2 + 0.6772s + 0.2018)(s^2 - 0.2131s + 0.1663)}$$

To convert to digital filter system function, we replace s with $(1 + z^{-1})/(1 - z^{-1})$, yielding

$$H^{HP}(s) = \frac{1.8160 \times 10^{-2}(1 - z^{-1})(1 + 0.5261z^{-1} + z^{-2})(1 - 0.4175z^{-1} + z^{-2})}{(1 + 0.3493z^{-1})(1 + 0.8498z^{-1} + 0.2792z^{-2})(1 + 1.2088z^{-1} + 0.6910z^{-2})}$$

The magnitude response and the phase response are plotted in Figure 19.19.

19.2.3.4 Bandpass Filters

A magnitude response specification for a digital BPF is depicted in Figure 19.20a. Note that there are two passband edges (f_{p1} and f_{p2}) and two stopband edges (f_{s1} and f_{s2}). For the bilinear transformation $s = (2/T)(1 - z^{-1})/(1 - z^{-1})$ we can transform the digital BPF specification to an analog BPF specification by letting

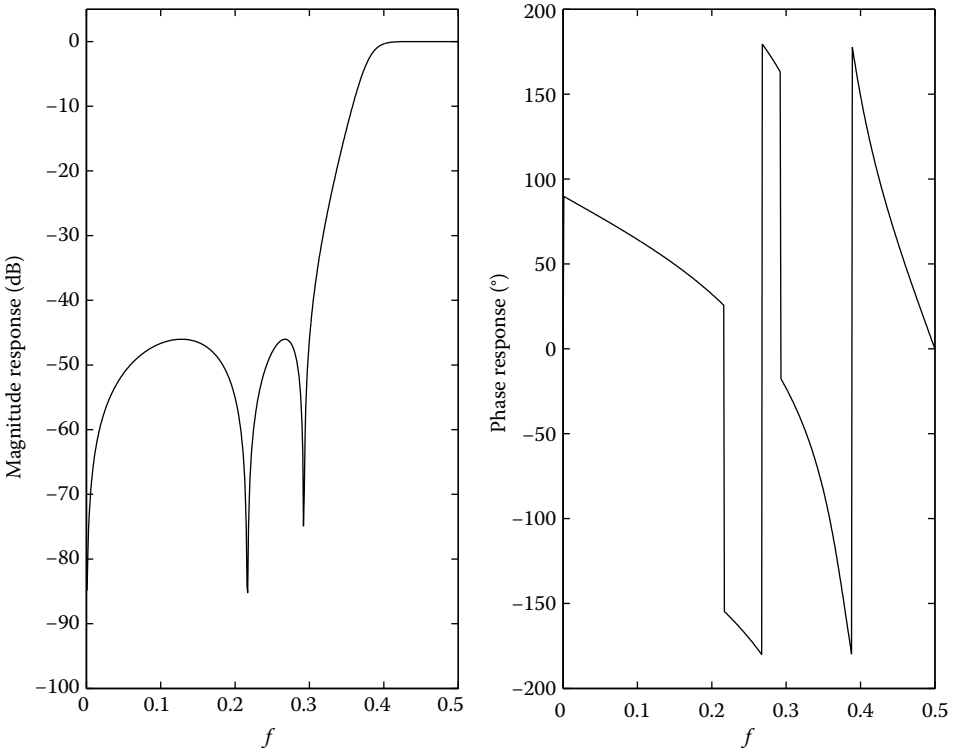

FIGURE 19.19 Frequency response of the HPF designed using bilinear transformation.

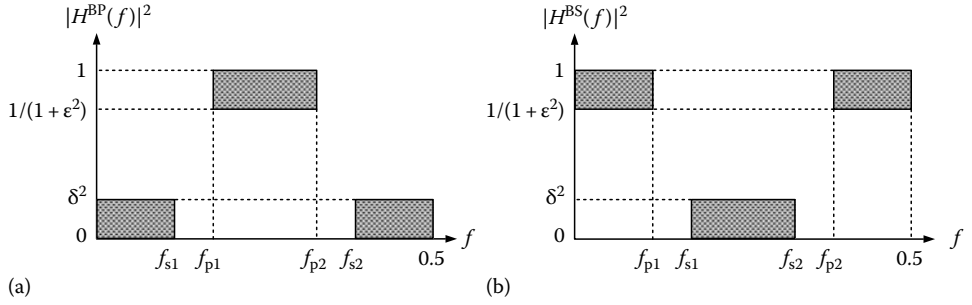

FIGURE 19.20 Magnitude specifications for digital BPF and BSF: (a) digital BPF specification and (b) digital BSF specification.

$$\begin{aligned} \lambda_{p1} &= 2T\tan(\pi f_{p1}) \quad \lambda_{p2} = 2T\tan(\pi f_{p2}) \\ \lambda_{s1} &= 2T\tan(\pi f_{s1}) \quad \lambda_{s2} = 2T\tan(\pi f_{s2}) \end{aligned} \tag{19.71}$$

and keeping the same ε and δ.

Now, we need a transformation between an analog BPF and an analog LPF. To distinguish between the variable s and λ for the two filters, let us use s' and λ' for the analog LPF and s and λ for the analog BPF, respectively. A transformation for converting an analog LPF to an analog BPF is given by

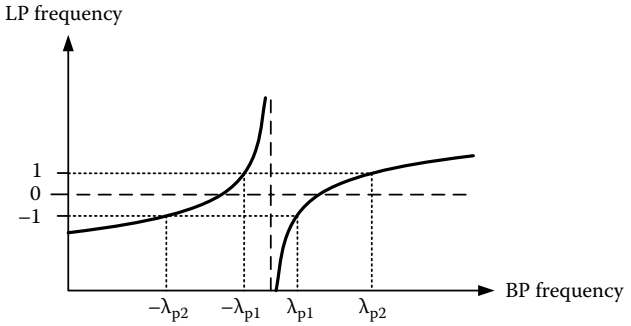

FIGURE 19.21 Relation between λ and λ' for bandpass-to-low-pass conversion.

$$s' = \frac{s^2 + \lambda_0^2}{Ws} \quad \text{or} \quad \lambda' = \frac{\lambda^2 - \lambda_0^2}{W\lambda} \tag{19.72}$$

where

$$W = \lambda_{p2} - \lambda_{p1} \quad \text{and} \quad \lambda_0^2 = \lambda_{p1}\lambda_{p2} \tag{19.73}$$

Figure 19.21 depicts an example of the relation between λ and λ'. Note that λ_{p1} and λ_{p2} get mapped to $\lambda' = -1$ and $+1$, respectively. Therefore, the analog LPF has a passband edge of 1. The values of λ_{s1} and λ_{s2} get mapped to $\lambda'_{s1} = -|(\lambda_{s1}^2 - \lambda_0^2)/(W\lambda_{s1})|$ and $\lambda'_{s2} = |(\lambda_{s2}^2 - \lambda_0^2)/(W\lambda_{s2})|$. However, these two values may not be negative of each other. Since the analog LPF must have a symmetric magnitude response, we must use the more stringent of the two stopband edges, i.e., the smaller of $|\lambda'_{s1}|$ and $|\lambda'_{s2}|$. Letting

$$\lambda'_s = \min\{|\lambda'_{s1}|, |\lambda'_{s2}|\} = \min\left\{\left|\frac{\lambda_{s1}^2 - \lambda_0^2}{W\lambda_{s1}}\right|, \left|\frac{\lambda_{s2}^2 - \lambda_0^2}{W\lambda_{s2}}\right|\right\} \tag{19.74}$$

we now have the analog LPF specification. Therefore, a prototype analog LPF can be designed.

The design process can be summarized as follows. First, the desired digital BPF magnitude specification is converted to an analog BPF magnitude specification using Equation 19.71. Then the analog BPF specification is converted to an analog LPF specification using λ'_s calculated from Equation 19.74 and $\lambda'_p = 1$. Next, a prototype analog LPF is designed with the values of $\varepsilon, \delta, \lambda'_p = 1$, yielding an analog LPF transfer function $H_a(s')$. The LPF transfer function is converted to an analog BPF transfer function $H_a^{HP}(s)$, using the transformation (from s' to s) given in Equation 19.72. Finally, the analog BPF transfer function is converted to a digital BPF transfer function $H^{BP}(z)$ using the bilinear transformation $s = (2/T)(1 - z^{-1})/(1 + z^{-1})$. As before, the value of T does not affect the result.

For example, let the desired digital BPF have the following specification:

$$|H^{BP}(f)|^2 \begin{cases} \geq 0.8\ (-0.97\ \text{dB}) & \text{for } 0.25 \leq f \leq 0.3 \\ \leq 2.5 \times 10^{-5}\ (-46.02\ \text{dB}) & \text{for } 0 \leq f \leq 0.2 \text{ and } 0.35 \leq f \leq 0.5 \end{cases}$$

which means $\varepsilon = 0.5, \delta = 0.005, f_{p1} = 0.25, f_{p2} = 0.3, f_{s1} = 0.2$, and $f_{s2} = 0.35$. Let $T = 2$ for convenience. Using $\lambda = \tan(\pi f)$, we obtain the analog BPF passband and stopband edges as $\lambda_{p1} = \tan(\pi f_{p1}) = 1.0$ rad/s, $\lambda_{p2} = \tan(\pi f_{p2}) = 1.3764$ rad/s, $\lambda_{s1} = \tan(\pi f_{s1}) = 0.7265$ rad/s, and $\lambda_{s2} = \tan(\pi f_{s2}) = 1.9626$ rad/s. Therefore, $\lambda_0^2 = 1.3764$ and $W = 0.3764$. So, we have $\lambda'_s = \min\{3.1030, 3, 3509\} = 3.1030$ rad/s. Suppose

that we use the elliptic LPF as an analog prototype filter. With $\varepsilon = 0.5$, $\delta = 0.005$, $\lambda'_p = 1$, and $\lambda'_s = 3.1030$ rad/s, we need an elliptic filter of order $N = 3$. The low-pass analog elliptic filter transfer function is

$$H_a(s') = \frac{4.1129 \times 10^{-2}(s'^2 + 12.6640)}{(s' + 0.5174)(s'^2 + 0.763s' + 1.0067)}$$

Replacing s' with $(s^2 + 1.3764)/(0.3764s)$ yields the analog BPF transfer function

$$H_a^{BP}(s) = \frac{1.5480 \times 10^{-2}s(s^4 + 4.5467s^2 + 1.8944)}{(s^2 + 0.1947s + 1.3764)(s^4 + 0.1793s^3 + 2.8953s^2 + 0.2467s + 1.8944)}$$

Note that an Nth-order LPF becomes a $2N$th-order BPF. To convert to digital filter system function, we replace s with $(1 - z^{-1})/(1 + z^{-1})$, yielding

$$H^{BP}(z) = \frac{7.2077 \times 10^{-3}(1 - z^{-2}) \times (1 + 0.4807z^{-1} + 1.1117z^{-2} + 0.4807z^{-3} + z^{-4})}{(1 + 0.2928z^{-1} + 0.8485z^{-2}) \times (1 + 0.5973z^{-1} + 1.8623z^{-2} + 0.5539z^{-3} + 0.8629z^{-4})}$$

The magnitude and phase responses are plotted in Figure 19.22.

Note that for the transformation in Equation 19.72, we can also let $W = \lambda_{s2} - \lambda_{s1}$ and $\lambda_0^2 = \lambda_{s1}\lambda_{s2}$, instead of Equation 19.73. Such a choice will give $\lambda'_s = 1$. The passband edge for the prototype LPF is now calculated from $\lambda'_p = \min\{|(\lambda_{p1}^2 - \lambda_0^2)/(W\lambda_{p1})|\ |\lambda_{p2}^2 - \lambda_0^2)/(W\lambda_{p2})|\}$.

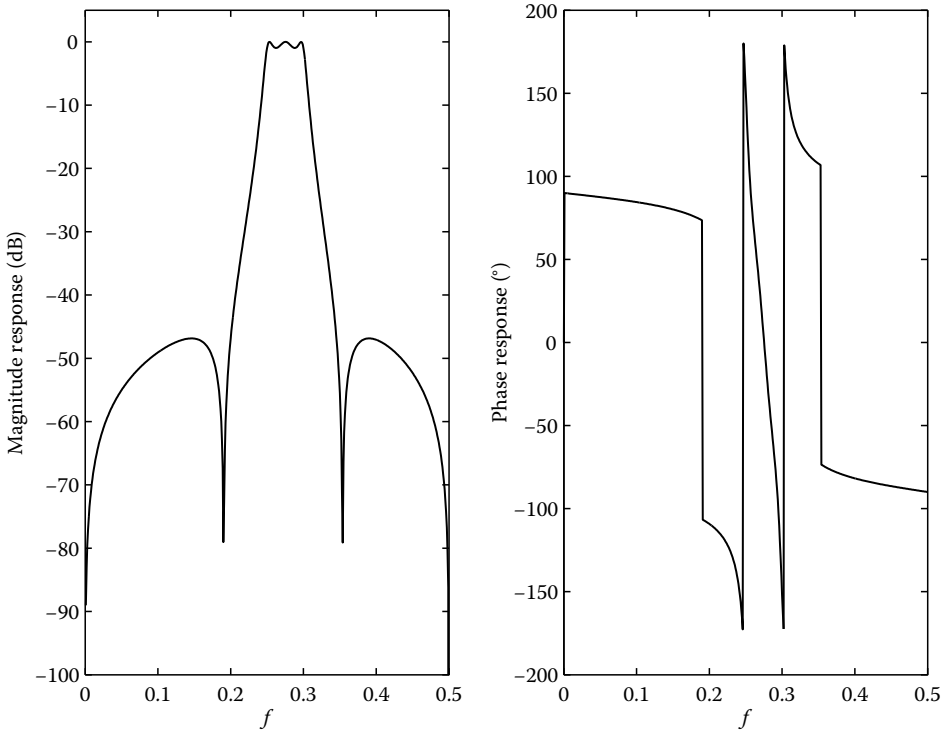

FIGURE 19.22 Frequency response of the designed digital BPF.

19.2.3.5 Bandstop Filters

A digital BSF specification is depicted in Figure 19.20b. As in the case of the BPF there are two passband edges (f_{p1} and f_{p2}) and two stopband edges (f_{s1} and f_{s2}). A transformation from analog BSF to analog LPF is given by

$$s' = \frac{Ws}{s^2 + \lambda_0^2} \quad \text{or} \quad \lambda' = \frac{W\lambda}{\lambda_0^2 - \lambda^2} \tag{19.75}$$

where W and λ_0^2 are given by Equation 19.73. Note that the expression for s in Equation 19.75 is the reciprocal of that in Equation 19.72. The relation between the LPF frequency λ' and the BSF frequency λ is depicted in Figure 19.23. The passband edges λ_{p1} and λ_{p2} get mapped to $\lambda' = 1$ and -1, respectively. The values of λ_{s1} and λ_{s2} get mapped to $\lambda'_{s1} = W\lambda_{s1}/(\lambda_0^2 - \lambda_{s1}^2)$ and $\lambda'_{s2} = W\lambda_{s2}/(\lambda_0^2 - \lambda_{s2}^2)$. Therefore, the passband edge and stopband edge of the prototype analog LPF are 1 and λ'_s, respectively, where

$$\lambda'_s = \min\{|\lambda'_{s1}|, |\lambda'_{s2}|\} = \min\left\{\left|\frac{W_{s1}\lambda}{\lambda_0^2 - \lambda_{s1}^2}\right|, \left|\frac{W\lambda_{s2}}{\lambda_0^2 - \lambda_{s2}^2}\right|\right\} \tag{19.76}$$

The design process for the BSF can follow the same process as the design for the BPF, except that we use Equations 19.75 and 19.76 instead of Equations 19.62 and 19.64.

Similar to the case of the BPF, we can also let $W = \lambda_{s2} - \lambda_{s1}$ and $\lambda_0^2 = \lambda_{s1}\lambda_{s2}$ instead of Equation 19.73, for the transformation in Equation 19.75. The stopband edge and the passband edge for the prototype LPF are now $\lambda'_s = 1$ and $\lambda'_p = \min\{|W\lambda_{p1}/(\lambda_0^2 - \lambda_{p1}^2)|, |W\lambda_{p2}/(\lambda_0^2 - \lambda_{p2}^2)|\}$.

19.2.4 Design Using Digital Frequency Transformations

This method assumes that we can design a digital LPF. The desired filter is then obtained from the digital LPF by transforming the digital LPF in the z domain. Let us denote the z variable for the digital LPF by z' and that for the desired digital filter by z. Similarly, we use f' for the digital frequency of the digital LPF and f for the frequency of the desired digital filter. Suppose that the digital LPF has system function $H(z')$ and the desired digital filter has system function $H^x(z)$, where x stands for LP, HP, BP, or BS. The system function $H^x(z)$ is obtained from $H(z')$ by replacing z' with an appropriate function of z. The LPF $H(z')$ can be designed using the method discussed in the Section 19.2.3, or by some other means. The specification for the digital LPF is obtained from the specification of the desired digital filter through the relation between f' and f. The relation depends on the specific transformation. Note that the

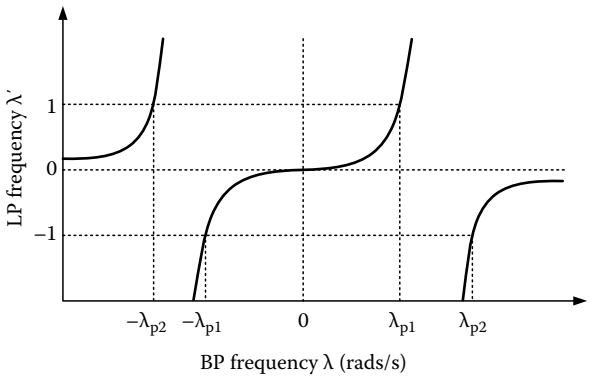

FIGURE 19.23 Relation between λ and λ' for bandstop-to-lowpass conversion.

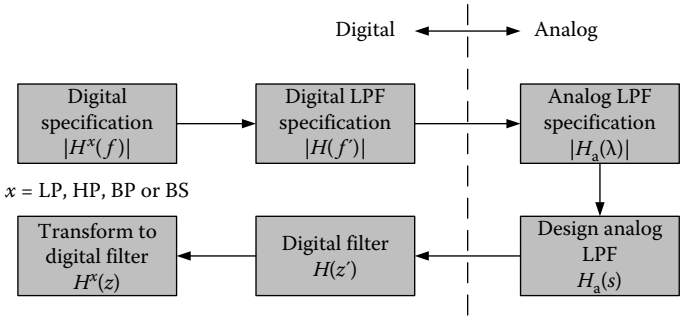

FIGURE 19.24 Design process using digital frequency transformation.

difference between the method in this section and the method described above is that the transformation between the desired type of filter and the LPF is in the digital domain (the z domain) for the current method whereas it is in the analog domain (the s domain) in the previous method. Figure 19.24 shows the design process using digital frequency transformation. The advantage of the current method is that in designing a desired digital HPF, BPF, or BSF, we design a digital LPF, which can make use of the impulse invariant method, in addition to the bilinear transformation. This is not the case for the method discussed previously, due to excessive aliasing.

19.2.4.1 Low-Pass Filters

We can transform a digital LPF to a digital LPF using the transformation

$$z' = \frac{z + \alpha}{1 + \alpha z} \quad |\alpha| < 1 \tag{19.77}$$

With $z = \exp(j2\pi f)$ and $z' = \exp(j2\pi f')$, we can show that the digital frequencies are related by

$$f' = \frac{1}{2\pi} \arctan\left[\frac{(1 - \alpha^2)\sin 2\pi f}{2\alpha + (1 + \alpha^2)\cos 2\pi f}\right] \tag{19.78}$$

The relation given by Equation 19.78 is plotted in Figure 19.25a. If $\alpha = 0$, then $z' = z$ and $f' = f$, which is the trivial case. When $\sigma \neq 0$, there is frequency warping introduced by the transformation. After choosing a, we can transform the desired digital LPF specification to another digital LPF specification, i.e., calculate f'_p and f'_s from f_p and f_s. With f_p, f_s, ε, and δ, a digital LPF can then be designed to satisfy the specification. The resulting system function is then transformed to the desired LPF using Equation 19.77. This method may yield a filter of lower or higher order (due to the frequency warping) compared to the case that there is no digital frequency transformation ($\alpha = 0$).

As an alternative to specifying α, we can specify f'_p, which, together with f_p, specifies the value of α, according to Equation 19.68. With the value of α, we can calculate f'_s from f_s. We can also exchange the role of the passband edge with the stopband edge, i.e., we specify f'_s and compute α from the values of f'_s and f_s. With α, f'_p can be determined from f_p.

19.2.4.2 High-Pass Filters

We can transform a digital LPF to a digital HPF using the transformation

$$z' = -\frac{z + \alpha}{1 + \alpha z} \quad |\alpha| < 1 \tag{19.79}$$

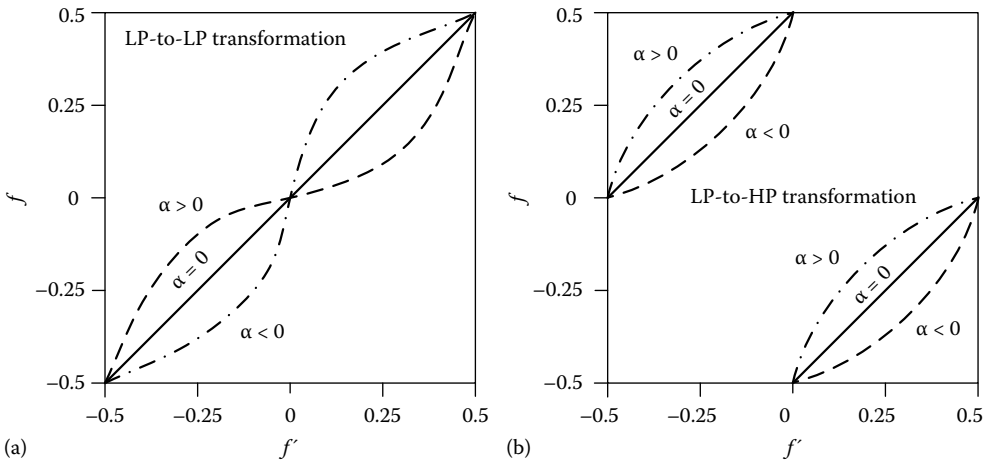

FIGURE 19.25 Frequency relation for digital frequency transformations: (a) lowpass to lowpass and (b) lowpass to highpass.

With $z = \exp(j2\pi f)$ and $z' = \exp(j2\pi f')$, we obtain the relation between the two digital frequencies:

$$f' = \frac{1}{2\pi}\arctan\left[\frac{-(1-\alpha^2)\sin 2\pi f}{-2\alpha - (1+\alpha^2)\cos 2\pi f}\right] \tag{19.80}$$

The relation is plotted in Figure 19.25b. If $\alpha = 0$, then $z' = -z$ and $f' = f + 0.5$. The design process proceeds as follows. After choosing the value of α, the desired digital HPF specification is transformed to the digital LPF specification, using the relation in Equation 19.80. Using the resulting values of f'_p and f'_s, together with the ripple specifications (ε and δ), a digital LPF is designed to satisfy the specification. The resulting LPF system function $H(z')$ is then transformed to the desired HPF by substituting z' with $-(z+\alpha)/(1+\alpha z)$, given by Equation 19.79. Similar to the case of the LPF, we can specify f'_p (instead of α) and calculate the required value of α from f'_p and f_p.

19.2.4.3 Bandpass Filters

To transform a digital LPF to a digital BPF using the transformation

$$z' = -\frac{1 + \frac{2\alpha k}{k+1}z + \frac{k-1}{k+1}z^2}{\frac{k-1}{k+1} + \frac{2\alpha k}{k+1}z + z^2} \quad |\alpha| < 1,\ k > 0 \tag{19.81}$$

This implies the following relation between the two digital frequencies:

$$f' = \frac{1}{2\pi}\arctan\left[\frac{(1-b)\{2a\sin 2\pi f + (1+b)\sin 4\pi f\}}{-a^2 - 2b - 2a(1+b)\cos 2\pi f - (b^2+1)\cos 4\pi f}\right] \tag{19.82}$$

where $a = 2\alpha k/(k+1)$ and $b = (k-1)/(k+1)$. An example of Equation 19.82 is plotted in Figure 19.26. If $\alpha = 0$, the curve would be odd symmetric with respect to $f = 0.25$. The design process is similar to the case of the HPF, except that there are now two passband edges, f'_{pi} and $|f'_{p2}|$, and two stopband

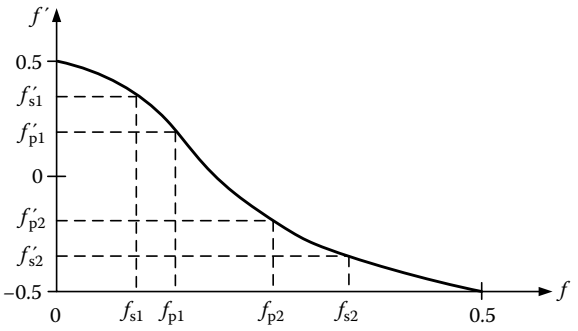

FIGURE 19.26 Frequency relation for BP to LP digital frequency transformation.

edges, f'_{s1} and $|f'_{p2}|$, for the digital LPF to satisfy (see Figure 19.25). To satisfy both sets, we let $f'_p = \max\{f'_{p1}, |f'_{p2}|\}$ and $f'_s = \min\{f_{s1}, |f'_{s2}|\}$ be the passband and stopband edges for the digital LPF filter.

If we specify f'_p, then together with f_{p1} and f_{p2}, they determine the values of α and k:

$$\alpha = \frac{\cos[\pi(f_{p2} + f_{p1})]}{\cos[\pi(f_{p2} - f_{p1})]} \quad k = \cot[\pi(f_{p2} - f_{p1})]\tan(\pi f'_p) \tag{19.83}$$

With the values of α and k, we calculate the values of f'_{s1} and f'_{s2}, from Equation 19.82 and let $f'_s = \min\{f'_{s1}, |f'_{s2}|\}$. Thus we have f'_p, f'_s, ε, and δ as the digital LPF specification. After a digital LPF is designed to satisfy this specification, it is converted to digital BPF by the transformation in Equation 19.81.

19.2.4.4 Bandstop Filters

To transform a digital LPF to a digital BSF, we can use

$$z' = \frac{1 + \frac{2\alpha k}{k+1}z + \frac{k-1}{k+1}z^2}{\frac{k-1}{k+1} + \frac{2\alpha k}{k+1}z + z^2} \quad |\alpha| < 1,\ k > 0 \tag{19.84}$$

The corresponding relation between the two digital frequencies is

$$f' = \frac{1}{2\pi}\arctan\left[-\frac{(1-b)\{2a\sin 2\pi f + (1+b)\sin 4\pi f\}}{a^2 + 2b + 2a(1+b)\cos 2\pi f + (b^2+1)\cos 4\pi f}\right] \tag{19.85}$$

where $a = 2\alpha k/(k+1)$ and $b = (k-1)/(k+1)$. An example is plotted in Figure 19.27. The design process is the same as described in Section 19.2.4.3.

When f'_{pi} is specified, together with f_{p1} and f_{p2}, the values of α and k can be calculated from

$$\alpha = \frac{\cos[\pi(f_{p2} + f_{p1})]}{\cos[\pi(f_{p2} - f_{p1})]} \quad k = \tan[\pi(f_{p2} - f_{p1})]\tan(\pi f'_p) \tag{19.86}$$

With these values, we calculate the values of f'_{s1} and f'_{s2} from Equation 19.85. Letting $f'_s = \min\{f'_{s1}, |f'_{s2}|\}$, we have f'_p, f'_s, ε, and δ, which constitute the digital LPF specification. A digital LPF is then designed and converted to digital BSF by the transformation in Equation 19.84.

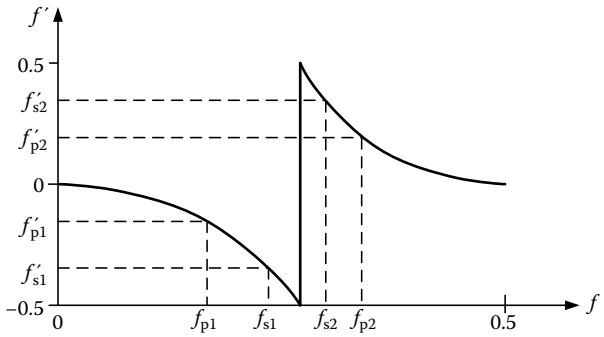

FIGURE 19.27 Frequency relation for BS to LP digital frequency transformation.

19.2.5 Computer-Aided Design

The general idea is to use an algorithm to search for coefficients such that the resulting response (magnitude and/or phase) is "close" to the desired response. The "closeness" is in some well-defined sense. The advantage of such method is that it can be used to design nonstandard filters such as multiband filters, phase equalizers, differentiators, etc. However, it requires a computer program to execute the algorithm. In addition, it usually cannot directly determine the filter order such that the passband and stopband ripples are within the desired ranges. The order is usually determined through several trials.

A large number of procedures have been studied for designing IIR filter in literatures. They can be classified into two categories. One is the indirect approach [2] which can be divided into two steps. First, an FIR filter that meets the required specifications is designed. Then, a lower order IIR filter is obtained, which maintains the original magnitude and phase specifications by applying model reduction techniques. The other is the direct approach in which IIR filters are directly designed to meet the frequency response specification using the least square criterion or Chebyshev (minimax) criterion. Several techniques are employed to achieve this propose. We review some of them in this section.

19.2.5.1 Least Squares ($\mathcal{L}_2$-Norm) Criterion

Consider the transfer function of an IIR filter given as

$$H(z) = \frac{Y(z)}{X(z)} = \frac{b_0 + b_1 z^{-1} + \cdots + b_M z^{-M}}{1 + a_1 z^{-1} + \cdots + a_N z^{-N}} \tag{19.87}$$

where $X(z)$ and $Y(z)$ are the denominator and numerator polynomials, respectively. We wish to design the frequency response $H(e^{j\omega})$ such that it optimally approximates the desired frequency response $D(e^{j\omega})$. The filter coefficients can be found by minimizing the weighted square error

$$E(\omega) = \int W^2(\omega)|D(e^{j\omega}) - H(e^{j\omega})|^2 \mathrm{d}\omega \tag{19.88}$$

where $W(\omega)$ denotes a nonnegative weighting function, which is zero in the transition band. The weighted least squares (WLS) method has been successfully applied to design an FIR filter [1] where its coefficients are obtained from a well-known least squares solution. However, for IIR filter design, the WLS criterion in Equation 19.88 is no longer a quadratic form of the filter coefficients. Therefore, nonlinear optimization techniques with some stability constraints are required to solve the cost function (Equation 19.88). However, the global minimum of $E(\omega)$ may not be guaranteed. We will leave the stability issue for the last part of this section.

To avoid the complexity of using nonlinear optimization techniques, the iterative procedure replaces the cost function as

$$\begin{aligned} E_k(\omega) &= \int |\varepsilon_k(\omega)|^2 d\omega \\ &= \int \frac{W^2(\omega)}{|X_{k-1}(e^{j\omega})|^2} |D(e^{j\omega})X_k(e^{j\omega}) - Y_k(e^{j\omega})|^2 d\omega \end{aligned} \tag{19.89}$$

where $X_k(e^{j\omega})$ and $Y_k(e^{j\omega})$ are polynomials to be determined in the kth iteration. Several methods have been proposed to solve this problem in the literature and we present a few of them here.

19.2.5.1.1 Adaptive Weighted Least Squares

The adaptive WLS method for IIR filter design can be formulated from the error function $E_k(\omega)$ in Equation 19.89

$$E_k(\omega) = \frac{W(\omega)}{X_{k-1}(e^{j\omega})} [D(e^{j\omega})X_k(e^{j\omega}) - Y_k(e^{j\omega})] \tag{19.90}$$

By defining the following vectors

$$\begin{aligned} \mathbf{c}_0 &= \left[e^{-j\omega} \cdots e^{-j\omega N}\right]^{\mathrm{T}} \\ \mathbf{c}_1 &= \left[1\ e^{-j\omega} \cdots e^{-j\omega M}\right]^{\mathrm{T}} \\ \mathbf{a}_k &= \left[a_1^{(k)} \cdots a_N^{(k)}\right]^{\mathrm{T}} \\ \mathbf{b}_k &= \left[b_0^{(k)} \cdots b_M^{(k)}\right]^{\mathrm{T}} \end{aligned}$$

the error function can be represented in matrix form as

$$E_k(\omega) = \frac{W(\omega)}{1 + \mathbf{c}_0^{\mathrm{T}}(\omega)\mathbf{a}_{k-1}} [D(e^{j\omega}) + D(e^{j\omega})\mathbf{c}_0^{\mathrm{T}}(\omega)\mathbf{a}_k - \mathbf{c}_1^{\mathrm{T}}(\omega)\mathbf{b}_k] \tag{19.91}$$

where $X_k(e^{j\omega}) = 1 + \mathbf{c}_0^{\mathrm{T}}(\omega)\mathbf{a}_k$ and $Y_k(e^{j\omega}) = \mathbf{c}_1^{\mathrm{T}}(\omega)\mathbf{b}_k$. Note that the superscript T denotes the transposition operation. Furthermore, if the above error function is evaluated on a dense frequency grid, the following vector equation can be formed

$$\mathbf{e}_k = \mathbf{W}_k(\mathbf{d} - \mathbf{C}\mathbf{x}_k) \tag{19.92}$$

where

$$\begin{aligned} \mathbf{e}_k &= \left[\varepsilon_k(e^{j\omega_1})\ \varepsilon_k(e^{j\omega_2}) \cdots\right]^{\mathrm{T}} \\ \mathbf{W}_k &= \mathrm{diag}[W_k(\omega_1)W_k(\omega_2) \cdots] \\ \mathbf{d} &= \left[D(e^{j\omega_1})\ D(e^{j\omega_2}) \cdots\right] \\ \mathbf{C} &= \begin{bmatrix} -e^{-j\omega_1}D(e^{j\omega_1}) & \cdots & -e^{-jN\omega_1}D(e^{j\omega_1}) & 1 & e^{-j\omega_1} & \cdots & e^{-jM\omega_1} \\ -e^{-j\omega_2}D(e^{j\omega_2}) & \cdots & -e^{-jN\omega_2}D(e^{j\omega_2}) & 1 & e^{-j\omega_2} & \cdots & e^{-jM\omega_2} \\ \vdots & & \vdots & \vdots & \vdots & \vdots & \vdots \end{bmatrix} \\ \mathbf{x}_k &= \begin{bmatrix} \mathbf{a}_k \\ \mathbf{b}_k \end{bmatrix} \end{aligned}$$

Here, the weighting function $\hat{W}_k(\omega)$ is defined as

$$\hat{W}_k(\omega) = \frac{W(\omega)}{|X_{k-1}(e^{j\omega})|} \tag{19.93}$$

The cost function in Equation 19.89 can be approximated as

$$E_k(\omega) = \|\varepsilon(\omega)\|_2^2 \approx \mathbf{e}_k^H \mathbf{e}_k \tag{19.94}$$

where superscript $(\cdot)^H$ denotes the conjugate transpose operation. Minimizing the cost function $E_k(\omega)$ leads to the well-known least squares solution,

$$\mathbf{x}_k = [\mathrm{Re}(\mathbf{C}^H)\mathbf{W}_k\mathrm{Re}(\mathbf{C}) + \mathrm{Im}(\mathbf{C}^H)\mathbf{W}_k\mathrm{Im}(\mathbf{C})]^{-1}[\mathrm{Re}(\mathbf{C}^H)\mathbf{W}_k\mathrm{Re}(\mathbf{d}) + \mathrm{Im}(\mathbf{C}^H)\mathbf{W}_k\mathrm{Im}(\mathbf{d})] \tag{19.95}$$

Once the filter coefficients are obtained, some weight updating procedures [1] are then applied to achieve the equiripple filter response.

19.2.5.1.2 Quadratic Programming

Using the same cost function in Equation 19.89, the problem can be formulated in a standard quadratic programming form as

$$E = \mathbf{x}_k^{\mathrm{T}}\mathbf{H}_k\mathbf{x}_k + \mathbf{x}_k^{\mathrm{T}}\mathbf{p}_k + \text{constant} \tag{19.96}$$

where

$$\mathbf{x}_k = \begin{bmatrix} \mathbf{a}_k \\ \mathbf{b}_k \end{bmatrix}, \quad \mathbf{H}_k = \begin{bmatrix} \mathbf{H}_{11} & \mathbf{H}_{12} \\ \mathbf{H}_{12}^T & \mathbf{H}_{22} \end{bmatrix}, \quad \text{and} \quad \mathbf{p}_k = \begin{bmatrix} \mathbf{p}_1 \\ \mathbf{p}_2 \end{bmatrix}$$

with

$$\mathbf{H}_{11} = \int \hat{W}_k(\omega)|D(e^{j\omega})|^2(\mathbf{c}_0\mathbf{c}_0^H)\mathrm{d}\omega$$

$$\mathbf{H}_{12} = \int \hat{W}_k(\omega)\mathrm{Re}(D(e^{j\omega})(\mathbf{c}_0\mathbf{c}_1^H))\mathrm{d}\omega$$

$$\mathbf{H}_{22} = \int \hat{W}_k(\omega)(\mathbf{c}_1\mathbf{c}_1^H)\mathrm{d}\omega$$

$$\mathbf{p}_1 = \int \hat{W}_k(\omega)|D(e^{j\omega})|^2\ \mathrm{Re}(\mathbf{c}_0)\mathrm{d}\omega$$

$$\mathbf{p}_2 = -\int \hat{W}_k(\omega)\mathrm{Re}(D(e^{j\omega})\mathbf{c}_1)\mathrm{d}\omega$$

$$\hat{W}_k(\omega) = \frac{W^2(\omega)}{|X_{k-1}(e^{j\omega})|^2}$$

The stability and amplitude requirements are taken care of by imposing linear inequality constraints [4]. Filter coefficients can be found by minimizing the cost function (Equation 19.96) using standard quadratic programming tools.

19.2.5.1.3 Eigenfilter

The eigenfilter approach was proposed in Ref. [5] for designing linear-phase FIR filters. The goal is to express the cost function (Equation 19.89) in form of

$$E = \mathbf{h}^{\mathrm{T}}\mathbf{P}\mathbf{h} \tag{19.97}$$

where

h is a vector containing the unknown filter coefficients matrix
P is symmetric, real, and positive-definite

If **h** has unit norm, i.e., $\mathbf{h}^{\mathrm{T}}\mathbf{h} = 1$, to avoid trivial solution, then the optimal **h** which minimizes the cost function E is simply the eigenvector corresponding to the minimum eigenvalue of **P**. The eigenfilter method can also be applied to design IIR filter. The problem may be formulated in two ways.

1. Time-domain approach
   In this method, the objective error function is formulated in time domain as

$$e(n) = \sum_{k=0}^{N} a(k)h_1(n-k) - \sum_{k=0}^{M} b(k)\delta(n-k) \tag{19.98}$$

   where $h_1(n)$ is the impulse response of a target transfer function $H(z) = H_1(z) + H_1(z^{-1})$. The filter $H_1(z)$ is stable and causal so that a noncausal implementation of the system is necessary. With some mathematical manipulation, the error function (Equation 19.98) can be expressed in the standard form of Equation 19.97. Therefore, the IIR filter coefficients $a(n)$ and $b(n)$ can be found. This method can also be extended to design 2-D IIR filters. However, to achieve good approximation in filter design, computation must be performed on matrices of very large size.
2. Frequency-domain approach
   In this approach, the error function in Equation 19.90 is used to formulate the problem in another way as

$$\varepsilon(\omega) = W(\omega)\mathbf{h}^{\mathrm{T}}\mathbf{c} \tag{19.99}$$

   where

$$\begin{aligned}\mathbf{c} &= [D(e^{j\omega})\ D(e^{j\omega})e^{-j\omega}\cdots D(e^{j\omega})e^{-j\omega N} - 1 - e^{-j\omega}\cdots e^{-j\omega M}]^{\mathrm{T}}\\ \mathbf{h} &= [a_0\ a_1\cdots a_N\ b_0\ b_1\cdots b_M]^{\mathrm{T}}\end{aligned} \tag{19.100}$$

   Consequently, the cost function in Equation 19.89 can be expressed as

$$E = \int \mathbf{h}^{\mathrm{T}}\mathbf{c}^{*}\mathbf{c}^{\mathrm{T}}\mathbf{h}W(\omega)\mathrm{d}\omega = \mathbf{h}^{\mathrm{T}}\mathbf{P}\mathbf{h}, \quad \omega \in \Omega \tag{19.101}$$

   where
   superscript * denotes the conjugation operation
   Ω is the frequency region of interest

   the matrix

$$\mathbf{P} = \int \mathbf{c}^{*}\mathbf{c}^{\mathrm{T}}W(\omega)\mathrm{d}\omega \tag{19.102}$$

   is a symmetric, real, positive-definite matrix.

By subjecting $\mathbf{h}$ to the usual unit norm condition $\mathbf{h}^{\mathrm{T}}\mathbf{h} = 1$, the optimum filter coefficients that minimize the cost function are the elements of the eigenvector of the matrix $\mathbf{P}$ corresponding to the minimum eigenvalue. The eigenfilter method can solve constrained filter design problem. However, to obtain equiripple filters, a weight adaptive procedure is needed.

19.2.5.2 Weighted Chebyshev ($\mathcal{L}_\infty$-Norm) Criterion

An IIR filter can also be formulated on weighted Chebyshev criterion. Filter coefficients are chosen such that its weighted Chebyshev (minimax) error between desired and actual frequency response is minimized. The iterative cost function in Equation 19.89 is now evaluated on Chebyshev criterion as

$$\begin{aligned} E &= \max_{\omega\in\Omega} \frac{W(\omega)}{|X_{k-1}(e^{j\omega})|} |D(e^{j\omega})X_k(e^{j\omega}) - Y_k(e^{j\omega})| \\ &= \max_{\omega\in\Omega} W_k(\omega)|D(e^{j\omega}) + \mathbf{x}_k^T\mathbf{s}| \end{aligned} \tag{19.103}$$

where

$$\mathbf{s} = [D(e^{j\omega})\mathbf{c}_0 - \mathbf{c}_1]^{\mathrm{T}}$$

$\mathbf{x}_k$ is the coefficient vector previously defined in Equation 19.92.

The solution of the minimax problem in Equation 19.103 can be found by solving the following equivalent linear programming problem

$$\min_{\mathbf{x}_k} \varepsilon_k \tag{19.104}$$

subject to

$$W_k(\omega)|D(e^{j\omega}) + \mathbf{x}_k^{\mathrm{T}}\mathbf{s}| \le \varepsilon_k \tag{19.105}$$

With a stability constraint, the above linear programming problem can be arranged in standard form of linear programming technique and solved using off-the-shelf linear programming software.

19.2.6 Stability Issues

An IIR filter can be unstable if there are some poles outside the unit circle. However, in case that the phase response is not important in the design, an unstable IIR filter obtained from a design algorithm can be stabilized by conjugate reciprocal substitution of the unstable factor without changing its amplitude. If, however, phase response is a part of design specification, some other techniques must be used. There are four major approaches that can be applied for filter stabilization when optimization techniques previously described are used. The following is a summary. More details and references can be found in Ref. [6].

1. First approach is proposed by Deczky [3]. In this method, a standard gradient-based optimization is modified so that the searching trajectory is only inside the border of stability. However, the algorithm has high computation complexity. A standard optimization tool cannot be used.
2. In the second approach, the target frequency response is chosen such that the desired filter is stable as in Ref. [7]. The target filter is restricted and may be too difficult to obtain filter stabilization.

3. Third approach is to impose constraints on the denominator X(z) of the filter transfer function. A stable IIR filter is achieved by imposing the real part of X(z) to be nonnegative. However, using these methods, some optimal solution that is excluded from the constraints may not be found.
4. Fourth approach is to transform a transfer function such that its optimum solution always lies in the stable area [6]. However, this method leads to a very complicated cost function that requires nonlinear optimization methods.

19.3 Lattice Digital Filters

Yong Ching Lim

19.3.1 Lattice Filters

There are several families of lattice structures for the implementation of IIR filters. Two of the most commonly encountered families are the tapped numerator structure shown in Figure 19.28 [3] and the injected numerator structure shown in Figure 19.29 [3]. It should be noted that not all the taps and injectors of the filters are nontrivial. For example, if $\lambda_i = 0$ for all i, the structure of Figure 19.28 simplifies to that of Figure 19.30 [1]. If $\phi_i = 0$ for $i > 0$, the structure of Figure 19.29 reduces to that of Figure 19.31. For both families, the denominator of the filter's transfer function is synthesized using a lattice network. The transfer function's numerator of the tapped numerator structure is realized by a

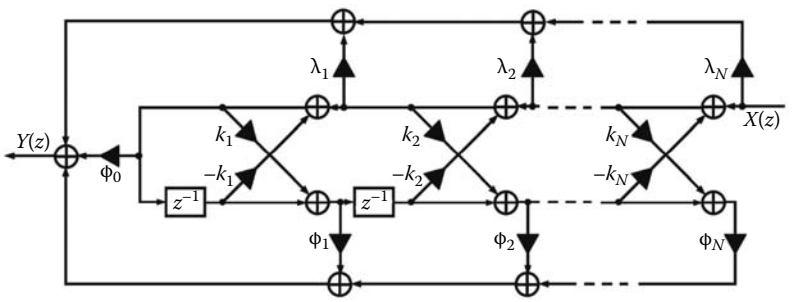

FIGURE 19.28 General structure of a tapped numerator lattice filter.

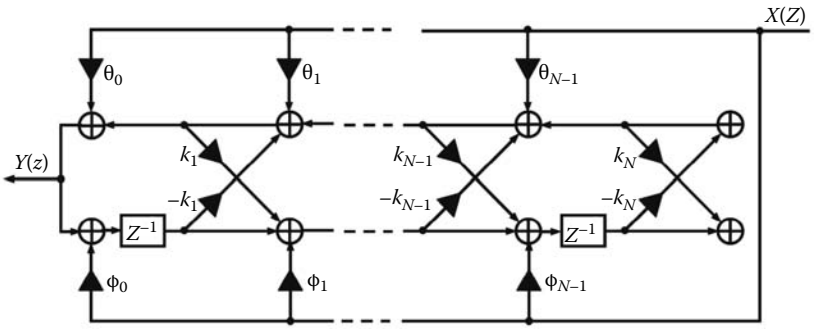

FIGURE 19.29 General structure of an injected numerator lattice filter.

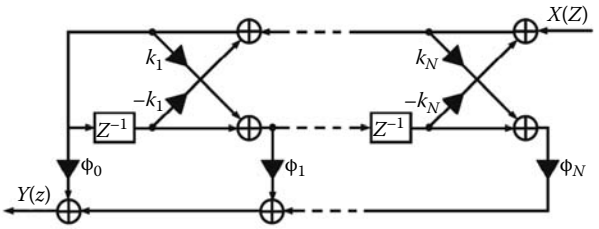

FIGURE 19.30 Structure of a tapped numerator lattice filter with $\lambda_i = 0$ for all i.

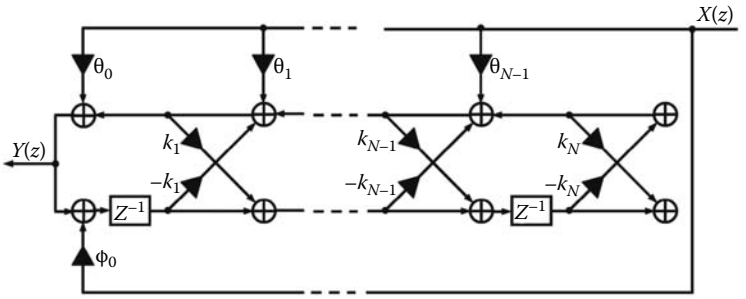

FIGURE 19.31 Structure of an injected lattice filter with $\phi_i = 0$ for $i > 0$.

weighted sum of the signals tapped from $N + 1$ appropriate points of the lattice. For the injected numerator structure, the transfer function's numerator is realized by weighting and injecting the input into $N + 1$ appropriate points on the lattice. The lattice itself may appear in several forms as shown in Figure 19.32 [1]. Figure 19.33 shows the structure of a third-order injected numerator filter synthesized using the one-multiplier lattice of Figure 19.32b.

19.3.2 Evaluation of the Reflection Coefficients k_n [2]

The nth reflection coefficient k_n for both families of filters may be evaluated as follows: Let the transfer function of the filter $H(z)$ be given by

$$H(z) = \frac{B(z)}{A(z)} \tag{19.106}$$

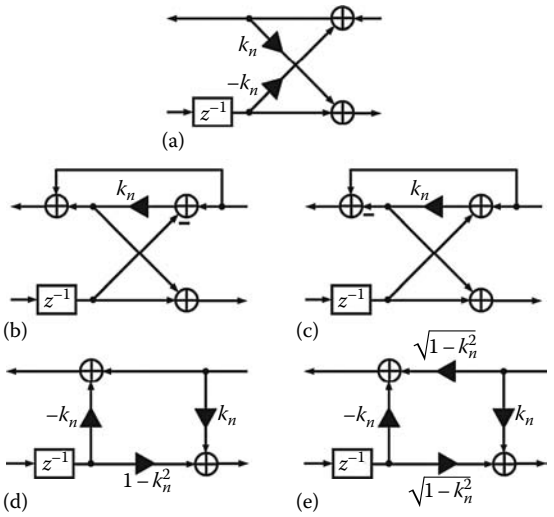

FIGURE 19.32 (a) Two-multiplier lattice; (b) and (c) one-multiplier lattice; (d) three-multiplier lattice; and (e) four-multiplier lattice.

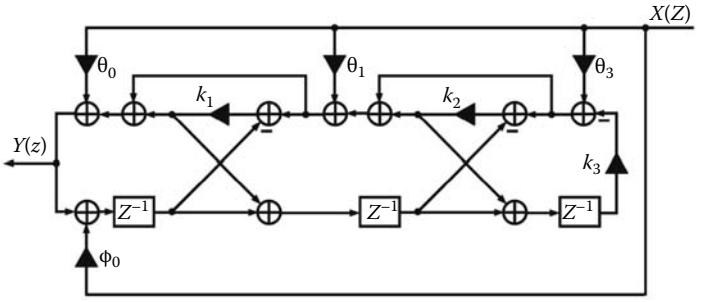

FIGURE 19.33 Third-order one-multiplier injected numerator lattice filter.

where

$$B(z) = \sum_{n=0}^{N} b_n z^{-n} \tag{19.107}$$

$$A(z) = 1 + \sum_{n=1}^{N} a_n z^{-n} \tag{19.108}$$

Define

$$D_N(z) = A(z) \tag{19.109}$$

$$D_{n-1}(z) = \frac{D_n(z) - k_n z^{-n} D_n(z^{-1})}{1 - k_n^2} \tag{19.110}$$

$$= 1 + \sum_{r=1}^{n-1} d_{n-1}(r) z^{-r} \tag{19.111}$$

The algorithm for computing k_n for all n runs as follows:

1. Set $n = N$.
2. Compute $D_n(z)$.
3. $k_n = d_n(n)$.
4. Decrement n.
5. If $n = 0$, stop; otherwise, go to 2.

19.3.3 Evaluation of the Tap Gains φ_n and λ_n [3]

For the tapped numerator filters, φ_n and λ_n may be computed as follows:
Define

$$\Gamma_N(z) = B(z) \tag{19.112}$$

$$\Gamma_{n-1}(z) = \Gamma_n(z) - \lambda_n D_n(z) - \psi_n z^{-n} D_n\left(z^{-1}\right) \tag{19.113}$$

$$= \sum_{r=0}^{n-1} \gamma_{n-1}(r) z^{-r} \tag{19.114}$$

The algorithm for computing φ_n and λ_n for all n runs as follows:

1. Set $n = N$.
2. Compute $\Gamma_n(z)$.
   Set either $\psi_n = 0$, $\lambda_n = 0$, or $\lambda_n = 0$.
   If $\psi_n = 0$, $\lambda_n = \gamma_n(n)/k_n$.
   If $\lambda_n = 0$, $\psi_n = \gamma_n(n)$.
3. Decrement n.
4. If $n = -1$, stop; otherwise, go to 2.

19.3.4 Evaluation of the Injector Gains θ_n and ϕ_n [3]

For the injected numerator filters, θ_n and ϕ_n may be computed as follows:
Define

$$L_0^0(z) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \tag{19.115}$$

$$L_m^n(z) = \begin{bmatrix} 1 & k_n z^{-1} \\ k_n & z^{-1} \end{bmatrix} L_m^{n-1}(z), \quad n > m \tag{19.116}$$

$$= \begin{bmatrix} P_m^n(z) & Q_m^n(z) \\ R_m^n(z) & S_m^n(z) \end{bmatrix} \tag{19.117}$$

$$P_m^n(z) = 1 + \sum_{r=1}^{n-m-1} p_m^n(r) z^{-r} \tag{19.118}$$

$$Q_m^n(z) = \sum_{r=1}^{n-m} q_m^n(r) z^{-r} \tag{19.119}$$

$$\Xi_{N-1} = B(z) + \phi_0 Q_0^N(z) \tag{19.120}$$

$$\Xi_{n-1}(z) = \Xi_n(z) + \phi_{N-n} Q_{N-n}^N(z) - \theta_{N-n-1} P_{N-n-1}^N(z) \tag{19.121}$$

$$= \sum_{r=0}^{n-1} \xi_{n-1}(r) z^{-r} \tag{19.122}$$

The algorithm for computing θ_n and ϕ_n for all n runs as follows:

1. $\phi_0 = -b_N / q_0^N(N)$.
   Set $n = 0$.
2. Increment n.
   Compute $\Xi_{N-n}(z)$.
   Set either $\phi_n = 0$ or $\theta_{n-1} = 0$.
   If $\phi_n = 0$, $\theta_{n-1} = \xi_{N-n}(N-n) / p_{n-1}^N(N-n)$
   If $\theta_{n-1} = 0$, $\phi_n = -\xi_{N-n}(N-n) / q_n^N(N-n)$
3. If $n = N - 1$ go to 4; otherwise, go to 2.
4. $\theta_{N-1} = \xi_0(0)$. Stop.

University of Tennessee Space Institute

Practical digital filters must be implemented with finite precision numbers and arithmetic. As a result, both the filter coefficients and the filter input and output signals are in discrete form. This leads to four types of finite wordlength effects.

Discretization (quantization) of the filter coefficients has the effect of perturbing the location of the filter poles and zeros. As a result, the actual filter response differs slightly from the ideal response. This *deterministic* frequency response error is referred to as coefficient quantization error.

The use of finite precision arithmetic makes it necessary to quantize filter calculations by rounding or truncation. Roundoff noise is that error in the filter output that results from rounding or truncation calculations within the filter. As the name implies, this error looks like low-level noise at the filter output.

Quantization of the filter calculations also renders the filter slightly nonlinear. For large signals this nonlinearity is negligible and roundoff noise is the major concern. However, for recursive filters with a zero or constant input, this nonlinearity can cause spurious oscillations called limit cycles.

With fixed-point arithmetic it is possible for filter calculations to overflow. The term overflow oscillation, sometimes also called adder overflow limit cycle, refers to a high-level oscillation that can exist in an otherwise stable filter due to the nonlinearity associated with the overflow of internal filter calculations.

In this chapter, we examine each of these finite wordlength effects. Both fixed-point and floating-point number representations are considered.

20.1 Number Representation

In digital signal processing, $(B+1)$-bit fixed-point numbers are usually represented as two's-complement signed fractions in the format

$$b_0 \cdot b_{-1} b_{-2} \cdots b_{-B}$$

The number represented is then

$$X = -b_0 + b_{-1}2^{-1} + b_{-2}2^{-2} + \cdots + b_{-B}2^{-B} \tag{20.1}$$

where b_0 is the sign bit and the number range is $-1 \le X < 1$. The advantage of this representation is that the product of two numbers in the range from -1 to 1 is another number in the same range.

Floating-point numbers are represented as

$$X = (-1)^s m 2^c \tag{20.2}$$

where

s is the sign bit
m is the mantissa
c is the characteristic *or* exponent

To make the representation of a number unique, the mantissa is *normalized* so that $0.5 \le m < 1$.

Although floating-point numbers are always represented in the form of Equation 20.2, the way in which this representation is actually *stored* in a machine may differ. Since $m \ge 0.5$, it is not necessary to store the 2^{-1}-weight bit of m, which is always set. Therefore, in practice numbers are usually stored as

$$X = (-1)^s (0.5 + f) 2^c \tag{20.3}$$

where f is an unsigned fraction, $0 \le f < 0.5$.

Most floating-point processors now use the IEEE Standard 754 32-bit floating-point format for storing numbers. According to this standard, the exponent is stored as an unsigned integer p where

$$p = c + 126 \tag{20.4}$$

Therefore, a number is stored as

$$X = (-1)^s (0.5 + f) 2^{p-126} \tag{20.5}$$

where s is the sign bit, f is a 23-b unsigned fraction in the range $0 \le f < 0.5$, and p is an 8-b unsigned integer in the range $0 \le p \le 255$. The total number of bits is $1 + 23 + 8 = 32$. For example, in IEEE format 3/4 is written $(-1)^0\ (0.5 + 0.25)2^0$ so $s = 0$, $p = 126$, and $f = 0.25$. The value $X = 0$ is a unique case and is represented by all bits zero (i.e., $s = 0$, $f = 0$, and $p = 0$). Although the 2^{-1}-weight mantissa bit is not actually stored, it does exist so the mantissa has 24 b plus a sign bit.

20.2 Fixed-Point Quantization Errors

In fixed-point arithmetic, a multiply doubles the number of significant bits. For example, the product of the two 5-b numbers 0.0011 and 0.1001 is the 10-b number 00.00011011. The extra bit to the left of the decimal point can be discarded without introducing any error. However, the least significant four of the remaining bits must ultimately be discarded by some form of quantization so that the result can be stored to 5 b for use in other calculations. In the example above this results in 0.0010 (quantization by rounding) or 0.0001 (quantization by truncating). When a sum of products calculation is performed,

the quantization can be performed either after each multiply or after all products have been summed with double-length precision.

We will examine three types of fixed-point quantization—rounding, truncation, and magnitude truncation. If X is an exact value then the rounded value will be denoted $Q_r(X)$, the truncated value $Q_t(X)$, and the magnitude truncated value $Q_{mt}(X)$. If the quantized value has B bits to the right of the decimal point, the quantization step size is

$$\Delta = 2^{-B} \tag{20.6}$$

Since rounding selects the quantized value nearest the unquantized value, it gives a value which is never more than $\pm\Delta/2$ away from the exact value. If we denote the rounding error by

$$\varepsilon_r = Q_r(X) - X \tag{20.7}$$

then

$$-\frac{\Delta}{2} \le \varepsilon_r \le \frac{\Delta}{2} \tag{20.8}$$

Truncation simply discards the low-order bits giving a quantized value that is always less than or equal to the exact value so

$$-\Delta < \varepsilon_t \le 0 \tag{20.9}$$

Magnitude truncation chooses the nearest quantized value that has a magnitude less than or equal to the exact value so

$$-\Delta < \varepsilon_{mt} < \Delta \tag{20.10}$$

The error resulting from quantization can be modeled as a random variable uniformly distributed over the appropriate error range. Therefore, calculations with roundoff error can be considered error-free calculations that have been corrupted by additive white noise. The mean of this noise for rounding is

$$m_{\varepsilon_r} = E\{\varepsilon_r\} = \frac{1}{\Delta}\int_{-\Delta/2}^{\Delta/2} \varepsilon_r \, d\varepsilon_r = 0 \tag{20.11}$$

where $E\{\ \}$ represents the operation of taking the expected value of a random variable. Similarly, the variance of the noise for rounding is

$$\sigma_{\varepsilon_r}^2 = E\{(\varepsilon_r - m_{\varepsilon_r})^2\} = \frac{1}{\Delta}\int_{-\Delta/2}^{\Delta/2} (\varepsilon_r - m_{\varepsilon_r})^2 \, d\varepsilon_r = \frac{\Delta^2}{12} \tag{20.12}$$

Likewise, for truncation,

$$\begin{aligned} m_{\varepsilon_t} &= E\{\varepsilon_t\} = -\frac{\Delta}{2} \\ \sigma_{\varepsilon_t}^2 &= E\{(\varepsilon_t - m_{\varepsilon_t})^2\} = \frac{\Delta^2}{12} \end{aligned} \tag{20.13}$$

and, for magnitude truncation

$$\begin{aligned} m_{\varepsilon_{\text{mt}}} &= E\{\varepsilon_{\text{mt}}\} = 0 \\ \sigma^2_{\varepsilon_{\text{mt}}} &= E\{(\varepsilon_{\text{mt}} - m_{\varepsilon_{\text{mt}}})^2\} = \frac{\Delta^2}{3} \end{aligned} \tag{20.14}$$

20.3 Floating-Point Quantization Errors

With floating-point arithmetic it is necessary to quantize after both multiplications and additions. The addition quantization arises because, prior to addition, the mantissa of the smaller number in the sum is shifted right until the exponent of both numbers is the same. In general, this gives a sum mantissa that is too long and so must be quantized.

We will assume that quantization in floating-point arithmetic is performed by rounding. Because of the exponent in floating-point arithmetic, it is the relative error that is important. The relative error is defined as

$$\varepsilon_{\text{r}} = \frac{Q_{\text{r}}(X) - X}{X} = \frac{\varepsilon_{\text{r}}}{X} \tag{20.15}$$

Since $X = (-1)^s m 2^c$, $Q_{\text{r}}(X) = (-1)^s\, Q_{\text{r}}(m) 2^c$ and

$$\varepsilon_{\text{r}} = \frac{Q_{\text{r}}(m) - m}{m} = \frac{\varepsilon}{m} \tag{20.16}$$

If the quantized mantissa has B bits to the right of the decimal point, $|\varepsilon_{\text{r}}| < \Delta/2$ where, as before, $\Delta = 2^{-B}$. Therefore, since $0.5 \le m < 1$,

$$|\varepsilon_{\text{r}}| < \Delta \tag{20.17}$$

If we assume that ε is uniformly distributed over the range from $-\Delta/2$ to $\Delta/2$ and m is uniformly distributed over 0.5 to 1,

$$\begin{aligned} m_{\varepsilon_{\text{r}}} &= E\left\{\frac{\varepsilon}{m}\right\} = 0 \\ \sigma^2_{\varepsilon_{\text{r}}} &= E\left\{\left(\frac{\varepsilon}{m}\right)^2\right\} = \frac{2}{\Delta}\int_{1/2}^{1}\int_{-\Delta/2}^{\Delta/2} \frac{\varepsilon^2}{m^2}\, d\varepsilon\, dm \\ &= \frac{\Delta^2}{6} = (0.167)2^{-2B} \end{aligned} \tag{20.18}$$

In practice, the distribution of m is not exactly uniform. Actual measurements of roundoff noise in Ref. [1] suggested that

$$\sigma^2_{\varepsilon_{\text{r}}} \approx 0.23\Delta^2 \tag{20.19}$$

while a detailed theoretical and experimental analysis in Ref. [2] determined

$$\sigma^2_{\varepsilon_{\text{r}}} \approx 0.18\Delta^2 \tag{20.20}$$

From Equation 20.15 we can represent a quantized floating-point value in terms of the unquantized value and the random variable ε_r using

$$Q_r(X) = X(1 + \varepsilon_r) \tag{20.21}$$

Therefore, the finite-precision product X_1X_2 and the sum $X_1 + X_2$ can be written

$$fl(X_1X_2) = X_1X_2(1 + \varepsilon_r) \tag{20.22}$$

and

$$fl(X_1 + X_2) = (X_1 + X_2)(1 + \varepsilon_r) \tag{20.23}$$

where ε_r is zero-mean with the variance of Equation 20.20.

20.4 Roundoff Noise

To determine the roundoff noise at the output of a digital filter we will assume that the noise due to a quantization is stationary, white, and uncorrelated with the filter input, output, and internal variables. This assumption is good if the filter input changes from sample to sample in a sufficiently complex manner. It is not valid for zero or constant inputs for which the effects of rounding are analyzed from a limit cycle perspective.

To satisfy the assumption of a sufficiently complex input, roundoff noise in digital filters is often calculated for the case of a zero-mean white noise filter input signal $x(n)$ of variance σ_x^2. This simplifies calculation of the output roundoff noise because expected values of the form $E\{x(n)x(n-k)\}$ are zero for $k \neq 0$ and give σ_x^2 when $k = 0$. This approach to analysis has been found to give estimates of the output roundoff noise that are close to the noise actually observed for other input signals.

Another assumption that will be made in calculating roundoff noise is that the product of two quantization errors is zero. To justify this assumption, consider the case of a 16-b fixed-point processor. In this case a quantization error is of the order 2^{-15}, while the product of two quantization errors is of the order 2^{-30}, which is negligible by comparison.

If a linear system with impulse response $g(n)$ is excited by white noise with mean m_x and variance σ_x^2, the output is noise of mean [3, pp. 788–790]

$$m_y = m_x \sum_{n=-\infty}^{\infty} g(n) \tag{20.24}$$

and variance

$$\sigma_y^2 = \sigma_x^2 \sum_{n=-\infty}^{\infty} g^2(n) \tag{20.25}$$

Therefore, if $g(n)$ is the impulse response from the point where a roundoff takes place to the filter output, the contribution of that roundoff to the variance (mean-square value) of the output roundoff noise is given by Equation 20.25 with σ_x^2 replaced with the variance of the roundoff. If there is more than one source of roundoff error in the filter, it is assumed that the errors are uncorrelated so the output noise variance is simply the sum of the contributions from each source.

20.4.1 Roundoff Noise in FIR Filters

The simplest case to analyze is a finite impulse response (FIR) filter realized via the convolution summation

$$y(n) = \sum_{k=0}^{N-1} h(k)x(n-k) \tag{20.26}$$

When fixed-point arithmetic is used and quantization is performed after each multiply, the result of the N multiplies is N-times the quantization noise of a single multiply. For example, rounding after each multiply gives, from Equations 20.6 and 20.12, an output noise variance of

$$\sigma_o^2 = N\frac{2^{-2B}}{12} \tag{20.27}$$

Virtually all digital signal processor integrated circuits contain one or more double-length accumulator registers which permit the sum-of-products in Equation 20.26 to be accumulated without quantization. In this case only a single quantization is necessary following the summation and

$$\sigma_o^2 = \frac{2^{-2B}}{12} \tag{20.28}$$

For the floating-point roundoff noise case we will consider Equation 20.26 for $N = 4$ and then generalize the result to other values of N. The finite-precision output can be written as the exact output plus an error term $e(n)$. Thus,

$$\begin{aligned} y(n) + e(n) = (\{[h(0)x(n)[1+\varepsilon_1(n)]] \\ &+ h(1)x(n-1)[1+\varepsilon_2(n)]\,[1+\varepsilon_3(n)] \\ &+ h(2)x(n-2)[1+\varepsilon_4(n)]\}\{1+\varepsilon_5(n)\} \\ &+ h(3)x(n-3)[1+\varepsilon_6(n)])[1+\varepsilon_7(n)] \end{aligned} \tag{20.29}$$

In Equation 20.29, $\varepsilon_1(n)$ represents the error in the first product, $\varepsilon_2(n)$ the error in the second product, $\varepsilon_3(n)$ the error in the first addition, etc. Notice that it has been assumed that the products are summed in the order implied by the summation of Equation 20.26.

Expanding Equation 20.29, ignoring products of error terms, and recognizing $y(n)$ gives

$$\begin{aligned} e(n) = h(0)x(n)[\varepsilon_1(n) + \varepsilon_3(n) + \varepsilon_5(n) + \varepsilon_7(n)] \\ + h(1)x(n-1)[\varepsilon_2(n) + \varepsilon_3(n) + \varepsilon_5(n) + \varepsilon_7(n)] \\ + h(2)x(n-2)[\varepsilon_4(n) + \varepsilon_5(n) + \varepsilon_7(n)] \\ + h(3)x(n-3)[\varepsilon_6(n) + \varepsilon_7(n)] \end{aligned} \tag{20.30}$$

Assuming that the input is white noise of variance σ_x^2 so that $E\{x(n)x(n-k)\}$ is zero for $k \neq 0$, and assuming that the errors are uncorrelated,

$$E\{e^2(n)\} = [4h^2(0) + 4h^2(1) + 3h^2(2) + 2h^2(3)]\sigma_x^2\sigma_{\varepsilon_r}^2 \tag{20.31}$$

In general, for any N,

$$\sigma_o^2 = E\{e^2(n)\} = \left[Nh^2(0) + \sum_{k=1}^{N-1}(N+1-k)h^2(k)\right]\sigma_x^2\sigma_{\varepsilon_r}^2 \tag{20.32}$$

Notice that if the order of summation of the product terms in the convolution summation is changed, then the order in which the $h(k)$'s appear in Equation 20.32 changes. If the order is changed so that the $h(k)$ with smallest magnitude is first, followed by the next smallest, etc., then the roundoff noise variance is minimized. However, performing the convolution summation in nonsequential order greatly complicates data indexing and so may not be worth the reduction obtained in roundoff noise.

20.4.2 Roundoff Noise in Fixed-Point IIR Filters

To determine the roundoff noise of a fixed-point infinite impulse response (IIR) filter realization, consider a causal first-order filter with impulse response

$$h(n) = a^n u(n) \tag{20.33}$$

realized by the difference equation

$$y(n) = ay(n-1) + x(n) \tag{20.34}$$

Due to roundoff error, the output actually obtained is

$$\hat{y}(n) = Q\{ay(n-1) + x(n)\} = ay(n-1) + x(n) + e(n) \tag{20.35}$$

where $e(n)$ is a random roundoff noise sequence. Since $e(n)$ is injected at the same point as the input, it propagates through a system with impulse response $h(n)$. Therefore, for fixed-point arithmetic with rounding, the output roundoff noise variance from Equations 20.6, 20.12, 20.25, and 20.33 is

$$\sigma_o^2 = \frac{\Delta^2}{12}\sum_{n=-\infty}^{\infty} h^2(n) = \frac{\Delta^2}{12}\sum_{n=0}^{\infty} a^{2n} = \frac{2^{-2B}}{12}\frac{1}{1-a^2} \tag{20.36}$$

With fixed-point arithmetic there is the possibility of overflow following addition. To avoid overflow it is necessary to restrict the input signal amplitude. This can be accomplished by either placing a *scaling* multiplier at the filter input or by simply limiting the maximum input signal amplitude. Consider the case of the first-order filter of Equation 20.34. The transfer function of this filter is

$$H(e^{j\omega}) = \frac{Y(e^{j\omega})}{X(e^{j\omega})} = \frac{1}{e^{j\omega} - a} \tag{20.37}$$

so

$$\left|H(e^{j\omega})\right|^2 = \frac{1}{1 + a^2 - 2a\cos(\omega)} \tag{20.38}$$

and

$$\left|H(e^{j\omega})\right|_{\max} = \frac{1}{1-|a|} \tag{20.39}$$

The peak gain of the filter is $1/(1-|a|)$ so limiting input signal amplitudes to $|x(n)| \leq 1-|a|$ will make overflows unlikely.

An expression for the output roundoff noise-to-signal ratio can easily be obtained for the case where the filter input is white noise, uniformly distributed over the interval from $-(1-|a|)$ to $(1-|a|)$ [4,5]. In this case

$$\sigma_x^2 = \frac{1}{2(1-|a|)} \int_{-(1-|a|)}^{1-|a|} x^2 \mathrm{d}x = \frac{1}{3}(1-|a|)^2 \tag{20.40}$$

so, from Equation 20.25,

$$\sigma_y^2 = \frac{1}{3}\frac{(1-|a|)^2}{1-a^2} \tag{20.41}$$

Combining Equations 20.36 and 20.41 then gives

$$\frac{\sigma_o^2}{\sigma_y^2} = \left(\frac{2^{-2B}}{12}\frac{1}{1-a^2}\right)\left(3\frac{1-a^2}{(1-|a|)^2}\right) = \frac{2^{-2B}}{12}\frac{3}{(1-|a|)^2} \tag{20.42}$$

Notice that the noise-to-signal ratio increases without bound as $|a| \to 1$.

Similar results can be obtained for the case of the causal second-order filter realized by the difference equation

$$y(n) = 2r\cos(\theta)y(n-1) - r^2 y(n-2) + x(n) \tag{20.43}$$

This filter has complex–conjugate poles at $re^{\pm j\theta}$ and impulse response

$$h(n) = \frac{1}{\sin(\theta)} r^n \sin[(n+1)\theta]\ u(n) \tag{20.44}$$

Due to roundoff error, the output actually obtained is

$$\hat{y}(n) = 2r\cos(\theta)y(n-1) - r^2 y(n-2) + x(n) + e(n) \tag{20.45}$$

There are two noise sources contributing to $e(n)$ if quantization is performed after each multiply, and there is one noise source if quantization is performed after summation. Since

$$\sum_{n=-\infty}^{\infty} h^2(n) = \frac{1+r^2}{1-r^2}\frac{1}{(1+r^2)^2 - 4r^2\cos^2(\theta)} \tag{20.46}$$

the output roundoff noise is

$$\sigma_o^2 = \nu\frac{2^{-2B}}{12}\frac{1+r^2}{1-r^2}\frac{1}{(1+r^2)^2 - 4r^2\cos^2(\theta)} \tag{20.47}$$

where $\nu = 1$ for quantization after summation, and $\nu = 2$ for quantization after each multiply.

To obtain an output noise-to-signal ratio we note that

$$H(e^{j\omega}) = \frac{1}{1 - 2r\cos(\theta)e^{-j\omega} + r^2 e^{-j2\omega}} \tag{20.48}$$

and, using the approach of [6],

$$\left|H(e^{j\omega})\right|^2_{\max} = \frac{1}{4r^2\left\{\left[\text{sat}\left(\frac{1+r^2}{2r}\cos(\theta)\right) - \frac{1+r^2}{2r}\cos(\theta)\right]^2 + \left[\frac{1-r^2}{2r}\sin(\theta)\right]^2\right\}} \tag{20.49}$$

where

$$\text{sat}(\mu) = \begin{cases} 1 & \mu > 1 \\ \mu & -1 \le \mu \le 1 \\ -1 & \mu < -1 \end{cases} \tag{20.50}$$

Following the same approach as for the first-order case then gives

$$\frac{\sigma_o^2}{\sigma_y^2} = \nu\frac{2^{-2B}}{12}\frac{1+r^2}{1-r^2}\frac{3}{(1+r^2)^2 - 4r^2\cos^2(\theta)} \times \frac{1}{4r^2\left\{\left[\text{sat}\left(\frac{1+r^2}{2r}\cos(\theta)\right) - \frac{1+r^2}{2r}\cos(\theta)\right]^2 + \left[\frac{1-r^2}{2r}\sin(\theta)\right]^2\right\}} \tag{20.51}$$

Figure 20.1 is a contour plot showing the noise-to-signal ratio of Equation 20.51 for $\nu = 1$ in units of the noise variance of a single quantization $2^{-2B}/12$. The plot is symmetrical about $\theta = 90°$, so only the range from 0° to 90° is shown. Notice that as $r \to 1$, the roundoff noise increases without bound. Also notice that the noise increases as $\theta \to 0°$.

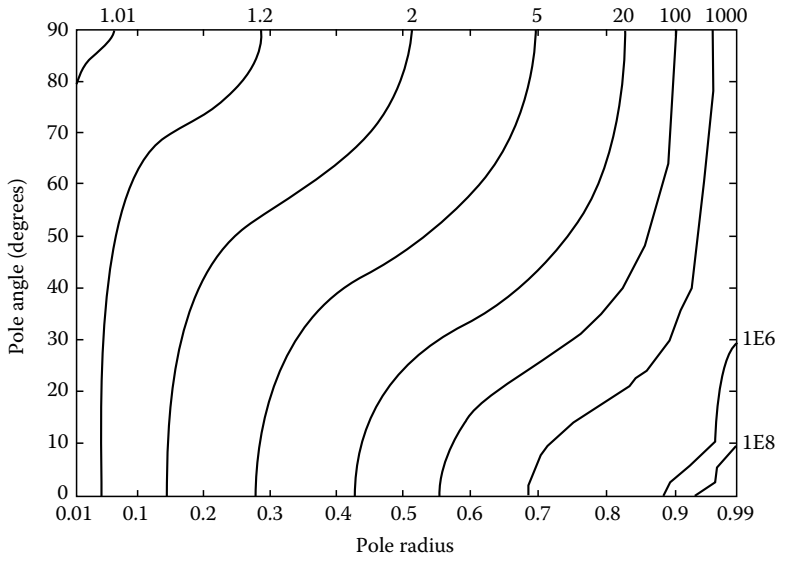

FIGURE 20.1 Normalized fixed-point roundoff noise variance.

It is possible to design state-space filter realizations that minimize fixed-point roundoff noise [7–10]. Depending on the transfer function being realized, these structures may provide a roundoff noise level that is orders-of-magnitude lower than for a nonoptimal realization. The price paid for this reduction in roundoff noise is an increase in the number of computations required to implement the filter. For an Nth-order filter the increase is from roughly $2N$ multiplies for a direct form realization to roughly $(N+1)^2$ for an optimal realization. However, if the filter is realized by the parallel or cascade connection of first- and second-order optimal subfilters, the increase is only to about $4N$ multiplies. Furthermore, near-optimal realizations exist that increase the number of multiplies to only about $3N$ [10].

20.4.3 Roundoff Noise in Floating-Point IIR Filters

For floating-point arithmetic it is first necessary to determine the injected noise variance of each quantization. For the first-order filter this is done by writing the computed output as

$$y(n) + e(n) = [ay(n-1)(1+\varepsilon_1(n)) + x(n)](1+\varepsilon_2(n)) \tag{20.52}$$

where

$\varepsilon_1(n)$ represents the error due to the multiplication
$\varepsilon_2(n)$ represents the error due to the addition

Neglecting the product of errors, Equation 20.52 becomes

$$\begin{aligned} y(n) + e(n) \approx\ & ay(n-1) + x(n) + ay(n-1)\varepsilon_1(n) \\ & + ay(n-1)\varepsilon_2(n) + x(n)\varepsilon_2(n) \end{aligned} \tag{20.53}$$

Comparing Equations 20.34 and 20.53, it is clear that

$$e(n) = ay(n-1)\varepsilon_1(n) + ay(n-1)\varepsilon_2(n) + x(n)\varepsilon_2(n) \tag{20.54}$$

Taking the expected value of $e^2(n)$ to obtain the injected noise variance then gives

$$\begin{aligned} E\{e^2(n)\} =\ & a^2E\{y^2(n-1)\}E\left\{\varepsilon_1^2(n)\right\} + a^2E\{y^2(n-1)\}E\left\{\varepsilon_2^2(n)\right\} \\ & + E\{x^2(n)\}E\left\{\varepsilon_2^2(n)\right\} + E\{x(n)y(n-1)\}E\left\{\varepsilon_2^2(n)\right\} \end{aligned} \tag{20.55}$$

To carry this further it is necessary to know something about the input. If we assume the input is zero-mean white noise with variance σ_x^2, then $E\{x^2(n)\} = \sigma_x^2$ and the input is uncorrelated with past values of the output so $E\{x(n)y(n-1)\} = 0$ giving

$$E\{e^2(n)\} = 2a^2\sigma_y^2\sigma_{\varepsilon_r}^2 + \sigma_x^2\sigma_{\varepsilon_r}^2 \tag{20.56}$$

and

$$\begin{aligned} \sigma_o^2 &= \left(2a^2\sigma_y^2\sigma_{\varepsilon_r}^2 + \sigma_x^2\sigma_{\varepsilon_r}^2\right)\sum_{n=-\infty}^{\infty} h^2(n) \\ &= \frac{2a^2\sigma_y^2 + \sigma_x^2}{1-a^2}\sigma_{\varepsilon_r}^2 \end{aligned} \tag{20.57}$$

However,

$$\sigma_y^2 = \sigma_x^2 \sum_{n=-\infty}^{\infty} h^2(n) = \frac{\sigma_x^2}{1-a^2} \tag{20.58}$$

$$\sigma_o^2 = \frac{1+a^2}{(1-a^2)^2}\sigma_{\varepsilon_r}^2\sigma_x^2 = \frac{1+a^2}{1-a^2}\sigma_{\varepsilon_r}^2\sigma_y^2 \tag{20.59}$$

and the output roundoff noise-to-signal ratio is

$$\frac{\sigma_o^2}{\sigma_y^2} = \frac{1+a^2}{1-a^2}\sigma_{\varepsilon_r}^2 \tag{20.60}$$

Similar results can be obtained for the second-order filter of Equation 20.43 by writing

$$\begin{aligned} y(n) + e(n) = \big([2r\cos(\theta)y(n-1)(1+\varepsilon_1(n)) - r^2y(n-2)(1+\varepsilon_2(n))] \\ \times [1+\varepsilon_3(n)] + x(n))(1+\varepsilon_4(n)) \end{aligned} \tag{20.61}$$

Expanding with the same assumptions as before gives

$$\begin{aligned} e(n) \approx\ & 2r\cos(\theta)y(n-1)[\varepsilon_1(n)+\varepsilon_3(n)+\varepsilon_4(n)] \\ & - r^2y(n-2)[\varepsilon_2(n)+\varepsilon_3(n)+\varepsilon_4(n)] + x(n)\varepsilon_4(n) \end{aligned} \tag{20.62}$$

and

$$\begin{aligned} E\{e^2(n)\} = {} & 4r^2\cos^2(\theta)\sigma_y^2\sigma_{\varepsilon_r}^2 + r^2\sigma_y^2 3\sigma_{\varepsilon_r}^2 \\ & + \sigma_x^2\sigma_{\varepsilon_r}^2 - 8r^3\cos(\theta)\sigma_{\varepsilon_r}^2 E\{y(n-1)y(n-2)\} \end{aligned} \tag{20.63}$$

However,

$$\begin{aligned} & E\{y(n-1)y(n-2)\} \\ & \quad = E\{2r\cos(\theta)y(n-2) - r^2y(n-3) + x(n-1)]y(n-2)\} \\ & \quad = 2r\cos(\theta)E\{y^2(n-2)\} - r^2E\{y(n-2)y(n-3)\} \\ & \quad = 2r\cos(\theta)E\{y^2(n-2)\} - r^2E\{y(n-1)y(n-2)\} \\ & \quad = \frac{2r\cos(\theta)}{1+r^2}\sigma_y^2 \end{aligned} \tag{20.64}$$

so

$$E\{e^2(n)\} = \sigma_{\varepsilon_r}^2\sigma_x^2 + \left[3r^4 + 12r^2\cos^2(\theta) - \frac{16r^4\cos^2(\theta)}{1+r^2}\right]\sigma_{\varepsilon_r}^2\sigma_y^2 \tag{20.65}$$

and

$$\begin{aligned} \sigma_o^2 &= E(n)\sum_{n=-\infty}^{\infty} h^2(n) \\ &= \xi\left[\sigma_{\varepsilon_r}^2\sigma_x^2 + \left[3r^4 + 12r^2\cos^2(\theta) - \frac{16r^4\cos^2(\theta)}{1+r^2}\right]\sigma_{\varepsilon_r}^2\sigma_y^2\right] \end{aligned} \tag{20.66}$$

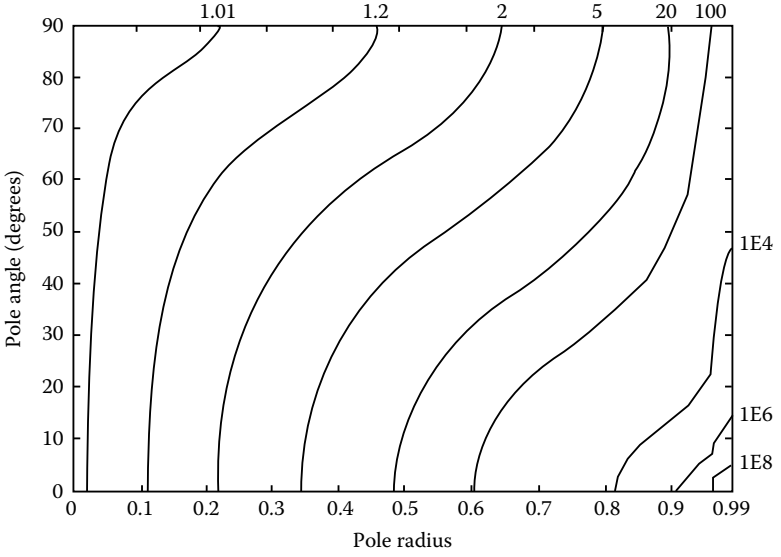

FIGURE 20.2 Normalized floating-point roundoff noise variance.

where from Equation 20.46,

$$\xi = \sum_{n=-\infty}^{\infty} h^2(n) = \frac{1+r^2}{1-r^2}\,\frac{1}{(1+r^2)^2 - 4r^2\cos^2(\theta)} \tag{20.67}$$

Since $\sigma_y^2 = \xi\sigma_x^2$, the output roundoff noise-to-signal ratio is then

$$\frac{\sigma_o^2}{\sigma_y^2} = \xi\left[1 + \xi\left[3r^4 + 12r^2\cos^2(\theta) - \frac{16r^4\cos^2(\theta)}{1+r^2}\right]\right]\sigma_{\varepsilon_r}^2 \tag{20.68}$$

Figure 20.2 is a contour plot showing the noise-to-signal ratio of Equation 20.68 in units of the noise variance of a single quantization $\sigma_{\varepsilon_r}^2$. The plot is symmetrical about $\theta = 90°$, so only the range from 0° to 90° is shown. Notice the similarity of this plot to that of Figure 20.1 for the fixed-point case. It has been observed that filter structures generally have very similar fixed-point and floating-point roundoff characteristics [2]. Therefore, the techniques of [7–10], which were developed for the fixed-point case, can also be used to design low-noise floating-point filter realizations. Furthermore, since it is not necessary to scale the floating-point realization, the low-noise realizations need not require significantly more computation than the direct form realization.

20.5 Limit Cycles

A limit cycle, sometimes referred to as a multiplier roundoff limit cycle, is a low-level oscillation that can exist in an otherwise stable filter as a result of the nonlinearity associated with rounding (or truncating) internal filter calculations [11]. Limit cycles require recursion to exist and do not occur in nonrecursive FIR filters.

As an example of a limit cycle, consider the second-order filter realized by

$$y(n) = Q_r\left\{\frac{7}{8}y(n-1) - \frac{5}{8}y(n-2) + x(n)\right\} \tag{20.69}$$

where $Q_r\{\ \}$ represents quantization by rounding. This is a stable filter with poles at $0.4375 \pm j0.6585$. Consider the implementation of this filter with 4-b (3 b and a sign bit) two's complement fixed-point arithmetic, zero initial conditions ($y(-1) = y(-2) = 0$), and an input sequence $x(n) = \frac{3}{8}\delta(n)$, where $\delta(n)$ is the unit impulse or unit sample. The following sequence is obtained:

$$
\begin{aligned}
y(0) &= Q_r\left\{\frac{3}{8}\right\} = \frac{3}{8} \\
y(1) &= Q_r\left\{\frac{21}{64}\right\} = \frac{3}{8} \\
y(2) &= Q_r\left\{\frac{3}{32}\right\} = \frac{1}{8} \\
y(3) &= Q_r\left\{-\frac{1}{8}\right\} = -\frac{1}{8} \\
y(4) &= Q_r\left\{-\frac{3}{16}\right\} = -\frac{1}{8} \\
y(5) &= Q_r\left\{-\frac{1}{32}\right\} = 0 \\
y(6) &= Q_r\left\{\frac{5}{64}\right\} = \frac{1}{8} \\
y(7) &= Q_r\left\{\frac{7}{64}\right\} = \frac{1}{8} \\
y(8) &= Q_r\left\{\frac{1}{32}\right\} = 0 \\
y(9) &= Q_r\left\{-\frac{5}{64}\right\} = -\frac{1}{8} \\
y(10) &= Q_r\left\{-\frac{7}{64}\right\} = -\frac{1}{8} \\
y(10) &= Q_r\left\{-\frac{1}{32}\right\} = 0 \\
y(12) &= Q_r\left\{\frac{5}{64}\right\} = \frac{1}{8} \\
&\vdots
\end{aligned}
\tag{20.70}
$$

Notice that while the input is zero except for the first sample, the output oscillates with amplitude 1/8 and period 6.

Limit cycles are primarily of concern in fixed-point recursive filters. As long as floating-point filters are realized as the parallel or cascade connection of first- and second-order subfilters, limit cycles will generally not be a problem since limit cycles are practically not observable in first- and second-order systems implemented with 32-b floating-point arithmetic [12]. It has been shown that such systems must have an extremely small margin of stability for limit cycles to exist at anything other than underflow levels, which are at an amplitude of less than 10^{-38} [12].

There are at least three ways of dealing with limit cycles when fixed-point arithmetic is used. One is to determine a bound on the maximum limit cycle amplitude, expressed as an integral number of quantization steps [13]. It is then possible to choose a word length that makes the limit cycle amplitude acceptably low. Alternately, limit cycles can be prevented by randomly rounding calculations up or down [14]. However, this approach is complicated to implement. The third approach is to properly choose the

filter realization structure and then quantize the filter calculations using magnitude truncation [15,16]. This approach has the disadvantage of producing more roundoff noise than truncation or rounding [see Equations 20.12 through 20.14].

20.6 Overflow Oscillations

With fixed-point arithmetic it is possible for filter calculations to overflow. This happens when two numbers of the same sign add to give a value having magnitude greater than one. Since numbers with magnitude greater than one are not representable, the result overflows. For example, the two's complement numbers 0.101 (5/8) and 0.100 (4/8) add to give 1.001 which is the two's complement representation of $-7/8$.

The overflow characteristic of two's complement arithmetic can be represented as $R\{\}$ where

$$R\{X\} = \begin{cases} X - 2 & X \geq 1 \\ X & -1 \leq X < -1 \\ X + 2 & X < -1 \end{cases} \tag{20.71}$$

For the example just considered, $R\{9/8\} = -7/8$.

An overflow oscillation, sometimes also referred to as an *adder overflow limit cycle,* is a high-level oscillation that can exist in an otherwise stable fixed-point filter due to the gross nonlinearity associated with the overflow of internal filter calculations [17]. Like limit cycles, overflow oscillations require recursion to exist and do not occur in nonrecursive FIR filters. Overflow oscillations also do not occur with floating-point arithmetic due to the virtual impossibility of overflow.

As an example of an overflow oscillation, once again consider the filter of Equation 20.69 with 4-b fixed-point two's complement arithmetic and with the two's complement overflow characteristic of Equation 20.71:

$$y(n) = Q_r\left\{R\left[\frac{7}{8}y(n-1) - \frac{5}{8}y(n-2) + x(n)\right]\right\} \tag{20.72}$$

In this case we apply the input

$$\begin{aligned} x(n) &= -\frac{3}{4}\delta(n) - \frac{5}{8}\delta(n-1) \\ &= \left\{-\frac{3}{4}, -\frac{5}{8}, 0, 0, \ldots\right\} \end{aligned} \tag{20.73}$$

giving the output sequence

$$\begin{aligned} y(0) &= Q_r\left\{R\left[-\frac{3}{4}\right]\right\} = Q_r\left\{-\frac{3}{4}\right\} = -\frac{3}{4} \\ y(1) &= Q_r\left\{R\left[-\frac{41}{32}\right]\right\} = Q_r\left\{\frac{23}{32}\right\} = \frac{3}{4} \\ y(2) &= Q_r\left\{R\left[\frac{9}{8}\right]\right\} = Q_r\left\{-\frac{7}{8}\right\} = -\frac{7}{8} \\ y(3) &= Q_r\left\{R\left[-\frac{79}{64}\right]\right\} = Q_r\left\{\frac{49}{64}\right\} = \frac{3}{4} \end{aligned}$$

$$
\begin{aligned}
y(4) &= Q_r\left\{R\left[\frac{77}{64}\right]\right\} = Q_r\left\{-\frac{51}{64}\right\} = -\frac{3}{4} \\
y(5) &= Q_r\left\{R\left[-\frac{9}{8}\right]\right\} = Q_r\left\{\frac{7}{8}\right\} = \frac{7}{8} \\
y(6) &= Q_r\left\{R\left[\frac{79}{64}\right]\right\} = Q_r\left\{\frac{-49}{64}\right\} = -\frac{3}{4} \\
y(7) &= Q_r\left\{R\left[-\frac{77}{64}\right]\right\} = Q_r\left\{\frac{51}{64}\right\} = \frac{3}{4} \\
y(8) &= Q_r\left\{R\left[\frac{9}{8}\right]\right\} = Q_r\left\{-\frac{7}{8}\right\} = -\frac{7}{8} \\
&\vdots
\end{aligned}
\tag{20.74}
$$

This is a large-scale oscillation with nearly full-scale amplitude.

There are several ways to prevent overflow oscillations in fixed-point filter realizations. The most obvious is to scale the filter calculations so as to render overflow impossible. However, this may unacceptably restrict the filter dynamic range. Another method is to force completed sums-of-products to saturate at ± 1, rather than overflowing [18,19]. It is important to saturate only the completed sum, since intermediate overflows in two's complement arithmetic do not affect the accuracy of the final result. Most fixed-point digital signal processors provide for automatic saturation of completed sums if their *saturation arithmetic* feature is enabled. Yet another way to avoid overflow oscillations is to use a filter structure for which any internal filter transient is guaranteed to decay to zero [20]. Such structures are desirable anyway, since they tend to have low roundoff noise and be insensitive to coefficient quantization [21].

20.7 Coefficient Quantization Error

Each filter structure has its own finite, generally nonuniform grids of realizable pole and zero locations when the filter coefficients are quantized to a finite word length. In general the pole and zero locations desired in a filter do not correspond exactly to the realizable locations. The error in filter performance (usually measured in terms of a frequency response error) resulting from the placement of the poles and zeros at the nonideal but realizable locations is referred to as coefficient quantization error.

Consider the second-order filter with complex–conjugate poles

$$
\begin{aligned}
\lambda &= re^{\pm j\theta} \\
&= \lambda_r \pm j\lambda_i \\
&= r\cos(\theta) \pm jr\sin(\theta)
\end{aligned}
\tag{20.75}
$$

and transfer function

$$
H(z) = \frac{1}{1 - 2r\cos(\theta)z^{-1} + r^2z^{-2}} \tag{20.76}
$$

realized by the difference equation

$$
y(n) = 2r\cos(\theta)y(n-1) - r^2y(n-2) + x(n) \tag{20.77}
$$

Figure 20.3 from Ref. [5] shows that quantizing the difference equation coefficients results in a nonuniform grid of realizable pole locations in the z plane. The grid is defined by the intersection of vertical lines

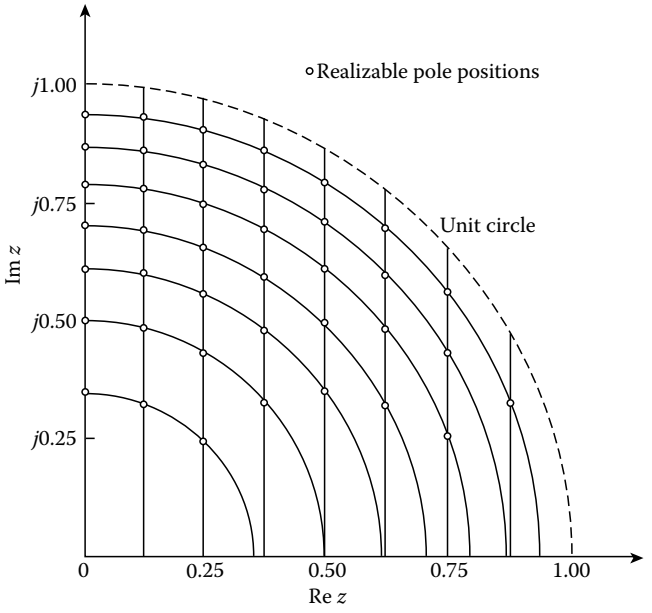

FIGURE 20.3 Realizable pole locations for the difference Equation of 20.76.

corresponding to quantization of $2\lambda_r$ and concentric circles corresponding to quantization of $-r^2$. The sparseness of realizable pole locations near $z = \pm 1$ will result in a large coefficient quantization error for poles in this region.

Figure 20.4 gives an alternative structure to Equation 20.77 for realizing the transfer function of Equation 20.76. Notice that quantizing the coefficients of this structure corresponds to quantizing λ_r and λ_i. As shown in Figure 20.5 from Ref. [5], this results in a uniform grid of realizable pole locations. Therefore, large coefficient quantization errors are avoided for all pole locations.

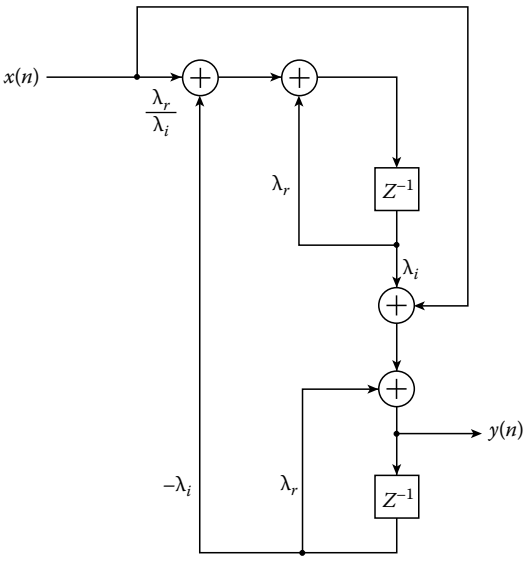

FIGURE 20.4 Alternate realization structure.

It is well established that filter structures with low roundoff noise tend to be robust to coefficient quantization, and vice versa [22–24]. For this reason, the uniform grid structure of Figure 20.4 is also popular because of its low roundoff noise. Likewise, the low-noise realizations of Ref. [7–10] can be expected to be relatively insensitive to coefficient quantization, and digital wave filters and lattice filters that are derived from low-sensitivity analog structures tend to have not only low coefficient sensitivity, but also low roundoff noise [25,26].

It is well known that in a high-order polynomial with clustered roots, the root location is a very sensitive function of the polynomial coefficients. Therefore, filter poles and zeros can be much more accurately controlled if higher order filters are realized by breaking them up into the parallel or cascade connection of first- and second-order subfilters. One exception to this rule is the case of linear-phase

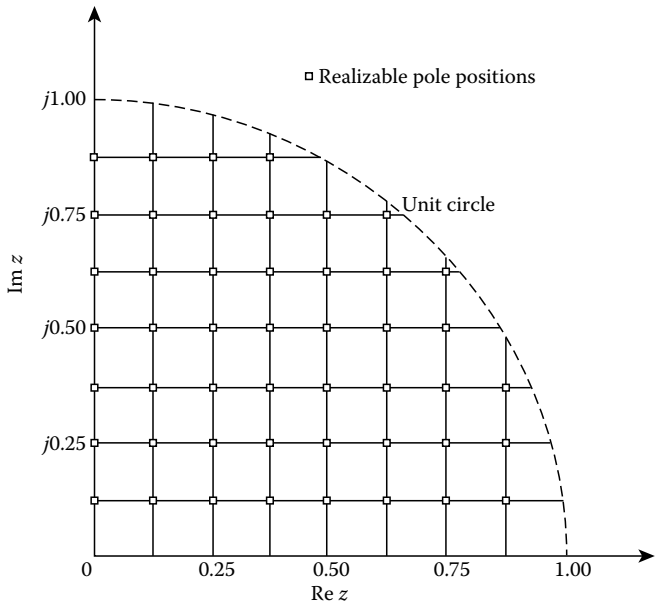

FIGURE 20.5 Realizable pole locations for the alternate realization structure.

FIR filters in which the symmetry of the polynomial coefficients and the spacing of the filter zeros around the unit circle usually permits an acceptable direct realization using the convolution summation.

Given a filter structure it is necessary to assign the ideal pole and zero locations to the realizable locations. This is generally done by simply rounding or truncating the filter coefficients to the available number of bits, or by assigning the ideal pole and zero locations to the nearest realizable locations. A more complicated alternative is to consider the original filter design problem as a problem in discrete optimization, and choose the realizable pole and zero locations that give the best approximation to the desired filter response [27–30].

20.8 Realization Considerations

Linear-phase FIR digital filters can generally be implemented with acceptable coefficient quantization sensitivity using the direct convolution sum method. When implemented in this way on a digital signal processor, fixed-point arithmetic is not only acceptable but may actually be preferable to floating-point arithmetic. Virtually all fixed-point digital signal processors accumulate a sum of products in a double-length accumulator. This means that only a single quantization is necessary to compute an output. Floating-point arithmetic, on the other hand, requires a quantization after every multiply and after every add in the convolution summation. With 32-b floating-point arithmetic these quantizations introduce a small enough error to be insignificant for many applications.

When realizing IIR filters, either a parallel or cascade connection of first- and second-order subfilters is almost always preferable to a high-order direct-form realization. With the availability of very low-cost floating-point digital signal processors, like the Texas Instruments TMS320C32, it is highly recommended that floating-point arithmetic be used for IIR filters. Floating-point arithmetic simultaneously eliminates most concerns regarding scaling, limit cycles, and overflow oscillations. Regardless of the arithmetic employed, a low roundoff noise structure should be used for the second-order sections. Good choices are given in Refs. [2,10]. Recall that realizations with low fixed-point roundoff noise also have low floating-point roundoff noise. The use of a low roundoff noise structure for the second-order

sections also tends to give a realization with low coefficient quantization sensitivity. First-order sections are not as critical in determining the roundoff noise and coefficient sensitivity of a realization, and so can generally be implemented with a simple direct form structure.

21.1 Introduction

Digital implementations of filters are preferred over analog realizations for many reasons. Improvements in VLSI technology have enabled digital filters to be used in an increasing number of application domains.

There are a variety of methods that can be used to implement digital filters. In this chapter we focus on the use of traditional VLSI digital logic families such as CMOS, rather than more exotic approaches. The vast majority of implementations encountered in practice make use of traditional technologies because the performance and cost characteristics of these approaches are so favorable.

Digital filter implementations can be classified into several categories based on the architectural approach used: general purpose, special purpose, and programmable logic implementations. The choice of a particular approach should be based upon the flexibility and performance required by a particular application. General-purpose architectures possess a great deal of flexibility, but are somewhat limited in performance, being best suited for relatively low sampling frequencies, usually under 10 MHz. Special-purpose architectures are capable of much higher performance, with sampling frequencies as high as 1 GHz, but are often only configurable for one application domain. Programmable logic implementations lie somewhere between these extremes, providing both flexibility and reasonably high performance, with sampling rates as high as 200 MHz.

Digital filtering implementations have been strongly influenced by evolution of VLSI technology. The regular computational structures encountered in filters are well suited for VLSI implementation. This regularity often translates into efficient parallelism and pipelining. Further, the small set of computational structures required in digital filtering makes automatic synthesis of special-purpose and programmable logic designs feasible. The design automation of digital filter implementation is relatively simple

compared to the general design synthesis problem. For this reason, digital filters are often the test case for evaluating new device and computer-aided design technologies.

21.2 General-Purpose Processors

General-purpose digital signal processors are by far the most commonly used method for digital filter implementation, particularly at audio bandwidths. These systems possess architectures well suited to digital filtering, as well as other digital signal processing (DSP) algorithms.

21.2.1 Historical Perspective

General-purpose digital signal processors trace their lineage back to the microprocessors of the early 1980s. The generic microprocessors of that period were ill suited for the implementation of DSP algorithms, due to the lack of hardware support for numerical algorithms of significant complexity in those architectures. The primary requirement for DSP implementation was identified to be hardware support for multiplication, due to the large number of multiply-accumulate (MAC) operations in DSP algorithms and their large contribution to computational delays. The earliest widely available single chip general-purpose DSP implementation was from AT&T, which evolved into the AT&T DSP20 family. Products such as the Texas Instruments TMS32010 and NEC 7720 soon followed this. The early DSP chips exhibited several shortcomings, such as difficult programming paradigms, awkward architectures for many applications, and limited numerical precision. Many of these difficulties were imposed by the limits of the VLSI technology of the time, and some by inexperience in this particular application area. Despite these shortcomings, however, the early processors were well suited to the implementation of digital filter algorithms, because digital filtering was identified as one of the target areas for these architectures. This match between architecture and algorithms continues to be exhibited in current general-purpose DSP chips.

21.2.2 Current Processors

There are a variety of general-purpose digital signal processors currently commercially available. We will look at several of the most common architectural families in detail, although this discussion will not be comprehensive by any means. The processors are best classified into two categories, fixed-point processors and floating-point processors. In both cases, these architectures are commonly (although not exclusively) based on a single arithmetic unit shared among all computations, which leads to constraints on the sampling rates that may be attained.

Fixed-point processors exhibit extremely high performance in terms of maximum throughput as compared to their floating-point counterparts. In addition, fixed-point processors are typically inexpensive as compared to floating-point options, due to the smaller integrated circuit die area occupied by fixed-point processing blocks. A major difficulty encountered in implementing filters on fixed-point processors is that overflow and underflow need to be prevented by careful attention to scaling, and round-off effects may be significant.

Floating-point processors, on the other hand, are significantly easier to program, particularly in the case of complex algorithms, at the cost of lower performance and larger die area. Given the regular structure of most digital filtering algorithms and computer-aided design support for filters based on limited precision arithmetic, fixed-point implementations may be the more cost effective option for this type of algorithm. Because of the prevalence of both types of general-purpose processor, examples of each will be examined in detail.

Two widely used floating-point processor families will be studied, although there are many contenders in this field. These families are the Texas Instruments family of floating-point DSPs, in particular the TI TMS320C3x (TI, 1992) family, and the Analog Devices ADSP-21020 family (Schweber, 1993). More

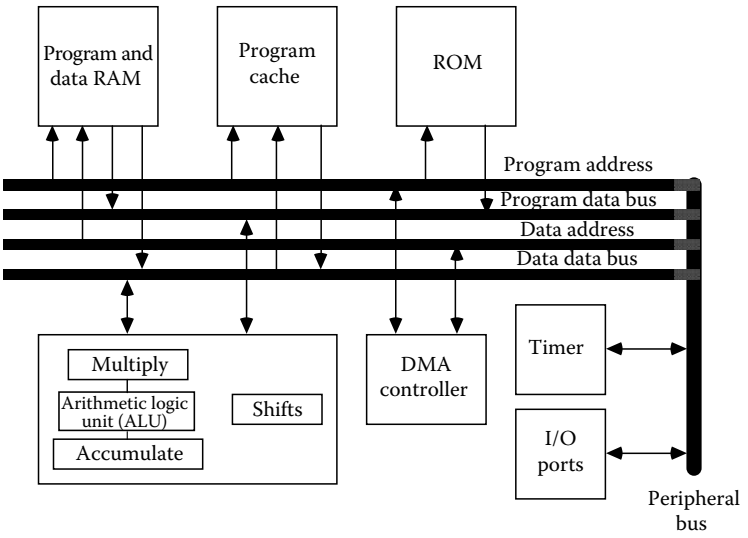

FIGURE 21.1 Texas Instruments TMS320C30 architecture.

recent examples of the TI family are the TMS320C67x DSP chips (TI, 2006a), and more recent Analog Devices parts are the ADSP-2116x SHARC chips (Analog Devices, 2006).

The architecture of the TI TMS320C30 is illustrated in Figure 21.1. The floating-point word size used by this processor was 32 bits. The most prominent feature of this chip was the floating-point arithmetic unit, which contains a floating-point multiplier and adder. This unit was highly pipelined to support high throughput, at the cost of latency; when data is input to the multiplier, for example, the results will not appear on the output from that unit until several clock cycles later. Other features included a separate integer unit for control calculations, and significant amounts (2k words) of SRAM for data and on-chip instruction memory. On-chip ROM (4k words) was also optionally provided in order to eliminate the need for an external boot ROM in some applications. This chip also included a 64-word instruction cache to allow its use with lower speed memories. The modified Harvard architecture, that is, the separate data and instruction buses, provided for concurrent instruction and data word transfers within one cycle time. The TMS320C30 offered instruction cycle times as low as 60 ns. A code segment which implements portions of an finite impulse response (FIR) filter on this device was

```
    RPTS   RC
    MPYF3  *AR0++(1),*AR1++(1)%,R0
||  ADDF3  R0,R2,R2
    ADDF   R0,R2,R0
```

where the `MPYF3` instruction performs a pipelined multiply operation in parallel with data and coefficient pointer increments. The `ADDF3` instruction is performed in parallel with the `MPYF3` instruction, as denoted by the "||" symbol. Because these operations are in parallel, only one instruction cycle per tap is required. An FIR filter tap was benchmarked at 60 ns on this chip. Similarly, a typical biquad infinite impulse response (IIR) filter code segment was

```
MPYF3  *AR0,*AR1,R0
MPYF3  *++AR0(1),*AR1--(1)%,R1
MPYF3  *++AR0(1),*AR1,R0
```

```
||  ADDF3  R0,R2,R2
    MPYF3  *++AR0(1),*AR1--(1)%,R0
||  ADDF3  R0,R2,R2
    MPYF3  *++AR0(1),R2,R2
||  STF    R2,*AR1++(1)%
    ADDF   R0,R2
    ADDF   R1,R2,R0
```

where the MPYF3 and ADDF3 instructions implement the primary filter arithmetic and memory pointer modification operations in parallel, as in the previous example. The biquad IIR benchmark on this processor was 300 ns. More recent members of the TI floating-point family such as the TMS320C6727 support two parallel FIR filter taps at 2.86 ns and two IIR biquad sections at 106 ns.

Another floating-point chip worthy of note is the Analog Devices ADSP-21020 series. The architecture of the ADSP-21020 chip is shown in Figure 21.2. This chip can be seen to share a number of features with the TMS320C3x family, that is, a 32 bit by 32 bit floating-point MAC unit (not pipelined), modified Harvard architecture, and 16 words of on-chip memory. In this case, the scratchpad memory was organized into register files, much like a general-purpose RISC architecture register set. The memory capacity of this device was significantly smaller than that of its competitors. As in the case of the TMS320C3x, on the other hand, an instruction cache (32 words) was also provided. The cycle time for the ADSP-21020 was 40 ns. An N tap FIR filter code segment illustrates the operation of this device,

```
        i0=coef;
        f9=0.0;
        f1=0; f4=dm(i0,m0); f5=pm(i8,m8);
        lcntr=N, DO bottom until lce;
bottom:     f1=f1+f9; f9=f4*f5; f4=dm(i0,m0); f5=pm(i8,m8);
        f1=f1+f9;
```

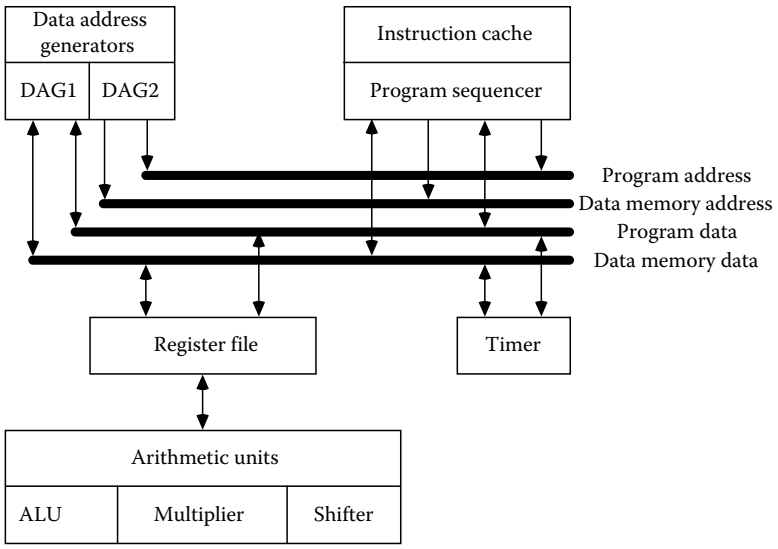

FIGURE 21.2 Analog devices ADSP-21020 architecture.

where the "*" and "+" instructions perform the MAC operations, and the dm() and pm() instructions perform the memory address update operations in parallel. An FIR filter tap thus executed in one instruction per tap on the ADSP-21020, or in 40 ns. An IIR filter biquad section required 200 ns on this chip. More recent members of this family such as the ADSP-21367 support FIR filter taps at 3 ns and IIR biquad sections at 60 ns. Note that while the assembly language for the Analog Devices chip was significantly different from that of the Texas Instruments chip, the architectural similarities are striking.

Two families of fixed-point digital signal processors will also be examined and compared. These are the Texas Instruments TMS320C5x family (TI, 1993) and the Motorola DSP56000 series of devices (Motorola, 1989). More recent examples of the TI family are the TMS320C62x DSP chips (TI, 2006b) and more recent Motorola parts are the DSP56300 series of chips (Motorola, 2007).

The Texas Instruments TMS320C5x series devices were high performance digital signal processors derived from the original TI DSP chip, the TMS32010, and its successor, the TMS320C2x. The architecture of the TMS320C50 is shown in Figure 21.3. This chip was based on the Harvard architecture, that is, separate data and instruction buses. This additional bandwidth between processing elements supported rapid concurrent transfers of data and instructions. This chip used a 16 bit by 16 bit fixed-point multiplier and a 32-bit accumulator, and up to 10k words on-chip scratchpad RAM. This architecture supported instruction rates of 50 ns. An FIR filter code segment is shown below, where the primary filter tap operations were performed by the `MACD` instruction,

```
RPTK  N
MACD  *-,COEFFP
```

This exhibits a general similarity with that for the TI floating-point chips, in particular a single instruction cycle per tap, although in this case a single instruction was executed as opposed to two parallel instructions on the TMS320C3x. The memory addressing scheme was also significantly different. An FIR filter on the TMS320C5x could thus be implemented in 25 ns per tap. An *N*th-order IIR filter code segment is show below, where the `MACD` and `AC` instructions performed the primary multiplication operations,

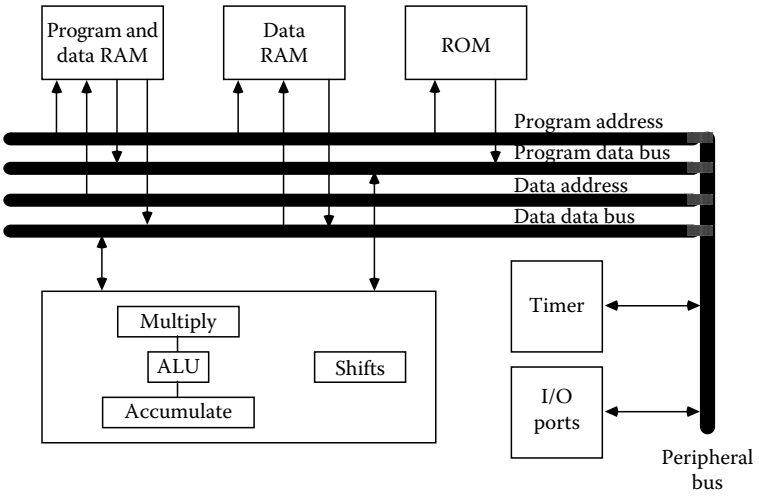

FIGURE 21.3 Texas Instruments TMS320C50 architecture.

```
ZPR
LACC  *,15,AR1
RPT   #(N−2)
AC    COEFFB,*−
APAC
SACH  *,1
ADRK  N−1
RPTZ  #(N-1)
MACD  COEFFA,*−
LTA   *,AR2
SACH  *,1
```

A single IIR biquad section could be performed in 250 ns on this chip. More recent members of the TI family such as the TMS320C6203C support two parallel FIR filter taps at 3.33 ns speeds and IIR biquad sections at 66.6 ns.

The Motorola 56001 series was a fixed-point architecture with 24-bit word size, as opposed to the smaller word sizes in most fixed-point DSP chips. The architecture of the 56001 is depicted in Figure 21.4. This chip shared many of the same features as other DSP chips, that is, Harvard architecture, on-chip scratchpad memory (512 words), and hardware MAC support, in this case 24 bit by 24 bit operators which form a 56 bit result. The instruction cycle time of the Motorola 56001 was 97.5 ns. An FIR filter implemented on the 56001 might use the code segment shown below,

```
MOVE  #AADDR, R0
MOVE  #BADDR+n, R4
NOP
```

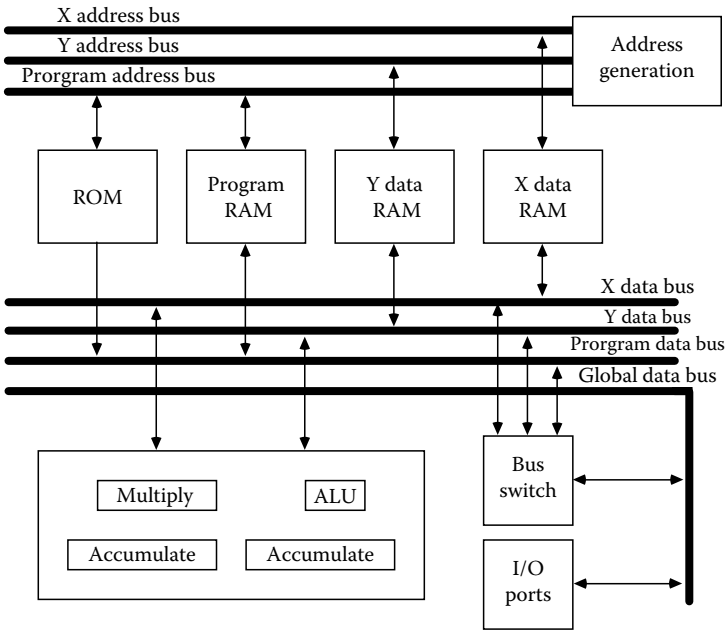

FIGURE 21.4 Motorola 56001 architecture.

```
CLR  A          X:(R0)+,X0  Y:(R4)-,Y0
REP  #N
MAC  X0,Y0,A    X:(R0)+,X0  Y:(R4)-,Y0
RND  A
```

where the MAC instruction retrieves data from the appropriate registers, loads it into the multiplier, and leaves the result in the accumulator. The 56001 could perform FIR filtering at a rate of one instruction per tap, or 97.5 ns per tap. An IIR filter code segment used the MAC instruction, as well as several others to set up the registers for the arithmetic unit, as shown below.

```
OR    #$08,MR
RND   A           X:(R0)-,X0    Y:(R4)+,Y0
MAC   -Y0,X0,A    X:(R0)-,X1    Y:(R4)+,Y0
MAC   -Y0,X1,A    X1,X:(R0)+    Y:(R4)+,Y0
MAC   Y0,X0,A     A,X:(R0)      Y:(R4),Y0
MAC   Y0,X1,A                   1
MOVE        A,X:OUTPUT
```

The 56001 could compute a second-order IIR biquad in seven instruction cycles, or 682.5 ns. More recent members of this family such as the DSP56L307 support FIR filter taps at an asymptotic speed of 6.25 ns and IIR biquad sections at 56.25 ns.

From these examples, it can be seen that general-purpose DSP processors possess many common features which make them well suited for digital filtering. The hardware MAC unit, Harvard architecture, and on-chip memory are consistent characteristics of these devices. The major shortcoming of such architectures for digital filtering is the necessity to multiplex a single arithmetic unit (or very small number of ALUs), which implies that sampling rates above $1/NT$ are not possible, where N is the number of atomic operations (e.g., FIR filter taps) and T is the time to complete those operations.

21.2.3 Future Directions

Several trends have become apparent as VLSI technology has improved. One trend of note is the increasing use of parallelism, both on-chip and between chips. The support for multiprocessor communications in the TI TMS320C80 provides an avenue for direct parallel implementation of algorithms. Architectures based upon multiple fixed-point DSP processors on a single chip have also been fielded.

Another trend has been the development of better programming interfaces for the general-purpose chips. In particular, high level language compilers have improved to the point where they provide for reasonably good performance for complex algorithms, although still not superior to that obtained by manual assembly language programming.

This trend is being accelerated by an initiative called GNURadio (GNU Radio, 2007), which is making it easier to implement all types of digital filters purely in software in order to enable creation of software radios. GNURadio provides signal processing blocks implemented in C++ that are connected together to form a complete communications system. The advantage of this software implementation is that it is generally hardware independent and can run on any general-purpose processor, opening up the world of digital implementations to anyone with a PC. The added flexibility comes at a loss of efficiency. Due to the generalized nature of the hardware independent system, the computations will not be implemented as efficiently as they would be if written in assembly for a specific processor. An IIR filter code segment from the GNURadio project is shown below:

```
acc=d_fftaps[0] * input;
for (i=1; i<n; i++)
  acc += (d_fftaps[i] * d_prev_input[latest+i]
        + d_fbtaps[i] * d_prev_output[latest+i]);
```

This C++ code segment from the GNURadio library implement a direct form 1 IIR filter where fftaps are the feed-forward taps and fbtaps are the feed-back taps. To use the GNURadio software for practical signal analysis, some sort of analog to digital apparatus is required. This can be as simple as a standard PC sound card or as complex as the universal software radio peripheral (USRP), which is sold by the maintainers of the GNURadio project as an RF front end that contains an onboard field programmable gate arrays (FPGA) and several optional daughter boards for the frequency band of interest (USRP, 2007).

Another trend that is worthy of note is the development of low-power DSP implementations. These devices are targeted at the wireless personal communications system (PCS) marketplace, where minimum power usage is critical. The developments in this area have been particularly striking, given the strong dependence of power consumption on clock frequency, which is usually high in DSP implementations. Through a combination of careful circuit design, power supply voltage reductions, and architectural innovations, extremely low power implementations have been realized.

A final trend is related to the progress of general-purpose processors relative to DSP chips. The evolution of general-purpose DSP implementations may have come full circle, as general-purpose processors such as the Intel Pentium family and digital equipment company (DEC) Alpha family possess on-chip floating-point multiplication units, as well as memory bandwidths equaling or exceeding that of the DSP chips. These features are reflected in the performance of these chips on standard benchmarks (Stewart et al., 1992), in which the DEC Alpha outperforms the fastest DSP engines. Similar results were obtained from the Pentium upon the implementation of the MMX capabilities; even older Pentium chipsets outperform most floating-point and fixed-point DSP chips (BTDI, 2000).

These trends, particularly multiple processor parallelism and general-purpose ease of programming, are illustrated by the Cell Broadband Engine Architecture developed via a joint effort between Sony, Toshiba, and IBM (IBM, 2007). The Cell combines a standard Power architecture core with streamlined coprocessing components, with the first major use of the Cell being in Sony's Playstation 3 console. It was designed to bridge the gap between general-purpose processors and more specialized high-performance processors. The architecture consists of a main processor called the power processing element (PPE), eight coprocessors called the synergistic processing elements (SPEs), and a high-bandwidth bus connecting all of these elements. The PPE is able to run a conventional operating system because of its Power Architecture core, and has control over the eight SPEs allowing high performance and mathematically intensive tasks to be achieved.

21.3 Special-Purpose Implementations

The tremendous growth in the capabilities of VLSI technology and the corresponding decrease in the fabrication costs have lead to the wide availability advent of application-specific integrated circuits (ASICs). These devices are tailored to a particular application or domain of applications in order to provide the highest possible performance at low per-unit costs.

Although it is difficult to generalize, special-purpose implementations share some common features. The first is the high degree of parallelism in these designs. For example, a typical special-purpose FIR filter implementation will contain tens or hundreds of MAC units, each of which executes a filter tap operation at the same time. This is in contrast to most general-purpose architectures, in which a single MAC unit is shared. Another common feature is extensive pipelining between arithmetic operators; this leads to high sampling rates and high throughput, at some cost in latency. Finally, these implementations are often lacking in flexibility, being designed for specific application domains. The number of filter taps

may be fixed, or the filter coefficients themselves may be fixed. In almost all instances, these implementations are based on fixed-point arithmetic.

Because the implementation cost of multiplication operations is so large compared to other operations, significant research effort has been expended on developing fast and efficient multiplier architectures, as well as digital filter design techniques that can be used to reduce the number of multiplications. A large number of multiplier architectures have been developed, ranging from bit-serial structures to bit and word level pipelined array designs (Ma and Taylor, 1990). The most appropriate architecture is a function of the application requirements, as various area versus speed options are available. The other major research direction is the minimization of multiplication operations. In this case, multiplications are eliminated by conscientious structuring of the realization, as in linear phase filters, circumvented by use of alternate number systems such as the residue number system (RNS), or simplified to a limited number of shift-and-add operations. The later option has been used successfully in a large number of both FIR and IIR realizations, some of which will be discussed below.

Historically, bit-serial implementations of digital filters have been of some interest to researchers and practitioners in the early days of VLSI because of the relatively high cost of silicon area devoted to both devices and routing (Denyer and Renshaw, 1985). Even in primitive technologies, bit-serial implementations could exploit the natural parallelism in digital filtering algorithms.

As clock rates have risen, and silicon area has become more economical, parallel implementations have become the most effective way of implementing high-performance digital filters. The concept of the systolic array has strongly influenced the implementation of both FIR and IIR filters (Kung, 1988). Systolic arrays are characterized by spatial and temporal locality, that is, algorithms and processing elements should be structured to minimize interconnection distances between nodes and to provide at least a single delay element between nodes. Interconnection distances need to be kept to a minimum to reduce delays associated with signal routing, which is becoming the dominant limiting factor in VLSI systems. Imposing pipeline delays between nodes minimizes computational delay paths and leads to high throughput.

These characteristic features of special-purpose digital filter designs will be illustrated by examples of FIR and IIR filter implementations. It should be noted that it is increasingly difficult to identify ASICs that only perform digital filtering; as VLSI capabilities increase, this functionality is more typically embedded with other functions in very application-focused devices.

21.3.1 FIR Filter Examples

FIR filters may be implemented in a number of ways, depending on application requirements. The primary factors that must be considered are the filter length, sampling rate, and area, which determine the amount of parallelism that can be applied. Once the degree of parallelism and pipelining are determined, the appropriate general filter structure can be determined.

A typical high-performance FIR filter implementation (Khoo et al., 1993) provided sampling rates of 180 MHz for 32 linear phase taps. This chip used canonical signed digit (CSD) coefficients. This representation is based on a number system in which the digits take the values $(-1, 0, 1)$. A filter tap can be implemented with a small number of these digits, and hence that tap requires a small number of shift-and-add operations. Each coefficient was implemented based on two bit shift-and-add units, as depicted in Figure 21.5. Delay elements are bypassed during configuration to allow realization of coefficients with additional bits. This chip also made use of extensive pipelining, carry-save addition, and advanced single-phase clocking techniques to provide high throughput.

In part due to the highly structured nature of FIR filtering algorithms, automatic design tools have been used to successfully implement high-performance FIR filters similar to that just presented. These methods often integrate the filter and architectural design into a unified process which can effectively utilize silicon area to provide the desired performance.

At the other extreme of performance was the Motorola 56200 FIR filter chip (Motorola, 1988) (Figure 21.6). This chip, although quite old, represents an approach to the custom implementation of

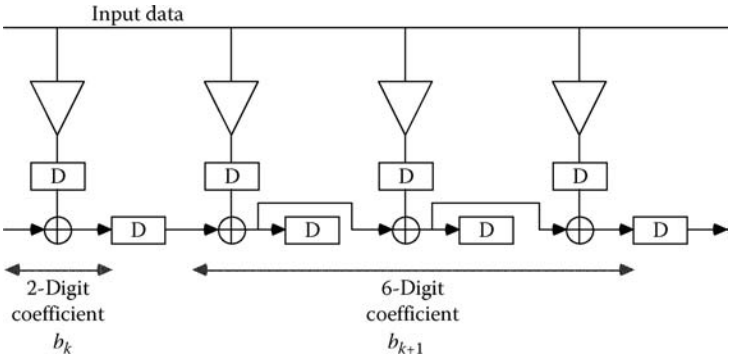

FIGURE 21.5 Custom FIR filter architecture for 180 MHz sampling rates.

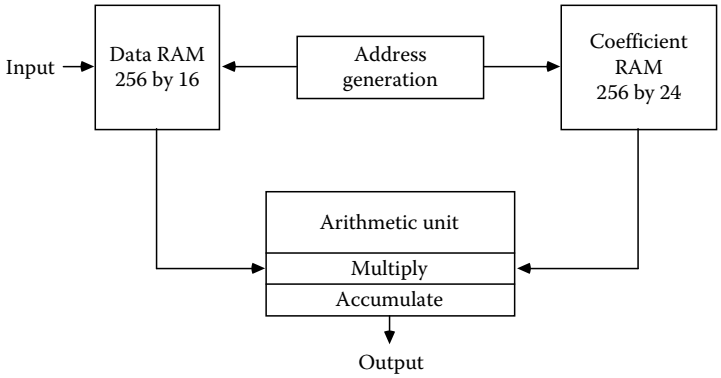

FIGURE 21.6 Motorola 56200 architecture.

long (several hundred taps) FIR filters. In this case, a single processing element was multiplexed among all of the filter taps, similar in concept to the approach used in general-purpose DSP processors. Due to the regularity of the filter structure, extensive pipelining in the arithmetic unit could be used to support a large number of taps at audio rates. This chip could be used to realize a 256 tap FIR filter at sampling rates up to 19 kHz, with higher performance for shorter filters. Longer filters could be implemented using cascaded processors.

A comparison of implementations (Hartley et al., 1989; Hatamian and Rao, 1990; Khoo et al., 1993; Laskowski and Samueli 1992; Ruetz, 1989; Yassa et al., 1987; Yoshino et al., 1990) illustrates the range of design and performance options. This is illustrated in Table 21.1, where the ''score'' is calculated

TABLE 21.1 FIR Filter ASIC Comparison

Design	Taps	Area (mm^2)	Rate (MHz)	Technology (μm)	Score
Khoo 93	32	20.1	180.0	1.2	495.2
Laskowski 92	43	40.95	150.0	1.2	139.3
Yoshino 90	64	48.65	100.0	0.8	33.68
Ruetz 89	64	225.0	22.0	1.5	21.12
Yassa 87	16	17.65	30.0 (est.)	1.25	53.12
Hartley 89	4	25.8 (est.)	37.0	1.25	11.20
Hatamian 90	40	22.0	100.0	0.9	132.5

according to the sampling rate multiplied by the number of taps per unit area, with normalization for the particular technology used. This simplistic comparison does not consider differences in word length or coefficient codings, but it does provide some insight into the results of the various design approaches. A significant number of other digital FIR filtering chips exist, both research prototypes and commercial products; this exposition only outlines some of the architectural options.

21.3.2 IIR Filter Examples

Custom IIR filter implementations are also most commonly based on parallel architectures, although there are somewhat fewer custom realizations of IIR filters than FIR filters. A significant difficulty in the implementation of high performance IIR filters in the need for feedback in the computation of an IIR filter section. This limits the throughput that can be attained to at least one MAC cycle in a straightforward realization. Another difficulty is the numerical stability of IIR filters with short coefficients, which makes aggressive quantization of coefficients less promising.

In order to address the difficulties with throughput limitation due to feedback, structures based on systolic concepts have been developed. Although the feedback problem imposes a severe constraint on the implementation, use of bit and word level systolic structures which pipeline data most significant digit first can minimize the impact of this restriction (Woods et al., 1990). Using these techniques, and a Signed Binary Number Representation (SBNR) similar to a CSD code, first-order sections with sampling rates of 15 MHz were demonstrated in a 1.5 μm standard cell process in an area of 21.8 mm^2. This particular design used fairly large coefficient and data words, however, at 12 bits and 11 bits, respectively.

The numerical stability problem has been addressed through a variety of techniques. One of these is based on minimizing limited precision effects by manipulation of traditional canonical filter structures and clever partitioning of arithmetic operations. A more recent and general approach is based on modeling the digital implementations of filters after their analog counterparts; these classes of filters are known as wave digital filters (WDFs) (Fettweis, 1986). WDFs exhibit good passband ripple and stopband attenuation, with high tolerance to limited wordlength effects. Because of the latter property, efficient implementations based on short word sizes are feasible. A WDF design for a second-order section in custom 1.5 μm CMOS based on a restricted coefficient set akin to CSD supported 10 MHz sampling rates in an area of 12.9 mm^2 (Wicks and Summerfield, 1993).

21.3.3 Future Trends

The future trends in digital filter implementation appear to be a fairly straightforward function of the increasing capability of VLSI devices. In particular, more taps and filter sections per chip and higher sampling rates are becoming achievable. Related to these trends are higher degrees of on-chip parallelism. Further, programmability is more reasonable as density and speed margins increase, although there is still a high cost in area and performance. Finally, special-purpose implementations show extraordinary promise in the area of low power systems, where custom circuit design techniques and application-specific architectural features can be combined to best advantage.

21.4 Programmable Logic Implementations

The rapid evolution of VLSI technology has enabled the development of several high-density programmable logic architectures. There are several novel features that make these devices of interest beyond their traditional field-of-state machine implementation. In particular, the density of the largest of these devices is over 12,000,000 gates (Xilinx, 2007), which encompasses the level of complexity found in the majority of ASICs (although some ASICs are significantly more complex). This level of complexity is sufficient to support many designs that would traditionally need to be implemented as ASICs. The speed of

programmable logic devices (PLDs) and FPGAs is quite reasonable, with toggle rates on the order of 550 MHz (Xilinx, 2007). While this is not as great as custom implementations, it does allow many applications to be realized in this new technology.

One of the most significant features of FPGA implementations is the capability for in-system reprogrammability in many FPGA families. Unlike traditional field programmable parts based on anti-fuse technology and which can only be programmed once, many of the new architectures are based on memory technology. This means that entirely new computational architectures can be implemented simply by reprogramming the logic functions and interconnection routing on the chip. Ongoing research efforts have been directed toward using FPGAs as generalized coprocessors for supercomputing and signal processing applications.

The implications of programmable device technology for filter implementation are significant. These devices provide an enormous amount of flexibility, which can be used in the implementation of a variety of novel architectures on a single chip. This is particularly useful for rapid prototyping of digital filtering algorithms, where several high-performance designs can be evaluated in a target environment on the same hardware platform. Further, complex adaptive systems based on this technology and which use a variety of signal processing and digital filter techniques are becoming increasingly popular in a variety of applications.

Because many of the programmable logic architectures are based on SRAM technology, the density of these devices can be expected to grow in parallel with the RAM growth curve, that is, at approximately 60% per year. Further, since these devices may be used for a large variety of applications, they have become high-volume commodity parts, and hence prices are relatively low compared to more specialized and low-volume DSP chips. This implies that new DSP systems that were not previously technically and economically feasible to implement in this technology are now feasible.

One of the extra costs of this approach, as opposed to the full custom strategy, is the need for support chips. Several chips are typically needed, including memory to store the programmable device configuration, as well as logic to control the downloading of the program. These issues are generally outweighed by the flexibility provided by programmable solutions.

We will next examine the implementation of several FIR and IIR digital filtering architectures based on FPGAs.

21.4.1 FIR Filter Implementations

Several approaches to the FPGA implementation of FIR filters can be taken. Due to the flexibility of these parts, switching from one architecture to the next only requires reprogramming the device, subject to constraints on I/O pin locations. Two fundamental strategies for realizing FIR filters will be illustrated here, one which is suited to relatively short filters (or longer filters cascaded across several chips) operating at high rates, and another which is suited for longer filters at lower rates.

A high-performance FIR filter example (Evans, 1993), illustrated in Figure 21.7, was based on the observation that since the entire device is reprogrammable, architectures in which filter coefficient multiplications are implemented as ''hardwired'' shifts can be easily reconfigured depending on the desired filter response. In this example, each of the coefficients was represented in a CSD code with a limited number of nontrivial (e.g., nonzero) bits, which allowed each tap to be implemented as a small number of shift-and-add operations. A filter tap could be implemented in two columns of logic blocks on a Xilinx 3100-series FPGA (Xilinx, 1993), where the two columns of full adders and associated delays implement a tap based on CSD coefficients with two nontrivial bits. With this architecture, up to 11 taps could be implemented on a single Xilinx XC3195 FPGA at sampling rates of above 40 MHz. Longer filters could be implemented by a cascade of FPGA devices.

An FIR filter architecture for longer filters was based upon implementation of several traditional MAC units on one chip, as shown in Figure 21.8. Each of these MAC units could then be shared among a large number of filter tap computations, much as the single MAC unit in the Motorola 56200 was multiplexed.

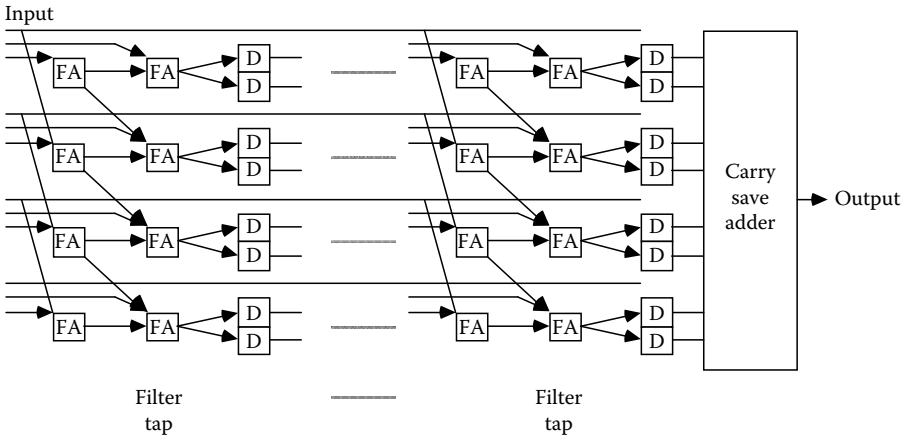

FIGURE 21.7 High-performance FIR architecture on FPGAs.

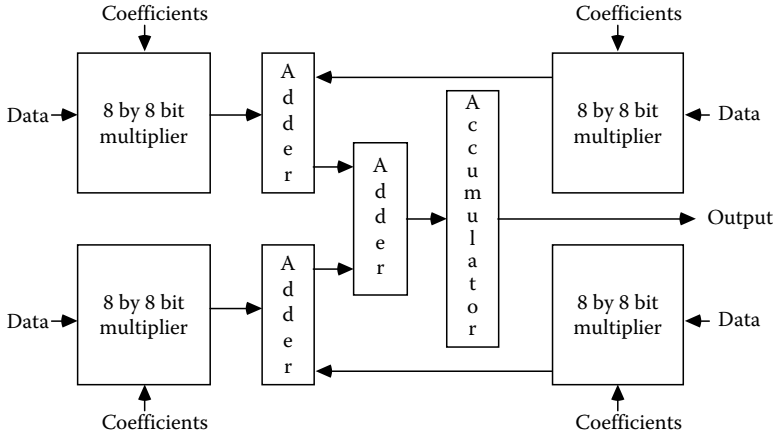

FIGURE 21.8 FIR architecture on FPGAs for large number of taps.

Since four multipliers could be implemented in the Xilinx 4000-series, the inherent parallelism of FIR filters can be exploited to support sampling rates of up to 1.25 MHz for 32 taps in that technology.

21.4.2 IIR Filter Implementations

As in the case of FIR filters, IIR filters can be implemented using a ''hardwired'' architecture suited to high performance, or a more traditional approach based on general MAC units. In the case of IIR filters, however, the hardwired implementation is significantly more desirable than the alternate approach due to the difficulty in rescheduling multiplexed processing elements in a system with feedback.

An architecture which is reconfigured to implement different filters will generally provide both high-performance and good area efficiency. An example of such a system is shown in Figure 21.9, in which two IIR biquad sections were implemented on a single FPGA using a traditional canonical filter structure (Chou et al., 1993). Each of the columns realized a shift-and-add for one nontrivial bit of a coefficient, where the shaded blocks also contained delay registers. This implementation yielded sampling rates of better than 10 MHz for typical coefficients.

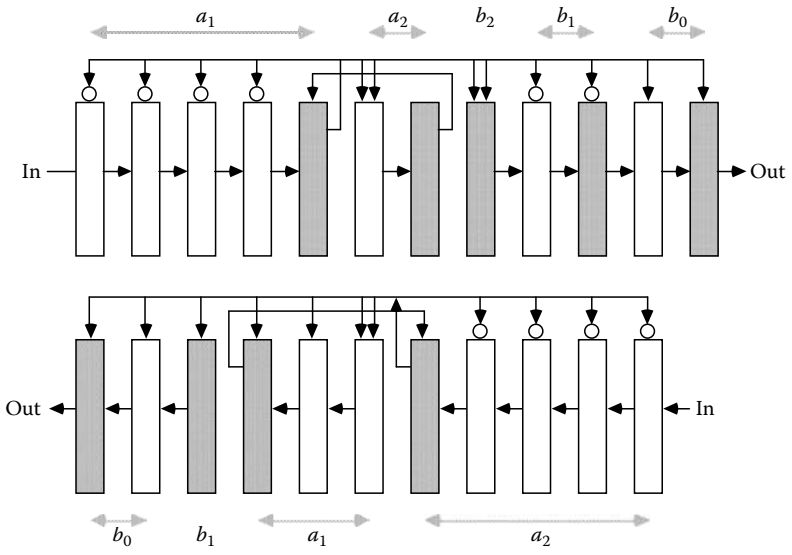

FIGURE 21.9 High-performance IIR architecture on FPGAs.

A more traditional approach to the realization of IIR filters using MAC units is also possible, but may be less efficient. The general architecture is similar to that of the FIR filter in Figure 21.8, with slight modifications to the routing between arithmetic units and support for scaling necessary in an IIR biquad section.

21.4.3 Future Trends

Because of the rapid advances in FPGA technology, higher performance digital filtering may in fact be possible with programmable logic than with typical custom ASIC approaches (Moeller, 1999). In addition, there are a wide variety of DSP core functions being offered by FPGA manufacturers (Xilinx, 2000) which will further accelerate this revolution in DSP implementation.

22.1 Introduction

In this chapter, methods of designing two-dimensional (2-D) finite-extent impulse response (FIR) discrete-time filters are described. 2-D FIR filters offer the advantages of phase linearity and guaranteed stability, which makes them attractive in applications. Over the years an extensive array of techniques for designing 2-D FIR filters has been accumulated [14,23,30]. These techniques can be conveniently classified into the two categories of general and specialized designs. Techniques in the category of general design are intended for approximation of *arbitrary* desired frequency responses usually with no structural constraints on the filter. These techniques include approaches such as windowing of the ideal impulse response (IIR) [22] or the use of suitable optimality criteria possibly implemented with iterative algorithms. On the other hand, techniques in the category of special design are applicable to restricted classes of filters, either due to the nature of the response being approximated or due to imposition of structural constraints on the filter used in the design. The specialized designs are a consequence of the observation that commonly used filters have characteristic underlying features that can be exploited to simplify the problem of design and implementation. The stopbands and passbands of filters encountered

in practice are often defined by straight-line, circular, or elliptical boundaries. Specialized design methodologies have been developed for handling these cases and they are typically based on techniques such as the transformation of one-dimensional (1-D) filters or the rotation and translation of separable filter responses. If the desired response possesses symmetries, then the symmetries imply relationships among the filter coefficients, which are exploited in both the design and the implementation of the filters. In some design problems it may be advantageous to impose structural constraints in the form of parallel and cascade connections.

The material in this chapter is organized as follows. A preliminary discussion of characteristics of 2-D FIR filters and issues relevant to the design methods appears in Section 22.2. Following this, methods of general and special FIR filter design are described in Sections 22.3 and 22.4, respectively. Several examples of design illustrating the procedure are also presented. Issues in 2-D FIR filter implementation are briefly discussed in Section 22.5. Finally, two-dimensional filter banks are briefly discussed in Section 22.6, and a list of sources for further information is provided.

22.2 Preliminary Design Considerations

In any 2-D filter design there is a choice between FIR and IIR filters, and their relative merits are briefly examined next. 2-D FIR filters offer certain advantages over 2-D IIR filters as a result of which FIR filters have found widespread use in applications such as image and video processing. One key attribute of an FIR filter is that it can be designed with strictly linear passband phase, and it can be implemented with small delays without the need to reverse the signal array during processing. A 2-D FIR filter impulse response has only a finite number of nonzero samples which guarantee stability. On the other hand, stability is difficult to test in the case of 2-D IIR filters due to the absence of a 2-D counterpart of the fundamental theorem of algebra, and a 2-D polynomial is almost never factorizable. If a 2-D FIR filter is implemented nonrecursively with finite precision, then it does not exhibit limit cycle oscillations. Arithmetic quantization noise and coefficient quantization effects in FIR filter implementation are usually very low. A key disadvantage of FIR filters is that they typically have higher computational complexity than IIR filters for meeting the same magnitude specifications, especially in cases where the specifications are stringent.

The term 2-D FIR filter refers to a linear shift-invariant system whose input–output relation is represented by a convolution [14]

$$y(n_1, n_2) = \sum_{(k_1,k_2)\in} \sum_{I} h(k_1, k_2)x(n_1 - k_1, n_2 - k_2), \tag{22.1}$$

where

$x(n_1, n_2)$ and $y(n_1, n_2)$ are the input and the output sequences, respectively
$h(n_1, n_2)$ is the impulse response sequence
I is the support of the impulse response sequence

FIR filters have compact support, meaning that only a finite number of coefficients are nonzero. This makes the impulse response sequence of FIR filters absolutely summable, thereby ensuring filter stability. Usually the filter support, I, is chosen to be a rectangular region centered at the origin, e.g., $I = \{(n_1, n_2)$: $-N_1 \le n_1 \le N_1$, $-N_2 \le n_2 \le N_2\}$. However, there are some important cases where it is more advantageous to select a nonrectangular region as the filter support [32].

Once the extent of the impulse response support is determined, the sequence $h(n_1, n_2)$ should be chosen in order to meet given filter specifications under suitable approximation criteria. These aspects are elaborated in Section 22.2.1. This is followed by a discussion of phase linearity and filter response symmetry considerations and then some guidelines on using the design methods are provided (Sections 22.2.2 and 22.2.3).

22.2.1 Filter Specifications and Approximation Criteria

The problem of designing a 2-D FIR filter consists of determining the impulse response sequence, $h(n_1, n_2)$, or its system function, $H(z_1, z_2)$, in order to satisfy given requirements on the filter response. The filter requirements are usually specified in the frequency domain, and only this case is considered here. The frequency response,* $H(\omega_1, \omega_2)$, corresponding to the impulse response $h(n_1, n_2)$, with a support, I, is expressed as

$$H(\omega_1, \omega_2) = \sum_{(n_1, n_2) \in I} h(n_1, n_2) e^{-j(n_1\omega_1 + n_2\omega_2)}. \tag{22.2}$$

Note that $H(\omega_1, \omega_2) = H(\omega_1 + 2\pi, \omega_2) = H(\omega_1, \omega_2 + 2\pi)$ for all (ω_1, ω_2). In other words, $H(\omega_1, \omega_2)$ is a periodic function with a period 2π in both ω_1 and ω_2. This implies that by defining $H(\omega_1, \omega_2)$ in the region $\{-\pi < \omega_1 \leq \pi, -\pi < \omega_2 \leq \pi\}$, the frequency response of the filter for all (ω_1, ω_2) is determined.

For 2-D FIR filters the specifications are usually given in terms of the magnitude response, $|H(\omega_1, \omega_2)|$. Attention in this chapter is confined to the case of a two-level magnitude design, where the desired magnitude levels are either 1.0 (in the passband) or 0.0 (in the stopband). Some of the procedures can be easily modified to accommodate multilevel magnitude specifications, as, for instance, in a case that requires the magnitude to increase linearly with distance from the origin in the frequency domain.

Consider the design of a 2-D FIR low-pass filter whose specifications are shown in Figure 22.1. The magnitude of the low-pass filter ideally takes the value 1.0 in the passband region, F_p, which is centered around the origin, $(\omega_1, \omega_2) = (0, 0)$, and 0.0 in the stopband region, F_s. As a magnitude discontinuity is not possible with a finite filter support, I, it is necessary to interpose a transition region, F_t, between F_p and F_s. Also, magnitude bounds $|H(\omega_1, \omega_2) - 1| \leq \delta_p$ in the passband and $|H(\omega_1, \omega_2)| \leq \delta_s$ in the stopband are specified, where the parameters δ_p and δ_s are positive real numbers, typically much less than 1.0. The frequency response $H(\omega_1, \omega_2)$ is assumed to be real. Consequently, the low-pass filter is specified in the frequency domain by the regions, F_p, F_s, and the tolerance parameters, δ_p and δ_s. A variety of stopband and passband shapes can be specified in a similar manner.

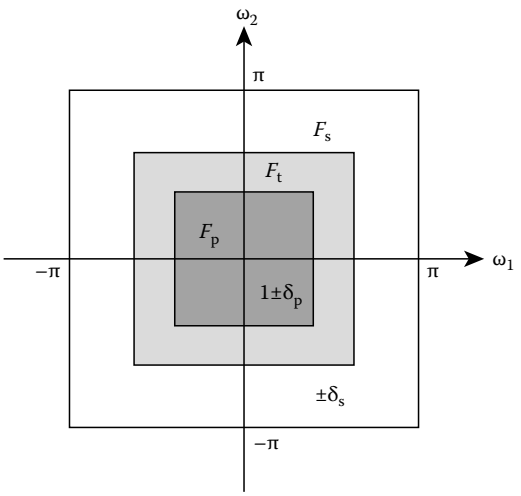

FIGURE 22.1 Frequency response specifications for a 2D low-pass filter ($|H(\omega_1, \omega_2) - 1| \leq \delta_p$ for $(\omega_1, \omega_2) \in F_p$ and $|H(\omega_1, \omega_2)| \leq \delta_s$ for $(\omega_1, \omega_2) \in F_s$).

In order to meet given specifications, an adequate filter order (defined here to be the number of nonzero impulse response samples) needs to be determined. If the specifications are stringent, with tight tolerance parameters and small transition regions, then the filter support region, I, must be large. In other words, there is a trade-off between the filter support region, I, and the frequency domain specifications. In the general case the filter order is not known *a priori*, and may be determined either through an iterative process or using estimation rules if available. If the filter order is given, then in order to determine an optimum solution to the design problem, an appropriate optimality criterion is needed. Commonly used criteria in 2-D filter design are minimization of the L_p norm, p finite, of the approximation error, or the L_∞ norm. If desired, a maximal flatness requirement at desired frequencies can be imposed

* Here $\omega_1 = 2\pi f_1$ and $\omega_2 = 2\pi f_2$ are the horizontal and vertical angular frequencies, respectively.

[24]. It should be noted that if the specifications are given in terms of the tolerance bounds on magnitude, as described above, then the use of L_∞ criterion is appropriate. However, the use of other criteria such as a weighted L_2 norm can serve to arrive at an almost minimax solution [2,10].

22.2.2 Zero-Phase FIR Filters and Symmetry Considerations

Phase linearity is important in many filtering applications. As in the 1-D case, a number of conditions for phase linearity can be obtained depending on the nature of symmetry. But the discussion here is limited to the case of ''zero phase'' design, with a purely real frequency response. A salient feature of 2-D FIR filters is that realizable FIR filters, which have purely real frequency responses, are easily designed. The term ''zero phase'' is somewhat misleading in the sense that the frequency response may be negative at some frequencies. The term should be understood in the sense of ''zero phase in passband'' because the passband frequency response is within a small deviation of the value 1.0. The frequency response may assume negative values in the stopband region where phase linearity is immaterial. In frequency domain, the zero-phase or real frequency response condition corresponds to

$$H(\omega_1, \omega_2) = H^*(\omega_1, \omega_2), \tag{22.3}$$

where $H^*(\omega_1, \omega_2)$ denotes the complex conjugate of $H(\omega_1, \omega_2)$. The condition Equation 22.3 is equivalent to

$$h(n_1, n_2) = h^*(-n_1, -n_2) \tag{22.4}$$

in the spatial-domain. Making a common practical assumption that $h(n_1, n_2)$ is real, the above condition reduces to

$$h(n_1, n_2) = h(-n_1, -n_2), \tag{22.5}$$

implying a region of support with the above symmetry about the origin.

Henceforth, only the design of zero-phase FIR filters is considered. With $h(n_1, n_2)$ real, and satisfying Equation 22.5, the frequency response, $H(\omega_1, \omega_2)$, is expressed as

$$\begin{aligned} H(\omega_1, \omega_2) &= h(0,0) + \sum_{(n_1, n_2) \in I_1} h(n_1, n_2) e^{-j(\omega_1 n_1 + \omega_2 n_2)} + \sum_{(n_1, n_2) \in I_2} h(n_1, n_2) e^{-j(\omega_1 n_1 + \omega_2 n_2)} \\ &= h(0,0) + \sum_{(n_1, n_2) \in I_1} 2h(n_1, n_2) \cos(\omega_1 n_1 + \omega_2 n_2), \end{aligned} \tag{22.6}$$

where I_1 and I_2 are disjoint regions such that $I_1 \cup I_2 \cup \{(0,0)\} = I$, and if $(n_1, n_2) \in I_1$, then $(-n_1, -n_2) \in I_2$.

In order to understand the importance of phase linearity in image processing, consider an example that illustrates the effect of nonlinear-phase filters on images. In Figure 22.2a, an image that is corrupted by white Gaussian noise is shown. This image is filtered with a nonlinear-phase low-pass filter and the resultant image is shown in Figure 22.2b. It is observed that edges and textured regions are severely distorted in Figure 22.2b. This is due to the fact that the spatial alignment of frequency components that define an edge in the original is altered by the phase nonlinearity. The same image is also filtered with a zero-phase low-pass filter, $H(\omega_1, \omega_2)$, which has the same magnitude characteristics as the nonlinear-phase filter. The resulting image is shown in Figure 22.2c. It is seen that the edges are perceptually preserved in Figure 22.2c, although blurred due to the low-pass nature of the filter. In this example, a separable zero-phase low-pass filter, $H(\omega_1, \omega_2) = H_1(\omega_1)\, H_1(\omega_2)$, is used, where $H_1(\omega)$ is a 1-D Lagrange filter with a cutoff $\pi/2$. In spatial domain $h(n_1, n_2) = h_1(n_1)\, h_1(n_2)$ where $h_1(n) = \{\ldots, 0, -1/32, 0, 9/32,$

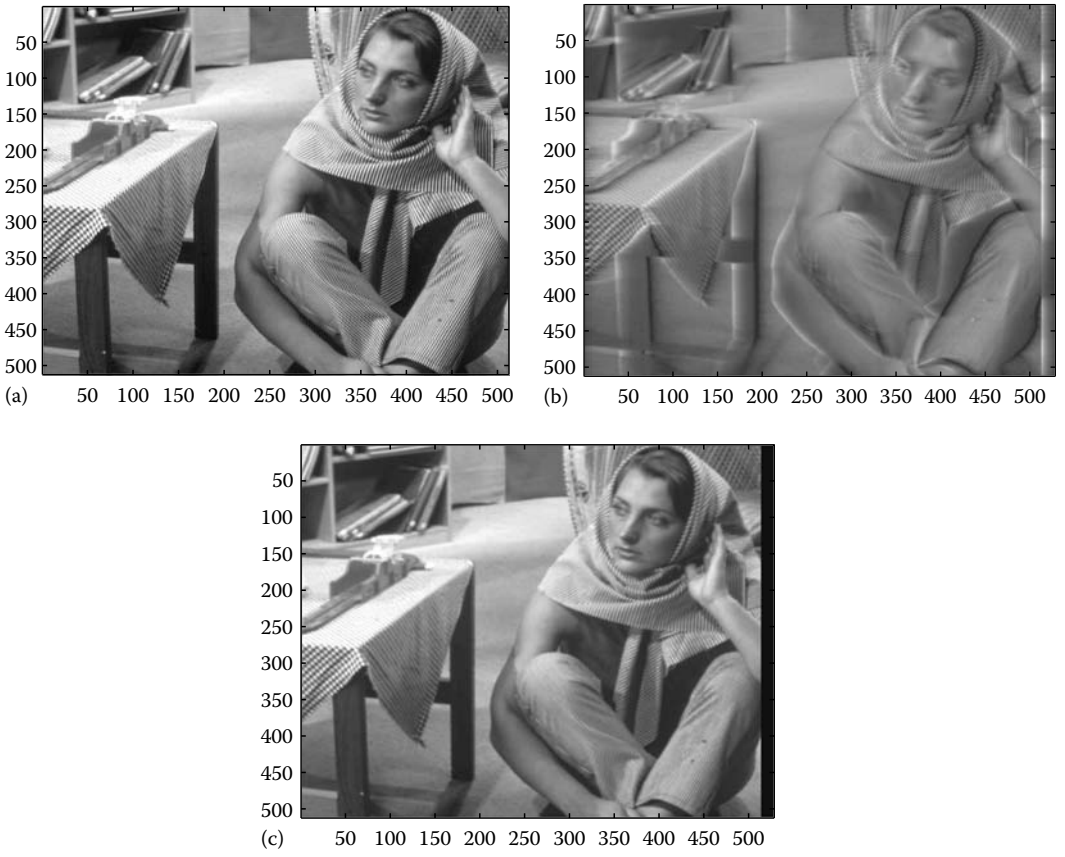

FIGURE 22.2 (a) Original image of 696×576 pixels; (b) nonlinear-phase low-pass filtered image; and (c) zero-phase low-pass filtered image.

$1/2, 9/32, 0, -1/32, 0, \ldots\}$ is the impulse response of the seventh-order symmetric (zero-phase) 1-D Lagrange filter. The nonlinear-phase filter is a cascade of the above zero-phase filter with an allpass filter.

In some filter design problems, symmetries in frequency domain specifications can be exploited by imposing restrictions on the filter coefficients and the shape of the support region for the impulse response. A variety of symmetries that can be exploited is extensively studied in Refs. [3,32,44,45]. For example, a condition often encountered in practice is the symmetry with respect to each of the two frequency axes. In this case, the frequency response of a zero-phase filter satisfies

$$H(\omega_1, \omega_2) = H(-\omega_1, \omega_2) = H(\omega_1, -\omega_2). \tag{22.7}$$

This yields an impulse response that is symmetric with respect to the n_1 and n_2 axes, i.e.,

$$h(n_1, n_2) = h(-n_1, n_2) = h(n_1, -n_2). \tag{22.8}$$

By imposing symmetry conditions, one reduces the number of independently varying filter coefficients that must be determined in the design. This can be exploited in reducing both the computational complexity of the filter design and the number of arithmetic operations required in the implementation.

22.2.3 Guidelines on the Use of the Design Techniques

The design techniques described in this chapter are classified into the two categories of general and specialized designs. The user should use the techniques of general design in cases requiring approximation of arbitrary desired frequency responses, usually with no structural constraints on the filter. The specialized designs are recommended in cases where filters exhibit certain underlying features that can be exploited to simplify the problem of design and implementation.

In the category of general design, four methods are described. Of these, the windowing procedure is quick and simple. It is useful in situations where implementation efficiency is not critical, especially in single-use applications. The second procedure is based on linear programming, and is suitable for design problems where equiripple solutions are desired to meet frequency domain specifications. The remaining two procedures may also be used for meeting frequency domain specifications, and lead to nearly equiripple solution. The third procedure provides solutions for L_p approximations. The fourth procedure is an iterative procedure that is easy to implement, and is convenient in situations where additional constraints are to be placed on the filter.

In the category of specialized design described here, the solutions are derived from 1-D filters. These often lead to computationally efficient implementation, and are recommended in situations where low implementation complexity is critical, and the filter characteristics possess features that can be exploited in the design. An important practical class of filters is one where specifications can be decomposed into a set of separable filter designs requiring essentially the design of suitable 1-D filters. Here the separable design procedure should be used. Another class of filters is one where the passbands and stopbands are characterized by circular, elliptical, or special straight-line boundaries. In this case a frequency transformation method called the McClellan transformation procedure proves effective. The desired 2-D filter constant-magnitude contours are defined by a proper choice of parameters in a transformation of variables applied to a 1-D zero-phase filter. Finally, in some cases filter specifications are characterized by ideal frequency responses in which passbands and stopbands are separated by straight-line boundaries that are not suitable for applying the McClellan transformation procedure. In this case the design may be carried out by nonrectangular transformations and sampling grid conversions. The importance of this design method stems from the implementation efficiency that results from a generalized notion of separable processing.

22.3 General Design Methods for Arbitrary Specifications

Some general methods of meeting arbitrary specifications are now described. These are typically based on extending techniques of 1-D design. However, there are important differences. The Parks–McClellan procedure for minimax approximation based on the alternation theorem does not find a direct extension. This is because the set of cosine functions used in the 2-D approximation does not satisfy the Haar condition on the domain of interest [25], and the Chebyshev approximation does not have a unique solution. However, techniques that employ exchange algorithms have been developed for the 2-D case [20,25,36].

Here we consider four procedures in some detail. The first technique is based on windowing. It is simple, but not optimum for Chebyshev approximation. The second technique is based on frequency sampling, and this can be used to arrive at equiripple solutions using linear programming. Finally, two techniques for arriving iteratively at a nearly equiripple solution are described. The first of these is based on L_p approximations using nonlinear optimization. The second is based on the use of alternating projections in the sample and the frequency domains.

22.3.1 Design of 2-D FIR Filters by Windowing

This design method is basically an extension of the window-based 1-D FIR filter design to the case of 2-D filters. An IIR sequence, which is usually an infinite-extent sequence, is suitably windowed to make the

support finite. 1-D FIR filter design by windowing and classes of 1-D windows are described in detail in Section 22.2.

Let $h_{\mathrm{id}}(n_1, n_2)$ and $H_{\mathrm{id}}(\omega_1, \omega_2)$ be the impulse and frequency responses of the ideal filter, respectively. The impulse response of the required 2-D filter, $h(n_1, n_2)$, is obtained as a product of the IIR sequence and a suitable 2-D window sequence which has a finite-extent support, I, that is,

$$h(n_1, n_2) = \begin{cases} h_{id}(n_1, n_2)w(n_1, n_2), & (n_1, n_2) \in I, \\ 0, & \text{otherwise}, \end{cases} \tag{22.9}$$

where $w(n_1, n_2)$ is the window sequence. The resultant frequency response, $H(\omega_1, \omega_2)$, is a smoothed version of the ideal frequency response as $H(\omega_1, \omega_2)$ is related to the $H_{\mathrm{id}}(\omega_1, \omega_2)$ via the periodic convolution, that is,

$$H(\omega_1, \omega_2) = \frac{1}{4\pi^2} \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} H_{\mathrm{id}}(\Omega_1, \Omega_2) W(\omega_1 - \Omega_1, \omega_2 - \Omega_2) \mathrm{d}\Omega_1 \mathrm{d}\Omega_2, \tag{22.10}$$

where $W(\omega_1, \omega_2)$ is the frequency response of the window sequence, $w(n_1, n_2)$.

As in the 1-D case, a 2-D window sequence, $w(n_1, n_2)$, should satisfy three requirements:

1. It must have a finite-extent support, I.
2. Its discrete-space Fourier transform should in some sense approximate the 2-D impulse function, $\delta(\omega_1, \omega_2)$.
3. It should be real, with a zero-phase discrete-space Fourier transform.

Usually 2-D windows are derived from 1-D windows. Three methods of constructing windows are briefly examined. One method consists of obtaining a separable window from two 1-D windows, that is,

$$w_{\mathrm{r}}(n_1, n_2) = w_1(n_1)w_2(n_2), \tag{22.11}$$

where $w_1(n)$ and $w_2(n)$ are the 1-D windows. Thus, the support of the resultant 2-D window, $w_{\mathrm{r}}(n_1, n_2)$, is a rectangular region. The frequency response of the 2-D window is also separable, i.e., $W_{\mathrm{r}}(\omega_1, \omega_2) = W_1(\omega_1)\ W_2(\omega_2)$.

The second method of constructing a window, due to Huang [22], consists of sampling the surface generated by rotating a 1-D continuous-time window, $w(t)$, as follows:

$$w_{\mathrm{c}}(n_1, n_2) = w\left(\sqrt{n_1^2 + n_2^2}\right), \tag{22.12}$$

where $w(t) = 0$, $t \geq N$. The impulse response support is $I = \left\{n_1, n_2 \colon \sqrt{n_1^2 + n_2^2} < N\right\}$. Note that the 2-D Fourier transform of the $w_{\mathrm{c}}(n_1, n_2)$ is not equal to the circularly rotated version of the Fourier transform of $w(t)$.

Finally, in the third method, proposed by Yu and Mitra [53], the window is constructed by using a 1-D to 2-D transformation belonging to a class called the McClellan transformations [33]. These transformations are discussed in greater detail in Section 22.4. Here we consider a special case of the transform that produces approximately circular contours in the 2-D frequency domain. Briefly, the discrete-space frequency transform of the 2-D window sequence obtained with a McClellan transformation applied to a 1-D window is given by

$$T(\omega_1, \omega_2) = \sum_{n=-N}^{N} w(n) e^{-j\omega n} \Big|_{\cos(\omega)=0.5\cos(\omega_1)+0.5\cos(\omega_2)+0.5\cos(\omega_1)\cos(\omega_2)-0.5}$$
$$= w(0) + 2\sum_{n=1}^{N} w(n)\cos(n\omega) \Big|_{\cos(\omega)=0.5\cos(\omega_1)+0.5\cos(\omega_2)+0.5\cos(\omega_1)\cos(\omega_2)-0.5}$$
$$= \sum_{n=0}^{N} b(n)\cos^n(\omega) \Big|_{\cos(\omega)=0.5\cos(\omega_1)+0.5\cos(\omega_2)+0.5\cos(\omega_1)\cos(\omega_2)-0.5} \tag{22.13}$$

where $w(n)$ is an arbitrary symmetric 1-D window of duration $2N+1$ centered at the origin, and the coefficients, $b(n)$, are obtained from $w(n)$ via Chebyshev polynomials [33]. After some algebraic manipulations it can be shown that

$$T(\omega_1, \omega_2) = \sum_{n_1=-N}^{N} \sum_{n_2=-N}^{N} w_t(n_1, n_2) e^{-j(n_1\omega_1 + n_2\omega_2)}, \tag{22.14}$$

where $w_t(n_1, n_2)$ is a zero-phase 2-D window of size $(2N+1) \times (2N+1)$ obtained by using the McClellan transformation.

The construction of 2-D windows using the above three methods is now examined. In the case of windows obtained by the separable and the McClellan transformation approaches, the 1-D prototype is a Hamming window,

$$w_h(n) = \begin{cases} 0.54 + 0.46\cos(\pi n/N), & |n| < N, \\ 0, & \text{otherwise.} \end{cases} \tag{22.15}$$

In the second case $w_c(n_1, n_2) = 0.54 + 0.46\cos(\pi\sqrt{n_1^2 + n_2^2}/N)$. By selecting $w_1(n) = w_2(n) = w_h(n)$ in Equation 22.11 we get a 2-D window, $w_r(n_1, n_2)$, of support $I = \{|n_1| < N,\ |n_2| < N\}$ which is a square-shaped symmetric region centered at the origin. For $N = 6$ the region of support, I, contains $11 \times 11 = 121$ points. Figure 22.3a shows the frequency response of this window. A second window is designed by using Equation 22.12, i.e., $w_c(n_1, n_2) = w_h(\sqrt{n_1^2 + n_2^2})$. For $N = 6$ the frequency response of this filter is shown in Figure 22.3b. The region of support is almost circular and it contains 113 points. From these examples, it is seen that the 2-D windows may not behave as well as 1-D windows. Speake and Mersereau [46] compared these two methods and observed that the main-lobe width and the highest attenuation level of the side-lobes of the 2-D windows differ from their 1-D prototypes.

Let us construct a 2-D window by the McClellan transformation with a 1-D Hamming window of order 13 ($N = 6$) as the prototype. The frequency response of the 2-D window, $w_t(n_1, n_2)$, is shown in Figure 22.3c. The frequency response of this window is almost circularly symmetric and it preserves the features of its 1-D prototype.

Consider the design of a circularly symmetric low-pass filter. The ideal frequency response for $(\omega_1, \omega_2) \in [-\pi, \pi] \times [-\pi, \pi]$ is given by

$$H_{id}(\omega_1, \omega_2) = \begin{cases} 1, & \sqrt{\omega_1^2 + \omega_2^2} \le \omega_c, \\ 0, & \text{otherwise,} \end{cases} \tag{22.16}$$

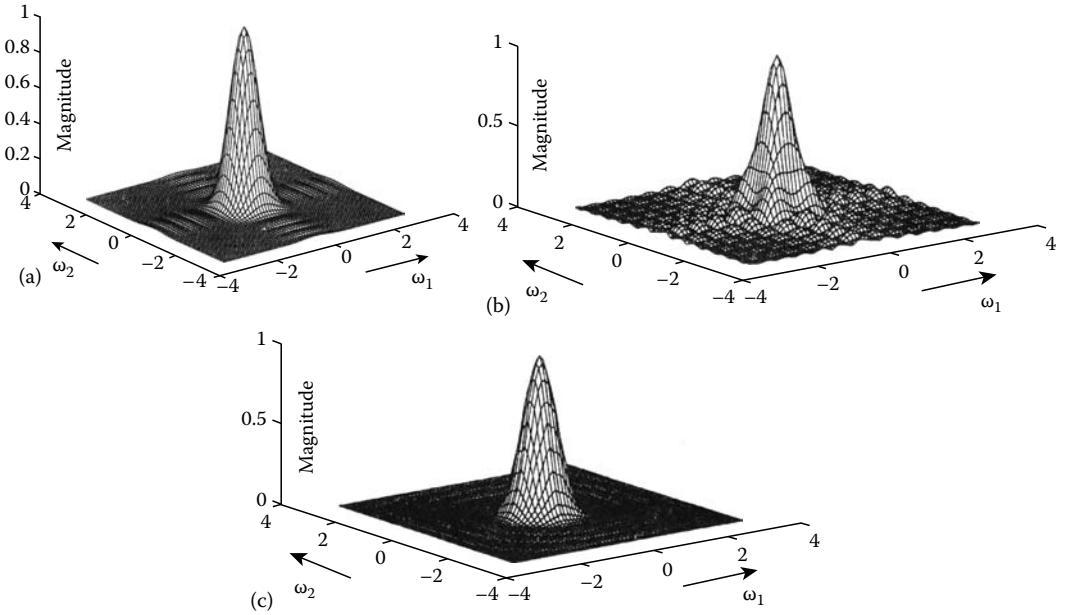

FIGURE 22.3 Frequency responses of the (a) separable, (b) Huang, and (c) McClellan 2D windows generated from a Hamming window of order 13 ($N = 6$).

whose impulse response is given by

$$h_{\text{id}}(n_1, n_2) = \frac{\omega_c J_1\left(\omega_c \sqrt{n_1^2 + n_2^2}\right)}{2\pi\sqrt{n_1^2 + n_2^2}}, \tag{22.17}$$

where

$J_1(\cdot)$ is the first-order Bessel function of the first kind
ω_c is the cutoff frequency

The frequency response of the 2-D FIR filter obtained with a rectangular window of size $2 \times 5 + 1$ by $2 \times 5 + 1$ is shown in Figure 22.4a. Note the Gibbs-phenomenon type ripples at the passband edges.

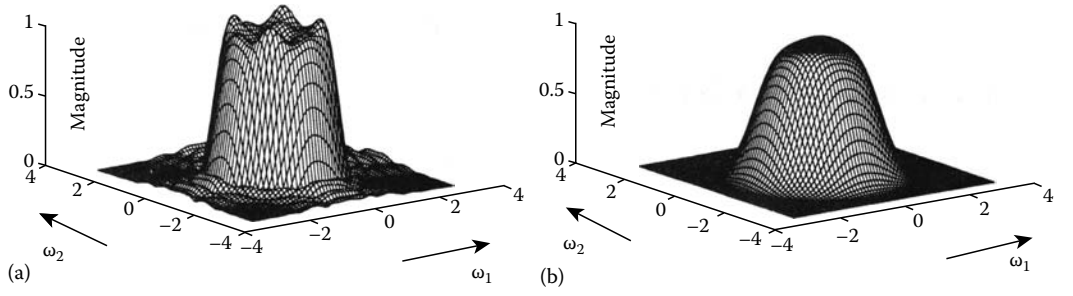

FIGURE 22.4 Frequency responses of the 2D filters designed with (a) a rectangular window and (b) a separable window of Figure 22.3a.

In Figure 22.4b the separable window of Figure 22.3a, derived from a Hamming window, is used to design the 2-D filter. Note that this 2-D filter has smaller ripples at the passband edges.

In windowing methods, it is often assumed that $H_{\mathrm{id}}(\omega_1, \omega_2)$ is given. However, if the specifications are given as described in Section 22.2, then a proper $H_{\mathrm{id}}(\omega_1, \omega_2)$ should be constructed. The ideal magnitudes are either 1.0 (in passband) or 0.0 (in stopband). However, there is a need to define a *cutoff* boundary, which lies within the transition band. This can be accomplished by using a suitable notion of "midway" cutoff between the transition boundaries. In practical cases where transition boundaries are given in terms of straight-line segments or smooth curves such as circles and ellipses, the construction of "midway" cutoff boundary is relatively straightforward. The IIR, $h_{\mathrm{id}}(n_1, n_2)$, is computed from the desired frequency response, $H_{\mathrm{id}}(\omega_1, \omega_2)$, either analytically (if possible), or by using the discrete Fourier transform (DFT). In the latter case the desired response, $H_{\mathrm{id}}(\omega_1, \omega_2)$, is first sampled on a rectangular grid in the Fourier domain, then an inverse DFT computation is carried out via a 2-D fast Fourier transform (FFT) algorithm to obtain an approximation to the sequence $h_{\mathrm{id}}(n_1, n_2)$. The resulting sequence is an aliased version of the IIR. Therefore, a sufficiently dense grid should be used in order to reduce the effects of aliasing.

In practice, several trials may be needed to design the final filter satisfying bounds both in the passbands and stopbands. The filter support is adjusted to obtain the smallest order to meet given requirements.

Filter design with windowing is a simple approach that is suitable for applications where a quick and nonoptimal design is needed. Additional information on windowing can be found in Refs. [26,46].

22.3.2 Frequency Sampling and Linear Programming-Based Method

This method is based on the application of the sampling theorem in the frequency domain. Consider the design of a 2-D filter with impulse response support of $N_1 \times N_2$ samples. The frequency response of the filter can be obtained from a conveniently chosen set of its samples on an $N_1 \times N_2$ grid. For example, the DFT of the impulse response can be used to interpolate the response for the entire region $[0, 2\pi] \times [0, 2\pi]$. The filter design then becomes a problem of choosing an appropriate set of DFT coefficients [21].

One choice of DFT coefficients consists of the ideal frequency response values, assuming a suitable cutoff. However, the resultant filters usually exhibit large magnitude deviations away from the DFT sample locations in the filter passbands and stopbands. The approximation error can be reduced by allowing the DFT values in the transition band to vary, and choosing them to minimize the deviation of the magnitude from the desired values. Another option is to allow all the DFT values to vary, and pick the optimal set of values for minimum error. The use of DFT-based interpolation allows for a computationally efficient implementation. The implementation cost of the method basically consists of a 2-D array product and inverse discrete Fourier transform (IDFT) computation, with appropriate addition.

Let us consider the set $S \subset Z^2$ that defines the equispaced frequency locations $\left(\frac{2k_1\pi}{N_1}, \frac{2k_2\pi}{N_2}\right)$:

$$S = \{(k_1, k_2): k_1 = 0, 1, \ldots, N_1, k_2 = 0, 1, \ldots, N_2\}. \tag{22.18}$$

The DFT values can be expressed as

$$H_{\mathrm{DFT}}[k_1, k_2] = |H(\omega_1, \omega_2)|_{(\omega_1, \omega_2) = \left(\frac{2k_1\pi}{N_1}, \frac{2k_2\pi}{N_2}\right)}, \ (k_1, k_2) \in S. \tag{22.19}$$

The filter coefficients, $h(n_1, n_2)$, are found by using an IDFT computation

$$h(n_1, n_2) = \frac{1}{N_1 N_2} \sum_{k_1=0}^{N_1-1} \sum_{k_2=0}^{N_2-1} H_{\mathrm{DFT}}[k_1, k_2] e^{j\left(\frac{2\pi}{N_1}k_1 n_1 + \frac{2\pi}{N_2}k_2 n_2\right)}, \ (n_1, n_2) \in S. \tag{22.20}$$

If Equation 22.20 is substituted in the expression for frequency response

$$H(\omega_1, \omega_2) = \sum_{n_1=0}^{N_1-1} \sum_{n_2=0}^{N_2-1} h(n_1, n_2) e^{-j(\omega_1 n_1 + \omega_2 n_2)}, \tag{22.21}$$

we arrive at the interpolation formula

$$H(\omega_1, \omega_2) = \sum_{k_1=0}^{N_1-1} \sum_{k_2=0}^{N_2-1} H_{\mathrm{DFT}}[k_1, k_2] A_{k_1 k_2}(\omega_1, \omega_2), \tag{22.22}$$

where

$$A_{k_1 k_2}(\omega_1, \omega_2) = \frac{1}{N_1 N_2} \left(\frac{1 - e^{-jN_1\omega_1}}{1 - e^{-j(\omega_1 - 2\pi k_1/N_1)}} \right) \left(\frac{1 - e^{-jN_2\omega_2}}{1 - e^{-j(\omega_2 - 2\pi k_2/N_2)}} \right). \tag{22.23}$$

Equation 22.22 serves as the basis of the frequency sampling design. As mentioned before, if the H_{DFT} are chosen directly according to the ideal response, then the magnitude deviations are usually large. To reduce the ripples, one option is to express the set S as the disjoint union of two sets S_t and S_c, where S_t contains indices corresponding to the transition band F_t, and S_c contains indices corresponding to the care-bands, i.e., the union of the passbands and stopbands, $F_p \cup F_s$. The expression for frequency response in Equation 22.22 can be split into two summations, one over S_t and the other over S_c

$$H(\omega_1, \omega_2) = \sum_{S_t} H_{\mathrm{DFT}}[k_1, k_2] A_{k_1 k_2}(\omega_1, \omega_2) + \sum_{S_c} H_{\mathrm{DFT}}[k_1, k_2] A_{k_1 k_2}(\omega_1, \omega_2), \tag{22.24}$$

where the first term on the right-hand side is optimized. The design equations can be put in the form

$$1 - \alpha\delta \le H(\omega_1, \omega_2) \le 1 + \alpha\delta, \quad (\omega_1, \omega_2) \in F_p \tag{22.25}$$

and

$$-\delta \le H(\omega_1, \omega_2) \le \delta, \quad (\omega_1, \omega_2) \in F_s, \tag{22.26}$$

where

δ is the peak approximation error in the stopband

$\alpha\delta$ is the peak approximation error in the passband, where α is any positive constant defining the relative weights of the deviations

The problem is readily cast as a linear programming problem with a sufficiently dense grid of points.

For equiripple design, all the DFT values H_{DFT} over S_t and S_c are allowed to vary. Following is an example of this design.

Example 22.1

The magnitude response for the approximation of a circularly symmetric response is shown in Figure 22.5. Here the passband is the interior of the circle $R_1 = \pi/3$ and the stopband is the exterior of the circle $R_2 = 2\pi/3$. With $N_1 = N_2 = 9$, the passband ripple is 0.08 dB and the minimum stopband attenuation is 32.5 dB.

22.3.3 FIR Filters Optimal in L_p Norm

A criterion different from the minimax criterion is briefly examined. Let us define the error at the frequency pair (ω_1, ω_2) as follows:

$$E(\omega_1, \omega_2) = H(\omega_1, \omega_2) - H_{\mathrm{id}}(\omega_1, \omega_2). \tag{22.27}$$

$R_1 = 1.5\pi/4.5$
$R_2 = 3\pi/4.5$
$N_1 = N_2 = 9$
Amplitude response

Log magnitude response
In-band ripple = 0.08
Peak attenuation = 32.5 dB

FIGURE 22.5 Frequency response of the circularly symmetric filter obtained by using the frequency sampling method. (From Hu, J.V. and Rabiner, L.R., *IEEE Trans. Audio Electroacoust.*, 20, 249, 1972. With permission. © 1972 IEEE.)

One design approach is to minimize the L_p norm of the error

$$\varepsilon_p = \left(\frac{1}{4\pi^2} \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} |E(\omega_1, \omega_2)|^p \, d\omega_1 d\omega_2 \right)^{\frac{1}{p}}. \tag{22.28}$$

Filter coefficients are selected by a suitable algorithm. For $p = 2$ Parseval's relation implies that

$$\varepsilon_2^2 = \sum_{n_1=-\infty}^{\infty} \sum_{n_2=-\infty}^{\infty} [h(n_1, n_2) - h_{\text{id}}(n_1, n_2)]^2. \tag{22.29}$$

By minimizing Equation 22.29 with respect to the filter coefficients, $h(n_1, n_2)$, which are nonzero only in a finite-extent region, I, one gets

$$h(n_1, n_2) = \begin{cases} h_{\text{id}}(n_1, n_2), & (n_1, n_2) \in I, \\ 0, & \text{otherwise}, \end{cases} \tag{22.30}$$

which is the filter designed by using a straightforward rectangular window. Due to the Gibbs phenomenon it may have large variations at the edges of passband and stopband regions. A suitable weighting function can be used to reduce the ripple [2], and an approximately equiripple solution can be obtained.

For the general case of $p \neq 2$ [32], the minimization of Equation 22.28 is a nonlinear optimization problem. The integral in Equation 22.28 is discretized and minimized by using an iterative nonlinear optimization technique. The solution for $p = 2$ is easy to obtain using linear equations. This serves as an excellent initial estimate for the coefficients in the case of larger values of p. As p increases, the solution becomes approximately equiripple. The error term, $E(\omega_1, \omega_2)$, in Equation 22.28 is nonuniformly weighted in passbands and stopbands, with larger weight given close to band-edges where deviations are typically larger.

22.3.4 Iterative Method for Approximate Minimax Design

We now consider a simple procedure based on alternating projections in the sample and frequency domains, which leads to an approximately equiripple response. In this method, the zero-phase FIR filter design problem is formulated to alternately satisfy the frequency domain constraints on the magnitude response bounds and spatial domain constraints on the impulse response support [1,11,12]. The algorithm is iterative and each iteration requires two 2-D FFT computations.

As pointed out in Section 22.2, 2-D FIR filter specifications are given as requirements on the magnitude response of the filter. It is desirable that the frequency response, $H(\omega_1, \omega_2)$, of the zero-phase FIR filter be within prescribed upper and lower bounds in its passbands and stopbands. Let us specify bounds on the frequency response $H(\omega_1, \omega_2)$ of the minimax FIR filter, $h(n_1, n_2)$, as follows:

$$H_{\mathrm{id}}(\omega_1, \omega_2) - E_{\mathrm{d}}(\omega_1, \omega_2) \leq H(\omega_1, \omega_2) \leq H_{\mathrm{id}}(\omega_1, \omega_2) + E_{\mathrm{d}}(\omega_1, \omega_2) \quad \omega_1, \omega_2 \in R, \tag{22.31}$$

where

$H_{\mathrm{id}}(\omega_1, \omega_2)$ is the ideal filter response

$E_{\mathrm{d}}(\omega_1, \omega_2)$ is a positive function of (ω_1, ω_2) which may take different values in different passbands and stopbands

R is a region defined in Equation 22.28 consisting of passbands and stopbands of the filter (note that $H(\omega_1, \omega_2)$ is real for a zero-phase filter)

Usually, $E_{\mathrm{d}}(\omega_1, \omega_2)$ is chosen constant in a passband or a stopband. Inequality equation (Equation 22.31) is the frequency domain constraint of the iterative filter design method.

In spatial domain the filter must have a finite-extent support, I, which is symmetric region around the origin. The spatial domain constraint requires that the filter coefficients must be equal to zero outside the region, I.

The iterative method begins with an arbitrary finite-extent, real sequence $h_0(n_1, n_2)$ that is symmetric ($h_0(n_1, n_2) = h_0(-n_1, n_2)$). Each iteration consists of making successive imposition of spatial and frequency domain constraints onto the current iterate. The kth iteration consists of the following steps:

- Compute the Fourier transform of the kth iterate $h_k(n_1, n_2)$ on a suitable grid of frequencies by using a 2-D FFT algorithm.
- Impose the frequency domain constraint as follows:

$$G_k(\omega_1, \omega_2) = \begin{cases} H_{\mathrm{id}}(\omega_1, \omega_2) + E_{\mathrm{d}}(\omega_1, \omega_2) & \text{if } H_k(\omega_1, \omega_2) > H_{\mathrm{id}}(\omega_1, \omega_2) + E_{\mathrm{d}}(\omega_1, \omega_2), \\ H_{\mathrm{id}}(\omega_1, \omega_2) - E_{\mathrm{d}}(\omega_1, \omega_2) & \text{if } H_k(\omega_1, \omega_2) < H_{\mathrm{id}}(\omega_1, \omega_2) - E_{\mathrm{d}}(\omega_1, \omega_2), \\ H_k(\omega_1, \omega_2) & \text{otherwise.} \end{cases} \tag{22.32}$$

- Compute the inverse Fourier transform of $G_k(\omega_1, \omega_2)$.
- Zero out $g_k(n_1, n_2)$ outside the region I to obtain h_{k+1}.

The flow diagram of this method is shown in Figure 22.6. It can be proven that the algorithm converges for all symmetric input sequences. This method requires the specification of the bounds or equivalently, $E_{\mathrm{d}}(\omega_1, \omega_2)$, and the filter support, I. In 2-D filter design, filter order estimates for prescribed frequency domain specifications are not available. Therefore, successive reduction of bounds is used. If the specifications are too tight, then the algorithm does not converge. In such cases one can either progressively enlarge the filter support region, or relax the bounds on the ideal frequency response.

The size of the 2-D FFT must be chosen sufficiently large. The passband and stopband edges are very important for the convergence of the algorithm. These edges must be represented accurately on the frequency grid of the FFT algorithm.

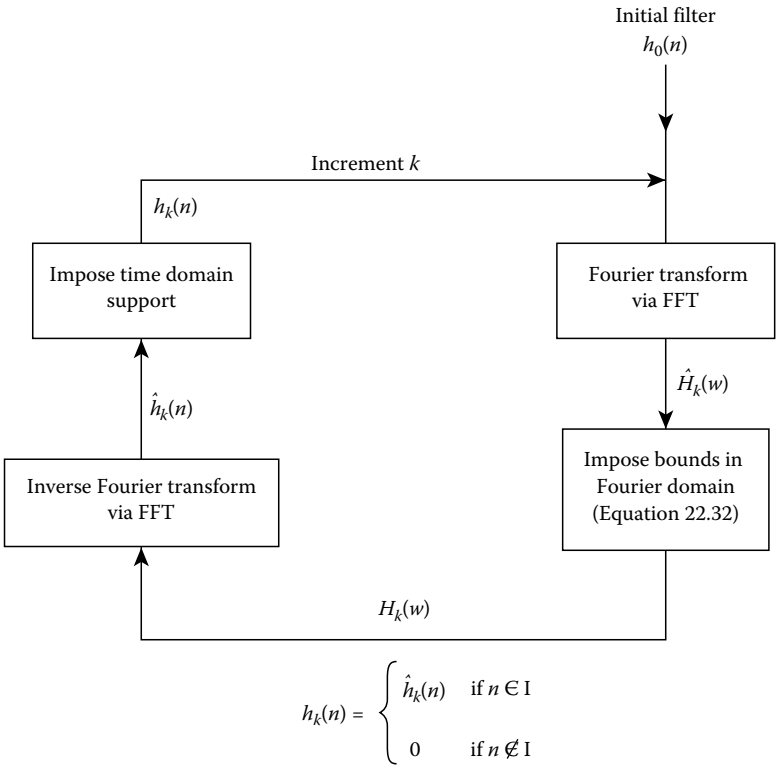

FIGURE 22.6 Flow diagram of the iterative filter design algorithm.

The shape of the filter support is very important in any 2-D filter design method. The support should be chosen to exploit the symmetries in the desired frequency response. For example, diamond-shaped supports show a clear advantage over the commonly assumed rectangular regions in designing diamond filters or 90° fan filters [4,17].

Since there are efficient FFT routines, 2-D FIR filters with large orders can be designed by using this procedure.

Example 22.2

Let us consider the design of a circularly symmetric low-pass filter. Maximum allowable deviation is $\delta_p = \delta_s = 0.05$ in both passband and the stopband. The passband and stopband cutoff boundaries have radii of 0.43 π and 0.63 π, respectively. This means that the functions $E_d(\omega_1, \omega_2) = 0.05$ in the passband and the stopband. In the transition band the frequency response is conveniently bounded by the lower bound of the stopband and the upper bound of the passband. The filter support is a square-shaped 17×17 region. The frequency response of this filter is shown in Figure 22.7.

Example 22.3

Let us now consider an example in which we observe the importance of filter support. We design a fan filter whose specifications are shown in Figure 22.8. Maximum allowable deviation is $\delta_p = \delta_s = 0.1$ in both passband and the stopband. If one uses a 7×7 square-shaped support which has 49 points, then it cannot meet the design specifications. However, a diamond-shaped support,

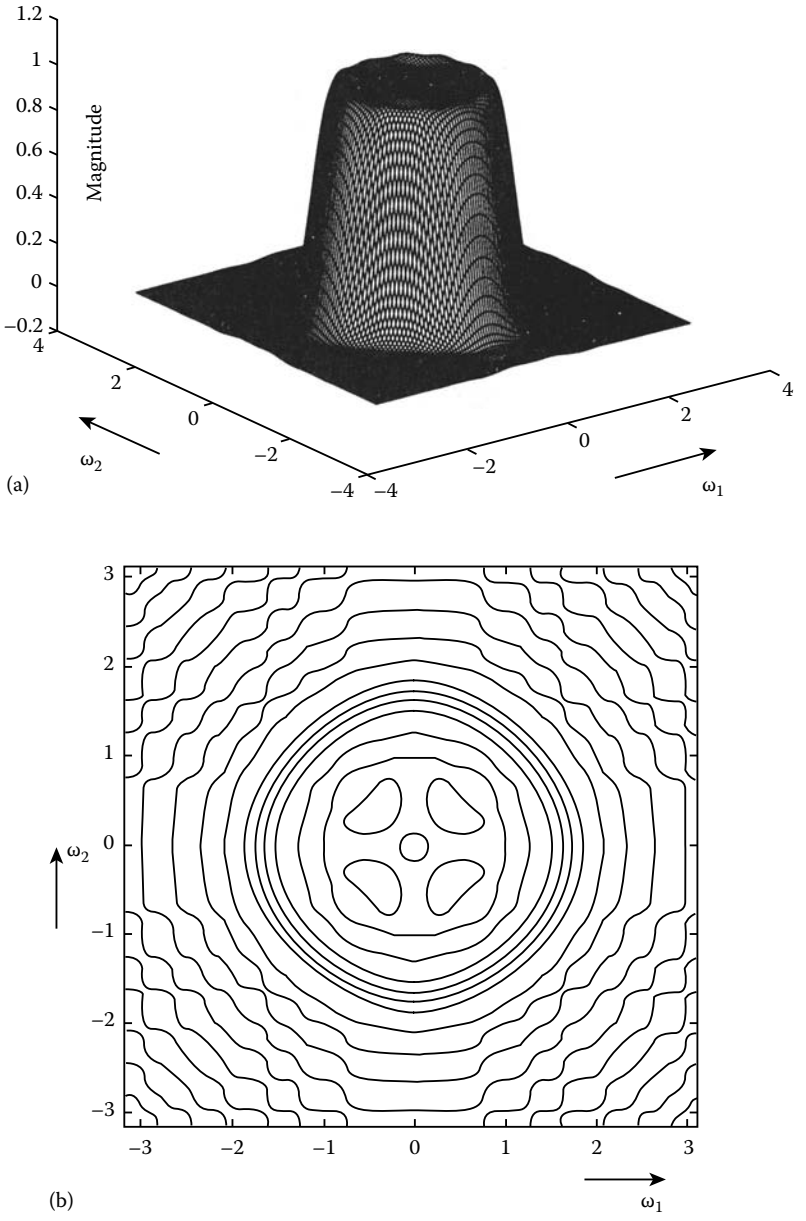

FIGURE 22.7 (a) Frequency response and (b) contour plot of the low-pass filter of Example 22.1.

$$I_d = \{-5 \le n_1 + n_2 \le 5\} \cap \{-5 \le n_1 - n_2 \le 5\}, \tag{22.33}$$

together with the restriction that ("de" for diamond-support with some eliminated samples)

$$I_{de} = I_d \cap \{n_1 + n_2 = \text{odd or } n_1 = n_2 = 0\} \tag{22.34}$$

produces a filter satisfying the bounds. The filter support region, I_{de}, contains 37 points. The resultant frequency response is shown in Figure 22.8.

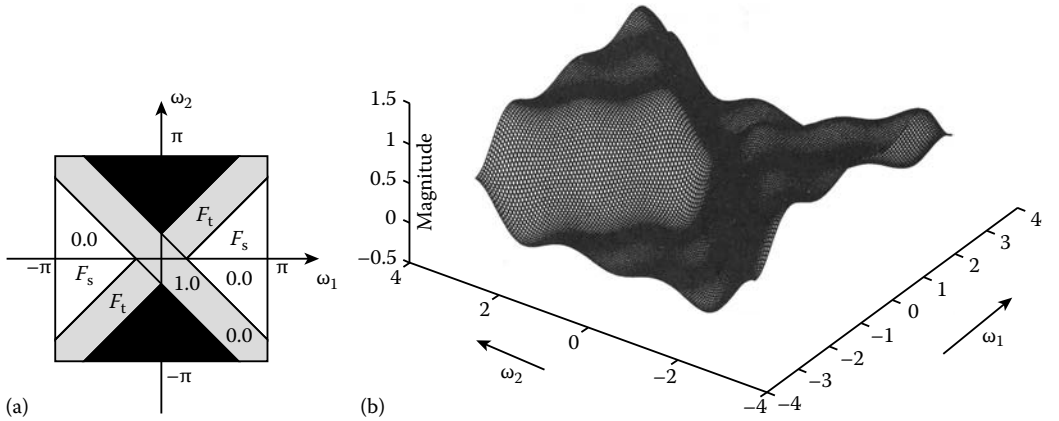

FIGURE 22.8 (a) Specifications and (b) perspective frequency response of the fan filter designed in Example 22.2.

22.4 Special Design Procedure for Restricted Classes

Many cases of practical importance typically require filters belonging to restricted classes. The stopbands and passbands of these filters are often defined by straight-line, circular, or elliptical boundaries. In these cases, specialized procedures lead to efficient design and low-cost implementation. The filters in these cases are derived from 1-D prototypes.

22.4.1 Separable 2-D FIR Filter Design

The design of 2-D FIR filters composed of 1-D building blocks is briefly discussed. In cases where the specifications are given in terms of multiple passbands in the shapes of rectangles with sides parallel to the frequency axes, the design problem can be decomposed into multiple designs. The resulting filter is a parallel connection of component filters that are themselves separable filters. The separable structure was encountered earlier in the construction of 2-D windows from 1-D windows in Section 22.3. The design approach is essentially the same. We will confine the discussion to cascade structures, which is a simple and very important practical case.

The frequency response of the 2-D separable FIR filter is expressed as

$$H(\omega_1, \omega_2) = H_1(\omega_1)H_2(\omega_2), \tag{22.35}$$

where $H_1(\omega)$ and $H_2(\omega)$ are frequency responses of two 1-D zero-phase FIR filters of durations N_1 and N_2. The corresponding 2-D filter is also a zero-phase FIR filter with $N \times M$ coefficients, and its impulse response is given by

$$h(n_1, n_2) = h_1(n_1)h_2(n_2), \tag{22.36}$$

where $h_1(n)$ and the $h_2(n)$ are the impulse responses of the 1-D FIR filters.

If the ideal frequency response can be expressed in a separable cascade form as in Equation 22.35, then the design problem is reduced to the case of appropriate 1-D filter designs. A simple but important example is the design of a 2-D low-pass filter with a symmetric square-shaped passband, PB = {(ω_1, ω_2): $|\omega_1| < \omega_c$, $|\omega_2| < \omega_c$}. Such a low-pass filter can be designed from a single 1-D FIR filter with a cutoff frequency of ω_c by using Equation 22.36. A low-pass filter constructed this way is used in Figure 22.2c.

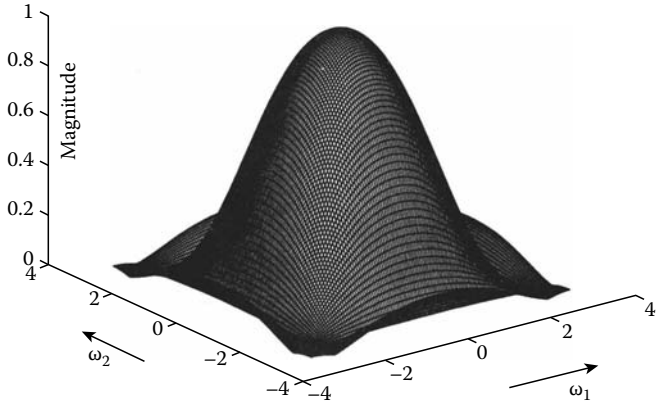

FIGURE 22.9 Frequency response of the separable low-pass filter $H(\omega_1, \omega_2) = H_1(\omega_1)H_1(\omega_2)$ where $H_1(\omega)$ is a seventh-order Lagrange filter.

The frequency response of this 2-D filter whose 1-D prototypes are seventh-order Lagrange filters is shown in Figure 22.9.

This design method is also used in designing 2-D filter banks which are utilized in subband coding of images and video signals [49,51,52]. The design of 2-D filter banks is discussed in Section 22.6.

22.4.2 Frequency Transformation Method

In this method a 2-D zero-phase FIR filter is designed from a 1-D zero-phase filter by a clever substitution of variables. The design procedure was first proposed by McClellan [33] and the frequency transformation is usually called the McClellan transformation [14,35,37,38].

Let $H_1(\omega)$ be the frequency response of a 1-D zero-phase filter with $2N + 1$ coefficients. The key idea of this method is to find a suitable transformation $\omega = G(\omega_1, \omega_2)$ such that the 2-D frequency response, $H(\omega_1, \omega_2)$, which is given by

$$H(\omega_1, \omega_2) = |H_1(\omega)|_{\omega = G(\omega_1, \omega_2)} \tag{22.37}$$

approximates the desired frequency response, $H_{\text{id}}(\omega_1, \omega_2)$.

Since the 1-D filter is a zero-phase filter, its frequency response is real, and it can be written as follows:

$$H_1(\omega) = h_1(0) + \sum_{n=1}^{N} 2h_1(n) \cos(\omega n), \tag{22.38}$$

where the term $\cos(\omega n)$ can be expressed as a function of $\cos(\omega)$ by using the nth-order Chebyshev polynomial, T_n,* i.e.,

$$\cos(\omega n) = T_n[\cos(\omega)]. \tag{22.39}$$

* Chebyshev polynomials are recursively defined as follows: $T_0(x) = 1$, $T_1(x) = x$, and $T_n(x) = 2xT_{n-1}(x) - T_{n-2}(x)$.

Using Equation 22.39, the 1-D frequency response can be written as

$$H_1(\omega) = \sum_{n=0}^{N} 2b(n)[\cos(\omega)]^n, \tag{22.40}$$

where the coefficients, $b(n)$, are related to the filter coefficients, $h(n)$.

In this design method the key step is to substitute a transformation function, $F(\omega_1, \omega_2)$, for $\cos(\omega)$ in Equation 22.40. In other words, the 2-D frequency response, $H(\omega_1, \omega_2)$, is obtained as follows:

$$\begin{aligned} H(\omega_1, \omega_2) &= H_1(\omega)\big|_{\cos(\omega)=F(\omega_1,\omega_2)} \\ &= \sum_{n=0}^{N} 2b(n)[F(\omega_1, \omega_2)]^n. \end{aligned} \tag{22.41}$$

The function, $F(\omega_1, \omega_2)$, is called the McClellan transformation.

The frequency response, $H(\omega_1, \omega_2)$, of the 2-D FIR filter is determined by two free functions, the 1-D prototype frequency response, $H_1(\omega)$, and the transformation, $F(\omega_1, \omega_2)$. In order to have $H(\omega_1, \omega_2)$ be the frequency response of an FIR filter, the transformation, $F(\omega_1, \omega_2)$, must itself be the frequency response of a 2-D FIR filter. McClellan proposed $F(\omega_1, \omega_2)$ to be the frequency response of a 3×3 zero-phase filter in Ref. [33]. In this case the transformation, $F(\omega_1, \omega_2)$, can be written as follows:

$$F(\omega_1, \omega_2) = A + B\ \cos(\omega_1) + C\ \cos(\omega_2) + D\ \cos(\omega_1 - \omega_2) + E\ \cos(\omega_1 + \omega_2), \tag{22.42}$$

where the real parameters, A, B, C, D, and E, are related to the coefficients of the 3×3 zero-phase FIR filter. For $A = -(1/2)$, $B = C = (1/2)$, $D = E = (1/4)$, the contour plot of the transformation, $F(\omega_1, \omega_2)$, is shown in Figure 22.10. Note that in this case the contours are approximately circularly symmetric around

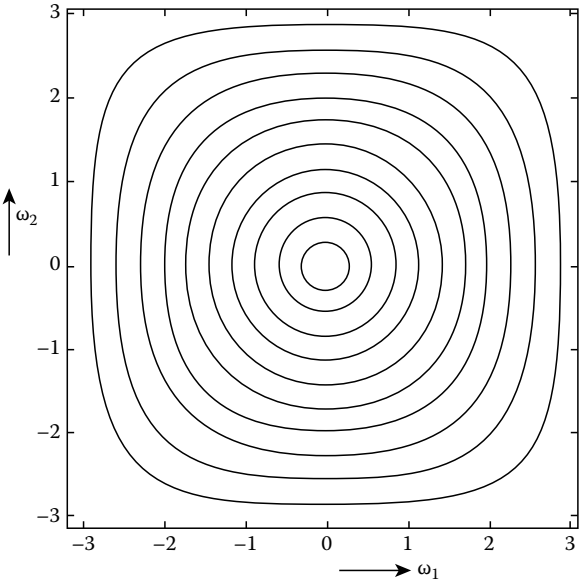

FIGURE 22.10 Contour plot of the McClellan transformation, $F(\omega_1, \omega_2) = 0.5\cos(\omega_1) + 0.5\cos(\omega_2) + 0.5\cos(\omega_1)\cos(\omega_2) - 0.5$.

the origin. It can be seen that the deviation from the circularity, expressed as a fraction of the radius, decreases with the radius. In other words, the distortion from a circular response is larger for large radii. It is observed from Figure 22.10 that, with the above choice of parameters, A, B, C, D, and E, the transformation is bounded ($|F(\omega_1, \omega_2)| \leq 1$), which implies that $H(\omega_1, \omega_2)$ can take only the values that are taken by the 1-D prototype filter, $H_1(\omega)$. Since $|\cos(\omega)| \leq 1$, the transformation, $F(\omega_1, \omega_2)$, which replaces $\cos(\omega)$ in Equation 22.41 must also take values between 1 and -1. If a particular transformation does not obey these bounds, then it can be scaled such that the scaled transformation satisfies the bounds.

If the transformation, $F(\omega_1, \omega_2)$, is real (it is real in Equation 22.42) then the 2-D filter, $H(\omega_1, \omega_2)$, will also be real or, in other words, it will be a zero-phase filter. Furthermore, it can be shown that the 2-D filter, $H(\omega_1, \omega_2)$, is an FIR filter with a support containing $(2M_1N + 1) \times (2M_2N + 1)$ coefficients, if the transformation, $F(\omega_1, \omega_2)$, is an FIR filter with $(2M_1 + 1) \times (2M_2 + 1)$ coefficients, and the order of the 1-D prototype filter is $2N + 1$. In (19.42) $M_1 = M_2 = 1$. As it can be intuitively guessed, one can design a 2-D approximately circularly symmetric low-pass (high-pass) (bandpass) filter with the above McClellan transformation by choosing the 1-D prototype filter, $H_1(\omega)$, a low-pass (high-pass) (bandpass) filter.

We will present some examples to demonstrate the effectiveness of the McClellan transformation.

Example 22.4

2-D window design by transformations [53]: In this example we design 2-D windows by using the McClellan transformation. Actually, we briefly mentioned this technique in Section 22.3. The 1-D prototype filter is chosen as an arbitrary 1-D symmetric window centered at the origin. Let $w(n)$ be the 1-D window of size $2N + 1$, and $W(\boldsymbol{\omega}) = \sum_{n=-N}^{N} w(n) \exp(-j\boldsymbol{\omega}n)$ be its frequency response. The transformation, $F(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2)$, is chosen as in Equation 22.42 with the parameters $A = -(1/2)$, $B = C = (1/2)$, $D = E = (1/4)$, of Figure 22.10. This transformation, $F(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2)$, can be shown to be equal to

$$F(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2) = 0.5 \cos(\boldsymbol{\omega}_1) + 0.5 \cos(\boldsymbol{\omega}_2) + 0.5 \cos(\boldsymbol{\omega}_1) \cos(\boldsymbol{\omega}_2) - 0.5. \tag{22.43}$$

The frequency response of the McClellan window, $H_t(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2)$, is given by

$$H_t(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2) = W(\boldsymbol{\omega})|_{\cos(\boldsymbol{\omega}) = F(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2)}. \tag{22.44}$$

The resultant 2-D zero-phase window, $w_t(n_1, n_2)$, is centered at the origin and of size $(2N + 1) \times (2N + 1)$ because $M_1 = M_2 = 1$. The window coefficients can be computed either by using the inverse Chebyshev relation,* or by using the inverse Fourier transform of Equation 22.44. The frequency response of a 2-D window constructed from a 1-D Hamming window of order 13 is shown in Figure 22.3c. The size of the window is 13×13.

Example 22.5

Let us consider the design of a circularly symmetric low-pass filter and a bandpass filter by using the transformation of Equation 22.43. In this case, if one starts with a 1-D low-pass (bandpass) filter as the prototype filter, then the resulting 2-D filter will be a 2-D circularly symmetric low-pass (bandpass) filter due to the almost circularly symmetric nature of the transformation. In this example, the Lagrange filter of order 7 considered in Section 22.2 is used as the prototype. The prototype 1-D bandpass filter of order 15 is designed by using the Parks–McClellan algorithm [41]. Frequency response and contour plots of the low-pass and bandpass filters are shown in Figures 22.11 and 22.12, respectively.

* $1 = T_0(x)$, $x = T_1(x) - T_0(x)$, $x^2 = (t_0(x) + T_2(x))$, $x^3 = (3T_1(x) + T_3(x))$ etc.

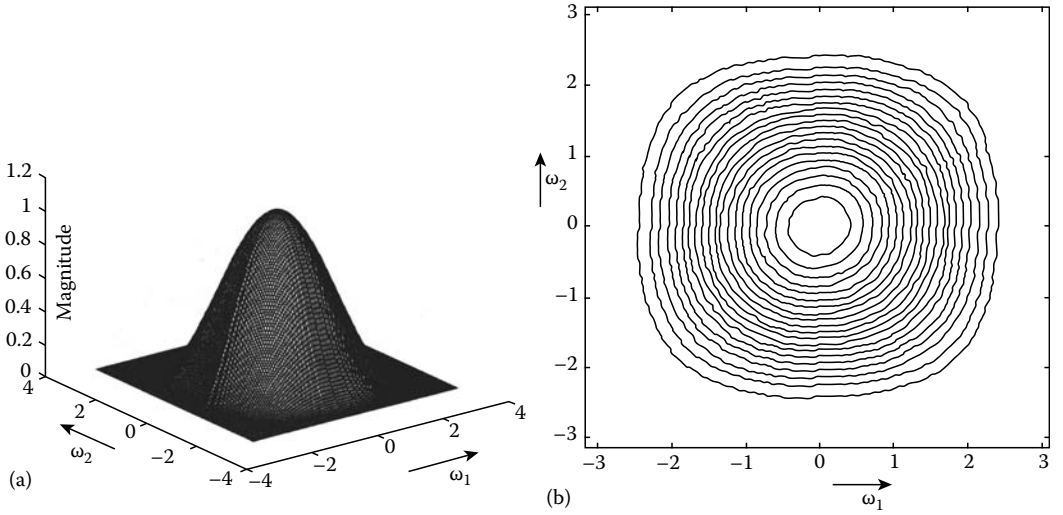

FIGURE 22.11 Frequency response and contour plots of the low-pass filter of Example 22.5.

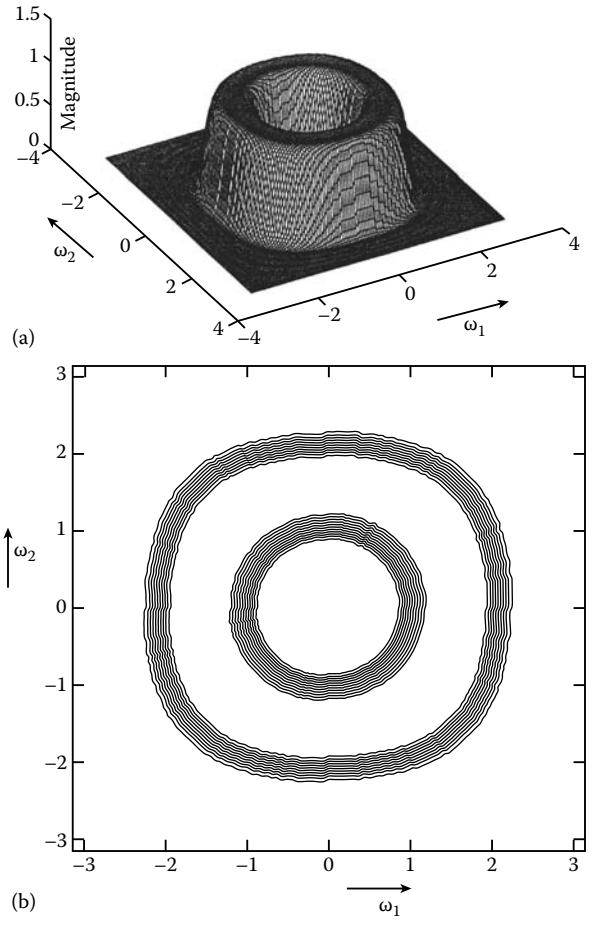

FIGURE 22.12 Frequency response and contour plots of the bandpass filter of Example 22.5.

It is seen from the above examples that filters designed by the transformation method appear to have better frequency responses than those designed by the windowing or frequency sampling methods. In other words, one can control the 2-D frequency response by controlling the frequency response of the 1-D prototype filter and choosing a suitable 2-D transformation. Furthermore, in some special cases it was shown that minimax optimal filters can be designed by the transformation method [20].

We have considered specific cases of the special transformations given by Equation 22.42. By varying the parameters in Equation 22.42 or expanding the transformation to include additional terms, a wider class of contours can be approximated. Ideally, the frequency transformation approach requires the simultaneous optimal selection of the transformation, $F(\omega_1, \omega_2)$, and the 1-D prototype filter $H_1(\omega)$ to approximate a desired 2-D frequency response. This can be posed as a nonlinear optimization problem. However, a suboptimal two-stage design by separately choosing $F(\omega_1, \omega_2)$ and $H_1(\omega)$ works well in practice. The transformation $F(\omega_1, \omega_2)$ should approximate $1(-1)$ in the passband (stopband) of the desired filter. The contour produced by the transformation corresponding to the 1-D passband (stopband) edge frequency, $\omega_p(\omega_s)$, should ideally map to the given passband (stopband) boundary in the 2-D specifications. However, this cannot be achieved in general given the small number of variable parameters in the transformation. The parameters are therefore selected to minimize a suitable norm of the error between actual and ideal (constant) values of the transformation over the boundaries.

Various transformations and design considerations are described in Refs. [37,38,40,42,43]. The use of this transformation in exact reconstruction filter bank design was proposed in Ref. [7].

Filters designed by the transformation method can be implemented in a computationally efficient manner [14,30]. The key idea is to implement Equation 22.41 instead of implementing the filter by using the direct convolution sum. By implementing the transformation, $F(\omega_1, \omega_2)$, which is an FIR filter of low-order, in a modular structure realizing Equation 22.41 is more advantageous than ordinary convolution sum [14,34].

In the case of circular passband design, it was observed that for low-order transformation, the transformation contours exhibit large deviations from circularity. A simple artifice to overcome this problem in approximating wideband responses is to use decimation of a 2-D narrowband filter impulse response [18]. The solution consists of transforming the specifications to an appropriate narrowband design, where the deviation from circularity is smaller. The narrow passband can be expanded by decimation while essentially preserving the circularity of the passband.

22.4.3 Design Using Nonrectangular Transformations and Sampling Rate Conversions

In some filter specifications the desired responses are characterized by ideal frequency responses in which passbands and stopbands are separated by straight-line boundaries that are not necessarily parallel to the frequency axes. Examples of these are the various kinds of fan filters [4,15,17,27] and diamond-shaped filters [6,48]. Other shapes with straight-line boundaries are also approximated [8,9,13,28,29,50]. Several design methods applicable in such cases have been developed and these methods are usually based on transformations related to concepts of sampling rate conversions. Often alternate frequency domain interpretations are used to explain the design manipulations. A detailed treatment of these methods is beyond the scope of this chapter. However some key ideas are described and a specific case of a diamond filter is used to illustrate the methods. The importance of these design methods stems from the implementation efficiency that results from a generalized notion of separable processing.

In the family of methods considered here, manipulations of a separable 2-D response using a combination of several steps are carried out. In the general case of designing filters with straight-line boundaries, it is difficult to describe a systematic procedure. However, in a given design problem, an appropriate set of steps in the design is suggested by the nature of the desired response.

Some underlying ideas can be understood by examining the problem of obtaining a filter with a parallelogram-shaped passband region. The sides of the parallelogram are assumed to be tilted with

respect to the frequency axes. One approach to solving this problem is to perform the following series of manipulations on a separable prototype filter with a rectangular passband. The prototype filter impulse response is upsampled on a *nonrectangular* grid. The upsampling is done by an integer factor greater than one and it is defined by a nondiagonal nonsingular integer matrix [39]. The upsampling produces a parallelogram by a rotation and compression of the frequency response of the prototype filter together with a change in the periodicity. The matrix elements are chosen to produce the desired orientation in the resulting response. Depending on the desired response, cascading to eliminate unwanted portions of the passband in the frequency response, along with possible shifts and additions, may be used. The nonrectangular upsampling is then followed by a rectangular decimation of the sequence to expand the passband out to the desired size. In some cases, the operations of the upsampling transformation and decimation can be combined by the use of nonrectangular decimation of impulse response samples. Results using such procedures produce efficient filter structures that are implemented with essentially 1-D techniques but where the orientations of processing are not parallel to the sample coordinates.

Consider the case of a diamond filter design shown in Figure 22.13. Note that the filter in Figure 22.13 can be obtained from the filter in Figure 22.14a by a transformation of variables. If $F_a(z_1, z_2)$ is the transfer function of the filter approximating the response in Figure 22.14a, then the diamond filter transfer function $D(z_1, z_2)$ given by

$$D(z_1, z_2) = F_a\left(z_1^{\frac{1}{2}} z_2^{\frac{1}{2}}, z_1^{-\frac{1}{2}} z_2^{\frac{1}{2}}\right) \tag{22.45}$$

will approximate the response in Figure 22.1a. The response in Figure 22.2a can be expressed as the sum of the two responses shown in Figure 22.2b and c. We observe that if $F_b(z_1, z_2)$ is the transfer function of the filter approximating the response in Figure 22.2b then

$$F_c(z_1, z_2) = F_b(-z_1, -z_2) \tag{22.46}$$

will approximate the response in Figure 22.14c. This is due to the fact that negating the arguments shifts the (periodic) frequency response of F_b by (π, π). The response in Figure 22.14b can be expressed as the product of two ideal 1-D low-pass filters, one horizontal and one vertical, which have the response shown in Figure 22.14d. This 1-D frequency response can be approximated by a half-band filter. Such an approximation will produce a response in which the transition band straddles both sides of the cutoff frequency boundaries in Figure 22.14a. If we wish to constrain the transition band to lie within the boundaries of the diamond-shaped region in Figure 22.13a, then we should choose a 1-D filter whose stopband interval is $(\pi/2, \pi)$. Let $H(z)$ be the transfer function of the prototype 1-D low-pass filter approximating the response in Figure 22.14d with a suitably chosen transition boundary. The transfer function $H(z)$ can be expressed as

$$H(z) = T_1(z^2) + zT_2(z^2). \tag{22.47}$$

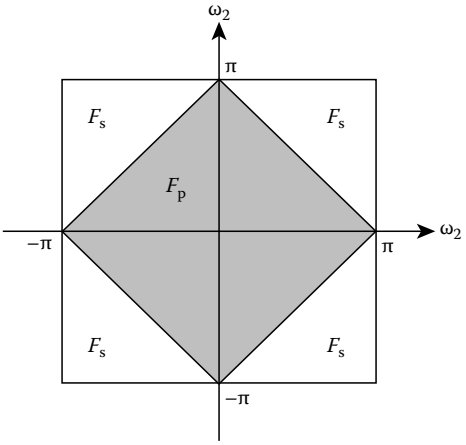

FIGURE 22.13 Ideal frequency response of a diamond filter.

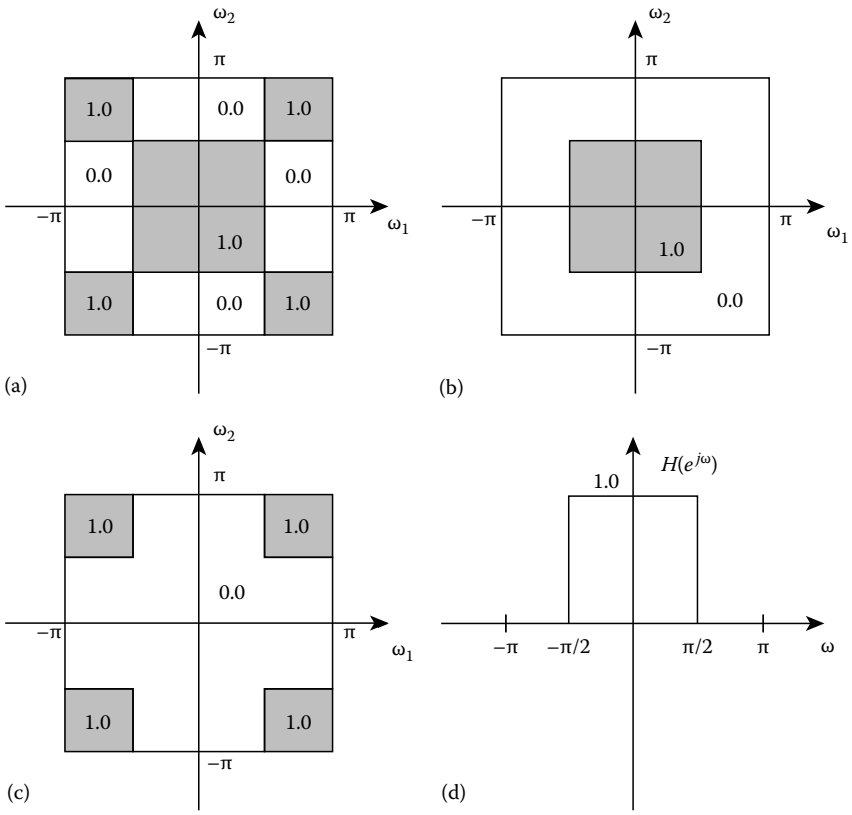

FIGURE 22.14 Ideal frequency responses of the filters: (a) $F_a(z_1, z_2)$, (b) $F_b(-z_1, -z_2)$, (c) $F_c(z_1, z_2)$, and (d) $H(z)$ in obtaining a diamond filter.

The transfer function F_a is given by

$$F_a(z_1, z_2) = H(z_1)H(z_2) + H(-z_1)H(-z_2). \tag{22.48}$$

Combining Equations 22.45, 22.47, and 22.48 we get

$$D(z_1, z_2) = 2T_1(z_1, z_2)T_1\left(z_1^{-1}z_2\right) + 2z_2T_2(z_1, z_2)T_2\left(z_1^{-1}z_2\right). \tag{22.49}$$

As mentioned before, $H(z)$ can be chosen to be a half-band filter with

$$T_1(z^2) = 0.5. \tag{22.50}$$

The filter T_2 can be either FIR or IIR. It should be noted that the result can also be obtained as a nonrectangular downsampling, by a factor of 2, of the impulse response of the filter $F_b(-z_1, -z_2)$.

Another approach that utilizes multirate concepts is based on a novel idea of applying frequency masking in the 2-D case [31].

22.5 2-D FIR Filter Implementation

The straightforward way to implement 2-D FIR filters is to evaluate the convolution sum given in Equation 22.1. Let us assume that the FIR filter has L nonzero coefficients in its region of support I. In order to get an output sample, L multiplications and L additions need to be performed. The number of arithmetic operations can be reduced by taking advantage of the symmetry of the filter coefficients, that is, $h(n_1, n_2) = h(-n_1, -n_2)$. For example, let the filter support be a rectangular region, $I = \{n_1 = -N_1, \ldots, 0, 1, \ldots, N_1, n_2 = -N_2, \ldots, 0, 1, \ldots, N_2\}$. In this case,

$$y(n_1, n_2) = \sum_{k_1=-N_1}^{N_1} \sum_{k_2=1}^{N_2} [h(k_1, k_2)x(n_1 - k_1, n_2 - k_2) + x(n_1 + k_1, n_2 + k_2)] + h(0,0)x(n_1, n_2) + \sum_{k_1=1}^{N_1} h_1(k_1, 0)[x(n_1 - k_1, n_2) + x(n_1 + k_1, n_2)], \quad (22.51)$$

which requires approximately half of the multiplications required in the direct implementation equation 22.1.

Any 2-D FIR filter can also be implemented by using an FFT algorithm. This is the direct generalization of 1-D FFT-based implementation [14,30]. The number of arithmetic operations may be less than the space domain implementation in some cases.

Some 2-D filters have special structures that can be exploited during implementation. As we pointed out in Section 22.4, 2-D filters designed by McClellan-type transformations can be implemented in an efficient manner [14,34,35] by building a network whose basic module is the transformation function which is usually a low order 2-D FIR filter.

2-D FIR filters that have separable system responses can be implemented in a cascade structure. In general, an arbitrary 2-D polynomial cannot be factored into subpolynomials due to the absence of a counterpart of fundamental theorem of algebra in two or higher dimensions (whereas in 1-D any polynomial can be factored into polynomials of lower orders). Since separable 2-D filters are constructed from 1-D polynomials, they can be factored and implemented in a cascade form. Let us consider Equation 22.35 where $H(x_1, x_2) = H_1(x_2)H_2(x_2)$ which corresponds to $h(n_1, n_2) = h_1(n_1)\, h_2(n_2)$ in space domain. Let us assume that orders of the 1-D filters $h_1(n)$ and $h_2(n)$ are $2N_1 + 1$ and $2N_2 + 1$, respectively. In this case the 2-D filter, $h(n_1, n_2)$, has the same rectangular support, I, as in Equation 22.51. Therefore,

$$y(n_1, n_2) = \sum_{k_2=-N_2}^{N_2} h_2(k_2) \sum_{k_1=-N_1}^{N_1} h(k_1)x(n_1 - k_1, n_2 - k_2). \quad (22.52)$$

The 2-D filtering operation in Equation 22.52 is equivalent to a two-stage 1-D filtering in which the input image, $x(n_1, n_2)$, is first filtered horizontally line by line by $h_1(n)$, then the resulting output is filtered vertically column by column by $h_2(n)$. In order to produce an output sample, the direct implementation requires $(2N_1 + 1) \times (2N_2 + 1)$ multiplications, whereas the separable implementation requires $(2N_1 + 1) + (2N_2 + 1)$ multiplications, which is computationally much more efficient than the direct form realization. This is achieved at the expense of memory space (separable implementation needs a buffer to store the results of first stage during the implementation). By taking advantage of the symmetric nature of h_1 and h_2, the number of multiplications can be further reduced.

Filter design methods by imposing structural constraints like cascade, parallel, and other forms are proposed by several researchers including Refs. [16,47]. These filters can be efficiently implemented because of their special structures. Unfortunately, the design procedure requires nonlinear optimization techniques which may be very complicated.

With advances in VLSI technology, the implementation of 2-D FIR filters using high-speed digital signal processors is becoming increasingly common in complex image processing systems.

22.6 Two-Dimensional Filter Banks

2-D subband decomposition of signals using filter banks (that implement a 2-D wavelet transform) find applications in a wide range of tasks including image and video coding, restoration, denoising, and signal analysis. For example, in recently finalized JPEG-2000 image coding standard an image is first processed by a 2-D filter bank. Data compression is then carried out in the subband domain. In this section we briefly discuss the case of four-channel separable filter banks. Chapter 24 provides a detailed description of 1-D filter banks.

In most cases, 2-D filter banks are constructed in a separable form with the use of the filters of 1-D filter banks, i.e., as a product of two 1-D filters [49,52]. We confine our attention to a 2-D four-channel filter bank obtained from a 1-D two-channel filter bank. Let h_0 and h_1 denote the analysis filters of a 1-D two-channel filter bank. The four analysis filters of the separable 2-D filter bank are given by

$$h_{i,j}(n_1, n_2) = h_i(n_1)h_j(n_2), \quad i, j = 0, 1. \tag{22.53}$$

The filters h_0 and h_1 can be either FIR or IIR. If they are FIR (IIR), then the 2-D filters, $h_{i,j}$, are also FIR (IIR). Frequency responses of these four filters, $H_{i,j}(\omega_1, \omega_2)$, $i,j = 0, 1$, are given by

$$H_{i,j}(\omega_1, \omega_2) = H_i(\omega_1)H_j(\omega_2), \quad i, j = 0, 1, \tag{22.54}$$

where $H_0(\omega_1)$ and $H_1(\omega_2)$ are the frequency responses of the 1-D low-pass (approximating an ideal cutoff frequency at $\pi/2$) and high-pass filters of a 1-D subband filter bank, respectively [51]. Any 1-D filter bank described in Chapter 24 can be used in Equation 22.53 to design 2-D filter banks. Feature-rich structures for 1-D filter banks are described in Ref. [6].

The 2-D signal is decomposed by partitioning its frequency domain support into four rectangular regions of equal areas. The ideal passband regions of the filters, $H_{i,j}(\omega_1, \omega_2)$, are shown in Figure 22.15. For example, the ideal passband of $H_{0,0}(\omega_1, \omega_2)$ is the square region $[-\pi/2, \pi/2] \times [-\pi/2, \pi/2]$. The 2-D filter bank is shown in Figure 22.16.

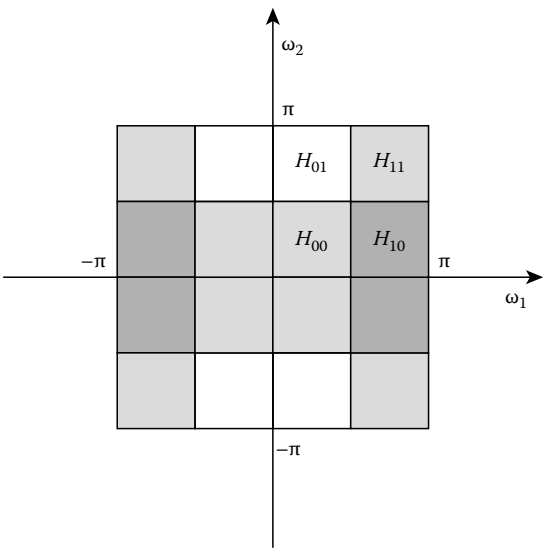

FIGURE 22.15 Ideal passband regions of the separable filters of a rectangular filter bank.

Corresponding 2-D synthesis filters are also constructed in a separable manner from the synthesis filters of the 1-D filter bank. If the 1-D filter bank has the perfect reconstruction (PR) property, then the 2-D filter bank also has the PR property. Subband decomposition filter banks (or filter banks implementing the 2-D wavelet transform) consist of analysis and synthesis filters, upsamplers, and downsamplers as discussed in Chapter 24. In the separable 2-D filter bank, downsampling is carried out both horizontally and vertically as follows:

$$x_0(n_1, n_2) = x_a(2n_1, 2n_2). \tag{22.55}$$

Here we consider the input 2-D signal x_a to be an image. The downsampled image x_0 is a quarter-size version of x_a. Only one sample out of four is retained in the downsampling operation described in Equation 22.55. The upsampling operation is the dual of the downsampling

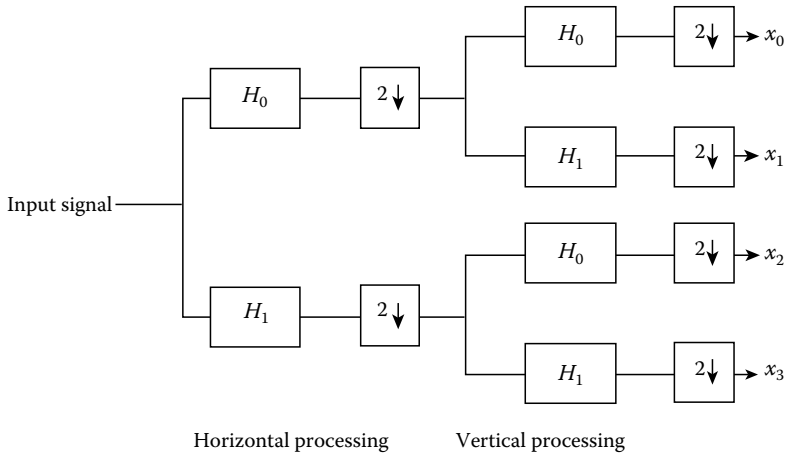

FIGURE 22.16 Block diagram of separable processing in 2D filter bank.

operation. In other words, a zero valued sample is inserted in upsampling corresponding to the location of each dropped sample during downsampling.

The implementation of the above filter bank can be carried out separably in a computationally efficient manner as described in Chapter 24 and Refs. [49,52]. The input image is first processed horizontally row by row by a 1-D filter bank with filters, h_0 and h_1. After the input signal is horizontally filtered with the 1-D two-channel filter bank, the signal in each channel is downsampled row-wise to yield two images. Each image is then filtered and downsampled vertically by the filter bank. As a result, four quarter-size subimages, x_i, $i = 0, 1, 2, 3$, are obtained. These images are the same as the images obtained by direct implementation of the analysis filter bank shown in Figure 22.16. The synthesis filter bank is also implemented in a separable manner.

Nonseparable 2-D filter banks [14] are not as computationally efficient as separable filter banks as discussed in Section 22.5.

In two or higher dimensions, downsampling and upsampling are not restricted to the rectangular grid, but can be carried out in a variety of ways. One example of this is quincunx downsampling where the downsampled image x_q is related to the input image x_a as follows:

$$x_q(n_1, n_2) = x_a(n_1 + n_2, n_2 - n_1). \tag{22.56}$$

In this case only the samples for which $n_1 + n_2$ is even are retained in the output. Filter banks employing quincunx and other downsampling strategies are described in Refs. [6,8,9,19,50,52] and in Chapter 25. Filter banks that employ quincunx downsampling have only two channels and the frequency support is partitioned in a diamond-shaped manner as shown in Figure 22.13. Filters of a quincunx filter bank which have diamond-shaped passbands and stopbands can be designed from a 1-D subband decomposition filter bank using the transformation method described in Equations 22.45 through 22.48. Chapter 25 provides a detailed discussion of the theory and applications of directional filter banks.

Acknowledgments

The authors would like to express their sincere thanks to Omer Nezih Gerek, Imad Abdel Hafez, and Ahmet Murat Bagci for the help they provided in preparing the figures for the chapter.

23.1 Introduction

A linear 2-D IIR digital filter can be characterized by its transfer function

$$H(z_1, z_2) = \frac{N(z_1, z_2)}{D(z_1, z_2)} = \frac{\sum_{i=0}^{N_2} \sum_{j=0}^{M_2} a_{ij} z_1^{-i} z_2^{-j}}{\sum_{i=0}^{N_1} \sum_{j=0}^{M_1} b_{ij} z_1^{-i} z_2^{-j}} \tag{23.1}$$

where the sampling period $T_i = 2\pi/\omega_{si}$ for $i = 1, 2$ with ω_{si} and the sampling frequencies a_{ij} and b_{ij} are real numbers known as the coefficients of the filter. Without loss of generality we can assume $M_1 = M_2 = N_1 = N_2 = M$ and $T_1 = T_2 = T$. Designing a 2-D filter is to calculate the filter coefficients a_{ij} and b_{ij} in such a way that the amplitude response and/or the phase response (group delay) of the designed filter approximates to some ideal responses while maintaining the stability of the designed filter. The latter requires that

$$D(z_1, z_2) \neq 0 \quad \text{for } |z_i| \geq 1,\ i = 1, 2 \tag{23.2}$$

The amplitude response of the 2-D filter is expressed as

$$M(\omega_1, \omega_2) = \left| H(e^{j\omega_1 T}, e^{j\omega_2 T}) \right| \tag{23.3}$$

the phase response as

$$\phi(\omega_1, \omega_2) = \arg H(e^{j\omega_1 T}, e^{j\omega_2 T}) \tag{23.4}$$

and the two group delay functions as

$$\tau_i(\omega_1, \omega_2) = \frac{d\phi(\omega_1, \omega_2)}{d\omega_i}, \; i = 1, 2 \tag{23.5}$$

Equation 23.1 is the general form of transfer functions of the nonseparable numerator and denominator 2-D IIR filters. It can involve two subclasses, namely, the separable product transfer function

$$\begin{aligned} H(z_1, z_2) &= H_1(z_1)H_2(z_2) \\ &= \frac{\sum_{i=0}^{N_2} a_{1i} z_1^{-i} \sum_{j=0}^{M_2} a_{2i} z_2^{-j}}{\sum_{i=0}^{N_1} b_{1i} z_1^{-i} \sum_{j=0}^{M_1} b_{2i} z_2^{-j}} \end{aligned} \tag{23.6}$$

and the separable denominator, nonseparable numerator transfer function given by

$$H(z_1, z_2) = \frac{\sum_{i=0}^{N_2} \sum_{j=0}^{M_2} a_{ij} z_1^{-i} z_2^{-j}}{\sum_{i=0}^{N_1} b_{1i} z_1^{-i} \sum_{j=0}^{M_1} b_{2j} z_2^{-j}} \tag{23.7}$$

The stability constraints for the above two transfer functions are the same as those for the individual two 1-D cases. These are easy to check and correspondingly the transfer function is easy to stabilize if the designed filter is found to be unstable. Therefore, in the design of the above two classes, in order to reduce the stability problem to that of the 1-D case, the denominator of the 2-D transfer function is chosen to have two 1-D polynomials in z_1 and z_2 variables in cascade. However, in the general formulation of nonseparable numerator and denominator filters, this oversimplification is removed. The filters of this type are generally designed either through transformation of 1-D filters, or through optimization approaches, as is discussed in the following.

23.2 Transformation Techniques

23.2.1 Analog Filter Transformations

In the design of 1-D analog filters, a group of analog filter transformations of the form $s = g(s')$ is usually applied to normalized continuous low-pass transfer functions like those obtained by using the Bessel, Butterworth, Chebyshev, and elliptic approximations. These transformations can be used to design low-pass, high-pass, bandpass, or bandstop filters satisfying piecewise-constant amplitude response specifications. Through the application of the bilinear transformation, corresponding 1-D digital filters can be designed, and since 2-D digital filters can be designed in terms of 1-D filters, these transformations are of considerable importance in the design of 2-D digital filters as well. In the 2-D cases, the transformations have a form of

$$s = g(s_1, s_2) \tag{23.8}$$

As a preamble, in this section two groups of transformations of interest in the design of 2-D digital filters are introduced, which essentially produce 2-D continuous transfer functions from 1-D ones.

23.2.1.1 Rotated Filter

The first group of transformations, suggested by Shanks, Treitel, and Justice [1], are of the form

$$g_1(s_1, s_2) = -s_1 \sin\beta + s_2 \cos\beta \tag{23.9a}$$

$$g_2(s_1, s_2) = s_1 \cos\beta + s_2 \sin\beta \tag{23.9b}$$

They map 1-D into 2-D filters with arbitrary directionality in a 2-D frequency response plane. These filters are called rotated filters because they are obtained by rotating 1-D filters.

If $H(s)$ is a 1-D continuous transfer function, then a corresponding 2-D continuous transfer function can be generated as

$$H_{D1}(s_1, s_2) = H(s)\Big|_{s=g_1(s_1,s_2)} \tag{23.10a}$$

$$H_{D2}(s_1, s_2) = H(s)\Big|_{s=g_2(s_1,s_2)} \tag{23.10b}$$

by replacing the s in $H(s)$ with $g_1(s_1, s_2)$ and $g_2(s_1, s_2)$, respectively.

It is easy to show [2] that a transformation of $g_1(s_1, s_2)$ or $g_2(s_1, s_2)$ will give rise to a contour in the amplitude response of the 2-D analog filter that is a straight line rotated by an angle β with respect to the s_1 or s_2 axis, respectively. Figure 23.1 illustrates an example of 1-D to 2-D analog transformation by (23.10a) for $\beta = 0^\circ$ and $\beta = 45^\circ$.

The rotated filters are of special importance in the design of circularly symmetric filters, as will be discussed in Section 23.4.

23.2.1.2 Transformation Using a Two-Variable Reactance Function

The second group of transformations is based on the use of a two-variable reactance function. One of the transformations was suggested by Ahmadi, Constantinides, and King [3,4]. This is given by

$$g_3(s_1, s_2) = \frac{a_1 s_1 + a_2 s_2}{1 + b s_1 s_2} \tag{23.11}$$

where a_1, a_2, and b are all positive constants.

Let us consider a 2-D filter designed by using a 1-D analog low-pass filter with cutoff frequency Ω_c. Equation 23.11 results in

$$\Omega_2 = \frac{\Omega_c - a_1 \Omega_1}{a_2 - b\Omega_c \Omega_1} \tag{23.12}$$

The mapping of $\Omega = \Omega_c$ onto the (Ω_1, Ω_2) plane for various values of b is depicted in Figure 23.2 [5]. The cutoff frequencies along the Ω_1 and Ω_2 axes can be adjusted by simply varying a_1 and a_2. On the other hand, the convexity of the boundary can be adjusted by varying b. We note that b must be greater than zero to preserve stability. Also, it should be noted that $g_3(s_1, s_2)$ becomes a low-pass to bandpass transformation along $s_1 = s_2$, and therefore the designed filter will behave like a bandstop filter along $\Omega_1 = \Omega_2$. This problem can be overcome by using a guard filter of any order.

King and Kayran [6] have extended the above technique by using a higher order reactance function of the form

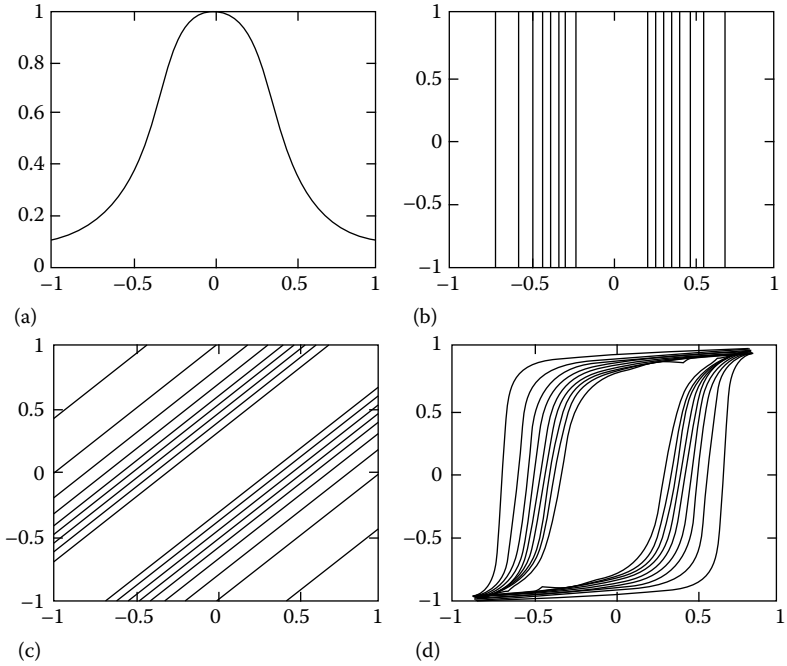

FIGURE 23.1 1D to 2D analog filter transformation. (a) Amplitude response of 1D analog filter. (b) Contour plot of 2D filter, $\beta = 0°$. (c) Contour plot of 2D filter, $\beta = 45°$. (d) Contour plot of 2D filter, $\beta = 45°$, after applying double bilinear transformation.

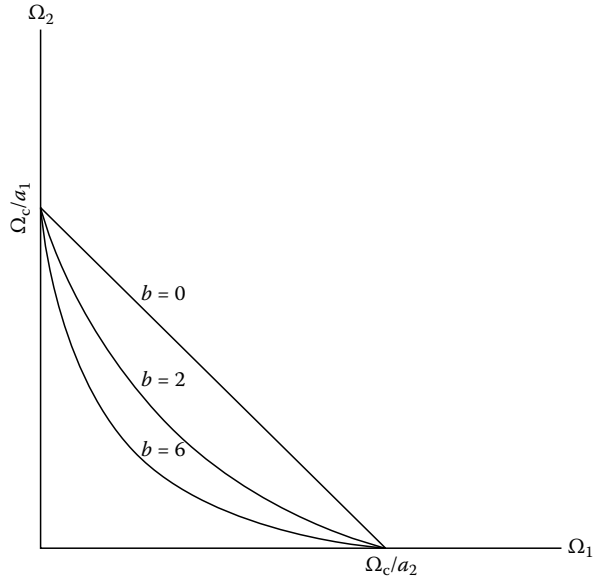

FIGURE 23.2 Plot of Equation 23.12 for different values of b.

$$g_4(s_1, s_2) = \frac{a_1 s_1 + a_2 s_2}{1 + b_1(s_1^2 + s_2^2) + b_2 s_1 s_2} \tag{23.13}$$

and they proved that the stability of $g_4(s_1, s_2)$ is ensured if

$$b_1 > 0 \tag{23.14}$$

and

$$b_1 > \frac{b_2^2}{4} - b_1^2 > 0 \tag{23.15}$$

However, it is necessary as earlier to include a guard filter, which may have the simple form of

$$G(z_1, z_2) = \frac{(1 + z_1)(1 + z_2)}{(d_1 + z_1)(d_2 + z_2)} \tag{23.16}$$

in order to remove the high-pass regions along all radii except the coordinate axes.

Then, through an optimization procedure, the coefficients of $g_4(s_1, s_2)$ and $G(z_1, z_2)$ are calculated subject to the constraints of Equations 23.14 and 23.15, so that the cutoff frequency of the 1-D filter is mapped into a desired cutoff boundary in the (Ω_1, Ω_2) plane.

23.2.2 Spectral Transformations

Spectral transformation is another kind of important transformation in the design of both 1-D and 2-D IIR filters. In this section, three groups of spectral transformations are discussed. Among them, the linear transformations map frequency axes onto frequency axes in the (Ω_1, Ω_2) plane, the complex transformation is of wide applications to the design of fan filters, and the Constantinides transformations transform a discrete function into another discrete function and through which any transformation of a low-pass filter to another low-pass, high-pass, bandpass, or bandstop filter becomes possible.

23.2.2.1 Linear Transformations

Consider a group of linear transformations that map frequency axes onto themselves in the (Ω_1, Ω_2) plane. There are eight possible such transformations [7,8] and they have the algebraic structure of a finite group under the operation of multiplication [2]; each transformation can be expressed as

$$\begin{bmatrix} \omega_1 \\ \omega_2 \end{bmatrix} := D(T) \begin{bmatrix} \omega_1 \\ \omega_2 \end{bmatrix} \tag{23.17}$$

where $D(T)$ is a 2×2 unitary matrix representing transformation $T\delta$. The eight transformations and their effect on the frequency response of the digital filter are as follows with a multiplication table being illustrated in Table 23.1 [2].

1. Identity (I):

$$D(I) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

2. Reflection about the ω_1 axis ($\rho_{\omega 1}$):

$$D(\rho_{\omega 1}) = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$$

TABLE 23.1 Multiplication Table of Group

	I	$\rho\omega 1$	$\rho\omega 2$	$\rho\psi 1$	$\rho\psi 2$	R_4	R_4^2	R_4^3
I	I	$\rho\omega 1$	$\rho\omega 2$	$\rho\psi 1$	$\rho\psi 2$	R_4	R_4^2	R_4^3
$\rho\omega 1$	$\rho\omega 1$	I	R_4^2	R_4^3	R_4	$\rho\psi 2$	$\rho\omega 2$	$\rho\psi 1$
$\rho\omega 2$	$\rho\omega 2$	R_4^2	I	R_4	R_4^3	$\rho\psi 1$	$\rho\omega 1$	$\rho\psi 2$
$\rho\psi 1$	$\rho\psi 1$	R_4	R_4^3	I	R_4^2	$\rho\omega 1$	$\rho\psi 2$	$\rho\omega 2$
$\rho\psi 2$	$\rho\psi 2$	R_4^3	R_4	R_4^2	I	$\rho\omega 2$	$\rho\psi 1$	$\rho\omega 1$
R_4	R_4	$\rho\psi 1$	$\rho\psi 2$	$\rho\omega 2$	$\rho\omega 1$	R_4^2	R_4^3	I
R_4^2	R_4^2	$\rho\omega 2$	$\rho\omega 1$	$\rho\psi 2$	$\rho\psi 1$	R_4^3	I	R_4
R_4^3	R_4^3	$\rho\psi 2$	$\rho\psi 1$	$\rho\omega 1$	$\rho\omega 2$	I	R_4	R_4^2

3. Reflection about the ω_2 axis ($\rho_{\omega 2}$):

$$D(\rho_{\omega 2}) = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}$$

4. Reflection about the ($\rho_{\psi 1}$):

$$D(\rho_{\psi 1}) = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$$

5. Reflection about the ($\rho_{\psi 2}$):

$$D(\rho_{\psi 2}) = \begin{bmatrix} 0 & -1 \\ -1 & 0 \end{bmatrix}$$

6. Counterclockwise rotation by 90° (R_4):

$$D(R_4) = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}$$

7. Counterclockwise rotation by 180° (R_4^2):

$$D\left(R_4^2\right) = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}$$

8. Counterclockwise rotation by 270° (R_4^3):

$$D\left(R_4^3\right) = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}$$

In the above symbolic representation, ψ_1 and ψ_2 represent axes that are rotated by 45° in the counterclockwise sense relative to the ω_1 and ω_2 axes, respectively, and R_k denotes rotation by $360°/k$ in the counterclockwise sense. These transformations could equivalently be defined in the (z_1, z_2) domain by complex conjugating and/or interchanging the complex variables z_1 and z_2 in the filter transfer function.

An important property of the group is that each transformation distributes over a product of functions of ω_1 and ω_2, that is,

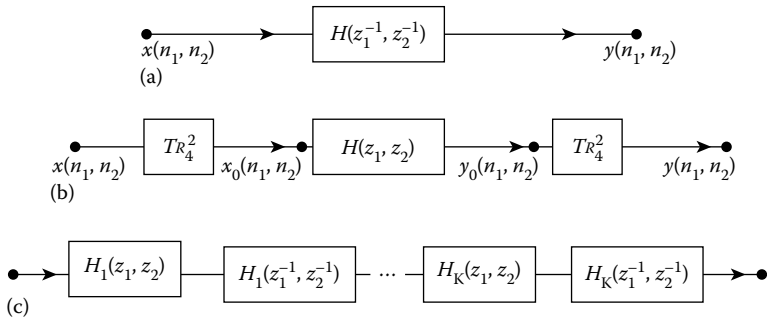

FIGURE 23.3 Design of zero-phase filters: (a) noncausal filter; (b) equivalent causal implementation; (c) cascade zero-phase filter.

$$T_\delta\left[\prod_{i=1}^{K} F_i(\omega_1, \omega_2)\right] = \prod_{i=1}^{K} T_\delta[F_i(\omega_1, \omega_2)] \tag{23.18}$$

where $T\delta$ represents any of the eight transformation operators. The validity of this property follows the definition of the transformations [8].

In the (z_1, z_2) domain, if $H(z_1, z_2)$ represents a causal filter with impulse response $h(n_1, n_2)$, then the filter represented by $H(z_1^{-1}, z_2^{-1})$will have an impulse response $h(-n_1, -n_2)$, and is therefore, noncausal, since $h(-n_1, -n_2) \neq 0$ for $n_1 < 0$, $n_2 < 0$. Such a filter can be implemented in terms of causal transfer function $H(z_1, z_2)$, i.e., by rotating the n_1 and n_2 axes of the input signal by 180°, processing the rotated signal by the causal filter, and then rotating the axes of the output signal by 180°, as illustrated in Figure 23.3b.

Noncausal filters can be used for the realization of zero-phase filters by cascading K pairs of filters whose transfer functions are $H_i(z_1, z_2)$ and $H(z_1^{-1}, z_2^{-1})$ for $i = 1, 2, \ldots, K$, as depicted in Figure 23.3c.

23.2.2.2 Complex Transformation and 2-D Fan Filters

Complex Transformation. A complex transformation is of the form [9]

$$z = e^{\phi} z_1^{\alpha_1/\beta_1} z_2^{\alpha_2/\beta_1} \tag{23.19}$$

by which a 2-D filter $H(z_1, z_2)$ can be derived from 1-D filter $H_1(z)$. The corresponding frequency transformation of Equation 23.19 is

$$\exp(j\omega) \rightarrow \exp\left\{j\left(\phi + \omega_1 \frac{\alpha_1}{\beta_1} + \omega_2 \frac{\alpha_2}{\beta_2}\right)\right\} \tag{23.20}$$

or

$$\omega \rightarrow \phi + \omega_1 \frac{\alpha_1}{\beta_1} + \omega_2 \frac{\alpha_2}{\beta_2} \tag{23.21}$$

There are three major effects of transformation Equation 23.20 on the resulting filter:

1. Frequency shifting along the ω_1 axis. The frequency response of the resulting filter will be shifted by ϕ along the ω_1 axis.
2. Rotation of the frequency response. The angle of rotation is

$$\theta = \arctan\left(\frac{\alpha_2}{\beta_2}\right) \tag{23.22}$$

Since the original filter is 1-D and a function of z_1, the angle of rotation will be defined by the fractional power of z_2.

3. Scaling the frequency response along the ω_1 axis. The fractional power of z_1 will scale the frequency response by a factor β_1/α_1. However, the periodicity of the frequency response will be $(\alpha_1/\beta_1)2\pi$ instead of 2π. Other effects may also be specified [9].

The complex transformation is of importance in the design of fan filters. By using a prototype lowpass filter with a cutoff frequency at $\omega_c = \pi/2$, and the transformation Equation 23.19, one obtains the shifted, scaled, and rotated characteristics in the frequency domain. We denote the transformed filter by

$$H\left(z_1, z_2; \frac{\alpha_1}{\beta_1}, \frac{\alpha_2}{\beta_2}\right) = H_1(z)\Big|_{z=e^{\phi} z_1^{\alpha_1/\beta_1} z_2^{\alpha_2/\beta_2}} \tag{23.23}$$

In general, the filter coefficients in function H will be complex and the variables z_1 and z_2 will have rational noninteger powers. However, appropriate combinations of transformed filters will remove both of these difficulties, as will be shown in the following.

Symmetric Fan Filters. An ideal symmetric fan filter has the specification of

$$H_{f1}(e^{j\omega_1 T}, e^{j\omega_2 T}) = \begin{cases} 1 & \text{for } |\omega_1| \geq |\omega_2| \\ 0 & \text{otherwise} \end{cases} \tag{23.24}$$

We introduce transfer function $\hat{H}_1(z_1, z_2)$, $\hat{H}_2(z_1, z_2)$, $\hat{H}_3(z_1, z_2)$, and $\hat{H}_4(z_1, z_2)$, of four filters generated by Equation 23.23 with $(\alpha_1/\beta_1, \alpha_1/\beta_2) = (1/2, 1/2)$, $(-1/2, 1/2)$, $(1/2, -1/2)$, and $(-1/2, -1/2)$, respectively, and $\phi = \pi/2$. The responses of the transformed filters, $\hat{H}_i(z_1, z_2)$, $i = 1, 2, 3, 4$, can be found in Figure 23.4 together with the prototype filter.

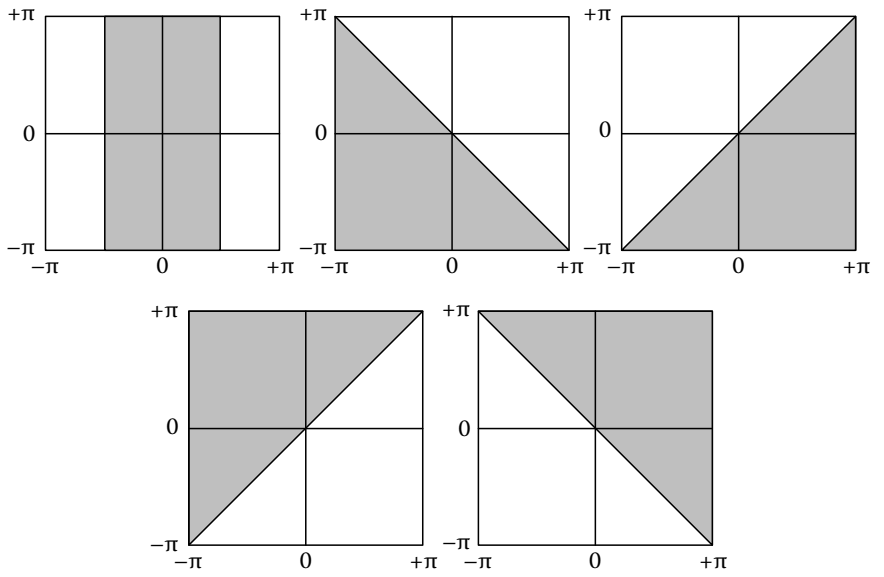

FIGURE 23.4 Basic building blocks of symmetric fan filters.

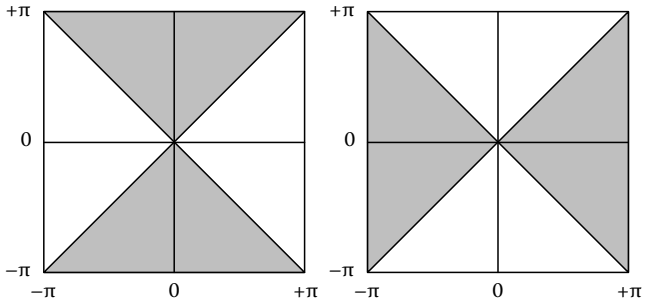

FIGURE 23.5 Amplitude characteristics of $G_{11}(z_1, z_2)$ and $G_{22}(z_1, z_2)$.

In this design procedure, the filters in Figure 23.4 will be used as the basic building blocks for a fan filter specified by Equation 23.24. One can construct the following filter characteristics:

$$G_{11}(z_1,z_2) = \hat{H}_1(z_1,z_2)\hat{H}_1^{\star}\left(z_1^{-1},z_2^{-1}\right)\hat{H}_2(z_1,z_2)\hat{H}_2^{\star}\left(z_1^{-1},z_2^{-1}\right) + \hat{H}_3(z_1,z_2)\hat{H}_3^{\star}\left(z_1^{-1},z_2^{-1}\right)\hat{H}_4(z_1,z_2)\hat{H}_4^{\star}\left(z_1^{-1},z_2^{-1}\right) \tag{23.25a}$$

$$G_{22}(z_1,z_2) = \hat{H}_1(z_1,z_2)\hat{H}_1^{\star}\left(z_1^{-1},z_2^{-1}\right)\hat{H}_3(z_1,z_2)\hat{H}_3^{\star}\left(z_1^{-1},z_2^{-1}\right) + \hat{H}_2(z_1,z_2)\hat{H}_2^{\star}\left(z_1^{-1},z_2^{-1}\right)\hat{H}_4(z_1,z_2)\hat{H}_4^{\star}\left(z_1^{-1},z_2^{-1}\right) \tag{23.25b}$$

which are shown in Figure 23.5.

Quadrant Fan Filters. The frequency characteristic of a quadrant fan filter is specified as

$$H_{f2}(e^{j\omega_1 T}, e^{j\omega_2 T}) = \begin{cases} 1 & \text{for } \omega_1\omega_2 \geq 0 \\ 0 & \text{otherwise} \end{cases} \tag{23.26}$$

We consider the same ideal prototype filter. Then the transformed filters $\hat{H}_{14}(z_1, z_2)$, $\hat{H}_{12}(z_1, z_2)$, $\hat{H}_{23}(z_1, z_2)$, and $\hat{H}_{34}(z_1, z_2)$, are obtained via Equation 23.23 with $(\alpha_1/\beta_1, \alpha_2/\beta_2)$ equal to (1, 0), (0, 1), $(-1, 0)$, and $(0, -1)$, respectively, and $\phi = \pi/2$. The subscripts on $\hat{H}$ refer to quadrants to which the low-pass filter characteristics have been shifted. Figure 23.6 illustrates the amplitude responses of these transformed filters together with the prototype.

The filters in Figure 23.6 will be used as the basic building blocks for fan filters specified by Equation 23.26. In a similar manner to Equations 23.25a and b, the filter characteristics $G_{13}(z_1, z_2)$ and $G_{23}(z_1, z_2)$ can be constructed as follows:

$$G_{13}(z_1,z_2) = \hat{H}_{12}(z_1,z_2)\hat{H}_{12}^{\star}\left(z_1^{-1},z_2^{-1}\right)\hat{H}_{14}(z_1,z_2)\hat{H}_{14}^{\star}\left(z_1^{-1},z_2^{-1}\right) + \hat{H}_{23}(z_1,z_2)\hat{H}_{23}^{\star}\left(z_1^{-1},z_2^{-1}\right)\hat{H}_{34}(z_1,z_2)\hat{H}_{34}^{\star}\left(z_1^{-1},z_2^{-1}\right) \tag{23.27a}$$

$$G_{24}(z_1,z_2) = \hat{H}_{12}(z_1,z_2)\hat{H}_{12}^{\star}\left(z_1^{-1},z_2^{-1}\right)\hat{H}_{23}(z_1,z_2)\hat{H}_{23}^{\star}\left(z_1^{-1},z_2^{-1}\right) + \hat{H}_{14}(z_1,z_2)\hat{H}_{14}^{\star}\left(z_1^{-1},\ z_2^{-1}\right)\hat{H}_{34}(z_1,z_2)\hat{H}_{34}^{\star}\left(z_1^{-1},z_2^{-1}\right) \tag{23.27b}$$

whose amplitude responses are depicted in Figure 23.7.

23.2.2.3 Constantinides Transformations

The so-called Constantinides [10,19] are of importance in the design of 1-D digital filters, and are of the form

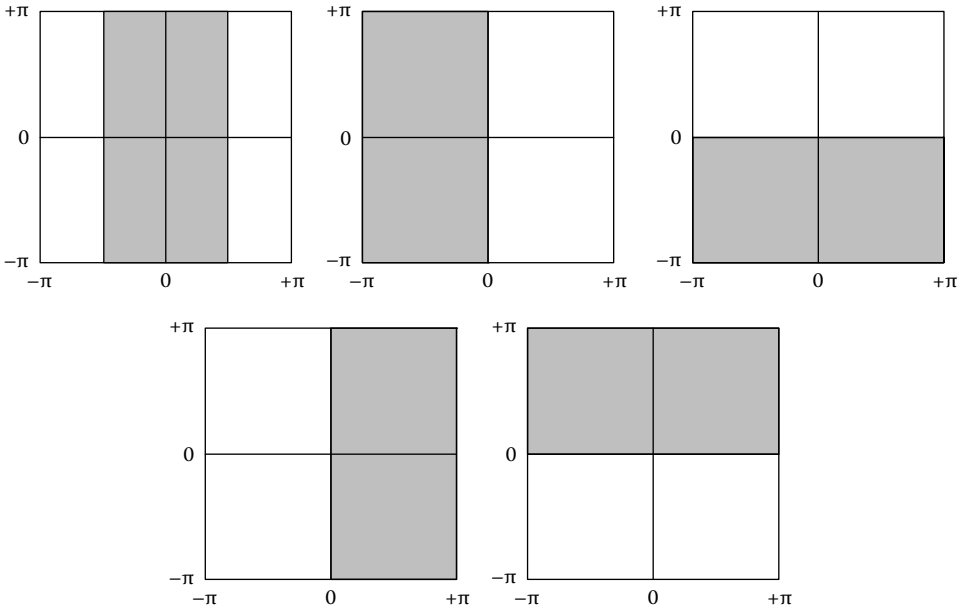

FIGURE 23.6 Basic building blocks for quadrant fan filter design.

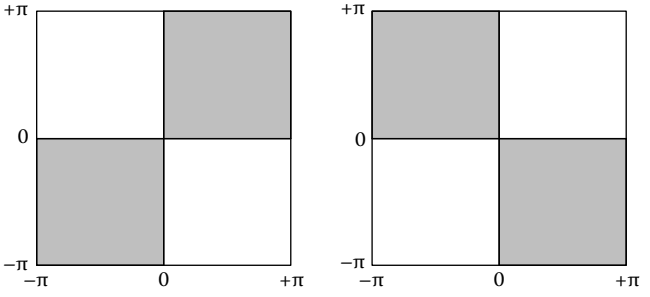

FIGURE 23.7 Two quadrant pass filters.

$$z = f(\bar{z}) = e^{jl\pi} \prod_{t=1}^{m} \frac{\bar{z} - a_t^{\star}}{1 - a_t \bar{z}} \tag{23.28}$$

where

l and m are integers

$a_t^{\star}$ is the complex conjugate of a_t

Pendergrass, Mitra, and Jury [11] showed that, in the decision of 2-D IIR filters, this group of transformations is as useful as in 1-D cases. By choosing the parameters l, m, and a_t in Equation 23.28 properly, a set of four specific transformations can be obtained that can be used to transform a low-pass transfer function into a corresponding low-pass, high-pass, bandpass, or a bandstop transfer function. These transformations are summarized in Table 23.2, where subscript i is included to facilitate the application of the transformation to 2-D discrete transfer functions.

Let Ω_i and ω_i for $i = 1, 2$ be the frequency variables in the original and transformed transfer function, respectively. Suppose $H_L(z_1, z_2)$ is a low-pass transfer function with respect to z_i, if each of z_1 and z_2 is

TABLE 23.2 Constantinides Transformations

Type	Transformation	Parameters
LP to LP	$z_i = \dfrac{\bar{z}_i - \alpha_i}{1 - \alpha_i \bar{z}_i}$	$\alpha_i = \dfrac{\sin\left[(\Omega_{pi} - \omega_{pi})T_i/2\right]}{\sin\left[(\Omega_{pi} + \omega_{pi})T_i/2\right]}$
LP to HP	$z_i = \dfrac{\bar{z}_i - \alpha_i}{1 - \alpha_i \bar{z}_i}$	$\alpha_i = \dfrac{\cos\left[(\Omega_{pi} - \omega_{pi})T_i/2\right]}{\cos\left[(\Omega_{pi} + \omega_{pi})T_i/2\right]}$
LP to BP	$z_i = -\dfrac{\bar{z}_i^2 - \dfrac{2\alpha_i k_i}{k_i+1}\bar{z}_i + \dfrac{k_i-1}{k_i+1}}{1 - \dfrac{2\alpha_i k_i}{k_i+1}\bar{z}_i + \dfrac{k_i-1}{k_i+1}\bar{z}_i^2}$	$\alpha_i = \dfrac{\cos\left[(\omega_{p2i} + \omega_{p1i})T_i/2\right]}{\cos\left[(\omega_{p2i} + \omega_{p1i})T_i/2\right]}$ $k_i = \tan\dfrac{\Omega_{pi}T_i}{2}\cot\dfrac{(\omega_{p2i} - \omega_{p1i})T_i}{2}$
LP to BS	$z_i = -\dfrac{\bar{z}_i^2 - \dfrac{2\alpha_i}{1+k_i}\bar{z}_i + \dfrac{1-k_i}{1+k_i}}{1 - \dfrac{2\alpha_i}{1+k_i}\bar{z}_i + \dfrac{1-k_i}{1+k_i}\bar{z}_i^2}$	$\alpha_i = \dfrac{\cos\left[(\omega_{p2i} + \omega_{p1i})T_i/2\right]}{\cos\left[(\omega_{p2i} + \omega_{p1i})T_i/2\right]}$ $k_i = \tan\dfrac{\Omega_{pi}T_i}{2}\tan\dfrac{(\omega_{p2i} - \omega_{p1i})T_i}{2}$

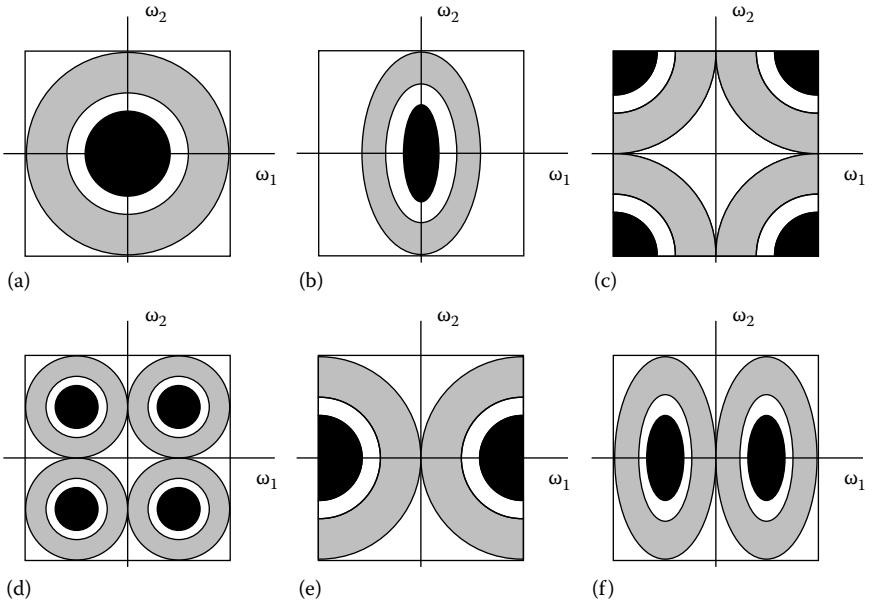

FIGURE 23.8 Application of Constantinides transformations to 2D IIR filters. (a) Circularly symmetric low-pass filter. (b) LP to LP for z_1 and z_2. (c) LP to HP for z_1 and z_2. (d) LP to BP for z_1 and z_2. (e) LP to HP for z_1 and LP to LP for z_2. (f) LP to BP for z_1 and LP to LP for z_2.

transformed to be low-pass, bandpass, or high-pass, then a number of different 2-D filter combinations can be achieved. As an example, some of the possible amplitude responses are illustrated in Figure 23.8a through f [2].

23.3 Design of Separable Product Filters

A 2-D IIR filter is characterized by a separable product transfer function of the form

$$H(z_1, z_2) = H_1(z_1)H_2(z_2) \tag{23.29}$$

if its passband or stopband is of the shape of a rectangular domain. The design of such a class of filters can be accomplished by using the method proposed by Hirano and Aggarwal [12]. The method can be used to design filters with quadrantal or half-plane symmetry.

23.3.1 Design of Quadrantally Symmetric Filters

A 2-D filter is said to be quadrantally symmetric if its amplitude response satisfies the equality

$$|H(z_1, z_2)| = |H(z_1^\star, z_1^\star)| = |H(z_1^\star, z_2)| = |H(z_1, z_1^\star)| \tag{23.30}$$

Consider two 1-D bandpass filters specified by two transfer functions $H_1(z)$ and $H_2(z)$, respectively, and let $z = z_1$ in the first one and $z = z_2$ in the second. If their frequency responses can be expressed by

$$\left|H_1(e^{j\omega_1 T_1})\right| = \begin{cases} 1 & \omega_{12} \le \omega_1 < \omega_{13} \\ 0 & 0 \le \omega_1 < \omega_{11} \text{ or } \omega_{14} \le \omega_1 < \infty \end{cases} \tag{23.31a}$$

and

$$\left|H_2(e^{j\omega_2 T_2})\right| = \begin{cases} 1 & \omega_{22} \le \omega_2 < \omega_{23} \\ 0 & 0 \le \omega_2 < \omega_{21} \text{ or } \omega_{24} \le \omega_2 \le \infty \end{cases} \tag{23.31b}$$

respectively, and since

$$\left|H(e^{j\omega_1 T_1}, e^{j\omega_2 T_2})\right| = \left|H_1(e^{j\omega_1 T_1})\right|\left|H_2(e^{j\omega_2 T_2})\right|$$

Equations 23.31a and b give

$$\left|H(e^{j\omega_1 T_1}, e^{j\omega_2 T_2})\right| = \begin{cases} 1 & \omega_{12} \le \omega_1 < \omega_{13} \text{ and } \omega_{22} \le \omega_2 < \omega_{23} \\ 0 & \text{otherwise} \end{cases}$$

Evidently, the 2-D filter obtained will pass frequency components that are in both passband of $H_1(z_1)$ and $H_2(z_2)$; that is, the passband $H_1(z_1, z_2)$ will be a rectangle with sides $\omega_{13} - \omega_{12}$ and $\omega_{23} - \omega_{22}$. On the other hand, frequency components that are in the stopband of either the first filter or the second filter will be rejected. Hence, the stopband of $H(z_1, z_2)$ consists of the domain obtained by combining the stopbands of the two filters.

By a similar method, if each of the two filters is allowed to be a low-pass, bandpass, or high-pass 1-D filter, then nine different rectangular passbands can be achieved, as illustrated in Figure 23.9. The cascade arrangement of any two of those filters may be referred to as a generalized bandpass filter [12].

Another typical simple characteristic is specified by giving the rectangular stopband region, which is referred to as the rectangular stop filter. Also, there are nine possible types of such a filter which are complementary to that of the generalized bandpass filter shown in Figure 23.9 (i.e., considering the shadowed region as the stopband). This kind of bandstop filter can be realized in the form of

$$H(z_1, z_2) = H_A(z_1)H_A(z_2) - e^{jk\pi}[H_1(z_1)H_2(z_2)]^2 \tag{23.32}$$

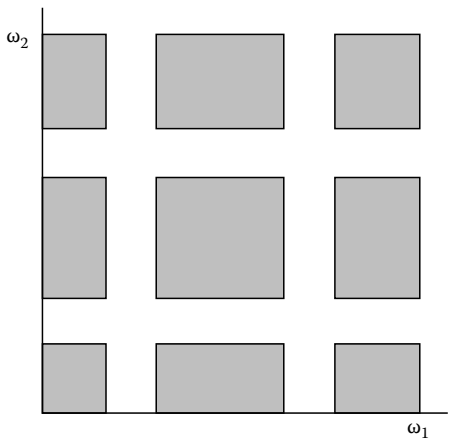

FIGURE 23.9 Idealized amplitude response of generalized bandpass filter.

where $H_1(z_1)H_2(z_2)$ is a generalized bandpass filter described above, and $H_A(z_1)$ and $H_A(z_2)$ are allpass 1-D filters [13] whose poles are poles of $H_1(z_1)$ and $H_2(z_2)$, respectively. Equation 23.32 can be referred to as a generalized bandstop filter.

Extending the principles discussed above, if a 2-D filter is constructed by cascading K 2-D filters with passbands P_i, stopbands S_i, and transfer function $H_i(z_1, z_2)$, the overall transfer function is obtained as

$$H(z_1, z_2) = \prod_{i=1}^{k} H_i(z_i, z_2)$$

and the passband P and stopband S of the cascaded 2-D filter are defined by

$$P = \bigcap P_i \quad \text{and} \quad S = \bigcup_{i=1}^{K} S_i$$

that is, the only frequency components not to be rejected will be those that will be passed by each and every filter in the cascade arrangement.

On the other hand, if a 2-D filter is constructed by connecting K 2-D filters in parallel, then

$$H(z_1, z_2) = \sum_{i=1}^{K} H_i(z_1, z_2)$$

Assuming that all the parallel filters have the same phase shift, and the passband $P_i = 1$ of the various filters are not overlapping, then the passband and stopband of the parallel arrangement is given by

$$P = \bigcup_{i=1}^{K} P_i \quad \text{and} \quad S = \bigcap S_i$$

Parallel IIR filters are more difficult to design than cascade ones, due to the requirement that the phase shifts of the various parallel filters be equal. However, if all the data to be filtered are available at the start of the processing, zero-phase filters can be used.

By combining parallel and cascade subfilters, 2-D IIR filters whose passbands or stopbands are combinations of rectangular regions can be designed, as illustrated by the following example.

Example 23.1

Design a 2-D IIR filter whose passband is the area between two overlapping rectangles, as depicted in Figure 23.10a.

Solution

1. Construct a first 2-D low-pass filter with rectangular passband ($\boldsymbol{\omega}_{12}$, $\boldsymbol{\omega}_{22}$) by using 1-D low-pass filters, as shown in Figure 23.10a.
2. Construct a second 2-D low-pass filter with rectangular passband ($\boldsymbol{\omega}_{11}$, $\boldsymbol{\omega}_{21}$) by 1-D low-pass filters. Then using Equation 23.32 to construct a 2-D high-pass filter with rectangular stopband ($\boldsymbol{\omega}_{11}$, $\boldsymbol{\omega}_{21}$), as shown in Figure 23.10c.
3. Cascade the first 2-D low-pass filter with the 2-D high-pass filter to obtain the required filter. The amplitude response of a practically designed 2-D filter is in Figure 23.10d.

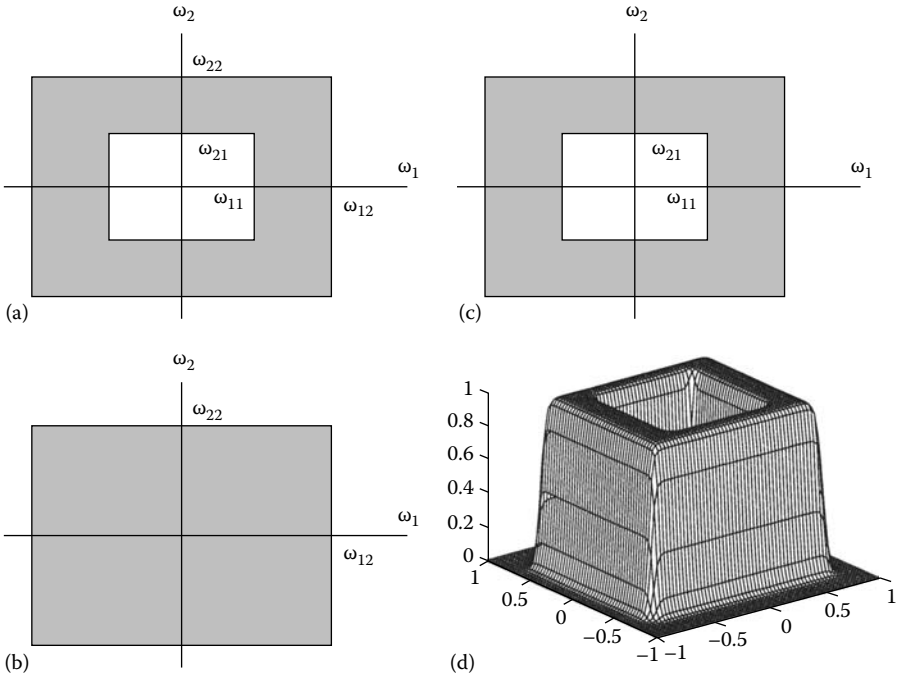

FIGURE 23.10 Amplitude response for the filter of Example 23.1: (a) specified response; (b) response of the 2D low-pass filter; (c) response of the 2D high-pass filter; (d) 3D plot of the amplitude response of a real 2D IIR filter.

23.3.2 Design of Half-Plane Symmetric Filters

A 2-D filter is said to be half-plane symmetric if its amplitude response satisfies

$$\left|H(z_1, z_2)\right| = \left|H(z_1^*, z_2^*)\right| \tag{23.33}$$

but

$$|H(z_1, z_2)| \neq |H(z_1^*, z_2)| \neq |H(z_1, z_2^*)| \tag{23.34}$$

that is, half-plane symmetry does not imply quadrantal symmetry.

The design of those filters can be accomplished by cascading two quadrant pass filters derived previously in Section 23.2.2.2 with quadrantally symmetric filters, as is demonstrated in Example 23.2.

Example 23.2

Design a 2-D half-plane symmetric filter whose passband is defined in Figure 23.11a.

Solution

1. Follow the steps 1 to 3 in Example 23.1 to construct a 2-D bandpass filter with the passband being the area between two overlapping rectangles, as shown in Figure 23.10a.

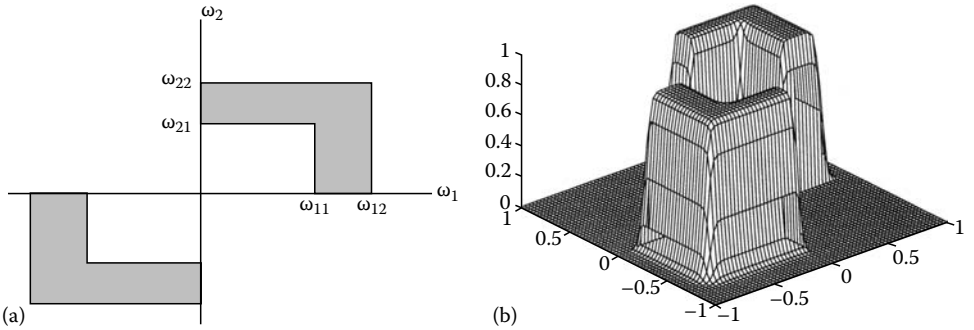

FIGURE 23.11 Amplitude response for the filter of Example 23.2: (a) specified response; (b) 3D plot of the amplitude response of a real 2D IIR filter.

2. Construct a two quadrant (first and third quadrants) pass filter as depicted in Figure 23.7a.
3. Cascade the 2-D bandpass filter with the two quadrant pass filters to obtain the required filter.

The amplitude response of a practically designed filter is shown in Figure 23.11b.

23.3.3 Design of Filters Satisfying Prescribed Specifications

The problem of designing filters that satisfy prescribed specifications to a large extent has been solved for the case of 1-D filters, and by extending the available methods, 2-D IIR filters satisfying prescribed specifications can also be designed.

Assume that we are to design a 2-D low-pass filter with the following specification:

$$|H(\omega_1, \omega_2)| = \begin{cases} 1 \pm \Delta p & \text{for } 0 \le |\omega_i| \le \omega_{pi} \\ \Delta a & \text{for } \omega_{ai} \le |\omega_i| \le \omega_{si}/2, \quad i = 1, 2 \end{cases} \tag{23.35}$$

where ω_{pi} and ω_{ai}, $i = 1, 2$ are passband and stopband edges along the ω_1 and ω_2 axes, respectively. The two 1-D filters that are cascaded to form a 2-D one are specified by ω_{pi}, ω_{ai}, δ_{pi}, and δ_{ai} $(i = 1, 2)$ as the passband edge, stopband edge, passband ripple, and stopband loss, respectively. From Equation 23.29 we have

$$\max\{M(\omega_1, \omega_2)\} = \max\{M_1(\omega_1)\} \max\{M_2(\omega_2)\}$$

and

$$\min\{M(\omega_1, \omega_2)\} = \min\{M_1(\omega_1)\} \min\{M_2(\omega_2)\}$$

Hence the derived 2-D filter will satisfy the specifications of Equation 23.35 if the following constraints are satisfied

$$(1 + \delta_{p1})(1 + \delta_{p2}) \le 1 + \Delta p \tag{23.36}$$

$$(1 - \delta_{p1})(1 - \delta_{p2}) \ge 1 - \Delta p \tag{23.37}$$

$$(1 + \delta_{p1})\delta_{a2} \le \Delta a \tag{23.38}$$

$$(1 + \delta_{p2})\delta_{a1} \le \Delta a \tag{23.39}$$

$$\delta_{a1}\delta_{a2} \le \Delta a \tag{23.40}$$

Constraints 23.36 and 23.37 can be expressed respectively in the alternative form

$$\delta_{p1} + \delta_{p2} + \delta_{p1}\delta_{p2} \leq \Delta p \tag{23.41}$$

and

$$\delta_{p1} + \delta_{p2} - \delta_{p1}\delta_{p2} \leq \Delta p \tag{23.42}$$

Hence if Equation 23.41 is satisfied, Equation 23.42 is also satisfied. Similarly, Constraints 23.38 through 23.40 will be satisfied if

$$\max\{(1 + \delta_{p1})\delta_{a2}, (1 + \delta_{p2})\delta_{a1}\} \leq \Delta a \tag{23.43}$$

since $(1 + \delta_{p1}) \gg \delta_{a1}$ and $(1 + \delta_{p2}) \gg \delta_{a2}$. Now if we assume that $\delta_{p1} = \delta_{p2} = \delta_p$ and $\delta_{a1} = \delta_{a2} = \delta_a$, then we can assign

$$\delta_p = (1 + \Delta p)^{1/2} - 1 \tag{23.44}$$

and

$$\delta_a = \frac{\Delta a}{(1 + \Delta p)^{1/2}} \tag{23.45}$$

so as to satisfy Constraints 23.36 through 23.40. And since $\Delta p \ll 1$, we have

$$\delta_p \approx \frac{\Delta p}{2} \tag{23.46}$$

$$\delta_a \approx \Delta a \tag{23.47}$$

Consequently, if the maximum allowable passband and stopband errors Δp and Δa are specified, the maximum passband ripple A_p and the maximum stopband attenuation A_a and dB for the two 1-D filters can be determined as

$$A_p = 20\log\frac{1}{1 - \delta_p} = 20\log\frac{2}{2 - \Delta p} \tag{23.48}$$

and

$$A_a = 20\log\frac{1}{\delta_p} = 20\log\frac{1}{\Delta a} \tag{23.49}$$

Finally, if the passband and stopband edges ω_{pi} and ω_{ai} are also specified, the minimum order and the transfer function of each of the two 1-D filters can readily be obtained using any of the approaches of the previous sections. Similar treatments for bandpass, bandstop, and high-pass filters can be carried out.

Example 23.3 [12]

Design a zero-phase filter whose amplitude response is specified in Figure 23.12a, with $A_p = 3$ dB, $A_a = 20$ dB.

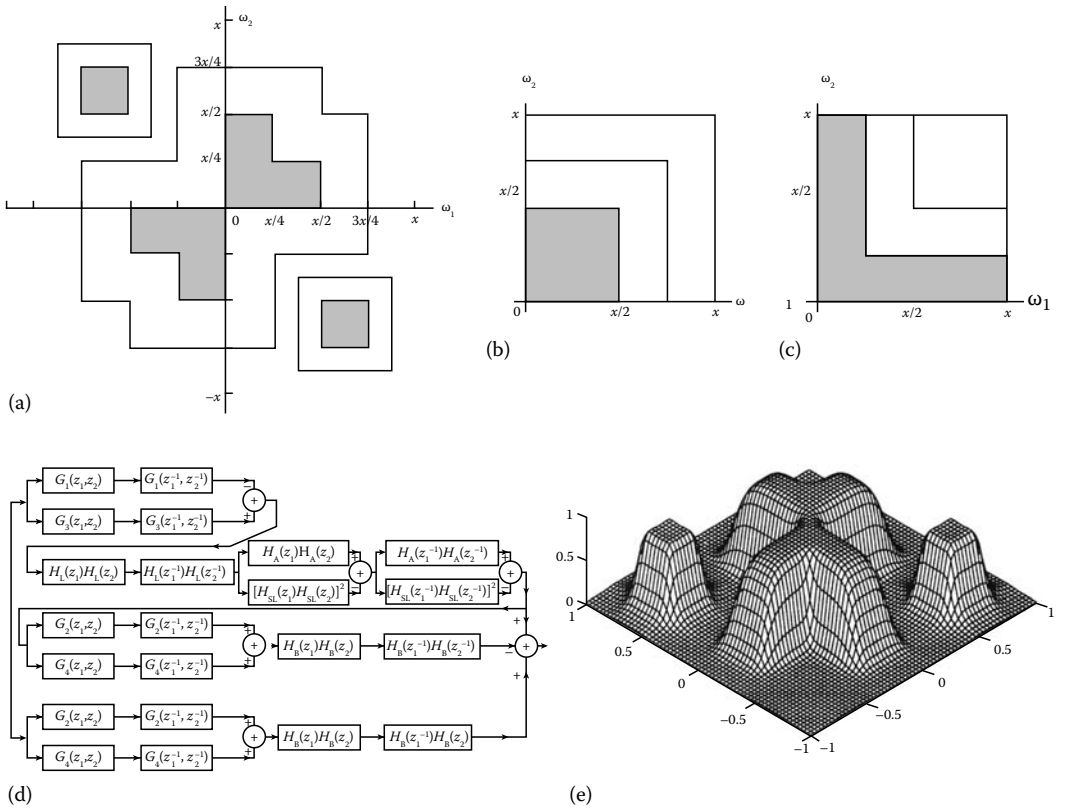

FIGURE 23.12 Amplitude responses of the filters in Example 23.3: (a) the given characteristics; (b) rectangular pass subfilter; (c) rectangular step subfilter; (d) final configuration of the 2D filter; (e) 3D plot of the amplitude response of the resulting 2D filter.

Solution

1. Decomposition: Because there are no contiguous passbands between the characteristics of the first and third quadrants and that of the second and fourth quadrants, in the first step of design, the required 2-D filter can be decomposed into two subfilters $H_{13}(z_1, z_2)$ and $H_{24}(z_1, z_2)$, which represent the characteristics of the first and third quadrants and that of the second and fourth quadrants, respectively. By connecting $H_{13}(z_1, z_2)$ and $H_{24}(z_1, z_2)$, in parallel, the required characteristics of the 2-D filter specified in Figure 23.12a can then be realized.

$$H(z_1, z_2) = H_{13}(z_1, z_2) + H_{24}(z_1, z_2)$$

   (a) Decomposition of $H_{13}(z_1, z_2)$: To accomplish the design of $H_{13}(z_1, z_2)$, further decompositions should be made. The characteristics of the first and third quadrants can be realized by cascading three subfilters, i.e., a two quadrant filter $G_{13}(z_1, z_2)$ [as shown in Figure 23.7a], a low-pass filter $H_L(z_1, z_2)$ [as shown in Figure 23.12b], and a rectangular stop filter $H_S(z_1, z_2)$ [as shown in Figure 23.12c],

$$H_{13}(z_1, z_2) = G_{13}(z_1, z_2)H_L(z_1, z_2)H_S(z_1, z_2)$$

   furthermore, the rectangular stop filter $H_S(z_1, z_2)$ can be designed by allpass filter $H_A(z_1, z_2)$ and low-pass filter $H_{SL}(z_1, z_2)$, using Equation 23.32

$$H_S(z_1, z_2) = H_A(z_1, z_2) - [H_{SL}(z_1, z_2)]^2$$

(b) Decomposition of $H_{24}(z_1, z_2)$: Similarly, $H_{24}(z_1, z_2)$ can be decomposed into the cascade of a two quadrant filter $G_{24}(z_1, z_2)$ [as is shown in Figure 23.7b], and a bandpass filter $H_B(z_1, z_2)$ which can be realized by using two 1-D bandpass filters for both directions.

$$H_{24}(z_1, z_2) = G_{24}(z_1, z_2)H_B(z_1, z_2)$$

The final configuration of the desired filter $H(z_1, z_2)$ is illustrated in Figure 23.12d, with the final transfer function being of the form

$$H(z_1, z_2) = H_{13}(z_1, z_2) + H_{24}(z_1, z_2) - H_{13}(z_1, z_2)H_{24}(z_1, z_2)$$

where the purpose of the term $H_{13}(z_1, z_2)H_{24}(z_1, z_2)$, is to remove the overlap that may be created by adding $H_{13}(z_1, z_2)$ and $H_{24}(z_1, z_2)$.

(2) Design of all the subfilters: At this point, the problem is to derive the two quadrant subfilters $G_{13}(z_1, z_2)$ and $G_{24}(z_1, z_2)$, the low-pass subfilters $H_L(z_1, z_2)$ and $H_{SL}(z_1, z_2)$, the allpass subfilter $H_A(z_1, z_2)$, and the bandstop filter $H_B(z_1, z_2)$.
Note the symmetry of the given characteristics, the identical 1-D sections can be used to develop all the above 2-D subfilters, and the given specifications can easily be combined into the designs of all the 1-D sections.

(3) By connecting all the 2-D subfilters in cascade or parallel as specified in Figure 23.12d, the required 2-D filter is obtained. The 3-D plot of the amplitude response of the final resulting 2-D filter is depicted in Figure 23.12e.

23.4 Design of Circularly Symmetric Filters

23.4.1 Design of LP Filters

As mentioned in Section 23.2.1, rotated filters can be used to design circularly symmetric filters. Costa and Venetsanopoulos [14] and Goodman [15] proposed two methods of this class, based on transforming an analog transfer function or a discrete one by rotated filter transformation, respectively. The two methods lead to filters that are, theoretically, unstable but by using an alternative transformation suggested by Mendonca et al. [16], this problem can be eliminated.

23.4.1.1 Design Based on 1-D Analog Transfer Function

Costa and Venetsanopoulos [14] proposed a method to design circularly symmetric filters. In their method, a set of 2-D analog transfer functions is first obtained by applying the rotated filter transformation in Equation 23.9a for several different values of the rotation angle β to a 1-D analog low-pass transfer function. A set of 2-D discrete low-pass functions are then deduced through the application of the bilinear transformation. The design is completed by cascading the set of 2-D digital filters obtained. The steps involved are as follows.

Step 1. Obtain a stable 1-D analog low-pass transfer function

$$H_{Al}(s) = \frac{Ns}{Ds} = K_0 \frac{\prod_{i=1}^{M}(s - z_{ai})}{\prod_{i=1}^{N}(s - p_{ai})} \tag{23.50}$$

where

z_{ai} and p_{ai} for $i = 1, 2, \ldots,$ are the zeros and poles of $H_{A1}(s)$, respectively

K_0 is a multiplier constant

Step 2. Let β_k for $k = 1, 2, \ldots, K$ be a set of rotation angles defined by

$$\beta_k = \begin{cases} \left(\dfrac{2k-1}{2K} + 1\right)\pi & \text{for even } K \\ \left(\dfrac{k-1}{K} + 1\right)\pi & \text{for even } K \end{cases} \tag{23.51}$$

Step 3. Apply the transformation of Equation 23.9a to obtain a 2-D analog transfer function as

$$|H_{A2k}(s_1, s_2) = H_{Al}(s)|_{s=-s_1 \sin\beta_k + s_2 \cos\beta_k} \tag{23.52}$$

for each rotation angle β_k identified in Step 2.

Step 4. Apply the double bilinear transformation to $H_{A2k}(s_1, s_2)$ to obtain

$$H_{D2k}(z_1, z_2) = |H_{A2k}(s_1, s_2)|_{s_i = 2(z_i - 1)/T_i(z_i + 1)}, \quad i = 1, 2 \tag{23.53}$$

Assuming that $T_1 = T_2 = T$, Equations 23.50 and 23.53 yield

$$H_{D2k}(z_1, z_2) = K_1 \prod_{i=1}^{M_0} H_{2i}(z_1, z_2) \tag{23.54}$$

where

$$H_{2i}(z_1, z_2) = \frac{a_{11i} + a_{21i} z_1 + a_{12i} z_2 + a_{22i} z_1 z_2}{b_{11i} + b_{21i} z_1 + b_{12i} z_2 + b_{22i} z_1 z_2} \tag{23.55}$$

$$K_1 = K_0 \left(\frac{T}{2}\right)^{N-M} \tag{23.56}$$

$$\begin{aligned} a_{11i} &= -\cos\beta_k + \sin\beta_k - \frac{Tz_{ai}}{2} \\ a_{21i} &= -\cos\beta_k - \sin\beta_k - \frac{Tz_{ai}}{2} \quad \text{for } 1 \le i \le M \\ a_{12i} &= \cos\beta_k + \sin\beta_k - \frac{Tz_{ai}}{2} \\ a_{22i} &= \cos\beta_k - \sin\beta_k - \frac{Tz_{ai}}{2} \\ a_{11i} &= a_{12i} = a_{21i} = a_{22i} = 1 \quad \text{for } M \le i \le M_0 \end{aligned} \tag{23.57a}$$

$$\begin{aligned} b_{11i} &= -\cos\beta_k + \sin\beta_k - \frac{Tp_{ai}}{2} \\ b_{21i} &= -\cos\beta_k - \sin\beta_k - \frac{Tp_{ai}}{2} \quad \text{for } 1 \le i \le N \\ b_{12i} &= \cos\beta_k + \sin\beta_k - \frac{Tp_{ai}}{2} \\ b_{22i} &= \cos\beta_k - \sin\beta_k - \frac{Tp_{ai}}{2} \\ b_{11i} &= b_{12i} = b_{21i} = b_{22i} = 1 \quad \text{for } N \le i \le M_0 \end{aligned} \tag{23.57b}$$

and

$$M_0 = \max(M, N)$$

Step 5. Cascade the filters obtained in Step 4 to yield an overall transfer function

$$H(z_1, z_2) = \prod_{k=1}^{K} H_{D2k}(z_1, z_2)$$

It is easy to find that, at point $(z_1, z_2) = (-1, -1)$, both the numerator and denominator polynomials of $H_{2i}(z_1, z_2)$ assume the value of zero. And thus each $H_{2i}(z_1, z_2)$ has nonessential singularity of the second kind on the unit bicircle

$$U^2 = \{(z_1, z_2):\ |z_1| = 1, |z_2| = 1\}$$

The nonessential singularity of each $H_{2i}(z_1, z_2)$ can be eliminated and, furthermore, each subfilter can be stabilized by letting

$$b'_{12i} = b_{12i} + \varepsilon b_{11i} \tag{23.58a}$$

$$b'_{22i} = b_{22i} + \varepsilon b_{21i} \tag{23.58b}$$

where ε is a small positive constant. With this modification, the denominator polynomial of each $H_{2i}(z_1, z_2)$ is no longer zero and, furthermore, the stability of the subfilter can be guaranteed if

$$\mathrm{Re}(p_{ai}) < 0 \tag{23.59}$$

and

$$270^\circ < \beta_k < 360^\circ \tag{23.60}$$

As can be seen in Equation 23.51, half of the rotation angles are in the range $180^\circ < \beta_k < 270^\circ$ and according to the preceding stable conditions they yield unstable subfilters. However, the problem can easily be overcome by using rotation angles in the range given by Equation 23.60 and the rotating the transfer function of the subfilter by -90° using linear transformations described in Section 23.2.1. For example, an effective rotation angle $\beta_k = 225^\circ$ is achieved by rotating the input data by 90°, filtering using a subfilter rotated by 315°, and then rotating the output data by -90°, as shown in Figure 23.13.

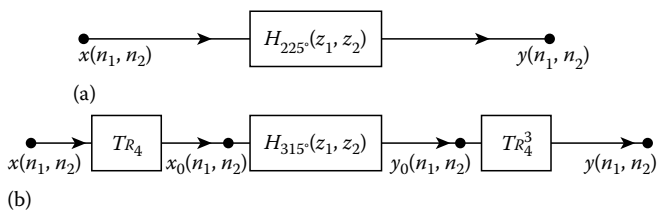

FIGURE 23.13 Realization of subfilter for rotation angle in the range $180^\circ < \beta_k < 270^\circ$. (a) An effective rotation angle $\beta_k = 225^\circ$ achieved by rotating the input by 90°. (b) Filtering using a subfilter rotated by 315°, and then rotating the output data by –90°.

In addition, a 2-D zero-phase filter can be designed by cascading subfilters for rotation angles $\pi + \beta_k$ for $k = 1, 2, \ldots, N$. The resulting transfer function is given by

$$H(z_1, z_2) = \prod_{k=1}^{K} H_{D2k}(z_1, z_2) H_{D2k}(z_1, z_2)$$

where the noncausal sections can be realized as illustrated in Figure 23.3.

23.4.1.2 Design Based on 1-D Discrete Transfer Function

The method proposed by Goodman [15] is based on the 1-D discrete transfer function transformation. In the method, a 1-D discrete transfer is first obtained by applying the bilinear transformation to a 1-D analog transfer function. Then, through the application of an allpass transformation that rotates the contours of the amplitude of the 1-D discrete transfer function, a corresponding 2-D transfer function is obtained. The steps involved are as follows.

Step 1. Obtain a stable 1-D analog low-pass transfer function $H_{A1}(s)$ of the form given by Equation 23.50.

Step 2. Apply the bilinear transformation to $H_{A1}(s)$ to obtain

$$H_{D1}(z) = H_{Al}(s)|_{s=2(z-1)/T(z+1)} \tag{23.61}$$

Step 3. Let β_k for $k = 1, 2, \ldots, K$ be a set of rotation angles given by Equation 23.51.

Step 4. Apply the allpass transformation defined by

$$z = f_k(z_1, z_2) = \frac{1 + c_k z_1 + d_k z_2 + e_k z_1 z_2}{e_k + d_k z_1 + c_k z_2 + z_1 z_2} \tag{23.62}$$

where

$$c_k = \frac{1 + \sin\beta_k + \cos\beta_k}{1 - \sin\ \beta_k + \cos\beta_k} \tag{23.63a}$$

$$d_k = \frac{1 - \sin\ \beta_k - \cos\ \beta_k}{1 - \sin\beta_k + \cos\beta_k} \tag{23.63b}$$

$$e_k = \frac{1 + \sin\beta_k - \cos\beta_k}{1 - \sin\beta_k + \cos\beta_k} \tag{23.63c}$$

to obtain the 2-D discrete transfer function

$$H_{D2k}(z_1, z_2) = H_{D1}(z)\Big|_{z=f_k(z_1,z_2)} \tag{23.64}$$

for $k = 1, 2, \ldots, K$. The procedure yields the 2-D transfer function of Equation 23.64, as can be easily demonstrated, and by cascading the rotated subfilters $H_{D2k}(z_1, z_2)$ the design can be completed.

The method of Goodman is equivalent to that of Costa and Venetsanopoulos and consequently, the resulting filter is subject to the same stability problem due to the nonessential singularity of the second kind at point $(z_1, z_2) = (-1, -1)$. To achieve a stable design, Goodman suggested that the transfer

function $H_{D2k}(z_1, z_2)$ for $k = 1, 2, \ldots, K$ be obtained directly by minimizing an appropriate objective function subject to the constraints

$$\begin{aligned} c_k + d_k - e_k &\leq 1 - \varepsilon \\ c_k - d_k + e_k &\leq 1 - \varepsilon \\ -c_k + d_k + e_k &\leq 1 - \varepsilon \\ -c_k - d_k - e_k &\leq 1 - \varepsilon \end{aligned}$$

through an optimization procedure. If ε is a small positive constant, the preceding constraints constitute necessary and sufficient conditions for stability and, therefore, such an approach will yield a stable filter.

23.4.1.3 Elimination of Nonessential Singularities

To eliminate the nonessential singularities in the preceding two methods, Mendonca et al. [16] suggested a new transformation of the form

$$s = g_5(s_1, s_2) = \frac{\cos\beta_k s_1 + \sin\beta_k s_2}{1 + cs_1 s_2} \tag{23.65}$$

by combining the transformations in Equations 23.9a and 23.11 to replace the transformation Equation 23.9a. If we ensure that

$$\cos\beta_k > 0, \quad \sin\beta_k > 0, \quad \text{and} \quad c > 0$$

then the application of this transformation followed by the application of the double bilinear transformation yields stable 2-D digital filters that are free of nonessential singularities of the second kind. If, in addition

$$c = \frac{1}{\omega_{\max}^2}$$

then local-type preservation can be achieved on the set Ω_2 given by

$$\Omega_2 = \{(\omega_1, \omega_2):\ \omega_1 \geq 0,\ \omega_2 \geq 0,\ \omega_1\omega_2 \leq \omega_{\max}\}$$

and if $\omega_{\max} \to \infty$, then a global-type preservation can be approached as closely as desired.

By using the transformation of Equation 23.65 instead of that in Equation 23.9a in the method of Costa and Venetsanopoulos, the transfer function of Equation 23.54 becomes

$$H_{D2k}(z_1, z_2) = K_1 P_{D2}(z_1, z_2) \times \prod_{i=1}^{M_0} \frac{a_{11i} + a_{21i}z_1 + a_{12i}z_2 + a_{22i}z_1z_2}{b_{11i} + b_{21i}z_1 + b_{12i}z_2 + b_{22i}z_1z_2} \tag{23.66}$$

where

$$K_1 = K_0\left(\frac{T}{2}\right)^{N-M} \tag{23.67a}$$

$$P_{D2}(z_1, z_2) = \left[1 + \frac{4c}{T^2} + \left(1 - \frac{4c}{T^2}\right)z_1 + \left(1 - \frac{4c}{T^2}\right)z_2 + \left(1 + \frac{4c}{T^2}\right)z_1z_2\right]^{N-M} \tag{23.67b}$$

and

$$
\begin{aligned}
a_{11i} &= -\cos\beta_k - \sin\beta_k - \left(\frac{T}{2} + \frac{2c}{T}\right) z_{ai} \\
a_{21i} &= \cos\beta_k - \sin\beta_k - \left(\frac{T}{2} + \frac{2c}{T}\right) z_{ai} \quad \text{for } 1 \le i \le M \\
a_{12i} &= -\cos\beta_k + \sin\beta_k - \left(\frac{T}{2} - \frac{2c}{T}\right) z_{ai} \\
a_{22i} &= \cos\beta_k + \sin\beta_k - \left(\frac{T}{2} + \frac{2c}{T}\right) z_{ai} \\
a_{11i} &= a_{21i} = a_{12i} = a_{22i} = 1 \quad \text{for } M \le i \le M_0 \\
b_{11i} &= -\cos\beta_k - \sin\beta_k - \left(\frac{T}{2} + \frac{2c}{T}\right) p_{ai} \\
b_{21i} &= \cos\beta_k - \sin\beta_k - \left(\frac{T}{2} - \frac{2c}{T}\right) p_{ai} \quad \text{for } 1 \le i \le N \\
b_{12i} &= -\cos\beta_k + \sin\beta_k - \left(\frac{T}{2} - \frac{2c}{T}\right) p_{ai} \\
b_{22i} &= \cos\beta_k + \sin\beta_k - \left(\frac{T}{2} - \frac{2c}{T}\right) p_{ai} \\
b_{11i} &= b_{21i} = b_{12i} = b_{22i} = 1 \quad \text{for } N \le i \le M_0 \\
M_0 &= \max(M, N)
\end{aligned}
$$

An equivalent design can be obtained by applying the allpass transformation of Equation 23.62 in Goodman's method with

$$
\begin{aligned}
c_k &= \frac{1 + \cos\beta_k - \sin\beta_k - 4c/T^2}{1 - \cos\beta_k - \sin\beta_k + 4c/T^2} \\
d_k &= \frac{1 - \cos\beta_k + \sin\beta_k - 4c/T^2}{1 - \cos\beta_k - \sin\beta_k + 4c/T^2} \\
c_k &= \frac{1 + \cos\beta_k + \sin\beta_k + 4c/T^2}{1 - \cos\beta_k - \sin\beta_k + 4c/T^2}
\end{aligned}
$$

23.4.2 Realization of HP, BP, and BS Filters

Consider two zero-phase rotated subfilters that were obtained from a 1-D analog high-pass transfer function using rotating angles $-\beta_1$ and β_1, where $0^\circ < \beta_1 < 90^\circ$. The idealized contour plots of the two subfilters are shown in Figure 23.14a and b. If these two subfilters are cascaded, the amplitude response of the combination is obtained by multiplying the amplitude responses of the subfilters at corresponding points. The idealized contour plot of the composite filter is thus obtained as illustrated in Figure 23.14c. As can be seen, the contour plot does not represent the amplitude response of a 2-D circularly symmetric high-pass filter, and, therefore, the design of high-pass filters cannot readily be achieved by simply cascading rotated subfilters as in the case of low-pass filters. However, the design of these filters can be accomplished through the use of a combination of cascade and parallel subfilters [16].

If the above rotated subfilters are connected in parallel, we obtain a composite filter whose contour plot is shown in Figure 23.14d. By subtracting the output of the cascade filter from the output of the parallel filter, we achieve an overall filter whose contour plot is depicted in Figure 23.14e. Evidently, this plot

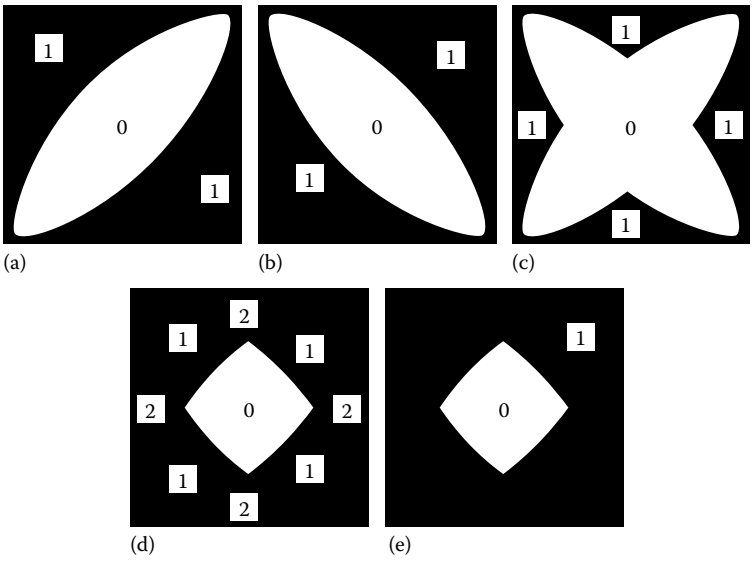

FIGURE 23.14 Derivation of 2D high-pass filter. (a) Contour plot of subfilter rotated by $-\beta_1$. (b) Contour plot of subfilter rotated by β_1. (c) Contour plot of subfilters in (a) and (b) connected in cascade. (d) Contour plot of subfilters in (a) and (b) connected in parallel. (e) Contour plot obtained by subtracting the amplitude response in (c) from that of (d).

resembles the idealized contour plot of a 2-D circularly symmetric high-pass filter, and, in effect, following this method a filter configuration is available for the design of high-pass filters.

The transfer function of the 2-D high-pass filter is then given by

$$\hat{H}_1 = \overline{H}_1 = H^{\beta_1} + H^{-\beta_1} - H^{\beta_1}H^{-\beta_1} \tag{23.68}$$

where

$$H^{\beta_1} = H_1(z_1, z_2)H_1(z_1^{-1}, z_2^{-1})$$

and

$$H^{-\beta_1} = H_1\left(z_1, z_2^{-1}\right)H_1\left(z_1^{-1}, z_2\right)$$

represent zero-phase subfilters rotated by angle β_1 and $-\beta_1$, respectively.

The above approach can be extended to two or more rotation angles in order to improve the degree of circularity. For N rotation angles, $\hat{H}_N$ is given by the recursive relation

$$\hat{H}_N = \hat{H}_{N-1} + \overline{H}_N - \hat{H}_{N-1}\overline{H}_N \tag{23.69}$$

where

$$\overline{H}_N = H^{\beta_N} + H^{-\beta_N} - H^{\beta_N}H^{-\beta_N}$$

and $\hat{H}_{N-1}$ can be obtained from $\overline{H}_{N-1}$ and $\hat{H}_{N-2}$. The configuration obtained is illustrated in Figure 23.15, where the realization of $\hat{H}_{N-1}$ is of the same as that of $\hat{H}_N$.

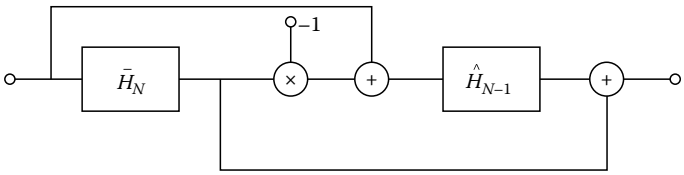

FIGURE 23.15 2D high-pass filter configuration.

As can be seen in Figure 23.15, the complexity of the high-pass configuration tends to increase rapidly with the number of rotations, and consequently, the number of rotations should be kept to a minimum. It should also be mentioned that the coefficients of the rotated filters must be properly adjusted, by using Equation 23.65, to ensure that the zero-phase is approximated. However, the use of this transformation leads to another problem: the 2-D digital transfer function obtained has spurious zeros at the Nyquist points. These zeros are due to the fact that the transformation in Equation 23.65 does not have type preservation in the neighborhoods of the Nyquist points but their presence does not appear to be of serious concern.

With the availability of circularly symmetric low-pass and high-pass filters, bandpass and bandstop filters with circularly symmetric amplitude responses can be readily obtained. A bandpass filter can be obtained by connecting a low-pass filter and a high-pass filter with overlapping passbands in cascade, whereas a bandstop filter can be realized by connecting a low-pass filter and a high-pass filter with overlapping passbands in parallel.

23.4.3 Design of Filters Satisfying Prescribed Specifications

A similar approach to that described in Section 23.3.3 can be used for the design of circularly symmetric filters satisfying prescribed specifications. Assume that the maximum/minimum passband and the maximum stopband gain of the 2-D filter are $(1 \pm \Delta p)$ and Δa, respectively, if K rotated filter sections are cascaded where half of the rotations are in the range of 180°–270° and the other half are in the range 270°–360°. Then, we can assign the passband ripple δ_p and the stopband loss δ_a to be [2]

$$\delta_p = \frac{\Delta p}{K} \tag{23.70}$$

and

$$\delta_a = \Delta a^{2/K} \tag{23.71}$$

The lower (or upper) bound of the passband gain would be achieved if all the rotated sections were to have minimum (or maximum) passband gains at the same frequency point. Although it is possible for all the rotated sections to have minimum (or maximum) gains at the origin of the (ω_1, ω_2) plane, the gains are unlikely to be maximum (or minimum) together at some other frequency point and, in effect, the preceding estimate for δ_p is low. A more realistic value for δ_p is

$$\delta_p = \frac{2\Delta p}{K} \tag{23.72}$$

If Δp and Δa are prescribed, then the passband ripple and minimum stopband attenuation of the analog filter can be obtained from Equations 23.72 and 23.71 as

$$A_p = 20 \log \left[\frac{K}{K - 2\Delta p} \right] \tag{23.73}$$

and

$$A_a = \frac{40}{K} \log\left[\frac{1}{\Delta a}\right] \tag{23.74}$$

If the passband Ω_p and stopband Ω_a are also prescribed, the minimum order and the transfer function of the analog filter can be determined using the method in preceding sections.

Example 23.4

Using the method of Costa and Venetsanopoulos, design a circularly symmetric low-pass filter satisfying the following specifications:

$$\omega_{s1} = \omega_{s2} = 2\pi \text{ rad/s}$$
$$\omega_p = 0.4\pi \text{ rad/s}, \quad \omega_a = 0.6\pi \text{ rad/s}$$
$$\delta_p = \delta_a = 0.1$$

Solution

The filter satisfying prescribed specifications can be designed through the following steps:

1. Select a prototype of approximation and suitably select the number of rotations K.
2. Calculate rotation angles by Equation 23.51.
3. Determine A_p and A_a from δ_p and δ_a, respectively, using Equations 23.73 and 23.74. Calculate the prewarped Ω_p and Ω_a, from ω_p and ω_a, respectively.
4. Use above calculated specifications to obtain the prewarped 1-D analog transfer function.
5. Apply the transformations of Equations 23.52, 23.53, 23.57, and 23.58 to obtain K rotated subfilters.
6. Cascade all the rotated subfilters.

The 3-D plot of the amplitude response of the resulting filter is shown in Figure 23.16, where $K = 10$.

23.5 Design of 2-D IIR Filters by Optimization

In the preceding sections, several methods for the solution of approximation problems in 2-D IIR filters have been described. These methods lead to a complete description of the transfer function in closed form, either in terms of its zeros and poles or its coefficients. They are, as a consequence, very efficient and lead to very precise designs. Their main advantage is that they are applicable only for the design of filters with piecewise-constant amplitude responses. In the following sections, the optimization methods for the design of 2-D IIR filters are considered. In these methods, a discrete transfer function is assumed and an error function is formulated on the basis of some desired amplitude and/or phase response. These methods are iterative and, as a result, they usually involve a large amount of computation. However, unlike the closed-form methods, they are suitable for the design of filters having arbitrary amplitude or phase responses.

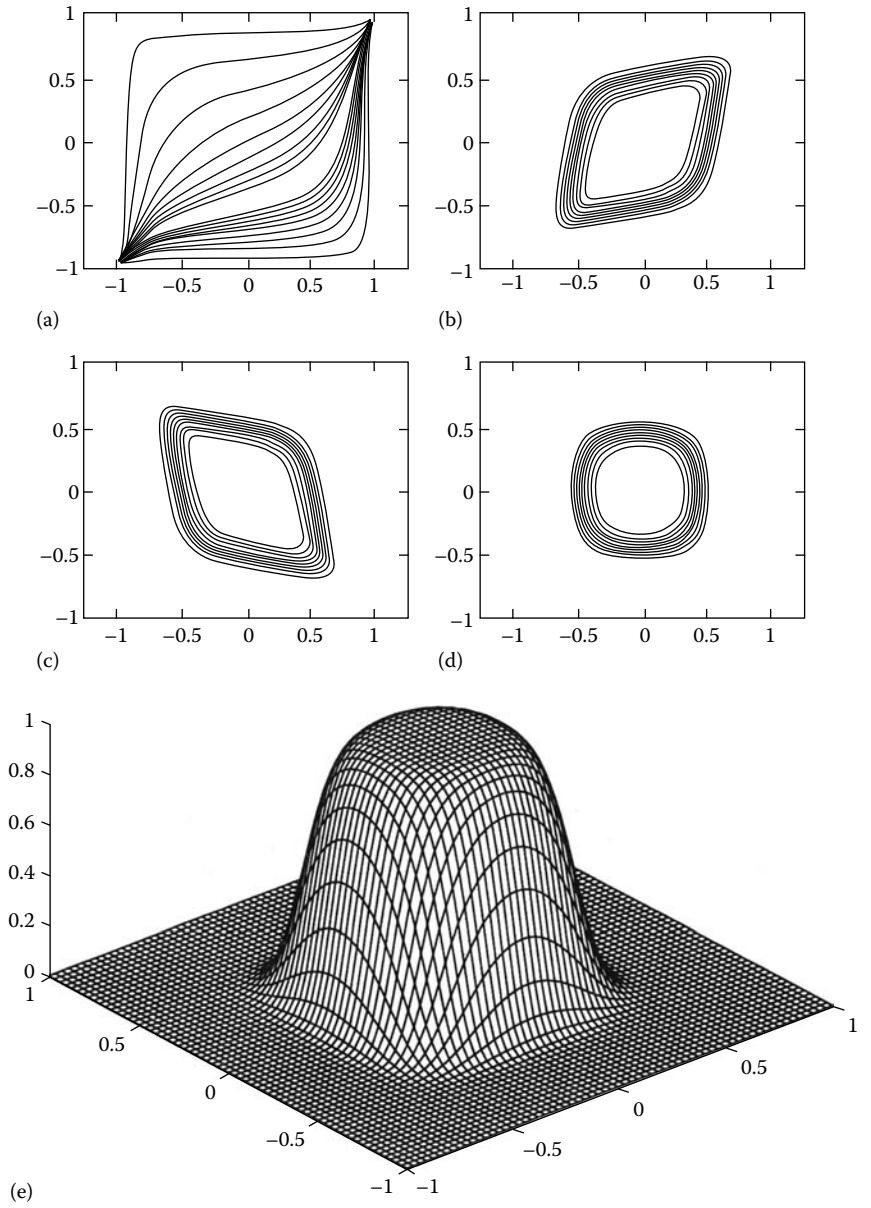

FIGURE 23.16 Amplitude response of a circularly symmetric filter in Example 23.4. (a) Subfilter for rotation angle of 243°. (b) Subfilters for rotation angles of 189°, 207°, 225°, 243°, and 261° in cascade. (c) Subfilters for rotation angles of 279°, 297°, 315°, 333°, and 351° in cascade. (d) All 10 subfilters in cascade. (e) 3D plot of the amplitude response of the resulting 2D low-pass filter.

23.5.1 Design by Least *p*th Optimization

The least *p*th optimization method has been used quite extensively in the past in a variety of applications. In this approach, an objective function in the form of a sum of elemental error functions, each raised to the *p*th power, is first formulated and is then minimized using any one of the available unconstrained optimization methods [17].

23.5.1.1 Problem Formulation

Consider the transfer function

$$H(z_1, z_2) = H_0 \prod_{k=1}^{K} \frac{N_k(z_1, z_2)}{D_k(z_1, z_2)} = H_0 \prod_{k=1}^{K} \frac{\sum_{l=0}^{L_{1k}} \sum_{m=0}^{M_{1k}} a_{lm}^{(k)} \, z_1^{-1} \, z_2^{-m}}{\sum_{l=0}^{L_{2k}} \sum_{m=0}^{M_{2k}} b_{lm}^{(k)} \, z_1^{-1} \, z_2^{-m}} \tag{23.75}$$

where $N_k(z_1, z_2)$ and $D_k(z_1, z_2)$ are polynomials of order equal to or less than 2 and H_0 is a constant, and let

$$\mathbf{x} = [\mathbf{a}^{\mathrm{T}} \quad \mathbf{b}^{\mathrm{T}} \quad H_0]^{\mathrm{T}} \tag{23.76}$$

where

$$\mathbf{a} = \left[a_{10}^{(1)} \quad a_{20}^{(1)} \quad \ldots \quad a_{L_{11}M_{11}}^{(1)} \quad a_{10}^{(2)} \quad a_{20}^{(2)} \quad \ldots \quad a_{L_{12}M_{12}}^{(2)} \quad \ldots \quad a_{L_{1K}M_{1K}}^{(\mathrm{K})} \right]^T$$

and

$$\mathbf{b} = \left[b_{10}^{(1)} \quad b_{20}^{(1)} \quad \ldots \quad b_{L_{11}M_{11}}^{(1)} \quad b_{10}^{(2)} \quad a_{20}^{(2)} \quad \ldots \quad b_{L_{12}M_{12}}^{(2)} \quad \ldots \quad b_{L_{2K}M_{2K}}^{(\mathrm{K})} \right]^T$$

are row vectors whose elements are the coefficients of $N_k(z_1, z_2)$ and $D_k(z_1, z_2)$, respectively. An objective function can be defined in terms of the L_p norm of $\mathbf{E}(\mathbf{x})$ as

$$J(\mathbf{x}) = L_p = \| \mathbf{E}(\mathbf{x}) \|_p = \left[\sum_{i=1}^{K} |E_{mn}(\mathbf{x})|^p \right]^{1/p} \tag{23.77}$$

where p is an even positive integer

$$E_{mn}(\mathbf{x}) = \mathbf{M}(\mathbf{m}, \mathbf{n}) - \mathbf{M}_1(m, n) \tag{23.78}$$

and

$$M(m, n) = \left| H(e^{j\omega_{1m}T_1}, e^{j\omega_{2n}T_2}) \right|, \quad m = 1, \ldots, M, \; n = 1, \ldots, N$$

are samples of the amplitude response of the filter at a set of frequency pairs (ω_{1m}, ω_{2n}) ($m = 1, \ldots, M$, $n = 1, \ldots, N$) with

$$\omega_{1m} = \frac{\omega_{s1}(m-1)}{2(M-1)} \quad \text{and} \quad \omega_{2n} = \frac{\omega_{s2}(n-1)}{2(N-1)}$$

$M_1(m, n)$ represents the desired amplitude response at frequencies (ω_{1m}, ω_{2n}).

Several special cases of the L_p norm are of particular interest. The L_1 norm, namely

$$L_1 = \sum_{i=1}^{K} \left| E_{mn}(x) \right|$$

is the sum of the magnitudes of the elements of $\mathbf{E}(\mathbf{x})$; the L_2 norm given by

$$L_2 = \left[\sum_{i=1}^{K} |E_{mn}(\mathbf{x})|^2\right]^{1/2}$$

is the well-known Euclidean norm; and L_2^2 is the sum of the squares of the elements of $\boldsymbol{E}(\mathbf{x})$. In the case where $p \to \infty$ and

$$E_M(\mathbf{x}) = \max_{m,n} \{E_{mn}(\mathbf{x})\} \neq 0$$

we can write

$$\begin{aligned} L_\infty &= \lim_{\mathrm{p}\to\infty} \left\{\sum_{k=1}^{K} |E_{mn}(\mathbf{x})|^p\right\}^{1/\mathrm{p}} \\ &= E_M(\mathbf{x}) = \lim_{p\to\infty} \left\{\sum_{k=1}^{K} \left|\frac{E_{mn}(\mathbf{x})}{E_M(\mathbf{x})}\right|^p\right\}^{1/\mathrm{p}} \\ &= E_M(\mathbf{x}) \end{aligned} \tag{23.79}$$

The design task at hand amounts to finding a parameter vector $\mathbf{x}$ that minimizes the least pth objective function $J(\mathbf{x})$ defined in Equation 23.77. If $J(\mathbf{x})$ is defined in terms of L_2^2, a least-squares solution is obtained; if the L_∞ norm is used, a so-called minimax solution is obtained, since in this case the largest element in $E(\mathbf{x})$ is minimized.

23.5.1.2 Quasi-Newton Algorithms

The design problem described above can be solved by using any one of the standard unconstrained optimization algorithms. A class of such algorithms that has been found to be very versatile, efficient, and robust is the class of quasi-Newton algorithms [17–19]. These are based on the principle that the minimum point $\mathbf{x}^*$ of a quadratic convex function $J(\mathbf{x})$ of N variables can be obtained by applying the correction

$$\delta = -\mathbf{H}^{-1}\gamma$$

to an arbitrary point $\mathbf{x}$, that is

$$\mathbf{x}^\star = \mathbf{x} + \mathbf{d}$$

where vector

$$\mathbf{g} = \nabla J(\mathbf{x}) = \left[\frac{\partial J}{\partial x_1}, \frac{\partial J}{\partial x_2}, \ldots, \frac{\partial J}{\partial x_N}\right]^{\mathrm{T}}$$

and $N \times N$ matrix

$$\mathbf{H} = \begin{vmatrix} \dfrac{\partial^2 J(\mathbf{x})}{\partial x_1^2} & \dfrac{\partial^2 J(\mathbf{x})}{\partial x_1 \partial x_2} & \cdots & \dfrac{\partial^2 J(\mathbf{x})}{\partial x_1 \partial x_N} \\ \dfrac{\partial^2 J(\mathbf{x})}{\partial x_2 \partial x_1} & \dfrac{\partial^2 J(\mathbf{x})}{\partial x_2^2} & \cdots & \dfrac{\partial^2 J(\mathbf{x})}{\partial x_2 \partial x_N} \\ \cdots & \cdots & \cdots & \cdots \\ \dfrac{\partial^2 J(\mathbf{x})}{\partial x_N \partial x_1} & \dfrac{\partial^2 J(\mathbf{x})}{\partial x_N \partial x_2} & \cdots & \dfrac{\partial^2 J(\mathbf{x})}{\partial x_N^2} \end{vmatrix}$$

are the gradient vector and Hessian matrix of $J(\mathbf{x})$ at point $\mathbf{x}$, respectively.

The basic quasi-Newton algorithm as applied to the 2-D IIR filter design problem is as follows [20].

ALGORITHM 1: Basic Quasi-Newton Algorithm

Step 1. Input $\mathbf{x}_0$ and ε. Set $\mathbf{S}_0 = \mathbf{I}_N$, where $\mathbf{I}_N$ is the $N \times N$ unity matrix and N is the dimension of $\mathbf{x}$, and set $k = 0$. Compute $\mathbf{g}_0 = -\mathbf{J}(\mathbf{x}_0)$.
Step 2. Set $\mathbf{d}_k = -\mathbf{S}_k\,\mathbf{g}_k$ and find α_k, the value of α that minimizes $\mathbf{J}(\mathbf{x}_k + \alpha\mathbf{d}_k)$, using a line search.
Step 3. Set $\mathrm{d}_k = \alpha_k\mathbf{d}_k$ and $\mathrm{x}_{k+1} = \mathbf{x}_k + \mathrm{d}_k$.
Step 4. If $\|\delta_K\| < \varepsilon$, then output $\mathbf{x}^* = \mathbf{x}_{k+1}$, $\mathbf{J}(\mathbf{x}^*) = \mathbf{J}(\mathbf{x}_{k+1})$ and stop, else go to step 5.
Step 5. Compute $\mathbf{g}_{k+1} = J(\mathbf{x}_{k+1})$ and set $\gamma_k = \mathbf{g}_{k+1} - \mathbf{g}_k$.
Step 6. Compute $\mathbf{S}_{k+1} = \mathbf{S}_k + \mathbf{C}_k$, where $\mathbf{C}_k$ is a suitable matrix correction.
Step 7. Check $\mathbf{S}_{k+1}$ for positive definiteness and if it is found to be nonpositive definite force it to become positive definite.
Step 8. Set $k = k + 1$ and go to step 2.

The correction matrix C_k required in step 6 can be computed by using either the Davidon–Fletcher–Powell (DFP) formula

$$\mathbf{C}_k = \frac{\mathbf{d}_k\mathbf{d}_k^{\mathrm{T}}}{\mathbf{g}_k^{\mathrm{T}}\mathbf{g}_k}\,\frac{\mathbf{S}_k\mathbf{g}_k\mathbf{g}_k^{\mathrm{T}}\mathbf{S}}{\mathbf{g}_k^{\mathrm{T}}\mathbf{S}_k\mathbf{g}_k} \tag{23.80}$$

or the Broyden–Fletcher–Goldfarb–Shanno (BFGS) formula

$$\mathbf{C}_k = \left(1 + \frac{\mathbf{g}_k^{\mathrm{T}}\mathbf{S}_k\mathbf{g}_k}{\mathbf{d}_k^{\mathrm{T}}\mathbf{d}_k}\right)\quad\frac{\mathbf{d}_k\mathbf{d}_k^{\mathrm{T}}}{\mathbf{g}_k^{\mathrm{T}}\mathbf{d}_k} - \frac{\mathbf{d}_k\mathbf{g}_k^{\mathrm{T}}\mathbf{S}_k + \mathbf{S}_k\mathbf{g}_k\mathbf{d}_k^{\mathrm{T}}}{\mathbf{g}_k^{\mathrm{T}}\mathbf{d}_k} \tag{23.81}$$

Algorithm 1 eliminates the need to calculate the second derivatives of the objective function; in addition, the matrix inversion is unnecessary. However, matrices $\mathbf{S}_1$, $\mathbf{S}_2, \ldots,$ $\mathbf{S}_k$ need to be checked for positive definiteness and may need to be manipulated. This can be easily done in practice by diagonalizing $\mathbf{S}_{k+1}$ and then replacing any nonpositive diagonal elements with corresponding positive ones. However, this would increase the computational burden quite significantly. The amount of computation required to complete a design is usually very large, due with the large numbers in 2-D digital filters and the large number of sample points needed to construct the objective function. Generally, the computational load can often be reduced by starting with an approximate design based on some closed-form solution. For example, the design of circularly or elliptical symmetric filters may start with filters that have square or rectangular passbands and stopbands.

Example 23.5 [20]

Design a circularly symmetric low-pass filter of order (2, 2) with $\boldsymbol{\omega}_{p1} = \boldsymbol{\omega}_{p2} = 0.08\boldsymbol{\pi}$ rad/s and $\boldsymbol{\omega}_{a1} = \boldsymbol{\omega}_{a2} = 0.12\boldsymbol{\pi}$ rad/s, assuming that $\boldsymbol{\omega}_{s1} = \boldsymbol{\omega}_{s2} = 2\boldsymbol{\pi}$ rad/s.

Solution

1. Construct the ideal discrete amplitude response of the filter

$$M_I(m,n) = \begin{cases} 1 & \text{for } \left(\boldsymbol{\omega}_{1m}^2 + \boldsymbol{\omega}_{2n}^2\right) \le 0.008\boldsymbol{\pi} \\ 0.5 & \text{for } 0.08\boldsymbol{\pi} \le \left(\boldsymbol{\omega}_{1m}^2 + \boldsymbol{\omega}_{2n}^2\right) \le 0.12\boldsymbol{\pi} \\ 0 & \text{otherwise} \end{cases}$$

where

$$\{\boldsymbol{\omega}_{1m}\} = \{\boldsymbol{\omega}_{2n}\} = 0, 0.02\boldsymbol{\pi}, 0.04\boldsymbol{\pi}, 0.2\boldsymbol{\pi}, 0.4\boldsymbol{\pi}, 0.6\boldsymbol{\pi}, 0.8\boldsymbol{\pi}, \boldsymbol{\pi}$$

2. To reduce the amount of computation, a 1-D low-pass filter with passband edge $\boldsymbol{\omega}_p = 0.08\boldsymbol{\pi}$ and stopband edge $\boldsymbol{\omega}_a = 0.1\boldsymbol{\pi}$ is first obtained with the 1-D transfer function being

$$H_1(z) = 0.11024 \frac{1 - 1.64382z^{-1} + z^{-2}}{1 - 1.79353z^{-1} + 0.84098z^{-2}}$$

and then a 2-D transfer function with a square passband is obtained as

$$H(z_1, z_2) = H_1(z_1)H_1(z_2)$$

3. Construct the objective function of Equation 23.77, using algorithm 1 to minimize the objective function $J(\mathbf{x})$. After 20 more iterations the algorithm converges to

$$H(z_1, z_2) = 0.00895 \times \frac{\begin{bmatrix} 1 & z_1^{-1} & z_1^{-2} \end{bmatrix} \begin{vmatrix} 1.0 & -1.62151 & 0.99994 \\ -1.62151 & 2.6370 & -1.62129 \\ 0.99994 & -1.62129 & 1.00203 \end{vmatrix} \begin{vmatrix} 1 \\ z_2^{-1} \\ z_2^{-2} \end{vmatrix}}{\begin{bmatrix} 1 & z_1^{-1} & z_1^{-2} \end{bmatrix} \begin{vmatrix} 1.0 & -1.78813 & 0.82930 \\ -1.78813 & 3.20640 & -1.49271 \\ 0.82930 & -1.49271 & 0.69823 \end{vmatrix} \begin{vmatrix} 1 \\ z_2^{-1} \\ z_2^{-2} \end{vmatrix}}$$

The amplitude response of the final optimal filter is depicted in Figure 23.17.

23.5.1.3 Minimax Algorithms

Least pth Minimax Algorithm. When a objective function is formulated in terms of the L_p norm of the error function and then minimizing $J(\mathbf{x})$ for increasing values of p, such an objective function can be obtained as

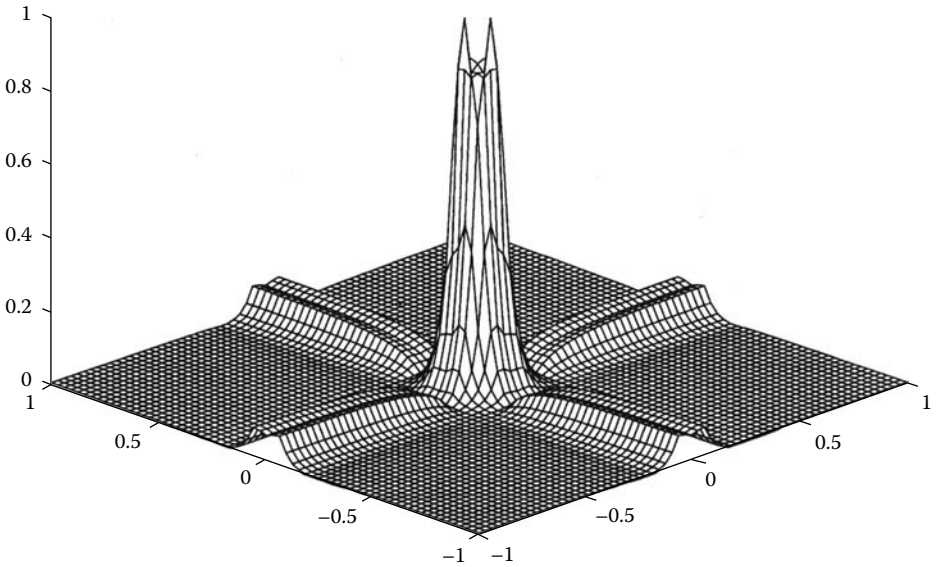

FIGURE 23.17 Amplitude response of the 2D optimal filter in Example 23.5.

$$J(x) = E_M(x)\left\{\sum_{i=1}^{m}\left|\frac{E(x,\omega_{1i},\omega_{2i})}{E_M(x)}\right|^p\right\}^{1/p} \tag{23.82}$$

where

$$E_M(\mathbf{x}) = \max_{1\le i\le m}\{E_i(\mathbf{x})\} = \max_{1\le i\le m}\{E_i(\mathbf{x},\omega_{1i},\omega_{2i})\} \tag{23.83}$$

A minimax algorithm based on $J(\mathbf{x})$ is as follows [21].

ALGORITHM 2: Least-*p*th Minimax Algorithm

Step 1. Input $\mathbf{x}_0$ and ε. Set $k=1$, $p=1$, $\mu=2$, $\mathbf{E}_0=10^{99}$.
Step 2. Initialize frequencies ω_{1i}, ω_{2i} for $i=1, 2,\ldots, m$.
Step 3. Using point $\mathbf{x}_{k-1}$ as initial point, minimize $J(\mathbf{x})$ with respect to $\mathbf{x}$ to obtain $\mathbf{x}_k$. Set $\mathbf{E}_k = E(\mathbf{x}_k)$.
Step 4. If $|E_{k-1} - E_k| < \varepsilon$, then output $\mathbf{x}^\star = \mathbf{x}_k$ and $\mathbf{E}_k$ and stop. Else, set $p=\mu p$, $k=k+1$ and go to step 3.

The minimization in step 3 can be carried out using algorithm 1 or any other unconstrained optimization algorithms.

Charalambous Minimax Algorithm. The preceding algorithm gives excellent results except that it requires a considerable amount of computation. An alternative and much more efficient algorithm is the minimax algorithm proposed by Charalambous and Antoniou [22,23]. This algorithm is based on principles developed by Charalambous [24] and involves the minimization of the objective function $J(\mathbf{x}, \zeta, \lambda)$, defined by

$$J(\mathbf{x},\zeta,\lambda) = \sum_{i\in I_1}\frac{1}{2}\lambda_i[J_i(\mathbf{x},\zeta)]^2 + \sum_{i\in I_2}\frac{1}{2}[J_i(\mathbf{x},\zeta)]^2 \tag{23.84}$$

where ζ and λ_i for $i=1, 2,\ldots, m$ are constants,

$$J_i(\mathbf{x},\zeta) = E_i(\mathbf{x}) - \zeta$$
$$I_1 = \{i: J_i(\mathbf{x},\zeta) > 0 \text{ and } \lambda_i > 0\}$$

and

$$I_2 = \{i: J_i(\mathbf{x},\zeta) > 0 \text{ and } \lambda_i > 0\}$$

The factor 1/2 in Equation 23.84 is included for the purpose of simplifying the gradient that is given by

$$\nabla J(\mathbf{x},\zeta,\lambda) = \sum_{i\in I_1}\lambda_i J_i(\mathbf{x},\zeta)\nabla J_i(x,\zeta) + \sum_{i\in I_2} J_i(\mathbf{x},\zeta)\nabla J_i(\mathbf{x},\zeta) \tag{23.85}$$

It can be shown that, if

1. The second-order sufficient conditions for a minimum hold at $x^\star$,
2. $\lambda_i = \lambda_i^*$, $i=1, 2,\ldots, m$, where λ_i^* are the minimax multipliers corresponding to a minimum optimum solution $\mathbf{x}^\star$, and
3. $E(\mathbf{x}^\star) - \xi$ is sufficiently small then $\mathbf{x}^\star$ is a strong local minimum point of $J(\mathbf{x}, \xi, \lambda)$.

Condition 1 is usually satisfied in practice. Therefore, a local minimum point $\mathbf{x}^*$ can be found by forcing λ_i to approach λ_i^* $(i = 1, 2, \ldots, m)$ and making $E(\mathbf{x}^*) - \xi$ sufficiently small. These two constraints can be simultaneously satisfied by applying the following algorithm.

ALGORITHM 3: Charalambous Minimax Algorithm

Step 1. Set $\xi = 0$ and $\lambda_i = 1$ for $i = 1, 2, \ldots, m$. Initialize $\mathbf{x}$.
Step 2. Minimize function $J(\mathbf{x}, \xi, \lambda)$ to obtain $\mathbf{x}$.
Step 3. Set

$$S = \sum_{i \in I_1} \lambda_i f_i(\mathbf{x}, \xi) + \sum_{i \in I_2} J_i(\mathbf{x}, \xi)$$

and update λ_i and ξ as

$$\lambda_i = \begin{cases} \lambda_i J_i(\mathbf{x}, \xi)/S & \text{if } \mathbf{J}_i(\mathbf{x}, \xi) \geq 0,\ \lambda_i \geq 0 \\ J_i(\mathbf{x}, \xi)/S & \text{if } \mathbf{J}_i(\mathbf{x}, \xi) \geq 0,\ \lambda = 0 \\ 0 & \text{if } \mathbf{J}_i(\mathbf{x}, \xi) < 0 \end{cases}$$

$$\xi = \sum_{i=1}^{\mathrm{m}} \lambda_i \mathbf{E}_i(\mathbf{x})$$

Step 4. Stop if

$$\frac{E_M(\mathbf{x}) - \xi}{E_M(\mathbf{x})} \leq \varepsilon$$

otherwise go to step 2.

The parameter ε is a prescribed termination tolerance. When the algorithm converges, conditions 2 and 3 are satisfied and $\mathbf{x} = \mathbf{x}^*$. The unconstrained optimization in step 2 can be accomplished by applying a quasi-Newton algorithm.

Example 23.6 [23]

Design a 2-D circularly symmetric filter with the same specifications as in Example 23.5, using algorithm 3.

Solution

1. Construct the ideal discrete amplitude response of the filter. Since the passband and stopband contours are circles, the sample points can be placed on arcs of a set of circles centered at the origin. Five circles with radii

$$r_1 = 0.3\boldsymbol{\omega}_p, \quad r_2 = 0.6\boldsymbol{\omega}_p, \quad r_3 = 0.8\boldsymbol{\omega}_p, \quad r_4 = 0.9\boldsymbol{\omega}_p, \quad \text{and} \quad r_5 = \boldsymbol{\omega}_p$$

are placed in the passband and five circles with radii

$$r_6 = \boldsymbol{\omega}_a, \quad r_7 = \boldsymbol{\omega}_a + 0.1(\boldsymbol{\pi} - \boldsymbol{\omega}_a), \quad r_8 = \boldsymbol{\omega}_a + 0.2(\boldsymbol{\pi} - \boldsymbol{\omega}_a), \quad r_9 = \boldsymbol{\omega}_a + 0.55(\boldsymbol{\pi} - \boldsymbol{\omega}_a), \quad \text{and} \quad r_{10} = \boldsymbol{\pi}$$

are placed in the stopband.

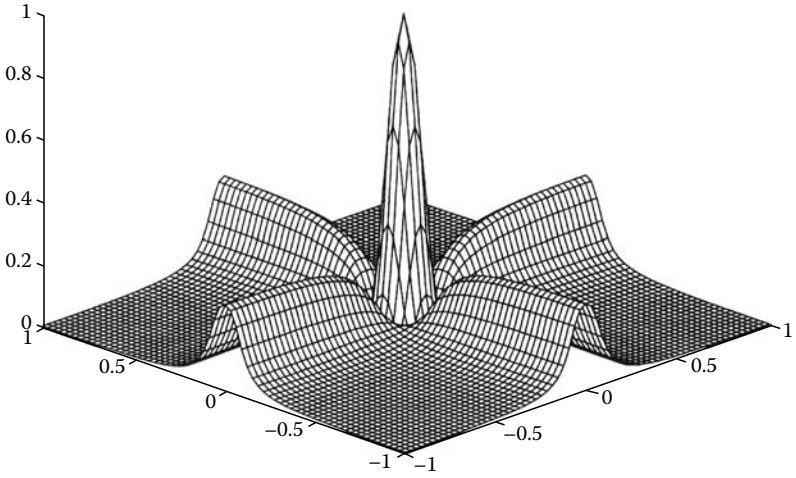

FIGURE 23.18 3D plot of the amplitude response of the filter in Example 23.6.

For circularly symmetric filters, the amplitude is uniquely specified by the amplitude response in the sector [0°, 45°]. Therefore, six equally spaced points on each circle described above between 0° and 45° are chosen. These points plus the origin $(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2) = (0,0)$ form a set of 61 sample points.

2. Select the 2-D transfer function. Because a circularly symmetric filter has a transfer function with separable denominator [24], we can select the transfer function to be of the form

$$H(z_1, z_2) = H_0(z_1, z_2)^{-1} \times \prod_{k=1}^{k} \frac{z_1 z_2 + z_1^{-1} z_2^{-1} + a_k\left(z_1 + z_1^{-1} + z_2 + z_2^{-1}\right) + z_1^{-1} z_2 + z_1 z_2^{-1} + b_k}{(1 + c_k z_1^{-1} + d_k z_1^{-2})(1 + c_k z_2^{-1} + d_k z_2^{-2})} \tag{23.86}$$

with parameter H_0 fixed as $H_0 = (0.06582)^2$, $K = 1$, $\varepsilon = 0.01$.

3. Starting from

$$a_1^{(0)} = -1.514, \quad b_1^{(0)} = (a_1^{(0)})^2, \quad c_1^{(0)} = -1.784, \quad d_1^{(0)} = 0.8166$$

and algorithm 3 yields the solution

$$a_1^* = 1.96493, \quad b_1^* = -10.9934, \quad c_1^* = -1.61564, \quad d_1^* = 0.66781$$

$$E_M(\mathbf{x}) = 0.37995$$

The 3-D plot of the amplitude response of the resulting filter is illustrated in Figure 23.18.

23.5.2 Design by Singular-Value Decomposition

As will be seen, an important merit of the design methods of 2-D IIR filters based on singular-value decomposition (SVD) is that the required 2-D filter is decomposed into a set of 1-D digital subfilters, which are much easier to design by optimization than the original 2-D filters.

23.5.2.1 Problem Formulation

In a quadrantally symmetric filter, $H(z_1, z_2)$ has a separable denominator [25]. Therefore, it can be expressed as

$$H(z_1, z_2) = \sum_{i=1}^{K} f_i(z_1) g_i(z_2) \tag{23.87}$$

In effect, a quadrantally symmetric filter can always be realized using a set of K parallel sections where the ith section is a separable subfilter characterized by the transfer function $f_i(z_1)\, g_i(z_2)$.

Consider the desired amplitude response sample of 2-D filter $H(z_1, z_2)$, we form a 2-D amplitude specification matrix $\mathbf{A}$ as

$$\mathbf{A} = \begin{vmatrix} a_{11} & a_{12} & \cdots & a_{1L} \\ a_{21} & a_{22} & \cdots & a_{2L} \\ \vdots & \vdots & & \vdots \\ a_{M1} & a_{M1} & \cdots & a_{ML} \end{vmatrix} \tag{23.88}$$

where $\{a_{ml}\}$ is a desired amplitude response sampled at frequencies $(\omega_{1l}, \omega_{2m}) = (\pi\mu_l/T_i, \pi\nu_m/T_2)$, with

$$\mu_l = \frac{l-1}{L-1}, \quad \nu_m = \frac{m-1}{M-1} \quad \text{for } 1 \le l \le L, \quad 1 \le m \le M$$

that is,

$$a_{ml} = \left| H\left(e^{j\pi\mu_1},\ e^{j\pi\nu_m}\right) \right|$$

If the matrix $\mathbf{A}$ can be decomposed into the form of

$$\mathbf{A} = \sum_{i=1}^{r} \mathbf{F}_i \mathbf{G}_i \tag{23.89}$$

then, by using the column vectors $\mathbf{F}_i$ and row vectors $\mathbf{G}_i$, we can construct matrices

$$\mathbf{F} = [\mathbf{F}_1 \quad \mathbf{F}_2 \quad \cdots \quad \mathbf{F}_r] \tag{23.90}$$

$$\mathbf{G} = [\mathbf{G}_1 \quad \mathbf{G}_2 \quad \cdots \quad \mathbf{G}_r]^{\mathrm{T}} \tag{23.91}$$

If all elements of $\mathbf{F}$ and $\mathbf{G}$ are nonnegative then they can be regarded as the amplitude specifications matrices of an r-input/1-output 1-D filter $F(z_1)$ and a 1-input/r-output 1-D filter $G(z_2)$,

$$F(z_1) = [f_1(z_1), f_2(z_1), \ldots, f_r(z_1)] \tag{23.92}$$

$$G(z_2) = [g_1(z_2),\ g_2(z_2), \ldots, g_r(z_2)]^{\mathrm{T}} \tag{23.93}$$

Therefore, the 2-D filter of Equation 23.87 can be approximated by

$$H(z_1, z_2) = F(z_1)G(z_2) \tag{23.94}$$

In this section, two design procedures are described that can be applied to the design of 2-D IIR filters whose amplitude responses are quadrantally symmetric.

23.5.2.2 Method of Antoniou and Lu

Antoniou and Lu proposed a method of 2-D IIR filter based on the SVD of the amplitude response matrix $\mathbf{A}$ [26]. The SVD of matrix $\mathbf{A}$ gives [27]

$$\mathbf{A} = \sum_{i=1}^{r} \sigma_i \mathbf{u}_i \mathbf{v}_i^{\mathrm{T}} = \sum_{i=1}^{r} \mathbf{f}_i \mathbf{g}_i^{\mathrm{T}} \tag{23.95}$$

where σ_i are the singular values of $\mathbf{A}$ such that $\sigma_1 \le \sigma_2 \le \cdots \le \sigma_r \le 0$ is the rank of $\mathbf{A}$, $\mathbf{u}_i$, and $\mathbf{v}_i$ are the ith eigenvector of $\mathbf{AA}^{\mathrm{T}}$ and $\mathbf{A}^{\mathrm{T}}\mathbf{A}$, respectively, $\boldsymbol{\phi}_i = \sigma_i^{1/2}\mathbf{u}_i$, $\boldsymbol{\gamma}_i = \sigma_i^{1/2}\mathbf{v}_i$, and $\{\Phi_i\colon 1 \le i \le r\}$ and $\{\gamma_i\colon 1 \le i \le r\}$ are sets of orthogonal L-dimensional and M-dimensional vectors, respectively.

An important property of the SVD can be stated as

$$\left\| \mathbf{A} - \sum_{i=1}^{K} \mathbf{F}_i \mathbf{g}_i^{\mathbf{T}} \right\| = \min_{\bar{\phi}, \bar{\gamma}} \left\| \mathbf{A} - \sum_{i=1}^{K} \overline{\mathbf{F}}_i \overline{\mathbf{g}}_i^{\mathrm{T}} \right\| \quad \text{for } 1 \le K \le r \tag{23.96}$$

where $\overline{\phi}_i \in R^L$, $\overline{\gamma}_i \in R^M$

To design a 2-D IIR filter by SVD, two steps are involved, namely

Step 1. Design of the main section.
Step 2. Design of the error correction sections as will be detailed below.

*Design of the Main Section***.** Note that Equation 23.95 can be written as

$$\mathbf{A} = \mathbf{f}_1 \mathbf{g}_1^{\mathrm{T}} + \varepsilon_1 \tag{23.97}$$

where $\varepsilon_1 = \Sigma_i^{\gamma} \Phi_i \gamma_i^{\mathrm{T}}$. And since all the elements of $\mathbf{A}$ are nonnegative, if follows that all elements of ϕ_1 and γ_1 are nonnegative.

On comparing Equation 23.97 with Equation 23.95 and assuming that $K = 1$ and that ϕ_1, γ_1 are sampled versions of the desired amplitude responses for the 1-D filters characterized by $f_1(z_1)$ and $g_1(z_2)$, respectively, a 2-D filter can be designed through the following procedures:

1. Design 1-D filters F_1 and G_1 characterized by $f_1(z_1)$ and $g_1(z_2)$.
2. Connect filters F_1 and G_1 in cascade, i.e.,

$$H_1(z_1, z_2) = f_1(z_1) g_1(z_2)$$

Step 1 above can be carried out by using an optimization algorithm such as the quasi-Newton algorithm or the minimax algorithm.

Since $f_1(z_1)g_1(z_2)$ corresponds to the largest singular value σ_1, the subfilter characterized by $f_1(z_1)\, g_1(z_2)$ is said to be the main section of the 2-D filter.

Design of the Error Correction Sections. The approximation error of $H_1(z_1, z_2)$ can be reduced by realizing more of the terms in Equation 23.95 by means of parallel filter sections. From Equation 23.97, we can write

$$\mathbf{A} = \mathbf{f}_1 \mathbf{g}_1^{\mathrm{T}} + \mathbf{f}_2 \mathbf{g}_2^{\mathrm{T}} + \varepsilon_{21} \tag{23.98}$$

Since ϕ_2 and λ_2 may have some negative components, a careful treatment in Equation 23.98 is necessary.

Let ϕ_2^- and γ_2^- be the absolute values of the most negative components of ϕ_2 and γ_2, respectively. If

$$\mathbf{e}_{\phi} = [1\ 1 \cdots 1]^{\mathrm{T}} \in R^L \quad \text{and} \quad \mathbf{e}_{\gamma} = [1\ 1 \cdots 1]^{\mathrm{T}} \in R^M$$

then all components of

$$\boldsymbol{\phi}_{2p} = \boldsymbol{\phi}_2 + \boldsymbol{\phi}_2^- \boldsymbol{\varepsilon}_{\phi}\ \boldsymbol{\alpha\nu\delta}\ \boldsymbol{\gamma}_{2p} = \boldsymbol{\gamma}_2 + \boldsymbol{\gamma}_2^- \boldsymbol{\varepsilon}_{\gamma}$$

are nonnegative. If it is possible to design 1-D linear-phase or zero-phase filters characterized by $f_1(z_1)$, $g_1(z_2)$, $f_{2p}(z_1)$, and $g_{2p}(z_2)$, such that

$$f_1(e^{j\pi\mu_i}) = \left|f_1(e^{j\pi\mu_i})\right| e^{j\alpha_1\mu_i}$$
$$g_1(e^{j\pi\nu_m}) = \left|g_1(e^{j\pi\nu_m})\right| e^{j\alpha_2\nu_m}$$

and

$$f_{2p}(e^{j\pi\mu_i}) = \left|f_{2p}(e^{j\pi\mu_i})\right| e^{j\alpha_1\mu_i}$$
$$g_{2p}(e^{j\pi\nu_m}) = \left|g_{2p}(e^{j\pi\nu_m})\right| e^{j\alpha_2\nu_m}$$

for $1 \le l \le L, \le m \le M$, where

$$\left|f_1(e^{j\pi\mu_1})\right| \approx \phi_{1l}$$
$$\left|g_1(e^{j\pi\nu_m})\right| \approx \gamma_{1m}$$
$$\left|f_{2p}(e^{j\pi\mu_l})\right| \approx \phi_{2lp}$$
$$\left|g_{2p}(e^{j\pi\nu_m})\right| \approx \gamma_{2mp}$$

In above ϕ_{1l}, ϕ_{2lp}, γ_{lm}, γ_{2mp} represent the lth component of ϕ_1, ϕ_{2p} and mth component of γ_1 and γ_{2p}, respectively. α_1 and α_2 are constants that are equal to zero if zero-phase filters are to be designed. Let

$$\alpha_1 = -\pi n_1, \quad \alpha_2 = -\pi n_2 \quad \text{with integers } n_1, n_2 \ge 0 \tag{23.99}$$

and define

$$f_2(z_1) = f_{2p}(z_1) - \phi_2^- z_1^{-n_1} \tag{23.100}$$

$$g_2(z_2) = g_{2p}(z_2) - \gamma_2^- z_2^{-n_2} \tag{23.101}$$

It follows that

$$f_2(e^{j\pi\mu_l}) = \left[f_{2p}(e^{j\pi\mu_l}) - \phi_2^-\right] e^{-j\pi n_1\mu_l} \approx \phi_{2l} e^{-j\pi\mu_l n_1}$$
$$g_2(e^{j\pi\nu_m}) = \left[g_{2p}(e^{j\pi\nu_m}) - \gamma_2^-\right] e^{-j\pi n_2\nu_m} \approx \gamma_{2m} e^{-j\pi\gamma_m n_2}$$

Furthermore, if we form

$$H_2(z_1, z_2) = f_1(z_1)g_1(z_2) + f_2(z_1)g_2(z_2) \tag{23.102}$$

then

$$\begin{aligned}\left|H_2(e^{j\pi\mu_l}, e^{j\pi\nu_m})\right| &= \left|f_1(e^{j\pi\mu_l})g_1(e^{j\pi\nu_m}) + f_2(e^{j\pi\mu_l})g_2(e^{j\pi\nu_m})\right| \\ &\approx |\phi_{1l}\gamma_{1m} + \phi_{2l}\gamma_{2m}|\end{aligned} \tag{23.103}$$

Follow this procedure, K–1 correction sections characterized by $k_2(z_1)g_2(x_2), \ldots, g_2(x_1)g_1(x_2)$ can be obtained, and $H_k(z_1, z_2)$ can be formed as

$$H_k(z_1, z_2) = \sum_{i=1}^{K} f_i(z_i)g_i(z_2) \tag{23.104}$$

and from Equation 23.96 we have

$$\left\|\mathbf{A} - \left|H_k(e^{j\pi\mu_l}, e^{j\pi\nu_m})\right|\right\| \approx \left\|\mathbf{A} - \sum_{i=1}^{K} \mathbf{f}_i \mathbf{g}_i^{\mathrm{T}}\right\|$$
$$\leq \left\|\varepsilon_K\right\| = \min_{\bar{\phi}_i, \bar{\gamma}_i} \left\| \sum_{i=1}^{K} \bar{\mathbf{f}}_i \bar{\mathbf{g}}_i{}^{\mathrm{T}} \right\| \tag{23.105}$$

In effect, a 2-D filter consisting of K sections is obtained whose amplitude response is a minimal mean-square-error approximation to the desired amplitude response.

The method leads to an asymptotically stable 2-D filter, provided that all 1-D subfilters employed are stable. The general configuration of the 2-D filter obtained is illustrated in Figure 23.19, where the various 1-D subfilters may be either linear-phase or zero-phase filters.

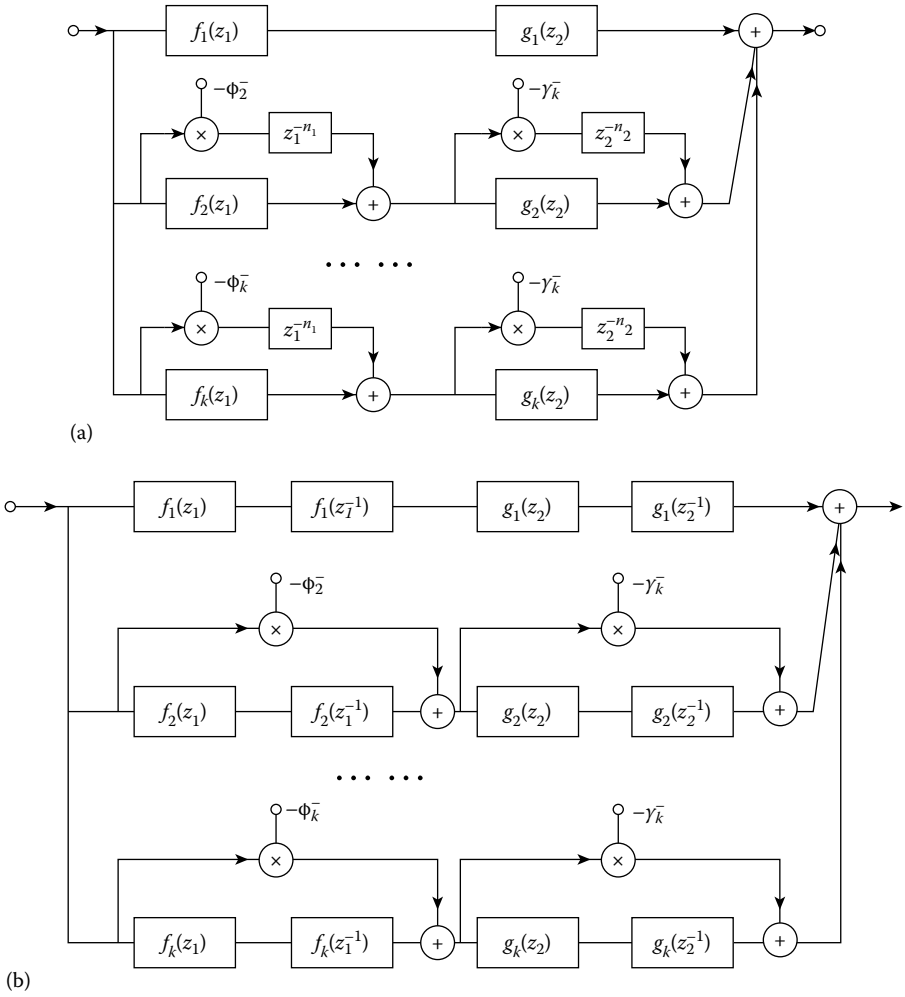

FIGURE 23.19 Configurations of 2D IIR filter by SVD. (a) General structure of 2D filter. (b) Structure using zero-phase IIR filters.

If linear-phase subfilters are to be used, the equalities in Equation 23.99 must be satisfied. This implies that the subfilters must have constant group delays. If zero-phase subfilters are employed, where $f_i(z_1)$ and $f_i(z_1^{-1})$,and $g_i(z_2)$ and $g_i(z_2^{-1})$contribute equally to the amplitude response of the 2-D filter. The design can be accomplished by assuming that the desired amplitude responses for subfilters F_i, G_i are $\phi_i^{1/2}$, $\gamma_i^{1/2}$, for $i = 1, 2, k, \ldots, K$, respectively.

Error Compensation Procedure. When the main section and correction sections are designed by an optimization procedure as described above, approximation errors inevitably occur that will accumulate and manifest themselves as the overall error. The accumulation of error can be reduced by the following compensation procedure.

When filters F_1 and G_1 are designed, the approximation error matrix $\mathbf{E}_1$ can be calculated as

$$\mathbf{E}_1 = \mathbf{A} - f_1(e^{j\pi\mu_l})g_1(e^{j\pi\nu_m}) \tag{23.106}$$

and then perform SVD on $\mathbf{E}_1$ to obtain

$$\mathbf{E}_1 = S_{22}\mathbf{f}_{22}\mathbf{g}_{22}^{\mathrm{T}} + \cdots + S_{r2}\mathbf{f}_{r2}\mathbf{g}_{r2}^{\mathrm{T}} \tag{23.107}$$

Data ϕ_{22} and γ_{22} can be used to deduce filters $f_2(z_1)$ and $g_2(z_2)$. Thus, the first correction section can be designed. Next, form the error matrix $\mathbf{E}_2$ as

$$\mathbf{E}_2 = \mathbf{E}_1 - S_{22}f_2(e^{j\pi\mu_l})g_2(e^{j\pi\nu_m}) \tag{23.108}$$

and then perform SVD on $\mathbf{E}_2$ to obtain

$$\mathbf{E}_2 = \mathbf{S}_{33}\ \mathbf{f}_{33}\ \mathbf{g}_{33}^{\mathrm{T}} + \cdots + S_{r3}\ \mathbf{f}_{r3}\ \mathbf{g}_{r3}^{\mathrm{T}} \tag{23.109}$$

and use data f_{33} and g_{33} to design the second correction section. The procedure is continued until the norm of the error matrix becomes sufficiently small that a satisfactory approximation to the desired amplitude response is reached.

Design of 1-D filters by using optimization can sometimes yield unstable filters. This problem can be eliminated by replacing poles outside the unit circle of the z plane by their reciprocals and simultaneously adjusting the multiplier constant to compensate for the change in gain [19].

Example 23.7 [26]

Design a circularly symmetric, zero-phase 2-D filter specified by

$$|H(\boldsymbol{\omega}_1, \boldsymbol{\omega}_2)| = \begin{cases} 1 & \text{for } \left(\boldsymbol{\omega}_1^2 + \boldsymbol{\omega}_2^2\right)^{1/2} < 0.35\boldsymbol{\pi} \\ 0 & \text{for} \left(\boldsymbol{\omega}_1^2 + \boldsymbol{\omega}_2^2\right)^{1/2} \geq 0.65\ \boldsymbol{\pi} \end{cases}$$

assuming that $\boldsymbol{\omega}_{s1} = \boldsymbol{\omega}_{s2} = 2\boldsymbol{\pi}$.

Solution

1. Construct a sampled amplitude response matrix. By taking $L = M = 21$ and assuming that the amplitude response varies linearly with the radius in the transition band, the amplitude response matrix can be obtained as

$$\mathbf{A} = \left| \begin{matrix} \mathbf{A}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{matrix} \right|_{21\times 21}$$

where

$$\mathbf{A} = \left| \begin{matrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 & 0 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 & 0 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 & 0 & 0 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 & 0 & 0 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 & 0 & 0 \\ 1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0.75 & 0.75 & 0.5 & 0.25 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0.75 & 0.75 & 0.5 & 0.5 & 0.25 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0.75 & 0.5 & 0.5 & 0.25 & 0.25 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0.5 & 0.25 & 0.25 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0.25 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{matrix} \right|$$

The ideal amplitude response of the filter is illustrated in Figure 23.20a.

2. Perform SVD to matrix **A** to obtain the amplitude response of the main section of the 2-D filter. It is worth noting that when a circularly symmetric 2-D filter is required, matrix **A** is symmetric and, therefore, Equation 23.95 becomes

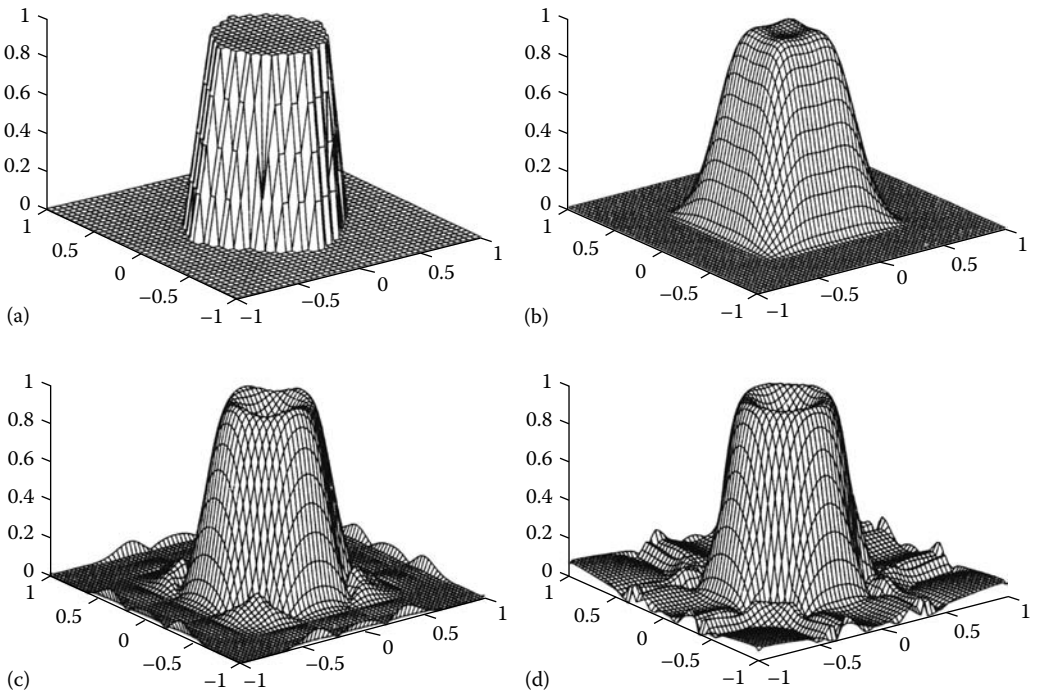

FIGURE 23.20 Amplitude responses of (a) the ideal circularly symmetric 2D filter; (b) the main section; (c) the main section plus the first correction; (d) the main section plus the first and second correction sections.

TABLE 23.3 Design Based on Fourth-Order Subfilters (Example 23.7)

The main section	$f_1(z) = 0.1255\dfrac{(z^2 + 0.7239z + 1)\ (z^2 + 1.6343z + 1)}{(z^2 + 0.1367z + 1)\ (z^2 - 0.5328z + 0.2278)}$
The first correction section	$f_2(z) = 0.6098\ \dfrac{(z^2 + 1.1618z + 0.1661)\ (z^2 + 0.8367z + 0.9958)}{(z^2 + 0.9953z)\ (z^2 + 0.5124z + 0.32)}$
	$S_2 = -1, \phi_2^- = 0.6266$
The second correction section	$f_3(z) = 0.4630\dfrac{(z^2 + 1.5381z + 0.4456)\ (z^2 - 1.397z + 1.1191)}{(z^2 + 2.0408z - 1)\ (z^2 - 0.7092z + 0.6961)}$
	$S_3 = +1, \phi_3^- = 0.2764$

$$\mathbf{A} = \sum_{i=1}^{r} S_i \mathbf{f}_i \mathbf{f}_i^T \tag{23.110}$$

where $S_1 = 1$ and $S_i = \pm 1$ or -1, for $2 \le i \le r$. This implies that each parallel section requires only one 1-D subfilter to be designed. As a consequence the design work is reduced by 50%.

When vector f_1 is obtained, by selecting a fourth-order approximation and after optimization, the transfer function of the main section $f_1(z)$ is obtained.

3. Design the correction sections. Successively perform SVD to the error $\mathbf{E}_1$ and $\mathbf{E}_2$, and apply the preceding design technique; the transfer functions of the first and second correction sections can be obtained.

   The transfer function of the main section and the first and second correction sections are listed in Table 23.3. And the amplitude responses of (1) the main section, (2) the main section plus the first correction, and (3) the main section plus the first and second correction sections are depicted in Figure 23.20b through d.

23.5.2.3 Method of Deng and Kawamata

In decomposing 2-D amplitude specifications into 1-D ones, the conventional SVD cannot avoid the problem that the 1-D amplitude specifications that result are often negative. Since negative values cannot be viewed as amplitude response, the problem of 1-D digital filter design becomes intricate. Deng and Kawamata [28] proposed a procedure that guarantees all the decomposition results to be always nonnegative and thus simplifies the design of correction sections.

The method decomposes the matrix **A** into the form

$$\mathbf{A} = \sum_{i=1}^{r} S_i \mathbf{F}_i \mathbf{G}_i \tag{23.111}$$

where all the elements of $\mathbf{F}_i$ and $\mathbf{G}_i$ are nonnegative and the decomposition error

$$\mathbf{E} = \| \mathbf{A} - \sum_{i=1}^{r} \mathbf{S}_i \mathbf{F}_i \mathbf{G}_i \| \tag{23.112}$$

is sufficiently small, and $S_i = 1$ or -1 for $i = 1, 2, \ldots, r$.

The design procedure can be desired as follows.

Step 1. Let $\mathrm{A}_1' = \mathrm{A}, \mathrm{A}_1^- = 0$, and perform the SVD on A_1^+ as

$$\mathbf{A}_1^+ = \sum_{i=1}^{r_i} \sigma_{1i} \mathbf{u}_{1i} \mathbf{v}_{1i} \approx \mathbf{F}_1^+ \mathbf{G}_1^+ \tag{23.113}$$

where σ_{1i} is the ith singular value of $\mathbf{A}_1^+(\sigma_{11} \geq \sigma_{12} \geq \cdots \geq \sigma_{1r_1})$ and $\mathbf{F}_1^+ = u_{11}\sigma_{11}^{1/2}, \mathbf{G}_1^+ = u_{11}\sigma_{11}^{1/2}$.

Let

$$\mathbf{F}_1 = \mathbf{F}_1^+, \quad \mathbf{G}_1 = \mathbf{G}_1^+, \quad \text{and} \quad S_1 = 1 \tag{23.114}$$

all the elements of $\mathbf{F}_1$ and $\mathbf{G}_1$ are nonnegative.

Step 2. Calculate the approximation error matrix $\mathbf{A}_2$ and decompose it into the sum of A_2^+ and A_2^- as

$$\mathbf{A}_2 = \mathbf{A} - S_1\mathbf{F}_1\mathbf{G}_1 = \mathbf{A}_2^+ + \mathbf{A}_2^- \tag{23.115}$$

where

$$\mathbf{A}_2^+(m,n) = \begin{cases} A_2(m,n) & \text{if } A_2(m,n) \geq 0 \\ 0 & \text{otherwise} \end{cases} \tag{23.116}$$

and

$$\mathbf{A}_2^-(m,n) = \begin{cases} A_2(m,n) & \text{if } A_2(m,n) \leq 0 \\ 0 & \text{otherwise} \end{cases} \tag{23.117}$$

To determine S_2 and $\mathbf{F}_2$ and $\mathbf{G}_2$ for approximating $\mathbf{A}_2$ as accurately as possible, the following three steps are involved.

1. Perform the SVD on A_2^1 and approximate it as

$$\mathbf{A}_2^+ = \sum_{i=1}^{r_2} \mathbf{s}_{2i}\mathbf{u}_{2i}\mathbf{v}_{2i} \approx \mathbf{F}_2^+\mathbf{G}_2^+ \tag{23.118}$$

   where $\mathbf{F}_2^+ = \mathbf{u}_{21}\sigma_{21}^{1/2}, \mathbf{G}_2^+ = \sigma_{21}^{1/2}\mathbf{v}_{21}$. All the elements of F_2^1 and G_2^1 and G^* are nonnegative. If $\mathbf{F}_2 = \mathbf{F}_2^+, \mathbf{G}_2 = \mathbf{G}_2^+$, and $S_2 = 1$, the approximation error is

$$\mathbf{E}_2^+ = \| \mathbf{A} - \sum_{i=1}^{2} \mathbf{S}_i\mathbf{F}_i\mathbf{G}_i \| \tag{23.119}$$

2. Perform the SVD on $-\mathbf{A}_2^-$ and approximate it as

$$-\mathbf{A}_2^- = \sum_{i=1}^{r_{2-}} \sigma_{2i-}\mathbf{u}_{2i-}\mathbf{v}_{2i-} \approx \mathbf{F}_2^-\mathbf{G}_2^- \tag{23.120}$$

   where $\mathbf{F}_2^- = \mathbf{u}_{21-}\sigma_{21-}^{1/2}, \mathbf{G}_2^- = \sigma_{21-}^{1/2}\mathbf{v}_{21-}$, and r_{2-} is the rank of A_2^-. All the elements of $\mathbf{F}_2^-$ and $\mathbf{G}_2^-$ are nonnegative. If $\mathbf{F}_2 = \mathbf{F}_2^-, \mathbf{G}_2 = \mathbf{G}_2^-$, and $S_2 = 1$, the approximation error $\mathbf{E}_2^-$ is

$$\mathbf{E}_2^- = \| \mathbf{A} - \sum_{i=1}^{2} S_i\mathbf{F}_i\mathbf{G}_i \| \tag{23.121}$$

3. According to the results from steps 1 and 2, the optimal vectors $\mathbf{F}_2$ and $\mathbf{G}_2$ for approximating $\mathbf{A}$ are determined as

$$\begin{aligned} &\mathbf{F}_2 = \mathbf{F}_2^+, \quad \mathbf{G}_2 = \mathbf{G}_2^+, \quad S_2 = 1 \quad \text{if } \mathbf{E}_2^+ \leq \mathbf{E}_2^- \\ &\mathbf{F}_2 = \mathbf{F}_2^-, \quad \mathbf{G}_2 = \mathbf{G}_2^-, \quad S_2 = -1 \quad \text{if } \mathbf{E}_2^+ \geq \mathbf{E}_2^- \end{aligned}$$

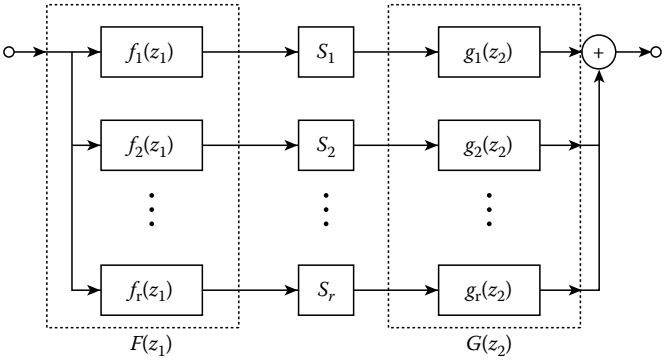

FIGURE 23.21 2D filter realization based on iterative SVD.

Successively decomposing the approximation error matrices $\mathbf{A}j$ $(j = 3, 4, \ldots, r)$ in the same way above described, a good approximation of matrix **A** can be obtained as in Equation 23.111.

Step 3. With the matrix **A** being decomposed into nonnegative vectors, the 1-D subfilters are designed through an optimization procedure, and a 2-D filter can then be readily realized, as shown in Figure 23.21.

It is noted that, in addition to SVD based methods as described in this section, design method based on other decomposition is also possible [29].

23.5.3 Design Based on Two-Variable Network Theory

Ramamoorthy and Bruton proposed a design method of 2-D IIR filters that always guarantees the stability of a filter and that involves the application of two-variable (2-*V*) strictly Hurwitz polynomials [30]. A 2 *V* polynomial $b(s_1, s_2)$ is said to be strictly Hurwitz if

$$b(s_1, s_2) \neq 0 \quad \text{for } \mathrm{Re}\{s_1\} \geq 0 \text{ and } \mathrm{Re}\{s_2\} \geq 0 \tag{23.122}$$

In their method, a family of 2-*V* strictly Hurwitz polynomials is obtained by applying network theory [31,32] to the frequency-independent, 2-*V* lossless network illustrated in Figure 23.22. The network has

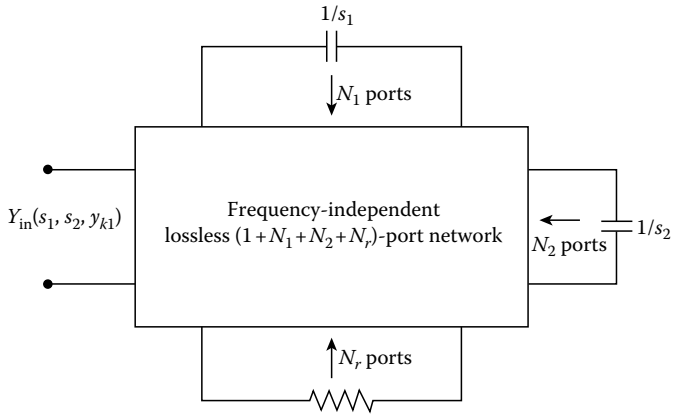

FIGURE 23.22 A $(1 + N_1 + N_2 + N_r)$-port 2-*V* lossless network.

$1 + N_1 + N_2 + N_r$ ports and N_1 and N_2 are terminated in unit capacitors in complex variables s_1 and s_2, respectively, and N_r is terminated in unit resistors. Since the network is lossless and frequency independent, its admittance matrix $\mathbf{Y}$ is a real and skew-symmetric matrix given by

$$\mathbf{Y} = \begin{vmatrix} 0 & y_{12} & y_{12} & \cdots & y_{1N} \\ -y_{12} & 0 & y_{23} & \cdots & y_{2N} \\ -y_{13} & -y_{23} & 0 & \cdots & y_{3N} \\ \vdots & \vdots & \vdots & & \vdots \\ -y_{1N} & -y_{2N} & -y_{3N} & \cdots & 0 \end{vmatrix} = \begin{vmatrix} \mathbf{Y}_{11} & \mathbf{Y}_{12} \\ -\mathbf{Y}_{12}^T & \mathbf{Y}_{22} \end{vmatrix} \quad N = 1 + N_1 + N_2 + N_r \tag{23.123}$$

If we define

$$\mathbf{Y}_{22}(s_1, s_2, y_{kl}) = \mathbf{Y}_{22} + \text{diag}\ \{\overset{N_r}{1 \cdots 1}\ \overset{N_1}{s_1 \cdots s_1}\ \overset{N_2}{s_2 \cdots s_2}\} \tag{23.124}$$

and

$$\Delta(s_1, s_2, y_{kl}) = \det\left[\Psi_{22}(s_1, s_2, y_{kl})\right] \tag{23.125}$$

where diag$(1 \cdots 1\ s_1 \cdots s_1\ s_2 \cdots s_2)$ represents a diagonal matrix in which each of the first N_r elements is unity, each of the next N_1 elements is s_1, and each of the last N_2, elements is s_2. Then, from the network theory, the input admittance at port 1 is given by

$$\mathbf{Y}_{\text{in}}(s_1, s_2, y_{kl}) = \frac{\mathbf{Y}_{12}\text{adj}\ [\mathbf{Y}_{22}(s_1, s_2, y_{kl})]\mathbf{Y}_{12}^{\text{T}}}{\det\left[\mathbf{Y}_{22}(s_1, s_2, y_{kl})\right]} = \frac{p(s_1, s_2, y_{kl})}{\Delta(s_1, s_2, y_{kl})} \tag{23.126}$$

where $\Delta(s_1, s_2, y_{kl})$ is defined by Equation 23.125 and is a strictly Hurwitz polynomial for any set of real values of the $(N-1)\ (N-2)/2$ independent parameters $\{y_{kl}: 1 < k < l \leq N\}$. Table 23.4 lists polynomial $\Delta(s_1, s_2, y_{kl})$ for $N_r = 1$ $(N_1, N_2) = (2, 1)$ and $(N_1, N_2) = (2, 2)$ [30].

Having obtained the parameterized strictly Hurwitz polynomial $\Delta(s_1, s_2, y_{kl})$ the design procedure of a 2-D IIR filter can be summarized as follows.

TABLE 23.4 2-*V* Strictly Hurwitz Polynomials

N_1	N_2	N	$\Delta(s_1, s_2, y_{kl})$
1	1	4	$s_1 s_2 + y_{24}^2 s_1 + y_{23}^2 s_2 + y_{34}^2$
2	1	5	$s_1^2 s_2 + y_{25}^2 s_1^2 + (y_{23}^2)(y_{23}^2 + y_{24}^2) s_1 s_2 + (y_{35}^2 + y_{45}^2) s_1 + y_{34}^2 s_2 + (y_{23}y_{46} - y_{24}y_{35} + y_{25}y_{34})^2$
2	2	6	$s_1^2 s_2^2 + (y_{23}^2 + y_{24}^2) s_1 s_2^2 + (y_{25}^2 + y_{26}^2) s_1^2 s_2 + y_{56}^2 s_1^2 + y_{34}^2 s_2^2 + (y_{35}^2 + y_{36}^2 - y_{45}^2 + y_{46}^2) s_1 s_2 + y_{34}^2 s_2 + [(y_{23}y_{56} - y_{25}y_{36} + y_{26}y_{35})^2 + (y_{24}y_{56} - y_{25}y_{46} + y_{26}y_{45})^2] s_1 + [(y_{23}y_{45} - y_{24}y_{35} + y_{25}y_{34})^2 + (y_{23}y_{46} - y_{24}y_{36} + y_{26}y_{34})^2] s_2 + (y_{34}y_{56} - y_{35}y_{46} + y_{36}y_{45})^2$

Step 1. Construct a parameterized analog transfer function of the 2-D IIR filter, by using the Hurwitz polynomial $\Delta(s_1, s_2, y_{kl})$

$$H(s_1, s_2, y_{kl}, a_{ij}) = \frac{p(s_1, s_2)}{\Delta(s_1, s_2, y_{kl})} \tag{23.127}$$

where

$$p(s_1, s_2) = \sum_{i=1}^{N_1} \sum_{j=1}^{N_2} a_{ij} s_1^i s_2^j$$

is an arbitrary 2-V polynomial in s_1 and s_2 with degree in each variable not greater than the corresponding degree of the denominator.

Step 2. Perform the double bilinear transformation to the parameterized analog transfer function obtained in step 1.

$$H(z_1, z_2, y_{kl}, a_{ij}) = \frac{p(s_1, s_2)}{\Delta(s_1, s_2, y_{kl})}\Big|_{s_i = 2(z_i - 1)/T_i(z_i + 1),\, i = 1, 2} \tag{23.128}$$

Step 3. Construct an objective function according to the given design specifications and the parameterized discrete transfer function obtained in step 2.

$$J(\mathbf{x}) = \sum_{n_1} \sum_{n_2} [M(n_1, n_2) - M_I(n_1, n_2)]^p \tag{23.129}$$

where p is an even positive, $M(n_1, n_2)$ and $M_I(n_1, n_2)$ are the actual and desired amplitude responses, respectively, of the required filter at frequencies $(\omega_{1n1}, \omega_{1n2})$, and $\mathbf{x}$ is the vector consisting of parameters $\{y_{kl}: 1 < k < l \leq N\}$ and $\{a_{ij}, 0 \leq i \leq N_1, 0 \leq j \leq N_2\}$.

Step 4. Apply an optimization algorithm to find the optimal vector $\mathbf{x}$ that minimizes the objective function and substitute the resulting x into Equation 23.128 to obtain the required transfer function $H(z_1, z_2)$.

Example 23.8 [33]

By using the preceding approach, design a 2-D circularly symmetric low-pass filter of order (5, 5) with $\omega_p = 0.2\pi$, assuming that $\omega_{s1} = \omega_{s2} = 1.2\pi$.

Solution

1. Construct the desired amplitude response of the desired filter

$$M_I(\omega_{1n_1}, \omega_{2n_2}) = \begin{cases} 1 & \text{for } \left(\omega_{1n_1}^2 + \omega_{2n_2}^2\right) \leq 0.2\pi \\ 0 & \text{otherwise} \end{cases}$$

where

$$\omega_{1n_1} = \begin{cases} 0.01\pi n_2 & \text{for } 0 \leq n_1 \leq 20 \\ 0.01\pi n_1 & \text{for } 21 \leq n_1 \leq 24 \end{cases}$$

and

$$\boldsymbol{\omega}_{2n_2} = \boldsymbol{\omega}_{1(24-n_2)} \quad \text{for } 0 \le n_2 \le 24$$

2. Construct the 2-D analog transfer function and perform double bilinear transformation to obtain the discrete transfer function. The analog transfer function at hand is assumed to be an all-pole transfer function of the form

$$\mathbf{H}(s_1, s_2, \mathbf{x}) = \frac{1}{\mathbf{D}(s_1, s_2, y_{kl})}$$

Therefore, the corresponding discrete transfer function can be written as

$$H(z_1, z_2, \mathbf{x}) = \frac{A(z_1 + 1)^5 \ (z_2 + 1)^5}{\sum_{i=0}^{5} \sum_{j=0}^{5} b_{ij} \ z_1^i z_2^j} \tag{23.130}$$

TABLE 23.5 Coefficients of Transfer Function in Equation 23.130
$[A = 0.28627, b_{ij}: 0 \le i \le 5, \ 0 \le j \le 5]$

0.0652	−0.6450	3.3632	−4.8317	0.3218	−0.1645

−0.4134	6.0739	−36.029	101.47	140.20	78.428

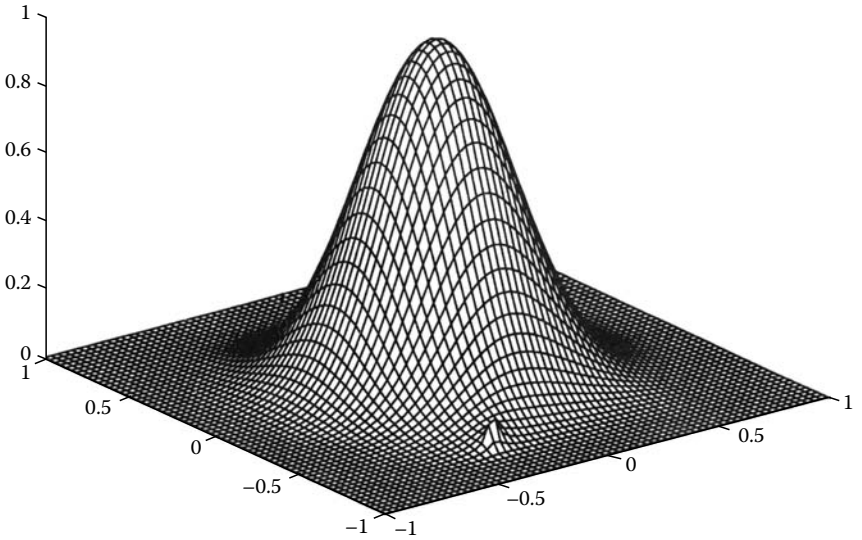

FIGURE 23.23 Amplitude response of circularly symmetric low-pass filter of Example 23.8.

where

$$\sum_{i=0}^{5}\sum_{j=0}^{5} b_{ij} z_1^i z_2^j = (z_1+1)^5 (z_2+1)^5 \Delta(s_1, s_2, y_{kl})\big|_{s_i=(z_i-1/z_i+1),\, i=1,2}$$

contains $(N-1)(N-2)/2 = 36$ parameters.

3. Optimization: A conventional quasi-Newton algorithm has been applied to minimize the objective function in Equation 23.129 with $p = 2$. The resulting coefficients are listed in Table 23.5. The amplitude response of the resulting filter is depicted in Figure 23.23.

24.1 Introduction: Why Use Filter Banks?

An important class of digital filter system is the multirate filter bank. In this chapter we shall only be considering the one-dimensional (1-D) type of filter bank, as might be applied to typical signals that evolve with time, such as audio waveforms and communications signals.

The reason that filter banks are important is that we can often achieve useful functionality by separating signals into various different frequency bands and applying different processing to each

band. Typical examples of this are the widely used MP3 digital audio compression systems. In order to achieve a low coded data file size for digital music tracks, the MP3 coding standard specifies that the audio signal should be split into many frequency bands and that separate adaptive quantization should be applied to each band. The quantization is designed to take maximum advantage of the noise masking properties of the human auditory system, such that frequency bands containing substantial audio energy are quantized quite coarsely (because the quantizing noise gets masked by the signal here), whereas bands with low levels of audio are quantized more finely (since the masking is only effective at frequencies close to those containing most of the audio energy).

Filter banks can operate with filtered outputs being sampled at the same rate as the input signal. However, with many filters operating in parallel, this can lead to an unacceptably large amount of output data being generated. It is therefore sensible to subsample the outputs of the filters in a filter bank so that the total output data rate from all the filters is similar to that of the input. Such filters are called multirate filters, and the complete system is a multirate filter bank. When signals are subsampled, aliasing can occur and cause degradation of signal quality, but, with careful design, aliasing effects can be eliminated in multirate filter banks as long as the total output data rate is no less than the input rate. Multirate filters can be implemented with much less computational cost than the equivalent full rate filters, and, in the case of compression systems, they generate much less data to be coded by the adaptive quantizers.

An alternative way to view the advantages of filter banks is that, with careful design, they can encourage signal sparsity, i.e., most of the energy of an input signal can be concentrated in a small proportion of the output samples from the filter bank. Sparsity has been shown to be a key element in successfully performing many signal processing tasks, such as compression, denoising, signal separation, and other enhancement techniques. Sparsity can be achieved if, at any given time, the input signal can be well approximated by a weighted sum of the impulse responses from just a few of the filters in the filter bank. This occurs when the filters are matched to typical components of the signal.

Digital filter banks have been actively studied since the 1960s. However their use achieved a considerable boost with the development of wavelet theory in the 1980s. The theory of wavelet transforms was developed principally by French and Belgian mathematicians, notably A. Grossman, J. Morlet, Y. Meyer, I. Daubechies, and S. Mallat, and efficient implementation of the wavelet transform is usually achieved with multirate filter banks. The two topics are now firmly linked and are of great importance for signal analysis and compression.

The discrete wavelet transform (DWT) may be used to analyze a wide variety of signals, particularly those that combine long low-frequency events with much shorter high-frequency events (e.g., transients). It has perhaps achieved its greatest success with images. Although these are two-dimensional (2-D) signals, the 1-D filters considered in this chapter are still highly relevant since 2-D wavelet transforms are usually achieved using separable 1-D processing along the rows and then down the columns of the image (or vice versa).

In this chapter we shall be introducing some of the basic ideas behind 1-D filter banks, and then will concentrate much of our coverage on the 2-band multirate filter bank, which is the workhorse of the DWT. In the final sections we shall extend the discussion to M-band ($M > 2$) filter banks and also to Hilbert pairs of filter banks, which lead to the dual-tree complex wavelet transform.

Most of the following discussions in this chapter will assume that the filters are finite-impulse-response (FIR) filters and that all samples of the input signal are available in the memory of the signal processing hardware. Hence causality of the filters is not an issue and filter taps corresponding to negative delays (positive powers of z in the z-transform) pose no implementation problems. In this situation, the most natural way to design filters is for zero overall delay (the zero-phase condition).

If these assumptions are not valid (e.g., in the case of a continuously evolving audio signal), then appropriate delays can usually be inserted so that the filters are still implementable. Only in the case of recursive infinite-impulse-response (IIR) filters is the causality issue a real potential problem; and so more care is required on this issue in Section 24.7. Elsewhere we shall ignore problems of causality.

24.2 2-Band Filter Bank

A simple analysis filter bank with just two bands is shown in Figure 24.1a. It comprises two filters H_0 and H_1 which split the input signal X into its lower and higher frequency components, respectively. If X is sampled at a rate of f_s Hz, then its frequency spectrum can occupy the range 0 to $\frac{1}{2} f_S$, while still satisfying Nyquist's rule; and so H_0 will normally be designed to pass frequencies from 0 to $\frac{1}{4} f_S$, and H_1 from $\frac{1}{4} f_S$ to $\frac{1}{2} f_S$. Hence, H_0 will be a low-pass filter and H_1 will be high-pass.

Let us initially consider the simplest practical form of 2-band filter bank in which H_0 and H_1 are both 2-tap FIR filters with coefficient vectors $\mathbf{h}_0 = [\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}]$ and $\mathbf{h}_1 = [\frac{1}{\sqrt{2}}, \frac{-1}{\sqrt{2}}]$ (corresponding to the well-known Haar wavelet basis). Hence the filter outputs may be expressed as

$$\begin{aligned} y_0(n) &= \frac{1}{\sqrt{2}} x(n-1) + \frac{1}{\sqrt{2}} x(n) \\ y_1(n) &= \frac{1}{\sqrt{2}} x(n-1) - \frac{1}{\sqrt{2}} x(n) \end{aligned} \tag{24.1}$$

As z-transforms, Equation 24.1 becomes

$$\begin{aligned} Y_0(z) &= H_0(z)X(z) \quad \text{where} \quad H_0(z) = \frac{1}{\sqrt{2}}(z^{-1} + 1) \\ Y_1(z) &= H_1(z)X(z) \quad \text{where} \quad H_1(z) = \frac{1}{\sqrt{2}}(z^{-1} - 1) \end{aligned} \tag{24.2}$$

(By substituting $z = e^{j\omega}$, the reader may check that these filters are indeed low-pass and high-pass, respectively. We shall later extend the filters to be more complicated.)

In practice, $y_0(n)$ and $y_1(n)$ are only calculated at alternate (say even) values of n so that the total number of samples in vectors $\mathbf{y}_0$ and $\mathbf{y}_1$ is the same as in the input vector $\mathbf{x}$. This is shown by the 2:1 downsamplers on the right in Figure 24.1a.

It is straightforward to invert Equation 24.1 to obtain the two samples of x back from the filter output samples, as follows:

$$\begin{aligned} x(n-1) &= \frac{1}{\sqrt{2}} y_0(n) + \frac{1}{\sqrt{2}} y_1(n) \\ x(n) &= \frac{1}{\sqrt{2}} y_0(n) - \frac{1}{\sqrt{2}} y_1(n) \end{aligned} \quad \text{for } n \text{ even.} \tag{24.3}$$

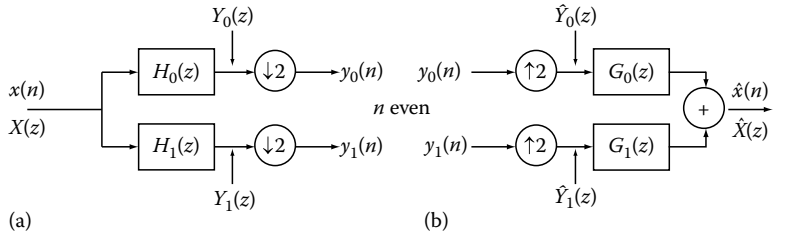

FIGURE 24.1 Two-band filter banks for analysis (a) and reconstruction (b).

Assuming that the missing samples of $\mathbf{y}_0$ and $\mathbf{y}_1$ are zero at odd values of n, we may combine the equations in Equation 24.3 into a single expression for $x(n)$, valid for all n:

$$x(n) = \frac{1}{\sqrt{2}}[y_0(n+1) + y_0(n)] + \frac{1}{\sqrt{2}}[y_1(n+1) - y_1(n)] \tag{24.4}$$

or as z-transforms

$$X(z) = G_0(z)Y_0(z) + G_1(z)Y_1(z) \tag{24.5}$$

where

$$G_0(z) = \frac{1}{\sqrt{2}}(z+1) \quad \text{and} \quad G_1(z) = \frac{1}{\sqrt{2}}(z-1) \tag{24.6}$$

Note that the factors of $\frac{1}{\sqrt{2}}$ in the coefficients of the H and G filters are chosen to ensure that the l_2-norm (energy) of each vector of filter coefficients is unity, so that total energy is preserved from the X-domain to the Y-domain and vice versa.

In Equation 24.5 the signals $Y_0(z)$ and $Y_1(z)$ are not really the same as $Y_0(z)$ and $Y_1(z)$ in Equation 24.2 because those in Equation 24.2 have not had alternate samples set to zero. Also, in Equation 24.5 $X(z)$ is the reconstructed output whereas in Equation 24.2 it is the input signal.

To avoid confusion we shall use $\hat{X}$, $\hat{Y}_0$, and $\hat{Y}_1$ for the signals in Equation 24.5, so it becomes

$$\hat{X}(z) = G_0(z)\hat{Y}_0(z) + G_1(z)\hat{Y}_1(z) \tag{24.7}$$

We may show this reconstruction operation as upsampling followed by two filters, as in Figure 24.1b, forming a 2-band reconstruction filter bank.

If $\hat{Y}_0$ and $\hat{Y}_1$ are not the same as Y_0 and Y_1, it is important to know how they do relate to each other. Now

$$\hat{y}_0(n) = y_0(n) \quad \text{for } n \text{ even}, \quad \hat{y}_0(n) = 0 \quad \text{for } n \text{ odd} \tag{24.8}$$

Therefore its z-transform, $\hat{Y}_0(z)$, is a polynomial in z, comprising *only* the terms in even powers of z from $Y_0(z)$. This may be written as

$$\hat{Y}_0(z) = \sum_{\text{even } n} y_0(n)z^{-n} = \sum_{\text{all } n} \frac{1}{2}[y_0(n)z^{-n} + y_0(n)(-z)^{-n}] = \frac{1}{2}[Y_0(z) + Y_0(-z)] \tag{24.9}$$

Similarly

$$\hat{Y}_1(z) = \frac{1}{2}[Y_1(z) + Y_1(-z)] \tag{24.10}$$

This is our general model for downsampling by two, followed by upsampling by two as defined in Equation 24.8.

Substituting Equations 24.9 and 24.10 into Equation 24.7 and then using Equation 24.2, we get

$$\begin{aligned}\hat{X}(z) &= \frac{1}{2}G_0(z)[Y_0(z) + Y_0(-z)] + \frac{1}{2}G_1(z)[Y_1(z) + Y_1(-z)] \\ &= \frac{1}{2}G_0(z)H_0(z)X(z) + \frac{1}{2}G_0(z)H_0(-z)X(-z) \\ &\quad + \frac{1}{2}G_1(z)H_1(z)X(z) + \frac{1}{2}G_1(z)H_1(-z)X(-z) \\ &= \frac{1}{2}X(z)[G_0(z)H_0(z) + G_1(z)H_1(z)] \\ &\quad + \frac{1}{2}X(-z)[G_0(z)H_0(-z) + G_1(z)H_1(-z)] \end{aligned} \tag{24.11}$$

This result will be used in Section 24.6.

24.3 Multirate Filtering

In order to be able to calculate the characteristics of more complicated configurations, for example, comprising cascaded filter banks such as used for wavelet transforms, it is necessary to derive some key results for multirate filter systems.

24.3.1 Multirate Filtering Theorem

To calculate the impulse and frequency responses for a multistage filter network with downsampling/upsampling between stages, we derive an important theorem for multirate filters.

THEOREM 24.1

The downsample–filter–upsample operation of Figure 24.2a *is equivalent to either the filter–downsample–upsample operation of Figure* 24.2b *or the downsample–upsample–filter operation of Figure* 24.2c, *if the filter is changed from* $H(z)$ *to* $H(z^2)$.

PROOF: Expressing the convolution and down + upsampling of Figure 24.2a in full:

$$\begin{aligned}\hat{y}(n) &= \sum_i x(n-2i)h(i) \quad \text{for } n \text{ even} \\ &= 0 \qquad\qquad\qquad\quad \text{for } n \text{ odd}\end{aligned} \tag{24.12}$$

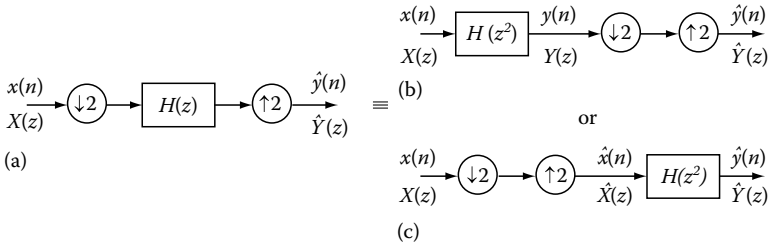

FIGURE 24.2 Multirate filtering (a). This figure shows the result of shifting a filter ahead of a downsampling operation (b) or after an upsampling operation (c).

Taking z-transforms

$$\hat{Y}(z) = \sum_n \hat{y}(n) z^{-n} = \sum_{\text{even } n} \sum_i x(n-2i) h(i) z^{-n} \tag{24.13}$$

Reversing the order of summation and letting $m = n - 2i$:

$$\begin{aligned}
\hat{Y}(z) &= \sum_i h(i) \sum_{\text{even } m} x(m) z^{-m} z^{-2i} \\
&= \sum_i h(i) z^{-2i} \sum_{\text{even } m} x(m) z^{-m} \\
&= H(z^2) \frac{1}{2} [X(z) + X(-z)] \qquad (24.14) \\
&= \frac{1}{2} [H(z^2) X(z) + H((-z)^2) X(-z)] \quad \text{since } (-z)^2 = z^2 \\
&= \frac{1}{2} [Y(z) + Y(-z)] \quad \text{where } Y(z) = H(z^2) X(z) \qquad (24.15)
\end{aligned}$$

Equation 24.15 describes the operations of Figure 24.2b. Hence the first result is proved. The result from Equation 24.14 gives

$$\hat{Y}(z) = H(z^2) \frac{1}{2} [X(z) + X(-z)] = H(z^2) \hat{X}(z) \tag{24.16}$$

This shows that the filter $H(z^2)$ may be placed after the down + upsampler as in Figure 24.2c, which proves the second result.

24.3.2 General Results for *M*:1 Subsampling

The results above may be extended to the case of M:1 down and upsampling as follows:

- $H(z)$ becomes $H(z^M)$ if shifted ahead of an M:1 downsampler or following an M:1 upsampler. (These two results are known as the Noble identities.)
- M:1 down + upsampling of a signal $X(z)$ produces

$$\hat{X}(z) = \frac{1}{M} \sum_{m=0}^{M-1} X(z e^{j2\pi m/M}) \tag{24.17}$$

These results will now be used to analyze binary filter trees.

24.4 Binary Filter Trees

For applications such as signal compression, the purpose of the 2-band filter bank is to compress most of the signal energy into the samples representing the low-frequency half of the signal band. Hence 50% of the filter-bank output samples (the low-pass half) may well contain 90% or more of the signal energy (if it is a signal with dominant low-frequency components such as an image or audio signal).

We may achieve greater compression if the low band is further split into two. This may be repeated a number of times to give the binary filter tree. An example with four levels of decomposition is shown in Figure 24.3.

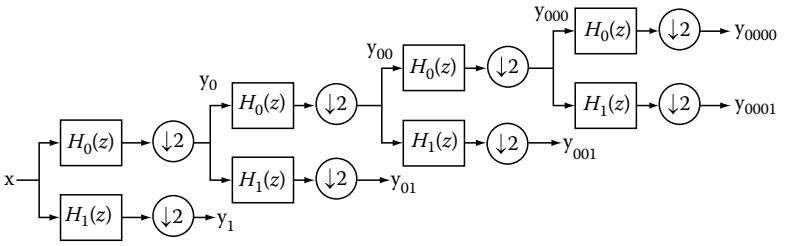

FIGURE 24.3 Extension of the 2-band filter bank into a binary filter tree. H_0 and H_1 are low-pass and high-pass filters.

For an N-sample input vector $\mathbf{x}$, sampled at a frequency f_s, the sizes and bandwidths of the signals of the 4-level filter tree are

Signal	No. of Samples	Approximate Pass Band
$\mathbf{x}$	N	$0 \rightarrow \frac{1}{2}f_s$
$\mathbf{y}_1$	$N/2$	$\frac{1}{4} \rightarrow \frac{1}{2}f_s$
$\mathbf{y}_{01}$	$N/4$	$\frac{1}{8} \rightarrow \frac{1}{4}f_s$
$\mathbf{y}_{001}$	$N/8$	$\frac{1}{16} \rightarrow \frac{1}{8}f_s$
$\mathbf{y}_{0001}$	$N/16$	$\frac{1}{32} \rightarrow \frac{1}{16}f_s$
$\mathbf{y}_{0000}$	$N/16$	$0 \rightarrow \frac{1}{32}f_s$

Because of the downsampling by 2 at each level, the total number of output samples equals N, regardless of the number of levels in the tree; so the process is nonredundant.

The H_0 filter is normally designed to be a low-pass filter with a passband from 0 to approximately $\frac{1}{4}$ of the input sampling frequency for that stage; and H_1 is a high-pass (bandpass) filter with a pass band approximately from $\frac{1}{4}$ to $\frac{1}{2}$ of the input sampling frequency.

When formed into a 4-level tree, the filter outputs have the approximate pass bands given in the above table. The final output $\mathbf{y}_{0000}$ is a low-pass signal, while the other outputs are all bandpass signals, each covering a band of approximately one octave.

An inverse tree, mirroring Figure 24.3, may be constructed using filters G_0 and G_1 instead of H_0 and H_1, as shown for just one level in Figure 24.1b. If the PR conditions of Equations 24.40 and 24.41 are satisfied, then the output of each level will be identical to the input of the equivalent level in Figure 24.3, and the final output will be a PR of the input signal.

24.4.1 Transformation of the Filter Tree

Using the result of Equation 24.15, Figure 24.3 can be redrawn as in Figure 24.4 with all downsamplers moved to the outputs. (Note Figure 24.4 requires much more computation than Figure 24.3,

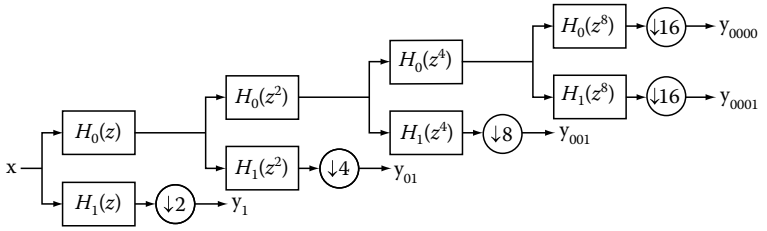

FIGURE 24.4 Binary filter tree, transformed so that all downsampling operations occur at the outputs.

but is a useful analysis aid.) We can now calculate the transfer function to each output (before the downsamplers) as

$$\begin{aligned} H_{01}(z) &= H_0(z)H_1(z^2) \\ H_{001}(z) &= H_0(z)H_0(z^2)H_1(z^4) \\ H_{0001}(z) &= H_0(z)H_0(z^2)H_0(z^4)H_1(z^8) \\ H_{0000}(z) &= H_0(z)H_0(z^2)H_0(z^4)H_0(z^8) \end{aligned} \tag{24.18}$$

In general the transfer functions to the two outputs at level k of the tree are given by

$$H_{k,1} = \left(\prod_{i=0}^{k-2} H_0(z^{2^i})\right) H_1(z^{2^{k-1}}) \quad \text{and} \quad H_{k,0} = \prod_{i=0}^{k-1} H_0(z^{2^i}) \tag{24.19}$$

For the Haar filters of Equation 24.2, the transfer functions to the outputs of the 4-level tree become

$$\begin{aligned} H_{01}(z) &= \frac{1}{2}[(z^{-3} + z^{-2}) - (z^{-1} + 1)] \\ H_{001}(z) &= \frac{1}{2\sqrt{2}}[(z^{-7} + z^{-6} + z^{-5} + z^{-4}) - (z^{-3} + z^{-2} + z^{-1} + 1)] \\ H_{0001}(z) &= \frac{1}{4}[(z^{-15} + z^{-14} + z^{-13} + z^{-12} + z^{-11} + z^{-10} + z^{-9} + z^{-8}) \\ &\quad - (z^{-7} + z^{-6} + z^{-5} + z^{-4} + z^{-3} + z^{-2} + z^{-1} + 1)] \\ H_{0000}(z) &= \frac{1}{4}(z^{-15} + z^{-14} + z^{-13} + z^{-12} + z^{-11} + z^{-10} + z^{-9} + z^{-8} \\ &\quad + z^{-7} + z^{-6} + z^{-5} + z^{-4} + z^{-3} + z^{-2} + z^{-1} + 1) \end{aligned} \tag{24.20}$$

These transfer functions are illustrated in Figure 24.5, simply by interpreting the coefficients of the z-transform polynomials as samples of the corresponding impulse responses; and by substituting $z = e^{j2\pi f/f_s}$ into the transfer functions and evaluating their magnitudes as a function of frequency, f, to obtain the frequency responses.

24.5 Wavelets and Scaling Functions

The process of creating the outputs $\mathbf{y}_1$ to $\mathbf{y}_{0000}$ from $\mathbf{x}$ in Figure 24.3 is known as the DWT; and the reconstruction process is the inverse DWT [1—3]. The term wavelet refers to the impulse response of the cascade of filters which leads to a given bandpass output.

Since the frequency responses of the bandpass bands are scaled down by 2:1 at each level (see Figure 24.5), their impulse responses become longer by the same factor at each level, but their shapes remain very similar. The basic impulse response wave shape is almost independent of scale and is known as the mother wavelet. The impulse response to a low-pass output $H_{k,0}$ is called the scaling function at level k.

Figure 24.5 shows these effects using the impulse responses and frequency responses for the five outputs of the 4-level tree of Haar filters, based on the z-transforms given in Equation 24.20. Notice the abrupt transitions in the midddle and at the ends of the Haar wavelets. These result in noticeable blocking artifacts in decompressed images and other signal types. For this reason we are interested in developing a more general theory of wavelets, with improved impulse and frequency responses.

There are several forms of the wavelet transform but the focus here will be on the form that is related to the 2-band filter bank. This form, which is the most popular in applications, is known as the DWT. Unless otherwise stated, it is assumed that the coefficients of all low-pass filters are scaled such that they

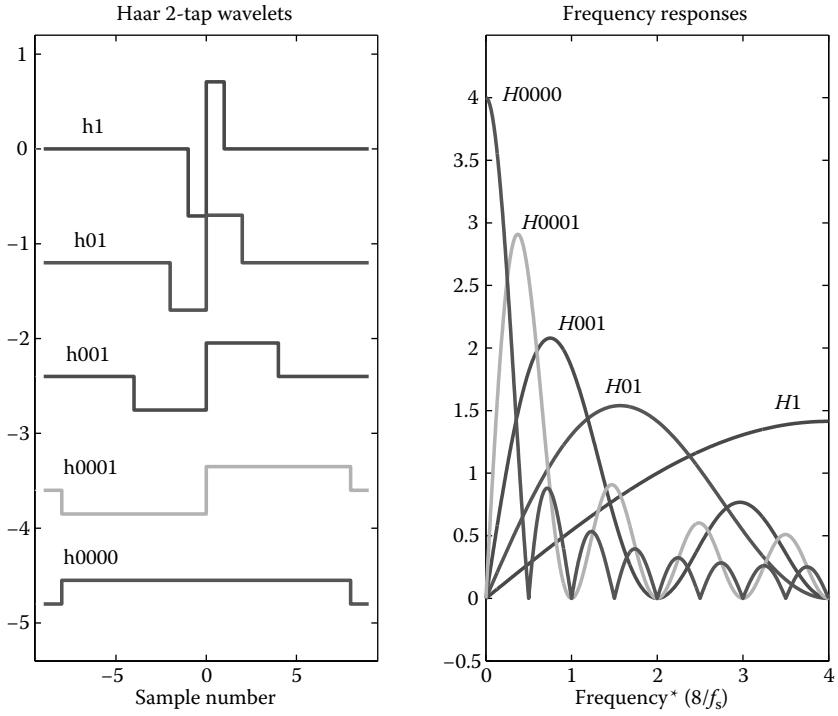

FIGURE 24.5 Impulse responses and frequency responses of the 4-level tree of Haar filters.

sum to the value $\sqrt{2}$, i.e., the DC frequency response is $H_0(e^{j0}) = H_0(1) = \sum_n h_0(n) = \sqrt{2}$. (This scaling has the effect of making the DWT tend to be an energy preserving transformation.)

Central to the principle of the DWT are the two-scale equations that link the discrete time filters of the filter bank to continuous time functions known as the scaling function and the mother wavelet. These equations exist both for the analysis side of the filter bank and for the synthesis side:

1. Analysis side equations:

$$\tilde{\phi}(t) = \sqrt{2}\sum_k h_0(k)\tilde{\phi}(2t-k) \tag{24.21}$$

$$\tilde{\psi}(t) = \sqrt{2}\sum_k h_1(k)\tilde{\phi}(2t-k) \tag{24.22}$$

where $\tilde{\phi}(t)$ and $\tilde{\psi}(t)$ are the analysis scaling function and mother wavelet, respectively. The coefficients of filters $H_0(z)$ and $H_1(z)$ are $h_0(k)$ and $h_1(k)$:
i.e.,

$$H_0(z) = \sum_k h_0(k)z^{-k} \quad \text{and} \quad H_1(z) = \sum_k h_1(k)z^{-k} \tag{24.23}$$

2. Synthesis side equations:

$$\phi(t) = \sqrt{2}\sum_k g_0(k)\phi(2t-k) \tag{24.24}$$

$$\psi(t) = \sqrt{2}\sum_k g_1(k)\phi(2t-k) \tag{24.25}$$

where $\phi(t)$ and $\psi(t)$ are the synthesis scaling function and mother wavelet, respectively. The coefficients of filters $G_0(z)$ and $G_1(z)$ are $g_0(k)$ and $g_1(k)$:
i.e.,

$$G_0(z) = \sum_k g_0(k)z^{-k} \quad \text{and} \quad G_1(z) = \sum_k g_1(k)z^{-k} \tag{24.26}$$

Note that the scaling functions ($\tilde{\phi}(t)$ or $\phi(t)$) are effectively the result of a cascade of low-pass filters (H_0 or G_0) across very many progressively finer scales. The mother wavelets ($\tilde{\psi}(t)$ or $\psi(t)$) are the result of cascading H_1 or G_1 at the coarsest scale, with very many low-pass filters at finer scales.

In the Fourier domain on the analysis side, this gives the infinite product formulae, achieved by transforming Equations 24.21 and 24.22 as follows:

$$\begin{aligned}
\tilde{\Phi}(\omega) &= \sqrt{2}\sum_k h_0(k)\int_{-\infty}^{\infty}\tilde{\phi}(2t-k)e^{-j\omega t}\,dt \\
&= \sqrt{2}\sum_k h_0(k)\int_{-\infty}^{\infty}\tilde{\phi}(\tau)e^{-j\omega\tau/2}e^{-j\omega k/2}\frac{d\tau}{2} \quad \text{if } \tau = 2t-k \\
&= \frac{1}{\sqrt{2}}H_0(e^{j\omega/2})\tilde{\Phi}(\omega/2) \\
&= \frac{1}{\sqrt{2}}H_0(e^{j\omega/2})\frac{1}{\sqrt{2}}H_0(e^{j\omega/4})\tilde{\Phi}(\omega/4) \\
&\vdots \\
&= \prod_{k=1}^{\infty}\left\{\frac{1}{\sqrt{2}}H_0\left(e^{j\omega/2^k}\right)\right\}\tilde{\Phi}(0)
\end{aligned} \tag{24.27}$$

Similarly

$$\begin{aligned}
\tilde{\Psi}(\omega) &= \frac{1}{\sqrt{2}}H_1(e^{j\omega/2})\tilde{\Phi}(\omega/2) \\
&= \frac{1}{\sqrt{2}}H_1(e^{j\omega/2})\prod_{k=2}^{\infty}\left\{\frac{1}{\sqrt{2}}H_0\left(e^{j\omega/2^k}\right)\right\}\tilde{\Phi}(0)
\end{aligned} \tag{24.28}$$

where $\tilde{\Phi}(\omega)$ and $\tilde{\Psi}(\omega)$ are the Fourier transforms of $\tilde{\phi}(t)$ and $\tilde{\psi}(t)$, respectively.

The above equations explicitly define the analysis scaling function and mother wavelet in terms of the analysis filters. Similar infinite product formulae exist linking the synthesis scaling function and wavelet to the synthesis filters.

Equations 24.27 and 24.28 are reminiscent of the equivalent transfer functions defined in Equation 24.19 for the binary filter tree. The relationships can be made more precise as follows. The transfer functions (repeated here for convenience) for the k level tree are

$$H_{k,0}(z) \equiv \prod_{i=0}^{k-1}H_0(z^{2^i}) = \sum_n h_{k,0}(n)z^{-n} \tag{24.29}$$

$$H_{k,1}(z) \equiv H_1(z^{2^{k-1}}) \prod_{i=0}^{k-2} H_0(z^{2^i}) = \sum_n h_{k,1}(n) z^{-n} \tag{24.30}$$

where $h_{k,0}(n)$ and $h_{k,1}(n)$ are the coefficients of $H_{k,0}(z)$ and $H_{k,1}(z)$.

From the coefficients of the equivalent filters, we construct the following piecewise constant functions:

$$\tilde{\phi}^{(k)}(t) \equiv 2^{k/2} h_{k,0}(n), \quad \frac{n}{2^k} \le t < \frac{n+1}{2^k} \tag{24.31}$$

$$\tilde{\psi}^{(k)}(t) \equiv 2^{k/2} h_{k,1}(n), \quad \frac{n}{2^k} \le t < \frac{n+1}{2^k} \tag{24.32}$$

Each coefficient defines a rectangular pulse of width 2^{-k}, and both $\tilde{\phi}^{(k)}(t)$ and $\tilde{\psi}^{(k)}(t)$ are made up of sequences of such pulses. The width of the pulse is halved with each increase in tree level (scale) k but the $2^{k/2}$ amplitude normalization ensures that the total energy of each function remains constant. When the number of levels k tends to infinity, the scaling function and mother wavelet are obtained:

$$\tilde{\phi}(t) = \lim_{k\to\infty} \tilde{\phi}^{(k)}(t) \quad \text{and} \quad \tilde{\psi}(t) = \lim_{k\to\infty} \tilde{\psi}^{(k)}(t) \tag{24.33}$$

i.e., the shape of the scaling function and wavelet are the shape of the impulse response of equivalent filters of the binary tree as $k \to \infty$. In practice, the shape of the scaling function and wavelet is obtained quite accurately after $k \simeq 6$ levels. Similar relationships exist on the synthesis side.

The discussion above involving infinite products assumes convergence but this is not always guaranteed. The filters must be properly designed to ensure convergence. One condition that is necessary for convergence is

$$H_0(e^{j\pi}) = H_0(-1) = 0 \quad \text{and} \quad G_0(e^{j\pi}) = G_0(-1) = 0 \tag{24.34}$$

i.e., the low-pass filter responses must vanish at the aliasing (half-sampling) frequency. This means that $(1 + z^{-1})$ must be a factor of both $H_0(z)$ and $G_0(z)$.

A simple degree-1 factor, i.e., $(1 + z^{-1})$, may not necessarily guarantee convergence; and even if convergence is achieved, the resultant scaling and wavelet functions may not be smooth. In general, higher order factors are usually imposed on the low-pass filters, such that

$$H_0(z) = 2^{-L_H}(1 + z^{-1})^{L_H} R_H(z) \tag{24.35}$$

$$G_0(z) = 2^{-L_G}(1 + z^{-1})^{L_G} R_G(z) \tag{24.36}$$

where $R_H(z)$ and $R_G(z)$ are the remainder factors of $H_0(z)$ and $G_0(z)$, respectively.

The orders L_H and L_G determine the numbers of vanishing moments (VM) of the corresponding wavelet function, such that

$$\int_{-\infty}^{+\infty} t^n \tilde{\psi}(t) \mathrm{d}t = 0 \quad \text{for } n = 0, \ldots, L_H - 1 \tag{24.37}$$

$$\int_{-\infty}^{+\infty} t^n \psi(t) \mathrm{d}t = 0 \quad \text{for } n = 0, \ldots, L_G - 1 \tag{24.38}$$

In general the higher the number of VM, the smoother will be the scaling and wavelet functions.

24.6 Good FIR Filters and Wavelets

24.6.1 Perfect Reconstruction Condition

One of the most important requirements for most filter banks is to be able to reconstruct perfectly the input signal $X(z)$ at the reconstruction filter bank output $\hat{X}(z)$ (see Figure 24.1).

We now wish to find the constraints on arbitrary filters, $\{H_0, H_1, G_0, G_1\}$, such that perfect reconstruction (PR) occurs.

Repeating the result from Equation 24.11, the input–output relationship for the pair of filter banks in Figure 24.1 is

$$\begin{aligned}\hat{X}(z) = &\frac{1}{2}X(z)[G_0(z)H_0(z) + G_1(z)H_1(z)] \\ &+ \frac{1}{2}X(-z)[G_0(z)H_0(-z) + G_1(z)H_1(-z)]\end{aligned} \tag{24.39}$$

If we require $\hat{X}(z) \equiv X(z)$—the PR condition—then

$$G_0(z)H_0(z) + G_1(z)H_1(z) \equiv 2 \tag{24.40}$$

and

$$G_0(z)H_0(-z) + G_1(z)H_1(-z) \equiv 0 \tag{24.41}$$

Equation 24.41 is known as the antialiasing condition because the term in $X(-z)$ in Equation 24.39 is the unwanted aliasing term caused by the 2 : 1 downsampling of $\mathbf{y}_0$ and $\mathbf{y}_1$.

It is straightforward to show that the expressions for $\{H_0, H_1, G_0, G_1\}$, given in Equations 24.2 and 24.6 for the filters based on the Haar wavelet basis, satisfy Equations 24.40 and 24.41. They are the simplest set of filters which do.

24.6.2 Good Filters/Wavelets

Our main aim now is to search for better filters which result in wavelets and scaling functions that are smoother than the Haar functions (i.e., which avoid the discontinuities evident in the waveforms of Figure 24.5).

We start our search with the two PR identities, Equations 24.40 and 24.41.

The usual way of satisfying the antialiasing condition Equation 24.41, while permitting H_0 and G_0 to have low-pass responses (passband where $\mathrm{Re}[z] > 0$) and H_1 and G_1 to have high-pass responses (passband where $\mathrm{Re}[z] < 0$), is with the following relations in which k must be an odd integer:

$$H_1(z) = z^{-k}G_0(-z) \quad \text{and} \quad G_1(z) = z^k H_0(-z) \tag{24.42}$$

Hence:

$$\begin{aligned}G_0(z)H_0(-z) + G_1(z)H_1(-z) &= G_0(z)H_0(-z) + z^k H_0(-z)(-z)^{-k}G_0(z) \\ &= G_0(z)H_0(-z) + (-1)^{-k}H_0(-z)G_0(z) \\ &\equiv 0 \quad \text{if } k \text{ is odd}\end{aligned} \tag{24.43}$$

and so Equation 24.41 is satisfied, as required.

Now we define the low-pass product filter:

$$P(z) = H_0(z)G_0(z) \tag{24.44}$$

and substitute relations in Equation 24.42 into Equation 24.40 to get

$$\begin{aligned} G_0(z)H_0(z) + G_1(z)H_1(z) &= G_0(z)H_0(z) + H_0(-z)G_0(-z) \\ &= P(z) + P(-z) \equiv 2 \end{aligned} \tag{24.45}$$

Hence satisfying Equation 24.40 requires that all $P(z)$ terms in even powers of z be zero, except the z^0 term which must be 1. However the $P(z)$ terms in odd powers of z may take any desired values since they cancel out in Equation 24.45. If P is low-pass, this type of filter is often known as a halfband filter since $P(e^{j\omega}) + P(e^{j(\omega+\pi)}) =$ a constant, and so the bandwidth of P must be half of the input bandwidth.

A further commonly applied constraint on $P(z)$ is that it should be zero phase,* in order to minimize the magnitude of any distortions due to samples from the high-pass filters being suppressed (perhaps as a result of quantization or denoising). Hence $P(z)$ should be of the form:

$$P(z) = \cdots + p_5 z^5 + p_3 z^3 + p_1 z + 1 + p_1 z^{-1} + p_3 z^{-3} + p_5 z^{-5} + \cdots \tag{24.46}$$

The design of a set of PR filters H_0, H_1 and G_0, G_1 can now be summarized as

1. Choose a set of coefficients $p_1, p_3, p_5 \cdots$ to give a zero-phase low-pass product filter $P(z)$ with desirable characteristics. (This is nontrivial and is discussed below.)
2. Factorize $P(z)$ into $H_0(z)$ and $G_0(z)$, preferably so that the two filters have similar low-pass frequency responses.
3. Calculate $H_1(z)$ and $G_1(z)$ from Equation 24.42.

It can help to simplify the tasks of choosing $P(z)$ and factorizing it if, based on the zero-phase requirement, we transform $P(z)$ into $P_t(Z)$ such that

$$P(z) = P_t(Z) = 1 + p_{t,1}Z + p_{t,3}Z^3 + p_{t,5}Z^5 + \cdots \quad \text{where} \quad Z = \frac{1}{2}(z + z^{-1}) \tag{24.47}$$

To calculate the frequency response of $P(z) = P_t(Z)$, let $z = e^{j\omega T_s}$.

Therefore

$$\therefore\ Z = \frac{1}{2}(e^{j\omega T_s} + e^{-j\omega T_s}) = \cos(\omega T_s) \tag{24.48}$$

This is a purely real function of ω, varying from 1 at $\omega = 0$ to -1 at $\omega T_s = \pi$ (half the sampling frequency). Hence we may substitute $\cos(\omega T_s)$ for Z in $P_t(Z)$ to obtain its frequency response directly.

24.6.3 Some Simple Filters/Wavelets (Haar and LeGall)

As discussed in Section 24.5, in order to achieve smooth wavelets after many levels of the binary tree, the low-pass filters $H_0(z)$ and $G_0(z)$ must both have a number of zeros at half the sampling frequency (at $z = -1$). These will also be zeros of $P(z)$, and so $P_t(Z)$ will have zeros at $Z = -1$ (each of which will correspond to a pair of zeros at $z = -1$).

* See the end of Section 24.1 for a discussion of causality assumptions related to this.

The simplest case is a single zero at $Z = -1$, so that $P_t(Z) = 1 + Z$.

$$\therefore\ P(z) = \frac{1}{2}(z + 2 + z^{-1}) = \frac{1}{2}(z + 1)(1 + z^{-1}) = G_0(z)H_0(z)$$

which gives the familiar Haar filters.

As we have seen in Figure 24.5, the Haar wavelets have significant discontinuities so we need to add more zeros at $Z = -1$. However to maintain PR, we must also ensure that all terms in even powers of Z in $P_t(Z)$ are zero, so the next more complicated P_t must be third-order and of the form

$$\begin{aligned} P_t(Z) &= (1 + Z)^2(1 + aZ) = 1 + (2 + a)Z + (1 + 2a)Z^2 + aZ^3 \\ &= 1 + \frac{3}{2}Z - \frac{1}{2}Z^3 \quad \text{if } a = -\frac{1}{2} \text{ to suppress the term in } Z^2 \end{aligned} \tag{24.49}$$

Allocating the factors of P_t such that $(1 + Z)$ gives H_0 and $(1 + Z)(1 + aZ)$ gives G_0:

$$\begin{aligned} H_0(z) &= \frac{1}{2}(z + 2 + z^{-1}) \\ G_0(z) &= \frac{1}{8}(z + 2 + z^{-1})(-z + 4 - z^{-1}) \\ &= \frac{1}{8}(-z^2 + 2z + 6 + 2z^{-1} - z^{-2}) \end{aligned} \tag{24.50}$$

Using Equation 24.42 with $k = 1$, the corresponding high-pass filters then become

$$\begin{aligned} G_1(z) &= zH_0(-z) = \frac{1}{2}z(-z + 2 - z^{-1}) \\ H_1(z) &= z^{-1}G_0(-z) = \frac{1}{8}z^{-1}(-z^2 - 2z + 6 - 2z^{-1} - z^{-2}) \end{aligned} \tag{24.51}$$

This is often known as the *LeGall 3,5-tap filter set*, since it was first published in the context of 2-band filter banks by Didier LeGall in 1988.

The wavelets of the LeGall 3,5-tap filters, H_0 and H_1 above, and their frequency responses are shown in Figure 24.6. The scaling function (bottom left) converges to a pure triangular pulse and the wavelets are the superposition of two triangular pulses of opposing polarity.

The triangular scaling function produces linear interpolation between consecutive lowband coefficients and also causes the wavelets to be linear interpolations of the coefficients of the H_1 filter, $-1, -2, +6, -2, -1$ (scaled appropriately).

These wavelets have quite desirable properties for signal compression (note the absence of waveform discontinuities and the much lower sidelobes of the frequency responses), and they are one of the simplest useful wavelet types. Unfortunately there is one drawback—the inverse wavelets are not very good. These are formed from the LeGall 5,3-tap filter pair, G_0 and G_1 above, whose wavelets and frequency responses are shown in Figure 24.7

The main problem here is that the wavelets do not converge after many levels to a smooth function and hence the frequency responses have large unwanted sidelobes. For example, the jaggedness of the scaling function and wavelets causes highly visible coding artifacts if these filters are used for reconstruction of a compressed image.

However the allocation of the factors of $P_t(Z)$ to H_0 and G_0 is a free design choice, so we may swap the factors (and hence swap G and H) from the choice made in Equation 24.50 in order that the

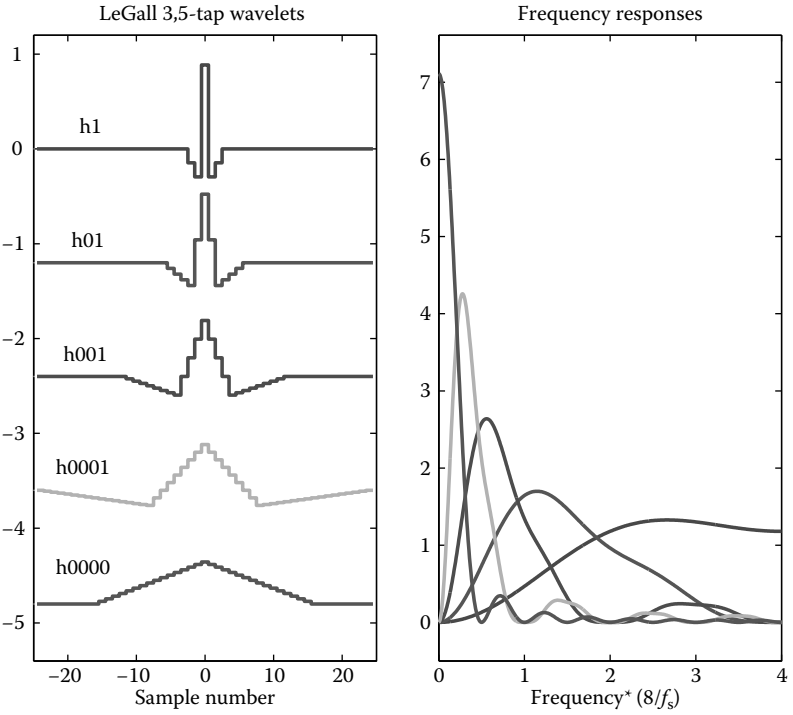

FIGURE 24.6 Impulse responses and frequency responses of the 4-level tree of LeGall 3,5-tap filters.

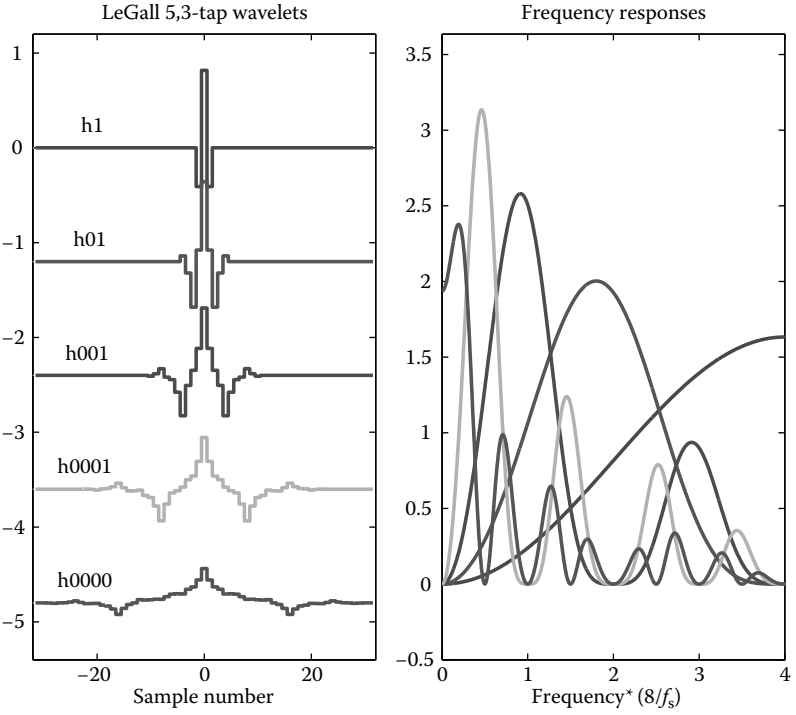

FIGURE 24.7 Impulse responses and frequency responses of the 4-level tree of LeGall 5,3-tap filters.

smoother 3,5-tap filters become G_0, G_1 and are used for reconstruction. It turns out that this leads to a good low-complexity solution for image compression and that the jaggedness of the analysis filters is not critical.

Unbalance between analysis and reconstruction filters/wavelets is nevertheless often regarded as being undesirable, particularly as it prevents the filtering process from being represented as an orthonormal transformation of the input signal and hence from preserving energy through the filter bank. An unbalanced PR filter system is often termed a biorthogonal filter bank.

We now consider ways to reduce this unbalance.

24.6.4 Filters with Balanced *H* and *G* Frequency Responses (but Nonlinear Phase Responses)—Daubechies Wavelets

In the above analysis, we used the factorization of $P_t(Z)$ to give us H_0 and G_0. This always gives unbalanced factors if terms of P_t in even powers of Z are zero, since $P_t(Z)$ must then be of odd-order.

However, each of these factors in Z may itself be factorized into a pair of factors in z, since

$$\begin{aligned}(\alpha z + 1)(1 + \alpha z^{-1}) &= \alpha z + (1 + \alpha^2) + \alpha z^{-1} \\ &= (1 + \alpha^2) + 2\alpha Z \qquad \text{if } Z = \frac{1}{2}(z + z^{-1}) \\ &= (1 + \alpha^2)(1 + \beta Z) \quad \text{where } \beta = \frac{2\alpha}{1 + \alpha^2}\end{aligned} \tag{24.52}$$

For each factor of $P_t(Z)$, we may allocate one of its z subfactors to $H_0(z)$ and the other to $G_0(z)$. Where roots of $P_t(Z)$ are complex, the subfactors must be allocated in conjugate pairs so that H_0 and G_0 remain purely real.

Since the subfactors occur in reciprocal pairs (roots at $z = \alpha$ and α^{-1} for any given β, as shown above), we find that

$$G_0(z) = H_0(z^{-1}) \tag{24.53}$$

This means that the impulse response of G_0 is the time-reverse of that of H_0.

Therefore, using the substitution $z = e^{j\omega T_s}$, their frequency responses are related by

$$G_0(e^{j\omega T_s}) = H_0(e^{-j\omega T_s}) \tag{24.54}$$

Hence, if H_0 and G_0 are real functions of z, the magnitudes of their frequency responses are the same, and their phases are opposite. It may be shown that this is sufficient to obtain orthogonal wavelet basis functions and scaling functions, but unfortunately the separate filters can no longer be zero (or linear) phase, apart from the unique case of the Haar wavelet. When the filters satisfy Equation 24.53, in addition to Equations 24.42 and 24.45, the filter bank is known as a conjugate quadrature filter bank (CQF).

The well-known Daubechies wavelets may be generated in this way, if we include the added constraint that the maximum number of zeros of $P_t(Z)$ are placed at $Z = -1$ (producing pairs of zeros of $P(z)$ at $z = -1$), consistent with terms in even powers of Z in $P_t(Z)$ being zero.

If $P_t(Z)$ is of order $2K - 1$, then it may have K zeros at $Z = -1$ such that

$$P_t(Z) = (1 + Z)^K R_t(Z) \tag{24.55}$$

where $R_t(Z)$ is of order $K - 1$ and its $K - 1$ roots may be chosen such that terms of $P_t(Z)$ in the $K - 1$ even powers of Z are zero.

Equation 24.49 is the $K = 2$ solution to Equation 24.55.

In this case, $R_t(Z) = 1 - \frac{1}{2}Z$, so $\beta = -\frac{1}{2}$ and, from Equation 24.52, the factors of $R(z)$ are

$$R(z) = \frac{(\alpha z + 1)(1 + \alpha z^{-1})}{1 + \alpha^2} \quad \text{where } \alpha = -2 \pm \sqrt{3}$$

since α must be a solution of $1 + \alpha^2 = 2\alpha/\beta$.

Also

$$(1 + Z)^2 = \frac{1}{2}(z + 1)^2 \frac{1}{2}(1 + z^{-1})^2$$

Hence

$$\begin{aligned} H_0(z) &= \frac{1}{2\sqrt{1 + \alpha^2}}(1 + z^{-1})^2\ (1 + \alpha z^{-1}) \\ &= 0.4830 + 0.8365z^{-1} + 0.2241z^{-2} - 0.1294z^{-3} \end{aligned} \tag{24.56}$$

and $G_0(z)$ is the time-reverse of this (replacing z^{-1} by z). Therefore

$$\begin{aligned} H_1(z) &= z^{-3}G_0(-z) = z^{-3}H_0(-z^{-1}) \\ &= 0.1294 + 0.2241z^{-1} - 0.8365z^{-2} + 0.4830z^{-3} \end{aligned} \tag{24.57}$$

The wavelets and frequency responses for these 4-tap filters are shown in Figure 24.8. It is clear that the wavelets and scaling function are no longer linear phase (symmetric about a central point) and

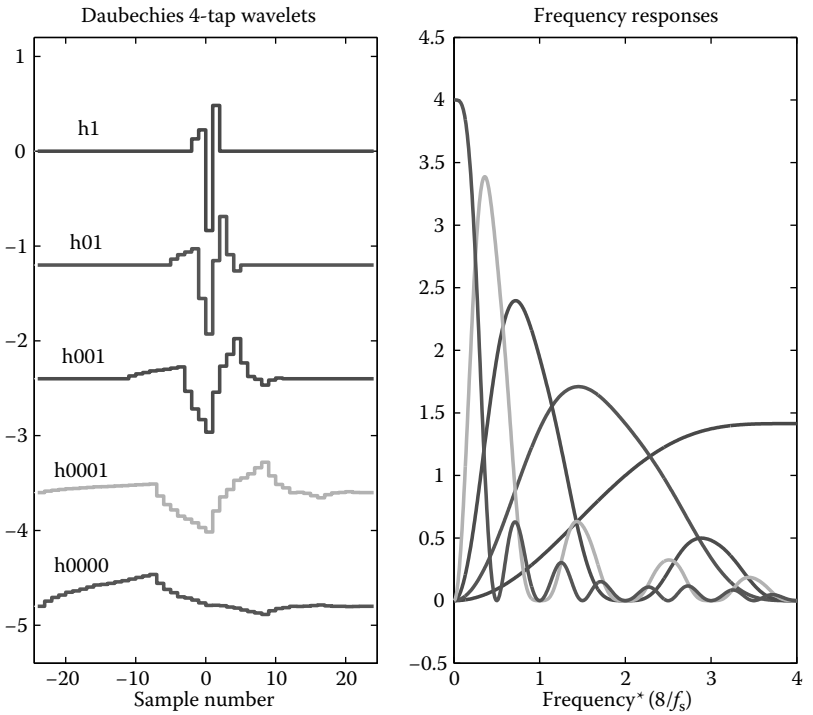

FIGURE 24.8 Impulse responses and frequency responses of the 4-level tree of Daubechies 4-tap filters.

are less smooth than those for the LeGall 3,5-tap filters. The frequency responses also show worse sidelobes. The G_0, G_1 filters give the time-reverse of these wavelets and identical frequency (magnitude) responses.

Higher order Daubechies filters achieve smoother wavelets but they still suffer from nonlinear phase. This tends to result in more visible image coding artefacts than linear phase filters, which distribute any artefacts equally on either side of sharp edges in the image.

When there is more than one root of the residual polynomial $R_t(Z)$, the designer may choose how the factors, $(1 + \alpha z)$ or $(1 + \alpha z^{-1})$, for each root are distributed to $H_0(z)$ and $G_0(z)$. While the distribution may be chosen to give maximum-phase or minimum-phase H_0 and G_0 filters, it is usual to attempt the distribution so as to approximate linear phase more closely. Depending on the choice of product filter order $2K - 1$, different levels of approximation to linear phase become possible.

A fairly good approximation to linear phase, often known as the Daubechies symlet, is obtained for the case when $K = 4$. This gives four zeros of $P_t(Z)$ at $Z = -1$ (and hence four pairs of zeros of $P(z)$ at $z = -1$, which can be shared equally between $H_0(z)$ and $G_0(z)$). The remainder polynomial $R_t(Z)$ is then third order. When converted back to being a function of z, the product filter is given by

$$\begin{aligned} P(z) = H_0(z)G_0(z) &= \frac{z^{-4}}{2048}(z+1)^8 R(z) \\ \text{where } R(z) &= 5z^3 - 40z^2 + 131z - 208 + 131z^{-1} - 40z^{-2} + 5z^{-3} \end{aligned} \tag{24.58}$$

$R(z)$ has real zeros at 0.3289 and 3.0407, and complex zeros at $0.2841 \pm 0.2432j$ and $2.0311 \pm 1.7390j$. To get the closest approximation to linear phase, we group the smaller conjugate pair with the larger real zero, and combine these with four of the zeros at $z = -1$ to obtain $H_0(z)$, while the remaining zeros of $P(z)$ give $G_0(z)$ (or vice versa). H_0 and G_0 are then both seventh-order polynomials (8-tap filters). The impulse and frequency responses of the wavelets and scaling functions from these filters are shown in Figure 24.9, from which we see the somewhat improved symmetry of the waveforms about their highest point (hence the name symlet), as compared with the 4-tap waveforms in Figure 24.8, as well as their greater smoothness and lower sidelobes in the frequency domain.

A useful way to obtain equations of the form of Equation 24.55, for arbitrary odd order $N \geq 2K - 1$ of the transformed product filter $P_t(z)$, is to use the Bernstein polynomial [4,5]:

$$B_N(x;\alpha) = \sum_{i=0}^{(N-1)/2} (1-\alpha_i)\binom{N}{i} x^i (1-x)^{N-i} + \sum_{i=(N+1)/2}^{N} \alpha_{N-i}\binom{N}{i} x^i (1-x)^{N-i} \tag{24.59}$$

where $\alpha = [\alpha_0 \ \alpha_1 \ \ldots \ \alpha_{(N-1)/2}]^{\mathrm{T}}$.

This polynomial has the property that, for any choice of x and α

$$B_N(x;\alpha) + B_N(1-x;\alpha) = 1 \tag{24.60}$$

For PR, from Equations 24.45 and 24.47, it is required that

$$P_t(Z) + P_t(-Z) = 2 \tag{24.61}$$

Hence, if we let $P_t(Z) = 2B_N(x;\alpha)$, where $x = (1 - Z)/2$ so that x goes from 0 to 1 as Z goes from $+1$ to -1, then $P_t(-Z) = 2B_N(1 - x;\alpha)$ and, from Equation 24.60, $P_t(Z)$ will satisfy the above PR condition (Equation 24.61) for any choice of α.

To obtain K zeros of $P_t(Z)$ at $Z = -1$, we require $B_N(x;\alpha)$ to have K zeros at $x = 1$, which may be easily obtained by setting $\alpha_i = 0$ for $i = 0 \ldots K - 1$, as long as $N \geq 2K - 1$.

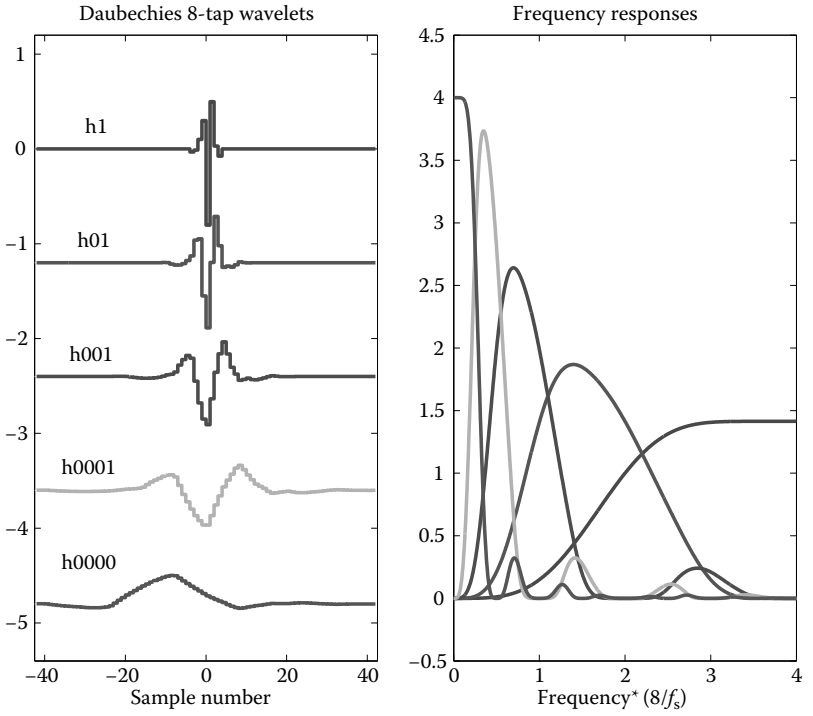

FIGURE 24.9 Impulse responses and frequency responses of the 4-level tree of Daubechies 8-tap symlet filters.

When $N = 2K - 1$, we have the maximum number of zeros at $Z = -1$ for a given N, as assumed above for the cases $K = 2$ and $K = 4$. Then are then no further degrees of freedom available to the designer. We shall see below that, in some situations, at least one additional degree of freedom can be very helpful, and this is achieved when $N = 2K + 1$ and the free parameter is α_K. More degrees of freedom may be achieved by increasing N in steps of two while keeping K constant.

24.6.5 Filters with Linear Phase and Nearly Balanced Frequency Responses

We have seen how to create filters with balanced frequency responses and an approximation to linear phase. Now we consider filters with exact linear phase and approximately balanced frequency responses.

Linear phase filters allow an elegant technique, known as symmetric extension, to be used at the outer edges of finite datasets such as images, where wavelet filters would otherwise require the size of the transformed data to be increased to allow for convolution with the filters. Symmetric extension assumes that the data is reflected by mirrors at each endpoint or edge. For images in 2-D, an infinitely tesselated plane of reflected images is generated. Reflections avoid unwanted edge discontinuities. If the filters are linear phase, then the resulting DWT coefficients also form reflections at the endpoints and no increase in size of the transformed data is necessary to accommodate convolution effects.

To ensure that the filters H_0, H_1 and G_0, G_1 are linear phase, the factors in Z must be allocated to H_0 or G_0 as a whole and not be split, as was done for the Daubechies filters. In this way, the symmetry between z and z^{-1} is preserved in all filters. Perfect balance of frequency responses between H_0 and G_0 is then not possible, if PR is preserved.

A popular linear-phase option, which works very well for image coding and is part of the JPEG 2000 standard, is a linear phase factorization of the same $P(z)$ product filter, used for the 8-tap Daubechies symlet and given in Equation 24.58. This factorization still distributes the eight zeros at $z = -1$ equally

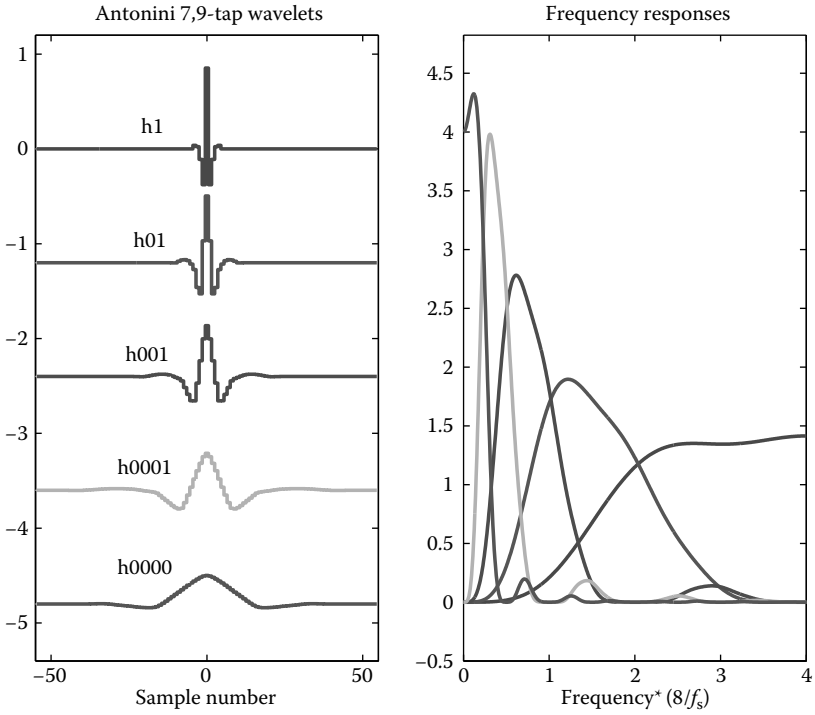

FIGURE 24.10 Impulse responses and frequency responses of the 4-level tree of Daubechies 7,9-tap filters.

between H_0 and G_0; but, to get linear phase and keep the filter coefficients purely real, it is necessary to allocate the two real zeros of $R(z)$ to one filter (say G_0) and the four complex zeros of $R(z)$ to the other filter (H_0). Linear phase is obtained because the zeros are in reciprocal pairs, and real coefficients are obtained because the complex zeros are also in conjugate pairs. The resulting 7-tap and 9-tap filters are known as the Daubechies biorthogonal 7,9-tap wavelet filters (and also known as Antonini filters) [6]. These 7,9-tap and 9,7-tap wavelets and scaling functions are shown in Figures 24.10 and 24.11.

The 7-tap filter from this pair tends to be somewhat smoother than the 9-tap one, and so is normally chosen for the reconstruction low-pass filter G_0 (and hence also generates the analysis high-pass filter H_1, Equation 24.42). In compression applications, where many higher frequency wavelet coefficients are set to zero, this tends to result in a smoother reconstructed signal. It may be seen that the smoother waveforms, with lower sidelobes in the frequency domain, occur in Figure 24.10 while the less smooth option is in Figure 24.11.

We have found a factorization of $P_t(Z)$ which achieves a much closer balance of the responses, by reducing K the number of zeros at $Z = -1$. This is

$$P_t(Z) = (1 + Z)(1 + aZ + bZ^2)(1 + Z)(1 + cZ) \tag{24.62}$$

This is a fifth order polynomial, and if the terms in Z^2 and Z^4 are to be zero, there are two constraints on the three unknowns [*a, b, c*] so that one of them (say *c*) may be regarded as a free parameter. These constraints require that

$$a = -\frac{(1 + 2c)^2}{2(1 + c)^2} \quad \text{and} \quad b = \frac{c(1 + 2c)}{2(1 + c)^2} \tag{24.63}$$

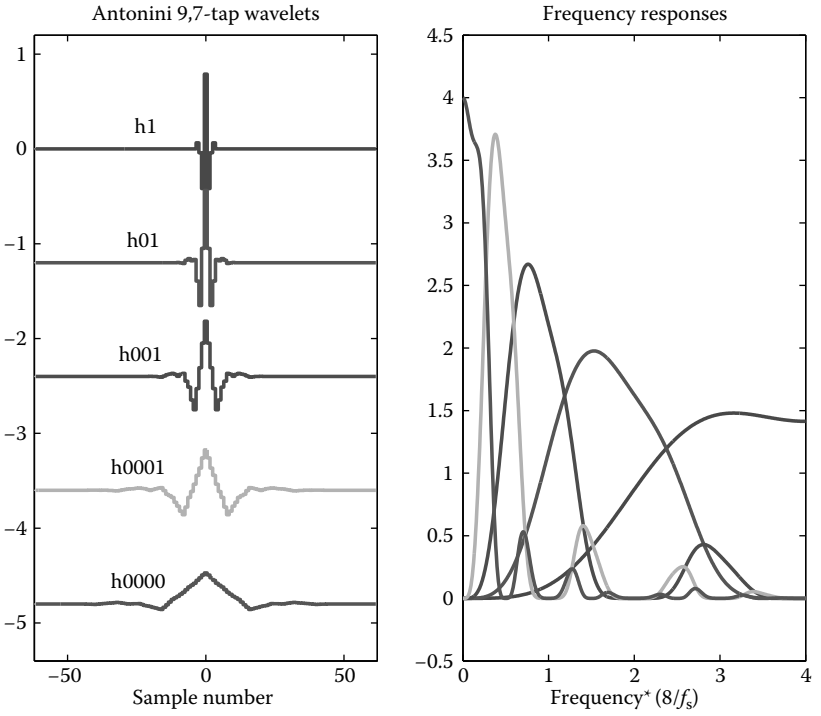

FIGURE 24.11 Impulse responses and frequency responses of the 4-level tree of Daubechies 9,7-tap filters.

c may then be adjusted to give maximum similarity between the left and right pairs of factors in Equation 24.62 as Z varies from 1 to -1 (i.e., as ωT_s varies from 0 to π).

It turns out that $c = -\frac{2}{7}$ gives good similarity and when substituted into Equations 24.62 and 24.63 gives

$$\begin{aligned} P_t(Z) &= \frac{1}{50}(1+Z)(50-9Z-6Z^2)\frac{1}{7}(1+Z)(7-2Z) \\ &= \frac{1}{50}(50+41Z-15Z^2-6Z^3)\frac{1}{7}(7+5Z-2Z^2) \end{aligned} \tag{24.64}$$

We get $G_0(z)$ and $H_0(z)$ by substituting $Z = \frac{1}{2}(z+z^{-1})$ into these two polynomial factors. This results in 5,7-tap filters whose wavelets and frequency responses are shown in Figure 24.12.

The near balance of the analysis and reconstruction responses may be seen from Figure 24.13 which shows the alternative 7,5-tap versions (i.e., with H and G swapped). It is quite difficult to spot the minor differences between these figures and it makes little difference which way round the filters are allocated.

These filters may also be obtained using the Bernstein polynomial method of equation (Equation 24.59), using $N = 5$, $K = 2$, and α_K as the free parameter. The value which corresponds to $c = -\frac{2}{7}$ is $\alpha_2 = \frac{477}{1750} = 0.2726$.

24.6.6 Smoother Wavelets

In all of the above designs we have used the substitution $Z = \frac{1}{2}(z+z^{-1})$. However other substitutions may be used to create improved wavelets. To preserve PR, the substitution should contain only odd powers of z (so that odd powers of Z produce only odd powers of z); and to produce zero phase, the coefficients of the substitution should be symmetric about z^0.

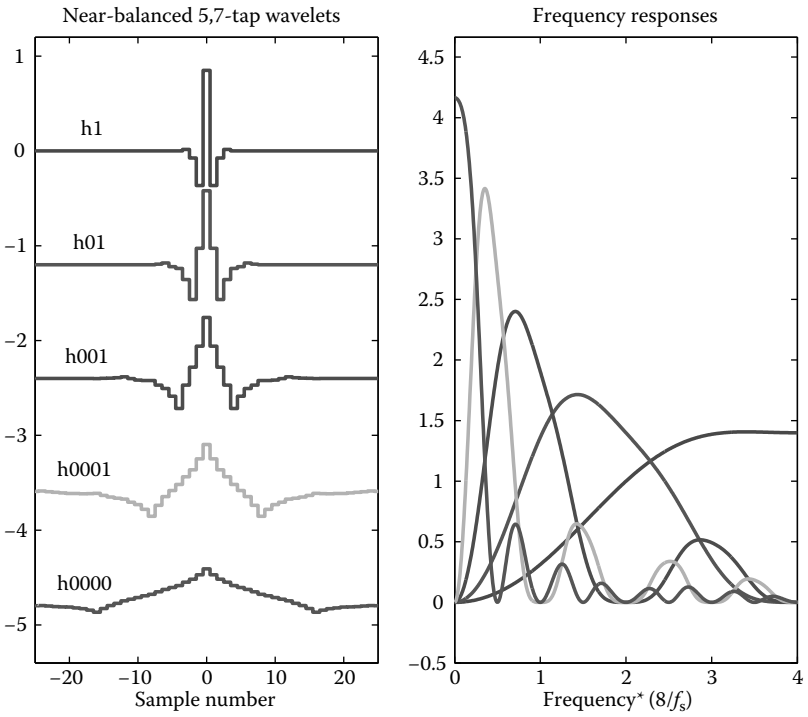

FIGURE 24.12 Impulse responses and frequency responses of the 4-level tree of near-balanced 5,7-tap filters.

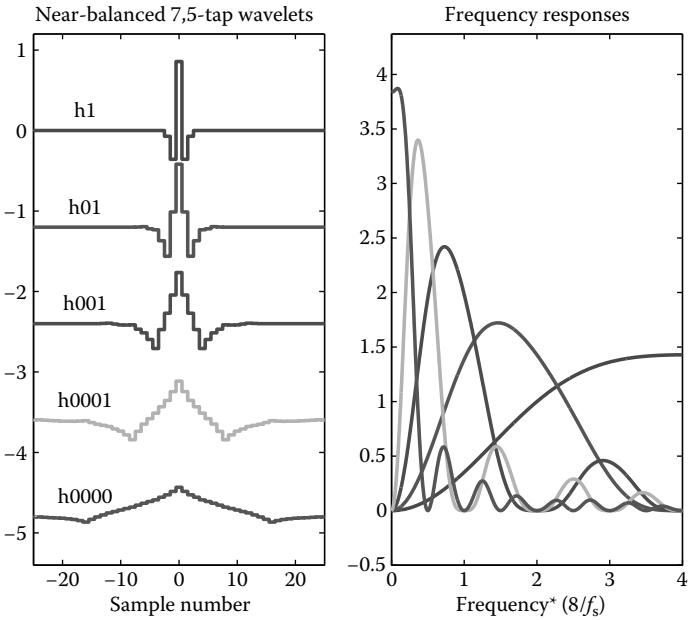

FIGURE 24.13 Impulse responses and frequency responses of the 4-level tree of near-balanced 7,5-tap filters.

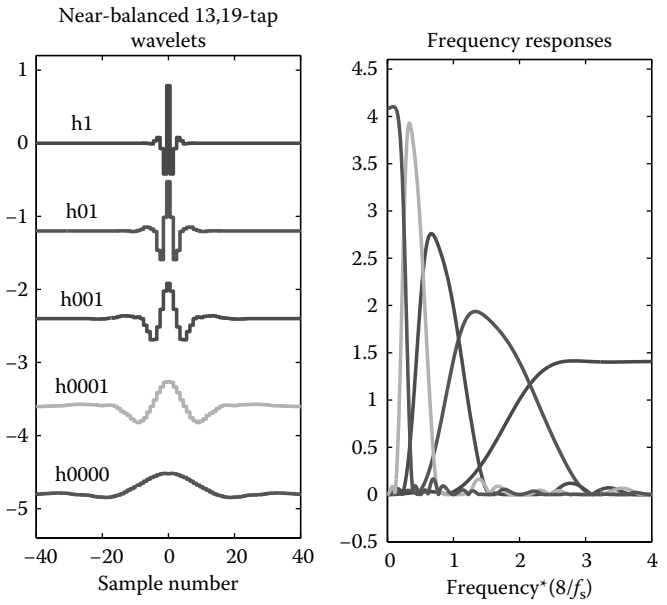

FIGURE 24.14 Impulse responses and frequency responses of the 4-level tree of near-balanced 13,19-tap filters.

A substitution, which can give much greater flatness near $z = \pm 1$ while still satisfying $Z = \pm 1$ when $z = \pm 1$, is

$$Z = pz^3 + (\tfrac{1}{2} - p)(z + z^{-1}) + pz^{-3} \tag{24.65}$$

Z then becomes the following function of frequency when $z = e^{j\omega T_s}$:

$$Z = (1 - 2p)\cos(\omega T_s) + 2p\cos(3\omega T_s) \tag{24.66}$$

Maximal flatness is achieved near $\omega T_s = 0$ and π, when $p = -\frac{1}{16}$. This is equivalent to more zeros at $z = -1$ for each $(Z + 1)$ factor than when $Z = \frac{1}{2}(z + z^{-1})$ is used. A high degree of flatness (with some ripple) and sharper transition bands is obtained if $p = -\frac{3}{32}$ instead.

The second order factor of $P_t(Z)$ in Equation 24.64 now produces terms from z^6 to z^{-6} and the third-order factor produces terms from z^9 to z^{-9}. Hence the filters become 13- and 19-tap filters, although two taps of each are zero and the outer two taps of the 19-tap filter are very small ($\sim 10^{-4}$).

Figure 24.14 shows the wavelets and frequency responses of the 13,19-tap filters, obtained by substituting Equation 24.65 into Equation 24.64 with $P = -3/32$. Note the smoother wavelets and scaling function and the much lower sidelobes in the frequency responses from these higher order filters.

Figure 24.15 demonstrates that the near-balanced properties of Equation 24.64 are preserved in the higher order filters.

There are many other types of wavelets with varying features and complexities, but we have found the examples given to be near optimum for applications such as image compression.

24.7 IIR Filter Banks

In general, for a given frequency response specification (e.g., transition bandwidth, stopband ripple magnitude), an IIR filter can achieve that specification with a lower computational complexity (e.g., number of

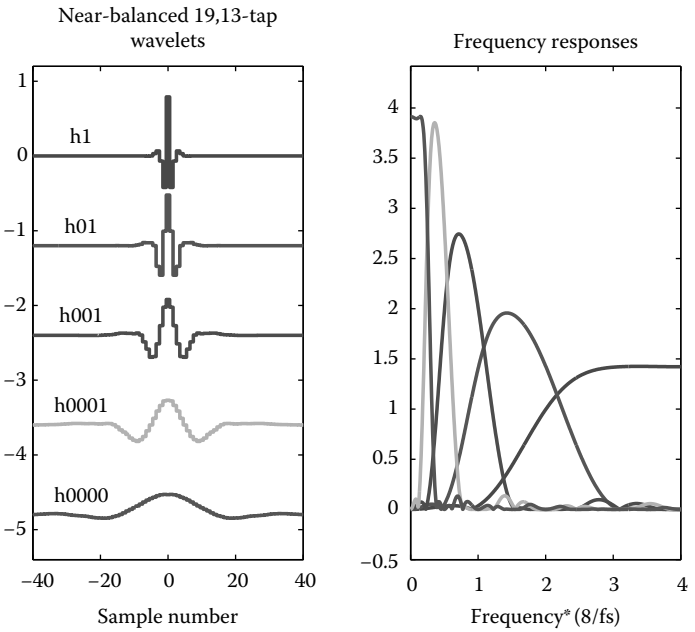

FIGURE 24.15 Impulse responses and frequency responses of the 4-level tree of near-balanced 19,13-tap filters.

multiplies per output sample) compared to an FIR filter. This is the potential advantage of IIR filter banks but the disadvantage is that their design and their implementation are usually more complicated. The main issue that needs to be considered when using IIR filters is stability. The well-known criterion for stability is that the poles of the IIR transfer function must lie inside the unit circle. This criterion, however, assumes that the IIR filter is implemented using a difference equation in the forward time direction, i.e., causal filtering. In some situations, in which the data is fully stored in memory and may therefore be processed backward as well as forward, anticausal filtering is feasible too. With anticausal filtering the poles need to be outside the unit circle for stability. There are therefore two types of IIR filter banks:

1. Causal stable IIR filter banks: used in situations where only causal filtering is allowed. Examples are real-time applications such as speech processing and echo-cancellation. All filters must then have poles inside the unit circle.
2. Noncausal IIR filter banks: used in situations which can allow off-line processing or when the signal is finite in duration (e.g., still images). Suppose an IIR filter $F(z)$ has poles both inside and outside the unit circle. The filter may be factored into a product of its minimum and maximum-phase components:

$$F(z) = F_{\min}(z)F_{\max}(z) \tag{24.67}$$

where the poles of $F_{\min}(z)$ are inside the unit circle, and those of $F_{\max}(z)$ are outside it. The filtering consists of two stages, in which causal filtering is first performed forward to implement $F_{\min}(z)$ and anticausal filtering is then performed backward to implement $F_{\max}(z)$.

Just as in FIR filter banks, the scaling functions and wavelets corresponding to IIR filter banks can be defined through the two-scale equation and infinite product formula. The main difference in the IIR case is that the corresponding continuous functions have support width that is infinite, i.e., the function

duration is infinite. For the causal stable case the function extends to positive infinity and for the noncausal case the function extends to infinity in both directions.

A versatile building block for IIR filters is the all-pass filter $a(z)$ which has the following two properties:

$$\frac{1}{a(z)} = a(z^{-1}) \quad \text{and} \quad |a(e^{j\omega})| = 1 \tag{24.68}$$

The all-pass filter $a(z)$ can be considered a generalization of the unit delay z^{-1} since $|e^{-j\omega}| = |a(e^{j\omega})| = 1$, i.e., both have the same magnitude response. The unit delay has a linear phase response but the all-pass filter can have a variety of phase responses. A wide family of IIR filters can be obtained by various interconnections of all-pass filters [7–9]. The simplest interconnection (described below) can give a large class of useful IIR filter banks.

24.7.1 All-Pass Filter Design Methods

Consider analysis filters obtained by the weighted sum and difference of two all-pass filters, a_0 and a_1:

$$\begin{aligned} H_0(z) &= \frac{1}{\sqrt{2}}[a_0(z) + a_1(z)] \\ H_1(z) &= \frac{1}{\sqrt{2}}[a_0(z) - a_1(z)] \end{aligned} \tag{24.69}$$

This can be considered an extension of the FIR Haar filter pair in Equation 24.2 to IIR filters. The terms 1 and z^{-1} (simple all-pass) have been replaced with a_0 and a_1, general all-pass filters. The Haar filters are quadrature mirror versions of each other. If the two all-pass filters are chosen to be of the form $a_0(z) = A_0(z^2), a_1(z) = z^{-1}A_1(z^2)$, then the analysis filters, given by

$$\begin{aligned} H_0(z) &= \frac{1}{\sqrt{2}}\left[A_0(z^2) + z^{-1}A_1(z^2)\right] \\ H_1(z) &= \frac{1}{\sqrt{2}}\left[A_0(z^2) - z^{-1}A_1(z^2)\right] \end{aligned} \tag{24.70}$$

will have the quadrature mirror characteristics:

$$|H_1(e^{j\omega})| = |H_0(e^{j(\pi-\omega)})|, \quad \text{i.e., be mirrored about } \omega = \frac{\pi}{2} \tag{24.71}$$

This means that if $H_0(e^{j\omega})$ has a low-pass frequency response, $H_1(e^{j\omega})$ will automatically have a high-pass response.

How should the all-pass filters be designed so that $H_0(e^{j\omega})$ is a good low-pass filter with half of the full bandwidth?

By denoting the phase response of the all-pass filters as $\phi_0(\omega) = \angle A_0(e^{j\omega})$ and $\phi_1(\omega) = \angle A_1(e^{j\omega})$, the magnitude response of the low-pass filter can be written as

$$\begin{aligned} |H_0(e^{j\omega})| &= \frac{1}{\sqrt{2}}\left|e^{j\phi_0(2\omega)} + e^{j(\phi_1(2\omega)-\omega)}\right| \\ &= \frac{1}{\sqrt{2}}\left|e^{j\phi_0(2\omega)}\right|\left|1 + e^{j(\phi_1(2\omega)-\phi_0(2\omega)-\omega)}\right| \\ &= \frac{1}{\sqrt{2}}\left|1 + e^{j(\theta(2\omega)-\omega)}\right| \quad \text{where} \quad \theta(\omega) \equiv \phi_1(\omega) - \phi_0(\omega) \end{aligned} \tag{24.72}$$

The term $e^{j(\theta(2\omega)-\omega)}$ can be considered a frequency dependent phasor that is added to the constant phasor 1. If the two phasors add constructively (i.e., if $e^{j(\theta(2\omega)-\omega)} \approx 1$), then $|H_0(e^{j\omega})| \approx \sqrt{2}$; and if the two phasors add destructively (i.e., if $e^{j(\theta(2\omega)-\omega)} \approx -1$), then $|H_0(e^{j\omega})| \approx 0$. Therefore the ideal criterion for the phase is

$$\theta(2\omega) - \omega = \begin{cases} 0, & 0 < \omega < \pi/2 \\ \pm\pi, & \pi/2 < \omega < \pi \end{cases} \tag{24.73}$$

What about the synthesis filters?

For the Haar filters, the synthesis filters were obtained from the analysis filters by replacing z^{-1} with z as shown in Equation 24.6, i.e., a reciprocal term is used. The situation now with all-pass filters (instead of delays) is, however, more complicated and there are two cases to consider:

1. No reciprocals are used and the synthesis filters are chosen as

$$\begin{aligned} G_0(z) &= \frac{1}{\sqrt{2}}\left[A_0(z^2) + z^{-1}A_1(z^2)\right] \\ G_1(z) &= -\frac{1}{\sqrt{2}}\left[A_0(z^2) - z^{-1}A_1(z^2)\right] \end{aligned} \tag{24.74}$$

   and are essentially the same as the analysis filters (apart from a sign change for G_1). Aliasing cancellation is achieved (because $G_0(z)H_0(-z) + G_1(z)H_1(-z) = 0$), but not PR. The transfer function between the input and output of the entire filter bank, i.e., the reconstruction function, is given from Equation 24.11 by

$$T(z) \equiv \frac{\hat{X}(z)}{X(z)} = \frac{1}{2}[G_0(z)H_0(z) + G_1(z)H_1(z)] = z^{-1}A_0(z^2)A_1(z^2) \tag{24.75}$$

   which is an all-pass function. If phase-distortion can be tolerated, e.g., for speech, then this may be acceptable as it stands. Alternatively some postfiltering to equalize the phase of $T(z)$ may be needed.

   If the poles of $A_0(z)$ and $A_1(z)$ are inside the unit circle then the whole filter bank is causal stable.

2. If the synthesis filters are instead chosen as

$$\begin{aligned} G_0(z) &= \frac{1}{\sqrt{2}}\left[\frac{1}{A_0(z^2)} + z\frac{1}{A_1(z^2)}\right] = \frac{1}{\sqrt{2}}\left[A_0(z^{-2}) + zA_1(z^{-2})\right] \\ G_1(z) &= \frac{1}{\sqrt{2}}\left[\frac{1}{A_0(z^2)} - z\frac{1}{A_1(z^2)}\right] = \frac{1}{\sqrt{2}}\left[A_0(z^{-2}) - zA_1(z^{-2})\right] \end{aligned} \tag{24.76}$$

   then PR is achieved, i.e., $T(z) = 1$. However, the filter bank then becomes noncausal as the inversion of the all-pass filters causes poles that were originally inside the unit circle now to be outside the unit circle.

24.7.2 Transformation-Based Design Methods

The frequency transformation technique, described in Section 24.6 for FIR filter banks, can also be used to construct IIR filter banks [10].

Recall that in the transformation technique, given the prototype linear phase low-pass filters, $H_t(Z)$ and $F_t(Z)$, the following transformation is applied:

$$Z = M(z) \tag{24.77}$$

where $M(z) = pz^3 + (\frac{1}{2} - p)(z + z^{-1}) + pz^{-3}$ (from Equation 24.65) and $p = 0$ or $-\frac{3}{32}$ depending on the desired complexity/smoothness required. It is necessary that the transformation is of the form $M(z) \equiv zT(z^2)$ (i.e., it must have terms in only odd powers of z).

Hence the transformation function $M(z)$ for the FIR case is an FIR filter that is related to a halfband filter,* $H_{\text{HB}}(z) \equiv \frac{1}{2}[1 + M(z)]$. IIR filter banks can be obtained by using an IIR transformation function instead of an FIR function and this is equivalent to using an IIR halfband filter. The transformation function should ideally approximate $+1$ in the passband and -1 in the stopband, i.e.,

$$M(e^{j\omega}) = e^{j\omega}T(e^{j2\omega}) \approx \begin{cases} +1, & 0 < \omega < \pi/2 \\ -1, & \pi/2 < \omega < \pi \end{cases} \tag{24.78}$$

Therefore a straightforward choice is for $M(z)$ to be an all-pass filter approximating the following ideal phase condition:

$$\phi_{\text{ideal}}(\omega) = \begin{cases} 0, & 0 < \omega < \pi/2 \\ \pm\pi, & \pi/2 < \omega < \pi \end{cases} \tag{24.79}$$

If the poles of $M(z)$ are inside the unit circle then the IIR filter bank is causal stable. Furthermore, PR is achieved.

A simple example for $M(z)$ is given by

$$M(z) = z\frac{k_1 + z^{-2}}{1 + k_1 z^{-2}}\frac{k_2 + z^{-2}}{1 + k_2 z^{-2}} \tag{24.80}$$

with $k_1 = -0.0991$ and $k_2 = 0.5426$ and the phase response is shown in Figure 24.16.

In Equation 24.49, we saw that a simple $H_t(Z)$ and $F_t(Z)$ are given by

$$\begin{aligned} H_t(Z) &= (1 + Z) \\ F_t(Z) &= \frac{1}{2}(1 + Z)(2 - Z) \end{aligned} \tag{24.81}$$

Using an all-pass filter for $Z = M(z)$ in Equation 24.81 will however result in a 4 dB overshoot (bump) in the frequency response of the filter $F_0(z) = F_t(M(z))$. With a more general filter for $M(z)$ (non all-pass) the overshoot can be reduced but the design becomes more complicated.

Alternatively, a different set of prototype filters may lead to a lower overshoot. The following set of prototype filters from the product filter in Equation 24.64:

$$\begin{aligned} H_t(Z) &= \frac{1}{7}(1 + Z)(7 - 2Z) \\ F_t(Z) &= \frac{1}{50}(1 + Z)(50 - 9Z - 6Z^2) \end{aligned} \tag{24.82}$$

* Halfband filters are defined as filters that satisfy $H_{\text{HB}}(z) + H_{\text{HB}}(-z) = 1$. The even index coefficients are zero except for the center (zero index) coefficient, which is one half.

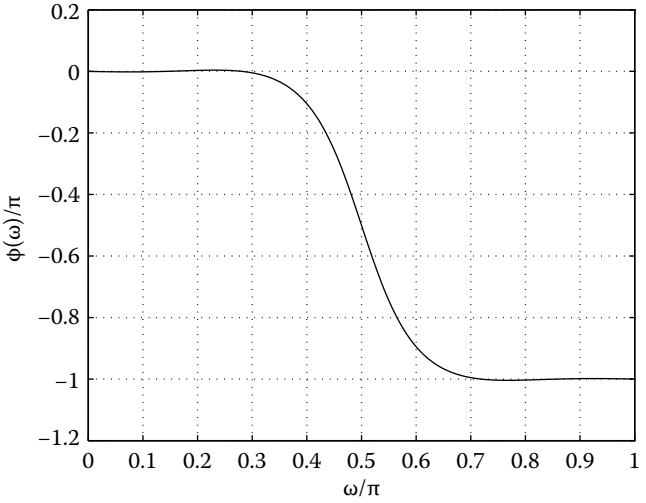

FIGURE 24.16 Phase response of IIR all-pass transformation in Equation 24.80.

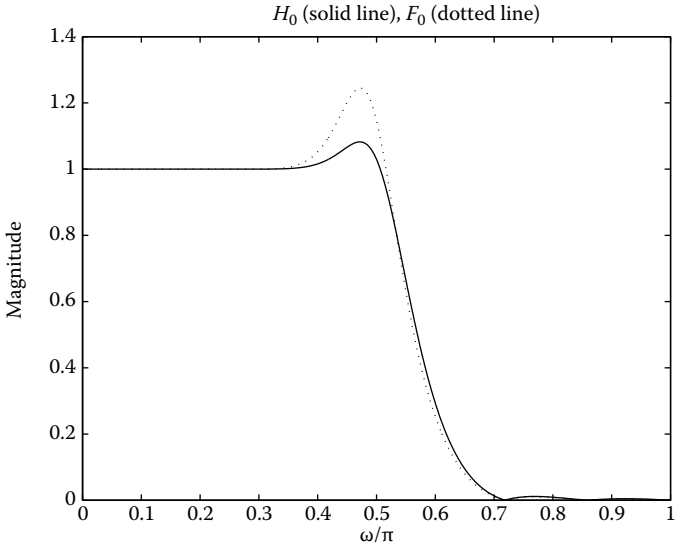

FIGURE 24.17 Magnitude responses of causal stable IIR filter bank given by Equation 24.82 with the transformation of Equation 24.80.

with an all-pass $M(z)$ will lead to IIR filters with overshoots of 0.68 dB and 1.90 dB, respectively. Using these prototypes with the transformation in Equation 24.80 gives low-pass filters with magnitude responses shown in Figure 24.17.

24.8 Polyphase Representations and the Lifting Scheme

The polyphase representation is an important tool in multirate systems, from both theoretical and application perspectives. Multirate systems are (periodically) linear time-varying systems due to the

presence of downsamplers and upsamplers. The polyphase decomposition allows a multirate system to be represented as a sum of linear time-invariant systems, thus simplifying its analysis and design [9,11,12]. The form of the representation depends on the downsampling/upsampling factor M, but the discussion here will focus on the simplest case of $M = 2$ which is relevant for 2-band filter-banks. Unless otherwise stated, all filters are assumed to be FIR in this section.

24.8.1 Basic Polyphase Concepts

The basic idea of an $M = 2$ polyphase representation is to separate the coefficients of a filter or a sequence into even-indexed and odd-indexed coefficients:

$$H(z) = \sum_n h(2n)z^{-2n} + \sum_n h(2n+1)z^{-2n-1} \tag{24.83}$$

By defining the polyphase components as

$$E_0(z) \equiv \sum_n h(2n)z^{-n} \quad \text{and} \quad E_1(z) \equiv \sum_n h(2n+1)z^{-n} \tag{24.84}$$

the filter function $H(z)$ can be written as

$$H(z) = E_0(z^2) + z^{-1}E_1(z^2) \tag{24.85}$$

The separation of $H(z)$ into $E_0(z)$ and $E_1(z)$ is known as the polyphase decomposition of the filter. The decomposition in Equation 24.85 is known as a type 1 decomposition. An alternative is the type 2 decomposition defined as

$$H(z) = z^{-1}R_0(z^2) + R_1(z^2) = z^{-1}\left[R_0(z^2) + zR_1(z^2)\right] \tag{24.86}$$

The polyphase components of both types are related as follows:

$$R_0(z) = E_1(z) \quad R_1(z) = E_0(z)$$

i.e., type 2 is a permutation of type 1.

By applying the type 1 polyphase decomposition to the 2-band analysis filter bank of Figure 24.1a, the following is obtained:

$$\begin{bmatrix} H_0(z) \\ H_1(z) \end{bmatrix} = \begin{bmatrix} E_{0,0}(z^2) & E_{0,1}(z^2) \\ E_{1,0}(z^2) & E_{1,1}(z^2) \end{bmatrix} \begin{bmatrix} 1 \\ z^{-1} \end{bmatrix} \tag{24.87}$$

The matrix

$$\mathbf{E}(z) \equiv \begin{bmatrix} E_{0,0}(z) & E_{0,1}(z) \\ E_{1,0}(z) & E_{1,1}(z) \end{bmatrix}$$

is known as the analysis polyphase matrix of the filter bank. The first row contains the polyphase components of the low-pass analysis filter H_0, and the second row those of the high-pass filter H_1.

For the synthesis filters, the type 2 polyphase decomposition is applied:

$$[G_0(z)\ G_1(z)] = [z^{-1}\ 1]\begin{bmatrix} R_{0,0}(z^2) & R_{1,0}(z^2) \\ R_{0,1}(z^2) & R_{1,1}(z^2) \end{bmatrix} \tag{24.88}$$

and the synthesis polyphase matrix is defined as

$$\mathbf{R}(z) \equiv \begin{bmatrix} R_{0,0}(z) & R_{1,0}(z) \\ R_{0,1}(z) & R_{1,1}(z) \end{bmatrix}$$

The first column contains the polyphase components of the low-pass synthesis filter G_0, and the second column those of the high-pass filter G_1.

Now suppose the input signal is decomposed as

$$X(z) = X_0(z^2) + zX_1(z^2)$$

which is similar to the type 2 polyphase decomposition except for absence of the delay z^{-1} (compare with Equation 24.86). The output of the analysis filter bank can then be written compactly as

$$\begin{bmatrix} Y_0(z) \\ Y_1(z) \end{bmatrix} = \begin{bmatrix} E_{0,0}(z) & E_{0,1}(z) \\ E_{1,0}(z) & E_{1,1}(z) \end{bmatrix}\begin{bmatrix} X_0(z) \\ X_1(z) \end{bmatrix} = \mathbf{E}(z)\begin{bmatrix} X_0(z) \\ X_1(z) \end{bmatrix} \tag{24.89}$$

By using a type 2 polyphase decomposition of the output signal

$$\hat{X}(z) = z^{-1}\hat{X}_0(z^2) + \hat{X}_1(z^2)$$

the output of the synthesis filter bank can be written compactly as

$$\begin{bmatrix} \hat{X}_0(z) \\ \hat{X}_1(z) \end{bmatrix} = \begin{bmatrix} R_{0,0}(z) & R_{1,0}(z) \\ R_{0,1}(z) & R_{1,1}(z) \end{bmatrix}\begin{bmatrix} Y_0(z) \\ Y_1(z) \end{bmatrix} = \mathbf{R}(z)\begin{bmatrix} Y_0(z) \\ Y_1(z) \end{bmatrix} \tag{24.90}$$

Equations 24.89 and 24.90 are the equivalent time-invariant representation of the multirate filter bank. Figure 24.18 shows the equivalent representation of the filter bank in polyphase form. The combination of the delay chain and downsampler on the analysis side provides a polyphase decomposition of the input signal. The combination of the upsamplers, delay chain, and adder on the synthesis side provides a reconstruction of the output signal from the polyphase components. The polyphase filter bank is operating at the lower sampling rate of the system and is thus more efficient than the original filter bank.

Combining Equations 24.89 and 24.90 gives the polyphase form of the input/output relationship of the entire filter bank:

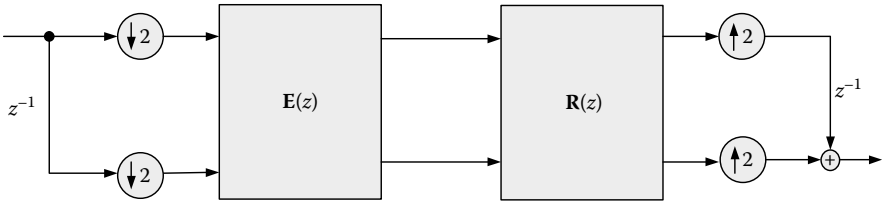

FIGURE 24.18 Polyphase form of filter bank.

$$\begin{bmatrix} \hat{X}_0(z) \\ \hat{X}_1(z) \end{bmatrix} = \mathbf{R}(z)\mathbf{E}(z) \begin{bmatrix} X_0(z) \\ X_1(z) \end{bmatrix}$$

The total system polyphase matrix is defined as

$$\mathbf{P}(z) \equiv \mathbf{R}(z)\mathbf{E}(z)$$

and if

$$\mathbf{P}(z) = \mathbf{R}(z)\mathbf{E}(z) = \mathbf{I} \tag{24.91}$$

then

$$\begin{bmatrix} \hat{X}_0(z) \\ \hat{X}_1(z) \end{bmatrix} = \begin{bmatrix} X_0(z) \\ X_1(z) \end{bmatrix}$$

Therefore

$$\hat{X}(z) = z^{-1}X_0(z^2) + X_1(z^2) = z^{-1}\left[X_0(z^2) + zX_1(z^2)\right] = z^{-1}X(z)$$

and PR (with one sample delay) is achieved. This is a convenient alternative formulation for PR to that given in Equations 24.40 and 24.41.

Equation 24.91 provides a concise condition for PR and the result is useful in the theoretical study and formulation of design techniques for filter banks. Conceptually, if synthesis filter bank is chosen such that

$$\mathbf{R}(z) = \mathbf{E}^{-1}(z) = \frac{\text{adj}(\mathbf{E}(z))}{\det(\mathbf{E}(z))} \tag{24.92}$$

where adj(·) and det(·) denote the adjoint and determinant of the matrix, respectively, then PR is assured. However, in general, this would lead to IIR synthesis filters which may be unstable (poles outside the unit circle) due to the presence of det (**E**(*z*)) in the denominator. Therefore to ensure that all filters are FIR in the filter bank, it is required that

$$\det(\mathbf{E}(z)) = cz^K \tag{24.93}$$

where c is a nonzero constant and K an integer.

An important property of determinants is that

$$\text{if } \mathbf{A} = \mathbf{A}_1\mathbf{A}_2 \quad \text{then } \det(\mathbf{A}) = \det(\mathbf{A}_1)\det(\mathbf{A}_2)$$

Therefore, a straightforward way to build polyphase matrices satisfying Equation 24.93 is through a cascade (product) of simpler matrices that satisfy Equation 24.93, i.e.,

$$\mathbf{E}(z) = \mathbf{E}_1(z)\mathbf{E}_2(z)\cdots\mathbf{E}_L(z) \tag{24.94}$$

where

$$\det(\mathbf{E}_i(z)) = c_i z^{K_i} \quad i = 1, \ldots, L$$

The cascade of polyphase matrices is the essence of virtually all design techniques of filter banks that are polyphase based.

24.8.2 Orthogonal Lattice Structures

This type of structure is also known as the lossless or paraunitary structure [13,14]. The polyphase matrix is given by

$$\mathbf{E}(z) = \mathbf{R}_L \mathbf{D}(z) \mathbf{R}_{L-1} \cdots \mathbf{D}(z) \mathbf{R}_0 = \mathbf{R}_L \prod_{i=0}^{L-1} [\mathbf{D}(z) \mathbf{R}_i] \tag{24.95}$$

where

$$\mathbf{D}(z) \equiv \begin{bmatrix} 1 & 0 \\ 0 & z^{-1} \end{bmatrix} \quad \text{and} \quad \mathbf{R}_i \equiv \begin{bmatrix} \cos\theta_i & \sin\theta_i \\ -\sin\theta_i & \cos\theta_i \end{bmatrix}$$

and $\theta_0 \ldots \theta_{L-1}$ are the L free parameters that define the filters. In the design process, these parameters are optimized with respect to some criterion, e.g., minimizing the stopband energy of the low-pass filter, which is given by

$$J = \int_{\omega_s}^{\pi} |H_0(e^{j\omega})|^2 \mathrm{d}\omega$$

where ω_s is the stopband edge. The matrices $\mathbf{R}_i$ are also known as rotation matrices and are orthogonal, i.e., $\mathbf{R}_i \mathbf{R}_i^{\mathrm{T}} = \mathbf{R}_i^{\mathrm{T}} \mathbf{R}_i = \mathbf{I}$ (where T denotes transpose).

Since $\mathbf{D}(z)\mathbf{D}^{\mathrm{T}}(z^{-1}) = \mathbf{D}^{\mathrm{T}}(z^{-1})\mathbf{D}(z) = \mathbf{I}$, the polyphase matrix satisfies

$$\mathbf{E}(z)\mathbf{E}^{\mathrm{T}}(z^{-1}) = \mathbf{E}^{\mathrm{T}}(z^{-1})\mathbf{E}(z) = \mathbf{I}$$

Therefore the synthesis polyphase matrix can be obtained as

$$\mathbf{R}(z) = \mathbf{E}^{\mathrm{T}}(z^{-1}) = \mathbf{R}_0^{\mathrm{T}} \mathbf{D}(z^{-1}) \cdots \mathbf{R}_{L-1}^{\mathrm{T}} \cdots \mathbf{D}(z^{-1}) \mathbf{R}_L^{\mathrm{T}}$$

The structure for such filter banks is shown in Figure 24.19

24.8.3 Linear Phase Structures

There are two types of structure that lead to linear phase filters [15,16]:

1. Type A: where all filters in the bank have even length. The low-pass analysis filter coefficients are symmetric, while the synthesis coefficients are antisymmetric.
   The polyphase matrix is given by

$$\mathbf{E}(z) = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \mathbf{D}(z) \mathbf{S}_{L-1} \cdots \mathbf{D}(z) \mathbf{S}_0 = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \prod_{i=0}^{L-1} [\mathbf{D}(z) \mathbf{S}_i] \tag{24.96}$$

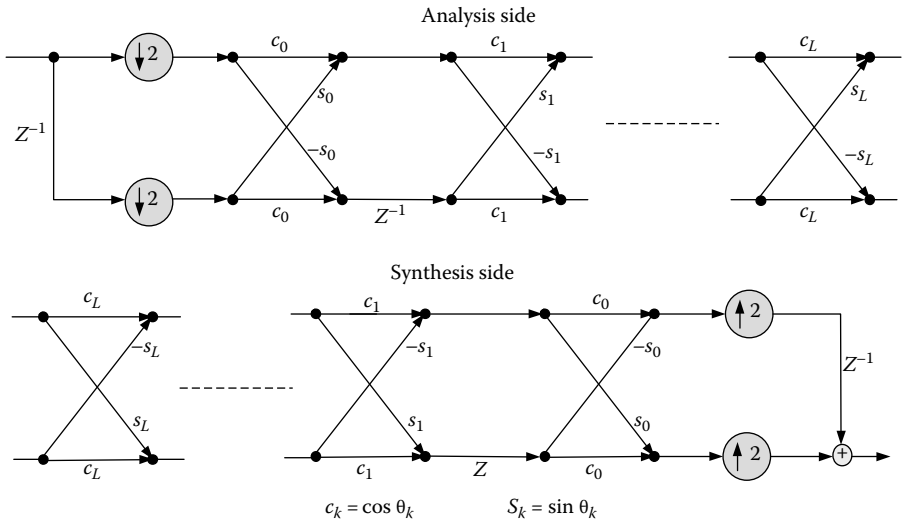

FIGURE 24.19 Orthogonal lattice structure.

where

$$\mathbf{D}(z) \equiv \begin{bmatrix} 1 & 0 \\ 0 & z^{-1} \end{bmatrix} \quad \text{and} \quad \mathbf{S}_i \equiv \begin{bmatrix} 1 & \alpha_i \\ \alpha_i & 1 \end{bmatrix}$$

and $\alpha_i \neq 0$ are the free parameters that define the filters. The structure here is similar to the orthogonal lattice structure except for a sign change in one of the element of $\mathbf{S}_i$.

2. Type B: where all filters in the bank have odd length. All filter coefficients are then symmetric. The polyphase matrix is given by

$$\mathbf{E}(z) = \prod_{i=1}^{L} \mathbf{B}_i(z) \tag{24.97}$$

where

$$\mathbf{B}_i(z) = \begin{bmatrix} 1 + z^{-1} & \alpha_i \\ 1 + \beta_i z^{-1} + z^{-2} & \alpha_i(1 + z^{-1}) \end{bmatrix}$$

and $\alpha_i \neq 0, \beta_i \neq 2$ are the free parameters that define the filters.

This structure can be used to implement all of the linear-phase odd-length wavelet filter banks discussed in Sections 24.6.3, 24.6.5, and 24.6.6, such as the (5,3), (7,5), (9,7), and (19,13)-tap filters and their inverses.

24.8.4 Lifting Scheme

The basic idea behind lifting [17–19] is simple:

Whatever change was performed to the signal by some process of addition can be undone by the equivalent process of subtraction.

This idea ties in nicely with the concept of PR where the synthesis filter bank is supposed to undo whatever processing was done by the analysis filter bank. There are two attractive features of lifting: (1) the construction of filter banks, because PR can be guaranteed at every step of the design stage and (2) the implementation of filter banks, because computational efficiency gains of up to 2:1 are possible when compared with separate filters for each band of the filter bank. The former aspect will be considered first.

24.8.4.1 Construction of Filter Banks

The basic building block in lifting is called the lifting step and is related to concept of elementary matrices which is fundamental in matrix analysis. Elementary matrices can be used to perform elementary operations on an arbitrary matrix by either the pre- or post-multiplication of the former with the latter. In the context of filter banks, the arbitrary matrix is the analysis or synthesis polyphase matrix (which is a matrix of Laurent series*). There are three types of elementary matrices (operations) but the type that is relevant in lifting is the one that performs the addition to the elements of a certain row (or column) of a multiple (factor) of the elements of another row (or column). For the analysis polyphase matrix there two types of lifting step:

1. Primal lifting: with elementary matrix given by

$$\begin{bmatrix} 1 & p(z) \\ 0 & 1 \end{bmatrix}$$

   where $p(z)$ is an arbitrary FIR factor. Premultipication by this matrix will change the first row of an arbitrary matrix.
2. Dual lifting: with elementary matrix given by

$$\begin{bmatrix} 1 & 0 \\ d(z) & 1 \end{bmatrix}$$

   where $d(z)$ is an arbitrary FIR factor. Premultipication by this matrix will change the second row of an arbitrary matrix.

Note that both of these lifting matrices have determinants of unity.

Now suppose that there is an existing set of analysis filters with corresponding polyphase matrix $\mathbf{E}^0(z)$; i.e.,

$$\begin{bmatrix} H_0^0(z) \\ H_1^0(z) \end{bmatrix} = \mathbf{E}^0(z^2)\begin{bmatrix} 1 \\ z^{-1} \end{bmatrix} = \begin{bmatrix} E_{0,0}^0(z^2) & E_{0,1}^0(z^2) \\ E_{1,0}^0(z^2) & E_{1,1}^0(z^2) \end{bmatrix}\begin{bmatrix} 1 \\ z^{-1} \end{bmatrix} \tag{24.98}$$

1. If the primal lifting is applied to $\mathbf{E}^0(z)$

$$\mathbf{E}^{\mathrm{p}}(z) \equiv \begin{bmatrix} 1 & p(z) \\ 0 & 1 \end{bmatrix}\mathbf{E}^0(z) \tag{24.99}$$

   then the new set of analysis filters becomes

$$H_0^p(z) = H_0^0(z) + H_1^0(z)p(z^2) \quad \text{and} \quad H_1^p(z) = H_1^0(z)$$

   i.e., the low-pass filter is changed but the high-pass is unchanged.

* Like polynomials but with both positive and negative powers of z.

2. If the dual lifting is applied to $\mathbf{E}^0(z)$

$$\mathbf{E}^{\mathrm{d}}(z) \equiv \begin{bmatrix} 1 & 0 \\ d(z) & 1 \end{bmatrix} \mathbf{E}^0(z) \tag{24.100}$$

then the new set of analysis filters becomes

$$H_0^{\mathrm{d}}(z) = H_0^0(z) \quad \text{and} \quad H_1^{\mathrm{d}}(z) = H_1^0(z) + H_0^0(z)d(z^2)$$

i.e., the high-pass filter is changed but the low-pass is unchanged.

Since the determinant of the lifting matrix is equal to one, the new polyphase matrix, $\mathbf{E}^p(z)$ or $\mathbf{E}^{\mathrm{d}}(z)$, will satisfy the PR condition (Equation 24.93) if the original matrix $\mathbf{E}^0(z)$ also satisfies the condition.

Starting with the trivial polyphase matrix $\mathbf{E}^0(z) = \mathbf{I}$ (identity), alternate primal and dual lifting can be used to construct a whole range of PR filter banks:

$$\begin{aligned} \mathbf{E}(z) &= \begin{bmatrix} K_0 & 0 \\ 0 & K_1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ d_M(z) & 1 \end{bmatrix} \begin{bmatrix} 1 & p_M(z) \\ 0 & 1 \end{bmatrix} \cdots \begin{bmatrix} 1 & 0 \\ d_1(z) & 1 \end{bmatrix} \begin{bmatrix} 1 & p_1(z) \\ 0 & 1 \end{bmatrix} \\ &= \begin{bmatrix} K_0 & 0 \\ 0 & K_1 \end{bmatrix} \prod_{i=M}^{1} \begin{bmatrix} 1 & 0 \\ d_i(z) & 1 \end{bmatrix} \begin{bmatrix} 1 & p_i(z) \\ 0 & 1 \end{bmatrix} \end{aligned} \tag{24.101}$$

The factors K_0 and K_1 are for normalizing the gains of the low-pass and high-pass filters, respectively.

Now consider the synthesis filter banks. First note that the inverse of the lifting step matrix can be easily obtained by negating the sign of the arbitrary factors, $p(z)$ or $d(z)$, since

$$\begin{bmatrix} 1 & p(z) \\ 0 & 1 \end{bmatrix}^{-1} = \begin{bmatrix} 1 & -p(z) \\ 0 & 1 \end{bmatrix}$$

and

$$\begin{bmatrix} 1 & 0 \\ d(z) & 1 \end{bmatrix}^{-1} = \begin{bmatrix} 1 & 0 \\ -d(z) & 1 \end{bmatrix}$$

Suppose the initial synthesis polyphase matrix of the analysis and synthesis banks, $\mathbf{E}^0(z)$ and $\mathbf{R}^0(z)$, satisfy the PR condition:

$$\mathbf{E}^0(z)\mathbf{R}^0(z) = \mathbf{I}$$

If the equation above is pre- and post-multiplied, respectively, by the primal and inverse primal lifting matrix, then

$$\begin{aligned} \left(\begin{bmatrix} 1 & p(z) \\ 0 & 1 \end{bmatrix} \mathbf{E}^0(z) \right) \left(\mathbf{R}^0(z) \begin{bmatrix} 1 & -p(z) \\ 0 & 1 \end{bmatrix} \right) &= \begin{bmatrix} 1 & p(z) \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & -p(z) \\ 0 & 1 \end{bmatrix} = \mathbf{I} \\ \Rightarrow \mathbf{E}^p(z)\mathbf{R}^p(z) &= \mathbf{I} \end{aligned} \tag{24.102}$$

where $\mathbf{E}^p(z)$ is the new analysis polyphase matrix by primal lifting as in Equation 24.99 and $\mathbf{R}^p(z)$ is the new synthesis polyphase matrix by inverse primal lifting:

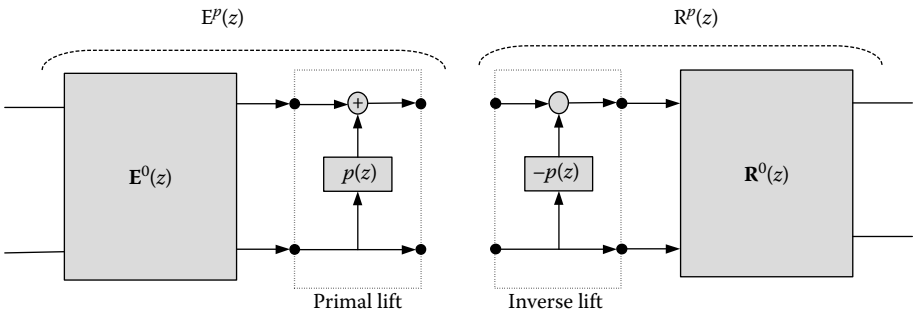

FIGURE 24.20 Primal lifting.

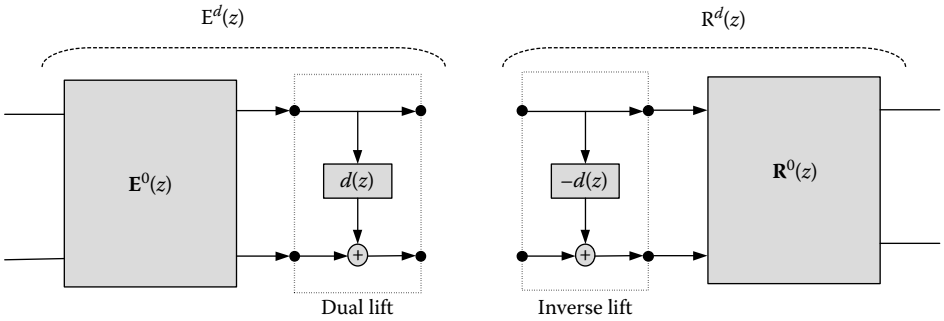

FIGURE 24.21 Dual lifting.

$$\mathbf{R}^p(z) \equiv \mathbf{R}^0(z)\begin{bmatrix} 1 & -p(z) \\ 0 & 1 \end{bmatrix} \tag{24.103}$$

With the combination of the primal/inverse-primal lifting, PR is preserved and this can also been easily seen in the structure in Figure 24.20: whatever was added in the analysis side has been exactly subtracted in the synthesis side.

Wherever the dual lifting is applied in the analysis side, as in Equation 24.100, then the inverse dual lifting should be applied in synthesis side:

$$\mathbf{R}^d(z) \equiv \mathbf{R}^0(z)\begin{bmatrix} 1 & 0 \\ -d(z) & 1 \end{bmatrix} \tag{24.104}$$

with the corresponding structure shown in Figure 24.21. Therefore, if the analysis polyphase matrix is as shown in Equation 24.101, the corresponding synthesis polyphase matrix is given by

$$\begin{aligned} \mathbf{R}(z) &= \begin{bmatrix} 1 & -p_1(z) \\ 0 & 1 \end{bmatrix}\begin{bmatrix} 1 & 0 \\ -d_1(z) & 1 \end{bmatrix} \cdots \begin{bmatrix} 1 & -p_M(z) \\ 0 & 1 \end{bmatrix}\begin{bmatrix} 1 & 0 \\ -d_M(z) & 1 \end{bmatrix}\begin{bmatrix} 1/K_0 & 0 \\ 0 & 1/K_1 \end{bmatrix} \\ &= \prod_{i=1}^{M}\begin{bmatrix} 1 & -p_i(z) \\ 0 & 1 \end{bmatrix}\begin{bmatrix} 1 & 0 \\ -d_i(z) & 1 \end{bmatrix} \cdot \begin{bmatrix} 1/K_0 & 0 \\ 0 & 1/K_1 \end{bmatrix} \end{aligned} \tag{24.105}$$

24.8.4.2 Implementation of Filter Banks

The lifting scheme is also useful for the efficient implementation of filter banks. The analysis or synthesis polyphase matrix of a PR filter bank can be factorized into a product of lifting matrices. The factorization can be achieved through the use of the Euclidean algorithm for Laurent series which is described next.

Given two Laurent series:

$$a(z) = \sum_{n=-L_a}^{M_a} a(n)z^{-n} \quad \text{and} \quad b(z) = \sum_{n=-L_b}^{M_b} b(n)z^{-n}$$

with degrees $|a(z)|$ and $|b(z)|$ defined as

$$|a(z)| = M_a + L_a \quad \text{and} \quad |b(z)| = M_b + L_b$$

The degree of a Laurent series in z is the length of the equivalent FIR filter minus one.

Without loss of generality, we assume $|a(z)| \geq |b(z)|$. Dividing $a(z)$ by $b(z)$ will yield a quotient $q(z)$ and remainder $r(z)$, such that

$$a(z) = b(z)q(z) + r(z) \quad \text{where } |q(z)| = |a(z)| - |b(z)| \text{ and } |r(z)| < |b(z)| \tag{24.106}$$

In Matlab, this operation may be performed using the function $[q, r] = \text{deconv}(a, b)$.

Unlike the case of regular polynomials (with only positive powers of z), the quotient and remainder in Equation 24.106 are not unique and there is some freedom in choosing $q(z)$, depending on how $r(z)$ is aligned within the range of the indices of $a(z)$. This means that in the following algorithm, there are multiple valid factorizations of a given pair of filter polynomials. The Matlab function, deconv(·), chooses to align $r(z)$ with the right-hand end of $a(z)$, assuming row vectors are used for the polynomial coefficients.

The Euclidean algorithm iteratively performs the division process on two Laurent series, $a(z)$ and $b(z)$, as follows:

$$\begin{bmatrix} a_{i+1}(z) & b_{i+1}(z) \end{bmatrix} = \begin{bmatrix} a_i(z) & b_i(z) \end{bmatrix} \begin{bmatrix} 0 & 1 \\ 1 & -q_i(z) \end{bmatrix} \tag{24.107}$$

starting with $a_0(z) = a(z)$ and $b_0(z) = b(z)$. At each iteration, $i + 1$, the higher degree series a_i is divided by the lower degree series b_i and the remainder is recorded as b_{i+1} for the next iteration, while b_i becomes a_{i+1}. The process continues until iteration n when the remainder b_n becomes zero. The whole process can be expressed as

$$\begin{bmatrix} a_n(z) & 0 \end{bmatrix} = \begin{bmatrix} a(z) & b(z) \end{bmatrix} \prod_{i=1}^{n} \begin{bmatrix} 0 & 1 \\ 1 & -q_i(z) \end{bmatrix} \tag{24.108}$$

where $a_n(z)$ is the greatest common factor (gcf) of $a(z)$ and $b(z)$, i.e., $a_n(z) = \text{gcf}(a(z), b(z))$.

Inverting the terms in the product gives

$$\begin{aligned} \begin{bmatrix} a(z) & b(z) \end{bmatrix} &= \begin{bmatrix} a_n(z) & 0 \end{bmatrix} \prod_{i=n}^{1} \begin{bmatrix} q_i(z) & 1 \\ 1 & 0 \end{bmatrix} \\ &= \begin{bmatrix} a_n(z) & 0 \end{bmatrix} \prod_{i=n/2}^{1} \begin{bmatrix} q_{2i}(z) & 1 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} q_{2i-1}(z) & 1 \\ 1 & 0 \end{bmatrix} \end{aligned} \tag{24.109}$$

where n is assumed to be even and the product is grouped into pairs of even and odd terms. If n is odd, it is increased by 1 and we set $q_n(z) = 0$.

Each term in the product can be expressed in two forms that involve a primal or a dual lifting matrix

$$\begin{bmatrix} q_i(z) & 1 \\ 1 & 0 \end{bmatrix} = \begin{bmatrix} 1 & q_i(z) \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ q_i(z) & 1 \end{bmatrix}$$

Using the first form for even terms in Equation 24.109 and the second form for odd terms gives

$$[\, a(z) \quad b(z) \,] = [\, a_n(z) \quad 0 \,] \prod_{i=n/2}^{1} \begin{bmatrix} 1 & q_{2i}(z) \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ q_{2i-1}(z) & 1 \end{bmatrix} \tag{24.110}$$

For the special case when gcf($a(z)$, $b(z)$) is a constant (i.e., there is no common factor), the following factorization in terms of lifting steps exists:

$$[\, a(z) \quad b(z) \,] = [\, K \quad 0 \,] \prod_{i=n/2}^{1} \begin{bmatrix} 1 & q_{2i}(z) \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ q_{2i-1}(z) & 1 \end{bmatrix} \tag{24.111}$$

Now suppose there is an analysis polyphase matrix, given by

$$\mathbf{E}(z) \equiv \begin{bmatrix} E_{0,0}(z) & E_{0,1}(z) \\ E_{1,0}(z) & E_{1,1}(z) \end{bmatrix}$$

and satisfying

$$\det(\mathbf{E}(z)) \equiv E_{0,0}(z)E_{1,1}(z) - E_{0,1}(z)E_{1,0}(z) = 1 \tag{24.112}$$

i.e., Equation 24.93 with $c = 1$ and $K = 0$ (no delay).* Equation 24.112 implies that gcf($E_{0,0}(z)$, $E_{0,1}(z)$) is a constant or else the determinant cannot be constant.

Using the Euclidean algorithm described above with $a(z) = E_{0,0}(z)$ and $b(z) = E_{0,1}(z)$ gives

$$[\, E_{0,0}(z) \quad E_{0,1}(z) \,] = [\, K \quad 0 \,] \prod_{i=n/2}^{1} \begin{bmatrix} 1 & q_{2i}(z) \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ q_{2i-1}(z) & 1 \end{bmatrix}$$

Form the following matrix

$$\mathbf{E}^0(z) = \begin{bmatrix} E_{0,0}(z) & E_{0,1}(z) \\ E^0_{1,0}(z) & E^0_{1,1}(z) \end{bmatrix} = \begin{bmatrix} K & 0 \\ 0 & 1/K \end{bmatrix} \prod_{i=n/2}^{1} \begin{bmatrix} 1 & q_{2i}(z) \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ q_{2i-1}(z) & 1 \end{bmatrix}$$

The matrix $\mathbf{E}^0(z)$ has unit determinant ($\det(\mathbf{E}^0(z)) = 1$), i.e. PR, and the corresponding low-pass filter is the same as that in matrix $\mathbf{E}(z)$ under consideration. As explained earlier, the dual lifting (Equation 24.100) can be used to change the high-pass filter while leaving the low-pass filter unchanged. Therefore

* There is no loss of generality here as any general matrix satisfying Equation 24.93 can be made into a matrix with unit determinant by muliplying the first (second) row with z^{-K}/c. This is equivalent to the introducing a scaling factor of $1/c$ and the delay z^{-2K} in the low-pass (high-pass) filter which does not significantly change its filtering properties.

by applying an appropriate dual lifting step, $\mathbf{E}^0(z)$ can be changed to any valid $\mathbf{E}(z)$ which produces PR, using

$$\begin{aligned}\mathbf{E}(z) &= \begin{bmatrix} 1 & 0 \\ d(z) & 1 \end{bmatrix} \mathbf{E}^0(z) \\ &= \begin{bmatrix} 1 & 0 \\ d(z) & 1 \end{bmatrix} \begin{bmatrix} K & 0 \\ 0 & 1/K \end{bmatrix} \prod_{i=n/2}^{1} \begin{bmatrix} 1 & q_{2i}(z) \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ q_{2i-1}(z) & 1 \end{bmatrix} \\ &= \begin{bmatrix} K & 0 \\ 0 & 1/K \end{bmatrix} \begin{bmatrix} 1 & 0 \\ K^2 d(z) & 1 \end{bmatrix} \prod_{i=n/2}^{1} \begin{bmatrix} 1 & q_{2i}(z) \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ q_{2i-1}(z) & 1 \end{bmatrix}\end{aligned} \tag{24.113}$$

Note that, if necessary, the scaling matrix can also be factorized into a sequence of lifting steps (but this is not usually helpful computationally):

$$\begin{bmatrix} K & 0 \\ 0 & 1/K \end{bmatrix} = \begin{bmatrix} 1 & K - K^2 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ -1/K & 1 \end{bmatrix} \begin{bmatrix} 1 & K-1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix} \tag{24.114}$$

Therefore it can be concluded that every perfect reconstructing polyphase matrix can be factorized into a sequence of lifting steps.

Example 24.1

The analysis polyphase matrix corresponding to the Haar wavelet filters and its factorization is given by

$$\mathbf{E}(z) = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} \\ -\frac{1}{2} & \frac{1}{2} \end{bmatrix} = \begin{bmatrix} \frac{1}{2} & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ -\frac{1}{2} & 1 \end{bmatrix} \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$$

which consist of one primal lift, one dual lift, and one scaling.

Example 24.2

The analysis polyphase matrix corresponding to the LeGall 3/5 filters and its factorization is given by

$$\mathbf{E}(z) = \begin{bmatrix} \frac{1}{2} & \frac{1}{4}(1+z) \\ -\frac{1}{4}(1+z^{-1}) & \frac{3}{4} - \frac{1}{8}(z^{-1}+z) \end{bmatrix} = \begin{bmatrix} \frac{1}{2} & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ -\frac{1}{4}(1+z^{-1}) & 1 \end{bmatrix} \begin{bmatrix} 1 & \frac{1}{2}(1+z) \\ 0 & 1 \end{bmatrix}$$

which consist of one primal lift, one dual lift, and one scaling.

24.9 Nonlinear Filter Banks

In general it is difficult to achieve PR if the linear filters H_0, H_1, G_0, and G_1 are replaced with nonlinear filters. Furthermore, there is no generic framework which can be used to analyze the properties of filter banks with nonlinear filters. The lifting scheme described earlier, which works in the polyphase domain, however provides a convenient way to generalize linear filter banks to nonlinear ones. If the primal (dual) lifting filter $p(z)(d(z))$, which is linear, is replaced with a nonlinear filter, PR will still be

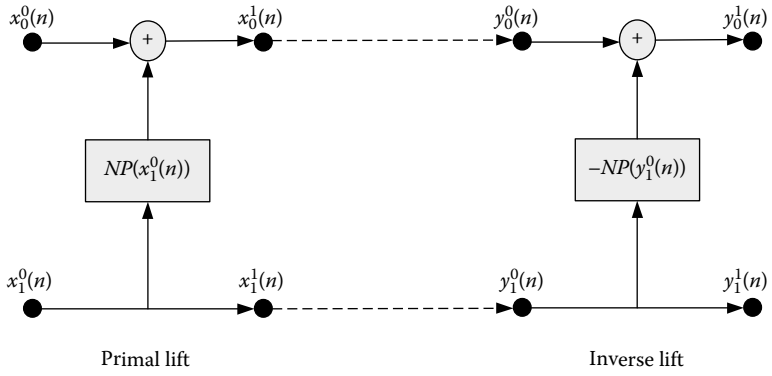

FIGURE 24.22 Nonlinear primal lifting.

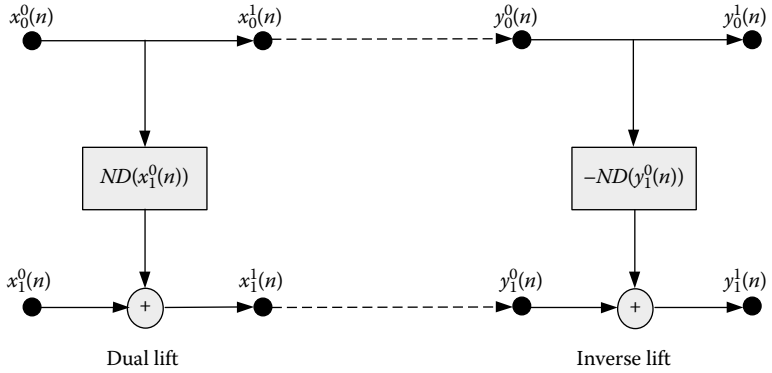

FIGURE 24.23 Nonlinear dual lifting.

maintained as can be easily seen in signal flow graph in Figures 24.22 and 24.23. Note that since the filter is nonlinear, the z-transform transfer function cannot (in general) be defined for the filter. The symbols $NP(\cdot)$ ($ND(\cdot)$) are used instead to denote the primal (dual) nonlinear operator on the signal in the time domain.

A particularly important type of nonlinear filter is the combination of a linear filter and a quantizer [20], such as

$$NP(x_1^0(n)) = \left\lfloor \sum_k p(k)x_1^0(n-k) + \frac{1}{2} \right\rfloor$$

$$ND(x_0^1(n)) = \left\lfloor \sum_k d(k)x_0^1(n-k) + \frac{1}{2} \right\rfloor$$

where $\lfloor x \rfloor$ denotes the largest integer that is no bigger than x, i.e., the floor operation, and $p(k)$ ($d(k)$) are the coefficients of the linear primal (dual) filter. If the inputs $(x_0^0(n), x_1^0(n))$ are integer valued, then the outputs with the primal lifting are given by

$$x_0^1(n) = x_0^0(n) + \left\lfloor \sum_k p(k) x_1^0(n-k) + \frac{1}{2} \right\rfloor$$
$$x_1^1(n) = x_1^0(n)$$

will also be integer valued as the final addition operation involves integers. The same applies with the dual lifting and any combinations of primal and dual liftings. Any linear lifting-based filter bank can therefore be converted into a filter bank that maps integer inputs to integer outputs by using the floor operation to the outputs of the lifting filters and the transform is known as an integer wavelet transform (IWT). The IWT shares most properties of the parent (nonquantized) transform, as long as the floor operations do not contribute a significant level of distortion to the processed signals. This transform is particularly useful for implementing lossless compression schemes, since it retains its PR properties despite the rounding distortions of each primal or dual filter.

Some other nonlinear filters that can be useful in lifting stages are

Median filters (or more general order-statistic filters), which can provide robustness to noise and outliers in the data

Motion-compensated prediction filters, which can be used to improve the performance of video compression systems that employ wavelets along the time axis as well as in the two spatial directions.

24.10 *M*-Band Filter Banks

The 2-band filter bank can be generalized to an arbitrary number of channel as shown in Figure 24.24. The input signal is ideally split into M nonoverlapping contiguous frequency subbands with equal bandwidth. Since there is a factor of M reduction in the bandwidth, downsampling by a factor of M can be applied to preserve the data rate. M-band filter banks are most conveniently analyzed by using the polyphase representation [3,9,12].

The type 1 polyphase decomposition of the analysis filters is given by

$$H_i(z) = E_{i,0}(z^M) + z^{-1}E_{i,1}(z^M) + \cdots + z^{-(M-1)}E_{i,M-1}(z^M) \tag{24.115}$$

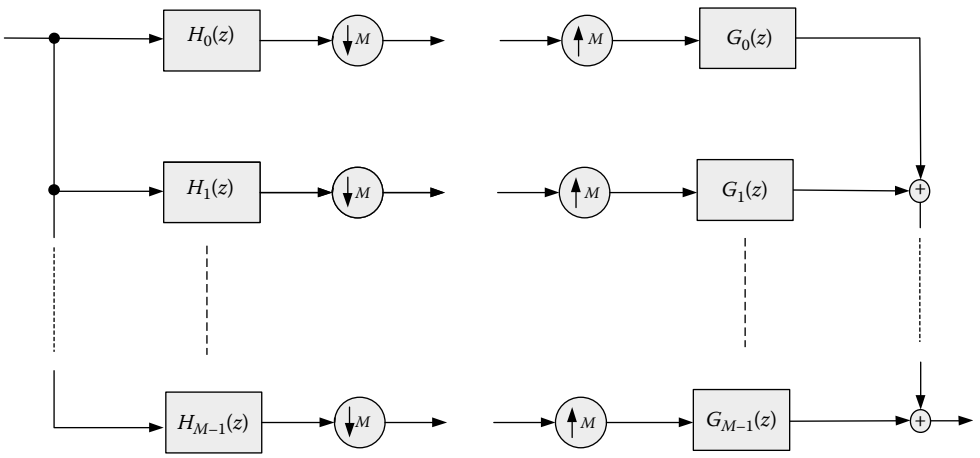

FIGURE 24.24 M-band filter bank.

for $i = 0, \ldots, M-1$; and the corresponding analysis polyphase matrix of size $M \times M$ is

$$\mathbf{E}(z) = \begin{bmatrix} E_{0,0}(z) & E_{0,1}(z) & \ldots & E_{0,M-1}(z) \\ E_{1,0}(z) & E_{1,1}(z) & \ldots & E_{1,M-1}(z) \\ \vdots & \vdots & \ddots & \vdots \\ E_{M-1,0}(z) & E_{M-1,1}(z) & \ldots & E_{M-1,M-1}(z) \end{bmatrix} \tag{24.116}$$

The type 2 polyphase decomposition of the synthesis filters is given by

$$G_i(z) = z^{-(M-1)} R_{i,0}(z^M) + z^{-(M-2)} R_{i,1}(z^M) + \cdots + R_{i,M-1}(z^M) \tag{24.117}$$

for $i = 0, \ldots, M-1$; and the corresponding synthesis polyphase matrix of size $M \times M$ is

$$\mathbf{R}(z) = \begin{bmatrix} R_{0,0}(z) & R_{1,0}(z) & \ldots & R_{M-1,0}(z) \\ R_{0,1}(z) & R_{1,1}(z) & \ldots & R_{1,M-1}(z) \\ \vdots & \vdots & \ddots & \vdots \\ R_{0,M-1}(z) & R_{1,M-1}(z) & \ldots & R_{M-1,M-1}(z) \end{bmatrix} \tag{24.118}$$

Figure 24.25 shows the equivalent representation of the M-band filter bank in polyphase form. Just as in the 2-band case, the total polyphase matrix is defined to be $\mathbf{P}(z) \equiv \mathbf{R}(z)\mathbf{E}(z)$ and the condition for PR is

$$\mathbf{P}(z) = \mathbf{R}(z)\mathbf{E}(z) = \mathbf{I} \tag{24.119}$$

For an FIR filter bank it is required that

$$\det(\mathbf{E}(z)) = cz^K \tag{24.120}$$

where c is a nonzero constant and K an integer.

As in the 2-band case, a product (cascade) of matrices satisfying Equation 24.120 will give a matrix that also satisfies Equation 24.120. Lifting can also be defined in the M-band setting but instead of just the

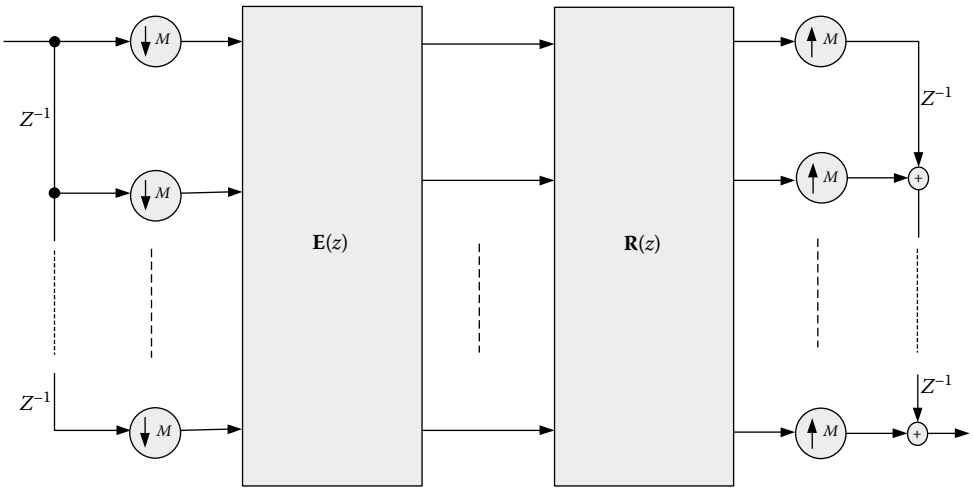

FIGURE 24.25 Polyphase form of the M-band filter bank.

primal and dual liftings, there are in general $M(M-1)$ types of lifting as there is a choice M bands that can be used to modify the signal in the other $M-1$ bands.

Special types of M-band filter banks are

1. Discrete fourier transform (DFT). Although the DFT is usually considered a transform that works on a block of data, it can also be viewed as an M-band filter bank. The analysis polyphase matrix in this case is the DFT matrix with elements given by

$$E_{i,k}(z) = \frac{1}{\sqrt{M}} W_M^{ik} \quad \text{where } W_M = \exp\left(-\frac{j2\pi}{M}\right) \quad \text{for } i,k = 0 \ldots M-1 \tag{24.121}$$

2. Discrete cosine transform (DCT). This can also be viewed as an M-band filter bank. The analysis polyphase matrix in this case is the DCT matrix with elements given by

$$\begin{aligned} E_{0,k}(z) &= \frac{1}{\sqrt{M}} && \text{for } k = 0 \ldots M-1 \\ E_{i,k}(z) &= \sqrt{\frac{2}{M}} \cos\left(\frac{(2k+1)i\pi}{2M}\right) && \text{for } \begin{cases} i = 1 \ldots M-1 \\ k = 0 \ldots M-1 \end{cases} \end{aligned} \tag{24.122}$$

3. Cosine modulated filter bank. The idea here is to design a single prototype low-pass filter for the low-pass subband and to use modulation on the prototype filter to obtain the other filters in the filter bank. The analysis/synthesis filter coefficients are given by

$$h_i(n) = g_i(n) = p(n)\sqrt{\frac{2}{M}} \cos\left(\frac{(2i+1)(2n+M+1)\pi}{4M}\right) \quad \text{for } i = 0 \ldots M-1 \tag{24.123}$$

The prototype filter is $p(n)$ and if it is of length $2M$ and satisfies

$$p(n) = p(2M-n) \quad \text{and} \quad p^2(n) + p^2(n+M) = 1 \tag{24.124}$$

then PR is achieved.

24.11 Hilbert Pairs of Filter Banks (the Dual Tree)

In this final section on 1-D multirate filter banks, we return to the case of the 2-band system, formed into a wavelet tree of filters, as shown in Figure 24.3. While the wavelet transform, implemented in this form, has been found to be remarkably effective as a tool for signal compression (coding) algorithms, it suffers from a rather serious drawback when used as a signal analysis tool. This problem is known as *shift dependence*, or a lack of shift invariance. It is caused by the 2:1 downsampling operations, shown in Figure 24.3, and manifests itself as aliased signal components which are generated by the downsamplers at each stage of the filter tree.

Although these aliased components do indeed cancel each other out when all the subbands are recombined in the reconstruction filter tree of the inverse wavelet transform (provided that the anti-aliasing condition of Equation 24.41 is satisfied), the aliased components are still very significant in the wavelet coefficients (subband outputs) themselves and tend to result in poor performance if the wavelet transform is used as a front-end for more complicated tasks such as signal classification and recognition, or for denoising.

One way to eliminate the aliasing distortion in each subband and obtain *shift invariance* is to use the modified filter tree of Figure 24.4, but without any of the downsamplers. This is known as the *à trous*

algorithm of Mallat [21]. However, for a K-level tree, it results in $(K+1)$ times as many wavelet coefficients being generated and also requires a similar increase in computation load to implement the filters, when compared with the standard nonredundant tree of Figure 24.3 (shown for $K = 4$). These factors become significantly worse for higher-dimensional signals such as images or 3-D datasets.

We now consider a more efficient alternative to the *à trous* algorithm.

24.11.1 Dual-Tree Wavelet Transform

The dual-tree wavelet transform [22] achieves approximate shift invariance with only 2:1 redundancy of coefficients and twofold increase in computation load, relative to the nonredundant tree. It simply employs a second tree of wavelet filters in parallel with the first tree, as shown in Figure 24.26.

The key to obtaining shift invariance from the dual-tree structure lies in designing the relative filter delays at each stage, such that the low-pass filter outputs in tree b are effectively sampled at points midway between the sampling points of the equivalent filters in tree a. This requires a delay difference between the a and b low-pass filters of 1 sample period at tree level 1, and of $\frac{1}{2}$ sample period at subsequent levels (because at these later levels half of the required delay has already been provided by earlier stages). At level 1 we can use any standard orthogonal or biorthogonal wavelet filters and produce the required delay shift trivially by insertion or deletion of unit delays. However, at subsequent levels, the $\frac{1}{2}$ sample delay difference is more difficult to achieve. In Ref. [23], Selesnick showed that these low-pass delay constraints produce a Hilbert pair relationship between the wavelet bases for the two trees. This leads naturally to the interpretation of the outputs from trees a and b as the real and imaginary parts, respectively, of complex wavelet coefficients. The two filter banks are then known as a Hilbert pair.

The $\pm\frac{1}{2}$ sample delay difference between filters $H_{0a}(z)$ and $H_{0b}(z)$ is difficult to express in the time domain as the filters are discrete, but it can be easily expressed in the frequency domain as

$$H_{0b}(e^{j\omega}) \simeq H_{0a}(e^{j\omega})e^{\pm j\omega/2} \tag{24.125}$$

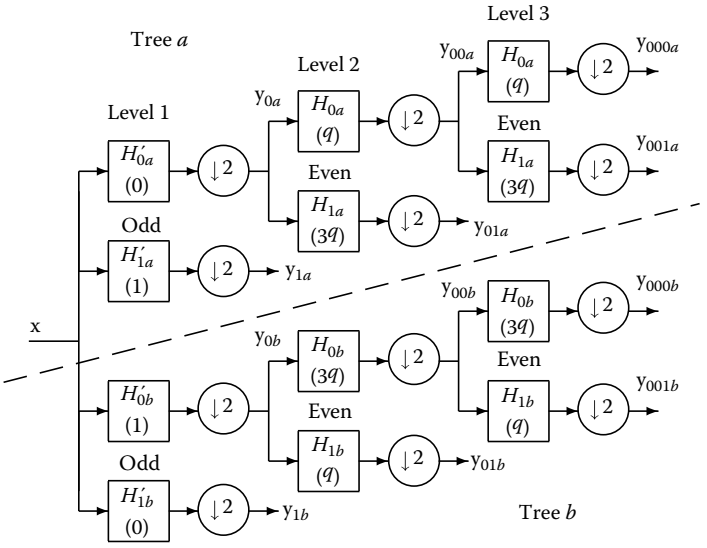

FIGURE 24.26 Dual-tree complex wavelet transform over three levels. The numbers in brackets indicate the delay of each filter (q = one quarter of a sample).

The approximation is necessary here assuming finite-order filters are being used. Solutions are possible if the phase responses are exact and the magnitude responses are approximate, or if the magnitude responses are exact and the phase responses are approximate. In the former case, odd-length and even-length linear-phase filters can be used for H_{0a} and H_{0b}, but better overall characteristics can usually be achieved with the latter case, which allows both filter banks to be CQFs, satisfying Equations 24.42, 24.45, and 24.53.

By convention, we select tree b to lag relative to tree a, so the polarity of the final exponent term in Equation 24.125 is selected to be negative.

24.11.2 Common-Factor Dual-Tree Filter Design

Selesnick [24] proposed a method of satisfying Equation 24.125 by letting

$$H_{0a}(z) = F(z)D(z) \quad \text{and} \quad H_{0b}(z) = F(z)z^{-L}D(z^{-1}) \tag{24.126}$$

where

$$A(z) = \frac{z^{-L}D(z^{-1})}{D(z)} \tag{24.127}$$

is an all pass filter, with group delay designed to approximate the required $\frac{1}{2}$ sample delay difference. Hence we require that

$$A(e^{j\omega}) \simeq e^{-j\omega/2} \tag{24.128}$$

Once $D(z)$ has been selected to satisfy Equations 24.127 and 24.128, we can design $F(z)$ such that both H_{0a} and H_{0b} result in CQFs. This is possible because the product filter $P(z)$ is the same in both cases, since

$$\begin{aligned} P_a(z) &= H_{0a}(z)H_{0a}(z^{-1}) \\ &= F(z)F(z^{-1})D(z)D(z^{-1}) \\ &= H_{0b}(z)H_{0b}(z^{-1}) = P_b(z) \end{aligned} \tag{24.129}$$

Hence $F(z)$ can be designed to contain the required number of zeros at $z = -1$ (to give the desired number of VM) and a factor $R(z)$ of sufficient order to eliminate all the nonzero even powers of z in $P(z)$. This is very similar to the method of choosing $R(z)$ used in Section 24.6.4.

There is a straightforward way to select $D(z)$ of a given order L using Thiran's filter:

$$D(z) = 1 + \sum_{n=1}^{L} \binom{L}{n} \left[\prod_{k=0}^{n-1} \frac{\tau - L + k}{\tau + 1 + k} \right] (-z)^{-n} \tag{24.130}$$

where $\tau = 0.5$ to get $\angle A(e^{j\omega}) \simeq \omega/2$. A range of filters designed with this method are given in Ref. [24].

The one disadvantage of this method of designing a Hilbert pair of filter banks is that the resulting complex basis functions will not be linear phase (i.e., conjugate-symmetric about their midpoint). To achieve this, $F(z)$ must be linear phase, which requires a biorthogonal factorization of $P(z)$ instead of the orthogonal CQF factorization, assumed above. The penalty then is that the reconstruction wavelets will differ from the analysis wavelets.

24.11.3 Q-Shift Dual-Tree Filter Design

A suitable way to employ CQFs and to obtain linear phase complex basis functions from the dual tree was proposed in Ref. [25]. The key here is to make the tree *b* filters equal to the time-reverse of the tree *a* filters. Hence

$$H_{0b}(z) = z^{-L} H_{0a}(z^{-1}) \tag{24.131}$$

The integer delay L is normally chosen so that H_{0a} and H_{0b} cover the same range of z indices.

The filters have real coefficients, so Equation 24.131 automatically ensures that

$$|H_{0b}(e^{j\omega})| = |H_{0a}(e^{j\omega})| \quad \text{and} \quad \angle H_{0b}(e^{j\omega}) = -L\omega - \angle H_{0a}(e^{j\omega})$$

It is also required, from Equation 24.125 (11.1), that $\angle H_{0b}(e^{j\omega}) - \angle H_{0a}(e^{j\omega}) \simeq -\frac{\omega}{2}$, thus giving

$$\angle H_{0a}(e^{j\omega}) \simeq -\frac{L\omega}{2} + \frac{\omega}{4} \quad \text{and} \quad \angle H_{0b}(e^{j\omega}) \simeq -\frac{L\omega}{2} - \frac{\omega}{4} \tag{24.132}$$

This shows that H_{0a} and H_{0b} must have delays that approximate $\pm\frac{1}{4}$ of a sample period relative to the midpoint of the filters at $L/2$ sample periods. Hence this type of 2-band filter system is called a Q-shift (quarter-shift) filter pair. A neat way to visualize the delay property of the Q-shift pair is shown in Figure 24.27, in which the filter taps of the two filters are interleaved to form a single smooth low-pass filter of even length and with symmetric filter coefficients (linear phase), given by

$$H_{L2}(z) = H_{0a}(z^2) + zH_{0b}(z^2) \tag{24.133}$$

The sample rate of the new filter H_{L2} is double that of H_{0a} and H_{0b} and its delay is therefore $(L - \frac{1}{2})$ sample periods. (In Figure 24.27, $L = 1$.)

As well as possessing the approximate Q-shift delay property, H_{0a} and H_{0b} must also satisfy the usual 2-band filter bank constraints of no aliasing and PR. Additionally it is advantageous in many emerging applications of complex wavelets that the Q-shift filters should be orthogonal (i.e., be CQFs) to make the transform a tight frame which conserves energy from the signal in the transform domain. This has the further advantage that the same filters (and their time-reverses) can be used in the forward and inverse transforms, as well as in the two trees *a* and *b*. Finally it is usually highly desirable that the filters have good smoothness properties when iterated over scale.

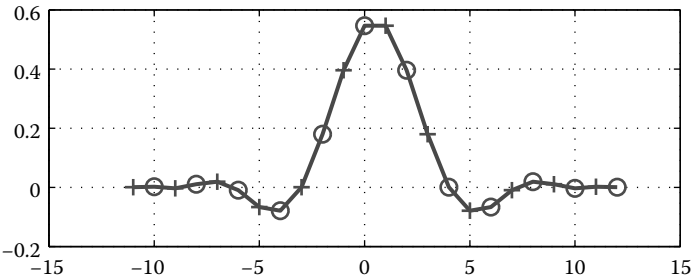

FIGURE 24.27 Impulse response of $H_{L2}(z)$ for $n = 6$. The H_{0a} and H_{0b} filters have $2n = 12$ taps each, shown as circles and crosses, respectively.

Two main design approaches have emerged to meet all of these constraints for Q-shift filter pairs:

Zero-forcing methods with search for good delay properties: The Daubechies orthonormal filters, described in Section 24.6.4, have the maximal number of zeros in the filters H_0 and G_0 at $z = -1$ and there are no further degrees of freedom. These are not able to produce filter pairs with good approximations to Q-shift delays. However the Bernstein method of equation (Equation 24.59) can produce much better approximations if $N = 2K + 1$, which allows one degree of freedom (the parameter α_K) that can be adjusted to optimize the Q-shift delays.

In Ref. [5], all even-length CQFs were evaluated from length 4 to 22. It was found that good approximations to the required Q-shift delay could be obtained for CQF lengths of 8, 12, 18, and 22. The optimal values of α_K in each case were found to be 0.0460, 0.1827, 0.2405, and 0.0245, respectively.

However, despite its good delay properties, the length-8 CQF, with 3 zeros at $z = -1$, was much less smooth than the longer filters, with 5, 8, and 10 zeros at $z = -1$, respectively. Figure 24.28 shows the impulse and frequency responses at level-4 of the DT-CWT, using length-12 Q-shift CQFs, designed with this method. Designs for other filter lengths are shown in Ref. [5]. In all the results of this section, the standard Daubechies 7,9-tap (Antonini) filters were used at level 1 of the dual tree (see Figure 24.10).

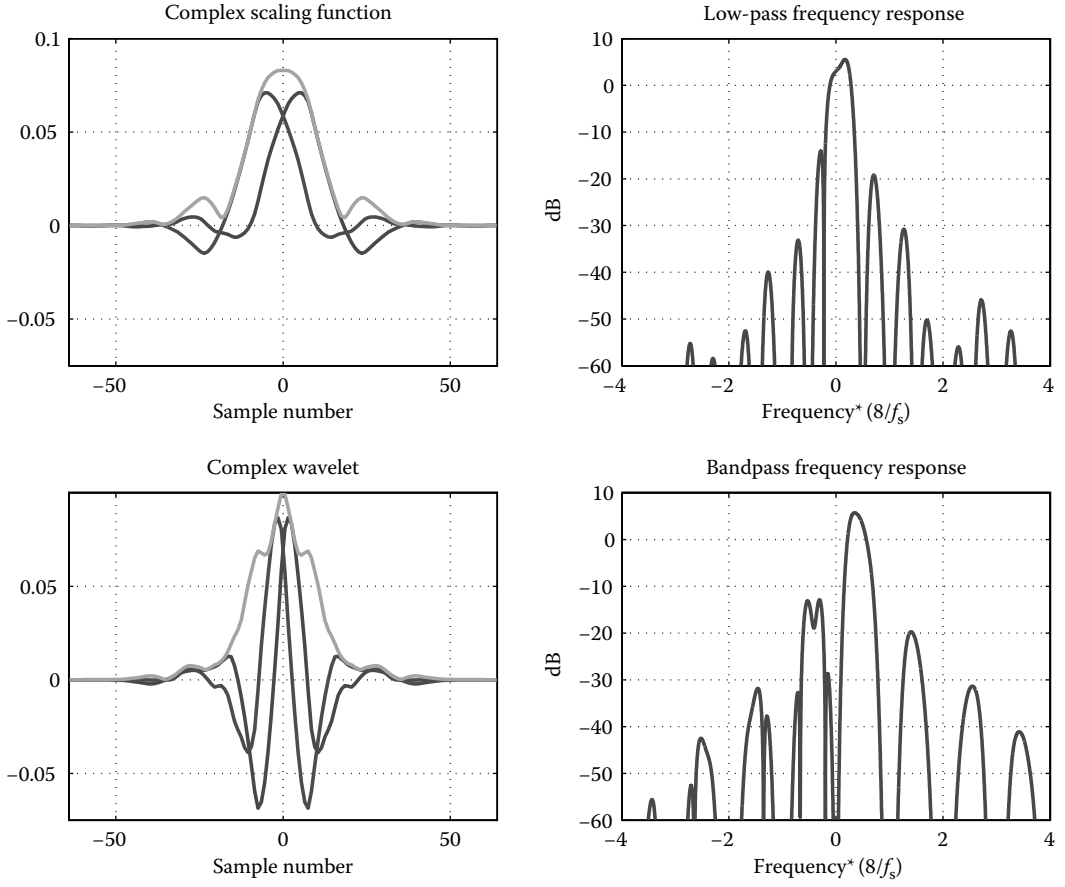

FIGURE 24.28 Impulse and frequency responses at level-4 of the DT-CWT, using length-12 Q-shift CQFs, designed with the zero-forcing method of Ref. [5]. In the impulse responses the two darker curves show the real and imaginary parts of the impulse responses, and the light gray curves show their magnitudes.

Iterative energy minimization methods: The other main design approach for Q-shift filter pairs has been presented in Ref. [26]. The aim is to design the filter $H_{0a}(z)$ (and hence also its time-reverse $H_{0b}(z)$) such that it satisfies the standard CQF conditions and also gives a smooth low-pass filter when formed into $H_{L2}(z)$ using Equation 24.133, which automatically produces the approximate $\frac{1}{4}$-sample (Q-shift) delay property if H_{L2} is smooth enough.

In Ref. [26] it is shown that the PR property of CQFs can be obtained if the product filter $H_{L2}(z)H_{L2}(z^{-1})$ has the property that the term in z^0 is unity and all terms in z^{4k} (k integer) are zero. Smoothness of the filter $H_{L2}(z)$ can be formulated as a need for all components of its spectrum to be approximately zero above about one-sixth of its sample rate ($\omega > \pi/3$). So the ideal design conditions for the length $4n$ symmetric low-pass filter H_{L2} have now been reduced to

1. Zero amplitude for all the terms of $H_{L2}(z)H_{L2}(z^{-1})$ in z^{4k} except the term in z^0, which must be unity
2. Zero (or near-zero) amplitude of $H_{L2}(e^{j\omega})$ for the stopband, $\frac{\pi}{3} \leq \omega \leq \pi$

Condition 1 is a set of quadratic constraints on the elements of the filter tap vector $\mathbf{h}_{L2}$, while condition 2 is a set of linear constraints on $\mathbf{h}_{L2}$, evaluated at a sufficiently fine set of frequencies covering the stopband. Together they form an overdetermined set of equations for the $2n$ unknowns that form one-half of the symmetric vector $\mathbf{h}_{L2}$ (where $2n$ is the length of filters H_{0a} and H_{0b}). If the constraints were all linear, the least mean square (LMS) error solution could be found in the standard way using the pseudo-inverse of the matrix which defines the equations.

To deal with the quadratic constraints, the problem is linearized using an iterative solution. If $\mathbf{h}_{L2}$ at iteration i is given by $\mathbf{h}_i = \mathbf{h}_{i-1} + \Delta\mathbf{h}_i$, then, since convolution (*) is commutative,

$$\begin{aligned}\mathbf{h}_i{*}\mathbf{h}_i &= (\mathbf{h}_{i-1} + \Delta\mathbf{h}_i){*}(\mathbf{h}_{i-1} + \Delta\mathbf{h}_i)\\ &= \mathbf{h}_{i-1}{*}(\mathbf{h}_{i-1} + 2\Delta\mathbf{h}_i) + \Delta\mathbf{h}_i{*}\Delta\mathbf{h}_i\end{aligned} \tag{24.134}$$

If the incremental update $\Delta\mathbf{h}_i$ is assumed to become small as i increases, the final term can be neglected and the convolution be expressed as a linear function of $\Delta\mathbf{h}_i$.

Hence the design problem can now be expressed as

$$\text{Solve for } \Delta\mathbf{h}_i \text{ such that:} \quad \mathbf{C}(\mathbf{h}_{i-1} + 2\Delta\mathbf{h}_i) = [\,0 \ldots 0 \quad 1\,]^{\mathrm{T}} \tag{24.135}$$

$$\mathbf{F}(\mathbf{h}_{i-1} + \Delta\mathbf{h}_i) \simeq [\,0 \ldots 0\,]^{\mathrm{T}} \tag{24.136}$$

where

C is a matrix which calculates every fourth term in the convolution with $\mathbf{h}_{i-1}$

F is a matrix which evaluates the Fourier transform at M discrete frequencies ω from $\frac{\pi}{3}$ to π (typically $M \simeq 8n$ to ensure that all sidelobe maxima and minima are captured reasonably accurately)

Note that only one side of the convolution is needed in **C**, since the result is symmetric about the central term. Also, the columns of **C** and **F** can be combined in pairs so that only the first half of the symmetric $\Delta\mathbf{h}_i$ need be solved for.

In typical applications of complex wavelets, it is often more important to ensure high accuracy in the PR condition than to produce highly smooth wavelets. This is why Equation 24.135 is shown as an equality while Equation 24.136 is only an approximation. Within an iterative LMS framework, high accuracy solutions to some equations can be produced by scaling these up by a factor, β_i, which is progressively increased with i. Hence the optimization may now be expressed as the iterative LMS solution of

$$\begin{bmatrix} 2\beta_i \mathbf{C} \\ \mathbf{F} \end{bmatrix} \Delta \mathbf{h}_i = \begin{bmatrix} \beta_i (\mathbf{c} - \mathbf{C}\ \mathbf{h}_{i-1}) \\ -\mathbf{F}\ \mathbf{h}_{i-1} \end{bmatrix} \tag{24.137}$$

$$\mathbf{h}_i = \mathbf{h}_{i-1} + \Delta \mathbf{h}_i \tag{24.138}$$

where $\mathbf{c} = [0 \ldots 01]^{\mathrm{T}}$. Typically one may choose $\beta_i = 2^i$, and iterate over about 20 iterations, so that reconstruction errors become of the order of $2^{-20} \simeq 10^{-6}$ of smoothness errors. There are two further refinements to this method, described in Ref. [26], which allow for transition band effects and can insert predefined zeros (e.g., VM) in the filters.

Figures 24.29 and 24.30 show some typical scaling functions and wavelets designed using the above method for filter lengths of 14 and 24, respectively. Note the high degree of smoothness that is achievable if the length of the filters is increased to 24. The frequency responses in Figures 24.28 through 24.30, with vertical scales in decibels, clearly show the much lower sidelobe levels and greater ability to reject negative frequencies, obtainable with longer filters. Many other intermediate results are possible with this energy minimization design method, and the method works satisfactorily for filter lengths up to 50 or more, which can be useful if sharp transition bands and/or very low sidelobe levels are required, such as for high-quality audio applications.

G., Design of Q-shift complex wavelets for image processing using frequency domain energy minimization. In *Proc. IEEE Int. Conf. Image Processing*, Barcelona, September 2003, pp. 1013–1016.

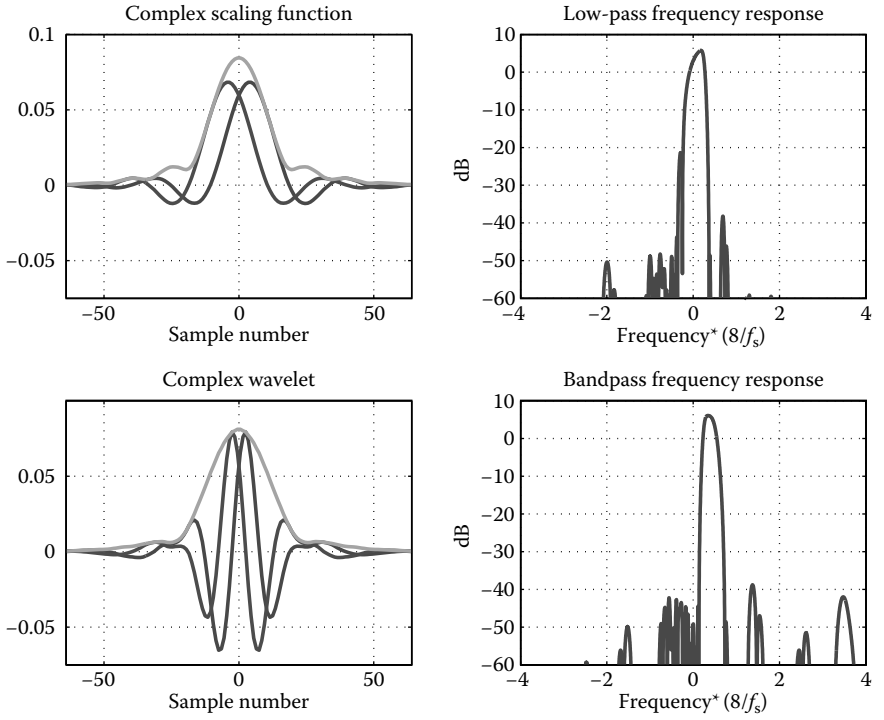

FIGURE 24.30 Impulse and frequency responses at level-4 of the DT-CWT, using length-24 Q-shift CQFs, designed with the energy minimization method of Kingsbury, N. G., Design of Q-shift complex wavelets for image processing using frequency domain energy minimization. In *Proc. IEEE Int. Conf. Image Processing*, Barcelona, September 2003, pp. 1013–1016.

Earlier papers on the dual-tree method [25,27] proposed some more heuristic methods for designing Q-shift filters. Most notable of these results are a very simple length-6 filter with fair performance and a length-14 filter with generally good performance (similar to Figure 24.29).

24.11.4 Metrics for Shift Dependence of a Filter Bank

Probably the most important feature of Hilbert pairs of wavelets, in addition to those of normal wavelet decompositions, is their approximate *shift invariance* or, expressed another way, their low level of *shift dependence*. This is discussed in detail in Ref. [27] and here we summarize the main technique from that paper for measuring shift dependence.

In order to examine the shift invariant properties of the dual tree, consider what happens when we choose to retain the coefficients of just one type (wavelet or scaling function) from just one level of the dual tree of Figure 24.26. For example, we might choose to retain only the level-3 wavelet coefficients y_{001a} and y_{001b}, and set all others to zero. If the signal $\hat{x}$, reconstructed from just these coefficients, is free of aliasing then we define the transform to be shift invariant at that level. This is because absence of aliasing implies that a given subband has a unique z-transfer function and so its impulse response is linear and time (shift) invariant. In this context we define a subband as comprising all coefficients from *both* trees at a given level and of a given type (either wavelet or scaling function).

Figure 24.31 shows the simplified analysis and reconstruction parts of the dual tree when coefficients of just one type and level are retained. All downsampling and upsampling operations are moved to the outputs of the analysis filter banks and the inputs of the reconstruction filter banks, respectively, using the transformation of Figure 24.4 on both trees, and the cascaded filter transfer functions are combined.

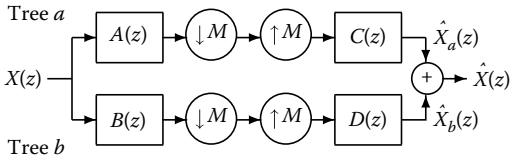

FIGURE 24.31 Basic configuration of the dual tree if either wavelet or scaling-function coefficients from just level m are retained ($M = 2^m$).

$M = 2^m$ is the total down/upsampling factor. For example if y_{001a} and y_{001b} from Figure 24.26 are the only sets of retained coefficients, then the subsampling factor $M = 8$, and $A(z) = H'_{0a}(z)H_{0a}(z^2)H_{1a}(z^4)$, the transfer function from x to y_{001a}. The transfer function $B(z)$ (from x to y_{001b}) is obtained similarly using $H_{\ldots b}(z)$; as are the inverse functions $C(z)$ and $D(z)$ from $G_{\ldots a}(z)$ and $G_{\ldots b}(z)$, respectively.

It is a standard result of multirate analysis that a signal $U(z)$, which is downsampled by M and then upsampled by the same factor (by insertion of zeros), becomes $\frac{1}{M}\sum_{k=0}^{M-1} U(W^k z)$, where $W = e^{j2\pi/M}$. Applying this result to Figure 24.31 gives

$$\hat{X}(z) = \hat{X}_a(z) + \hat{X}_b(z) = \frac{1}{M}\sum_{k=0}^{M-1} X(W^k z)\left[A(W^k z)C(z) + B(W^k z)D(z)\right] \tag{24.139}$$

The aliasing terms in this summation correspond to those for which $k \neq 0$, because only the term in $X(z)$ (when $k = 0$ and $W^k = 1$) corresponds to a linear time (shift) invariant response. For shift invariance, the aliasing terms must be negligible, so we must design $A(W^k z)C(z)$ and $B(W^k z)D(z)$ either to be very small or to cancel each other when $k \neq 0$. Now W^k introduces a frequency shift equal to kf_s/M to the filters A and B (where f_s is the input sampling frequency), so for larger values of k the shifted and unshifted filters have negligible passband overlap and it is quite easy to design the functions $B(W^k z)D(z)$ and $A(W^k z)C(z)$ to be very small over all frequencies, $z = e^{j\theta}$. But at small values of k (especially $k = \pm 1$) this becomes virtually impossible due to the significant width of the transition bands of short-support filters. In these cases it is necessary to design for cancellation when the two trees are combined, and this is what is achieved by the half-sample delay difference strategy outlined above.

A useful way of quantifying the shift dependence of a transform is to examine Equation 24.139 and determine the ratio of the total energy of the unwanted aliasing transfer functions (the terms with $k \neq 0$) to the energy of the wanted transfer function (when $k = 0$), as given by the aliasing energy ratio:

$$R_a = \frac{\sum_{k=1}^{M-1} \mathcal{E}\{A(W^k z)C(z) + B(W^k z)D(z)\}}{\mathcal{E}\{A(z)C(z) + B(z)D(z)\}} \tag{24.140}$$

where $\mathcal{E}\{U(z)\}$ calculates the energy, $\sum_r |u_r|^2$, of the impulse response of a z-transfer function, $U(z) = \sum_r u_r z^{-r}$. Note that $\mathcal{E}\{U(z)\}$ may alternatively be calculated as the integral of the squared magnitude of the frequency response, $\frac{1}{2\pi}\int_{-\pi}^{\pi} |U(e^{j\theta})|^2 d\theta$ from Parseval's theorem. Since R_a is an energy ratio, it is convenient to measure it in decibels.

In Table 3 of Ref. [27], values of R_a are given for various single-tree and dual-tree filter combinations. It is shown that R_a is typically only -3.5 dB for a single-tree DWT, whereas it may be improved to approximately -31 dB with 18-tap Q-shift filters in the dual-tree complex wavelet transform (DT-CWT). Longer filters can reduce the aliasing energy much further if needed, while shorter filters tend to produce more aliasing energy and hence somewhat greater shift dependence.

Other metrics for shift dependence of filter-bank transforms can be based on the amount of shift-dependent variation in the impulse or step responses of the transform, as illustrated in Figure 8

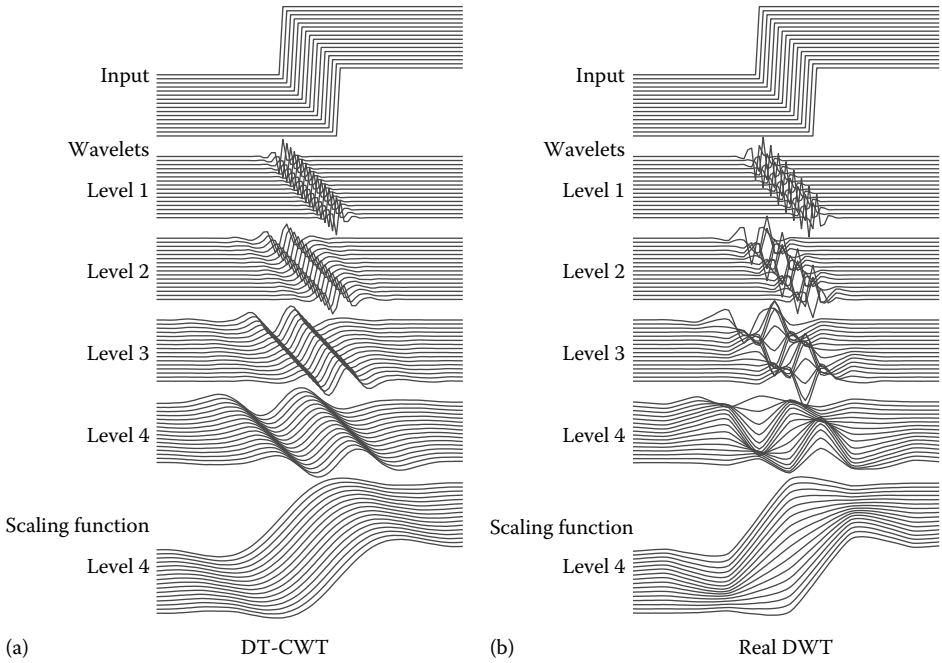

FIGURE 24.32 Wavelet and scaling-function components at levels 1–4 of 16 shifted step responses of the DT-CWT (a) with 18-tap Q-shift filters and the real DWT (b) with 13,19-tap filters.

of Ref. [27], part of which is reproduced here in Figure 24.32. Good transforms have responses that are visually almost identical (Figure 24.32a), whereas poor transforms (e.g., the DWT) have dramatically fluctuating responses (Figure 24.32b).

In this relatively short discussion of dual-tree/Hilbert pair ideas, we have not discussed the important extension of these ideas to two- and three-dimensional datasets, in which a second and very important advantage of the complex nature of the wavelet coefficients lies in their ability to produce strongly directionally selective wavelets while still retaining the computational advantages of separable filtering [22]. In addition, extension of the dual-tree ideas to M-band filter banks has been achieved by Chaux et al. [28], making even greater directional selectivity possible in two and three dimensions.

25.1 Introduction

Directional filter banks (DFBs), which were introduced by Bamberger in 1989 [1–3], are digital analysis–synthesis filter banks that allow an image to be represented as a collection of subbands. In the analysis section, filters succeeded by downsampling matrix operators decompose an image into a set of subbands. In the synthesis section, these subbands are upsampled via a complementary set of matrix operators, then filtered and merged to reconstruct the original image. Such a description is strikingly reminiscent of a conventional 2-D analysis–synthesis filter bank. The distinguishing feature is that the DFB subbands embody angular information (a different angle for each subband), as opposed to the traditional low-, mid-, and high-frequency information. The directional subbands in the DFB are maximally decimated so that the total number of pixels in the full set of subbands is equal to the number of pixels in the original image. Thus, the subbands are nonredundant or, equivalently stated, they form a critically sampled representation.

The DFB has the property that it can achieve exact reconstruction. That is, if the constituent filters are properly designed, the output of the synthesis section can reconstruct the original image from the

decimated subbands exactly. This property is important in applications where modifications are performed in the subband domain for the purpose of enhancing image quality in synthesis. In addition, DFBs are very efficient from a computational perspective and are typically designed for implementation in a separable two-hand filter bank tree structure. This is a noteworthy characteristic as it enables the DFB to have arithmetic complexity comparable to (though a little higher than) the popular 2-D transforms, like discrete Fourier transforms (DFTs) and discrete cosine transforms (DCTs).

DFBs are attractive for many image-processing applications that can benefit from directional analysis such as noise reduction, edge sharpening, feature enhancement, compression, object recognition, and texture synthesis, to mention a few. Furthermore, DFBs are also attractive from a visual information-processing perspective. Research has shown that the first layer of cells in the human visual cortex responds to different orientations and scales. Consequently, DFBs can model in an approximate way the human visual system. All of these reasons have motivated much of the study and interest in directional analysis–synthesis systems in recent years.

Since the introduction of the DFB in 1989, there have been a number of extensions and variations that have been considered, such as relaxation of the maximum decimation condition (leading to directional pyramids), multidimensional extensions of the DFB, nonseparable implementations, and mixed low-, mid-, high-frequency angular decompositions [4–7]. To avoid confusion among these variations, we will refer to the original DFB as the Bamberger DFB (BDFB) in our subsequent discussion and use the term DFB to refer more generically to the broad class of directional decompositions.

25.2 Basic Theory of 2-D Multirate Systems

To set the foundation for the later discussion on the DFB, we start by reviewing the basic concepts of 2-D multirate filter banks. The reader seeking a more comprehensive treatment on the subject is referred to Refs. [8,9].

First, we assume that the digital input signal $x[n_0, n_1]$ is a sampled version of a continuous time signal $x_a(t_0, t_1)$ such that

$$x[n_0, n_1] = x_a(n_0 T_0, n_1 T_1),$$

where T_0 and T_1 are the sampling periods. In matrix notation,* this equates to $x[\mathbf{n}] = x_a(\mathbf{Vn})$ where

$$\mathbf{n} = \begin{bmatrix} n_0 \\ n_1 \end{bmatrix}, \quad \mathbf{V} = \begin{bmatrix} T_0 & 0 \\ 0 & T_1 \end{bmatrix}.$$

More generally, $\mathbf{V}$ can be any nonsingular real matrix, which implies that there are an infinite number of ways to sample a 2-D signal. Each sampling matrix gives rise to a different sampling geometry or lattice in the 2-D plane. The ''lattice'' generated by the sampling matrix $\mathbf{V}$ is the set of all points $\mathbf{t}$, which implies that $\mathbf{t} = \mathbf{Vn}$, where $\mathbf{n} \in \mathcal{N}$ (the set of all integer vectors). The lattice associated with $\mathbf{V}$ is denoted as $LAT(\mathbf{V})$. Such a lattice corresponds to all the ''integer'' linear combinations of the columns of $\mathbf{V}$, which can be written as $\mathbf{V} = [\mathbf{v}_0|\mathbf{v}_1]$. It should be noted that the relationship between $\mathbf{V}$ and $LAT(\mathbf{V})$ is not one-to-one. Hence different sampling matrices can give rise to the same lattice, a fact that will be useful in later discussion.

An important component of multirate 2-D systems is the unimodular matrix. An integer matrix $\mathbf{E}$ is unimodular if and only if its inverse is an integer matrix, or equivalently if $|\det \mathbf{E}| = 1$. A couple of useful unimodular matrix properties are summarized in the following theorem [8]:

* Boldface capital letters denote matrices and boldface lowercase letters denote vectors.

THEOREM 25.1

Let $\mathbf{V}$ *be a* 2×2 *real nonsingular matrix generating a lattice LAT(*$\mathbf{V}$*).*

1. *Let* $\hat{\mathbf{V}} = \mathbf{VE}$*, where* $\mathbf{E}$ *is a* 2×2 *unimodular matrix. Then* $LAT(\mathbf{V}) = LAT(\mathbf{VE}) = LAT(\hat{\mathbf{V}})$.
2. *Let* $\hat{\mathbf{V}}$ *also be a basis for LAT(*$\mathbf{V}$*). Then there exists a unimodular matrix* $\mathbf{E}$ *such that* $\hat{\mathbf{V}} = \mathbf{VE}$.

Note that $LAT(\mathbf{V}) = LAT(\hat{\mathbf{V}})$ does not imply $x_a(\mathbf{Vn}) = x_a(\hat{\mathbf{V}}n)$. Although the lattice points are the same for both matrices, they do not occur in the same order, i.e., the samples of $x_a(\mathbf{Vn})$ are rearranged samples of $x_a(\hat{\mathbf{V}}n)$. This property is useful and was employed in Ref. [3] as a "change-of-variables" procedure to simplify the DFB design.

To illustrate the idea of lattice resampling with unimodular matrices, consider the lattice generated by the matrix

$$\mathbf{V} = \begin{bmatrix} 1 & 1 \\ -1 & 1 \end{bmatrix} = [\mathbf{v}_0 | \mathbf{v}_1]. \tag{25.1}$$

It generates what is known as the quincunx lattice, shown in Figure 25.1a, where the heavy dark dots correspond to elements of $LAT(\mathbf{V})$. The geometry of the lattice is established by vectors $\mathbf{v}_0$ and $\mathbf{v}_1$. A set of trivial unimodular matrices can be obtained by choosing variations of the matrices

$$\begin{bmatrix} \pm 1 & 0 \\ 0 & \pm 1 \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} 0 & \pm 1 \\ \pm 1 & 0 \end{bmatrix}. \tag{25.2}$$

Resampling with these matrices, we can produce rotations and reflections of any lattice. In particular, there are eight variations/permutations of the quincunx sampling matrix.

Another useful type of unimodular matrix is

$$\mathbf{E} = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}. \tag{25.3}$$

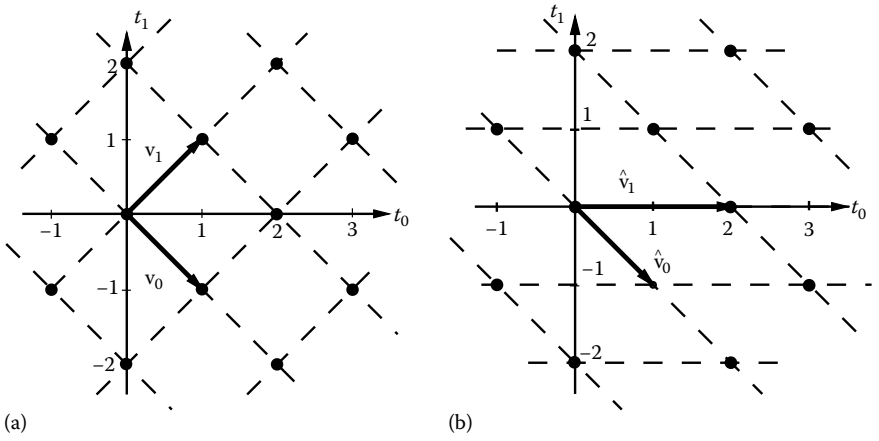

FIGURE 25.1 Examples of 2-D lattices. (a) Lattice generated by sampling with a quincunx matrix. (b) Lattice generated by resampling a quincunx matrix with a unimodular matrix. Note that the sample density of the lattice is same in both figures, but the geometry of the lattice is different.

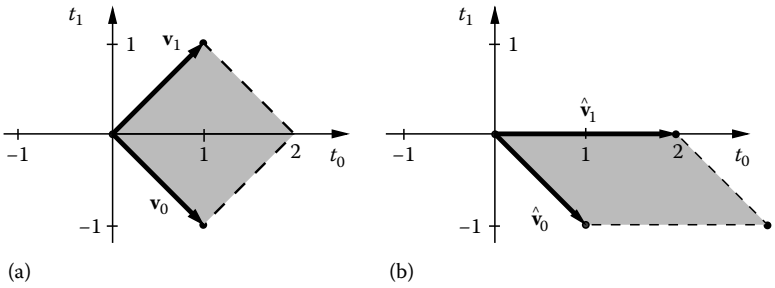

FIGURE 25.2 Fundamental parallepipeds for (a) the quincunx lattice and (b) the resampled quincunx lattice.

It generates the sampling matrix

$$\hat{\mathbf{V}} = \mathbf{VE} = \begin{bmatrix} 1 & 2 \\ -1 & 0 \end{bmatrix}, \tag{25.4}$$

whose lattice is illustrated in Figure 25.1. It is easy to see that $LAT(\mathbf{V}) = LAT(\hat{\mathbf{V}})$, but the geometry imposed by $\hat{\mathbf{v}}_0$ and $\hat{\mathbf{v}}_1$ is different than that of $\mathbf{V}$, i.e., the samples in the lattice have been permuted or reindexed. In the frequency domain, the reindexing of the lattice induces skewings and rotations in the frequency domain of the 2-D signal but does not alter the sample density.

The fundamental parallepiped of $\mathbf{V}$, denoted by $FPD(\mathbf{V})$, is defined by

$$FPD(\mathbf{V}) = \left\{\text{Set of all points } \mathbf{Vx} \text{ with } \mathbf{x} \in [0,1)^2\right\}. \tag{25.5}$$

Graphically, this is represented by the parallelogram formed by the sampling vectors $\mathbf{v}_0$ and $\mathbf{v}_1$, as shown in Figure 25.2 for $\mathbf{V}$ and $\hat{\mathbf{V}}$.

25.2.1 2-D Decimation and Interpolation

As in the 1-D case, decimation is performed by filtering (to reduce aliasing) followed by downsampling. Here, the downsampling is performed with a resampling matrix $\mathbf{M}$. Keep in mind that a 2-D resampling matrix does not only alter the sampling rate, but it also introduces a geometric modification to the sampling lattice, as illustrated in the previous figures. Thus a 2-D downsampler is implemented by

$$y[\mathbf{n}] = x[\mathbf{Mn}], \tag{25.6}$$

where $\mathbf{M}$ is a 2×2 nonsingular integer matrix. The signal $y[\mathbf{n}]$ retains only those samples of $x[\mathbf{n}]$ that reside on $LAT(\mathbf{M})$. The dark dots in Figure 25.3a illustrate this point for the case of quincunx resampling. The dark samples of $x[\mathbf{n}]$ are the ones retained by resampling with the quincunx matrix $\mathbf{Q}$ defined as

$$\mathbf{Q} = \begin{bmatrix} 1 & -1 \\ 1 & 1 \end{bmatrix} = [\mathbf{v}_0 | \mathbf{v}_1]. \tag{25.7}$$

Figure 25.3b illustrates how the samples are rearranged over the (n_0, n_1) plane. For this quincunx downsampling, the samples experience a clockwise rotation of 45°. For 2-D resampling matrices, the decimation ratio is the determinant of the matrix. Thus for the quincunx resampling case above, the decimation ratio is $|\det \mathbf{Q}| = 2$, as is evident from Figure 25.3.

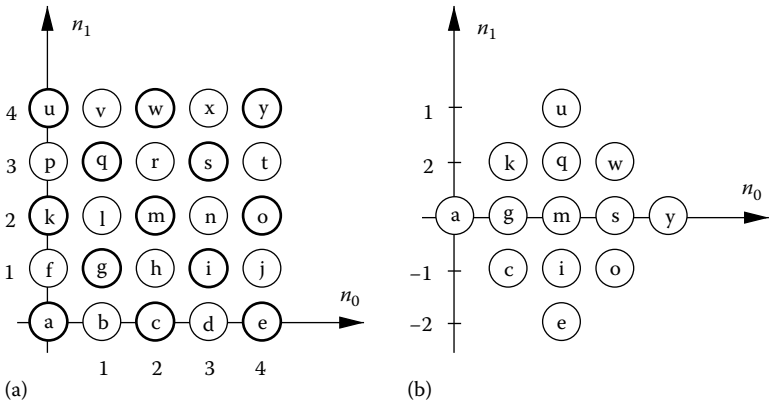

FIGURE 25.3 Downsampling with a quincunx matrix. (a) Original position of samples in the 2-D plane; samples in bold are retained by the downsampling operation. (b) Resulting data after quincunx downsampling with matrix **Q** in Equation 25.7.

To show that this property is true in general, consider the set

$$\mathcal{N}(\mathbf{M}) = \{\text{Set of integer vectors in } FPD(\mathbf{M})\} = \{\text{Set of integers of the form } \mathbf{Mx},\ \mathbf{x} \in [0,1)^2\}.$$

It is easy to see that the cardinality of the set $J(\mathbf{M})$ is $|\mathcal{N}(\mathbf{M})| = |\det \mathbf{M}|$. For instance, if we consider quincunx downsampling, then

$$\mathcal{N}(\mathbf{Q}) = \left\{ \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 1 \\ 0 \end{bmatrix} \right\} = \{\mathbf{k}_0, \mathbf{k}_1\}. \tag{25.8}$$

The vectors $\mathbf{k}_i$ are known as coset vectors.

Assuming the signal $x(\mathbf{t})$ has been sampled with $\mathbf{V} = \mathbf{I}$ (i.e., a rectangular uniform grid over the 2-D plane), then any other sublattice $LAT(\mathbf{M})$ obtained by downsampling $LAT(\mathbf{I})$ is known as a sublattice of **I**. For matrix **M**, we can obtain $J(\mathbf{M})$ distinct, nonoverlapping sublattices from **I**, expressed as

$$x_i[\mathbf{n}] = x(\mathbf{Mn} + \mathbf{k}_i). \tag{25.9}$$

Each sublattice is also known as a coset of $LAT(\mathbf{M})$. Figure 25.3a shows graphically that there are two sublattices, $x_0[\mathbf{n}]$ and $x_1[\mathbf{n}]$ for the quincunx matrix **Q**. From a multirate systems perspective, cosets are the equivalent of polyphase components.

25.2.2 Alias-Free 2-D Decimation

In the 1-D case, an antialiasing filter is generally applied to the signal prior to downsampling. For decimation by a factor of M, the filter has an ideal cutoff frequency of π/M, where M is the decimation ratio. In two dimensions there is an analogous cutoff frequency requirement but also a prescribed region of support determined by the geometry of $LAT(\mathbf{M})$, where **M** is the downsampling matrix.

Let $X(\boldsymbol{\omega})$ be the 2-D DTFT of $x[\mathbf{n}]$, which is 2π-periodic in $\boldsymbol{\omega}$ over the 2-D frequency plane with $\boldsymbol{\omega} = [\omega_0 \omega_1]^{\mathrm{T}}$. For convenience, with abuse of notation, $X(\boldsymbol{\omega})$ will be used in place of $X(e^{j\omega_0}, e^{j\omega_1})$.

The region of support for an antialiasing filter needed to ideally downsample by **M** is given by [8]

$$\boldsymbol{\omega} = \pi \mathbf{M}^{-\mathrm{T}} \mathbf{x} + 2\pi \mathbf{m}, \quad \mathbf{x} \in [-1,1)^2, \quad \mathbf{m} \in \mathcal{N}. \tag{25.10}$$

The term "$2\pi\mathbf{m}$" represents the periodicity of the antialias region of support, while the term "$\pi\mathbf{M}^{-\mathrm{T}}\mathbf{x}$" corresponds to the fundamental frequency cell (or region of support) that is periodically replicated over the frequency plane. If

$$\mathbf{M} = \begin{bmatrix} m_{00} & m_{01} \\ m_{10} & m_{11} \end{bmatrix}, \tag{25.11}$$

the frequency cell can be expressed as

$$-\pi \leq m_{00}\omega_0 + m_{10}\omega_1 < \pi \ \cap \ -\pi \leq m_{01}\omega_0 + m_{11}\omega_1 < \pi. \tag{25.12}$$

It is also illuminating to examine the 2-D decimator in the frequency domain. The key here is understanding the 2-D downsampling process. Suppose a signal $X(\boldsymbol{\omega})$ is downsampled with the matrix $\mathbf{M}$. The frequency-domain expression for the downsampled signal $Y(\boldsymbol{\omega})$ in terms of $X(\boldsymbol{\omega})$ is (analogous to the 1-D case)

$$Y(\boldsymbol{\omega}) = \frac{1}{J(\mathbf{M})} \sum_{\mathbf{k}\in\mathcal{N}(\mathbf{M}^T)} X(\mathbf{M}^{-\mathrm{T}}(\boldsymbol{\omega} - 2\pi\mathbf{k})), \tag{25.13}$$

where $X(\mathbf{M}^{-\mathrm{T}}\boldsymbol{\omega})$ is a "stretched" version of $X(\boldsymbol{\omega})$. For the case of the signal $X(\boldsymbol{\omega})$ shown in Figure 25.4a that undergoes quincunx downsampling, we have

$$Y(\boldsymbol{\omega}) = \frac{1}{2}X(\mathbf{Q}^{-\mathrm{T}}\boldsymbol{\omega}) + \frac{1}{2}X(\mathbf{Q}^{-\mathrm{T}}(\boldsymbol{\omega} - 2\pi\mathbf{k}_1)), \tag{25.14}$$

where $\mathbf{k}_1 = [1 \ \ 0]^{\mathrm{T}}$ is the second coset vector of $\mathbf{Q}$. Figure 25.4b shows the result after the downsampling operation. In this case, from Equation 25.10, the support for the term $X(\mathbf{Q}^{-\mathrm{T}}\boldsymbol{\omega})$ is $\boldsymbol{\omega} = \pi\mathbf{x} + 2\pi\mathbf{Q}^{\mathrm{T}}\mathbf{m}$,

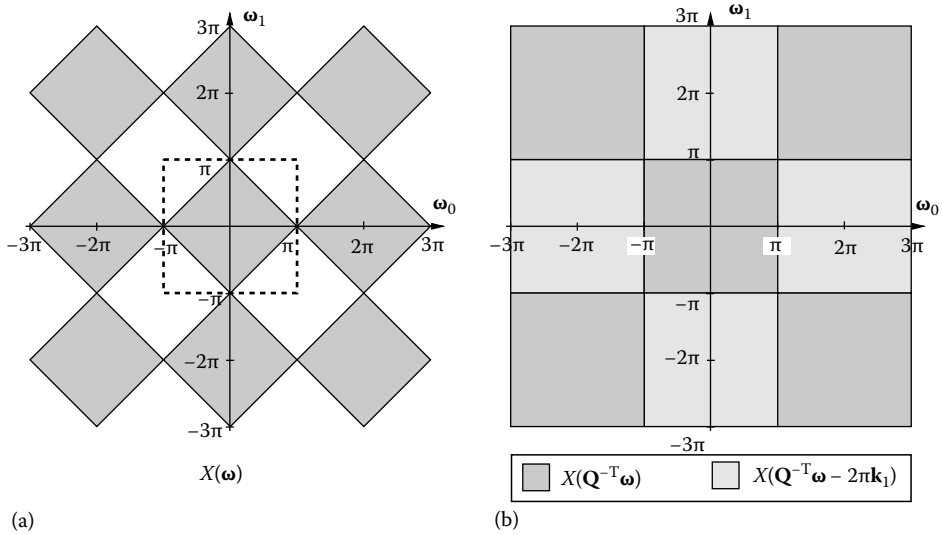

FIGURE 25.4 Effect of downsampling by $\mathbf{Q}$. (a) Diamond band limited signal. (b) The diamond region is stretched by a factor of two and rotated by 45° covering the full unit cell. The empty regions in (a) are covered by $X(\mathbf{Q}^{-\mathrm{T}}(\boldsymbol{\omega} - 2\pi\mathbf{k}_1))$.

which corresponds to the full $[-\pi, \pi)^2$ support periodically replicated with periodicity matrix $2\pi\mathbf{Q}^{\mathrm{T}}$. Hence the frequency support of $X(\boldsymbol{\omega})$ has been stretched by a factor of 2 and rotated by 45°. The complementary regions are filled by the term $X(\mathbf{Q}^{-\mathrm{T}}(\boldsymbol{\omega} - 2\pi\mathbf{k}_1))$.

25.2.3 Effect of Unimodular Matrices in the Frequency Domain

Previously, we used the unimodular matrix $\mathbf{E}$ from Equation 25.3 to modify $LAT(\mathbf{V})$. Similar properties follow for the case of resampling a discrete signal using unimodular matrices. For instance, we can modify the quincunx lattice generated by $\mathbf{Q}$ using $\mathbf{E}$ such that $LAT(\mathbf{QE})$ contains the same points as $LAT(\mathbf{Q})$ but with a different sample ordering. From Equation 25.12 the frequency support for a signal lying over $LAT(\mathbf{QE})$ is given by

$$-\pi \leq \omega_0 - \omega_1 < \pi \ \cap \ -\frac{\pi}{2} \leq \omega_0 < \frac{\pi}{2}. \tag{25.15}$$

This represents a skewing of the frequency cell associated with $LAT(\mathbf{Q})$.

25.2.4 2-D Upsamplers and Interpolators

Complementary to the decimation operation is the interpolation operation, which is composed of an upsampler followed by an anti-imaging filter. For a 2-D signal $x[\mathbf{n}]$, the upsampling operation with matrix $\mathbf{M}$ generates the signal

$$y[\mathbf{n}] = \begin{cases} x(\mathbf{M}^{-1}\mathbf{n}) & \text{if } \mathbf{n} \in LAT(\mathbf{M}), \\ 0 & \text{otherwise.} \end{cases} \tag{25.16}$$

This means that a matrix $\mathbf{M}$ with $J(\mathbf{M})$ coset vectors maps all the samples of $x[\mathbf{n}]$ to the sublattice produced by $\mathbf{k}_0$, while the remaining sublattices are populated by zeros.

The frequency domain expression for the interpolator is

$$Y(\boldsymbol{\omega}) = X(\mathbf{M}^{\mathrm{T}}\boldsymbol{\omega}), \tag{25.17}$$

which implies $Y(\omega)$ has a periodicity matrix $2\pi\mathbf{M}^{-\mathrm{T}}$, and there are $|\det \mathbf{M}|$ compressed images of $X(\omega)$ in the $[-\pi, \pi]^2$ frequency cell. Decimators and interpolators are the basic elements of multirate systems and will be used extensively in the discussions that follow.

25.3 2-D Maximally Decimated Filter Banks

A more general condition than Equation 25.10 to derive the support of the antialias filter is

$$\boldsymbol{\omega} = \mathbf{c} + \pi\mathbf{M}^{-\mathrm{T}}\boldsymbol{x} + 2\pi\mathbf{m}, \quad \boldsymbol{x} \in [-1,1)^2, \quad \mathbf{m} \in \mathcal{N}, \tag{25.18}$$

where $\mathbf{c}$ is some arbitrary constant vector. This implies there are an infinite number of possible antialiasing filter support regions for sampling matrix $\mathbf{M}$. There are, however, a few choices of $\mathbf{c}$ that are of more practical importance as our intuition can suggest.

Going back to the 1-D case, an M-channel maximally decimated filter bank requires having M nonoverlapping (ideal) filters with bandwidth $\frac{\pi}{M}$, so that the range $[-\pi, \pi)$ is completely covered by the M channels. This concept can be generalized to two dimensions by finding the nonoverlapping regions whose union covers the frequency cell $[-\pi, \pi)^2$. Such regions are obtained by choosing

$$\mathbf{c} = 2\pi\mathbf{M}^{-\mathrm{T}}\mathbf{k}, \quad \mathbf{k} \in \mathcal{N}(\mathbf{M}^{\mathrm{T}}) \tag{25.19}$$

in Equation 25.18. It is easy to show that for each of the $J(\mathbf{M})$ coset vectors $\mathbf{k}_i$, there is a different nonoverlapping frequency region. From the filter bank perspective, each of these regions can be used as the frequency-domain region for a subband whose information can be extracted with the properly designed subband filter. This concept is illustrated next with a couple of examples.

25.3.1 Diamond and Fan Filter Banks

Two popular 2-D filter banks are the diamond and fan filter banks (FFBs) shown in Figure 25.5. They form the building blocks for a broad class of directional decompositions, which we will discuss later. The diamond filter has a passband as shown in Figure 25.5a in the $[-\pi, \pi)^2$ region. These filters can provide alias-free decimation for the quincunx resampling matrix $\mathbf{Q}$. Using the corresponding coset vectors (Equation 25.8) in Equations 25.18 and 25.19, we obtain the support regions

$$\begin{aligned} \Omega_0&: \ -\pi \le \omega_0 - \omega_1 < \pi \ \cap \ -\pi \le \omega_0 + \omega_1 < \pi, \\ \Omega_1&: \ \pi \le \omega_0 - \omega_1 < 3\pi \ \cap \ -\pi \le \omega_0 + \omega_1 < \pi. \end{aligned} \tag{25.20}$$

Related to the diamond filter is the fan filter which has the passband shown in Figure 25.5b. It is identical to the diamond filter except that it is frequency shifted (either in ω_0 or ω_1) by π. We can show that fan support is a valid antialias passband for the quincunx matrix by finding the vector $\mathbf{c}$ that satisfies Equation 25.18. If we let

$$\mathbf{c}_0 = \begin{bmatrix} \pi \\ 0 \end{bmatrix}, \quad \mathbf{c}_1 = \begin{bmatrix} 0 \\ \pi \end{bmatrix},$$

we get the two fundamental complementary fan-shaped regions for $F_0(\omega)$ and $F_1(\omega)$:

$$\begin{aligned} \Omega_0&: \ 0 \le \omega_0 - \omega_1 < 2\pi \ \cap \ 0 \le \omega_0 + \omega_1 < 2\pi, \\ \Omega_1&: \ -2\pi \le \omega_0 - \omega_1 < 0 \ \cap \ 0 \le \omega_0 + \omega_1 < 2\pi. \end{aligned} \tag{25.21}$$

Again, the diamond filter bank and the FFB play a crucial role in the construction of DFBs.

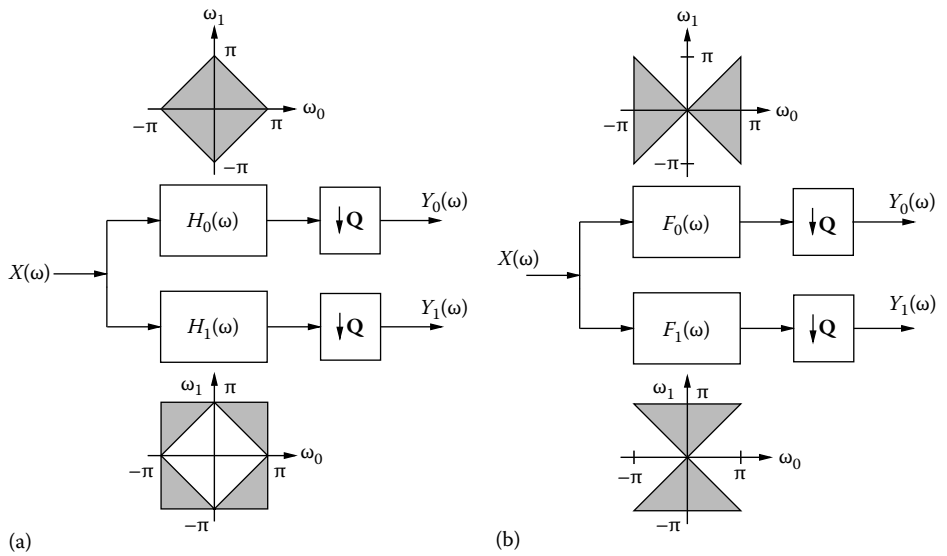

FIGURE 25.5 Block diagram for the diamond and FFBs showing the ideal support for the 2-D filters.

25.4 Bamberger Directional Filter Bank

In this chapter, we present the theory of the DFB introduced in Refs. [2,3]. The BDFB splits the frequency cell $[-\pi, \pi)^2$ into an even number of wedge-shaped regions as shown in Figure 25.6. The BDFB employs a tree-structured 2-D filter bank that diagrammatically is analogous to a 1-D tree-structured filter bank.

Using this approach, Bamberger introduced BDFBs with different numbers of subbands such as 6, 10, 18, and more [2]. However, the BDFBs that have received most attention over the years are the uniform N-stage tree structure filter banks that generate $M = 2^N$ subbands. Given the extensive number of applications in which $M = 2^N$ BDFBs are employed, we focus on this case in the reminder of this chapter.

The BDFB is implemented with a small set of well-defined building blocks, each with low computational complexity. Without loss of generality, we present the BDFB for the $M = 8 (N = 3)$ case, which achieves the frequency plane partitioning shown in Figure 25.6d. The extension to 16 bands, 32 bands, and higher follows by a straightforward extension of the tree structure. The block diagram for an eight-band BDFB analysis stage is shown in Figure 25.7. The primary building block is the two-channel FFB.

The third stage of the BDFB includes additional resampling matrices $\mathbf{U}_i$ and $\mathbf{B}_i$, which are unimodular. The matrices $\mathbf{U}_i$ resample the four subbands from the second stage to remap their frequency support to a fan-shaped region. This allows the use of the FFB on all stages. The function of the $\mathbf{B}_i$ matrices is to adjust the sampling lattice of the resulting subbands so they have a rectangular geometry (i.e., the overall sampling matrix is diagonal with a downsampling rate of M). The use of $\mathbf{U}_i$ matrices was introduced by

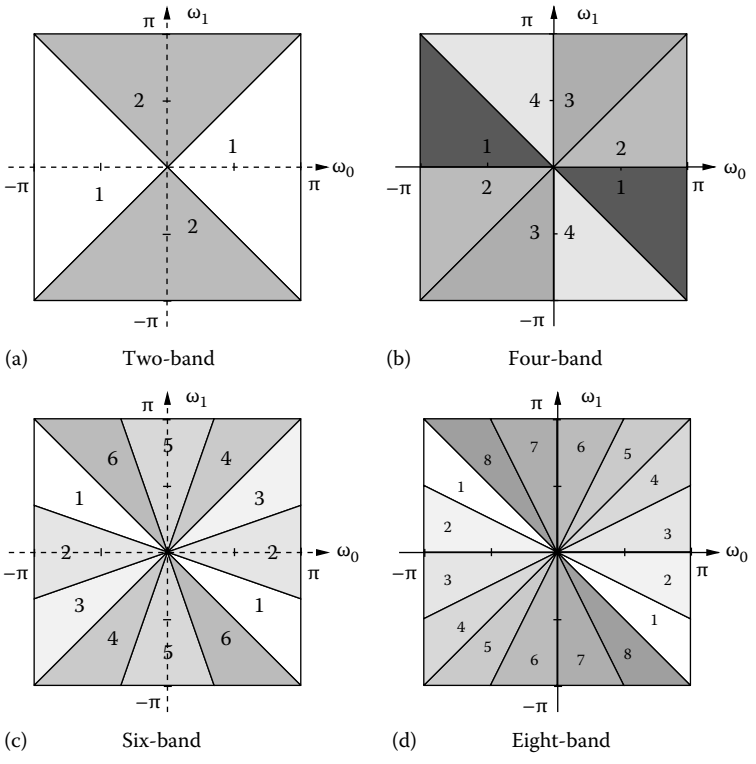

FIGURE 25.6 Frequency band partitions achieved by the BDFB. (a) Two-band. (b) Four-band. (c) Six-band. (d) Eight-band.

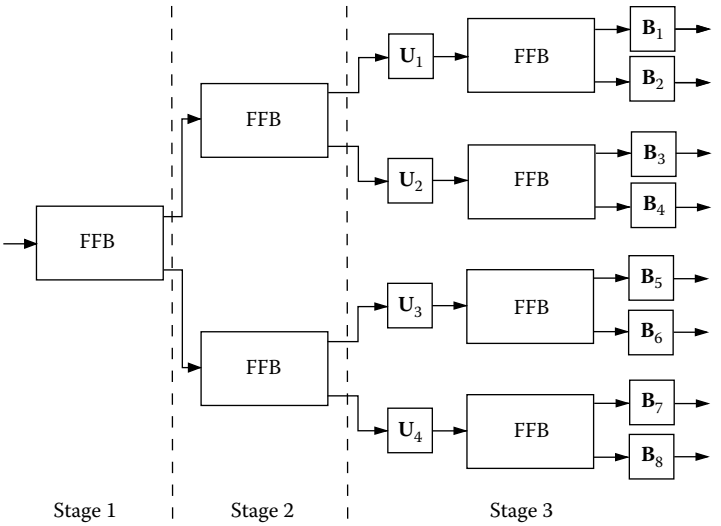

FIGURE 25.7 Implementation of an eight-band BDFB using a tree structure with FFBs and backsampling matrices.

Park et al. [10] as a way to achieve a more geometrically accurate subband representation. According to the selection rules developed in Ref. [10], we have chosen the following matrix values for $\mathbf{U}_i$:

$$\mathbf{U}_1 = \begin{bmatrix} 1 & -1 \\ 0 & 1 \end{bmatrix}, \quad \mathbf{U}_2 = \begin{bmatrix} -1 & 1 \\ 0 & 1 \end{bmatrix}, \quad \mathbf{U}_3 = \begin{bmatrix} 0 & 1 \\ -1 & 1 \end{bmatrix}, \quad \mathbf{U}_4 = \begin{bmatrix} 1 & 0 \\ -1 & 1 \end{bmatrix}. \tag{25.22}$$

Similarly, the values for the $\mathbf{B}_i$ matrices are given by

$$\begin{aligned} \mathbf{B}_1 = \mathbf{B}_2 &= \begin{bmatrix} -1 & 1 \\ 0 & -1 \end{bmatrix}, \quad \mathbf{B}_3 = \mathbf{B}_4 = \begin{bmatrix} -1 & -1 \\ 0 & 1 \end{bmatrix}, \\ \mathbf{B}_5 = \mathbf{B}_6 &= \begin{bmatrix} 1 & 1 \\ -1 & 0 \end{bmatrix}, \quad \mathbf{B}_7 = \mathbf{B}_8 = \begin{bmatrix} -1 & 1 \\ -1 & 0 \end{bmatrix}. \end{aligned} \tag{25.23}$$

A detailed stage-by-stage analysis of the BDFB structure is presented in Refs. [2,11]. Here, we analyze the BDFB by collapsing the tree structure into the M-channel parallel structure shown in Figure 25.8. Using the multirate identity that states "downsampling by $\mathbf{M}$ followed by $H(\omega)$ is equivalent to $H(\mathbf{M}^{\mathrm{T}}\omega)$ followed by downsampling by $\mathbf{M}$," it is possible to migrate all the filters in the tree structure to the left and the downsampling operations to the right of the tree structure. For instance, for an eight-band BDFB, the overall analysis filters are given by

$$G_\ell(\omega) = F_j(\omega)F_k(\mathbf{Q}_1^{\mathrm{T}}\omega)F_m(\mathbf{U}_i^{\mathrm{T}}\mathbf{Q}_2^{\mathrm{T}}\mathbf{Q}_1^{\mathrm{T}}\omega), \tag{25.24}$$

where

$j, k, m \in \{0, 1\}$
$i \in \{1, 2, 3, 4\}$
$\ell = 1, 2, \ldots, 8$

Looking at the tree structure as a binary tree, we have $\ell = j + 2k + 4m + 1$. The multiplication of the three frequency responses in Equation 25.24 results in the filters $G_\ell(\omega)$ with the wedge-shaped passbands

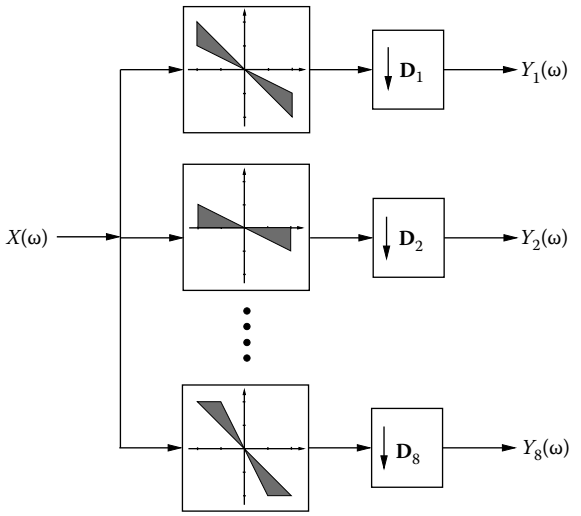

FIGURE 25.8 Parallel implementation of a maximally decimated eight-band DFB. Note that $|\det(\mathbf{D}_i)| = 8$.

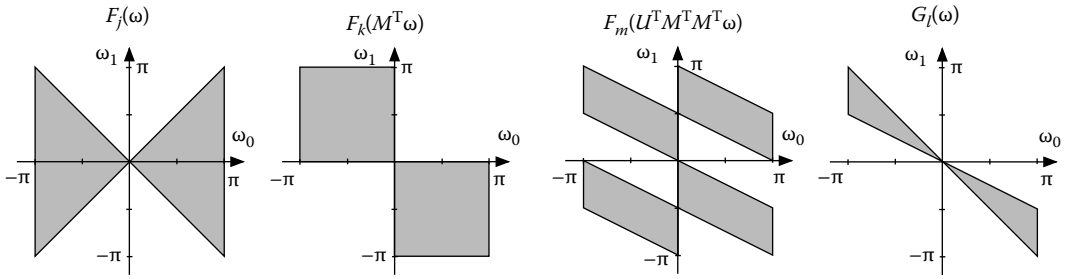

FIGURE 25.9 Illustration of the synthesis of wedge passband for an eight-band DFB. The wedge support is obtained by taking the product of the frequency responses as described by Equation 25.24.

shown in Figure 25.6d. As an illustration, Figure 25.9 shows graphically how the cascade of filters depicted in Equation 25.24 produces a wedge-shaped passband. The fan-shaped support for $F_0(\omega)$ and $F_1(\omega)$ is rotated, skewed, or scaled according to the resampling operations indicated by Equation 25.24. Analogous operations can be implemented to generate the remaining wedge filters.

Viewing the analysis tree structure as a parallel form structure, the eight-band BDFB has overall downsampling matrices given by

$$\mathbf{D}_\ell = \mathbf{Q}_1\mathbf{Q}_2\mathbf{U}_i\mathbf{Q}_3\mathbf{B}_i, \tag{25.25}$$

for $\ell = 1, 2, \ldots, 8$ and $i = \lceil \frac{\ell}{2} \rceil$. This implies that $\mathbf{D}_{2i-1} = \mathbf{D}_{2i}$. It is easy to show that $\mathbf{D}_\ell$ is diagonal with one of the following values:

$$\mathbf{C}_1 = \begin{bmatrix} 2 & 0 \\ 0 & 4 \end{bmatrix} \quad \text{and} \quad \mathbf{C}_2 = \begin{bmatrix} 4 & 0 \\ 0 & 2 \end{bmatrix}. \tag{25.26}$$

We can conclude three things from the above result:

1. Decimation ratio for all channels is $|\det(\mathbf{C}_1)| = |\det(\mathbf{C}_2)| = 8$, giving us a maximally decimated system as expected.
2. Since the $\mathbf{D}_\ell$ matrices are diagonal, the corresponding sampling grids and fundamental parallelepipeds are rectangular. We should note that this is a consequence of the judicious selection of the unimodular matrices $\mathbf{U}_i$ and $\mathbf{B}_i$. Having the data lie on a rectangular lattice makes further processing easier.
3. Half of the bands ($\ell = 1, 2, 3, 4$) are subsampled by two in the horizontal direction and by four in the vertical direction. The remaining bands ($\ell = 5, 6, 7, 8$) have the opposite structure.

For brevity we focussed on the analysis stage of the BDFB in our discussion. However, it should be noted that the same multirate concepts can be applied to the synthesis stage in an analogous manner.

The generation of BDFBs with $16, 32, \ldots, 2^N$ subbands is achieved by replicating the third stage in Figure 25.7. For an N-stage BDFB, the subbands will have an overall downsampling matrix given by

$$\mathbf{C}_1 = \begin{bmatrix} 2 & 0 \\ 0 & 2^{N-1} \end{bmatrix} \quad \text{or} \quad \mathbf{C}_2 = \begin{bmatrix} 2^{N-1} & 0 \\ 0 & 2 \end{bmatrix}.$$

In summary, we have shown how to construct directional filters using multirate operations and FFBs as building blocks. In Section 25.5, we show how to design the FFB filters, $F_0(\omega)$ and $F_1(\omega)$.

25.5 Design of 2-D Two-Channel Fan Filter Banks

Filter banks are usually designed to either satisfy aliasing-cancelation (AC) or perfect-reconstruction (PR) constraints in addition to the usual frequency response specifications. For the 2-D case, a commonly used approach for filter bank design is to derive separable filters from a 1-D systems. The typical consequence of separable filter banks is rectangular tilings of the frequency plane. Implementations of multidimensional filter banks for nonrectangular filters have been reported in the literature [8,9,12–15,58,59]. However, the resulting filters are, in general, nonseparable and require a high order to achieve good frequency selectivity. A more efficient approach is to use low-complexity FFBs. FFBs can be designed using the change-of-variable method, which involves a 1-D to 2-D mapping. Similar to separable implementations, we can take advantage of well-known 1-D filter bank design techniques. The resulting filter banks have efficient polyphase implementations that only require separable filtering operations.

25.5.1 FFB Design Using 1-D Quadrature Mirror Filters

Thus far, the BDFB theory has been developed using filters with ideal frequency responses. In practice, one designs the FFB filters to meet either AC or PR constraints while approximating good passband characteristics. Designing 2-D filter banks with diamond, fan, and other 2-D geometries has been studied by several authors [9,15–17,59,60] where different alias-free and PR 2-D filter banks have been proposed. Bamberger's approach [2] was different in that he presented a design method for FIR PR nonseparable systems using McClellan transformations. In addition, he generalized the change-of-variables scheme introduced by Ansari [18] to produce Quadrature Mirror Filter (QMF) finite impulse response (FIR) and infinite impulse response (IIR) implementations, which provides an efficient polyphase implementation. A drawback of this scheme is that the FIR implementations are not PR. More recently, Rosiles and Smith [19,20] reported the use of the ladder-based filter banks [16,17] to implement the BDFB with FIR PR filters. Ladder networks also have an efficient implementation and consequently are attractive. In this section, we discuss the QMF and ladder structure implementation of the FFB.

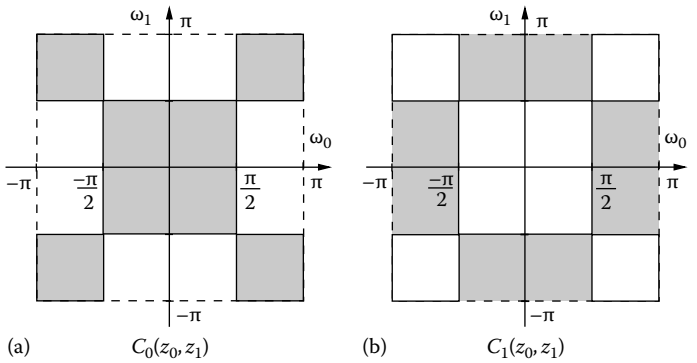

FIGURE 25.10 Ideal checkerboard magnitude responses needed for the generation of the FFB using 1-D QMFs.

The development that follows starts with the design of 2-D diamond filter banks. This system consists of two filters $H_0(\omega_0, \omega_1)$ and $H_1(\omega_0, \omega_1)$ with complementary diamond passband/stopband regions, as shown in Figure 25.5. Fan-shaped filters are obtained by a modulation operation, which in the frequency domain is expressed by $F_0(\omega_0, \omega_1) = H_0(\omega_0 - \pi, \omega_1)$ and $F_1(\omega_0, \omega_1) = H_1(\omega_0 - \pi, \omega_1)$.

The change-of-variables design method [2,18] requires the availability of a 2-D filter $C_0(\omega_0, \omega_1)$ with checker board geometry and the complementary filter $C_1(\omega_0, \omega_1)$. The required passbands and stopbands are shown in Figure 25.10. To achieve the desired filter geometries, the sampling matrix **M** with the corresponding FPD is used to apply the following change of variables in the frequency domain

$$\begin{bmatrix} \omega_0' \\ \omega_1' \end{bmatrix} = \frac{\mathbf{Q}^{\mathrm{T}}}{|\det(\mathbf{Q})|} \begin{bmatrix} \omega_0 \\ \omega_1 \end{bmatrix}. \tag{25.27}$$

For the case of diamond (and fan) filters, the quincunx matrix **Q** provides the appropriate mapping, which simplifies to $\omega_0' = (\omega_0 + \omega_1)/2$ and $\omega_1' = (\omega_1 - \omega_0)/2$. In the z-domain, we can express the change of variables as*

$$z_0 \rightarrow z_0^{\frac{1}{2}} z_1^{\frac{1}{2}} \quad \text{and} \quad z_1 \rightarrow z_0^{-\frac{1}{2}} z_1^{\frac{1}{2}}. \tag{25.28}$$

We should note that this scheme is general and works for other sampling matrices. The effect of the change of variables is to scale, rotate, and skew the passband regions of $C_0(\omega_0, \omega_1)$ and $C_1(\omega_0, \omega_1)$ to obtain the desired geometries.

To design an FFB with an efficient implementation, select a pair of 1-D prototypes that satisfy the QMF relationship

$$H_0(z) = H_1(-z). \tag{25.29}$$

It is well known that the polyphase representation for these filters is

$$\begin{aligned} H_0(z) &= E_0(z^2) + z^{-1}E_1(z^2), \\ H_1(z) &= E_0(z^2) - z^{-1}E_1(z^2). \end{aligned} \tag{25.30}$$

* In this chapter z_0 and z_1 are used to denote the 2-D z-transform complex variables.

It is easy to see that the checker board filters from Figure 25.10 can be designed from the 1-D prototypes using separable filtering operations. In the z-domain this is expressed as

$$\begin{aligned} C_0(z_0, z_1) &= H_0(z_0)H_0(z_1) + H_0(-z_0)H_0(-z_1) = 2[E_0(z_0^2, z_1^2) + z_0^{-1}z_1^{-1}E_1(z_0^2, z_1^2)], \\ C_1(z_0, z_1) &= H_0(z_0)H_1(z_1) + H_0(-z_0)H_1(-z_1) = 2[E_0(z_0^2, z_1^2) - z_0^{-1}z_1^{-1}E_1(z_0^2, z_1^2)]. \end{aligned} \tag{25.31}$$

The 2-D polyphase filters are defined as

$$\begin{aligned} E_0(z_0, z_1) &= E_0(z_0)E_0(z_1), \\ E_1(z_0, z_1) &= E_1(z_0)E_1(z_1). \end{aligned} \tag{25.32}$$

Finally, the diamond filters are obtained by applying the change of variables in Equation 25.28 to $C_0(z_0, z_1)$ and $C_1(z_0, z_1)$. This step produces the geometric transformation on the checkerboard support to obtain the desired diamond support filters. In the frequency domain, we have

$$\begin{aligned} H_0(\boldsymbol{\omega}) &= E_0(\mathbf{Q}^{\mathrm{T}}\boldsymbol{\omega}) + e^{-j\boldsymbol{\omega}^{\mathrm{T}}\mathbf{k}_1}E_1(\mathbf{Q}^{\mathrm{T}}\boldsymbol{\omega}), \\ H_1(\boldsymbol{\omega}) &= E_0(\mathbf{Q}^{\mathrm{T}}\boldsymbol{\omega}) - e^{-j\boldsymbol{\omega}^{\mathrm{T}}\mathbf{k}_1}E_1(\mathbf{Q}^{\mathrm{T}}\boldsymbol{\omega}), \end{aligned} \tag{25.33}$$

where $\mathbf{Q}$ is the quincunx matrix and $k_1 = [1\ 0]^{\mathrm{T}}$. These expressions are similar to those of Equation 25.30 for the 1-D case, implying that the filters are implementable in the polyphase domain. Moreover, the 2-D polyphase components are separable, providing a 2-D structure with low computational complexity. The resulting two-channel analysis structure is shown in Figure 25.11. The corresponding synthesis stage is analogous.

For the 1-D prototype $H_0(z)$, one can use the Johnston QMFs [21], which are aliasing-free but not PR. Another choice is to use the IIR linear phase filters proposed by Smith and Eddins in Ref. [22]. These filters have the form

$$H_0(z) = \frac{b_0 + b_1z^{-1} + b_2z^{-2} + b_2z^{-3} + b_1z^{-4} + b_0z^{-5}}{a_0 + a_1z^{-2} + a_0z^{-4}} \tag{25.34}$$

and can achieve exact reconstruction. The IIR filters are noncausal, but can be used for the case of finite length signals (like images), using forward and backward difference equations. Moreover, the implementation is very efficient, requiring only 5.1 multiplies and 5.6 adds per output sample, while achieving similar passband characteristics to that of the 32 tap Johnston QMF.

To construct fan filters, we apply the change of variables $z_0 \rightarrow -z_0$ in $H_0(z_0, z_1)$ and $H_1(z_0, z_1)$ to induce a shift by π along the ω_0-axis. Thus "off-the-shelf" QMFs can be used to generate high-quality

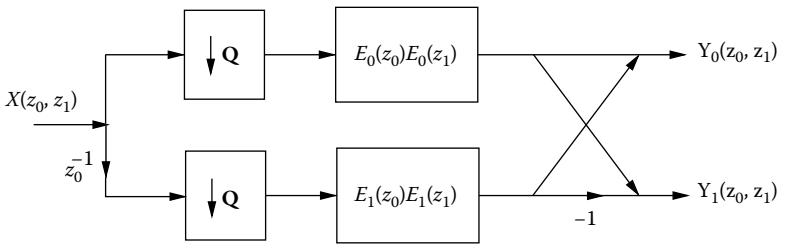

FIGURE 25.11 Efficient polyphase domain implementation of diamond filter bank. The filtering operations are separable.

fan filters. Similarly these QMFs can be applied in successive stages as discussed previously to produce directional filters. To illustrate this point, four directional filters are shown in Figure 25.12. These filters were designed using the Johnston 32D QMF, and are the constituent filters of the eight-band BDFB. Such filter banks can be used to decompose images, an example of which is shown in Figure 25.13.

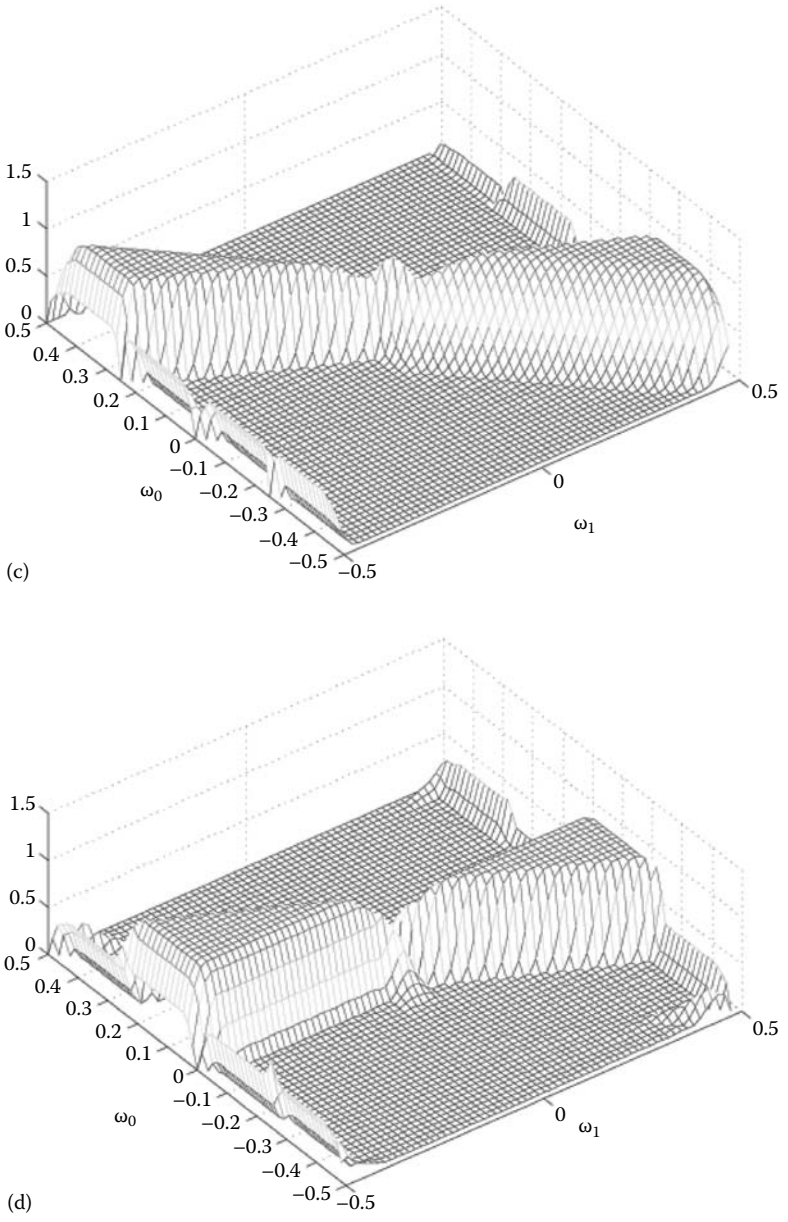

FIGURE 25.12 (continued)

25.5.2 BDFB Design Using Ladder Structures

Ladder structures (also known as lifting schemes [23]) are flexible structures for implementing filter banks and discrete wavelet transforms. The construction of wavelets is achieved by cascading simple filtering elements successively in ladder steps. The PR property is imposed structurally without the explicit need to meet the conditions used in the early PR filter bank design methodology. The construction of biorthogonal systems using ladder networks has been reported in various articles [23–25].

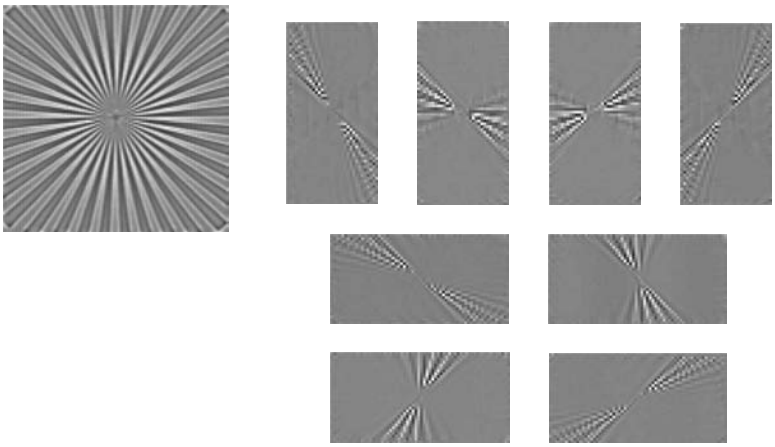

FIGURE 25.13 Example of an eight-band BDFB using a test image with localized directional structure.

Additionally, ladder structures allow straightforward implementation of nonlinear filter banks like integer-to-integer wavelet transforms [26], and adaptation to irregular sampling grids [27].

In this section, ladder structures are used as the framework for the design of digital fan-shaped filters. These structures have been explored for 2-D and multidimensional filter bank implementations [16,17,24,25,28], where the design method involves transforming a 1-D filter to a 2-D filter with a simple mapping. This 1-D to 2-D mapping was introduced by Kim and Ansari [61] and Phoong et al. [16] in the context of a two-stage ladder structure and was extended to a three-stage structure by Ansari et al. [17]. The three-stage design was shown to improve the control of filter frequency responses.

To begin, consider the 1-D case. The 1-D system is designed by constructing the analysis polyphase matrix as the product of ladder steps given by

$$\mathbf{E}(z) = \begin{bmatrix} 1 & 0 \\ -p_2\beta_2(z) & 1 \end{bmatrix} \begin{bmatrix} 1 & zp_1\beta_1(z) \\ 0 & 1/(1+p) \end{bmatrix} \begin{bmatrix} p_0 & 0 \\ -p\beta_0(z) & 1 \end{bmatrix}, \tag{25.35}$$

which generates the analysis filters

$$H_0(z) = p_0 + p_1 z\beta_1(z^2)A(-z) \quad \text{and} \quad H_1(z) = A(-z) - p_2 H_0(z)\beta_2(z^2), \tag{25.36}$$

where

$$A(z) = \frac{(1 + z\beta_0(z^2))}{1+p} \tag{25.37}$$

and the constants p_0, p_1, p_2 are given by $p_0 = p_1 = (1+p)/2$ and $p_2 = (1-p)/(1+p)$.

This 1-D filter bank structure is illustrated graphically in Figure 25.14. The inherent structure associated with ladder filters implies that the filter bank is biorthogonal and consequently the relationship between the analysis and synthesis filters is given by

$$G_0(z) = -z^{-1}H_1(-z), \quad G_1(z) = z^{-1}H_0(-z), \tag{25.38}$$

where

$H_0(z)$ and $H_1(z)$ are the analysis filters
$G_0(z)$ and $G_1(z)$ are the synthesis filters

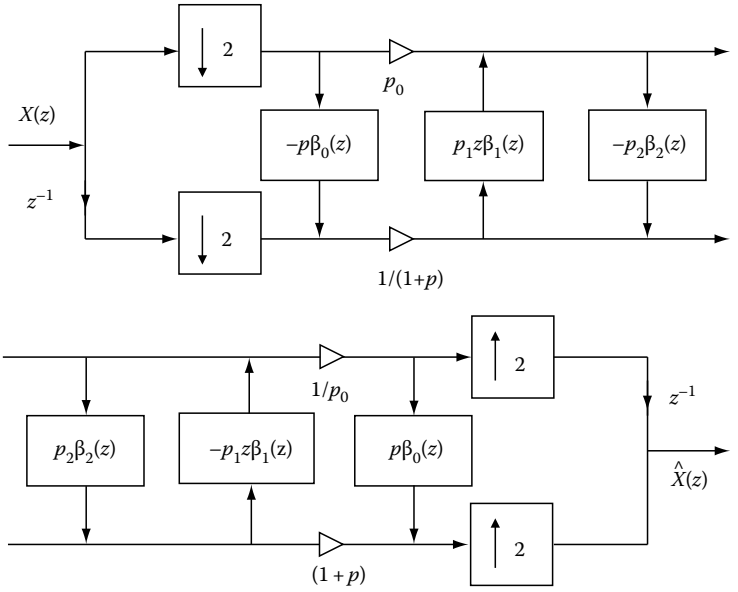

FIGURE 25.14 Analysis–synthesis ladder structure with three ladder steps, as proposed in Ref. [17].

It is easy to show that $H_0(z)$ and $G_0(z)$ are halfband filters. In order to obtain ideal lowpass filters, the following condition for the $\beta_i(z)$ functions must be met

$$\beta_i(e^{j2\omega}) = \begin{cases} e^{j(-2N+1)\omega} & \text{for} \quad 0 \le \omega \le \pi/2, \\ -e^{j(-2N+1)\omega} & \text{for} \quad \pi/2 < \omega \le \pi, \end{cases} \tag{25.39}$$

which implies $\beta_i(e^{j\omega})$ has allpass behavior. An FIR solution that approximates Equation 25.39 is obtained by designing an even length, linear phase function with a magnitude response optimized to approximate unity. This is a very simple requirement that can be satisfied with widely available filter design algorithms. It is possible to design the $\beta_i(z)$ filters separately or to choose the same function by making $\beta(z) = \beta_1(z) = \beta_2(z) = \beta_3(z)$, which significantly simplifies the design procedure. We note that $H_0(z)$ and $H_1(z)$ inherit the linear phase property of $\beta(z)$. Analysis filters obtained by approximating $\beta_i(z)$ using the Parks–McClellan algorithm with $L = 8$ are shown in Figure 25.16a. Additionally, these design constraints can be met by IIR designs, however here we focus on the FIR case [16].

Maximally flat 1-D ladder filters can be obtained using the closed-form Lagrange formula

$$v_k = \frac{(-1)^{N-k-1} \prod_{i=0}^{2N} (N + 1/2 - i)}{2(N-k)!(N-1+k)!(2k-1)}, \tag{25.40}$$

where

$N = L/2$ is the half length of $\beta(z)$

$\beta_{N-k} = \beta_{N+k-1} = v_k$ for $k = 1, 2, \ldots, N$

The maximally flat design method is relevant for the generation of regular biorthogonal wavelets.

For our purposes, the most attractive feature of ladder structures is the implementation of 2-D FFBs using a simple 1-D to 2-D change of variables. This transformation reported in Ref. [16] is applied to the entries of $\mathbf{E}(z)$ expressed in terms of lifting steps. First, the 1-D transfer function $\beta(z)$ is replaced with the

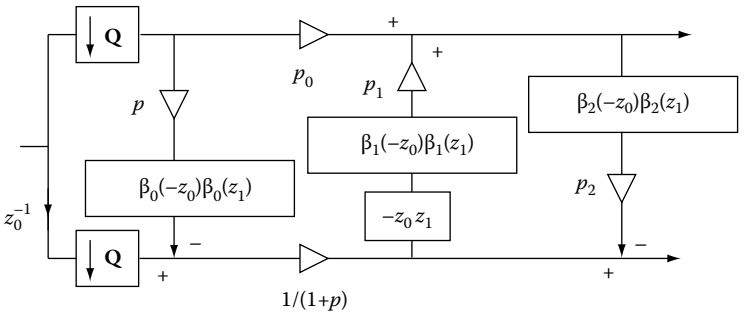

FIGURE 25.15 Ladder structure for the implementation of a 2-D two-channel biorthogonal analysis filter bank.

separable 2-D transfer function $\beta(z_0)\beta(z_1)$. Then, the 1-D delays z^{-1} are replaced with the 2-D delays $z_0^{-1}z_1^{-1}$. The resulting 2-D filters $H_0(z_0, z_1)$ and $H_1(z_0, z_1)$ have diamond-shaped support. In order to obtain the fan-shaped filters $F_0(z_0, z_1)$ and $F_1(z_0, z_1)$ the diamond filters are modulated by π letting $z_0 \rightarrow -z_0$. Following this procedure, the three-stage ladder structure from Figure 25.14 is transformed to the 2-D structure in Figure 25.15. The 2-D fan filter responses $|F_0(z_0, z_1)|$ and $|F_1(z_0, z_1)|$ obtained with this transformation are presented in Figure 25.16 using the same $\beta(z)$ function for all ladder stages.

An important property of this FFB implementation is its low computational complexity. The filtering operations can be implemented in the polyphase domain and only involve separable operations. Moreover since $\beta(z)$ is even length with linear phase, the number of multiplies per output is half the length of $\beta(z)$.

As in Section 25.5.1, the tree-structured BDFB from Figure 25.7 can be realized as a three-stage ladder FFB. The biorthogonal property is preserved by the 1-D to 2-D mapping and the resulting BDFBs have the attractive properties that (1) PR is achieved for FIR systems, (2) the filtering is separable in the polyphase domain and hence is efficient, (3) the 2-D filter quality can be controlled by a single function, (4) any 1-D filter design technique can be employed to generate $\beta(z)$, and (5) any set of

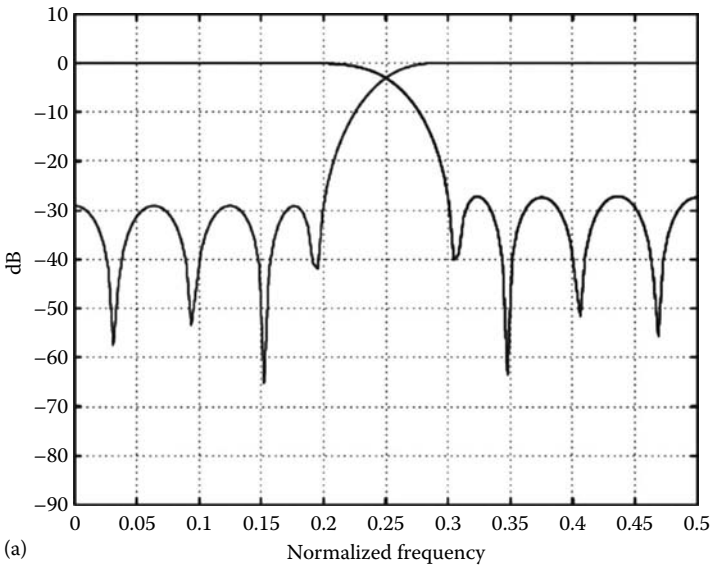

FIGURE 25.16 Magnitude response of the analysis fan filters obtained with a three-stage ladder structure. (a) Lowpass and highpass 1-D filter prototypes.

(*continued*)

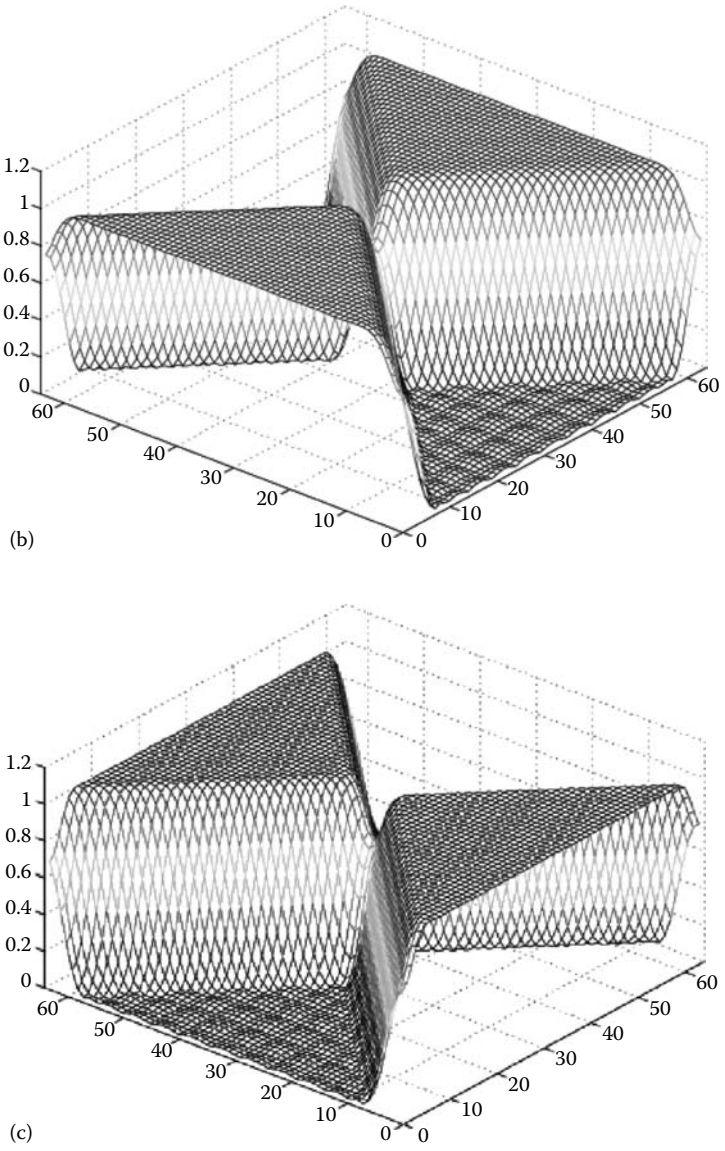

FIGURE 25.16 (continued) (b) and (c) Corresponding 2-D fan shaped filters.

biorthogonal wavelet filters can be used to implement the BDFB by factoring them into ladder steps and applying the 1-D to 2-D mapping.

25.6 Undecimated Directional Filter Bank

In many applications like pattern recognition and image enhancement, shift invariance is considered an important property. To achieve shift invariance the subbands cannot be maximally decimated. In the case of the 2-D discrete wavelet transform (DWT), shift invariance is achieved by removing the downsampling operations from the filter bank structure. This is the so-called undecimated DWT. It can be shown that PR can still be preserved under conditions of partial decimation and in the complete

absence of decimation [29]. While the undecimated representation is shift invariant, the coefficients are not decorrelated anymore. Thus, there is a trade-off.

For a number of applications it is desirable to have an undecimated version of the BDFB. A shift-invariant BDFB can be obtained from Figure 25.8 by removing the downsampling matrices D_ℓ and using the filters $G_\ell(\omega)$ as defined by Equation 25.24. This undecimated BDFB has a high computational cost since the filters are nonseparable and, in order to achieve good frequency selectivity, filters generally need to have order of 120×120 or higher. Although frequency domain implementations are possible, the boundary effects are more difficult to control.

Fortunately, there are ways to address efficiency. The BDFB tree structure from Figure 25.7 can be modified to obtain an UDFB. The derivation of the UDFB is explained in detail in Refs. [20,30]. The UDFB is obtained from the BDFB through the use of multirate identities and results in a modified tree structure. To illustrate this, the UDFB tree structure for the eight-band case is shown in Figure 25.19. In this case two building blocks are needed, the undecimated FFB (UFFB) and an undecimated checkerboard filter bank (UCFB). The UCFB is a two-channel structure with the complementary passbands and stopbands as shown in Figure 25.17.

For additional efficiency the UFFB can be implemented in a ladder structures as shown in Figure 25.18 where

$$\mathbf{Q} = \begin{bmatrix} -1 & 1 \\ 1 & 1 \end{bmatrix}.$$

The UCFB is obtained from the UFFB structure by simply removing the resampling operations in Figure 25.18. This relationship has been described in Ref. [18] where fan filters are derived from checkerboard

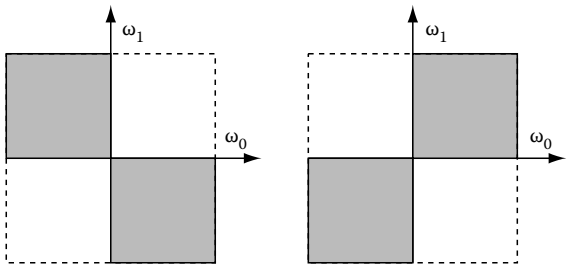

FIGURE 25.17 Ideal magnitude responses for the two-channel UCFB.

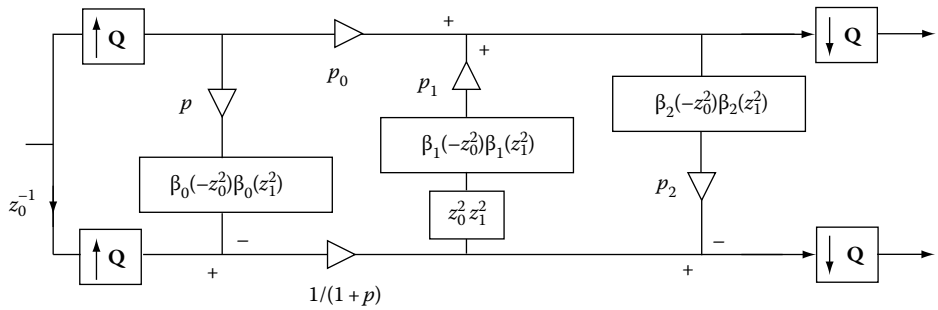

FIGURE 25.18 Ladder structure implementation for the UFFB.

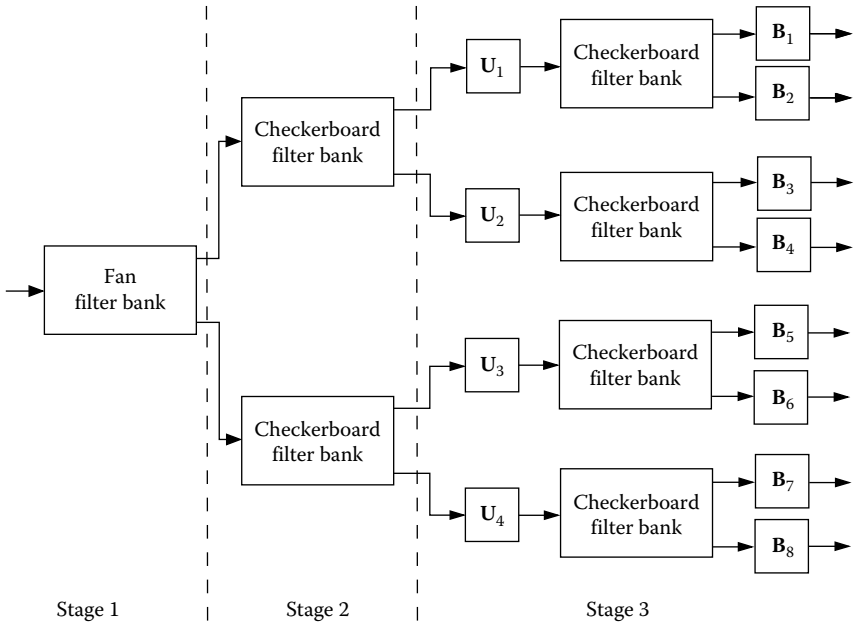

FIGURE 25.19 Implementation of an eight-band UDFB using a tree structure with UFFBs and UCFBs.

filters by a change-of-variables transformation. Finally, the filtering operations in Figure 25.18 remain separable and the $\beta_i(z)$ functions are changed to $\beta_i(z^2)$, which implies that each function has been upsampled by a factor of 2. As a result, low computational complexity of the BDFB is retained in the undecimated case.

The overall UDFB tree structure is shown in Figure 25.19. Similar to the maximally decimated case, it is possible to generate a 2^N-band UDFB by cascading UFFB and UCFB structures. The eight-band UDFB is implemented with a UFFB in the first stage and UCFBs in the remaining stages. UFFBs could be used in the third stage, but UCFBs are more efficient. As before, the third stage requires the use of unimodular resampling matrices $\mathbf{U}_i$. A possible set of matrices is given by

$$\mathbf{U}_1 = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \quad \mathbf{U}_2 = \begin{bmatrix} 1 & -1 \\ 0 & 1 \end{bmatrix}, \quad \mathbf{U}_3 = \begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix}, \quad \mathbf{U}_4 = \begin{bmatrix} 1 & 0 \\ -1 & 1 \end{bmatrix}.$$

Finally, the matrices $\mathbf{B}_i$ are used in order to reestablish a rectangular sampling geometry. In this case $\mathbf{B}_i = \mathbf{U}_i^{-1}$. An example of an eight-band UDFB decomposition is shown in Figure 25.20. Note that all the subbands have the same size and that the decomposition is shift invariant.

25.7 Bamberger Pyramids

Other image decompositions like the 2-D DWT, the steerable pyramid [31], the complex-valued wavelet transform [32], and 2-D Gabor representations [33,34] separate information across different resolutions as well as directions. This multiresolution (MR) process could be an implicit part of the decomposition (e.g., the DWT), or could be implemented as a separate structure (e.g., the steerable pyramid [31]). In the latter case, we say that the decomposition is polar-separable, implying that a radial frequency decomposition (i.e., a pyramid) is performed independently of the angular decomposition.

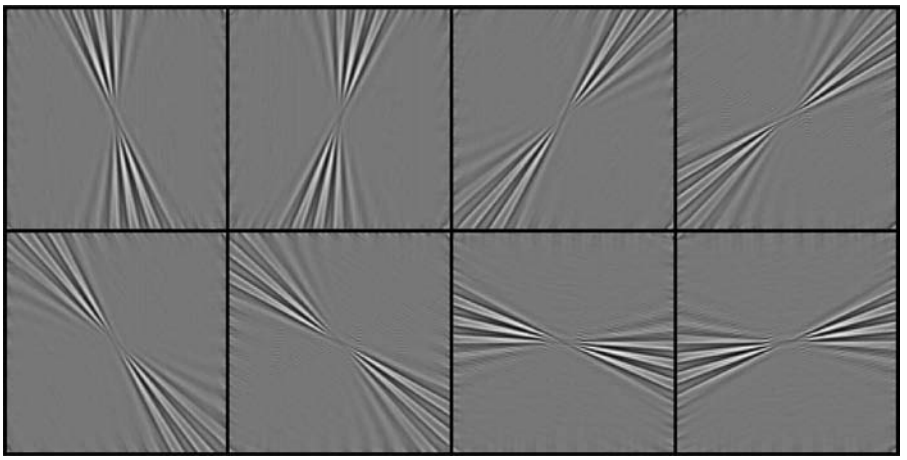

FIGURE 25.20 Example of an eight-band UDFB decomposition.

Given that many problems of interest in image processing and image analysis require MR directional analysis, extending the theory of the BDFB to polar-separable representations is desirable. As it turns out polar-separable versions of the BDFB and UDFB can be constructed and are straightforward to derive.

Different types of radial pyramids can be considered [30], but here we focus on a couple of examples associated with the BDFB. The simplest Bamberger pyramid consists of a "lowpass–highpass" decomposition. The image is first filtered with a lowpass filter $L_{\omega_c}(z_0, z_1)$ with cutoff frequency ω_c. A high frequency component is obtained by subtracting the filtered version from the original image. The resulting high frequency channel is decomposed into directional subbands using the BDFB or the UDFB, depending on the application.

Another straightforward Bamberger pyramid can be formed by combining a *J*-level Laplacian pyramid with the BDFB [4,30]. The analysis structure is presented in Figure 25.21. At the high- and mid-frequency levels the subbands can be processed with the BDFB. If required, the UDFB can be used in

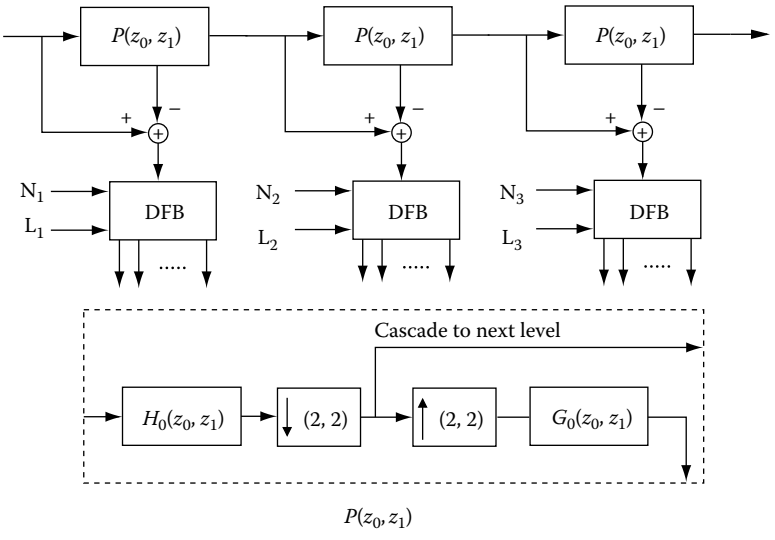

FIGURE 25.21 Bamberger pyramid using the Laplacian pyramid structure combined with the BDFB.

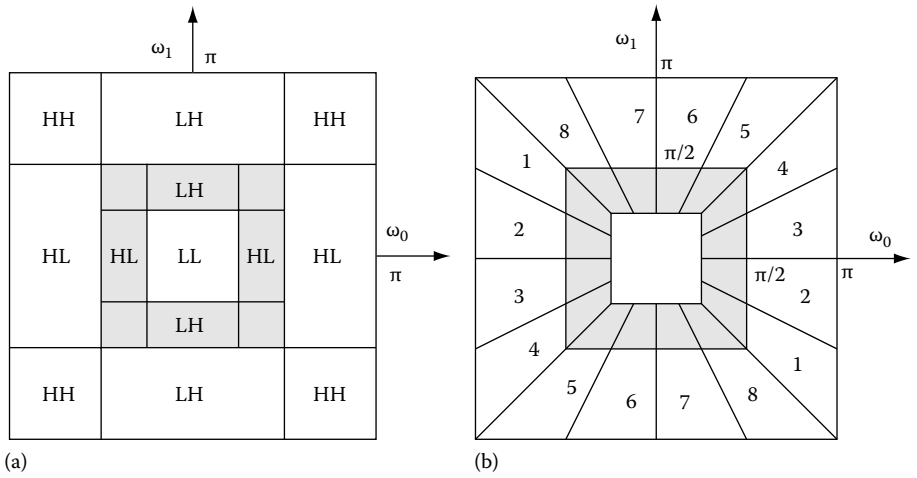

FIGURE 25.22 Comparison of the frequency plane partitioning of the 2-D separable DWT (a) and the proposed directional pyramids (b).

place of the BDFB. More generally the directional decomposition can be designed independently at each resolution. For instance, the number of subbands and the order of the $\beta_i(z)$ filters can be chosen independently. Since the polar components of Bamberger pyramids are invertible, it is easy to see that the overall system is PR.

For the maximally decimated case, the Laplacian-BDFB structure increases the data by approximately a factor of $\frac{4}{3}$. For the cases where the UDFB is used, the increase in data is significantly larger. For the case where all radial bands are decomposed into an N-band UDFB, the data increase is given by a factor of $\frac{4N}{3}$. Where shift invariance is needed at all resolutions and orientations, we can remove all downsampling operations from the Laplacian pyramid and modify the lowpass kernels resulting in $H_0(z_0^{2^j}, z_1^{2^j})$ and $G_0(z_0^{2^j}, z_1^{2^j})$ at each resolution level, where $j = 0, 1, \ldots, J-1$. When combined with the BDFB, the resulting Bamberger pyramid is overcomplete by a factor of J. If the UDFB is used, the data increases by a factor of $N(J-1)+1$.

A comparison of the frequency plane partitioning obtained with the Bamberger pyramids described above and the traditional separable 2-D DWT (and its undecimated version) is shown in Figure 25.22. The 2-D DWT has limited angular sensitivity (mixed-diagonal, horizontal, and vertical directions), while Bamberger pyramids can have 2^N directional subbands.

25.8 Applications

The BDFB has proven to be a useful tool for different problems in image processing and analysis. In this section, we present a summary of different applications reported in the literature. Detailed development and discussion is out of the scope of this work and can be obtained from the references.

25.8.1 Texture Analysis and Segmentation

Texture is an important characteristic present in many images that often contains useful information, which can be exploited in analysis applications. Multichannel methods are among the best in exploiting texture information and include Gabor decompositions, DCTs, DSTs, wavelets, wavelet packets, and dual-tree complex wavelets [35–37]. Decompositions based on the BDFB provide some of the best results for texture classification and segmentation reported in the literature [5,19,30,38,39].

Texture information is distributed across different scales and orientations according to the structural and statistical properties of the image and thus useful texture components can often be separated with a multichannel transform. A simple way to obtain a texture characterization is to measure the subband energies and form a feature vector **f**. Such feature vectors can be used in combination with a classifier or clustering algorithm for recognition or segmentation.

In texture classification the objective is to assign an unknown texture sample to a particular class within a set of known texture classes. The Bayes minimum distance classifier has been used extensively in texture classification [29,35,38,40,41]. This classifier is a supervised scheme that requires the estimation of the mean feature vector and feature covariance matrix for each class. The BDFB was evaluated for texture classification using the Brodatz data set [42] and the methodology described in Ref. [35]. BDFB-based classifiers provide some of the best results for this data set, achieving 99.62% correct classification using 10 features [30,38]. The BDFB results are comparable to the tree-structured wavelet transform and discrete sine transform reported as the best performers in Ref. [35].

In practice, classification systems have to deal with geometrical distortions like rotation. For this problem, rotation-invariant features can be attractive. Multichannel decompositions that split the frequency plane into directionally selective channels can achieve rotation invariance using a DFT-encoding step [39,43,44]. In this approach, a feature vector **f** is formed from the set of directional subbands at each resolution. Then, a DFT is computed for the features at each resolution separately. The resulting DFT coefficients are grouped in a vector **F**. A rigid texture rotation is encoded in **f** as a circular shift which in **F** is encoded as a complex exponential factor. A rotation-invariant feature set is obtained by taking the magnitude of **F** and discarding half of its components.

For instance, in Ref. [38] a Bamberger pyramid is used as the front end of a rotation-invariant classification system. The pyramid consists of an undecimated J-level Laplacian pyramid and an N-band BDFB which achieve the frequency plane partitioning shown in Figure 25.22b. A rotation-invariant feature set is obtained after applying DFT encoding to each pyramid resolution separately. Using the Bayes distance classifier, the system was tested with the data set introduced by Haley and Manjunath [41], which consists of 13 texture classes, each scanned at rotations of $0°, 30°, 60°, 90°, 120°$, and $150°$. The BDFB-based system obtained correct classification rates of 96.96% with 15 features. These results compare favorably with those reported by Haley and Manjunath [41] using a class of 2-D analytic Gabor wavelets; in their system they achieve 96.8% correct classification using a feature vector with 204 components.

Multichannel schemes have also been applied to texture segmentation. In this case a feature vector is used for each pixel in order to capture the local rather than global texture cues. A generic segmentation system is presented in Figure 25.23. The nonlinear operations are used as limiters that control the presence of outliers. For each spatial location (n, m) the local energy is estimated across all subbands. A weighted sum of squared coefficients is typically used in this step, usually composed of a squaring operation followed by a Gaussian smoothing operator. The local energy estimates are then grouped to form feature vectors. In the final step, a classifier is used to produce a segmentation map that assigns a label to each (n, m) location. Bamberger pyramids are well suited for this purpose [19,30]. A segmentation example is presented in Figure 25.24 that corresponds to an undecimated Bamberger pyramid with a redundancy factor of JN where $J = 4$ and $N = 8$. The learning vector quantization (LVQ) algorithm from Kohonen [45] was selected as the classifier following the work in Ref. [36]. The segmentation error

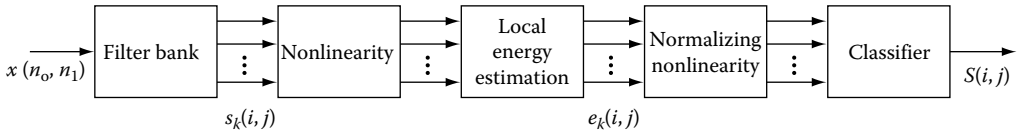

FIGURE 25.23 Classical segmentation system based on multichannel filtering.

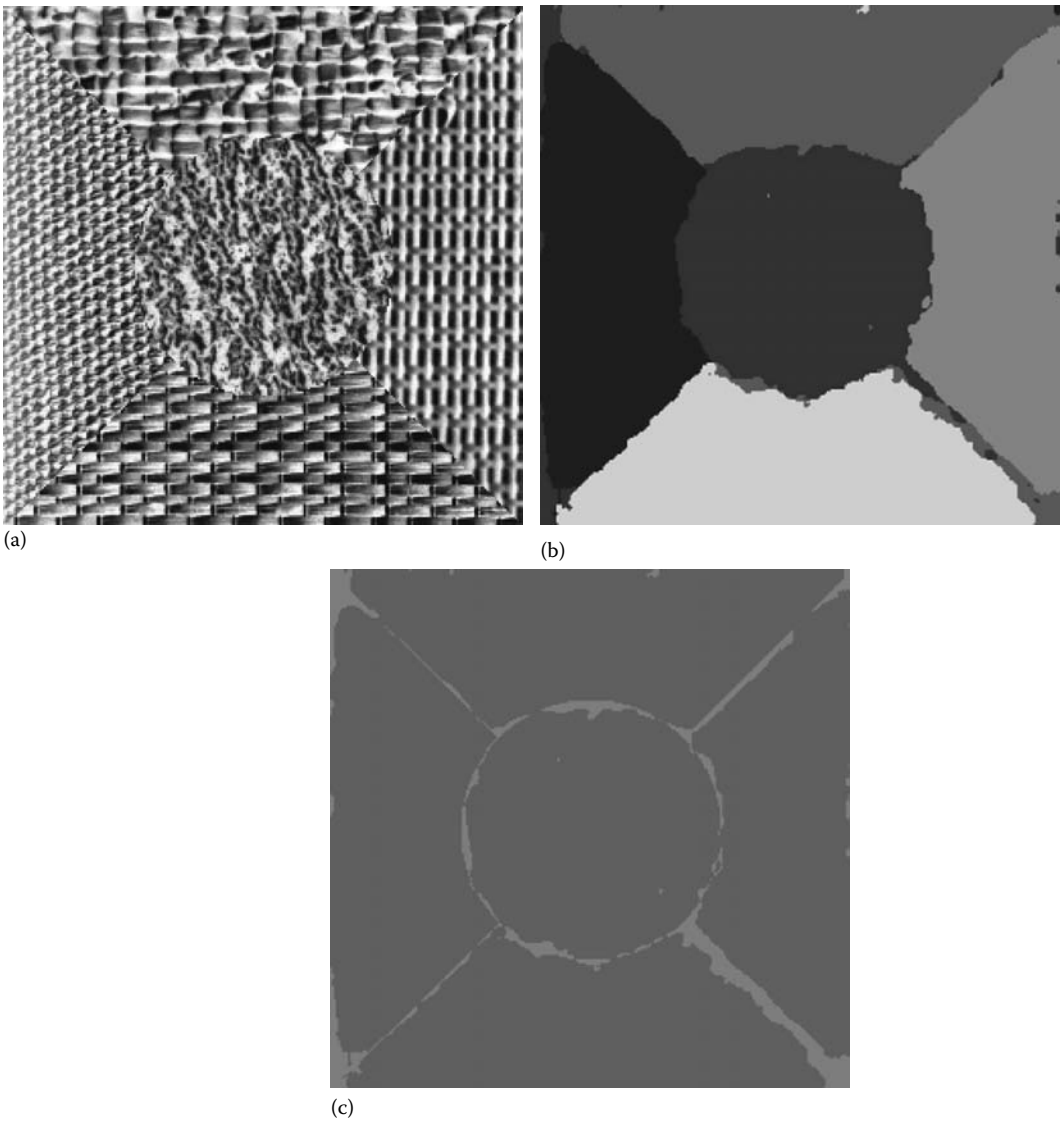

FIGURE 25.24 Example of texture segmentation using Bamberger pyramids. (a) Five texture mixture. (b) Segmentation map identifying the five texture classes. (c) Segmentation error, localized mainly along the texture boundaries.

for this example is 4.67%. A comparative study [30] showed that on average Bamberger pyramids provide the best performance compared to other multichannel decompositions like the DCT, DWT, undecimated uniform filter banks [36], and the DT-CWT [37].

25.8.2 Image Denoising Using Bamberger Pyramids

Denoising is a popular application in which wavelets have been employed. The goal in denoising is to enhance the quality of an image that has been contaminated by additive noise, often assumed to be Gaussian white noise. The basic wavelet denoising procedure consists of first decomposing the noisy image into subbands, after which each subband is processed by a subband-specific nonlinearity. In the last step, the processed subbands are recombined in a synthesis transform to reconstruct a noise

suppressed version of the noisy original. Since the forward and inverse transforms amount to an identity system, it is evident that the noise suppression can be directly attributed to the nonlinear operations performed on the subbands.

Typically, the nonlinearity is a shrinking or coring operation which takes a subband coefficient and modifies its magnitude. Small coefficients tend to be suppressed and large coefficients maintain their values. A commonly used operator for images is soft thresholding, whereby a subband coefficient $x(n_0, n_1)$ is modified to $\hat{x}(n_0, n_1) = \text{sgn}(x(n_0, n_1))(|x(n_0, n_1)| - T)$ when the coefficient magnitude is greater than T, and the coefficient is set to zero otherwise. The value of the threshold is set explicitly within each subband or adapted individually to each coefficient based on some criterion, such as energy or statistical characteristics [46,47].

This approach was first explored with maximally decimated filter banks and later with undecimated transforms. It turns out that better results are generally achieved with undecimated (shift-invariant) decompositions.

Since the Bamberger pyramid, whose decomposition is shown in Figure 25.22, provides both radial and angular subband resolution, one might imagine that it would perform well in a denoising application [47,48]. In fact such is the case as shown by the comparisons in Figure 25.25. Bamberger pyramids can provide better directional selectivity across resolutions along with shift invariance when the UDFB is used. Shown in Figure 25.25c is the denoising result for an undecimated Bamberger pyramid with frequency plane partitioning similar to the Steerable pyramid [31]. The midband pyramid levels in this particular system are decomposed with an eight-band UDFB.

For threshold selection, the spatially adaptive wavelet thresholding (SAWT) algorithm [46] was used, where a threshold is computed for each subband coefficient using local statistics under a Bayesian framework.

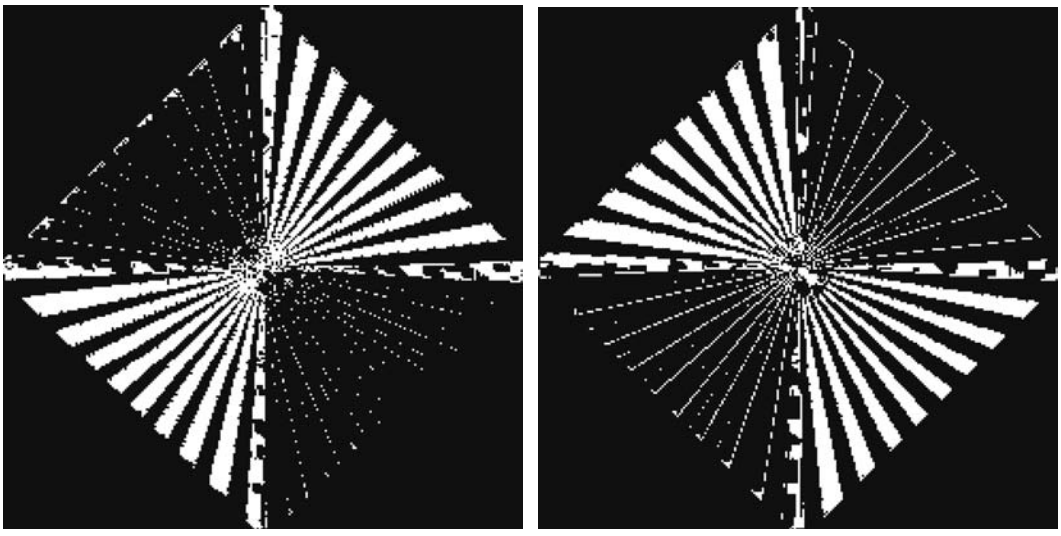
(a) (b) (c)

FIGURE 25.25 Denoising results using Lenna (a) Image with additive white Gaussian noise with $\sigma = 22.5$. (b) Denoised image using the UDWT. (c) Denoised image using Bamberger pyramids.

Also considered is a similar system using the undecimated DWT (UDWT) instead of the UDFB. The denoised image from the DWT system is shown in Figure 25.25b. Both the DWT and DFB systems have good performance as can be seen in contrast to the original image with visible additive noise shown in Figure 25.25a. Both UDWTs and DFBs are good choices for denoising applications.

25.8.3 Fingerprint Enhancement and Recognition

The analysis of fingerprint images can be a challenging problem. The obvious goal is to identify a fingerprint image as belonging to a particular individual from among a huge set of candidates. DFBs can play a role in the recognition process. Park et al. [49] proposed a new image-based fingerprint matching method that is robust to diverse rotations and translations of an input fingerprint. This scheme does not require minutiae extraction, as is the typical approach. Rather, the scheme of Park represents the fingerprint in terms of directional energies. The area within a certain radius around a reference point is used as a region of interest (ROI) for feature extraction. Fingerprint features are then extracted from the ROI using the BDFB. More specifically, the ROI for each subband is divided into blocks and directional energy values are calculated for each block. Only the blocks with dominant energy are retained, while the rest of the directional energies are set to zero, which effectively treats them as noise. As part of the matching process, rotational and translational alignments between the input and template are performed through a normalized Euclidean distance. Experimental results reported by Park et al. [49] demonstrate that the proposed DFB method has comparable verification accuracy to the other leading techniques while having faster processing speed and greater robustness to positional variation.



25.8.4 Iris Recognition

Another biometric identification system that has received attention in recent years uses iris patterns. The physiological characteristics of the iris provides a biometric difficult to modify or reproduce by synthetic methods. The work pioneered by Daugman [50] generates an iris code based on localized energy measurements of the iris texture using 2-D multiscale directional Gabor filters. As is well known the implementation of Gabor filter banks is computationally expensive and the frequency selectivity is limited. The BDFB has been explored as an alternative to Gabor filter banks. Helen Sulochana and Selvan [51] reported on a system that produces a feature vector from the BDFB subbands by dividing each subband into 9×9 blocks and calculating the energy from each block. The energies are then thresholded to form a binary iris signature. The BDFB-based system has similar performance to the leading systems, but is less complex and faster.

25.8.5 Finite-Field DFBs

BDFBs can also be applied to binary images using binary arithmetic. An important property of the ladder structure is that it allows for a straightforward implementation of nonlinear filter banks with PR. Since ladder steps are added in the analysis and subtracted in lock step in the synthesis, exact reconstruction is preserved regardless of the kind of ladder step operation being performed. Consequently nonlinear operations can be accommodated, such as quantization, rounding, rank order filtering, and so on. For instance, true integer-to-integer wavelet transforms are possible by adding rounding operations after each filtering step.

Since FFBs can be realized with ladder structures, nonlinear BDFBs can be constructed. A particular case of interest is processing bilevel or binary images with binary arithmetic. Randolph and Smith [52] reported on a binary BDFB that produces directional subbands that are also binary. To achieve binary valued subbands, a threshold is applied after filtering by $\beta(Z_0)\beta(Z_1)$ in the two-stage ladder FFB. The threshold maps negative values to zero and positive values to one. All remaining operations in the ladder

(a) (b)

FIGURE 25.26 Output of a two-channel binary BDFB. The subbands are binary valued.

structure are implemented using modulo-two arithmetic. An example of the output for a two-channel binary BDFB is shown in Figure 25.26 for a binary version of the image in Figure 25.13.

The binary BDFB has been explored in the context of printed character enhancement and character recognition. Specifically, it has been applied to rotation and scale-invariant character recognition [53] and enhancement of low-resolution documents [54,55].

25.8.6 Velocity Selective Filter Banks

Motion analysis is a critical element in video compression, object tracking, computer vision, and situation analysis. Popular approaches for analyzing motion have included optical flow and block matching techniques. An alternative, explored more recently, has been the use of velocity tuning filters where motion is determined by looking at the spatiotemporal distribution of energy along planes in the 3-D frequency domain. As objects move, they trace a trajectory in time captured by their spatial displacement from frame to frame. In Ref. [56], object trajectories have been extracted using a 3-D continuous wavelet transform (CWT). This transform can be tuned to find motion using spatial translation, temporal translation, scale, velocity magnitude, and velocity orientation. Such flexibility comes with a high computational cost. However, velocity selective filter banks (VSFB) have been reported in Refs. [11,57] that provide an attractive alternative to the oversampled CWT. The implementation boils down to a 3-D generalization of the BDFB which requires the use of full-rate or undecimated subbands. The VSFB is spatiotemporally separable meaning that the BDFB is computed for each individual frame and then subbands along a specific orientation across different frames are grouped and processed temporally using the BDFB. The VSFB produces 3-D wedges as depicted in Figure 25.27a. This wedge captures motion for objects moving along the directions over the fixed velocities captured by the temporal aperture of the wedge. The CWT is capable of additionally separating information across scales as shown in Figure 25.27b. Compared to the CWT, the VSFB is constrained to the speed and position resolutions determined by the number of directional subbands. On the other hand, its computational complexity is an order of magnitude lower than the CWT.

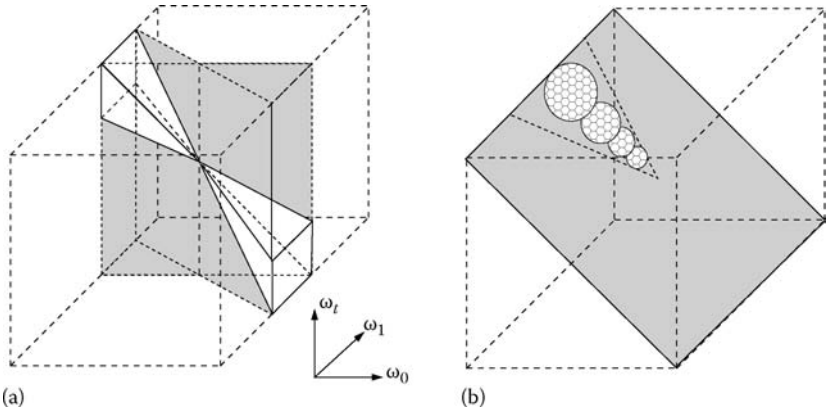


FIGURE 25.27 Comparison of the 3-D frequency supports generated by velocity tuning filters (a) VSFB (b) CWT.

25.9 Closing Remarks

DFBs have many properties that are both interesting and important. They can provide decompositions with a wide variety of angular resolutions, the filters can be designed to have good passband characteristics, and they can be designed to have exact reconstruction. Furthermore, DFBs can accommodate a range of decimation factors for the subbands, from maximally decimated to undecimated. This flexibility can be important in applications where either a compact representation is desirable, like image compression, or applications where shift invariance is deemed important, as is the case with image denoising.

This chapter is not intended as a comprehensive review of directional transforms, but rather an overview of the basic multidimensional theory, the DFB tree structure, the design and efficient implementation of the filter bank, and some applications that have been considered. The interested reader seeking a more comprehensive discussion of this material is directed to the references provided at the end of this chapter.

26.1 Introduction

Linear methods that satisfied the principle of superposition dominate current signal processing theory and practice. Linear signal processing is founded in the rich theory of linear systems, and in many applications linear signal processing methods prove to be optimal. Moreover, linear methods are inherently simple to implement, with their low computational cost, perhaps the dominant reason for their widespread use in practice. While linear methods will continue to play a leading role in signal processing applications, nonlinear methods are emerging as viable alternative solutions.

The rapid emergence of nonlinear signal processing algorithms is motivated by the growth of increasingly challenging applications, for instance in the areas of multimedia processing and communications. Such applications require the use of increasingly sophisticated signal processing algorithms. The growth of challenging applications is coupled with continual gains in digital signal processing hardware, in terms of speed, size, and cost. These gains enable the practical deployment of more sophisticated and computationally intensive algorithms. Thus, nonlinear algorithms and filtering methods are being developed and employed to address an increasing share of theoretical problems and practical applications.

A disadvantage of nonlinear approaches is that, unlike their linear counterparts, nonlinear methods lack a unified and universal set of tools for analysis and design. The lack of unifying theory has led to the

development of hundreds of nonlinear signal processing algorithms. These algorithms range from theoretically derived broad filter classes, such as polynomial and rank–order based methods [1–9], to boutique methods tailored to specific applications. Thus the dynamic growth of nonlinear methods and lack of unifying theory makes covering the entirety of such operators in a single chapter impossible. Still, large classes of nonlinear filtering algorithms can be derived and studied through fundamentals that are well founded.

The fundamental approach adopted in this chapter is that realized through the coupling of statistical signal modeling with optimal estimation-based filter development. This general approach leads to a number of well-established filtering families, with the specific filtering scheme realized depending on the estimation methodology adopted and the particular signal model deployed. Particularly amenable to filter development is the maximum likelihood estimation (M-estimation) approach. Originally developed in the theory of robust statistics [10], M-estimation provides a framework for the development of statistical process location estimators, which, when employed with sliding observation windows, naturally extend to statistical filtering algorithms.

The characteristics of a derived family of filtering operators depend not only on the estimation methodology upon which the family is founded, but also on the statistical model employed to characterize a sequence of observations. The most commonly employed statistical models are those based on the Gaussian distribution. Utilization of the Gaussian distribution is well founded in many cases, for instance due to the central limit theorem, and leads to computationally simple linear operations that are optimal for the assumed environment. There are many applications, however, in which the underlying processes are decidedly non-Gaussian. Included in this broad array of applications are important problems in wireless communications, teletrafic, networking, hydrology, geology, economics, and imaging [11–15]. The element common to these applications, and numerous others, is that the underlying processes tend to produce more large magnitude observations, often referred to as outliers or impulses, than is predicted by Gaussian models. The outlier magnitude and frequency of occurrence predicted by a model is governed by the decay rate of the distribution tail. Thus, many natural sequences of interest are governed by distributions that have heavier tails (e.g., lower tail decay rates) than that exhibited by the Gaussian distribution. Modeling such sequences as Gaussian processes leads not only to a poor statistical fit, but also to the utilization of linear operators that suffer serious degradation in the presence of outliers.

Couplings, an estimation (filtering) methodology with a statistical model appropriate for the observed sequence, significantly improves performance. This is particularly true in heavy tailed environments. As an illustrative example, consider the restoration of an image corrupted by (heavy tailed) salt and pepper noise. Typical sources of salt and pepper include flecks of dust on the lens or inside the camera, or, in digital cameras, faulty CCD elements. Figure 26.1 shows a sample corrupted image, the results of two-dimensional linear and nonlinear filtering, and the true underlying (desired) image. It is clear that the linear filter, unable to exploit the characteristics of the corrupting noise, provides an unacceptable result. On the other hand, the nonlinear filter, utilizing the statistics of the image, provides a very good result. The nonlinear filtering utilized in this example is the median, which is derived to be optimal for certain heavy tailed processes. This appropriate statistical modeling results in performance that is far superior to linear processing, which is inherently based on the processing of light tailed samples.

To formally address the processing of heavy tailed sequences, this chapter first considers sequences of samples drawn from the generalizes Gaussian distribution (GGD). This family generalizes the Gaussian distribution by incorporating a parameter that controls the rate of exponential tail decay. Setting this parameter to 2 yields the standard Gaussian distribution, while for values less than two the GGD tails decay slower than in the standard Gaussian case, resulting in heavier tailed distributions. Of particular interest is the first order exponential decay case, which yields the double exponential, or Laplacian, distribution. The Gaussian and Laplacian GGD special cases warrant particular attention due to their theoretical underpinnings, widespread use, and resulting classes of operators when deployed in an M-estimation framework. Specifically, it is shown here that M-estimation of Gaussian distributed

FIGURE 26.1 The original figure depicted in (a) is corrupted with transmission noise, the result of which is given in (b). The received image is then processed with (c) linear (mean) and (d) nonlinear (median) filters.

observations samples leads to traditional linear filtering, while the same framework leads to median filtering for Laplacian distributed samples. Thus as linear filters are optimal for Gaussian processes, the median filter and its weighted generalizations are optimal for Laplacian processes. Median type filters are more robust than linear filters and operate more efficiently in impulsive environments, characteristics that result directly from the heavy tailed characteristic of the Laplacian distribution.

Although the Laplacian distribution has a lower rate of tail decay than the Gaussian distribution, extremely impulsive processes are not well modeled as Laplacian. The GGD family, in fact, is limited in its ability to appropriately model extremely impulsive sequences due to the constraint that, while incorporating freedom in the detail decay rate, the tail decay rate is, nonetheless, restricted to be exponential. Appropriate modeling of such sequences is of critical importance, as a wide variety of extremely impulsive processes are observed in practice. Many such sequences arise as the superposition of numerous independent effects. Examples of which include radar clutter, formed as the sum of many signal reflections from irregular surfaces, the received sum of multiuser transmitted signals observed at a detector in a communications problem, the many impulses caused by the contact of rotating machinery parts in electromechanical systems, and atmospheric noise resulting from the superposition of lightning-based electrical discharges around the globe.

The superposition nature of many observed heavy tailed processes has led to the utilization of α-Stable distributions as signal models for such processes [16–19]. Indeed, the family of α-Stable distributions can be justified by the Generalized Central Limit Theorem [19–25]. Moreover, the distribution family (other than the Gaussian limiting case) possesses algebraic tales, making α-Stable modeling of heavy tailed processes more accurate than exponential tailed GGD family modeling. Although an accurate model for many heavy tailed processes, the utility of the α-Stable family is limited by the fact that only a single heavy tailed distribution in the family possesses a closed form, namely the Cauchy distribution. Thus heavy-tail focused theories and methods derived from the α-Stable family are limited, and based on a single distribution.

To overcome the drawbacks associated with GGD and α-Stable based approaches, we present methods derived from a robust extension to *M*-estimation referred to as *LM*-estimation. The *LM*-estimation formulation yields operators that are significantly more robust than traditional (GGD) *M*-estimation based methods. Moreover, *LM*-estimation is statistically related to, and derives its optimality from, the generalized Cauchy density (GCD). Utilization of GCD derived methods is particularly advantageous in that (1) the GCD is a family of distributions possessing algebraic tail decay rates and that (2) they have closed form expressions. Thus like the α-Stable family, the GCD is an appropriate model for extremely impulsive phenomena. But in contrast to the α-Stable family (and like the GGD), the GCD is a broad family of distributions that can be represented in closed form, thereby presenting a framework from which estimation and filtering procedures can be derived. Thus the GCD combines the advantages of the α-Stable and GGD families (accurate heavy tailed modeling and closed form expressions), while eliminating their respective disadvantages.

Much like the Gaussian and Laplacian distributions represent special cases of importance within the GGD, the GCD possesses several special cases that are worthy of thorough investigation. Specifically, we cover in depth the Cauchy and Meridian distribution special cases of the GCD. These distributions are coupled with the *LM*-estimation framework and shown to yield the Myriad and Meridian filtering operations [26–29]. These filtering classes are proven and shown to be significantly more robust than traditional linear, and even median, filtering. Additionally, they contain a free parameter that controls the level of robustness. This degree of freedom allows for a wide array of filtering characteristics including limiting cases that converge to traditional filtering algorithms. Specifically, the (least robust) limiting case of the Myriad filter is the traditional linear filter, while the median filter is the (least robust) limiting case of the Meridian filter. This illustrates the broad range of filtering characteristics exhibited by GCD-based methods and justifies their in-depth coverage within this chapter.

The remainder of the chapter is organized as follows. Section 26.2 introduces *M*-estimation and couples this approach with the GGD signal modeling. Particular attention is given to the Gaussian and Laplacian distribution special cases and the resulting linear and median filtering operations. The *LM*-estimation robust extension to *M*-estimation is covered in Section 26.3. The link between the GCD family and *LM*-estimation is covered along with in-depth coverage of the Myriad and Meridian special cases. Coverage includes an analysis of the filtering objective functions, limiting special cases, evaluations of properties and characteristics, as well as the presentation of optimization procedures. Applications and numerical examples illustrating and contrasting the capabilities of covered filtering methods are presented in Section 26.4. Specifically considered applications are basedband communications, recently emerging powerline communications, and highpass filtering. Finally, conclusions are drawn and future research directions noted in Section 26.5.

26.2 *M*-Estimation

To address the filtering problem, we begin by formally developing the *M*-estimation framework and the commonly employed GGD statistical model. This development allows the problem to be rigorously addressed, but also presents an intuitive approach from which filtering algorithms can be derived and understood. It is shown that combining the GGD statistical model and a special case of *M*-estimation referred to as maximum likelihood estimation (ML), results in simple norms that, among other

applications, can be used to define filtering structures. The norms are distribution specific, and we consider in depth the Gaussian and Laplacian special cases of the GGD showing that the resulting norms are the commonly utilized L_2 and L_1 metrics, respectively. Moreover, the Gaussian distribution and L_2 metric directly lead to the class of linear filters, while the Laplacian and L_1 metric correspond to the family of median filters. The difference in norm and filtering characteristics is directly dependent on the distribution tail decay rates, with those derived from the heavier detailed Laplacian distribution being more robust than those derived from light tailed Gaussian distribution.

26.2.1 Generalized Gaussian Density and Maximum Likelihood Estimation

Perhaps the most fundamental form of estimation is the problem of location estimation. While fundamentally simple, location estimation is easily extended to the filtering problem through utilization of a sliding observation window. To develop location estimation based filtering operations, we first consider the slightly more general problem of ML estimation, which was developed as a special case of *M*-estimation within the theory of robust statistics [10,30].

To establish the estimation and filtering operators, consider a set of observations (input samples), $\{x(i) : i = 1, 2, \ldots, N\}$, formed from a signal $s(i; \theta)$, with and underlying parameter of interest θ, corrupted by additive noise, i.e.,

$$x(i) = s(i; \theta) + n(i), \tag{26.1}$$

where $n(i)$ represents the additive noise samples that are distributed as $n(i) \sim f_n(\cdot)$. The assumed model is quite general, as is the *M*-estimation formulation for the underlying parameter of interest, which is stated in the following definition.

Definition 26.1: Given the set of observations $\{x(i; \theta): i = 1, 2, \ldots, N\}$, the *M*-estimate of θ is given by

$$\hat{\theta}_M = \arg\min_{\theta} \sum_{i=1}^{N} \rho(x(i) - s(i; \theta)), \tag{26.2}$$

where $\rho(\cdot)$ is defined as the cost function of the *M*-estimate.

Note that the cost function can take on many forms, and can be tailored to a particular signal model or application. One particularly simple single model is to assume that the observation samples are statistically independent. Coupling this assumption with a cost function tied directly to the statistics of the observed samples, namely $\rho(u) = -\log\{f_n(u)\}$, yields the class of ML estimators. Maximum likelihood estimators have received broad attention, and have been applied across a large array of sample distributions and to a vast number of applications.

The effectiveness of ML estimation depends on the statistical model employed in the cost function, and how well this model represents the observation sequence. The most commonly employed statistical model is the Gaussian distribution, which in its generalized density form is expressed as

$$f_{\mathrm{GGD}}(u) = \frac{\beta}{2\alpha\Gamma(1/\beta)} \exp\left\{-\left(\frac{|u|}{\alpha}\right)^{\beta}\right\}, \tag{26.3}$$

where $\Gamma(\cdot)$ is the gamma function. The parameter α determines the width of the density peak (standard deviation), while β controls the tail decay rate. Generally, α is referred to as the scale parameter while β is

called the shape parameter. The GGD can be used to model a broad range of noise processes. Moreover, taking the $n(i)$ terms in Equation 26.1 to be independent, identically distributed (i.i.d.) GGD samples yields a particularly simple form for the ML estimate of θ. That is, Equation 26.2 reduces to a compact, intuitive expression, which is given in the following theorem.

THEOREM 26.1

Consider the set of observations $\{x(i) : i = 1, 2, \ldots, N\}$ *corrupted by i.i.d. GGD distributed noise. The ML estimate of* θ *is the solution to the following minimization problem*:

$$\hat{\theta} = \arg\min_{\theta} \sum_{i=1}^{N} |x(i) - s(i;\theta)|^{\beta}. \tag{26.4}$$

This result is obtained by letting $\rho(u) = -\log\{f_{\mathrm{GGD}}(u)\}$ and substituting the result into the M-estimation expression, Equation 26.2. To appreciate this result, it is instructive to consider the range of distributions within the GGD. An intuitive appreciation of the distribution family can be obtained through the examination of two special cases, namely the Gaussian and Laplacian distributions. The Gaussian distribution is realized for $\beta = 2$. For all $\beta < 2$ cases, the resulting distributions are heavier detailed than the Gaussian distribution. This is illustrated in Figure 26.2, which shows that density function for several values of β including the Laplacian distribution special case ($\beta = 1$). The figure clearly illustrates the relationship between β and the distribution tail decay rate—decreasing β increases the tail heaviness and vice versa.

A review of the ML estimate in the GGD case, Equation 26.4, makes clear that the distribution tail decay rate directly affects the estimate. Namely, the tail decay rate defines a norm under which the estimate is formulated. Thus, the GGD corresponds directly to norms of the form $\rho(u) = |u|^{\beta}$, where

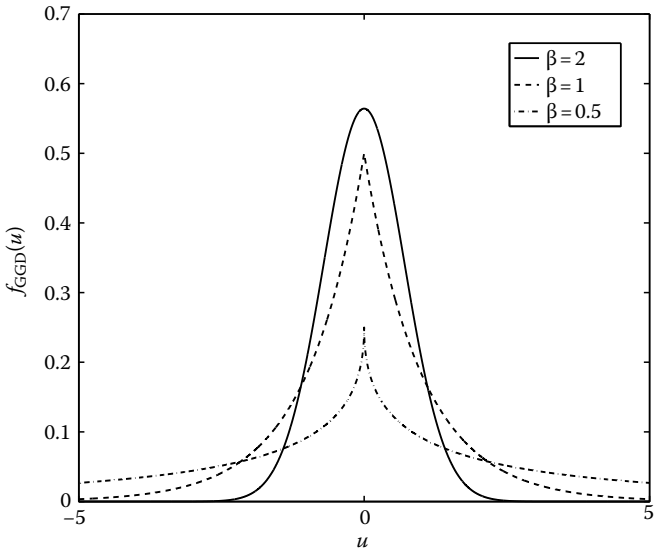

FIGURE 26.2 Generalized Gaussian density function for $\alpha = 1$ and $\beta \in \{2,1,0.5\}$. Note that the $\beta = 2$ and $\beta = 1$ cases correspond to the Gaussian and Laplacian distributions, respectively, and that the rate of the tail decay is proportional to β.

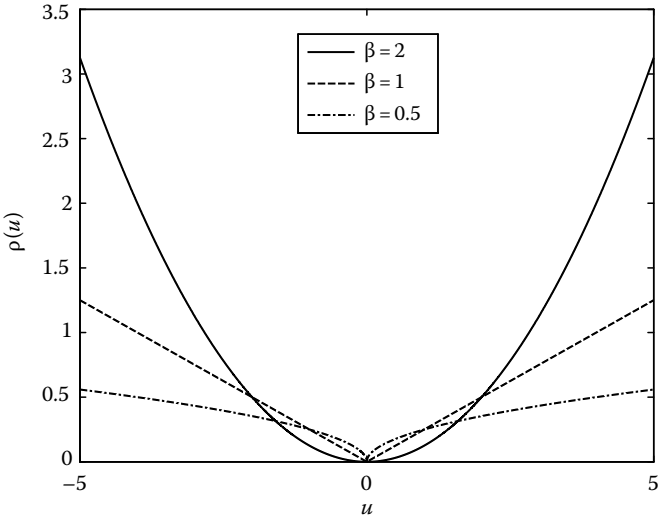

FIGURE 26.3 GCD derived $\rho(u) = |u|^{\beta}$ norms for $\beta \in \{2,1,0.5\}$. Note that the $\beta = 2,1$, and 0.5 cases correspond to the squared, absolute deviation, and fractional lower order moment formulations, respectively, and that the norm robustness is inversely proportional to β.

$\beta \in [0, 2]$. The special cases $\beta = 2$, $\beta = 1$, and $\beta < 1$ thus reduce to least-squares, least-absolute deviations, and fractional lower order moment formulations. These norms are widely applied in a range of applications including curve fitting, segmentation, filtering, and the vast majority of optimization problems. The behavior of the L_β norms, as they are sometimes referred to, is illustrated in Figure 26.3. Of note is the influence outliers have on the norms. In the $\beta = 2$ (Gaussian/L_2) case, the effect of outliers is squared, while outliers have a linear effect in the $\beta = 1$ (Laplacian/L_1) case and even less influence in the fractional lower order moment case. That is to say that as β decreases, the error norms become more robust, behavior directly linked to the prevalence of outliers in GCD distributions with small β values.

Having established the GGD family of distributions, ML estimation for the additive noise model, and the norms that arise from the GGD–ML coupling, these tools can now be applied to the development of filtering algorithms for specific distribution cases.

26.2.2 Gaussian Statistics: Linear Filtering

To directly address the filtering problem, the observed signal model in Equation 26.1 is simplified to be a direct location function of θ. This yields observation samples of the form

$$x(i) = \theta + n(i) \tag{26.5}$$

and reduces the *M*-estimation expression to simply

$$\hat{\theta}_M = \arg\min_{\theta} \sum_{i=1}^{N} \rho(x(i) - \theta). \tag{26.6}$$

This simplified observation model and estimation structure yields standard operations when combined with commonly utilized distribution models. Consider first the case in which the $n(i)$ observation noise samples are Gaussian distributed,

$$f(u) = \frac{1}{2\sigma^2} \exp\left\{ -\left(\frac{|u|^2}{2\sigma^2} \right) \right\}. \tag{26.7}$$

The following theorem addresses this case and shows that the resulting filter is a simple linear operator.

THEOREM 26.2

Consider a set of N independent samples $\{x(i) : i = 1, 2, \ldots, N\}$ *each obeying the Gaussian distribution with location* θ *and variance* σ^2*. The ML estimate of location is given by*

$$\hat{\theta} = \arg\min_{\theta} \left[\sum_{i=1}^{N} (x(i) - \theta)^2 \right] = \frac{1}{N} \sum_{i=1}^{N} x(i) = \text{mean}\{x(i) : i = 1, 2, \ldots, N\}. \tag{26.8}$$

This result follows from steps similar to those utilized in Section 26.2.1. The expression in Equation 26.8 shows clearly that the optimization criteria in this case reduces to the L_2 norm. Moreover, the resulting expression can be interpreted as a mean filtering structure, $y = 1/N \sum_{i=1}^{N} x(i)$, where y denotes the filter output. Windowing of the observation sequence can be used to form sliding observation sets, yielding an indexed output $y(i)$ and making the filtering operation explicit.

Although the results of the previous theorem can be interpreted as yielding a filtering operation, the realized operation is somewhat limited in that it does not utilize weights to control the characteristics of the filter. This is a direct result of the somewhat restrictive i.i.d. assumption imposed in the theorem. Fortunately, the identically distributed constraint can be relaxed. This results in a more general signal model and yields a more traditional linear filtering structure that incorporates sample weighting.

THEOREM 26.3

Consider a set of N independent samples $\{x(i) : i = 1, 2, \ldots, N\}$ *each obeying the Gaussian distribution with common location* θ *and (possibly) different variances* $\sigma^2(i)$*. The ML estimate of location is given by*

$$\hat{\theta} = \arg\min_{\theta} \left[\sum_{i=1}^{N} \frac{1}{\sigma^2(i)} (x(i) - \theta)^2 \right] = \frac{\sum_{i=1}^{N} h(i)x(i)}{\sum_{i=1}^{N} h(i)} \stackrel{\Delta}{=} \text{mean}\{h(i) \cdot x(i) : i = 1, 2, \ldots, N\}, \tag{26.9}$$

where $h_i = 1/\sigma^2(i) > 0$.

This is simply a linear filtering structure, $y = \sum_{i=1}^{N} \tilde{h}(i)x(i)$, where the $\tilde{h}(i) = h(i)/\sum_{i=1}^{N} h(i)$ terms are the normalized filter weights. As derived in this development, the weights are inversely proportional to individual sample variances. This is an intuitive result, as samples with high variability will be given small weight and have minimal influence on the result. The positivity constraint, however, restricts the resulting operators to the class of smoothers. In practice, this constraint is relaxed enabling the resulting class of linear finite impulse response (FIR) filters to employ both positive and negative weights that provide a wide array of spectral characteristics.

26.2.3 Laplacian Statistics: Median Filtering

The ML-based filter development can be extended to any distribution within the GGD, or, in fact, any valid distribution. Although not all distributions yield compact filtering expressions, specific special cases do correspond to simple, effective filtering structures. To derive such a structure that is more robust to

sample outliers than the Gaussian distribution optimal linear filter, consider the heavier tailed Laplacian distribution ($\beta = 1$) special case of the GGD,

$$f(u) = \frac{1}{2\sigma} \exp\left\{ -\left(\frac{|u|}{\sigma} \right) \right\}. \tag{26.10}$$

The following theorem shows that the median filter is the optimal operator for Laplacian distributed samples.

THEOREM 26.4

Consider a set of N independent samples $\{x(i) : i = 1, 2, \ldots, N\}$ *each obeying the Laplacian distribution with common location* θ *and variance* σ^2*. The ML estimate of location is given by*

$$\hat{\theta} = \arg\min_{\theta} \left[\sum_{i=1}^{N} |x(i) - \theta| \right] = \text{median}\{x(i) : i = 1, 2, \ldots, N\}. \tag{26.11}$$

The arguments utilized previously, with the appropriate distribution substitution, prove the result. The expression in Equation 26.11 shows that, in this case, the optimization criteria reduces to the more robust L_1 norm. Moreover, the resulting expression is simply a median filter structure, $y = \text{median}\{x(i) : i = 1, 2, \ldots, N\}$, where y denotes the filter output. This operation is clearly nonlinear as the output is formed by sorting the observation samples and taking the middle, or median, value as the output.*

Similarly to the mean filtering case, the median filtering operation can be generalized to admit weights. The theoretical motivation for this generalization is, like in the previous case, the relaxation of the identically distributed constraint placed on the observation samples in the above theorem.

THEOREM 26.5

Consider a set of N independent samples $\{x(i) : i = 1, 2, \ldots, N\}$ *each obeying the Laplacian distribution with common location* θ *and (possibly) different variances* $\sigma^2(i)$*. The ML estimate of location is given by*

$$\hat{\theta} = \arg\min_{\theta} \left[\sum_{i=1}^{N} \frac{1}{\sigma^2(i)} |x(i) - \theta| \right] = \text{median}\{h(i) \diamond x(i) : i = 1, 2, \ldots, N\}. \tag{26.12}$$

where $h_i = 1/\sigma^2(i) > 0$ *and* $\diamond$ *is the replication operator defined as* $h(i) \diamond x(i) = \overbrace{x(i), x(i), \ldots, x(i)}^{h(i)\text{times}}$.

The weighting operation in this case is achieved through repetition, rather than the scaling employed in the linear filter. But like the linear case, sample weights are inversely proportional to the sample variances, indicating again that samples with large variability contribute less to the determination of the output than well behaved (smaller variance) samples. This magnitude relationship between a sample's weight and its influence holds even for the relaxed case of positive and negative weights. This relaxation on the weights employs sign coupling and enables a broader range of filtering characteristics to be realized by weighted median (WM) filters [31]:

$$y = \text{median}\{|h(i)| \diamond \text{sgn}(h(i))x(i) : i = 1, 2, \ldots, N\}, \tag{26.13}$$

* For cases in which the number of observation samples is an even number, the median value is set as the average of the two central samples in the ordered set.

where

$$\text{sgn}(x) = \begin{cases} 1 & \text{if } x > 0, \\ 0 & \text{if } x = 0, \\ -1 & \text{if } x < 0. \end{cases} \tag{26.14}$$

Considerable analysis is available in the literature on the detail preservation and outliers rejection characteristics of WM filters [8,31–36].

To contrast the performance of linear and WM filters, consider the simple problem of running (constant) location estimation from noisy measurements. Figure 26.4 shows such an example for two noise processes, Laplacian and α-Stable distributed samples. The Laplacian distribution is within the

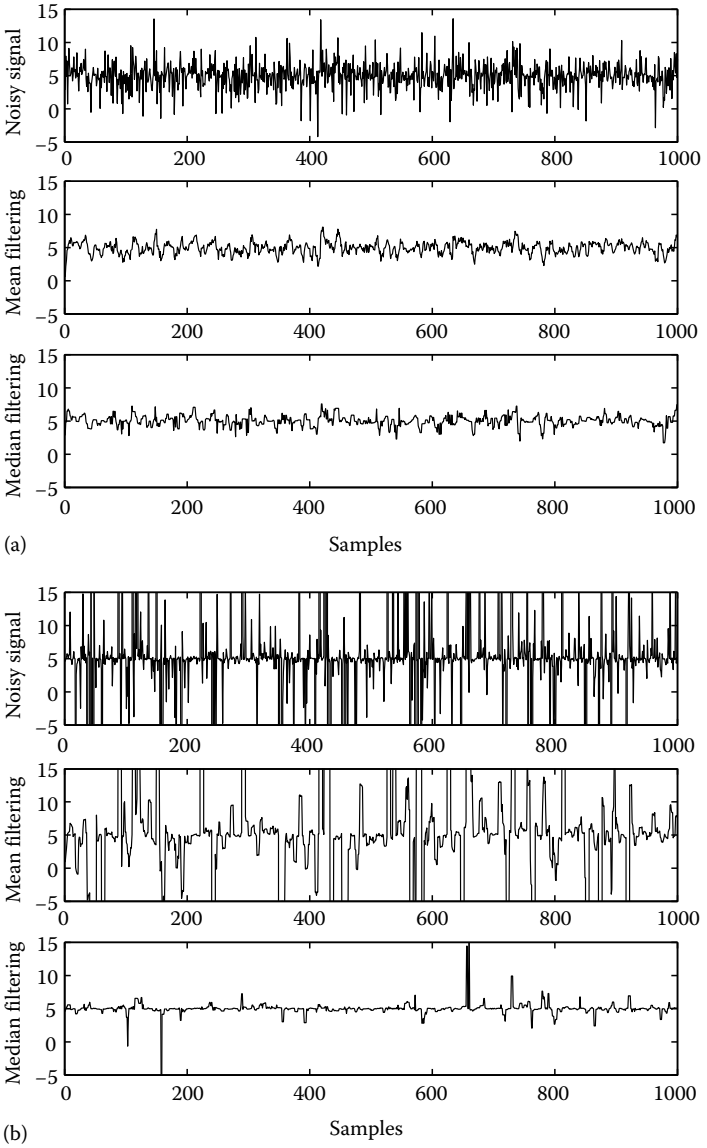

FIGURE 26.4 Constant signal corrupted with (a) Laplacian and (b) α-Stable noise ($\alpha = 0.5$) processed with mean and median filters.

GGD family, and as such the linear and WM filters perform well in this case, with the Laplacian noise optimal WM returning the best performance. The α-Stable distribution, however, has significantly heavier tails and both linear and WM filters breakdown in this environment. This indicates that GGD-based methods are not well suited to extremely impulsive environments, and that more sophisticated methods for addressing samples characterized by very heavy (algebraic) tailed distributions must be developed and employed.

26.3 *LM*-Estimation

Many contemporary applications contain samples with very heavy tailed statistics including the aforementioned powerline communications, economic forecasting, network traffic processing, and biological signal processing problems [15,37–44]. The GGD family of distributions, while representing a broad class of statistics with varying tail parameters, is, nevertheless, restricted to distributions with an exponential rate of tail decay. Distributions with exponential rates of tail decay are generally considered light tailed, and do not accurately model the prevalence or magnitude of outliers in true heavy-tailed processes. Such processes are often modeled utilizing the α-Stable family of distributions [16–19]. While α-Stable distributions do possess tails with algebraic decay rates, and are thus appropriate models for impulsive sequences, the distribution lacks a full-family closed form expression and it is therefore not easily coupled with estimation techniques such as ML.

To overcome the drawbacks of GGD and α-Stable-based techniques, we derive a generalization of the *M*-estimation framework that exhibits a spectrum of optimality characteristics including greater robustness. This generalization is referred to as *LM*-estimation, the general form of which is given in the following definition.

Definition 26.2: Given the set of independent observations $\{x(i) : i = 1, 2, \ldots, N\}$ formed as $x(i) = s(i;\theta) + n(i)$, the L*M*-estimate of θ is defined as

$$\hat{\theta}_{LM} = \arg\min_{\theta} \sum_{i=1}^{N} \log\{\delta + \rho(x(i) - s(i;\theta))\}, \tag{26.15}$$

where $\delta > 0$ and $\rho(\cdot)$ are the robustness parameter and cost function, respectively.

In the following, we show that *LM*-estimation is statistically related to the GCD. The GCD family consists of algebraic detailed distributions with closed form expressions, and is therefore an appropriate model for heavy tailed sequences and a family from which estimation and filtering techniques can be derived. We consider GCD and *LM*-estimation based filters, focusing on the Cauchy and Meridian distribution special cases and their resulting filter structures. Properties of the filters are detailed along with optimization procedures. While the GGD-based results are well established and reported in numerous works, the *LM*-estimation and GCD material presented represents the newest developments in this area, and as such proofs for many results are included.

26.3.1 Generalized Cauchy Density and Maximum Likelihood Estimation

As the previous section covering GGD-based methods shows, the robustness of error norms, estimation techniques, and filtering algorithms derived from a density is directly related to the density tail decay rate. The robustness of *LM*-estimation derives from its statistical relation to the GCD. The GCD function is defined by

$$f_{\mathrm{GCD}}(u) = \frac{\lambda\Gamma(2/\lambda)}{2[\Gamma(1/\lambda)]^2} \frac{\nu}{(\nu^{\lambda} + |u|^{\lambda})^{2/\lambda}}. \tag{26.16}$$

As in the GGD case, ν is referred to as the scale parameter while λ is called the shape parameter.

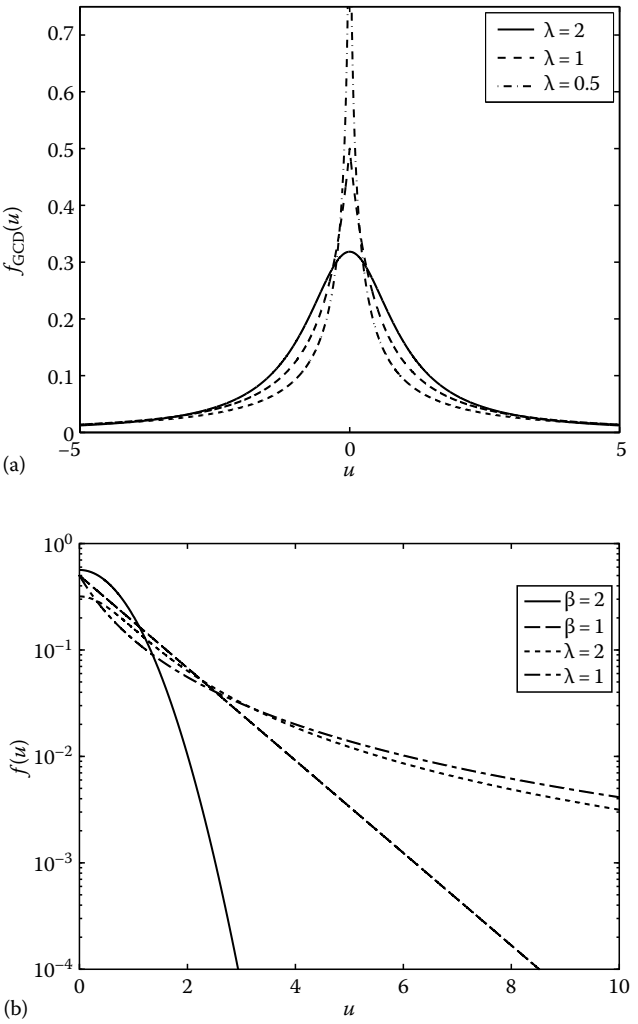

FIGURE 26.5 (a) GCD function for $\nu = 1$ and $\lambda \in \{2,1,0,5\}$; and (b) enlarged tail function for select GGD and GCD distributions.

The Generalized Cauchy distribution was first proposed by Rider in 1957 [45], and "rediscovered" under a different parametrization by Miller and Thomas in 1972 [14]. Distributions within the GCD family have algebraically decaying tails and are thus appropriate models of impulsive sequences. Indeed, the GCD is used in several studies of impulsive radio noise [14,46,47]. Of note within the GCD family are two special cases, namely the Cauchy and Meridian distributions that are realized for $\lambda = 2$ and $\lambda = 1$, respectively [8,28,29]. The GCD is depicted in Figure 26.5a for the $\lambda \in \{2,1,0.5\}$ cases, all with $\nu = 1$. The slow rate of GCD tail decay, which is inversely proportional to λ, is clearly seen in the figure. To make plain the difference in GGD and GCD tail decay rates, Figure 26.5b plots enlargements of tail sections from distributions in each family.

The utility of a heavy-tailed distribution family defined by closed forum expressions is that it can readily be applied in ML estimation, as detailed for the GCD in the following theorem.

THEOREM 26.6

Consider the set of observations $\{x(i) : i = 1, 2, \ldots, N\}$ *corrupted by i.i.d. GCD distributed noise. The ML estimate of* θ *is the solution to the following minimization problem:*

$$\hat{\theta} = \arg\min_{\theta} \sum_{i=1}^{N} \log\{\nu^{\lambda} + |x(i) - s(i;\theta)|^{\lambda}\}. \tag{26.17}$$

Proof: The ML estimate is defined by

$$\hat{\theta} = \arg\max_{\theta} \prod_{i=1}^{N} f_x(x(i)). \tag{26.18}$$

Substituting the GCD expression and denoting $C(\lambda) = \lambda\Gamma(2/\lambda)/(2[\Gamma(1/\lambda)]^2)$ yields

$$\hat{\theta} = \arg\max_{\theta} \prod_{i=1}^{N} C(\lambda) \frac{\nu}{(\nu^{\lambda} + |x(i) - s(i;\theta)|^{\lambda})^{2/\lambda}}. \tag{26.19}$$

Taking the natural $\log\{\cdot\}$ and noting that $C(\lambda)$ and ν are constant with respect to the maximization of θ gives

$$\hat{\theta} = \arg\max_{\theta} \sum_{i=1}^{N} -\frac{2}{\lambda} \log\{\nu^{\lambda} + |x(i) - s(i;\theta)|^{\lambda}\}. \tag{26.20}$$

Finally, noting that maximizing $g(u)$ is equivalent of minimizing $-g(u)$, and that $2/\lambda$ is constant with respect to θ, gives the desired result.

This theorem shows that the ML estimate for GCD distributed samples is simply a special case of LM estimation. Comparing Equations 26.15 and 26.17 shows the equivalence holds for $\rho(\cdot) = |\cdot|^{\lambda}$ and $\delta = \nu^{\lambda}$. Thus LM estimation is a more general framework, but one that derives its optimality from GCD–ML estimation. Moreover, *M*-estimation is a (least robust) limiting case of *LM*-estimation, as is shown in the following proposition. This theorem utilizes the somewhat simplified case of location estimation (i.e., $s(i;\theta) = \theta$), which we again consider from this point forward as it is most directly related to filter development.

PROPOSITION 26.1

The LM-estimator reduces to an M-estimator as δ *tends to infinity, i.e.*,

$$\lim_{\delta\to\infty} \hat{\theta}_{LM} = \arg\min_{\theta} \sum_{i=1}^{N} \rho(x(i) - \theta) \tag{26.21}$$

with cost function $\rho(\cdot)$.

Proof: Utilizing the properties of arg min and log functions, we have the following equalities

$$\lim_{\delta\to\infty} \hat{\theta}_{LM} = \lim_{\delta\to\infty} \arg\min_{\theta} \sum_{i=1}^{N} \log\{\delta + \rho(x(i) - \theta)\} \tag{26.22}$$

$$= \lim_{\delta\to\infty} \arg\min_{\theta} \sum_{i=1}^{N} \log\left\{1 + \frac{\rho(x(i)-\theta)}{\delta}\right\} + \log\{\delta\} \tag{26.23}$$

$$= \lim_{\delta\to\infty} \arg\min_{\theta} \sum_{i=1}^{N} \log\left\{1 + \frac{\rho(x(i)-\theta)}{\delta}\right\} \tag{26.24}$$

$$= \lim_{\delta\to\infty} \arg\min_{\theta} \sum_{i=1}^{N} \delta \log\left\{1 + \frac{\rho(x(i)-\theta)}{\delta}\right\} \tag{26.25}$$

$$= \lim_{\delta\to\infty} \arg\min_{\theta} \sum_{i=1}^{N} \log\left\{1 + \frac{\rho(x(i)-\theta)}{\delta}\right\}^{\delta}. \tag{26.26}$$

Applying the fact that

$$\lim_{\delta\to\infty} \log\left\{1 + \frac{u}{\delta}\right\}^{\delta} = u \tag{26.27}$$

yields the desired result.

The fact that *M* estimation is a limiting case of *LM* estimation indicates that the latter is a more general family of estimators and that methods derived under this framework are, consequently, more general and subsume those emanating from *M* estimation. Thus, *LM* estimation based methods are inherently more efficient than (or at least equally efficient to) *M* estimation based methods. It should also be recalled that in the *LM* estimation definition, Equation 26.15, δ is referred to as the robustness parameter. Thus the above shows equality between *LM* and *M* estimation at the robustness limit. It is easy to see that this is the least robust limit of *LM* estimation. To make this plain, consider the error norm defined by the GCD in case of Equation 26.15, which can be expressed in simplified form as

$$\rho(u) = \log\left\{1 + \frac{|u|^{\lambda}}{\delta}\right\}^{\delta}. \tag{26.28}$$

Figure 26.6 plots this norm, showing the effects of varying δ and λ. The impact of δ on robustness is clear, justifying the naming of this parameter and indicating that the $\delta \to \infty$ case is indeed the least robust case. Also evident is the greater robustness of GCD norms over their GGD counterparts, with equality occurring at the limit point (up to a scaling factor). Having established *LM* estimation and the related GCD norms, these tools are now employed to develop filtering algorithms that arise from the consideration of specific distribution cases, namely the Cauchy and Meridian distributions.

26.3.2 Running Myriad Smoothers: Myriad Filtering

Consider first the Cauchy distribution special case ($\lambda = 2$). The following theorem sets the sample myriad as the optimal estimate of location for samples obeying this distribution.

THEOREM 26.7

Consider a set of N independent samples $\{x(i) : i = 1, 2, \ldots, N\}$ *each obeying the Cauchy distribution with common location* θ *and scale* γ*. The ML estimate of location, or sample myriad, is given by*

$$\hat{\theta} = \arg\min_{\theta} \left[\sum_{i=1}^{N} \log\{\gamma^2 + (x(i)-\theta)^2\}\right] = \text{myriad}\{x(i) : i = 1, 2, \ldots, N; \gamma\}, \tag{26.29}$$

where γ *is the linearity parameter.*

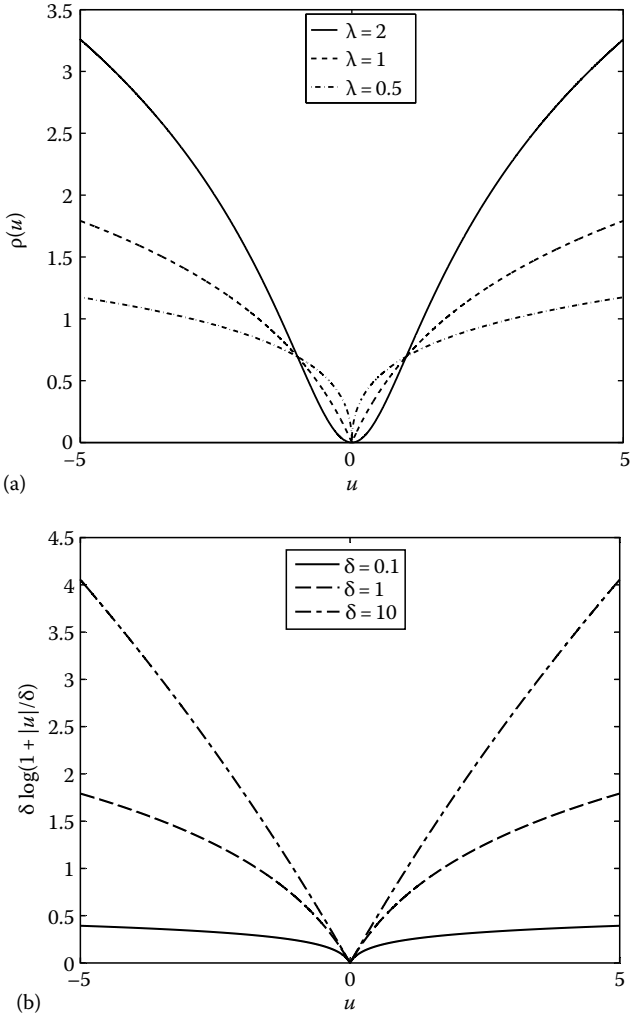

FIGURE 26.6 The error norms defined by the GCD function for (a) $\lambda \in \{0.5,1,2\}$ with $\delta = 1$ and (b) $\lambda = 1$ and $\delta \in \{0.1,1,10\}$.

Note the slight change in notation, γ replacing ν, which we employ to be consistent with the literature [26–28]. Also, the reference to γ as the linearity parameter is made clear in subsequent properties. An appreciation of the myriad operator is obtained through an investigation of the cost function defining the operator. Thus, let $Q(\theta)$ denote the objective function minimized in Equation 26.29, i.e.,

$$Q(\theta) \stackrel{\Delta}{=} \sum_{i=1}^{N} \log\{\gamma^2 + (x(i) - \theta)^2\}. \tag{26.30}$$

The following proposition brings together a few key properties of the myriad cost function. The properties are illustrated by Figure 26.7, which shows the form of a typical objective function.

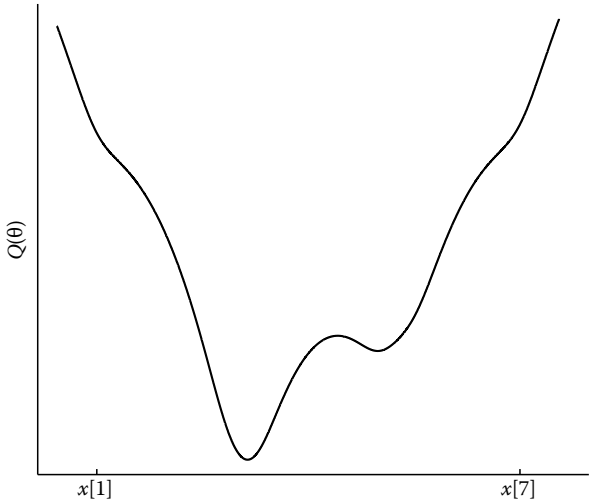

FIGURE 26.7 Typical sketch of the objective function minimized by the myriad operator (for $\gamma = 0.5$ and randomly generated $N = 7$ samples).

PROPOSITION 26.2

Let x[*i*] *signify the order statistics (samples sorted in increasing order of amplitude) of the input samples* $\{x(i) : i = 1, 2, \ldots, N\}$, *with the smallest* $x[1]$ *and the largest* $x[N]$. *The following statements hold*:

(1) *Objective function* $Q(\theta)$ *has a finite number* (*at most N*) *of local extrema*.
(2) *Myriad is one of the local minima of* $Q(\theta)$: $Q'(\theta) = 0$.
(3) $Q'(\theta) > 0$ [$Q(\theta)$ *strictly increasing*] *for* $\theta > x[N], Q'(\theta) < 0$ *and* [$Q(\theta)$ *strictly decreasing*] *for* $\theta < x[1]$.
(4) *All the local extrema of* $Q(\theta)$ *lie within the range* [$x[1]$, $x[N]$] *of the input samples*.
(5) *Myriad is in the range of input samples*: $x[1] \leq \hat{\theta} \leq x[N]$.

Note that, unlike the mean or median, the definition of the myriad involves the free-tunable parameter γ. Importantly, Proposition 26.1 shows that in the limit of this parameter (or equivalently δ) *LM*-estimation converges to *M*-estimation. A particularly interesting realization of this general result holds for the myriad case. Namely, the myriad converges to the mean in the limiting case, as formally defined in the following.

COROLLARY 26.1

Given a set of samples $\{x(i): i = 1, 2, \ldots, N\}$, *the sample myriad* $\hat{\theta}$ *converges to the sample mean as* γ *tends to infinity. That is*,

$$\lim_{\gamma \to \infty} \hat{\theta} = \frac{1}{N} \sum_{i=1}^{N} x(i). \tag{26.31}$$

The fact that an infinite value of γ converts the nonlinear myriad operation to the linear sample average illustrates why γ is aptly named the linearity parameter: the larger the value of γ, the closer the behavior

of the myriad is to the (linear) mean estimator. As γ is decreased, the myriad becomes more robust. In the limit, when γ tends to zero, the estimator treats every observation as a possible outlier, assigning more credibility to the most repeated observation values. This "mode-type" characteristic is reflected in the name mode–myriad given this limiting case.

COROLLARY 26.2

Given a set of samples $\{x(i) : i = 1, 2, \ldots, N\}$, *the sample myriad* $\hat{\theta}$ *converges to a mode–type estimator as* $\gamma \to 0$. *That is,*

$$\lim_{\gamma \to 0} \hat{\theta} = \arg \min_{x(j) \in \mathcal{M}} \left[\prod_{i=1,\, x(i) \neq x(j)}^{N} |x(i) - x(j)| \right], \tag{26.32}$$

where $\mathcal{M}$ *is the set of most repeated values.*

The linearity parameter also allows the meridian filter to address three special cases of the α-Stable distribution family. Those three cases are (1) $\alpha = 1$, which yields the Cauchy distribution for which the myriad is optimal, (2) $\alpha = 2$, which yields the Gaussian distribution under which optimal filtering is realized by letting $\gamma \to \infty$, and (3) $\alpha \to 0$, in which case the distribution is extremely impulsive and $\gamma = 0$ yields the optimal results. These three optimality points have been complemented with a simple empirical formula relating γ to the characteristic exponent (α) and dispersion parameter (κ) of an α-Stable asymmetric distribution,

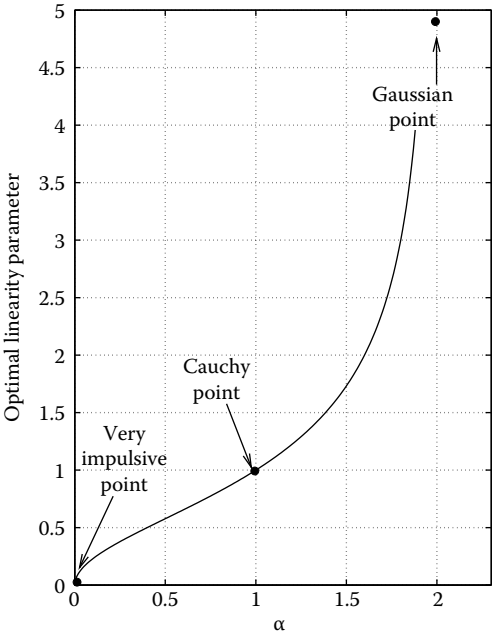

FIGURE 26.8 Empirical α–γ curve for α-Stable distributions. The curve values at $\alpha = 0$,1, and 2 constitute the optimality points of the α-Stable triplet. (From Gonzalez, J. G. and Arce, G. R., *IEEE Trans. Signal Process.*, 49, 438, 2001. With permission.)

$$\gamma(\alpha) = \sqrt{\frac{\alpha}{2 - \alpha}} \kappa^{1/\alpha}, \tag{26.33}$$

which is plotted in Figure 26.8.

Having established the myriad filter, the role of the linearity parameter, and two limiting cases (sample mean and mode–myriad), we present three myriad filter properties that are of importance in signal processing, namely, no under-shoot/overshoot, shift and sign invariance, and unbiasedness. To simplify the notation in the properties, the myriad output is written compactly as $\hat{\theta}(\mathbf{x}) = \text{myriad}\{x(i) : i = 1, 2, \ldots, N; \gamma\}$, where $\mathbf{x} \stackrel{\Delta}{=} [x(1), x(2), \ldots, x(N)]^T$.

PROPERTY 26.1 (No Undershoot/Overshoot)

The output of the myriad estimator operating on samples $\{x(i) : i = 1, 2, \ldots, N\}$ is always bounded by

$$x[1] \leq \hat{\theta}(\mathbf{x}) \leq x[N]. \tag{26.34}$$

PROPERTY 26.2 (Shift and Sign Invariance)

Consider the observation set $\{x(i) : i = 1, 2, \ldots, N\}$ and let $z(i) = x(i) + b$. Then,

(1) $\hat{\theta}(\mathbf{z}) = \hat{\theta}(\mathbf{x}) + b$;
(2) $\hat{\theta}(\mathbf{z}) = -\hat{\theta}(-\mathbf{z})$.

PROPERTY 26.3 (Unbiasedness)

Given a set of samples $\{x(i) : i = 1, 2, \ldots, N\}$ that are independent and symmetrically distributed around a symmetry center c, $\hat{\theta}(\mathbf{x})$ is also symmetrically distributed around c. In particular, if $\mathbb{E}\{\hat{\theta}(\mathbf{x})\}$ exists, then $\mathbb{E}\{\hat{\theta}(\mathbf{x})\} = c$.

The shift invariance and unbiasedness of the myriad filter show that the operator can be applied without concerns to an overall change in location (e.g., a shift in the mean luminance of an image) and that the operator preserves the mean. The undershoot/overshoot property shows that the myriad can be applied without concerns of introducing amplifying artifacts, such as ringing effects.

While the myriad filter offers increased robustness over GGD-based methods and possesses several properties of importance, the equal treatment of samples within the observation set limits the filter, as defined above, to a single operation. Weighting of samples provides a much broader range of filtering operations. This is theoretically justified in a fashion analogous to that utilized in the generalizations of the mean and median operators. Specifically, the following theorem shows that considering samples with a common location but varying scale factors leads to the weighted myriad operator.

THEOREM 26.8

Consider a set of N independent samples $\{x(i) : i = 1, 2, \ldots, N\}$ *each obeying the Cauchy distribution with common location* θ *and (possibly) varying scale factors* $s(i) = \gamma/\sqrt{w(i)}$ [8,28]. *The ML estimate of location, or weighted myriad, is given by,*

$$\hat{\theta} = \arg\min_{\beta} \left[\sum_{i=1}^{N} \log\{\gamma^2 + w(i)(x(i) - \beta)^2\} \right] = \text{myriad}\{w(i) \circ x(i) : i = 1, 2, \ldots, N; \gamma\}, \qquad (26.35)$$

where $\circ$ *denotes the weighting operation in the minimization problem.*

As in the weighted linear and median filter cases, the weight applied to a sample in the myriad filter is inversely proportional to the sample's variability. This not only minimizes the effect of unreliable samples (those with large scale), but can also be used to exploit correlations between samples. This is the case, for instance, when a sliding window is employed and higher weights are assigned to samples at spatial locations that are most highly correlated with the desired output, e.g., samples further away in time and less correlated are given smaller weight. Weighting thus allows myriad filters to take on a wide array of characteristics and to be tuned to the needs of specific applications. Moreover, the properties detailed above for the unweighted myriad filter also hold in the weighted case. The properties are not restated for the weighted case since they are identical. We do, however, formally state corollaries governing the behavior of the weighted myriad operator at the limiting cases of the linearity parameter.

COROLLARY 26.3

Given a set of samples $\{x(i): i = 1, 2, \ldots, N\}$ *and corresponding (positive) weights* $\{w(i): i = 1, 2, \ldots, N\}$, *the weighted myriad* $\hat{\theta}$ *converges to a normalized linear estimate as* γ *tends to infinity. That is,*

$$\lim_{\gamma \to \infty} \hat{\theta} = \frac{\sum_{i=1}^{N} w(i)x(i)}{\sum_{i=1}^{N} w(i)}. \tag{26.36}$$

COROLLARY 26.4

Given a set of samples $\{x(i) : i = 1, 2, \ldots, N\}$ *and corresponding (positive) weights* $\{w(i): i = 1, 2, \ldots, N\}$, *the weighted myriad* $\hat{\theta}$ *converges to a weighted mode-type estimate as* γ *tends to* 0. *That is,*

$$\lim_{\gamma \to 0} \hat{\theta} = \arg \min_{x(j) \in \mathcal{M}} \left(\frac{1}{w(j)} \right)^{r/2} \left[\prod_{i=1, x(i) \neq x(j)}^{N} |x(i) - x(j)| \right], \tag{26.37}$$

where $\mathcal{M}$ *is the set of most repeated values* and *r is the number of times a member of* $\mathcal{M}$ *is repeated in the sample.*

The linearity parameter again controls the behavior of the weighted myriad, ranging between a normalized linear operator, in the least robust limit, and a weighted mode operator, in the most robust limit. Thus weighted myriad filters are more general than linear filters, including the latter as a special case. But unlike linear filters, or even median-based filters, the output of the weighted myriad is not available in explicit form. Computation of the output is therefore nontrivial, requiring minimization of the weighted myriad objective function, $Q(\theta)$. Fortunately, $Q(\theta)$ has a number of characteristics that can be exploited to construct fast iterative methods for computing the objective function minimum.

Recall that the weighted myriad is given by

$$\begin{aligned} \hat{\theta} &= \arg \min_{\theta} \; Q(\theta) \\ &= \arg \min_{\theta} \sum_{i=1}^{N} \log \left[1 + \left(\frac{x(i) - \theta}{s(i)} \right)^2 \right], \end{aligned} \tag{26.38}$$

where the change in notation, $s(i) = \gamma / \sqrt{w(i)}$, introduced in Theorem 26.8 is employed. As the output is a local minima of $Q(\theta)$, these points can be identified by determining $Q'(\hat{\theta})$, which, after some manipulations, can be written as

$$Q'(\theta) = 2 \sum_{i=1}^{N} \frac{\left(\frac{\theta - x(i)}{s(i)^2} \right)}{1 + \left(\frac{x(i) - \theta}{s(i)} \right)^2}. \tag{26.39}$$

Defining $\psi(\upsilon) \stackrel{\Delta}{=} \frac{2\upsilon}{1+\upsilon^2}$, the following equation is obtained for the local extrema of $Q(\theta)$:

$$Q'(\theta) = -\sum_{i=1}^{N} \frac{1}{s(i)} \cdot \psi \left(\frac{x(i) - \theta}{s(i)} \right) = 0. \tag{26.40}$$

By introducing the positive functions

$$h(i;\theta)\stackrel{\Delta}{=}\frac{1}{s(i)^2}\cdot\varphi\left(\frac{x(i)-\theta}{s(i)}\right)>0, \tag{26.41}$$

for $i=1,2,\ldots,N$, where $\varphi(v)\stackrel{\Delta}{=}\frac{\psi(v)}{v}=\frac{2}{1+v^2}$, the local extrema of $Q(\theta)$ in Equation 26.40 can be formulated as

$$Q'(\theta)=-\sum_{i=1}^{N}h(i;\theta)\cdot(x(i)-\theta)=0. \tag{26.42}$$

This formulation implies that the *sum of weighted deviations* of the samples is zero, with the (positive) weights themselves being functions of θ. This property, in turn, leads to a simple fixed point iterative procedure for computing the myriad weights.

To develop the fixed point algorithm, note that Equation 26.42 can be written as

$$\theta=\frac{\sum_{i=1}^{N}h(i;\theta)\cdot x(i)}{\sum_{i=1}^{N}h(i;\theta)}, \tag{26.43}$$

which is a weighted mean of the input samples, $x(i)$. Since the weights $h(i;\theta)$ are always positive, the right-hand side of Equation 26.43 is in $[x[1],x[N]]$, confirming that all the local extrema lie within the range of the input samples. By defining the mapping

$$T(\theta)\stackrel{\Delta}{=}\frac{\sum_{i=1}^{N}h(i;\theta)\cdot x(i)}{\sum_{i=1}^{N}h(i;\theta)}, \tag{26.44}$$

the local extrema of $Q(\theta)$, or the roots of $Q'(\theta)$, are seen to be the *fixed points* of $T(\cdot)$:

$$\theta^\star=T(\theta^\star). \tag{26.45}$$

The following fixed point iteration results in an efficient algorithm to compute these fixed points:

$$\theta_{m+1}\stackrel{\Delta}{=}T(\theta_m)=\frac{\sum_{i=1}^{N}h(i;\theta_m)\cdot x(i)}{\sum_{i=1}^{N}h(i;\theta_m)}. \tag{26.46}$$

In the classical literature, this is also called the *method of successive approximation* for the solution of the equation $\theta=T(\theta)$. This method is proven to converge to a fixed point of $T(\cdot)$, indicating that

$$\lim_{m\to\infty}\theta_m=\theta^\star=T(\theta^\star). \tag{26.47}$$

The speed of convergence depends on the initial value θ_0. A simple approach to initializing the algorithm is to set $\hat{\theta}_0$ equal to the input sample $x(i)$ that yields the smallest cost $P(x(i))$, where $\log(P(\theta))\stackrel{\Delta}{=}Q(\theta)$, i.e., $P(\theta)=\prod_{i=1}^{N}\left(\gamma^2+w(i)(x(i)-\theta)^2\right)$. The fixed point weighted myriad optimization can now be summarized as follows.

Fixed point weighted myriad search

Step 1: Select the initial point $\hat{\theta}_0$ among the values of the input samples:

$$\hat{\theta}_0 = \arg\min_{x(i)} P(x(i)).$$

Step 2: Using $\hat{\theta}_0$ as the initial value, perform L iterations of the fixed point recursion $\theta_{m+1} = T(\theta_m)$, the full expression of which is given in Equation 26.46. The final value of these iterations is then chosen as the weighted myriad output, $\hat{\theta} = T^{(L)}(\hat{\theta}_0)$.

This algorithm is compactly written as

$$\hat{\theta} = T^{(L)}\left(\arg\min_{x(i)} P(x(i))\right). \tag{26.48}$$

Note that for the special case $L = 0$, no fixed point iterations are performed and the above algorithm computes the selection weighted myriad.

26.3.3 Running Meridian Smoothers: Meridian Filtering

Having established the myriad as the optimal filtering operation that arises from the location estimation problem in Cauchy distributed samples, we consider a second special case of the GCD, namely the Meridian distribution. This special case ($\lambda = 1$) has even heavier tails than the Cauchy distribution, and is an appropriate model for the most impulsive sequences seen in practice. As the Cauchy and Meridian distributions fall within the GCD, the development for the Meridian is similar to that for the Cauchy and so many proofs with similar steps are omitted.

THEOREM 26.9

Consider a set of N independent samples $\{x(i) : i = 1, 2, \ldots, N\}$ *each obeying the Myriad distribution with common location* θ *and scale* δ. *The ML estimate of location, or sample meridian, is given by*

$$\hat{\theta} = \arg\min_{\theta}\left[\sum_{i=1}^{N} \log\{\delta + |x(i) - \theta|\}\right] = \text{meridian}\{x(i) : i = 1, 2, \ldots, N; \delta\}, \tag{26.49}$$

where δ *is referred to as the medianity parameter.*

As in all previous cases, the performance of the meridian filter is directly related to the defining objective function. Properties describing the objective function are given in the following proposition. The properties described therein are illustrated in Figure 26.9, which plots an example of the objective function, $Q(\theta)$, that results from a set of typical observation samples in the $N = 7$ case.

PROPOSITION 26.3

Let

$$Q(\theta) \stackrel{\Delta}{=} \sum_{i=1}^{N} \log\{\delta + |x(i) - \theta|\}. \tag{26.50}$$

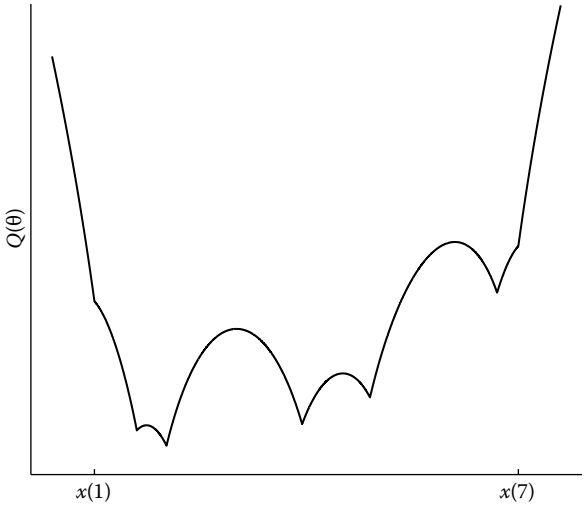

FIGURE 26.9 Typical plot of the objective function minimized by the meridian operator (for $\delta = 0.5$ and randomly generated $N = 7$ samples). (From Aysal, T. C. and Barner, K. E., *IEEE Trans. Signal Process.*, 55, 3949, 2007. With permission.)

The following statements hold:

(1) $Q'(\theta) > 0$ ($Q(\theta)$ *is strictly increasing*) *for* $\theta > x[N]$, *and* $Q'(\theta) < 0$ ($Q(\theta)$ *is strictly decreasing*) *for* $\theta < x[1]$.
(2) *All local extrema of* $Q(\theta)$ *lie within the range of input samples*, $[x[1], x[N]]$.
(3) *Objective function* $Q(\theta)$ *has a finite number of local minima* (*at most equal to the number of input samples*, N).
(4) *Meridian* $\hat{\theta}$ *is one of the local minima of* $Q(\theta)$, *i.e., one of the input samples.*

The meridian estimator output is hence the input sample that yields the smallest $Q(\theta)$ function value. The selective nature of the meridian estimator, shared with the median estimator, facilitates the filter output computation which is formulated as

$$\hat{\theta} = \arg\min_{\theta \in \mathbf{x}} \sum_{i=1}^{N} \log\{\delta + |x(i) - \theta|\}. \tag{26.51}$$

The behavior of the meridian operator is markedly dependent on the value of δ, which is referred to as the *medianity* parameter. As the name suggests, we show in the following that the sample meridian is equivalent to the sample median for large values of δ, whereas the estimator acquires the form of the sample mode for small δ.

COROLLARY 26.5

Given a set of samples $\{x(i): i = 1, 2, \ldots, N\}$, *the sample meridian* $\hat{\theta}$ *converges to the sample median as* $\delta \to \infty$. *That is*,

$$\lim_{\delta \to \infty} \hat{\theta} = \lim_{\delta \to \infty} \text{meridian}\{x(i) : i = 1, 2, \ldots, N; \delta\} = \text{median}\{x(i): i = 1, 2, \ldots, N\}. \tag{26.52}$$

Thus the family of meridian estimators subsumes the sample median as a limiting case. This simple fact makes the meridian filter class inherently more efficient than (or at least equally efficient to) median filters over all noise distribution including the Laplacian. The opposite limiting case, which results in the mode–meridian operator, is addressed in the following.

COROLLARY 26.6

Given a set of samples $\{x(i) : i = 1, 2, \ldots, N\}$, *the sample meridian* $\hat{\theta}$ *converges to a mode–type estimator as* $\delta \to 0$. *That is,*

$$\lim_{\delta \to 0} \hat{\theta} = \arg\min_{x(j) \in \mathcal{M}} \left[\prod_{i=1,\, x(i) \neq x(j)}^{N} |x(i) - x(j)| \right], \tag{26.53}$$

where $\mathcal{M}$ *is the set of most repeated values.*

Thus the myriad and meridian operators converge to a common mode operator as their linearity/medianity parameters go to 0.

Since all the operators covered in this chapter belong to the class of *M-estimators* [10], many robust statistics tools are available for evaluating their robustness [10,48]. *M*-estimators are formulated by a set of implicit functions, where $\rho(\cdot)$ is an arbitrary objective function. Assuming that $\psi(x) = \partial(\rho(x))/\partial x$ exists, the *M-estimator* is obtained by solving

$$\sum_{i=1}^{N} \psi(x(i) - \theta) = 0, \tag{26.54}$$

where $\psi(\cdot)$ is proportional to the so-called influence function. The influence function of an estimator is important in that it determines the effect of contamination on the estimator.

To further characterize *M*-estimates, it is useful to list the desirable features of a robust influence function [10,48]:

- B-robustness. An estimator is *B-robust* if the supremum of the absolute value of the influence function is finite.
- Rejection Point. The *rejection point* defined as the distance from the center of the influence function to the point where the influence function becomes negligible, should be finite. The rejection point measures whether the estimator rejects outliers and, if so, at what distance.

The influence functions for the sample mean, median, myriad, and meridian can be shown to be

$$\psi(x) = 2x, \tag{26.55}$$

$$\psi(x) = \text{sgn}(x), \tag{26.56}$$

$$\psi(x) = \frac{2x}{\gamma^2 + x^2}, \tag{26.57}$$

$$\psi(x) = \frac{\text{sgn}(x)}{\delta + |x|}, \tag{26.58}$$

respectively. Figure 26.10 plots each of these for comparison. Since the influence function of the mean is unbounded, a gross error in the observations leads to severe distortion in the estimate. The mean is

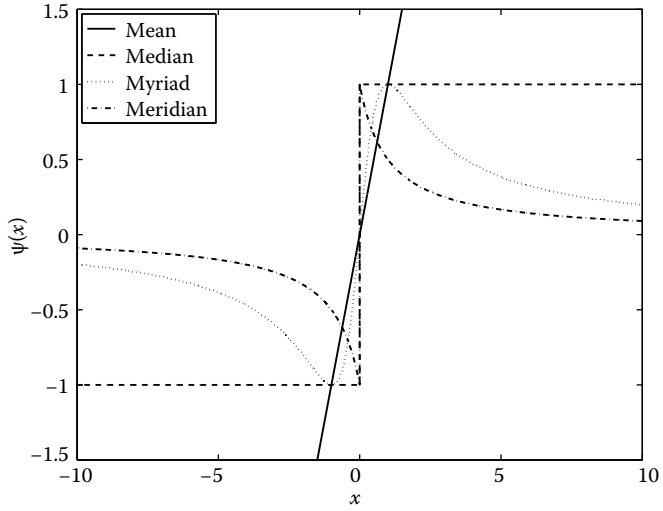

FIGURE 26.10 Influence functions for (solid:) the sample mean, (dashed:) the sample median, (dotted:) the sample myriad, and (dash–dotted:) the sample meridian. (From Aysal, T. C. and Barner, K. E., *IEEE Trans. Signal Process.*, 55, 3949, 2007. With permission.)

clearly not B-robust and its rejection point is infinite. On the other hand, a similar gross error has a limited effect on the median estimate.

While the median is B-robust, its rejection point, like the mean, is not finite. Thus the median estimate is always affected by outliers. The myriad estimate is clearly B-robust and the effect of the errors decreases as the error increases. The meridian estimate is also B-robust, and, in addition, its rejection point is smaller than that of myriad. This indicates that the operators can be ordered from least to most robust as: linear, median, myriad, and meridian.

In addition to desirable influence function characteristics, the meridian possesses the following properties important in signal processing applications.

PROPERTY 26.4

Given a set of samples $\{x(i) : i = 1, 2, \ldots, N\}$, let $\delta < \infty$. Then the meridian output is such that

$$\lim_{x(N)\to\pm\infty} \hat{\theta}(x(1), x(2), \ldots, x(N)) = \hat{\theta}(x(1), x(2), \ldots, x(N-1)). \tag{26.59}$$

According to Property 26.4, large errors are efficiently eliminated by a meridian estimator with a finite medianity parameter. Note that this is not the case for the median estimate, as large positive or negative values can always shift the output. In robust statistics, *M*-estimators satisfying the outlier rejection property are called redescending. It can be proven that a necessary and sufficient condition for an *M*-estimator to be redescending is that $\lim_{x\to\pm\infty} \partial/\partial x(\rho(x)) = 0$. Note that this condition holds for meridian and myriad operators, whereas it does not for the mean and median. The meridian also possesses the same no undershoot/overshoot, shift and sign invariance, and unbiasedness properties as the myriad.

PROPERTY 26.5 (No Undershoot/Overshoot)

The output of the meridian estimator operating on samples $\{x(i) : i = 1, 2, \ldots, N\}$ is always bounded by

$$x[1] \leq \hat{\theta}(\mathbf{x}) \leq x[N]. \tag{26.60}$$

PROPERTY 26.6 (Shift and Sign Invariance)

Consider the observation set $\{x(i) : i = 1, 2, \ldots, N\}$ and let $z(i) = x(i) + b$. Then,

(1) $\hat{\theta}(\mathbf{z}) = \hat{\theta}(\mathbf{x}) + b$;
(2) $\hat{\theta}(\mathbf{z}) = -\hat{\theta}(-\mathbf{z})$.

PROPERTY 26.7 (Unbiasedness)

Given a set of samples $\{x(i) : i = 1, 2, \ldots, N\}$ that are independent and symmetrically distributed around a symmetry center c, $\hat{\theta}(\mathbf{x})$ is also symmetrically distributed around c. In particular, if $\mathbb{E}\{\hat{\theta}(\mathbf{x})\}$ exists, then $\mathbb{E}\{\hat{\theta}(\mathbf{x})\} = c$.

The meridian characteristics can be broadened through the introduction of weights. The weighted meridian possesses the same properties as the unweighted version and converges to the expected special cases in the limit of the medianity parameter. The weighted case is formally defined and the limiting cases stated, but the properties are omitted due to their direct similarity to the previous formulations.

THEOREM 26.10

Consider a set of N independent samples $\{x(i) : i = 1, 2, \ldots, N\}$ *each obeying the Meridian distribution with common location* θ *and (possibly) varying scale parameters* $v(i) = \delta/w(i)$. *The ML estimate of location, or weighted meridian, is given by*

$$\hat{\theta} = \arg\min_{\beta} \left[\sum_{i=1}^{N} \log\{\delta + w(i)|x(i) - \theta|\} \right] = \text{meridian}\{w(i) \star x(i) : i = 1, 2, \ldots, N\}, \tag{26.61}$$

where $\star$ *denotes the weighting operation in the minimization problem.*

COROLLARY 26.7

Given a set of samples $\{x(i) : i = 1, 2, \ldots, N\}$ *and corresponding (positive) weights* $\{w(i): i = 1, 2, \ldots, N\}$, *the weighted meridian* $\hat{\theta}$ *converges to the weighted median as* $\delta \to \infty$. That is,

$$\lim_{\delta \to \infty} \hat{\theta} = \lim_{\delta \to \infty} \text{meridian}\{w(i) \star x(i) : i = 1, 2, \ldots, N; \delta\} = \text{median}\{w(i) \diamond x(i) : i = 1, 2, \ldots, N\}. \tag{26.62}$$

COROLLARY 26.8

Given a set of samples $\{x(i): i = 1, 2, \ldots, N\}$ *and corresponding (positive) weights* $\{w(i): i = 1, 2, \ldots, N\}$, *the weighted meridian* $\hat{\theta}$ *converges to one of the most repeated values in the sample set as* $\delta \to 0$. *That is*,

$$\lim_{\delta \to 0} \hat{\theta} = \arg\min_{x_j \in \mathcal{M}} \left[\left(\frac{1}{w(j)} \right)^r \prod_{i=1,\, x(i) \neq x(j)}^{N} |x(i) - x(j)| \right], \tag{26.63}$$

where $\mathcal{M}$ *is the set of most repeated values* and r *is the number of times a member of* $\mathcal{M}$ *is repeated in the sample set.*

Table 26.1 summarizes the *M*-estimators and filters covered in this chapter. The GGD derived operators, for $\beta = 2$ and $\beta = 1$ are reported on table rows 1, 2 and 5, 6, while the GCD optimal operators, for $\lambda = 2$ and $\lambda = 1$, are reported on rows 3, 4 and 7, 8. This table brings together and contrast the objective functions for the GGD-based linear and median filters and the GCD-based myriad and meridian filters.

26.3.4 Introduction of Real-Valued Weights and Optimization

The coverage to this point has enforced the positivity constraint that arises naturally in each of the operators' estimation-based development. Only in the median case is the sign coupling approach utilized to allow the introduction of real-valued (positive and negative) weights. See Equations 26.13 and 26.14. For convenience, Equation 26.13 is repeated here:

$$\hat{\theta} = \arg\min_{\theta} \left[\sum_{i=1}^{N} |h(i)| \cdot |\mathrm{sgn}(h(i))x(i) - \theta| \right] = \mathrm{median}\{|h(i)| \ \diamond \ \mathrm{sgn}(h(i))x(i)|_{i=1}^{N}\}. \tag{26.64}$$

TABLE 26.1 *M*-Estimator and M-Smoother (Weighted *M*-Estimator) Objective Functions and Outputs for Various Filter Families

Smoother	Cost Function	Filter Output
Mean	$\sum_{i=1}^{N} (x(i) - \theta)^2$	$\mathrm{Mean}\{x(i): i = 1, 2, \ldots, N\}$
Median	$\sum_{i=1}^{N} \lvert x(i) - \theta \rvert$	$\mathrm{Median}\{x(i): i = 1, 2, \ldots, N\}$
Myriad	$\sum_{i=1}^{N} \log\{\gamma^2 + (x(i) - \theta)^2\}$	$\mathrm{Myriad}\{x(i): i = 1, 2, \ldots, N; \gamma\}$
Meridian	$\sum_{i=1}^{N} \log\{\delta + \lvert x(i) - \theta \rvert\}$	$\mathrm{Meridian}\{x(i): i = 1, 2, \ldots, N; \delta\}$
Weighted mean	$\sum_{i=1}^{N} w(i)(x(i) - \theta)^2$	$\mathrm{Mean}\{w(i) \cdot x(i): i = 1, 2, \ldots, N\}$
Weighted median	$\sum_{i=1}^{N} w(i)\lvert x(i) - \theta \rvert$	$\mathrm{Median}\{w(i) \diamondsuit x(i): i = 1, 2, \ldots, N\}$
Weighted myriad	$\sum_{i=1}^{N} \log\{\gamma^2 + w(i)(x(i) - \theta)^2\}$	$\mathrm{Myriad}\{w(i) \circ x(i): i = 1, 2, \ldots, N; \gamma\}$
Weighted meridian	$\sum_{i=1}^{N} \log\{\delta + w(i)\lvert x(i) - \theta \rvert\}$	$\mathrm{Meridian}\{w(i) \star x(i): i = 1, 2, \ldots, N; \delta\}$

Source: Aysal, T. C. and Barner, K. E., *IEEE Trans. Signal Process.*, 55, 3949, 2007. With permission.

The most general cases of the myriad and meridian are, by direct analogy, given by

$$\hat{\theta} = \arg\min_{\theta} \left[\sum_{i=1}^{N} \log\{\gamma^2 + |h(i)| \cdot (\mathrm{sgn}(h(i))x(i) - \theta)^2\} \right] = \mathrm{myriad}\{|h(i)| \circ \mathrm{sgn}(h(i))x(i)|_{i=1}^{N}\} \quad (26.65)$$

and

$$\hat{\theta} = \arg\min_{\theta} \left[\sum_{i=1}^{N} \log\{\delta + |h(i)| \cdot |\mathrm{sgn}(h(i))x(i) - \theta|\} \right] = \mathrm{meridian}\{|h(i)| \star \mathrm{sgn}(h(i))x(i)|_{i=1}^{N}\}, \quad (26.66)$$

respectively. Under this formulation, the operators are no longer restricted to be smoothers and can, therefore, be set to exhibit a wide range of frequency-selective filtering operations, including bandpass and highpass filtering.

Also of importance is that the filter weights can be optimized. This is most easily done through a training process, typically under the mean absolute error (MAE). For instance, using a steepest descent approach yields a relatively simple weight update for the myriad case,

$$h(i; n+1) = h(i; n) - \mu e(n) \left[\frac{\gamma^2 \mathrm{sgn}(h(i)) \left(\hat{\theta} - \mathrm{sgn}(h(i))x(i)\right)}{\left(\gamma^2 + |h(i)| \cdot \left(\hat{\theta} - \mathrm{sgn}(h(i))x(i)\right)^2\right)^2} \right], \quad (26.67)$$

where $e(n)$ is simply the error between the filter output and the desired signal and μ is the iteration step size.

It is important to note that the optimal filtering action is independent of the choice of γ; the filter only depends on the value of $w/(\gamma^2)$. Note that similar updates can be derived for the median and meridian filters—all are analagous to the LMS update for the linear filter.

For cases in which no training sequence is available, there are simple, suboptimal approaches to setting the operator parameters. Recall that the myriad has the linearization free parameter (γ), while the meridian has medianization free parameter (δ). These parameters control the robustness of the operators. Numerous optimization techniques exist for linear and median filters. Thus one approach to setting the filter parameters is to design weights for the simpler linear or median filter that address the problem at hand, then decrease the free parameter value to achieve the desired level of additional robustness. This is referred to as myriadization in the myriad case and meridianization in the meridian case. This approach allows the rich set of design tools in the more traditional filtering domains to be applied to the newer, more robust operators.

26.4 Applications of Robust Nonlinear Estimators/Filters

The covered filtering methods are evaluated in two communications problems, standard baseband communications and power line communications, as well as an illustrative frequency selective filtering problem. In each of these applications, an underlying desired signal is to be extracted. Complicating the extraction is additive noise. While many different noise distributions can be investigated and justified by various problem physics, we avoid direct use of either GGD or GCD densities. Employing, for instance, Gaussian noise will yield the obvious result of linear filtering providing the best performance, while the myriad filter is clearly optimal for applications in which the noise is Cauchy distributed. The presentation of such obvious results provides little information or insight into the characteristics of the individual

algorithms. Rather, results are presented for the commonly utilized α-Stable density family. This provides a fairer comparison and illustrates the performance of the filters operating on a widely used heavy-tailed distribution, but one that shares only tail order with the GCD.

Utilization of α-Stable distributed samples, like Gaussian distributed samples, is very appealing for the modeling of real-life phenomena because they constitute the only variables that can be described as the superposition of many small independent and identically distributed effects [15]. The class of symmetric α-Stable distributions is usually described by its characteristic function:

$$\phi(\omega) = \exp\left(-\kappa|\omega|^{\alpha}\right). \tag{26.68}$$

The parameter κ, which is commonly called the *dispersion*, is a positive constant related to the scale of the distribution and $\kappa^{1/\alpha}$ is the scale parameter of the distribution. In order for Equation 26.68 to define a characteristic function, the value of α must be restricted to the interval [0, 2]. Importantly, α determines the impulsiveness, or tail heaviness, of the distribution, where smaller values of α indicate increased levels of impulsiveness. The limit $\alpha = 2$ case corresponds to the zero-mean Gaussian distribution with variance 2κ. All other values of α correspond to impulsive distributions with infinite variance and algebraic tail behavior [15]. Indeed, α-Stable distributions are successfully utilized to model impulsive environments accross a wide array of applications [8,12,15,23,28,31,34,46,49].

26.4.1 Baseband Communications

Consider first the baseband communication model given in Figure 26.11 [50]. Suppose that A (real) is to be communicated over the channel. Denote $s(t)$ as the combined impulse response of the transmitter and channel, and take the pulse $As(t)$ to be corrupted by additive white noise. The received pulse is then given by

$$r(t) = As(t) + n(t), \tag{26.69}$$

which, after sampling at rate $1/T$, corresponds to the sequence

$$r(kT) = As(kT) + n(kT). \tag{26.70}$$

Taking the common case assumption that $s(kT) \neq 0$ only for k an integer, the communications goal is to estimate A using the samples $As(kT) + n(kT), k = 1, 2, \ldots, K$.

The formulated problem is well known to be optimally addressed through matched filtering. Moreover, each of the covered filters can be formulated in matched form. Thus to compare the performances of the matched linear, median, myriad, and meridian filters, 10,000 Gaussian distributed $\{A(i) : i = 1, 2, \ldots, 10{,}000\}$ parameters are generated, sent through the baseband communication channel, sampled with $K = 21$, and filtered with each of the matched filters to obtain the estimates $\{\hat{A}(i) : i = 1, 2, \ldots, 10{,}000\}$. The corrupting channel noise is α-Stable distributed with $\alpha = 0.4$. The

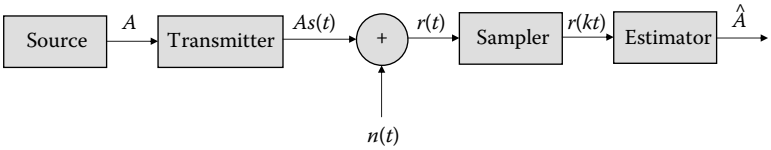

FIGURE 26.11 Baseband communication model: $s(t)$ denotes the combined impulse response of the transmitter and the channel, and $As(t)$ is corrupted by additive white noise $n(t)$.

TABLE 26.2 Matched Linear, Median, Myriad and Meridian Filters Output MAEs and MSEs

Performance Criteria	Matched Linear	Matched Median	Matched Myriad	Matched Meridian
MAE	5.9215×10^3	0.2080	0.1605	0.1121
MSE	3.2949×10^7	0.1687	0.0520	0.0380

Source: Aysal, T. C. and Barner, K. E., *IEEE Trans. Signal Process.*, 55, 3949, 2007. With permission.

pulse carrying the symbol is taken to be rectangular. The mean absolute and squared errors of the matched filter outputs are tabulated in Table 26.2. The tabulated results show that the linear filter completely breaks down in the presence of the heavy tailed corruption. The median is significantly more robust, but still suffers from its inability to completely discount outliers. The myriad and meridian operators, both derived for such algebraic tailed environments, provide significantly better results than the GGD-based methods. The noise parameter utilized in this example, $\alpha = 0.4$, results in extremely impulsive corruption, which is why the best performance is provided by the most robust operator covered, the matched meridian filter.

26.4.2 Power Line Communications

Consider next the problem of power line communications (PLCs). The use of existing power lines for transmitting data and voice has received considerable interest in recent years [51–54]. The advantages of PLCs are obvious due to the ubiquity of power lines and power outlets. The potential of power lines to deliver broadband services, such as fast Internet access, telephone, fax services, and home networking is emerging in new communications industry technology. However, there remain considerable challenges for PLCs, such as communications channels that are hampered by the presence of large amplitude noise superimposed on top of traditional white Gaussian noise. The overall interference is appropriately modeled as an algebraic tailed process, with α-Stable ($\alpha \approx 1$) often chosen as the parent distribution [51].

To compare the various filtering algorithms, consider a PLC problem in which there are a set of voltage levels, $\mathcal{V} = \{-2, -1, 0, 1, 2\}$ unknown at the receiver.* A signal randomly composed of these voltage levels, an example of which is shown in Figure 26.12a, is transmitted through a powerline. The observed signal is given in Figure 26.12b, where the noise is modeled as α-Stable distributed with $\alpha = 1.25$. Note that this results in corruption that is somewhat less impulsive than in the previously considered example. The observed powerline signal is processed with mean, median, myriad, and meridian filters, each utilizing window length $N = 9$, the results of which are given in Figures 26.12c through, respectively.

Inspection of the figures shows that the mean is vulnerable to impulsive noise even when α is relatively large. The median, myriad, and meridian, in contrast, all perform relatively well. The fact that the median performs well in this example indicates that the noise impulsivity is reasonably close to the GGD Laplacian distribution special case. The meridian is, perhaps, overly robust for the level of corruption observed in this example, but still performs nearly as well as the myriad and median. This example shows that the myriad and meridian give up little in terms of performance in relatively light tailed environments while, as the previous example shows, offering considerably better performance in the presence of truly heavy tailed observations.

26.4.3 Highpass Filtering of a Multitone Signal

As a final example, consider the problem of preserving a high-frequency tone while removing all low frequency terms. This requires highpass filtering, which employs both positive and negative weights within the filter window. Such a problem demonstrates not only the utilization of positive and negative

* In the case where the signal alphabet is known at the receiver, the linear, median, myriad, and meridian estimators are readily extended to detectors.

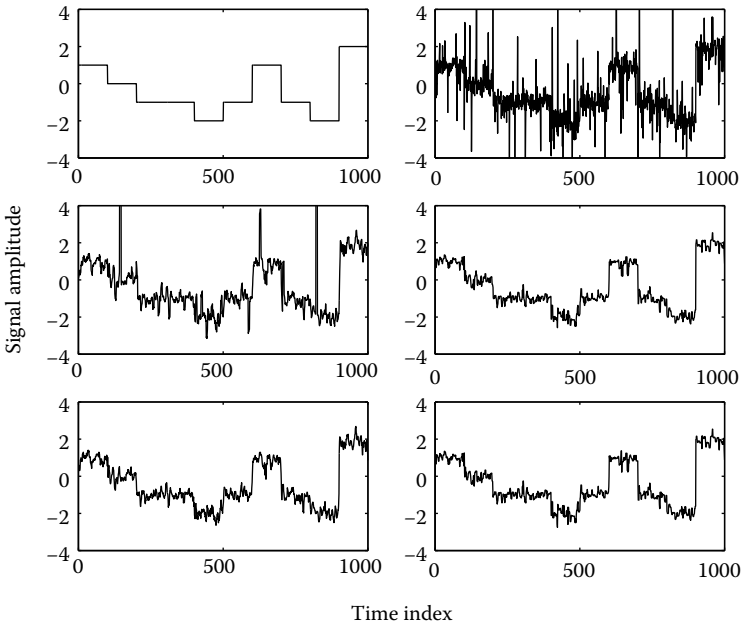

FIGURE 26.12 Power line communications signal enhancement: (a) transmitted signal, (b) observed signal corrupted by $\alpha = 1.25$ noise, output of the (c) mean [2.5388]{8.6216}, (d) median [2.4267]{7.4393}, (e) myriad [2.4385]{7.4993}, and (f) meridian filters [2.4256]{7.4412}, where $[\cdot]$ and $\{\cdot\}$ denotes the mean absolute and squared error for the corresponding filtering structure.

weights, but also the ability of robust nonlinear filters to perform frequency selectivity that is traditionally accomplished through linear filtering. Figure 26.13a depicts a two-tone signal with normalized frequencies 0.02 and 0.4 Hz. The signal is 1000 samples long, although a cropped version of the original signal $\{0,200\}$ is shown for presentation purposes. Figure 26.13b shows the multitone signal filtered by a 40-tap linear FIR filter designed by the MATLAB fir1 command with a normalized cutoff frequency of 0.3 Hz. The myriad and median filter weights are optimized in this case utilizing the adaptive methods detailed in the previous section.* Noting that the median filter is a limiting case of the meridian filter, the meridian filter weights are set equal to those of the median.

The clean multitone input signal is corrupted by additive α-Stable noise with $\alpha = 0.4$ to form a corrupted observation from which the single high frequency tone must be extracted, Figure 26.13c. The noisy multitone signal is processed by the linear, median, myriad, and meridian filters with the results given in Figures 26.13d through g, respectively. Similarly to the first example, the observation signal in this case contains very heavy tailed outliers. These outliers cause the linear filter to, once again, break down. Each of the nonlinear filters, in contrast, offers more robust processing, with the outputs more closely reflecting the range and frequency content of the desired signal. The increasing robustness of the operators is again apparent, with the myriad being more robust to outliers than the median and the meridian being the most robust. It should be noted that the nonlinear filters not only minimize the influence of outliers, but their flexible weighted structures are able to effectively pass desired frequency content while rejecting content outside the desired frequency band. The ability to simultaneously reject

* The clean multitone signal and the desired high-frequency signal are utilized as the input and desired signals, respectively. For more detail see Refs. [28,29,31].

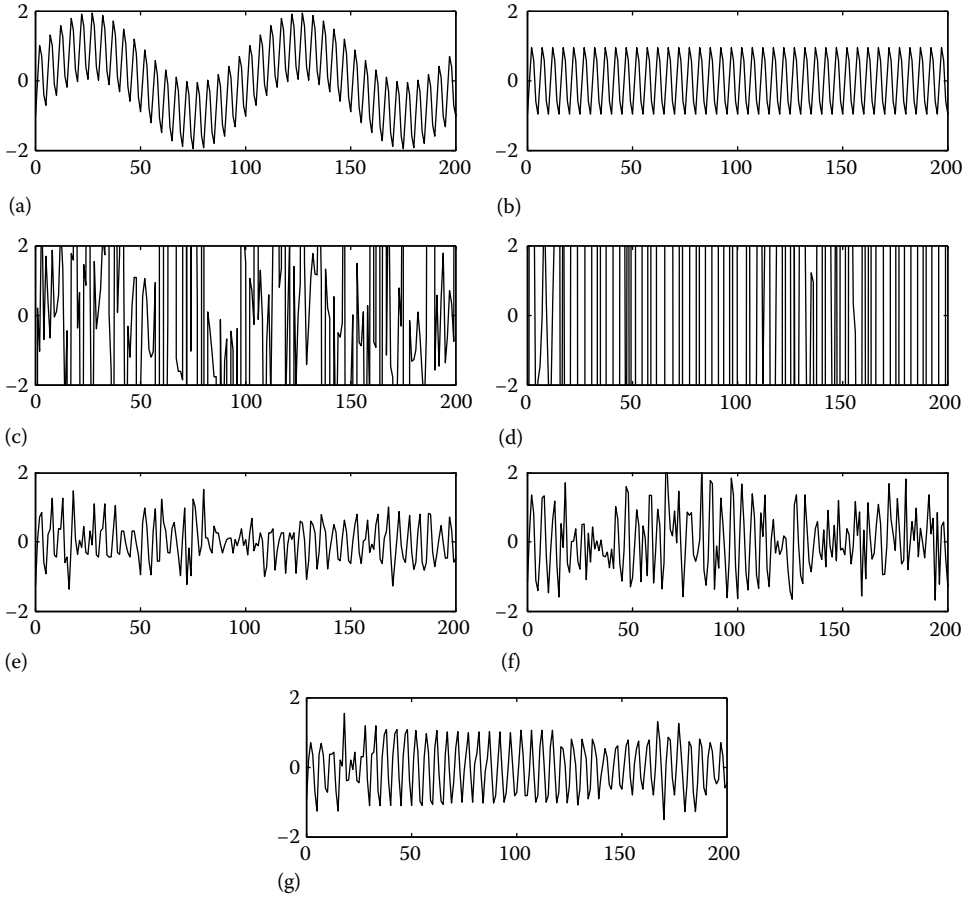

FIGURE 26.13 High frequency–selection filtering in impulsive noise: (a) clean two-tone input signal, (b) (desired) highpass component of the input signal (processed with lowpass FIR filter), (c) two-tone signal corrupted with stable noise ($\alpha = 0.4$), noisy two-tone input signal processed with (d) linear, (e) median, (f) myriad, and (g) meridian filters. outliers and perform frequency selectivity enables the nonlinear median, myriad, and meridian filters to be deployed in a wide range of applications, including those previously dominated by, but not necessarily well addressed by, linear filtering.

26.5 Concluding Remarks and Future Directions

The development and application of nonlinear filters is necessitated by the complexity and challenging environments of many contemporary problems. In this chapter we have taken a fundamental approach to filter development, considering operators from the first principles of location estimation. This development focused on two important broad classes of distributions, generalized Gaussian and generalized Cauchy distribution families. Within the GGD family, particular focus was placed on the Gaussian and Laplacian distribution special cases and their resulting linear and median filtering operations. It was shown that while the GGD family constitutes a broad array of distributions with varying tail parameters, distributions within the family are not capable of accurately modeling the most impulsive and environment seen in practice due to the constraint that GGD density tail decay rates be exponential. The consequence of this tail decay rate constraint is that the linear and median filters deriving their optimality from the

GGD are not effective in the processing of very impulsive sequences. The GCD family, in contrast, consists of distributions with algebraic tail decay rates that do accurately modeled these most demanding impulsive environments. Within this family we again focus on two special cases, the Cauchy and Meridian distributions and their resulting myriad and meridian filtering operations. As these filters are derived from heavy tailed distributions, they are well suited for applications dominated by very impulsive statistics.

Properties and optimization procedures are presented for each of the filters covered. In particular, we show that the operators can be ordered in terms of their robustness, from least to most robust, as linear, median, myriad, and meridian. Moreover, myriad filters contain linear filters as special cases, while meridian filters contain median operators as special cases. Thus the myriad and meridian operators are inherently more efficient than their traditional (subset) counterparts. Simulations presented in communications and frequency selective filtering applications show and contrast the performances of the filters in applications with varying levels of heavy tailed statistics. As expected, linear operators breakdown in these environments while the robust, nonlinear operators yield desirable results.

Although the presentation in this chapter ranges from theoretical development through properties, optimization, and applications, the coverage is, in fact, simply an overview of one segment within the broad array of nonlinear filtering algorithms. To probe further, the interested reader is referred to the cited articles, as well as numerous other works in this area. Additionally, there are many other areas of research in nonlinear methods that are under active investigation. Research areas of importance include (1) order-statistic based signal processing, (2) mathematical morphology, (3) higher order statistics and polynomial methods, (4) radial basis function and kernel methods, and (5) emerging nonlinear methods. Researchers and practitioners interested in the broader field of nonlinear signal processing are encouraged to see the many good books, monographs, and research papers covering these, and other, areas in nonlinear signal processing.

Denoising is one of the fundamental problems in digital image processing and can be defined as the removal of noise from observed image data, for example in broadcast and surveillance as well as in medical imaging applications. Often performed as a preprocessing step prior to any analysis or modeling of the images, denoising improves the image quality thus reducing the effects of noise on the output of any subsequent operations. Let $f(\mathbf{r})$ denote some original image data corrupted by additive white Gaussian noise $\nu(\mathbf{r})$, resulting in observed image data $g(\mathbf{r})$, where $\mathbf{r}$ denotes the n-dimensional coordinates of the image data, and $n \in \{2, 3, 4\}$. For $n = 2, \mathbf{r}$ usually represents the horizontal and vertical coordinates (often denoted by x and y), whereas for $n = 4$ for instance in case of real-time capture of three-dimensional (3-D) images (such as fMRI image data), $\mathbf{r}$ may be composed of the three spatial coordinates (x, y, and z) and a time coordinate. Corruption of the original image data can, therefore, be expressed in the following form,

* Parts of this chapter have appeared in the Proceedings of Baiona SPC'2003, ICIP'2004, and WIAMIS'2004, and ICIP'2005. Much of the material in Section 27.2 appears in Yao's PhD thesis, submitted to the University of Warwick in October 2007, and is in preparation for submission to a journal.

$$g(\mathbf{r}) = f(\mathbf{r}) + \nu(\mathbf{r}) \tag{27.1}$$

where $\nu = \mathcal{N}(0, \sigma^2)$ denotes uncorrelated, zero-mean, Gaussian noise with a standard deviation of σ. The addition of white Gaussian noise often takes place at the imaging side, for instance due to the finite exposure time of the imaging devices, thermal noise in the CCD arrays, quantization noise, or a combination of some or all of these. The problem of image denoising can be stated as follows.

PROBLEM STATEMENT:

Given the observed image data $g(\mathbf{r})$ and our knowledge about the noise process $\nu(\mathbf{r})$ being the white Gaussian noise with the level of noise being unknown, find an approximation $\tilde{f}(\mathbf{r})$ of the original image data such that the following criterion of total distortion

$$\sum_{\mathbf{r}\in\Omega} \|f(\mathbf{r}) - \tilde{f}(\mathbf{r})\|^2 \tag{27.2}$$

is minimized, where $\Omega \subset \mathcal{R}^n$ is the set of all coordinates for the image data.

It is evident from the above problem statement that denoising is an *inverse problem* as well as an ill-posed one, since the objective here is to find a mapping $\Phi: g(\mathbf{r}) \mapsto \tilde{f}(\mathbf{r})$ which minimizes the sum of squared errors between $f(\mathbf{r})$ and $\tilde{f}(\mathbf{r})$, without having any prior knowledge of $f(\mathbf{r})$.

27.1 Filtering for Image Denoising

Denoising methods proposed in the literature can be categorized into two main classes: spatial (or spatiotemporal) and transform domain. Spatial or spatiotemporal denoising methods modify the intensity of the observed image data elements by applying a *linear* filter (e.g., averaging or Gaussian smoothing) or *nonlinear* (median filtering, edge-preserving filter such as Kuwahara filter or anisotropic diffusion) filtering operation on intensity values of the observed image data. Denoising methods that operate in the transform domain aim to amend the transform coefficients in such a way that prominent features of the original image are retained or highlighted and noise-related coefficients or noisy components of the transform coefficients are suppressed. The modification of transform coefficients can also be done in a linear, for example, multiplication or convolution, or nonlinear, thresholding or manipulation of coefficients using a nonlinear function such as $\tanh(\cdot)$, fashion.

Linear filters in both spatial and transform domains usually face the dilemma that although they can be computationally inexpensive, they often result in smoothing (also known as *blurring*) of important features, such as edges in images.

Nonlinear filters, on the other hand, aim at preserving image features that are crucial to the fidelity of reconstructed image data. Furthermore, nonlinear filtering in the transform domain offers the added advantage that it can faithfully reconstruct as well as highlight prominent image features, provided an appropriate transform for representing the image data is employed. Assuming the representation is sparse, filtering can be performed by simply thresholding the transform coefficients. The overall mapping function $\Phi(g)$ can then be defined as follows:

$$\Phi(g) = \tilde{f} = \Gamma^{-1}(\mathcal{T}\{\Gamma(g)\}), \tag{27.3}$$

where

Γ and Γ^{-1}, respectively, denote the forward and inverse transforms
$\mathcal{T}\{\cdot\}$ denotes the thresholding operation

The denoising function Φ is a nonlinear filter, even when a unitary transform Γ is employed, due to the presence of the thresholding operator $\mathcal{T}$, which is a highly nonlinear operator.

27.1.1 Nonlinear Filtering in the Transform Domain

The use of multiresolution image representations in the restoration of noisy images dates back to the late 1980s [1], in which a statistical estimator based on a simple quadtree image model was used in smoothing images corrupted by additive Gaussian noise. For image denoising, the transform Γ in Equation 27.3 ought to be chosen such that it is an appropriate representation of the most prominent spatial or spatiotemporal features present in $g(\mathbf{r})$ with the help of basis functions with suitable shape and localization. An additional advantage of the transform-based approach to filtering is that it allows one to extract important features for analysis purposes; for example, curvilinear features in still images, moving edges in video sequences, tissue interfaces in medical images, or fault surfaces in seismic images.

But what criteria should one use to choose an appropriate transform? Sparsity of a representation is widely believed to be one of the criteria used to judge its effectiveness for a particular type of feature. A representation can be regarded as being *efficient* if its basis functions resemble closely the type of feature being sought in the image data, thus resulting in its sparse representation. It is believed that during the millenia of evolution, the external visual stimuli of complex natural scenarios have influenced the human visual system (HVS), so that cells in the primary visual cortex can respond to certain important spatiotemporal features. Hubel and Wiesel [2] first showed that biological visual systems in mammals actually analyze images along dimensions such as orientation, scale, and frequency. More recently, it was shown by Olshausen and Field [3,4] that the sparse components generated by image-dependent linear transformation known as independent component analysis (ICA) resemble simple-cell receptive fields. This matches the hypothesis that the HVS captures essential information with a minimum number of excited neurons, which can be understood as a biological form of sparse representation.

27.1.2 Transform: Separable or Nonseparable?

The ordinary separable wavelet transform offers most of the desiderata that a suitable representation mimicking the HVS is required to satisfy multiresolution, sparse, localized. However, the fact that it is computed separably, i.e., on rows and columns in 2-D, for instance, implies that its basis functions are simply tensor products of 1-D wavelet basis functions along the rows and columns, resulting in capturing edges along only three orientations in 2-D: horizontal, vertical, and diagonal. Since the separable 2-D wavelet basis functions can only capture features of three possible orientations, the ordinary

wavelet transform results in a nonsparse representation of edges in other directions. This limited *orientation selectivity* can be a severe limitation in applications where detection, coding, or denoising where reconstruction of strong directional features is important. In higher dimensions also, separability seriously limits the ability of wavelets to efficiently represent higher dimensional features (such as lines in images or planes in 3-D image volumes). To overcome this limitation, several nonseparable geometric wavelets (mostly in 2-D) have been proposed in the last decade or so. These are commonly referred to as the *X-lets* in the literature, such as ridgelets [5], curvelets [6,7], wedgelets [8], beamlets [9], contourlets [10,11], brushlets [12], and arclets [13].

27.1.3 Transform: Fixed or Adaptive?

Most of the nonseparable *X-lets* mentioned above employ fixed basis functions. Some researchers believe that since the type of features that would excite the retinal neurons is fixed, it also suggests that the HVS is more likely a representation with a fixed basis rather than an adaptive one like the ICA. However, in some cases, image-dependent adaptive bases have been shown to be superior in terms of their ability to represent prominent image features, particularly when the representation is not *overcomplete*.* They offer the advantage of compactly representing the image features using basis functions that are adapted to the contents of the image data. In summary, while the fixed transform idea is appealing in terms of its computational complexity and in its comparison to the HVS, the adaptive transform may be better suited in some cases due to its adaptability but may be prohibitively expensive computation-wise.

27.1.4 Chapter Organization

In this chapter, we describe three wavelet-like representations employed to filter noisy 2-D and 3-D image data:

- Polar cosine transform (PCT) is a nonseparable 2-D transform designed to capture two of the most important features in 2-D images: curvilinear edges and texture. The development of PCT is motivated by the fact that natural images contain not only piecewise smooth regions separated by edges, but also regions with strong textural characteristics. Two constructions of PCT, one using Radon transform and another using DCT and DST in a butterfly fashion, are described in Section 27.2. The former PCT construction can also be tailored to be image-dependent such that it can be adapted to both directional linear features as well as directional textures in a unified manner according to the "*image* = *edge* + *texture*" model.
- Planelets are nonseparable 3-D basis functions, resembling planar wave functions and having compact support in space–time as well as spatiotemporal frequency. Locally planar structures can be found in many 3-D applications, including video sequences, where they represent sweeping luminance edges, and medical volume data, where they represent the interfaces between different tissue types, for example. Planelets can be regarded as an extension of the complex wavelet bases [14] which have been increasing in popularity in recent years. Because transformation to the new basis is efficient computationally, the overall denoising algorithm is highly efficient. The representation is translation invariant, offers good directional selectivity, and can be computed efficiently. The success of the approach is demonstrated using noisy video sequence and a noisy human knee MR image volume.

* An overcomplete representation is one that employs more basis functions than are required for an exact reconstruction of the original image data.

- Adaptive 3-D wavelet packet (A3-DWP) representation, which is separable but uses basis functions that are adapted to the contents of a given 3-D image data, a video sequence, or an image volume. The A3-DWP representation is optimal in terms of compactly representing local, in both space and time, spatiotemporal frequencies in the given image data. In order to reduce the effects of Gibbs phenomenon in the restored image data, translation dependence is removed by averaging the restored instances of the shifted data in all three directions.

27.2 Polar Cosine Transform

It is widely recognized that natural images consist of piecewise smooth regions separated by edges as well as textured regions. While various different models for curved edges exist, including some of the *X-lets* mentioned in Section 27.1, texture representation has faced difficulties due to lack of a single widely accepted mathematical definition of texture patterns that can be found in images. There are, however, certain assumptions that can be made for most natural textures:

- Oriented. Many spatial textures have a prominent direction, for example wood patterns and seismograms, or a combination of several such components.
- Periodic. The texture tends to repeat certain basic elements at a given frequency and tends to repeat itself with a degree of affine invariance.
- Localized. In natural images, the textures are usually confined within a particular region. In other words, they are spatially localized.

Over the years, several wave packet bases such as local cosines [15,16], wavelet packets [17,18], and brushlets [19] have been proposed as suitable representations for oscillatory textures. However, they either lack orientation selectivity, or their spatial-frequency localization is not satisfactory. Moreover, due to the Uncertainty Principle, a sparse representation for both singularities and periodic oscillations in a fixed basis is a fundamental dilemma [20]. The resort is to find an image-dependent *adaptive* basis which can accommodate both directional linear features as well as directional textures in a unified manner according to the "*image* = *edge* + *texture*" model.

27.2.1 Continuous Transform

A prototypical oriented texture pattern can be seen as a higher dimensional function which has a waveform constant along a fixed direction. Such functions are usually referred to as "planar waves" or "ridge functions" in approximation related literature [21]. Formally, a ridge function is a multivariate function of the form $\psi(\vec{\xi} \cdot \vec{\theta})$ where $\psi(\cdot)$ is a univariate function usually referred to as the *ridge profile*, with spatial coordinate vector $\vec{\xi} \in \mathbb{R}^d$ and $\vec{\theta} \in \mathbf{S}^{d-1}$. This means $\vec{\theta}$ is on the unit sphere $\mathbf{S}^{d-1}$ in dimension $d > 1$ and indicates the orientation.

In order to model oriented texture, a real-to-complex ridge profile $\psi: \mathbb{R} \to \mathbb{C}$ can be defined as

$$\psi_\omega(\xi) = e^{i\omega\xi}. \tag{27.4}$$

which is basically the 1-D Fourier basis function, and the corresponding multivariate ridge function by definition is

$$\psi_\omega(\vec{\xi} \cdot \vec{\theta}) = e^{i\omega(\vec{\xi}\cdot\vec{\theta})}. \tag{27.5}$$

The ridge function gives a complex trigonometric oscillatory constant along the direction $\vec{\theta}$. Taking the inner product of it with a function $f(\vec{\xi})$ gives

$$\hat{f}(\omega, \vec{\theta}) = \langle f(\vec{\xi}),\ \psi_\omega(\vec{\xi} \cdot \vec{\theta}) \rangle = \int f(\vec{\xi}) e^{-i\omega(\vec{\xi}\cdot\vec{\theta})} d\vec{\xi}. \tag{27.6}$$

This is exactly the *d*-dimensional Fourier transform expressed in polar coordinate form, or just simply *polar Fourier transform*. The conversion to Cartesian coordinates can be done by separating the radial frequency into a frequency vector:

$$\vec{\omega} = \omega\vec{\theta}. \tag{27.7}$$

With a slight rearrangement of Equation 27.6, the equivalence becomes obvious:

$$\hat{f}(\omega, \vec{\theta}) = \int f(\vec{\xi}) e^{-i\vec{\xi}\cdot(\omega\vec{\theta})}\ d\vec{\xi} = \int f(\vec{\xi}) e^{-i\vec{\xi}\cdot\vec{\omega}}\ d\vec{\xi} = \hat{f}(\vec{\omega}). \tag{27.8}$$

Meanwhile, the definition for the continuous Radon transform in *d*-dimensions is

$$\mathcal{R}f(t, \vec{\theta}) = \int f(\vec{\xi}) \delta(\vec{\xi} \cdot \vec{\theta} - t) d\vec{\xi}. \tag{27.9}$$

The relationship between the Radon transform and the polar Fourier transform is stated as the Fourier Slice Theorem [22]:

THEOREM 27.1 (Fourier Slice Theorem)

The 1-D Fourier transform with respect to t of the projection $\mathcal{R}f(t, \vec{\theta})$ *is equal to a central slice, at a given orientation* $\vec{\theta}$*, of the higher dimensional Fourier transform of the function* $f(\vec{\xi})$*, that is,*

$$\widehat{\mathcal{R}f(t,\ \vec{\theta})} = \hat{f}(\omega,\ \vec{\theta}). \tag{27.10}$$

If some boundary condition is to be posed at each polar orientation, instead of being defined on $\mathbb{R}$, the Radon slice $\mathcal{R}_{\vec{\theta}} f(t)$ is assumed to be an even function $\mathcal{R}_{\vec{\theta}} f(t) = \mathcal{R}_{\vec{\theta}} f(-t)$, then its Fourier transform can be written as follows:

$$\widehat{\mathcal{R}f(t, \vec{\theta})} = \sqrt{\frac{2}{\pi}} \int_0^{+\infty} \mathcal{R}f(t, \vec{\theta}) \cos(\omega t) dt. \tag{27.11}$$

It is noted that only the real cosine part remains in the above equation due to the even boundary assumption on the slices. This is equivalent to a cosine tranform with ridge-type basis functions defined as

$$\psi_\omega^{\mathcal{C}}(\vec{\xi} \cdot \vec{\theta}) = \sqrt{\frac{2}{\pi}} \cos(\omega\vec{\xi} \cdot \vec{\theta}). \tag{27.12}$$

In the same way by assuming $\mathcal{R}_\theta f(t) = -\mathcal{R}_\theta f(-t)$, the sine counterpart is

$$\psi_\omega^{\mathcal{S}}(\vec{\xi}\cdot\vec{\theta}) = \sqrt{\frac{2}{\pi}}\sin(\omega\vec{\xi}\cdot\vec{\theta}). \tag{27.13}$$

Correspondingly, the continuous polar cosine and sine transform are denoted, respectively, as

$$\mathcal{C}f(\omega,\vec{\theta}) = \langle f(\vec{\xi}),\ \psi_\omega^{\mathcal{C}}(\vec{\xi}\cdot\vec{\theta})\rangle = \sqrt{\frac{2}{\pi}}\int_0^{+\infty} f(\vec{\xi})\cos(\omega\vec{\xi}\cdot\vec{\theta})\mathrm{d}\vec{\xi} \tag{27.14}$$

and

$$\mathcal{S}f(\omega,\vec{\theta}) = \langle f(\vec{\xi}),\ \psi_\omega^{\mathcal{S}}(\vec{\xi}\cdot\vec{\theta})\rangle = \sqrt{\frac{2}{\pi}}\int_0^{+\infty} f(\vec{\xi})\sin(\omega\vec{\xi}\cdot\vec{\theta})\mathrm{d}\vec{\xi}. \tag{27.15}$$

These two transforms, along with the polar Fourier transform, can be regarded as a family of *Polar Trigonometric Transforms*. In the context of image processing, the PCT is the transform of interest in this work, due to its better approximation convergence properties attributed to the even boundary extension [23]. Since it is essentially the Fourier transform, the completeness of the transform makes the transform operator $\mathcal{C}$ unitary which means $\mathcal{C}^{-1} = \mathcal{C}^\star$. Since the transform is real, the operator is self-conjugate, making the inverse transform exactly the same as the forward transform:

$$\mathcal{C}^{-1} = \mathcal{C}. \tag{27.16}$$

The same also holds for the continuous polar sine transform and its inverse.

27.2.2 Discrete Transform

The continuous PCT essentially replaces the polar Fourier transform's complex basis with a real cosine sinusoid as the ridge function, by assuming the projected Radon slice is even. In a discrete case, the Fourier-related transforms that operate on a function over a finite domain can be thought of as implicitly defining an extension of that function outside the domain. The discrete Fourier transform (DFT) implies a periodic extension of the original function. A discrete cosine transform (DCT), like the continuous cosine transform, implies an even extension of the original function.

However, when the transform is to operate on finite, discrete sequences, two issues arise that are not relevant in case of the continuous cosine transform. First, one has to specify whether the function is even or odd at both the left and right boundaries of the domain. Second, one has to specify around what point the function is even or odd. These issues result in several different versions of DCTs, a full list of which along with corresponding DSTs is given in Table 27.1. For a discrete polar cosine transform, any of the DCTs can be adopted to form the basis ridge function. In particular, the so-called DCT-II is widely used in many applications such as the famed JPEG compression [24] due to its even boundary extensions on both ends, which gives better approximation convergence. The 1-D DCT-II function is defined by the ridge profile:

$$\psi_k[n] = \cos\left[\frac{\pi}{N}\left(n+\frac{1}{2}\right)k\right]. \tag{27.17}$$

where

N is the possible number of frequencies as well as the length of the Radon projection slice
$k = 0, 1, \ldots, N-1$ is the frequency index

TABLE 27.1 List of DCTs and DSTs

DCT-I	$\frac{1}{2}(x_0 + (-1)^k x_{N-1}) + \sum_{n=1}^{N-2} x_n \cos\left[\frac{\pi}{N-1} nk\right]$
DCT-II	$\sum_{n=0}^{N-1} x_n \cos\left[\frac{\pi}{N}(n+\frac{1}{2})k\right]$
DCT-III	$\frac{1}{2}x_0 + \sum_{n=1}^{N-1} x_n \cos\left[\frac{\pi}{N} n\left(k+\frac{1}{2}\right)\right]$
DCT-IV	$\sum_{n=0}^{N-1} x_n \cos\left[\frac{\pi}{N}\left(n+\frac{1}{2}\right)\left(k+\frac{1}{2}\right)\right]$
DST-I	$\sum_{n=0}^{N-1} x_n \sin\left[\frac{\pi}{N+1}(n+1)(k+1)\right]$
DST-II	$\sum_{n=0}^{N-1} x_n \sin\left[\frac{\pi}{N}\left(n+\frac{1}{2}\right)(k+1)\right]$
DST-III	$\sum_{n=0}^{N-2} x_n \sin\left[\frac{\pi}{N}(n+1)\left(k+\frac{1}{2}\right)\right]$
DST-IV	$\sum_{n=0}^{N-1} x_n \sin\left[\frac{\pi}{N}\left(n+\frac{1}{2}\right)\left(k+\frac{1}{2}\right)\right]$

In the context of image processing, the discussion of discretization of the PCT will be further restricted to the 2-D case, which means the unit orientation vector becomes

$$\vec{\theta} = \begin{bmatrix} \cos\theta \\ \sin\theta \end{bmatrix}. \tag{27.18}$$

With $\vec{\xi} = [\xi_1, \xi_2]$, the discrete cosine ridge function is

$$\psi_k[\xi_1 \cos\theta + \xi_2 \sin\theta] = \cos\left[\frac{\pi}{N}\left(\xi_1 \cos\theta + \xi_2 \sin\theta + \frac{1}{2}\right)k\right]. \tag{27.19}$$

Then the discrete polar cosine transform on an $M \times M$ 2-D image $f[\vec{\xi}]$ can be defined as

$$\begin{aligned} \mathcal{C}f[k,\theta] &= \left\langle f[\vec{\xi}],\ \psi_k[\xi_1 \cos\theta + \xi_2 \sin\theta] \right\rangle \\ &= \sum_{\xi_1=0}^{M-1} \sum_{\xi_2=0}^{M-1} f\left[\xi_1, \xi_2\right] \cos\left[\frac{\pi}{N}\left(\xi_1 \cos\theta + \xi_2 \sin\theta + \frac{1}{2}\right)k\right]. \end{aligned} \tag{27.20}$$

The inverse transform for DCT-II is the DCT-III transform. The corresponding cosine ridge function for the inverse transform is

$$\psi_k^{-1}[\xi_1 \cos\theta + \xi_2 \sin\theta] = \lambda_k \cos\left[\frac{\pi}{N}\left(\xi_1 \cos\theta + \xi_2 \sin\theta + \frac{1}{2}\right)\left(k+\frac{1}{2}\right)\right], \tag{27.21}$$

where

$$\lambda_k = \begin{cases} 1/2 & \text{if } k = 0, \\ 1 & \text{if } k \neq 0, \end{cases}$$

and the discrete inverse polar cosine transform operator $\mathcal{C}^{-1}$ is given by

$$\begin{aligned} \mathcal{C}^{-1}f[k,\theta] &= \langle f[\vec{\xi}],\ \psi_k[\xi_1 \cos\theta + \xi_2 \sin\theta] \rangle \\ &= \sum_{\xi_1=0}^{M-1} \sum_{\xi_2=0}^{M-1} f[\xi_1,\ \xi_2] \lambda_k \cos\left[\frac{\pi}{N}\left(\xi_1 \cos\theta + \xi_2 \sin\theta + \frac{1}{2}\right)\left(k+\frac{1}{2}\right)\right]. \end{aligned} \tag{27.22}$$

27.2.3 Radon-Based Digital Implementation

Equations 27.10 and 27.11 suggest that the discrete PCT can be implemented by a Radon transform, that is, taking the 1-D DCT on Radon slices:

$$\mathcal{C}f[k,\ \theta] = \sum_{t=0}^{N-1} \mathcal{R}f[t, \theta] \cos\left[\frac{\pi}{N}\left(t + \frac{1}{2}\right)k\right]. \tag{27.23}$$

As the Fourier Slice Theorem shows, the Radon transform can be implemented by taking the central slice in the Fourier spectrum and then performing a 1-D inverse Fourier transform on it. Applying DCT on the Radon slices, we can obtain the discrete PCT.

This gives a means for a digital implementation of the discrete polar cosine transform. For the Radon transform, various ways to implement it in a discrete fashion have been attempted, among which the Fast Slant Stack [25] was chosen, which is based on a pseudo-polar Fast Fourier Transform (FFT) [26]. According to Ref. [25], the transform is computationally efficient, algebraically exact, geometrically faithful, and its inversion is numerically stable.

With the implementation described above, the PCT basis vectors for an 8×8 image block can be seen in Figure 27.1. The basis vectors are indexed by frequency k and orientation θ. As a result of the Cartesian-to-polar conversion in the frequency domain, the low-frequency basis vectors are clearly being over-sampled, resulting in a redundant frame where the number of coefficients is four times the original data size.

27.2.4 Butterfly-Based Digital Implementation

The above digital implementation of the PCT based on the Radon transform is akin to the digital ridgelet transform [27]. Such a Radon-based approach is flexible in constructing various directional ridge-type transforms, but it suffers from several drawbacks of the underlying Radon transform. First is the high computational requirement both for the forward and inverse transforms. The forward transform includes a pseudo-polar Fourier transform, 1-D inverse Fourier transforms on polar slices, and forward cosine

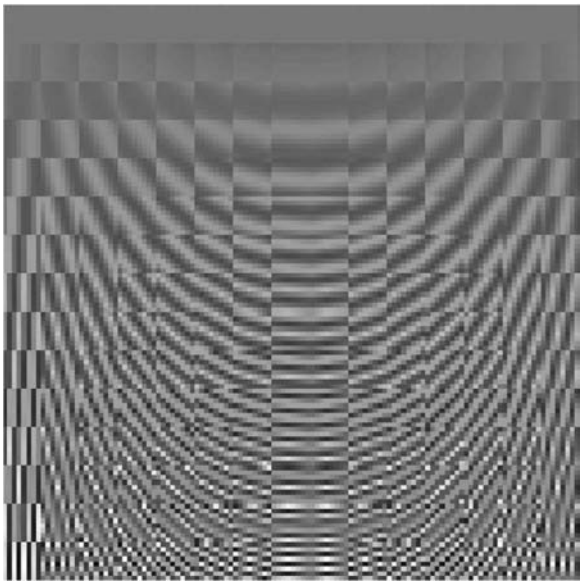

FIGURE 27.1 8×8 discrete polar cosine basis vectors.

transforms. The inverse Fast Slant Stack uses an iterative algorithm in the reconstruction to minimize numerical instability. Secondly, the redundancy factor could be an issue in some applications. While it seems implausible to construct a digital ridgelet transform without invoking the Radon transform, it does not necessarily hold true for the PCT. A possible construction of such directional real trigonometric transform in the context of modulated lapped transforms was discussed in Ref. [28]. The same construction is adopted here in implementing a digital PCT.

It can be observed from Table 27.1 that the DCT-IV and DST-IV share the same function parameters. In 2-D, Cartesian separable basis functions can be formed by the tensor product of 1-D bases:

$$\psi^{\mathcal{C}}_{k_1,k_2}[\xi_1,\,\xi_2] = \cos\left[\frac{\pi}{N}\left(\xi_1+\frac{1}{2}\right)\left(k_1+\frac{1}{2}\right)\right]\cos\left[\frac{\pi}{N}\left(\xi_2+\frac{1}{2}\right)\left(k_2+\frac{1}{2}\right)\right]. \tag{27.24}$$

$$\psi^{\mathcal{S}}_{k_1,k_2}[\xi_1,\,\xi_2] = \sin\left[\frac{\pi}{N}\left(\xi_1+\frac{1}{2}\right)\left(k_1+\frac{1}{2}\right)\right]\sin\left[\frac{\pi}{N}\left(\xi_2+\frac{1}{2}\right)\left(k_2+\frac{1}{2}\right)\right]. \tag{27.25}$$

By setting $A = \frac{\pi}{N}(\xi_1+\frac{1}{2})(k_1+\frac{1}{2})$ and $B = \frac{\pi}{N}(\xi_2+\frac{1}{2})(k_2+\frac{1}{2})$, the expression is simplified as follows:

$$\begin{aligned}\psi^{\mathcal{C}}_{k_1,k_2}[\xi_1,\,\xi_2] - \psi^{\mathcal{S}}_{k_1,k_2}[\xi_1,\,\xi_2] &= \cos A\cos B - \sin A\sin B\\ &= \cos\left[A+B\right]\\ &= \cos\left[\frac{\pi}{N}\left(\left(\xi_1+\frac{1}{2}\right)\left(k_1+\frac{1}{2}\right)+\left(\xi_2+\frac{1}{2}\right)\left(k_2+\frac{1}{2}\right)\right)\right]\\ &= \cos\left[\frac{\pi}{N}\left(\xi_1k_1+\xi_2k_2+\frac{1}{2}(\xi_1+\xi_2+k_1+k_2+1)\right)\right].\end{aligned} \tag{27.26}$$

Therefore the difference between the 2-D basis functions of DCT-IV and DST-IV at given frequencies can be reduced into a cosine component. Furthermore, since $k_1 = k\cos\theta$, $k_2 = k\sin\theta$, where $k = \sqrt{k_1^2+k_2^2}$ is the polar frequency index and $\theta = \arctan(k_2/k_1)$, Equation 27.26 can be rewritten in the polar cosine form:

$$\begin{aligned}\psi^{\chi}_{k,\theta}[\xi_1,\,\xi_2] &= \psi^{\mathcal{C}}_{k\cos\theta,k\sin\theta}[\xi_1,\,\xi_2] - \psi^{\mathcal{S}}_{k\cos\theta,k\sin\theta}[\xi_1,\,\xi_2]\\ &= \cos\left[\frac{\pi}{N}\left((\xi_1\cos\theta+\xi_2\sin\theta)k+\frac{1}{2}(\xi_1+\xi_2+k\cos\theta+k\sin\theta+1)\right)\right].\end{aligned} \tag{27.27}$$

However, it should be noted that compared with the PCT-II defined in Equation 27.20, although the basis vectors do not represent a strict form of ridge functions, they are directional and can be arranged in polar form. The above is set for the case when $k_1 = 0, \ldots, N-1$ and $k_2 = 0, \ldots, N-1$. For negative frequencies, it is clear that

$$\begin{aligned}\psi^{\chi}_{k_1,-k_2-1}[\xi_1,\xi_2] &= \psi^{\mathcal{C}}_{k_1-k_2-1}[\xi_1,\,\xi_2] - \psi^{\mathcal{S}}_{k_1,-k_2-1}[\xi_1,\,\xi_2]\\ &= \cos A\cos\left[-B\right] - \sin A\sin\left[-B\right]\\ &= \cos A\cos B + \sin A\sin B\\ &= \psi^{\mathcal{C}}_{k_1,k_2}[\xi_1,\,\xi_2] + \psi^{\mathcal{S}}_{k_1,k_2}[\xi_1,\xi_2].\end{aligned} \tag{27.28}$$

This suggests that for $-k_2-1 = -1, \ldots, -N$, the basis function is just the sum of DCT-IV and DST-IV. In the same way, it is not difficult to see that when $k_1 = -1, \ldots, -N$ and $k_2 = -N, \ldots, N-1$, which is the basis functions for the lower half-plane of the frequency spectrum:

$$\psi^{\chi}_{k_1,k_2}[\xi_1,\xi_2] = \psi^{\chi}_{-k_1-1,-k_2-1}[\xi_1,\,\xi_2]. \tag{27.29}$$

Thus the corresponding transform domain exhibits the same Hermite symmetry as the Fourier transform, with basis functions very close to the FFT's basis functions. As a result, the transform

$$\chi f[k_1, k_2] = \langle f[\xi_1, \xi_2],\ \psi^{\chi}_{k_1,k_2}[\xi_1, \xi_2] \rangle \tag{27.30}$$

is only twice redundant, by removing a half-plane of the spectrum and can be efficiently implemented by a butterfly computation. A schematic illustration of the transform can be seen in Figure 27.2. For the sake of convenience, this particular digital implementation will be referred to as PCT-X. A complete basis for size 8×8 is shown in Figure 27.3.

It is observed that the PCT-X is closely related to the Fourier transform itself, despite the new transform being real. The expansion of PCT-X, therefore, can be expected to have similarities with the Fourier magnitude spectrum.

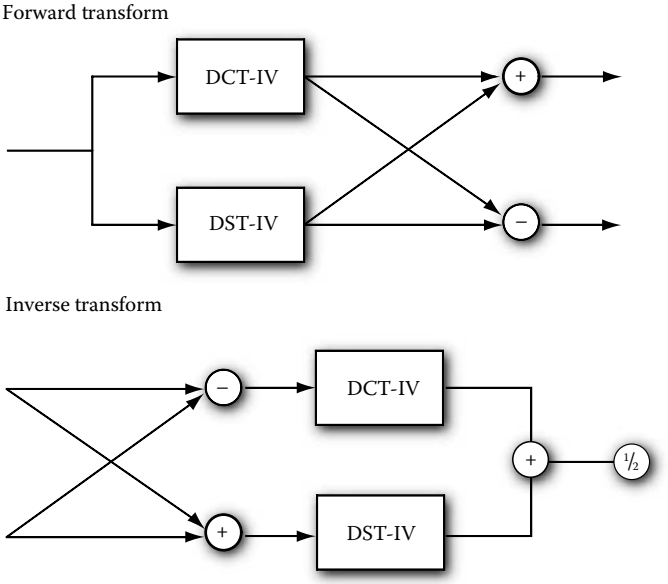

FIGURE 27.2 Forward PCT-X transform and the inverse transform.

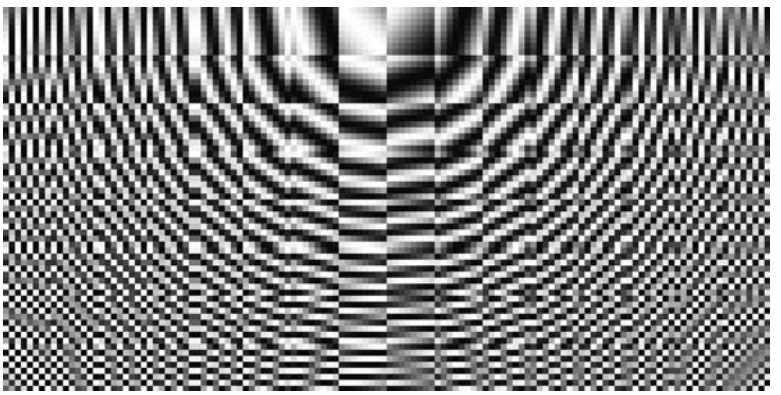

FIGURE 27.3 8×8 discrete polar cosine basis vectors.

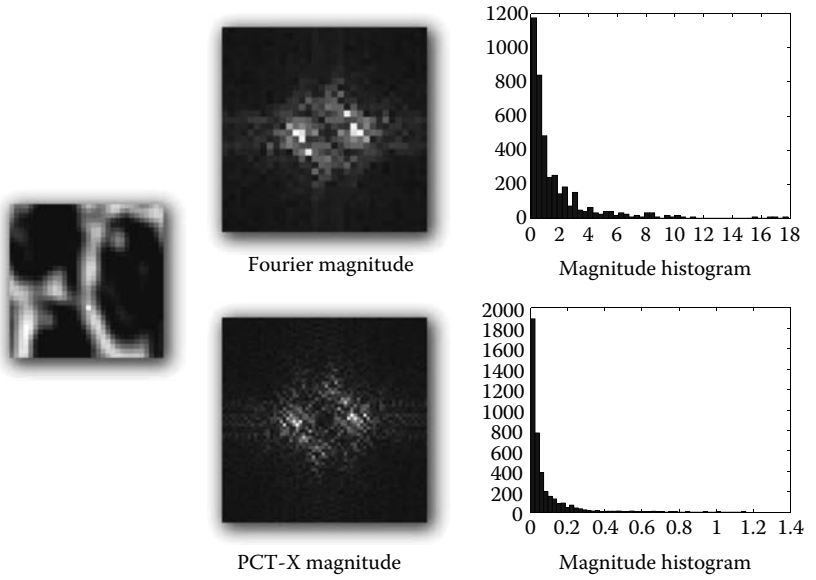

FIGURE 27.4 Spectrum comparison between the PCT-X and the Fourier transform.

In Figure 27.4, a comparison between the PCT-X spectrum and the Fourier spectrum is made. A reptile texutre patch is chosen as the test data and the two transforms yield very similar magnitude responses. However, the histograms suggest that the coefficients of the PCT-X expansion are sparser than those of the Fourier transform, attributed to the symmetric boundary extension of the underlying DCT-IV and DST-IV.

27.2.5 Nonlinear Approximation

As previously mentioned in Section 27.2, with the difficulty in mathematically formulating texture, it is hard to approach the nonlinear approximation problem quantitatively. The theoretical study of the transform in the context of computational harmonic analysis is beyond the scope of this thesis, where the main concern is on examining its effectiveness in providing sparsity in the transformed expansion. The approach taken here is more empirical, where the nonlinear approximation results are presented in the form of output from numerical experiments.

Two digital PCT implementations were selected for nonlinear approximation experiments: the Radon-based PCT with DCT-II as ridge profile (PCT-II) and the butterfly PCT-X implementation as shown in Figure 27.2. They are compared with three other transforms: the FFT; the DCT-II, which is a Cartesian separable real-to-real implementation of FFT; and the *fast curvelet transform* (FCT) which is implemented by wrapping of specially selected subbands of Fourier samples [29].

Two different image patches are tested for nonlinear approximation. The first one contains a portion of a fingerprint image, which consists of repeated curved ridges. The second one is a simple straight line. The purpose of including such a linear singularity is that although it is not ideal to be represented by an oscillatory basis, it would be still worth comparing with other trigonometric transforms. All the patches are sized 256×256, cropped from the original 512×512 images. They are prewhitened by taking the highpass subband Laplacian pyramid.

The nonlinear approximation results are represented in Figures 27.5 and 27.6 as PSNR curves. The PSNR values are plotted against the top percentage of coefficients, from 2% to 50%. The percentage

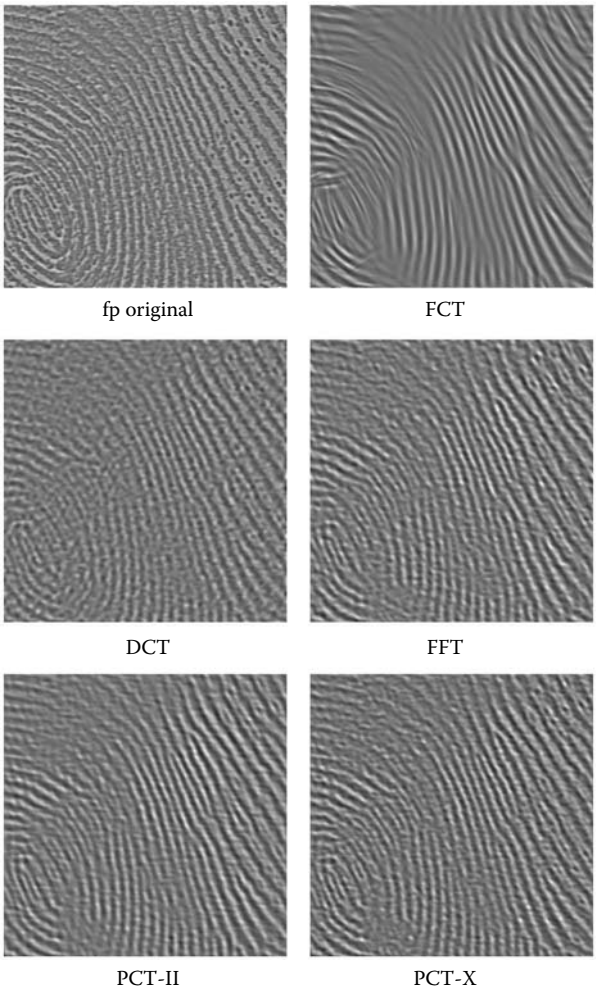

FIGURE 27.5 Nonlinear approximation PSNR curves for fp.

instead of the number of coefficients is used due to the fact that different transforms yield different number of coefficients. For the sake of convenience, a table of percentages and the corresponding retained numbers of coefficients for different transforms are listed in Table 27.2. It is observed that for the textured image **fp**, the PCTs outperform the other candidates consistently. With fewer coefficients, the PCT-X's PSNR is usually close to the PCT-II, occasionally outperforms it (on **fp**). This is due to the fact that PCT-II's reconstruction is less stable with fewer coefficients while PCT-X's inverse transform is exact. However, the goodness of DCT-II's even symmetric boundaries eventually yields better PSNR with relatively more coefficients involved. While low PSNR performances are to be expected from the trigonometric transforms, it is also reassuring that the two PCTs give better PSNR than the DCT and FFT.

Figure 27.7 shows the reconstructions from the top 2% coefficients of these four transforms on **fp**. The reconstruction from FCT looks artificial, due to its inability to capture directional harmonics of the image, an oscillatory pattern has to be described as several directional singularities. The DCT reconstruction, while being closer to the original, does not highlight the oriented patterns as well as

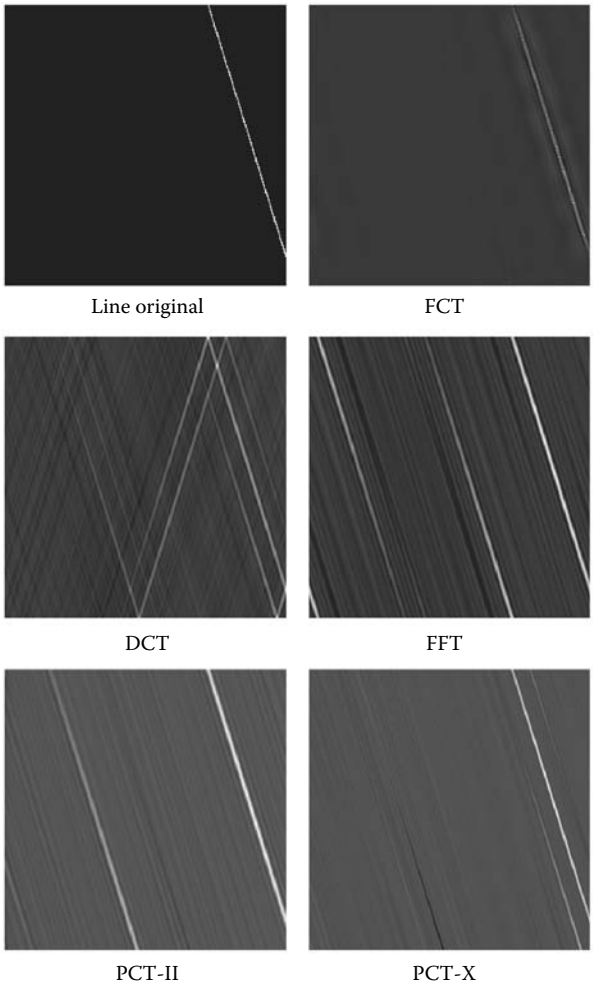

FIGURE 27.6 Nonlinear approximation PSNR curves for line.

TABLE 27.2 Percentage versus Number of Retained Coefficients for Different Transforms

Percentage (%)	FCT	DCT	FFT	PCT-II	PCT-X
0.1	185	66	66	262	132
2	3700	1311	1311	5243	2622
15	27748	9830	9830	39322	19660
100	184985	65536	65536	262144	131072

the PCTs. The results from FFT and PCTs are very similar, while the PCTs give slightly better reconstructions with the directional regularities on the fingerprint ridges, particularly by PCT-X.

Another example is the line in Figure 27.8. The percentage of coefficients is kept as little as 0.1%. It is not surprising that the FCT restores the line faithfully even at such a low ratio. The reconstructions from the four Fourier-type bases (DCT, FFT, and the two PCTs) all exhibit the ''ghosting'' artifacts sometimes referred to as the Gibbs phenomenon, due to suppressing too many high frequency

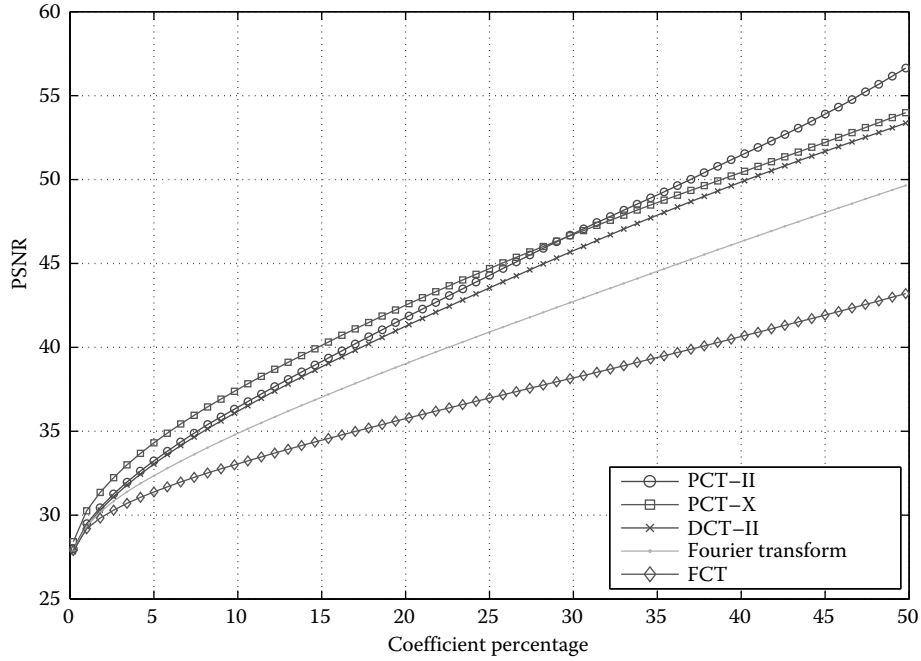

FIGURE 27.7 Illustrative results for nonlinear approximation on fp.

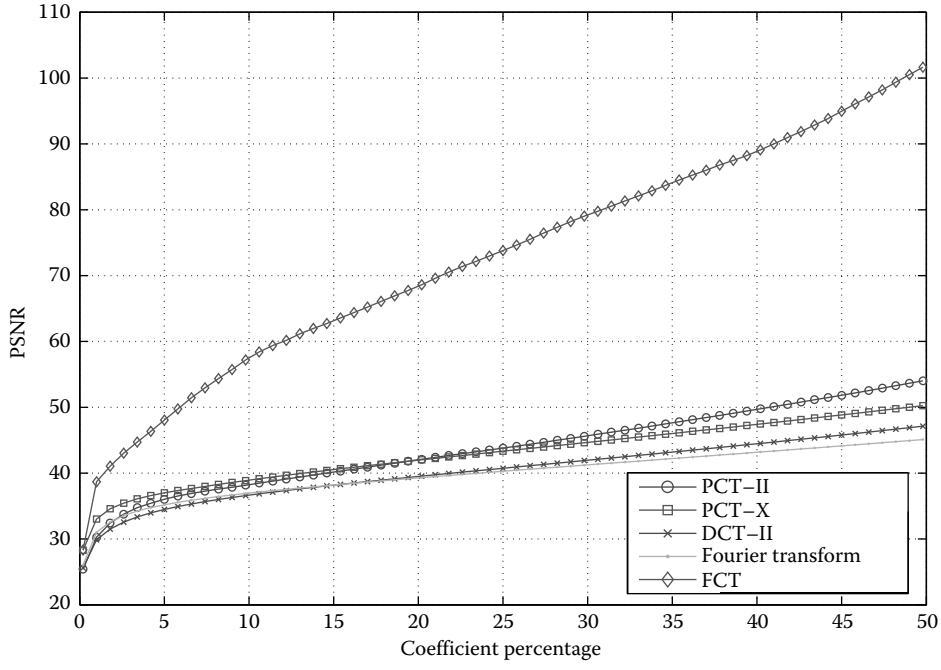

FIGURE 27.8 Illustrative results for nonlinear approximation on line.

coefficients. The DCT shows the ghosting artifact on two different orientations, the FFT has two ghost lines appearing on the reconstruction. The PCT-II, on the other hand, due to the boundary extension being assumed on the Radon slices, shows only one significant ghost line. The ghosting artifact is further reduced in PCT-X's reconstruction.

27.2.6 Polar Cosine Packets

As previously discussed, the Radon transform can reduce the PCT into a matter of performing the cosine transform on Radon slices. This also makes it possible to analyze directional features other than sinusoidal ridges. This is achieved by taking the transform in separate spatial windows. Local trigonometric bases proposed by Coifman and Meyer [30] and by Malvar [31] use smooth window functions to split the signal and to fold overlapping parts back into the original pieces so that the orthogonality is preserved. This treatment can avoid the discontinuity artifacts caused by a rectangular window, while introducing no redundancy.

The local cosine basis is composed of basis functions of the form

$$\varphi_{p,k}(t) = w_p(t)\sqrt{\frac{2}{|I_p|}}\cos\left[\pi\left(k+\frac{1}{2}\right)\frac{t-c_p}{|I_p|}\right]. \tag{27.31}$$

The Cosine-VI basis is used and modulated by a window function $w_p(t)$ which lies on an interval $[a_{p-1}, a_p]$ with $c_p = (a_p + a_{p-1})/2$, and $|I_p| = c_{p+1} - c_p$ being the length of the window, with the overlapping part included. With a careful choice of the window (see Ref. [15]), the set $\{a_p\} \subset \mathbb{R}$ forms a partition of unity and the local cosine basis associated to such partition is said to form a library of orthonormal bases usually referred to as the cosine packets.

The polar cosine packets can be implemented by placing the 1-D cosine packets on the Radon slices; the operator is denoted as

$$\mathcal{P}f[p,k,\theta] = \langle \mathcal{R}f[t,\theta], \varphi_{p,k}[t]\rangle. \tag{27.32}$$

Unfortunately, due to its implementation, it is not possible to construct similar polar cosine packets with the PCT-X.

27.2.7 Best Basis Selection

The arbitrary choice over the library of local trigonometric bases over a compact interval U is of an extremely large range. To seek a feasible "best basis," the library of cosine packets is reduced to only taking dyadically partitioned decomposition of U only. This organization is depicted schematically in Figure 27.9. Then I_{00} is a cosine basis on the entire U and $I_{p,s}$ will correspond to the local cosine basis over interval p of the 2^s intervals at level s of the tree. The best basis can be found by induction on s.

Let $B_{p,s}$ denote the cosine basis vectors corresponding to interval $I_{p,s}$, and $A_{p,s}$ be the best basis. For $s = 0$, the best basis $A_{p,0} = B_{p,0}$, otherwise

$$A_{p,s+1} = \begin{cases} B_{p,s+1} & \text{if } \mathcal{M}(B_{p,s+1}x) < \mathcal{M}(A_{2p,s}x) + \mathcal{M}(A_{2p+1,s}x), \\ A_{2p,s} \oplus A_{2p+1,s} & \text{otherwise.} \end{cases} \tag{27.33}$$

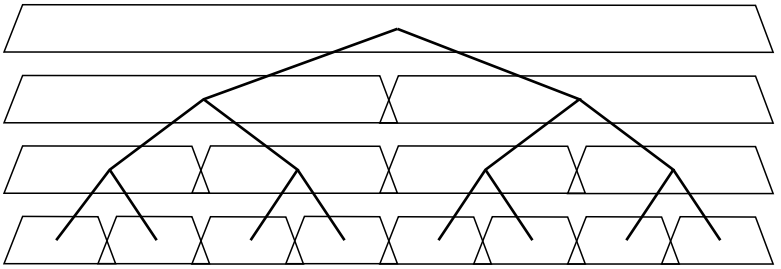

FIGURE 27.9 Binary tree of the localization of partitioned intervals.

where

$\oplus$ denotes a concatenation operation

$\mathcal{M}(\cdot)$ is a certain cost function

The resulting best basis is optimal relative to the cost function $\mathcal{M}$, which means different choices of the cost function reflecting certain criterion can result in different selections of the best basis. Such an approach is called ''entropy-based best basis selection.'' For a complete treatment on the subject, see Ref. [32].

The best basis can be sought with the local cosine basis on the Radon slices. The resulting transform is called the polar cosine packet transform (PCPT), while the choice of the cost function $\mathcal{M}$ depends on the application.

27.2.8 Multiscale Polar Cosine Transform

It was recognized, as early as in 1978 [33], that, for an image representation to be useful, the transform should be well spatially localized. More importantly, the transform should be multiscale, in order to capture patterns of interest at different scales. While the PCT is able to provide a sparse expansion for directional patterns with good frequency resolution, putting it into a multiresolution, spatially localized manner is required. The result is a new wavelet-type transform called the multiscale polar cosine transform (MPCT), which is discussed in the following sections.

27.2.8.1 Construction of MPCT

A prototypical multiscale polar cosine function has the form

$$\Psi_{k,\vec{\theta},s,\vec{\eta}}(\vec{\xi}) = w\left(\frac{\vec{\xi}-\vec{\eta}}{s}\right)\psi_k\left(\frac{(\vec{\xi}-\vec{\eta})\cdot\vec{\theta}}{s}\right). \tag{27.34}$$

where

$k, \vec{\theta}, \vec{\eta}$, and s denote the frequency, orientation, location, and scale parameters of the function, respectively

$w(\cdot)$ is the smooth window function chosen along with the sampling interval to ensure invertibility of the discrete form of the transform

Effectively the transform can be viewed as a stack of windowed polar cosine transforms at a range of scales, with different block sizes for windowing. The coarser the scale s is, the larger the window becomes. The digital implementation of such a multiscale lapped transform requires two operators: a

level operator which decomposes the signal into different scales, and a local operator which handles the decomposition locally within a block—in this case could be either the PCT operator $\mathcal{C}$ or the Polar cosine packet operator $\mathcal{P}$, which gives us the multiscale polar cosine packet transform (MPCPT).

A desirable level operator should have the following two properties:

1. Operator should be able to separate the signal into different frequency subbands.
2. Decomposed subbands should be isotropic, which then can be exploited well by the high-frequency resolution and the directional selectivity of the PCT.

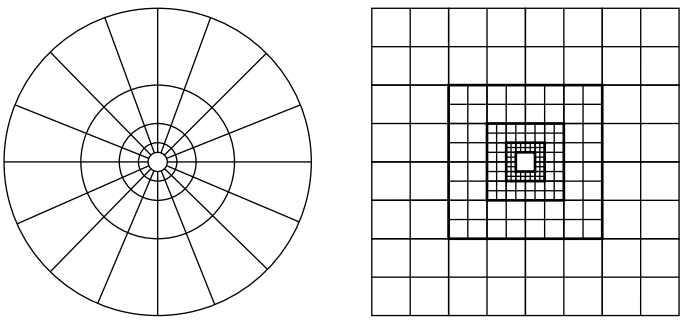
A reasonable choice of the level operator is the Laplacian pyramid [34]. As in Chapter 3, for a particular level x_s of subband, it is computed as

$$x_s(\vec{\eta}) = (\mathbf{I} - \mathbf{G}_{s,s+1}\mathbf{G}_{s+1,s})x'_s. \tag{27.35}$$

where

$\mathbf{I}$ is the identity operator

x'_s is the Gaussian lowpass pyramid representation of $x(\vec{\eta})$



$$x'_s(\vec{\eta}) = \sum_{l=0}^{s-1} \mathbf{G}_{l+1,l}x(\vec{\eta}). \tag{27.36}$$

$\mathbf{G}_{s,s+1}, \mathbf{G}_{s+1,s}$ are the raising and lowering operators associated with transitions between levels in the Gaussian pyramid, as defined previously in Chapter 3

Due to the dyadic decimation, the pyramid is known to have some 33% extra redundancy in 2-D, which is acceptable for general use in many image processing tasks. This also allows us to use a constant window size over different scales, which is equivalent to a dyadic increment of the window size.

27.2.8.2 Basis Functions and Frequency Tiling

The basis functions of the MPCT are 2-D cosine ridges with certain frequency, orientation confined to certain spatial location and scale. Several MPCT basis functions are shown in both spatial and frequency domains in Figure 27.10. These are three members of the MPCT basis at increasing scales on a 256×256 grid. Every function oscillates coherently in a preferred direction and frequency and confined by a

Continuous case Discrete case

FIGURE 27.10 Basis functions at different scales and their frequency responses.

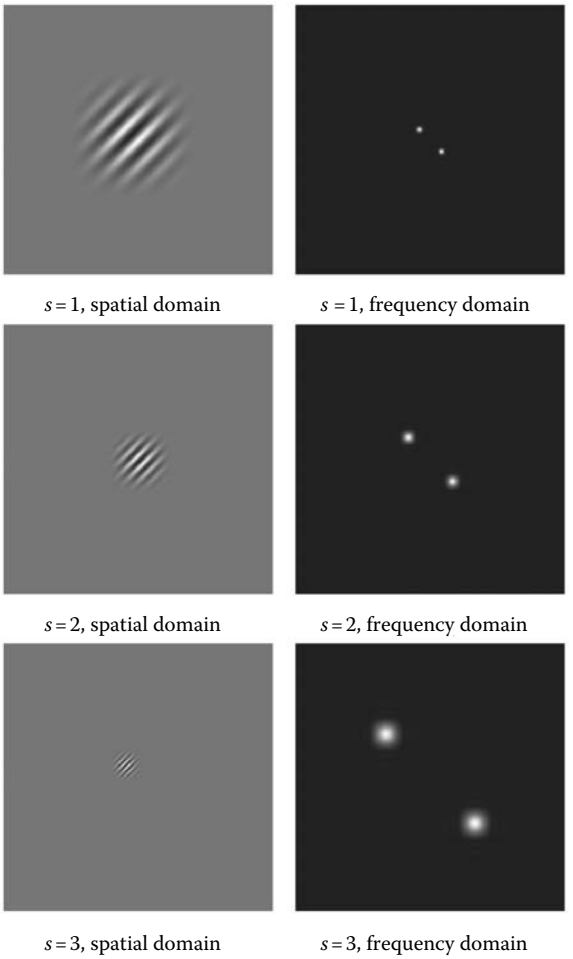


FIGURE 27.11 Frequency tilings of the MPCT.

cosine-squared window. In the frequency domain, the Fourier transform of these functions is well-localized as well, exhibiting two symmetric blobs at an orientation perpendicular to that of the spatial functions. The size of the frequency blob increases with the scale, while the spatial window size decreases dyadically.

Figure 27.11 schematically demonstrates how the frequency plane is partitioned by the MPCT decomposition, both in continuous and discrete cases. It is clear that the polar orientation resolutions at different scales are the same and each of the subbands from the level operator is partitioned into equal number of boxes.

27.2.9 Relationship with Other Transforms

The construction of the MPCT presented here follows a long legacy in both harmonic analysis and image processing, and is directly connected with many other transforms proposed in the literature.

27.2.9.1 Multiresolution Fourier Transform

The multiresolution Fourier transform (MFT) is a windowed Fourier transform at different resolutions and the digital implementation is usually done by a similar lapped block transform like the MPCT with a

local FFT operator. Due to the close relationship between PCT and FFT, the MPCT can also be seen as a real version of the MFT, and the assumption of polar symmetric boundary extension increases the sparsity of the transformed coefficients. Unlike the conventional 2-D DCT, which is constructed by tensor product of the 1-D transform, the local operator PCT of MPCT is a true polar transform, combining the merits of both FFT and DCT into one setting.

27.2.9.2 Ridgelets and Curvelets

The first digital curvelet transform, the so-called curvelet-99 implementation proposed in Ref. [7] also adopts a multiscale lapped block transform approach. The level operator used in that specific transform was an undecimated *á trous* wavelet transform. While the redundancy is useful in the denoising task, substituting it with a less redundant operator like the Laplacian pyramid would still retain the curvelet notion. The local operator is the digital ridgelet transform which is a 1-D wavelet transform on Fast Slant Stack Radon slices. Therefore, the essential difference between the curvelet-99 transform and the MPCT transform is just the 1-D transform performed on Radon slices: one being the wavelet and another being the cosine transform.

In Ref. [35], implementations of possible digital ridgelet packets were discussed. One of these uses a basis on the Radon domain from a wavelet packet or cosine packet dictionary. This coincides with the polar cosine packets discussed before, which can be used to deal with features like both ridgelet and polar cosine basis functions.

It is clear that the Fourier Slice Theorem is the fundamental tool in implementing the Radon transform, and it links the curvelets, polar cosine, and Fourier transforms. The relationship between these multiscale lapped transforms can be illustrated schematically as in Figure 27.12.

27.2.9.3 Brushlets and Wave Atoms

The brushlets, proposed by Meyer and Coifman [19], partition the Fourier frequency plane by local cosine windowing, achieving basis functions of directional oscillating patterns localized in orientation, frequency, location, and scale. However, due to the nature of frequency implementation and the choice of the window, the basis functions are not well localized in space, with significant spreads. The recently introduced 2-D wave atoms frame [36] as implemented by using the Villemoes wavelet packets [37] in the frequency domain. The resulting basis functions are much like brushlets, but with only two bumps in the spatial domain.

The MPCT's basis functions are in essence same as the brushlets and wave atoms, but the transform is implemented by spatial windowing instead of frequency windowing. The MPCT and these two transforms are spatial-frequency duals of the same idea, like wavelet packets and the local trigonometric bases.

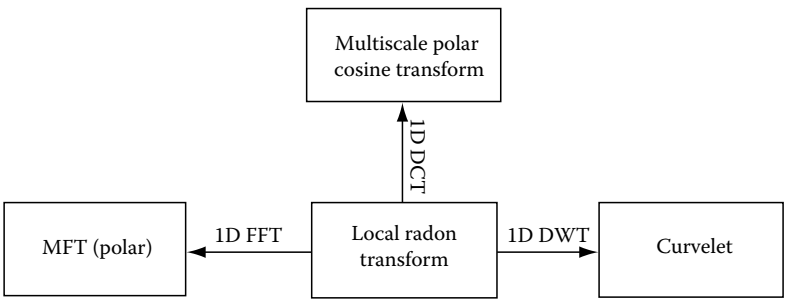

FIGURE 27.12 Relationships between MFT, local radon, curvelet, and MPCT.

27.2.10 Image Denoising in the PCT Domain

In order to demonstrate the effectiveness of the MPCT transform, the transform is applied to the task of noise removal in 2-D by thresholding the transformed coefficients.

The MPCT implementation used in the denoising has the following configuration:

1. Level of decomposition, or the total number of scales is set to $J = 5$.
2. Local window is 16×16, modulated with a squared cosine.
3. Windows are overlapped by 50%.
4. Threshold for each scale is computed as

$$\mathcal{T}_s = a \frac{\sqrt{2 \log M^2} \sigma}{1.23^{J-s}} \tag{27.37}$$

with a set to $a = 0.08$ for the MPCT and $a = 0.062$ for the MPCPT. In the above equation, σ is the standard deviation of the noise. The best basis is computed according to the cost function [38]:

$$\mathcal{M}(f, \mathcal{T}_s) = \sum_{i=1}^{N} \Phi\left(|\langle f, \psi_k[i] \rangle|^2\right), \tag{27.38}$$

where

$$\Phi(u) = \begin{cases} u - \sigma^2 & \text{if } u \leq \mathcal{T}_s^2, \\ \sigma^2 & \text{if } u > \mathcal{T}_s^2. \end{cases} \tag{27.39}$$

27.2.11 Denoising Results

The potential of nonlinear filtering in the PCT domain is demonstrated here for two standard images: barbara which contains some directional and nondirectional periodic textures and lena which can be regarded as one of the ''curvelet-friendly'' images, since it mainly consists of linear singularities at different scales. These images are given in Figure 27.13.

It can be seen from the denoising results in Figures 27.14 and 27.15 that the wave atoms approach produces unpleasant artifacts on lena, due to the fact that its basis functions are not well localized

Barbara Lena

FIGURE 27.13 Two standard images for denoising experiments.

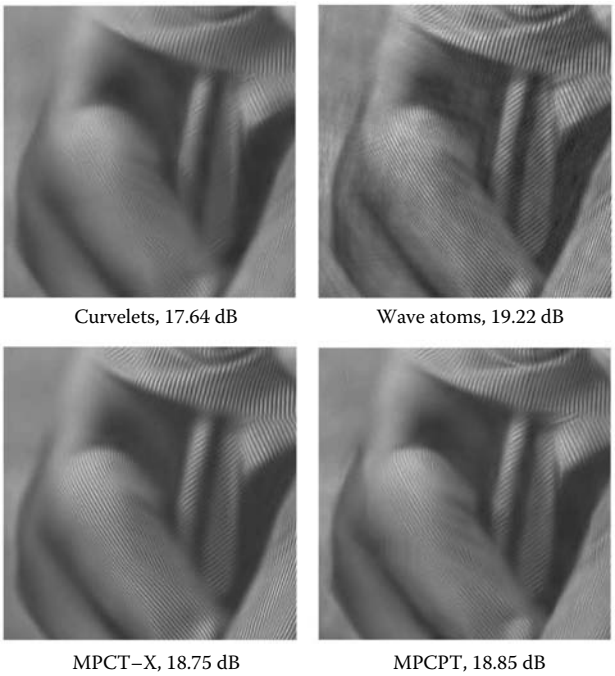

FIGURE 27.14 Comparative denoising results on detailed 10 dB barbara.

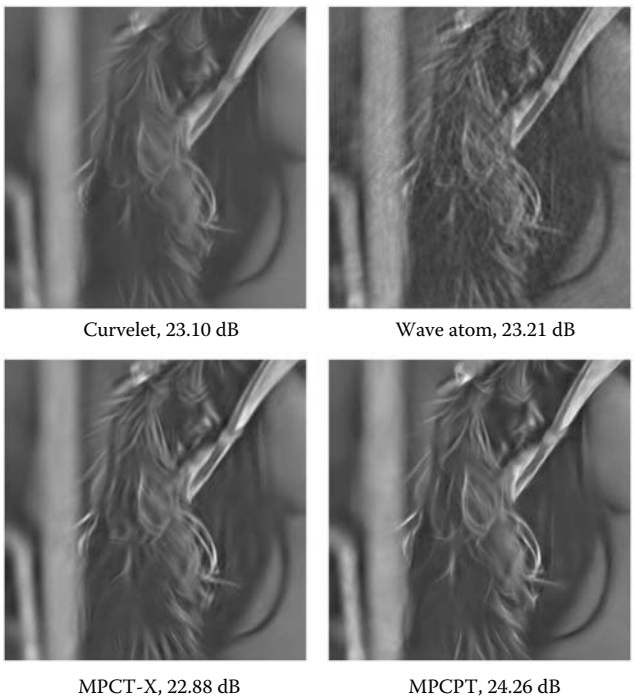

FIGURE 27.15 Comparative denoising results on detailed 15 dB lena.

in space and due to its inability to model edges well. The curvelet transform, MPCT, and MPCPT are all constructed by block-based local transforms on top of the Laplacian pyramid. The MPCT gives consistently better numerical results than curvelets, as well as well-matched visual results. Although the underlying local operator has an oscillatory pattern instead of anisotropic ridge forms, the overlapping blocks effectively compensate for the drawback in edge areas by confining the oscillations locally. In textural regions, the MPCT shows significant gains over the curvelets. The MPCT packet denoising, as expected, combines the merits of both curvelet transform and the MPCTs into one setting.

The difference in the numerical results between the MPCT-II and MPCT-X is compatible with the nonlinear approximation results in Section 27.2.5. The MPCT-X generally performs better with heavier noise, and MPCT-II can outperform MPCT-X by a significant margin when there is less noise. However, visually, the two implementation do not differ significantly. Overall, the MPCPT can be regarded as the winner for its better visual quality as well as numerical error measures.

27.3 Planelets

We now turn our attention to planelets, a special-purpose nonseparable representation for 3-D image data.

27.3.1 Introduction

As mentioned earlier in this chapter, locally planar structures, such as moving edges or interfaces between volumes, convey most of the information in 3-D image data. Preservation of such features requires a basis in which they are sparsely represented. An obvious choice might, therefore, seem to be the Fourier basis, since a planar surface in a volume corresponds to a line in the Fourier domain. Of course, this misses the key epithet: *local*; all image data show only local planarity, with curvature a significant feature at larger scales.

Planelets are designed specifically to efficiently represent planar singularities in 3-D image data. Extraction of such planar features may be useful in various applications, such as video denoising, video coding, geometry estimation [39], and tracking of objects in video sequences. Planelet representation offers translation invariance, good orientation-selectivity, localization in both space and time, invertibility, and efficient computation. The planelet basis has a combination of scaling, locality, and directional characteristics which are well matched to the locally planar surfaces of interest in applications.

Planelets can be regarded as a modification of the complex wavelet bases proposed in Refs. [40,41]. The computational complexity of a planelet transform is $O(n)$, where n is the number of points in analysis window. The computational complexity of planelet denoising is essentially equivalent to a windowed Fourier transform (WFT) and it does not require any motion estimation. In its current form, the representation provides a nonorthogonal basis and is redundant by less than 14%.

27.3.2 Continuous Planelet Transform

A prototypical planelet basis function in 1-D is of the following form:

$$f_{\xi,\omega,a}(x) = win\left(\frac{x-\xi}{a}\right)\exp\left[-j\frac{\omega(x-\xi)}{a}\right], \tag{27.40}$$

where ξ, ω, and a are, respectively, the location, frequency, and scale parameters of the function. The function $win(\cdot)$ is a window function, chosen alongwith the sampling interval to ensure invertibility

of the discrete form of the transform. In 2-D, the planelet basis can be regarded as a modification of the complex wavelet bases proposed in Refs. [40,41], which show both translation invariance and directional selectivity, and may be used as an alternative to the ridgelet representation. In 3-D, the basis comprises of the set of Cartesian products over ξ, ω at each scale a. That the continuous transform defined by Wilson et al. [40] is invertible follows directly from the observation that it is simply the MFT [40].

27.3.3 Discrete Planelet Transform

The discrete form, however, is significantly different from that described in Ref. [40]. The discrete planelet transform (DPT) is a combination of two well-known image transforms: the Laplacian pyramid [42] and the WFT. In some ways, it is similar to the octave band Gabor representation proposed in Ref. [43], but avoids some of the more unpleasant numerical properties of the Gabor functions. The DPT of a video sequence x, in vector form, at scale m is given by

$$\hat{X}_m = \mathcal{F}_n(I - G_{m,m+1}G_{m+1,m})x_m, \tag{27.41}$$

where

$\hat{X}_m$ denotes the DPT at scale m
$\mathcal{F}_n$ is the WFT operator with window size $n \times n \times n$
I is the identity operator
x_m is the Gaussian pyramid representation of x at level m

$$x_m = \prod_{0}^{m-1} G_{l+1,l}x \tag{27.42}$$

$G_{m,m+1}, G_{m+1,m}$ are the raising and lowering operators associated with transitions between levels in the Gaussian pyramid

Invertibility follows directly from Equations 27.41 and 27.42.

THEOREM 27.2

The representation defined by Equation 27.41 is invertible.

Proof: First we note that the WFT operator $\mathcal{F}_n$ has an inverse, which can be denoted by $\mathcal{F}_n^{-1}$. Second, we know from Burt and Adelson that the Laplacian pyramid is invertible, since, trivially,

$$x_m = x_m - G_{m,m+1}x_{m+1} + G_{m,m+1}x_{m+1} \tag{27.43}$$

and the proof is completed by induction on m.

Importantly, although both the pyramid and WFT operators are Cartesian separable, the closeness of the Burt and Adelson filter to a Gaussian function gives the pyramid virtually isotropic behavior, which can be exploited well by the high-frequency resolution of a Fourier basis. The planelet basis functions resemble planar structures and have compact support in both space–time and spatiotemporal frequency.

27.3.4 Denoising Algorithm

The denoising algorithm works in three steps: forward DPT, adaptive thresholding, and inverse DPT. The coefficients of D forward DPT of the image volume are computed using the algorithm outlined in Section 27.3.3. Since the presence of additive Gaussian white noise means that almost all the DPT coefficients are affected by it, soft thresholding would reduce the contribution of noise to the restored image volume. Based on the assumption that the coefficients relatively small in magnitude at each resolution (i.e., below a certain threshold) are most probably due to the noise variation, coefficients with magnitude above a certain threshold are kept while the remaining ones are discarded. The inverse DPT, therefore, provides an estimation of the original uncorrupted image volume.

The choice of threshold is crucial to the performance of this type of transform domain denoising. Donoho and Johnstone [44] have shown that an adaptive threshold θ given by

$$\theta = \sigma\sqrt{2\log n} \tag{27.44}$$

is an asymptotically optimal choice for threshold value when denoising a 1-D noisy signal, where n denotes the number of samples in the signal and σ is standard deviation of the additive Gaussian white noise. Our experiments showed that using an adaptive threshold for coefficients at different resolutions gives better denoising results as compared to using same threshold value for transform coefficients at all resolutions. We use threshold value θ_i for coefficients at level i of the pyramid as given by

$$\theta_i = \mathcal{L}(\sigma)\sqrt{2\log n_i}, \tag{27.45}$$

where

n_i denotes the number of pixels at level i of the pyramid
$\mathcal{L}(\sigma)$ is a suitably chosen function of σ

The following expression for $\mathcal{L}(\sigma)$ was empirically chosen for our experiments:

$$\mathcal{L}(\sigma) = a\log_{10}\sigma + b, \tag{27.46}$$

where $a, b \in \Re$ and $b = 2a$.

27.3.5 Planar Feature Extraction

Planelets provide an ideal tool for representing local planes in a video sequence (or an image volume, in general) due to their ability to localize planar surfaces which correspond to lines in the Fourier domain. The presence of planar surface in a local analysis window can be inferred by computing the eigenvalues of the local inertia tensor in the window and analysing them. The parameters for orientation of the local planar surface and translation from center of the window can also be estimated by analyzing the most significant coefficients in the locality. Consider a video sequence synthesized by moving the center of a circle on a sinusoidal wave in the time direction. Nonlinear approximations of this sequence using only 0.07% of the wavelet and planelet coefficients are shown in Figures 27.16a and b, respectively. It is clear from this example that the planelet approximation of a video sequence containing locally planar surfaces can result in a smaller approximation error as compared to that using wavelets. Planelets, therefore, can also be used for a piecewise planar

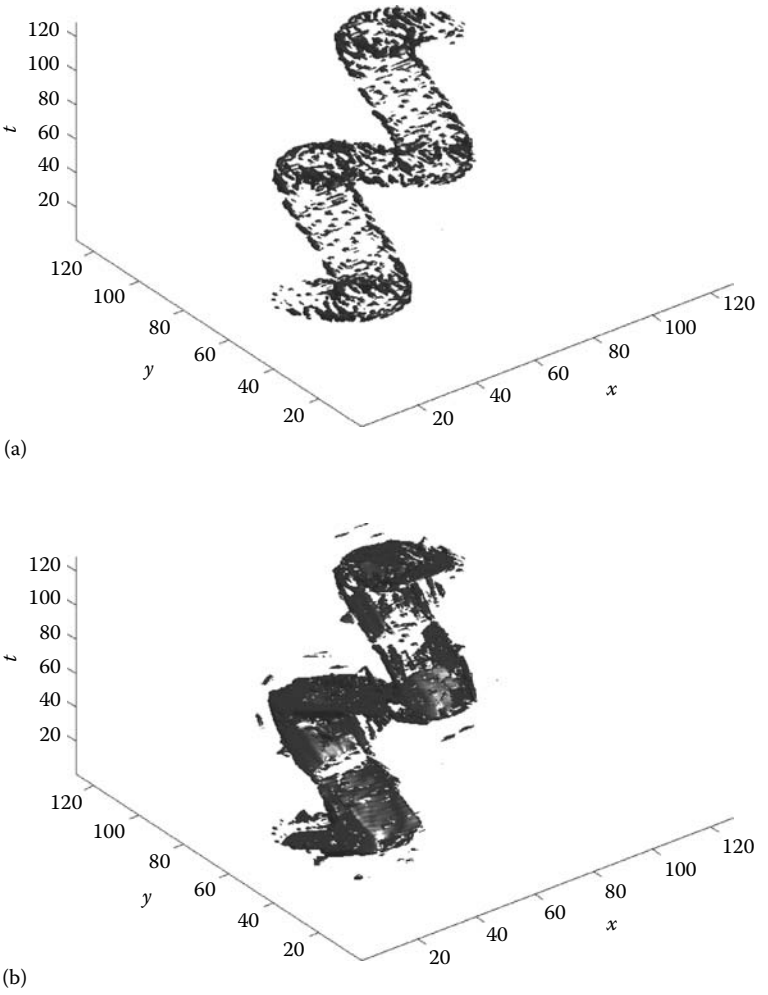

FIGURE 27.16 Nonlinear approximation of a video sequence containing a moving circle using (a) wavelets and (b) planelets.

approximation of a video sequence. Moreover, the approximation can be made to be adaptive to the local scale of the planar surfaces.

27.4 3-D Wavelet Packets

The case for thresholding in spatiotemporal wavelet domain is supported by the fact that certain errors in motion estimation can be overcome by including the temporal direction in the realm of wavelet domain. Recent attempts to solve the video restoration problem have included combined spatial and temporal wavelet denoising [45], and the use of thresholding in nonseparable transform domains, such as oriented 3-D ridgelets [46] and 3-D complex wavelets [47].

Although wavelet shrinkage performs significantly better than most other commonly used denoising methods, visual quality of the restored video can sometimes suffer from *ringing* type of artifacts, valleys

around the edges, due to the Gibbs phenomenon. The shift-variant nature of the wavelet transform worsens the effect of the Gibbs phenomenon, resulting in unpleasant artifacts. Translation invariant (TI) wavelet denoising of Coifman and Donoho [48] was developed to counter such artifacts by averaging out the translation dependence. Another feature of wavelet denoising is that it imposes a fixed dyadic wavelet basis on all types of input signals. Not only can the use of dyadic wavelets result in a blurred reconstruction, it can also limit the analysis of a locally occurring phenomenon in the spatiotemporal frequency domain. The solution to this problem lies in the use of basis functions which are well localized in spatiotemporal frequency as well as in space and time.

27.4.1 Adaptive 3-D WP Transform

The ability of wavelet packets to capture locally occurring frequency phenomena in a signal has led to their successful application to many problems including image coding [49,50]. The fundamental idea is to relax the restricted decomposition of only the lowpass subband and allow the exploration of all frequency bands up to the maximum depth. The discrete wavelet packet transform (DWPT) of a 1-D signal x of length N can be computed as follows:

$$
\begin{aligned}
w_{2n,d,l} &= \sum_k g_{k-2l} w_{n,d-1,k} \quad && l = 0, 1, \ldots, N2^{-d} - 1, \\
w_{2n+1,d,l} &= \sum_k h_{k-2l} w_{n,d-1,k} \quad && l = 0, 1, \ldots, N2^{-d} - 1, \\
w_{0,0,l} &= x_l && l = 0, 1, \ldots, N - 1,
\end{aligned}
$$

where $d = 1, 2, \ldots, J-1$ is the scale index, with $J = \log_2 N$, n and l, respectively, denote the frequency and position indices, $\{h_n\}$ and $\{g_n\}$ correspond to the lowpass and highpass filters, respectively, for a two-channel filter bank and the transform is invertible if appropriate dual filters $\{\tilde{h}_n\}, \{\tilde{g}_n\}$ are used on the synthesis side. These equations can be used to compute full wavelet packet (FWP) tree of the signal decomposition. However, this implies that a large number of combinations of basis functions is now available to completely represent the signal. A tree-prunning approach such as Ref. [51] can be used to efficiently select the *best basis* with respect to a cost function.

The 3-D DWPT can be computed by applying above equations separably in all three directions to get the FWP decomposition up to the coarsest resolution of subbands. The best basis can be selected in $O(N \log N)$ time, where N denotes the number of samples (frame resolution times the number of frames) in the video sequence. Given the goal here is to capture the significant spatiotemporal frequency phenomena in a video sequence, we used the Coifman–Wickerhauser entropy [51] as a cost function to select the best basis.

27.4.2 Restoration Algorithm

The effect of the Gibbs phenomenon can be weakened by averaging the restored signal over a range of circular shifts [48]. For this reason, we apply soft threhsolding to the 3-D wavelet packet coefficients of the shifted (in all three directions) noisy video sequence. A modified BayesShrink [52] method is used to compute the optimal value of threshold adaptively for each subband. Threshold θ_b for a subband of length N in an L-level WP decomposition is given by

$$\theta_b = \sqrt{\log N/L}\left(\frac{\sigma^2}{\sqrt{\max\left(\sigma_b^2 - \sigma^2, 0\right)}}\right),$$

where
σ_b^2 is the subband variance
σ^2 is the noise variance

If σ^2 is not known, a robust median estimate for noise standard deviation $\hat{\sigma}$ is obtained as follows:

$$\hat{\sigma} = \mathcal{E}\{\hat{\Sigma}\}, \quad \hat{\sigma}_i = \frac{\text{Median}(|Y_i|)}{0.6745},$$

where $\hat{\sigma}_i \in \hat{\Sigma}$, $Y_i \in \{\mathcal{Y}\}$, set of all HHH bands in the decomposition tree, and the mean $\mathcal{E}$ is taken only on the smaller half of the sorted $\hat{\Sigma}$ excluding the smallest value.

27.5 Discussion and Conclusion

The denoising algorithms presented in Sections 27.3.4 and 27.4.2 were tested against a number of other algorithms for restoration of several standard video sequences, three of which are included here: *Miss America, Hall,* and *Football*, all at a resolution of 128^3. The video sequences were corrupted with additive white Gaussian noise, with the SNR of the noisy sequences being 0, 5, 10, and 15 dB. Table 27.3 gives denoising results in terms of SNR for these noisy sequences using the following algorithms: TI hard thresholding in 3-D wavelet domain (TIW3-D) 3-D wavelet packet (WP3-D) with BayesShrink [52], both non-TI and TI 3-D wavelet packet (TIWP3-D) with the modified form of

TABLE 27.3 SNR Results for Three Standard Video Sequences

		Denoising Algorithm (Transform + Thresholding)

BayesShrink described in Section 27.4.2, and nonseparable planelet [53] domain thresholding using SUREShrink [54] method. Comparative SNR curves for individual frames for two of the test sequences are provided in Figure 27.17. For all our experiments, the proposed algorithm produces by far the best results in terms of both overall and individual SNR. Some of the frames of the test sequences restored by our algorithm and TIW3-D-Hard, a 3-D realization of the algorithm in Ref. [48], are shown in Figure 27.18. While TIW3-D restores clean and smooth version of the original frames, some of the details are restored by TIWP3-D.

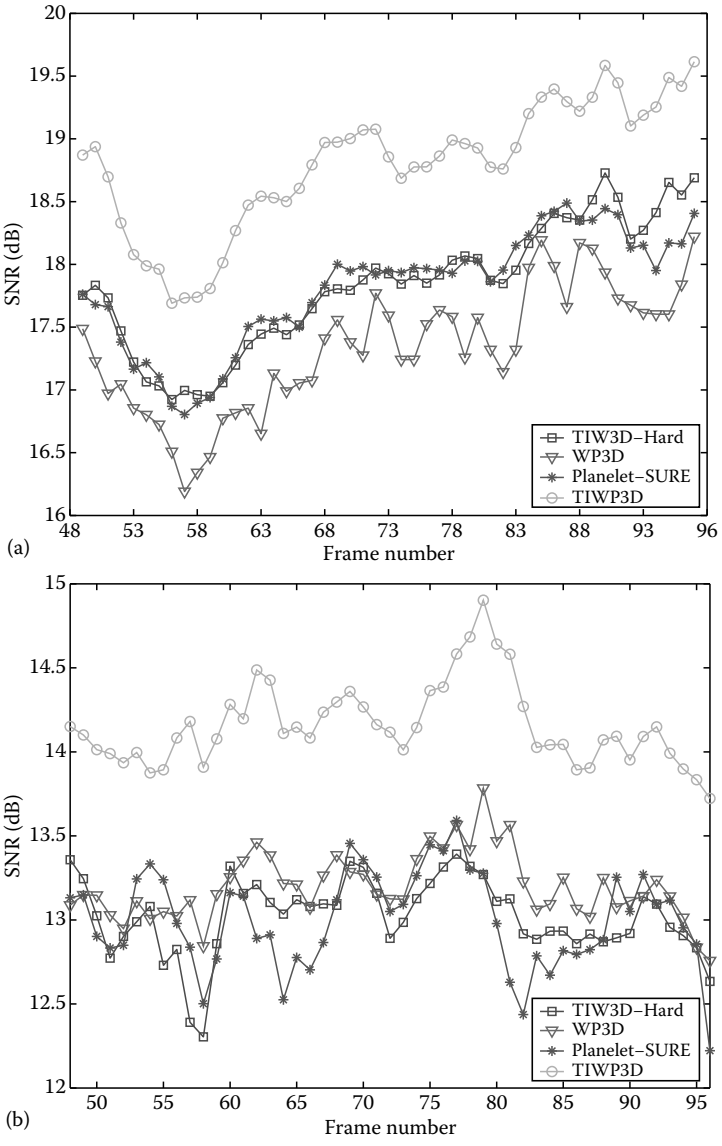

FIGURE 27.17 Frame-by-frame comparative results (a) *Miss America* and (b) *Football*.

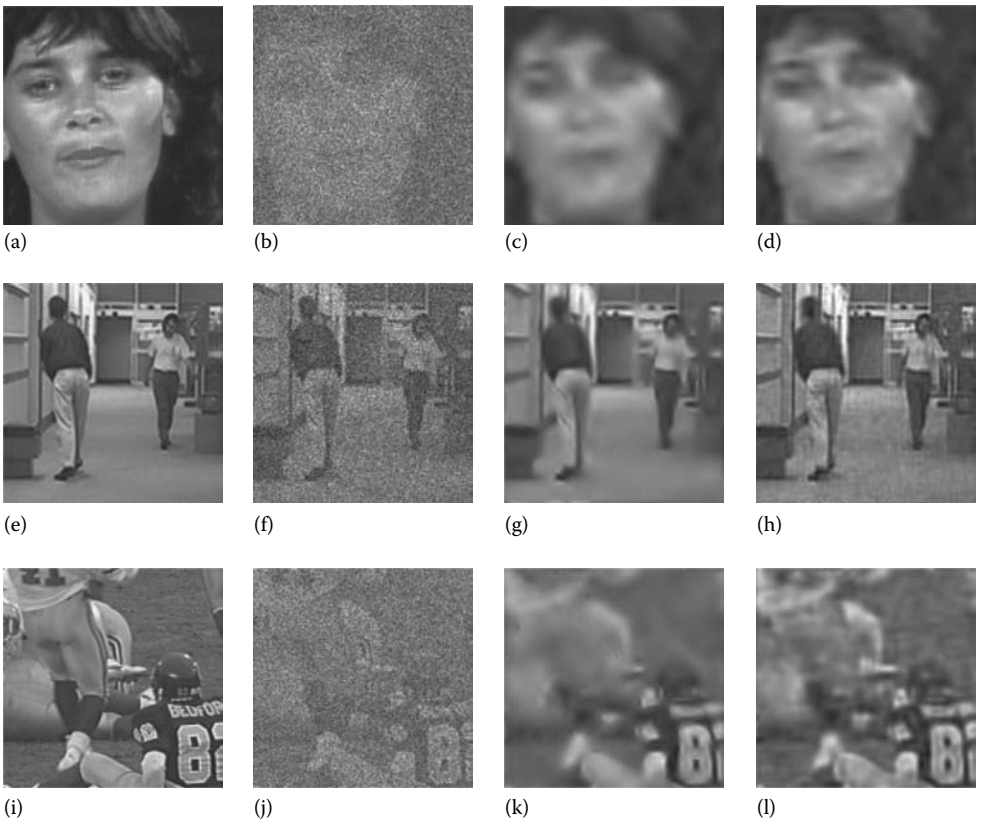

FIGURE 27.18 Denoising results for three standard video sequences. Frame# 90 of *Miss America*: (a) Original, (b) Noisy (SNR = 0 dB), (c) TIW3D-Hard (SNR = 17.9 dB), and (d) TIWP3D (SNR = 18.9 dB); Frame# 106 of *Hall*: (e) Original, (f) Noisy (SNR = 10 dB), (g) TIW3D-Hard (SNR = 19.0 dB), and (h) TIWP3D (SNR = 21.3 dB); Frame# 60 of *Football*: (i) Original, (j) Noisy (SNR = 5 dB), (k) TIW3D-Hard (SNR = 13.1 dB), and (l) TIWP3D (SNR = 14.3 dB).

For comparison purposes, computational complexity for each of the algorithms considered is also provided in Table 27.4. It is clear from this table that the planelet algorithm of Ref. [53] is the least computationally expensive, whereas the TI implementations of 3-D wavelet and 3-D WP are towards the more expensive side with TIWP3-D being the most expensive due to the additional one-off cost of best basis selection.

TABLE 27.4 Computational Complexity of the Tested Algorithms

Algorithm	Complexity
TIW3D Hard	$O(N + l^3 N)$
WP3D Bayes	$O(N \log N)$
WP3D Proposed	$O(N \log N)$
TIWP3D Proposed	$O(N \log N + l^3 N)$
Planelet SURE	$O(n)$

Note: N and n, respectively, denote sequence size and the planelet window size, and l denotes length of the wavelet filter.

In conclusion, planelets are an efficient representation tool for 3-D functions with planar singularities. Such singularities are commonly found in video sequences in the form of moving luminance edges. A piecewise planar approximation of a video sequence can be obtained by using a very small fraction of transform coefficients in the planelet domain. The ability of planelets to extract planar features from a video sequence makes them an attractive tool for analysis in various applications. It is worth noting that while being the least expensive, the planelet method [53] produces SNR results which are still comparable to those of TIW3-D-Hard. These results also suggest that the localization of spatiotemporal frequency, achieved by TIWP3-D, is a desirable feature of the domain in which video sequences are represented.

28.1 Introduction

Consumer-level digital cameras were introduced in mid-1990s; in about a decade, the digital camera market has grown rapidly to exceed film camera sales. Today, there are point-and-shoot cameras with more than 8 million pixels; professional digital single lens reflex (SLR) cameras with more than 12 million pixels are available; resolution, light sensitivity, and dynamic range of the sensors have been improved significantly. Image quality of digital cameras has become comparable to that of film cameras.

During an image capture process, a digital camera performs a significant amount of processing to produce a viewable image. This processing includes auto focus, white balance adjustment, color interpolation, color correction, compression, and more. A very important part of the imaging pipeline is color filter array interpolation or demosaicking.

To produce a high-quality color image, there should be at least three color samples at each pixel location. One approach is to use beam-splitters along the optical path to project the image onto three separate sensors as illustrated in Figure 28.1. Using a color filter in front of each sensor, three full-channel color images are obtained. This is a costly approach as it requires three sensors and these sensors should be aligned precisely. A more convenient approach is to put a color filter array (CFA) in front of the sensor to capture one color component at a pixel and then interpolate the missing two color components. Because of the mosaic pattern of the CFA, this interpolation process is known as demosaicking.

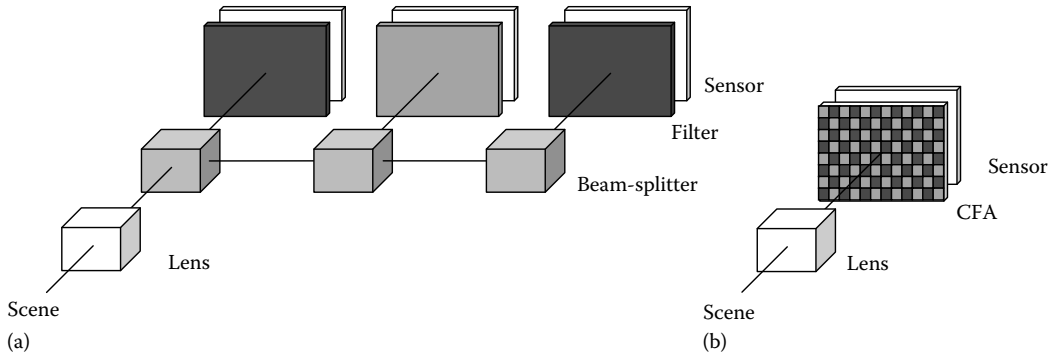

FIGURE 28.1 Illustration of optical paths for multichip and single-chip digital cameras.

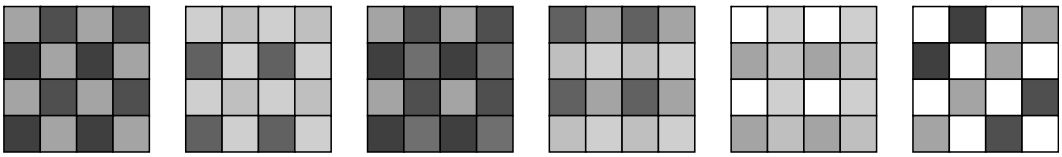

FIGURE 28.2 Several CFA designs are illustrated. From left to right: (a) This is the most commonly used CFA pattern: the Bayer CFA pattern. It consists of red, green, and blue samples. It leads to very good color reproduction performance. (b) This is the Bayer pattern with subtractive primaries: yellow, magenta, and cyan. The color filters have high transmittance values; therefore, good performance in low-light conditions is expected. (c) This pattern uses red, green, blue, and emerald. It is recently used in some Sony cameras. (d) This is a pattern commonly used in video cameras; it consists of yellow, magenta, cyan, and green. (e) This pattern consists of yellow, cyan, and green filters, and unfiltered pixels. The unfiltered pixels improve light sensitivity. (f) This is a pattern that is introduced very recently by Kodak. It has red, green, blue, and unfiltered pixels.

A variety of patterns exist for the color filter array. Some of these patterns are illustrated in Figure 28.2. Among these, the most common array is the Bayer color filter array. The Bayer array measures the green image on a quincunx grid and the red and blue images on rectangular grids. The green image is measured at a higher sampling rate because the peak sensitivity of the human visual system lies in the medium wavelengths, corresponding to the green portion of the spectrum (see Figure 28.3). Although this chapter discusses the demosaicking problem with reference to the Bayer CFA, the discussions and algorithms can in general be extended to other patterns.

The simplest solution to the demosaicking problem is to apply a standard image interpolation technique to each channel separately. However, this neglects the correlation among color channels and results in visible artifacts. For example, in Figure 28.4, Bayer sampling is applied on a full-color image and later bicubic interpolation is applied on each channel. The resulting image suffers from color artifacts. This result motivates the need to find a specialized algorithm for the demosaicking problem. There have been many algorithms published on this topic; this chapter surveys the main approaches.

28.2 Imaging Model

Most demosaicking algorithms model the imaging process as subsampling from a full-color image to a mosaicked data. This is a sufficient model when the goal is only to estimate the missing color samples. (When the goal is to obtain a higher resolution image, then the modulation transfer function of the camera should also be taken into account.)

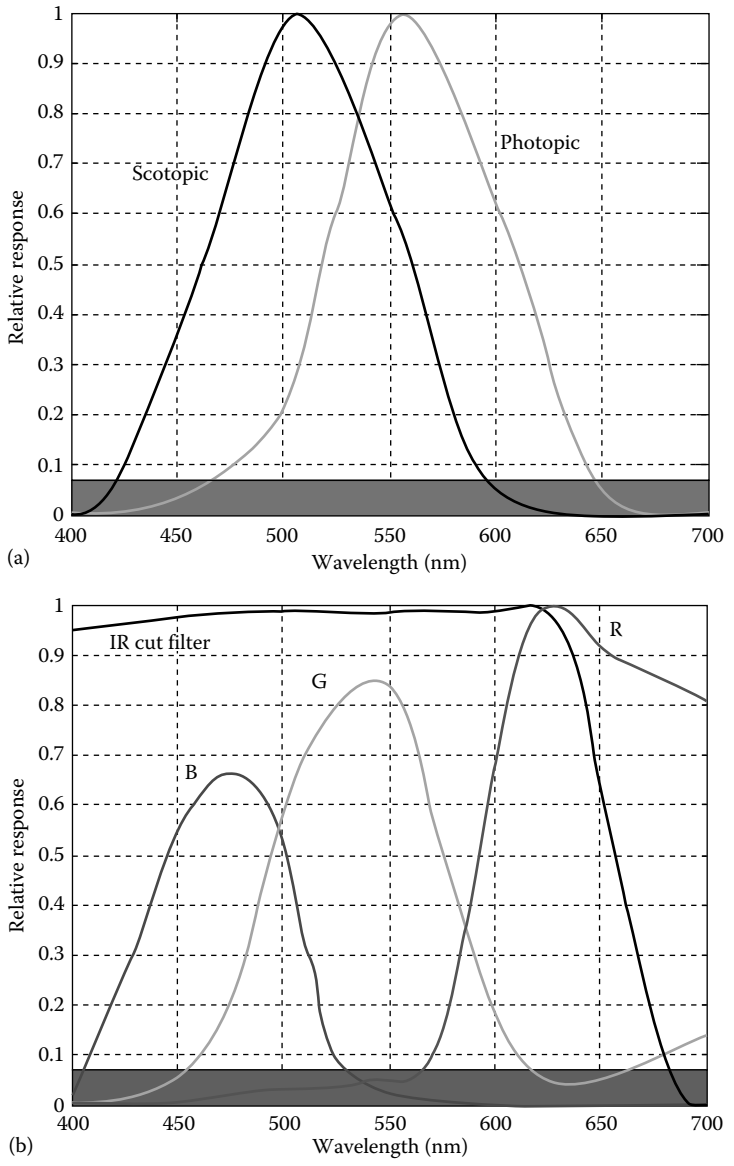

FIGURE 28.3 (a) Luminous efficiency of human visual system. Photopic response is the luminance response of the cone receptors. Scotopic response is the luminance response of the rod receptors, that is, response in low-light conditions. (b) Typical color filter responses in a digital camera.

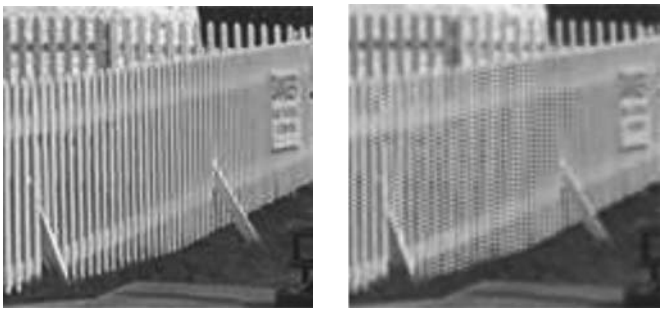

According to this model, a full-color channel S, where $S = R$ for red, $S = G$ for green, and $S = B$ for blue, is converted to a mosaicked observation z according to a CFA sampling pattern:

$$z = \sum_{S=R,G,B} z_S = \sum_{S=R,G,B} M_S S, \tag{28.1}$$

where

z_R, z_G, z_B are the subsampled color channels

mask M_S takes a color sample at a pixel according to the CFA pattern

(a) (b)

FIGURE 28.4 Bicubic interpolation used for color filter array interpolation results in numerous artifacts. (a) Original image and (b) bicubic interpolation.

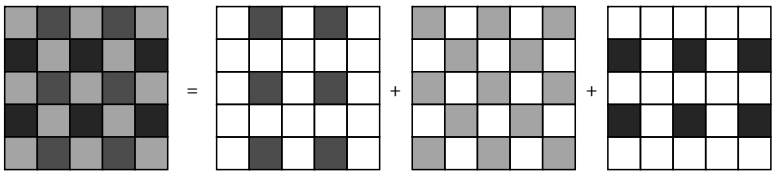

FIGURE 28.5 The mosaicked image z and the sampled components z_R, z_G, and z_B for the Bayer pattern.

For example, at a red pixel location, $[M_R, M_G, M_B]$ is [1, 0, 0].

In Ref. [1], the masks are explicitly written for a Bayer CFA in terms of cosine functions:

$$\begin{aligned} z_R(i,j) &= M_R(i,j)R(i,j) = \frac{1}{4}(1-\cos\pi i)(1+\cos\pi j)R(i,j), \\ z_G(i,j) &= M_G(i,j)G(i,j) = \frac{1}{2}(1+\cos\pi i\cos\pi j)G(i,j), \\ z_B(i,j) &= M_B(i,j)B(i,j) = \frac{1}{4}(1+\cos\pi i)(1-\cos\pi j)B(i,j), \end{aligned} \tag{28.2}$$

where (i, j) indicate the pixel coordinates, starting with $(0, 0)$. Figure 28.5 illustrates the CFA image z and the sampled components z_R, z_G, and z_B.

28.3 Demosaicking Methods

28.3.1 Single-Channel Interpolation

Single-channel interpolation methods treat each channel separately without utilizing any interchannel correlation. Standard image interpolation techniques, such as bilinear interpolation, bicubic interpolation, spline interpolation, and adaptive methods (e.g., edge-directed interpolation) are applied to each color channel individually. These methods, in general, do not perform as well as the methods that use interchannel correlation.

Among these methods, bilinear interpolation is commonly used as a part of other demosaicking methods. Figure 28.6 provides the linear filters used to perform bilinear interpolation.

$$\begin{bmatrix} 0 & 1/4 & 0 \\ -1/4 & 1 & 1/4 \\ 0 & 1/4 & 0 \end{bmatrix} \quad \begin{bmatrix} 1/4 & 1/2 & 1/4 \\ 1/2 & 1 & 1/2 \\ 1/4 & 1/2 & 1/4 \end{bmatrix}$$

(a) (b)

FIGURE 28.6 Filters for bilinear interpolation. (a) Filter applied on z_G to obtain the green channel and (b) filter applied on z_R/z_B to obtain the red/blue channels.

28.3.2 Constant-Hue-Based Interpolation

One commonly used assumption in demosaicking is that the hue (color ratios or differences) within an object in an image is constant. Although this is a simplification of image formation, it is a reasonable assumption within small neighborhoods of an image. This perfect interchannel correlation assumption is formulated such that the color ratios or differences within small neighborhoods are constant. This prevents abrupt changes in color intensities, and has been extensively used for the interpolation of the chrominance (red and blue) channels [2–6]. This approach is called the constant-hue-based interpolation approach.

As a first step, these algorithms interpolate the luminance (green) channel, which is typically done using bilinear or edge-directed interpolation. The chrominance (red and blue) channels are then estimated from the interpolated ''red hue'' (red-to-green ratio) and ''blue hue'' (blue-to-green ratio). To be more explicit, the interpolated ''red hue'' and ''blue hue'' values are multiplied by the green value to determine the missing red and blue values at a particular pixel location. The hues can be interpolated with any method (bilinear, bicubic, edge-directed, etc.).

As mentioned, instead of interpolating the color ratios, it is also possible to interpolate the color differences or the logarithm of the color ratios. This is illustrated in Figure 28.7.

It is also possible to update all color channels iteratively. That is, the green channel is interpolated first. The red/blue channels are interpolated using constant-hue-based interpolation. The green channel is then updated using the interpolated red/blue channels; and so on [7].

The constant difference idea is sometimes combined with median filtering and used as a postprocessing step to reduce color artifacts [5,8,9]. For example, in Ref. [9], the interpolated color channels are updated as follows:

$$\begin{aligned} G'(i,j) &= \frac{\left(R(i,j) - \underset{(i,j)}{\text{median}}(R-G)\right) + \left(B(i,j) - \underset{(i,j)}{\text{median}}(B-G)\right)}{2}, \\ R'(i,j) &= G'(i,j) + \underset{(i,j)}{\text{median}}(R-G), \\ B'(i,j) &= G'(i,j) + \underset{(i,j)}{\text{median}}(B-G), \end{aligned} \tag{28.3}$$

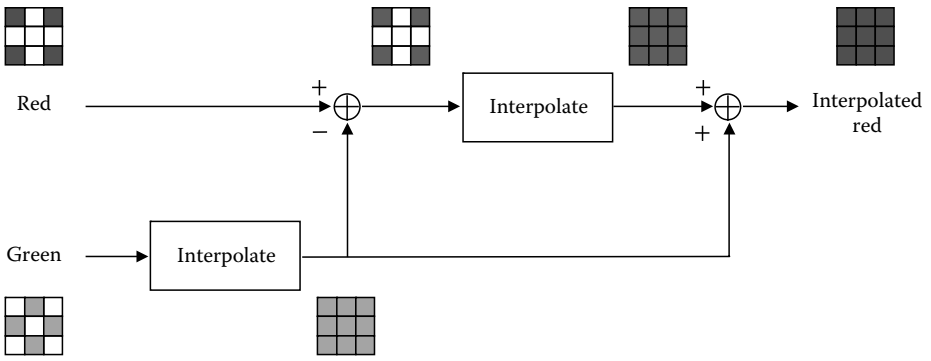

FIGURE 28.7 Constant-hue-based interpolation is illustrated for the interpolation of red channel. (From Gunturk, B. K., et al., *IEEE Signal Process. Mag.*, 22, 44, 2005. With permission.)

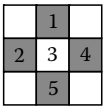
where median$_{(i,j)}(\cdot)$ returns the median within a small neighborhood of (i,j). In Ref. [8], red and blue channels are updated first as given in the above equation, followed by the green channel update. This procedure is repeated several times.

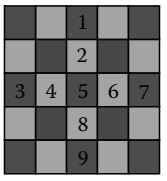
28.3.3 Edge-Directed Interpolation



Although nonadaptive algorithms can provide satisfactory results in smooth regions of an image, they usually fail in textured regions and edges. Edge-directed interpolation is an adaptive approach, where edge detection is performed for each pixel in question, and interpolation is done along the edges rather than across them.

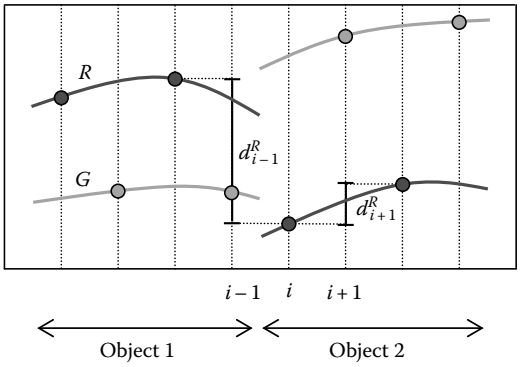
In the demosaicking problem, edge-directed interpolation is first applied to the green channel, which is sampled more densely and therefore is less likely to be aliased. Red and blue channel interpolations follow, based on the edge directions found for the green channel. A simple way of performing edge detection is to compare the absolute difference among the neighboring pixels [10]. Referring to Figure 28.8, horizontal and vertical gradients at a missing green location can be calculated from the horizontally and vertically adjacent green pixels. If the horizontal gradient is larger than the vertical gradient, suggesting a possible edge in the horizontal direction, interpolation is performed along the vertical direction. If the vertical gradient is larger than the horizontal gradient, interpolation is performed only in the horizontal direction. When the horizontal and vertical gradients are equal, the green value is obtained by averaging its four neighbors. It is also possible to compare the gradients against a predetermined threshold value [10].

The edge-directed interpolation approach in Ref. [10] can be modified by using larger regions (around the pixel in question) with more complex predictors and by exploiting the texture similarity in different color channels. In Ref. [4], the red and blue channels (in the 5×5 neighborhood of the missing pixel) are used instead of the green channel to determine the gradients. In order to determine the horizontal and vertical gradients at a blue (red) sample, second-order derivatives of blue (red) values are computed in the corresponding direction. This algorithm is illustrated in Figure 28.9.



Once the missing samples of the green channel are computed, the red and blue channels are interpolated. A typical approach for the red/blue interpolation is constant-hue-based interpolation, which was explained in Section 28.3.2.

In the algorithms explained so far, the edge direction is determined first, and then the missing sample is estimated by interpolating along the edge. This is a ''hard'' decision process. Instead, the likelihood of an edge in a certain direction can be found, and the interpolation can be done based on the edge likelihoods. Such



ΔH = |G2 – G4| //horizontal gradient
ΔV = |G1–G5| //vertical gradient
if ΔH > ΔV,
    G3 = (G1 + G5)/2
else if ΔH < V,
    G3 = (G2 + G4)/2
else
    G3 = (G1 + G5 + G2 + G4)/4

FIGURE 28.8 Edge-directed interpolation in Ref. [10] is illustrated. *G*1, *G*2, *G*4, and *G*5 are measured green values; *G*3 is the estimated green value at pixel 3. (From Gunturk, B. K., et al., *IEEE Signal Process. Mag.*, 22, 44, 2005. With permission.)

ΔH = |(R3 + R7)/2 – R5| //horizontal gradient
ΔV = |(R1 + R9)/2 – R5| //vertical gradient
if ΔH > ΔV,
    G5 = (G2 + G8)/2
else if ΔH < V,
    G5 = (G4 + G6)/2
else
    G5 = (G2 + G8 + G4 + G6)/4

FIGURE 28.9 Edge-directed interpolation in Ref. [4] is illustrated for estimating the green (*G*) value at pixel 5. The red (*R*) values are used to determine the edge direction. When the missing green pixel is at a blue pixel, the blue values are used to determine the edge direction. (From Gunturk, B. K., et al., *IEEE Signal Process. Mag.*, 22, 44, 2005. With permission.)

Define:

$$d_i^S = S(i+1) - S(i-1)$$

$$e_i^S = \frac{1}{\sqrt{1 + \left(d_i^S\right)^2}}$$

- Interpolate the green at the missing locations:

$$G(i) = \frac{e_{i-1}^R G(i-1) + e_{i+1}^R G(i+1)}{e_{i-1}^R + e_{i+1}^R}$$

- Repeat for three times:
  - Interpolate the red using the ratio rule:

$$R(i) = G(i)\,\frac{e_{i-1}^G \dfrac{R(i-1)}{G(i-1)} + e_{i+1}^G \dfrac{R(i+1)}{G(i+1)}}{e_{i-1}^G + e_{i+1}^G}$$

  - Correct the green to fit the ratio rule:

$$G(i) = R(i)\,\frac{e_{i-1}^R \dfrac{G(i-1)}{R(i-1)} + e_{i+1}^R \dfrac{G(i+1)}{R(i+1)}}{e_{i-1}^R + e_{i+1}^R}$$

FIGURE 28.10 Reference [6] is illustrated for a one-dimensional signal. S is a generic symbol for red (R) and green (G). d_i^S is the gradient for channel S at location i; and e_i^S is the corresponding edge indicator.

an algorithm is presented in Ref. [6]. The algorithm defines edge indicators in several directions as measures of edge likelihood in those directions, and determines a missing pixel intensity as a weighted sum of its neighbors. If the likelihood of an edge crossing in a particular direction is high, the edge indicator returns a small value, which results in less contribution from the neighboring pixel of that direction. The algorithm for one-dimensional signals is illustrated in Figure 28.10. The green channel is interpolated first; the red and blue channels are interpolated from the red/green and blue/green ratios. The color channels are then updated iteratively to obey the color-ratio rule. The extension to two-dimensional images is given in Ref. [6].

A similar algorithm is proposed in Ref. [9], where edge indicators are determined in a 7×7 window for the green and a 5×5 window for the red/blue channels. In this case, the edge indicator function is based on the L_1 norm (absolute difference) as opposed to the L_2 norm of Ref. [6]. In Ref. [11], gradients are filtered adaptively using local means and variances before deciding edge directions. Based on the edge directions, interpolation is done horizontally, vertically, or bidirectionally. This edge direction selection procedure is illustrated in Figure 28.11.

28.3.4 Using Gradients as Correction Terms

Linear interpolation methods have much less computational complexity compared to nonlinear methods, but do not perform as well. When interchannel correlation is included in the linear interpolation, much better performance can be achieved. Recently, the authors of Ref. [12] demonstrated that gradients in one

Calculate horizontal gradients

$$\Delta H(i) = 2\big(G(i+1) - G(i-1)\big) + \big(R(i+2) - R(i-2)\big)$$

Calculate mean and variance of horizontal gradients

$$\mu_i = \frac{1}{3}\sum_{j=i-1}^{i+1} \Delta H(j)$$

$$\sigma_i^2 = \frac{1}{3}\sum_{j=i-1}^{i+1} \big(\Delta H(j) - \mu_j\big)^2$$

Filter the horizontal gradients

$$\Delta H^*(i) = \mu_{i-1} + \frac{\sigma_{i-1}^2}{\sigma_{i-1}^2 + \sigma_{i+1}^2}\big(\mu_{i+1} - \mu_{i-1}\big)$$

Repeat the same procedure to obtain vertical gradients $\Delta V^*(i)$

If $|\Delta H^*(i)| < \alpha |\Delta V^*(i)|$, then interpolate horizontally

Else if $|\Delta V^*(i)| < \alpha |\Delta H^*(i)|$, then interpolate vertically

Else interpolate bidirectionally

FIGURE 28.11 Reference [11] is illustrated. Gradients are calculated, and then adaptively filtered. The interpolation direction at a pixel is selected based on the relative magnitude of filtered gradients. α is a number in the range [0–1].

channel can improve the interpolation performance in another one; and it can be put in a linear interpolation framework: Suppose, the green value at a red location will be estimated by adding the gradient of the red channel to an initial estimate:

$$\hat{G}(i,j) = \hat{G}_{\text{bilinear}}(i,j) + \alpha \Delta_R(i,j), \tag{28.4}$$

where

$\hat{G}_{\text{bilinear}}(i,j)$ is the initial estimate obtained through bilinear interpolation

α is a scale factor that controls the amount of correction

$\Delta_R(i,j)$ is the gradient of the red channel defined as follows:

$$\Delta_R(i,j) = R(i,j) - \frac{1}{4}\sum_{(m,n)=\{(0,-2),\,(0,2),\,(-2,0),\,(2,0)\}} R(i+m, j+n). \tag{28.5}$$

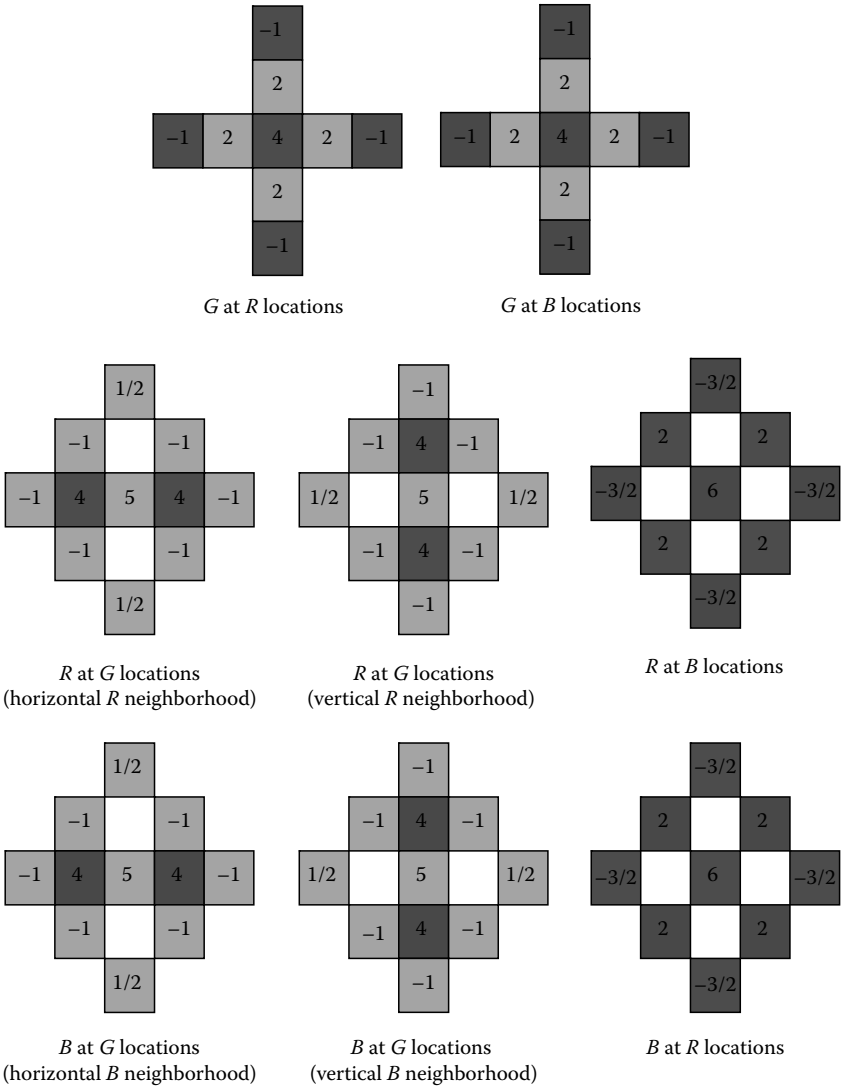
Similarly, the red pixel values at green and blue locations can be estimated using green and blue gradients:

$$\hat{R}(i,j) = \hat{R}_{\text{bilinear}}(i,j) + \beta \Delta_G(i,j) \tag{28.6}$$

and

$$\hat{R}(i,j) = \hat{R}_{\text{bilinear}}(i,j) + \gamma \Delta_B(i,j). \tag{28.7}$$

Specific green and blue gradient definitions are given in Ref. [12]. (Similar equations can be written for the green pixels at blue locations and for the blue pixels at green and red locations.) To determine appropriate values for the gain parameters α, β, γ, Ref. [12] uses training images to find the least squares estimates for the gain parameters. These gain parameters are then approximated by integer multiples of



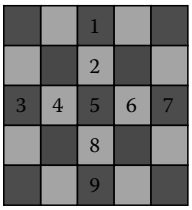


FIGURE 28.12 Filters (From Malvar, H. S., et al., *Proc. IEEE Int. Conf. Acoustics, Speech and Signal Processing*, Montreal, Canada, 3, 485–488, 2004. With permission.)

small powers of 1/2. The final results are $\alpha = 1/2$, $\beta = 5/8$, and $\gamma = 3/4$. The equivalent linear FIR filter coefficients for each interpolation case are shown in Figure 28.12.

It is possible to incorporate edge-directed interpolation idea to this approach. Reference [13] presents such an algorithm. The gradient terms are added in either horizontal or vertical directions. The direction is chosen adaptively based on edge direction estimates. (Historically earlier than Ref. [12], Ref. [13] does not use training to obtain the optimal coefficients.) Figure 28.13 illustrates this algorithm.

28.3.5 Frequency-Domain Approach

There are two observations that are important for the demosaicking problem. The first is that for natural images, there is a high correlation among the red, green, and blue channels. All three channels are very

$\Delta H = |G4 - G6| + |-R3 + 2 \times R5 - R7|$ //horizontal gradient
$\Delta V = |G2 - G8| + |-R1 + 2 \times R5 - R9|$ //vertical gradient
if $\Delta H > \Delta V$,
    $G5 = (G2 + G8)/2 + (-R1 + 2 \times R5 - R9)/4$
else if $\Delta H < V$,
    $G5 = (G4 + G6)/2 + (-R3 + 2 \times R5 - R7)/4$
else
    $G5 = (G2 + G8 + G4 + G6)/4 + (-R1 - R3 - R7 - R9 + 4 \times R5)/8$

FIGURE 28.13 Graphical illustration. (From Gunturk, B. K., et al., *IEEE Signal Process. Mag.*, 22, 44, 2005. With permission.)

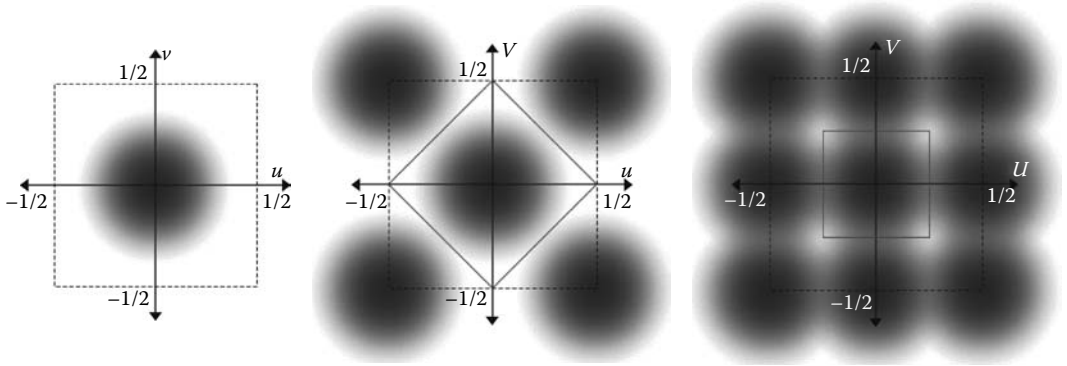

FIGURE 28.14 Frequency domain analysis of CFA sampling. (a) Suppose this is the frequency spectrum of the red, green, and blue channels; (b) frequency spectrum of the sampled green channel; and (c) frequency spectrum of the red/blue channels. Note that while there is no aliasing for the green channel, red and blue channels are aliased. The green channel can be fully recovered with a low-pass filter whose pass-band is outlined in the middle figure. For the red/blue channels, such a low-pass filtering operation cannot eliminate the aliasing.

likely to have the same texture and edge locations. (Because of the similar edge content, we expect this interchannel correlation to be even higher when it is measured between the high-frequency components of the channels [14].) The second observation is that digital cameras often use a CFA in which the luminance (green) channel is sampled at a higher rate than the chrominance (red and blue) channels. Therefore, the green channel is less likely to be aliased, and details are preserved better in the green channel than in the red and blue channels. This is illustrated in Figure 28.14.

28.3.5.1 Alias Canceling Interpolation

In Ref. [15], it is assumed that the high-frequency contents of green and red/blue channels are identical; therefore, high-frequency content of the green image is used to remove aliasing in the red and blue images. First, the red and blue images are interpolated with a rectangular low-pass filter according to the rectangular sampling grid. This fills in the missing values in the grid, but allows aliasing distortions into the red and blue output images. These output images are also the missing high-frequency components needed to produce a sharp image. However, because the green image is sampled at a higher rate, the high-frequency information can be taken from the green image to improve an initial interpolation of the red and blue images. A horizontal high-pass filter and a vertical high-pass filter are applied to the green image. This provides the high-frequency information that the low sampling rate of the red and blue images cannot preserve. Aliasing occurs when high-frequency components are shifted into the low-frequency portion of the spectrum, so if the outputs of the high-pass filters are modulated into the low-frequency regions, an estimate of the aliasing in the red and blue images can be found. This estimate is used to reduce the aliasing in the red and blue images, as illustrated in Figure 28.15. This method relies

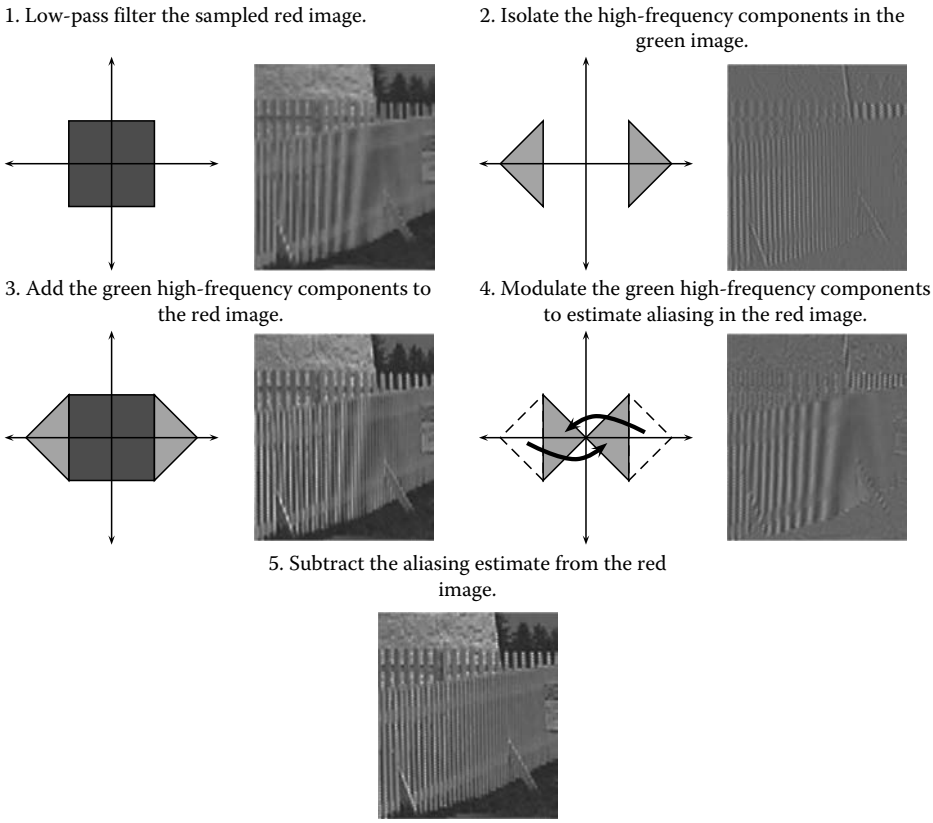

FIGURE 28.15 An illustration of Ref. [15] by John Glotzbach. High-frequency information from the green image is modulated and used to cancel aliasing in the red image. (From Gunturk, B. K., et al., *IEEE Signal Process. Mag.*, 22, 44, 2005. With permission.)

on the assumption that the high-frequency information in the red, green, and blue images is identical. If this assumption does not hold, the addition of the green information into the red and blue images can add unwanted distortions. This method also makes the assumption that the input image is band-limited within the diamond-shaped Nyquist region of the green quincunx sampling grid (the region outlined in Figure 28.14). When this assumption fails, the aliasing artifacts are enhanced instead of reduced because the green image also contains aliasing. This system is composed entirely of linear filters, making it efficient to implement.

28.3.5.2 Frequency-Domain Filtering

In Ref. [1], the CFA-sampled image is reorganized into newly defined luminance and chrominance components. Analyzing the CFA sampling in Fourier domain, filters that recover these components are designed. The derivation is as follows. Using Equation 28.2, the mosaicked image can be written as

$$\begin{aligned} z(i,j) &= z_R(i,j) + z_G(i,j) + z_B(i,j) \\ &= \tfrac{1}{4}(R(i,j) + 2G(i,j) + B(i,j)) \\ &\quad + \tfrac{1}{4}(B(i,j) - R(i,j))(\cos \pi i - \cos \pi j) \\ &\quad + \tfrac{1}{4}(-R(i,j) + 2G(i,j) - B(i,j)) \cos \pi i \cos \pi j. \end{aligned} \tag{28.8}$$

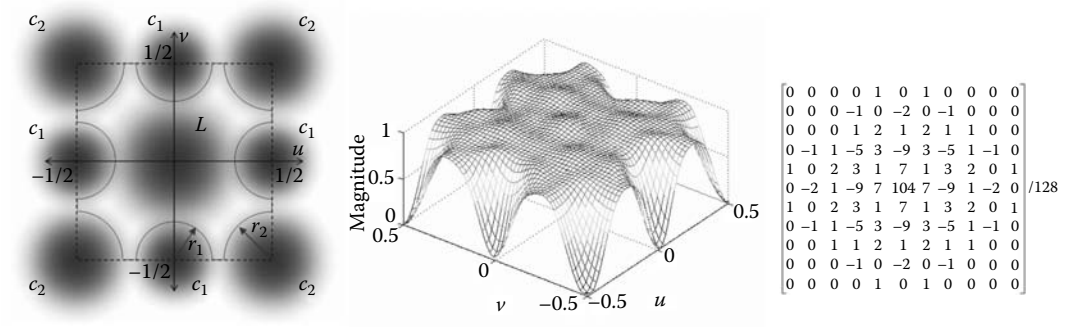

FIGURE 28.16 Filter design in Ref. [1]. Left: Luminance and chrominance components when the Fourier transform of the mosaicked image is taken. The red line outlines the passband of the filter. The radii r_1 and r_2 are design parameters, whose values are determined empirically. Middle and Right: Fourier domain and spatial domain representations of the filter used in Ref. [1].

In this equation, $L(i,j) = (1/4)[R(i,j) + 2G(i,j) + B(i,j)]$ is defined as the luminance component, and $C_1(i,j) = (1/4)[B(i,j) - R(i,j)]$ and $C_2(i,j) = (1/4)[-R(i,j) + 2G(i,j) - B(i,j)]$ as the chrominance components. With these definitions, Equation 28.8 becomes

$$z(i,j) = L(i,j) + C_1(i,j)\ (\cos \pi i - \cos \pi j) + C_2(i,j) \cos \pi : \cos \pi j, \tag{28.9}$$

where

$$\begin{bmatrix} L \\ C_1 \\ C_2 \end{bmatrix} = \begin{bmatrix} 1/4 & 1/2 & 1/4 \\ -1/4 & 0 & 1/4 \\ -1/4 & 1/2 & -1/4 \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix}. \tag{28.10}$$

When the Fourier transform of Equation 28.9 is taken, the luminance component stays in the baseband, the C_1 component will be modulated at frequencies (0.5, 0) and (0, 0.5), and the C_2 component will be modulated at frequency (0.5, 0.5). This is illustrated in Figure 28.16. By designing appropriate filters, the luminance and chrominance components can be recovered. Using the inverse of the matrix given in Equation 28.10, the red/green/blue values are obtained. Figure 28.16 also shows the filter to recover the luminance component.

An extension of this approach is given in Ref. [16], where it is noticed that the C_1 component suffers from spectral overlap, and the overlap often occurs in only one of the (horizontal/vertical) directions. Therefore, a weighted sum of the horizontally and vertically filtered C_1 components is taken, where the weight is less for the one with least crosstalk.

Reference [17] gives another extension of Ref. [1]. This time adaptive filtering is applied on the luminance component. The luminance values at green locations are estimated using a filter similar to the one in Ref. [1]; while the values at red/blue locations are estimated as a weighted sum of neighboring luminance values, where the weights are selected according to the horizontal and vertical gradients (edge indicators).

28.3.6 Homogeneity-Directed Interpolation

Instead of choosing the interpolation direction based on edge indicators, Ref. [8] uses local homogeneity as an indicator. The homogeneity-directed interpolation imposes the similarity of the luminance and chrominance values within small neighborhoods, and it leads to very good perceptual results. The

underlying idea is to interpolate color channel horizontally and vertically, and to pick up either the horizontally interpolated pixel values or the vertically interpolated pixel values at every pixel location based on the homogeneity.

Reference [8] defines the homogeneity as follows. Suppose that $R(i,j)$, $G(i,j)$, $B(i,j)$ are the values in the RGB space, and $L(i,j)$, $a(i,j)$, $b(i,j)$ are the corresponding luminance and chrominance values in the CIELab space. Three neighbor sets of (i,j) are defined. The first one is the set of pixel locations that are close in space:

$$N_D(i,j) = \left\{(m,n) \,|\, \left[(m-i)^2 + (n-j)^2\right]^{1/2} \leq \varepsilon_D\right\}. \tag{28.11}$$

The other two neighbor sets are the sets of pixel locations with similar luminance and chrominance values:

$$N_L(i,j) = \{(m,n) \mid |L(m,n) - L(i,j)| \leq \varepsilon_L\} \tag{28.12}$$

and

$$N_C(i,j) = \left\{(m,n) \mid \left([a(m,n) - a(i,j)]^2 + [b(m,n) - b(i,j)]^2\right)^{1/2} \leq \varepsilon_C\right\}. \tag{28.13}$$

Then the homogeneity is defined as

$$H(i,j) = \frac{\text{size}[N_D(i,j) \cap N_L(i,j) \cap N_C(i,j)]}{\text{size}[N_D(i,j)]}. \tag{28.14}$$

Referring to Figure 28.17, the algorithm works as follows. The RGB data is first interpolated horizontally and vertically. (The green channel is interpolated using red and blue data as correction terms, as in Ref. [13]. The red and blue channels are interpolated from the interpolated red–green difference and blue–green difference as shown in Figure 28.7.) The interpolated images are then converted to the CIELab space. The homogeneity maps for horizontally and vertically interpolated images are found. The homogeneity maps are smoothed with a 3×3 averaging filter. At each pixel, either the horizontally or the vertically interpolated color values are taken depending on which has the largest homogeneity.

In Ref. [8], the neighborhood parameter ε_D is kept constant, while ε_L and ε_C are determined adaptively at each pixel such that they reflect typical variations among pixels of the same object. This

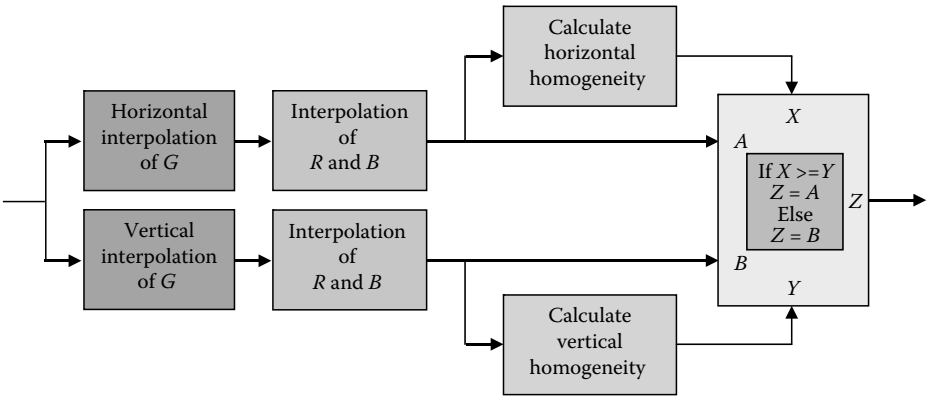

FIGURE 28.17 Block diagram of the homogeneity-directed interpolation (From Hirakawa, K. and Parks, T. W., *IEEE Trans. Image Process.*, 14, 360, 2005. With permission.)

is achieved by analyzing the four nearest neighbors of the pixel in question. ε_L at location (i,j) is calculated as follows:

$$\begin{aligned}\varepsilon_{LH}(i,j) &= \max\{|L(i-1,j) - L(i,j)|,\ |L(i+1,j) - L(i,j)|\},\\ \varepsilon_{LV}(i,j) &= \max\{|L(i,j-1) - L(i,j)|,\ |L(i,j+1) - L(i,j)|\},\\ \varepsilon_{L}(i,j) &= \min\{\varepsilon_{LH}(i,j), \varepsilon_{LV}(i,j)\},\end{aligned} \tag{28.15}$$

where the first two equations give the maximum variations in horizontal and vertical directions, and the last equation picks up the minimum of these, by which the maximum variation within the object is determined. ε_C is determined similarly.

28.3.7 Projections onto Convex Sets Approach

The algorithm presented in Ref. [15] proposes to decompose the green channel into its frequency components and then add the high-frequency components of the green channel to the low-pass filtered red and blue channels. This is based on the observation that the high-frequency components of the red, blue, and green channels are similar and the fact that the green channel is less likely to be aliased. One problem with this approach is that the high-frequency components of the red, green, and blue channels may not be identical. Therefore, replacement of the high-frequency components of the red and blue channels with those of the green channel may not work well. Reference [14] proposes an algorithm that ensures data consistency at the cost of higher computational complexity. The algorithm defines two constraint sets, one ensuring that the restored images are consistent with the measured data and the other imposing similar high-frequency components in the color channels, and reconstructs the color channels using the projections onto convex sets (POCS) technique.

28.3.7.1 Constraint Sets

The first constraint set guarantees that the restored color channels are consistent with (are identical to) the color samples captured by the digital camera.

The second constraint set is a result of the high interchannel correlation. Reference [14] shows that color channels have very similar detail (high-frequency) subbands. This information would not be enough to define constraint sets if all channels lost the same amount of information in sampling. However, the red and blue channels lose more information (details) than the green channel when captured with a color filter array. Therefore, it is reasonable to define constraint sets on the red and blue channels that force their high-frequency components to be similar to the high-frequency components of the green channel. The similarity is imposed such that the detail coefficients are within a fixed proximity.

28.3.7.2 Alternating Projections Algorithm

The block diagram of the POCS algorithm is given in Figure 28.18. The projection onto the observation constraint set inserts the observed data into their corresponding locations in the current image. This is illustrated in Figure 28.19. The projection operation onto the detail constraint set is illustrated in

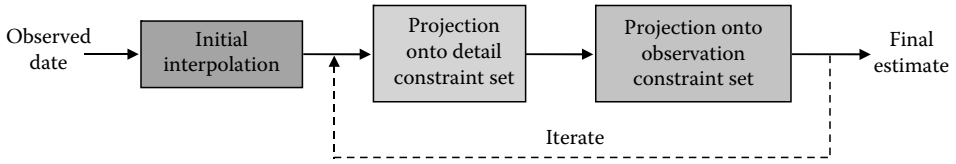

FIGURE 28.18 Block diagram of the algorithm given in Ref. [14]. Red/green/blue channels are interpolated first. The red/blue channels are then updated by iteratively projecting on the detail and observation constraint sets.

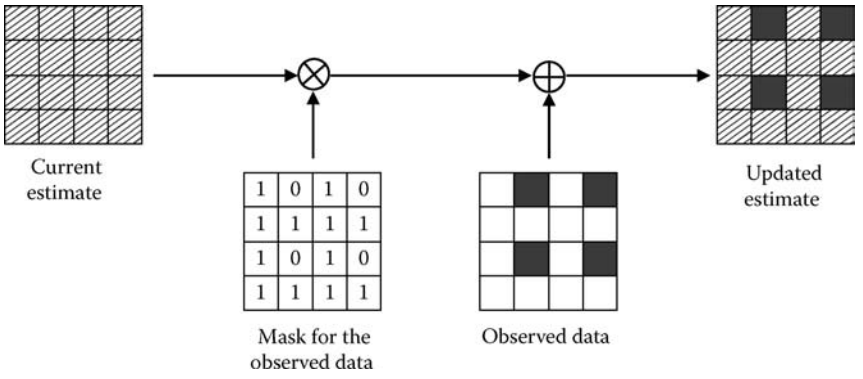

FIGURE 28.19 Projection onto observation constraint set (From Gunturk, B. K., Altunbasak, Y. and Mersereau, R. M., *IEEE Trans. Image Process*., 11, 997, 2002. With permission.)

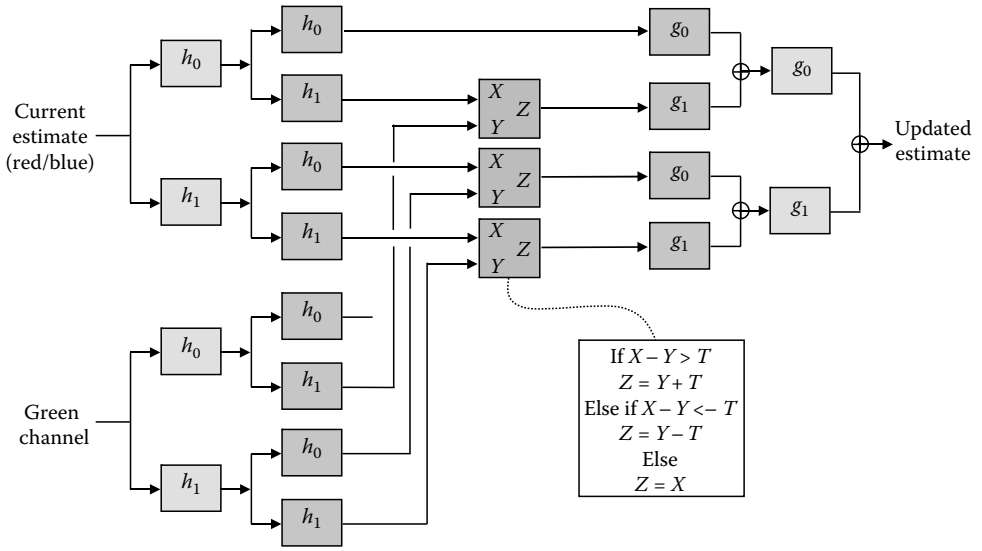

FIGURE 28.20 Projection onto detail constraint set [14]. h_0 and h_1 are the low-pass and high-pass analysis filters. g_0 and g_1 are the corresponding synthesis filters.

Figure 28.20. By alternately applying these two projections onto the initial red and blue channel estimates, these channels are enhanced.

28.3.8 Spectral Response Modeling

The last group of methods models the image formation process and formulates the demosaicking problem based on this model. To understand this approach, we first need to understand the imaging process. The image acquisition process is usually modeled as a linear process between the light radiance arriving at the camera and the pixel intensities produced by the sensors. An image sensor has a specific spectral response $L_S(\lambda)$, which is a function of the spectral wavelength λ, and a spatial response $h_S(x, y)$, which results from optical blur and the spatial integration at each sensor site. (Typical spectral sensor sensitivities are illustrated in Figure 28.3. The λ space is typically modeled as a 7–11 dimensional space.) The imaging process can be formulated as

$$S(x,y) = \iiint L_S(\lambda) h_S(x-u, y-v) r(u,v,\lambda) \mathrm{d}u \; \mathrm{d}v \; \mathrm{d}\lambda + N_S(x,y), \tag{28.16}$$

where

$S(x, y)$ is the pixel value at spatial location (x, y)
$r(x, y, \lambda)$ is the incident radiance
$N_S(x, y)$ is the additive noise that is a result of thermal/quantum effects and quantization

There are couple of assumptions in this formulation: (1) the input–output relation is assumed to be linear; (2) the spatial blur $h_S(x, y)$ is assumed to be space-invariant and independent of wavelength; and (3) only the additive noise is considered. These assumptions are reasonable for practical purposes.

Since we are dealing with digital data, we need to have the discrete version of Equation 28.16

$$S(i,j) = \sum_{l} \sum_{m,n} L_S(l) h_S(i-m, j-n) r(m,n,l) + N_S(i,j). \tag{28.17}$$

The color filters sample the signal $S(i, j)$ to produce a mosaicked data $z(i, j)$ as given in Equation 28.21. Therefore, the observation model is a linear system, which can be written in the compact form

$$\mathbf{z} = \mathbf{H}\mathbf{r} + \mathbf{N}, \tag{28.18}$$

where

r, **z**, and **N** are the stacked forms of $r(m, n, l)$, $z(i, j)$, and CFA-sampled $N_S(i, j)$, respectively
H is the matrix that includes the combined effects of optical blur, sensor blur, spectral response, and CFA sampling

In Refs. [18–20] the minimum mean square error (MMSE) solution of Equation 28.18 is given:

$$\mathbf{r}^{\mathrm{MMSE}} = E\left[\mathbf{r}\mathbf{z}^{\mathrm{T}}\right]\left(E\left[\mathbf{z}\mathbf{z}^{\mathrm{T}}\right]\right)^{-1}\mathbf{z}, \tag{28.19}$$

where $E[\cdot]$ is the expectation operation. In Ref. [20], the point spread function (PSF) is taken as an impulse function; and **r** is represented as a weighted sum of spectral basis functions to reduce the dimensionality of the problem. (Later, Ref. [21] extended Ref. [20] to include the PSF in the reconstruction.) In Ref. [19], adaptive reconstruction and ways to reduce computational complexity are discussed. Reference [18] constructs a FIR filter based on a wide sense stationary assumption.

28.4 Demosaicking of Video and Super-Resolution Reconstruction

When there are multiple images, it is possible to estimate the missing samples than in the case of a single image. Even if a color sample does not exist in an image as a result of Bayer sampling, that particular sample could have been captured in another frame (due to motion). By warping all captured samples onto the common frame to be demosaicked, a better estimate of a missing sample can be obtained.

Figure 28.21 illustrates this multiframe interpolation idea. In the figure, red channels of three Bayer-sampled images are shown. The grid locations with ''triangles,'' ''circles,'' and ''squares'' show the red samples in these images. We would like to estimate the missing samples in the middle image. The other two images are warped onto the middle image. The estimation problem now becomes an interpolation problem from a set of nonuniformly sampled data. Taking the weighted of these samples, where the weights are inversely proportional with the distance to the pixel in question, the missing sample can be estimated.

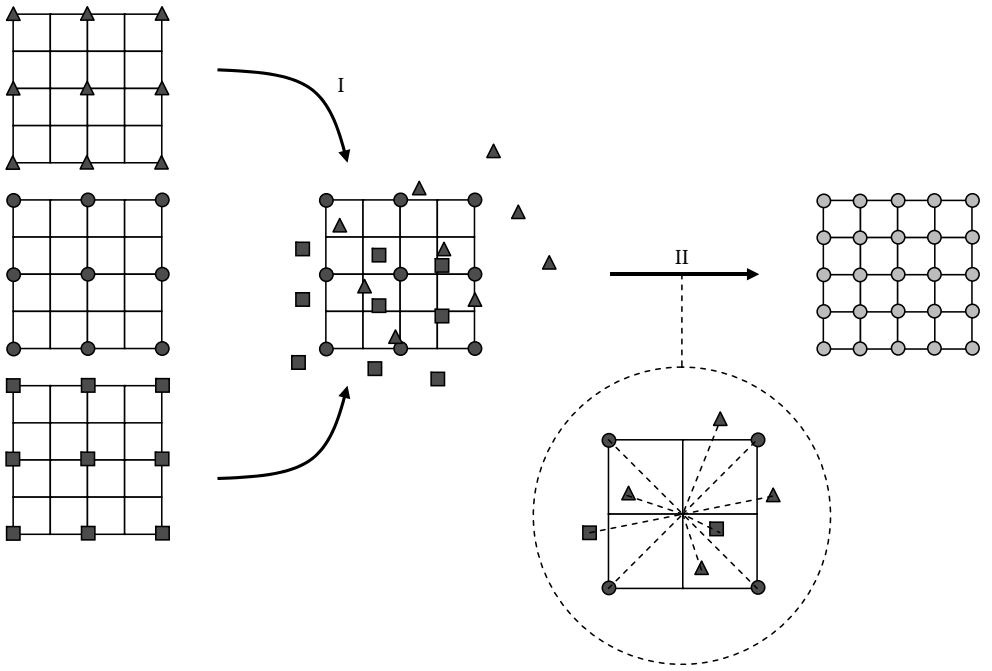

FIGURE 28.21 I: Input images are warped onto reference frame. II: Weighted average of samples are taken to find values on the reference sampling grid.

This idea can be combined with the other demosaicking ideas, such as constant-hue-based interpolation, to formulate a solution. When these multiple frame are available, we can now talk about a spatiotemporal neighborhood instead of a spatial neighborhood of a pixel.

It is also possible to obtain subpixel resolution by combining multiple images. This is known as super-resolution reconstruction, and it was recently applied to CFA sampled color images. The imaging model for super-resolution reconstruction starts with a high-resolution image: Let x_S be a color channel of a high-resolution image, where a channel can be red (x_R), green (x_G), or blue (x_B). The ith observation, $S^{(i)}$, is obtained from this high-resolution image through spatial warping, blurring, and downsampling operations:

$$S^{(i)} = DCW^{(i)}x_S, \quad \text{for } S = R, G, B, \quad \text{and} \quad i = 1, 2, \ldots, K, \tag{28.20}$$

where

K is the number of input images
$W^{(i)}$ is the warping operation (to account for the relative motion between observations)
C is the convolution operation (to account for the point spread function of the camera)
D is the downsampling operation (to account for the spatial sampling of the sensor)

The full-color image $(R^{(i)}, G^{(i)}, B^{(i)})$ is then converted to a mosaicked observation $z^{(i)}$ according to a CFA sampling pattern:

$$z^{(i)} = \sum_{S=R,\,G,\,B} M_S y_S^{(i)} \tag{28.21}$$

as we explained earlier. Then, the super-resolution problem becomes estimation of the high-resolution image $x_S, S = R, G, B$, from low-resolution mosaicked data $z^{(i)}$, $i = 1, 2, \ldots, K$. A typical flowchart of super-resolution reconstruction is illustrated in Figure 28.22.

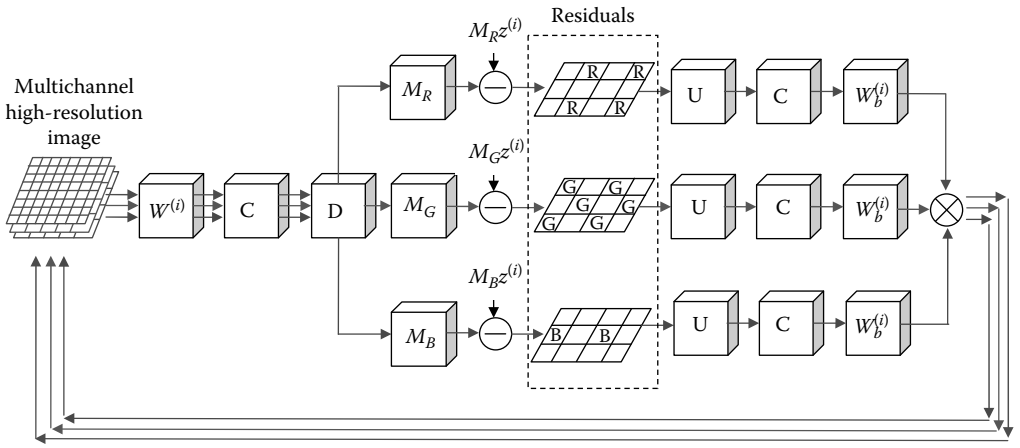

FIGURE 28.22 Typical super-resolution reconstruction algorithm is illustrated. The algorithm starts with a high-resolution image estimate. Simulated observations are obtained by forward imaging operations, including the CFA sampling. The residuals are computed on Bayer pattern samples for each channel, and then back-projected. The notation in the figure is as follows. $W^{(i)}$: Spatial warping onto ith observation, C: Convolution with the PSF, D: Downsampling by the resolution enhancement factor, U: Upsampling by zero insertion, $W_b^{(i)}$: Back-warping to the reference grid.

In Ref. [22], data fidelity and regularization terms are combined to produce high-resolution images. The data fidelity term is based on a cost function that consists of the the sum of residual differences between actual observations and high-resolution image projected onto observations (simulated observations). Regularization functions are added to this cost function to eliminate color artifacts and preserve edge structures. These additional constraints are defined as luminance, chrominance, and orientation regularization [22]. A similar algorithm is presented in Ref. [23]. Reference [24] extends the POCS algorithm of Ref. [14] to multiple frames, where observation constraint set is obtained through bilateral filtering of samples.

28.5 Related Research Problems

In this chapter, we have covered some of the basic demosaicking approaches. There are various others, such as the Bayesian estimation based [25,26] and the neural network based [27]. There are also research problems that are related to the CFA sampling, some of which are listed below:

Denoising: Denoising becomes critical in a digital camera pipeline, especially for images captured in low-light conditions and with high ISO speed. Although standard denoising algorithms can be combined with standard demosaicking algorithms, denoising and demosaicking can be done jointly. Reference [28] proposes such a joint technique based on the total least squares denoising method. The technique reports superior image quality compared to sequential applications of standard denoising and demosaicking algorithms.

Compression: Compression is the last process in a digital camera pipeline. Typically, demosaicking is done on raw CFA data to obtain full-color images, which are later compressed with a compression algorithm, such as the JPEG for still images or the MPEG for videos. The image/video compression algorithms generally decompose images into luminance and chrominance channels and then down-samples chrominance channels to achieve higher compression rates. Because of this downsampling, it seems redundant to do demosaicking before compression. Compression could be done on CFA data; and demosaicking could be added to the end of the decoding processing. Recent studies [29,30] show that, with this alternative processing chain, higher image quality can be achieved at low compression rates. Also, the processing cost is reduced at the camera side.

Camera identification and forgery detection: Due to the demosaicking process, pixels in a digital image are correlated; since different cameras use different demosaicking algorithms, the correlation among the pixels can be used to identify the camera or to detect image forgeries, such as cropping and pasting a region from one image to another [31,32].

Optimal spectral sensitivity functions: Selection of the spectral sensitivity functions is an important part of the digital camera design. The Bayer RGB CFA is known for its superior color reproduction; while the CMYG CFA has better signal-to-noise ratio performance in low-light conditions. Methods for designing optimal spectral sensitivities for color reproduction have been studied earlier [33]. Recently, importance of spectral sensitivities on demosaicking [34] and design of optimal sensitivities for both color and spatial reproduction [35] are discussed.

28.6 Evaluation of Demosaicking Algorithms

Since raw CFA data is not available for most digital cameras, demosaicking methods have been compared based on simulations: Full color images are sampled according to a CFA pattern; the original and the restored images are later compared quantitatively. (This neglects many of the processes in the camera pipeline, most importantly, optical low-pass filtering. Therefore, simulation results may be misleading;

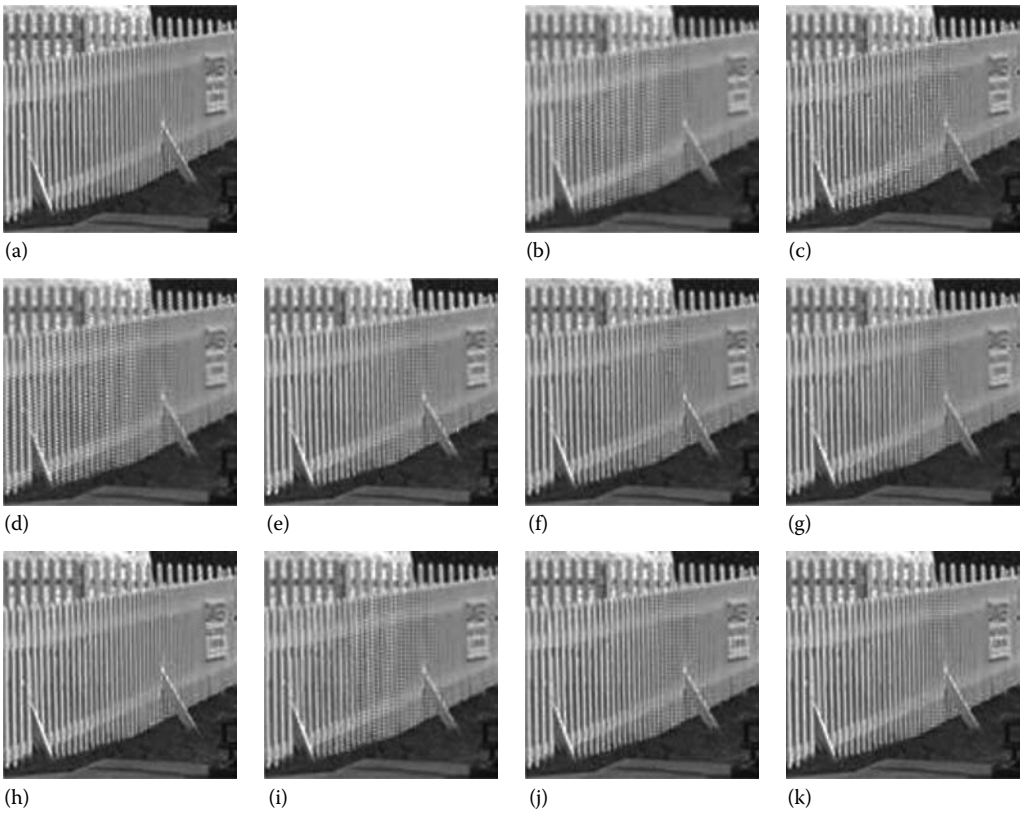

FIGURE 28.23 Result images for example lighthouse image. (a) Original image, (b) bilinear interpolation, (c) edge-directed interpolation in Ref. [10], (d) constant hue-based interpolation in Ref. [3], (e) weighted sum in Ref. [6], (f) second-order gradients as correction terms in Ref. [13], (g) Bayesian approach in Ref. [25], (h) homogeneity-directed in Ref. [8], (i) pattern matching (Chang) in Ref. [39], (j) Alias cancellation in Ref. [15], and (k) POCS in Ref. [14].

the demosaicking algorithms should be tested on raw data; different cameras may have different demosaicking algorithms working best for them.) Two commonly used quantitative measures for evaluating demosaicking algorithms are mean square error and peak signal-to-noise ratio. Euclidean distances in the perceptually uniform CIELab and CIELuv spaces and the s-CIELab [36] are better measures considering the human visual perception.

For the demosaicking algorithms, the Kodak color image database [37] has become a standard test image set. Many algorithms evaluate their performances using these images, enabling comparison among different algorithms. Figure 28.23 provides a visual comparison of several demosaicking algorithms available in 2005 [38]. Recent papers present improvement over these methods.

In addition to the restoration performance, computational complexity is also an important factor for demosaicking algorithms due to the limited resources of a digital camera. The trade-off between the image quality and computational time should be considered in designing the camera pipeline.

28.7 Conclusions and Future Directions

As the sensor technology and processing power of digital cameras advance, the image quality of digital still and video cameras will continue to improve. Eventually, the image quality of consumer level digital cameras will catch and exceed the quality of film cameras. Digital video cameras will be able to produce images with the quality of digital still cameras.

Although the manufacturers are able to fit more and more pixels in a fixed size chip, higher pixel count does always not correspond to higher image quality. As the dimensions of the photosensitive region of a pixel decrease, the dynamic range and noise performance of the sensor decreases. The solution is therefore to produce larger size sensor chips and to increase the fill ratio (photosensitive region area/pixel area).

There is also research to develop alternative sensor technologies. For example, a recent technology exploits the absorption characteristics of silicon to eliminate CFA and increase resolution. The blue portion of the light is absorbed at the surface of a silicon, while the red portion penetrates deeper. By putting detectors at various depths, color information can be extracted without the need of a CFA. However, for such a sensor, the color components are convoluted, the color reproduction and noise performance could be problematic. Another approach is to place micrograting above pixels. These micrograting diffract light according their spectral content, and detectors capture different spectral information.

Although these technologies look promising, single-chip image capture, and therefore, demosaicking seem to remain essential for some time. Soon HDTVs will become widespread, and higher image quality from digital video cameras will be expected. Some of the demosaicking algorithms that we explained in this article cannot be included in a camera due to the limited resources. However, the computational power of cameras will increase, and advanced image processing algorithms will be utilized in digital cameras. The research on the inter-channel correlation can also help in modeling and restoration of multi-frame and hyper-spectral data.

Acknowledgments

This chapter is an extension of Ref. [38]. We would like to acknowledge the vital contributions of John Glotzbach, Ronald W. Schafer, and Russell M. Mersereau. This work is supported in part by the National Science Foundation under Grant 0528785.

A

Active filters
  cascaded realization
    CAD methods, 4-24
    operational amplifier, 4-26
    polynomial coefficient, 4-23
    Q-factor, 4-26–4-28
    stages, 4-25–4-26
  cascade realization, 1-23–1-24
  first-order *RC* network, 1-25
  inductorless filter, 1-23
  Thévenin equivalent circuit, 1-24
  transfer function, 1-24–1-25
Active *RC* prototype, *see* Tow–Thomas biquad
Adaptive 3-D wavelet packet transform, 27-27
Åkerberg–Mossberg biquad, 13-24–13-25
Alias-free 2-D decimation
  antialiasing filter, 25-5
  frequency cell, 25-6
  periodicity matrix, 25-6–25-7
  quincunx downsampling, 25-6
Allpass filters, 1-19
  block diagram, 19-10
  cascade filter, 19-9–19-10
  magnitude response, 19-8
  phase response, 19-9
  pole-zero reciprocal pair, 19-8–19-9
All-pole filter, *see* Chebyshev filters
Analog filter characteristics
  allpass filters, 1-19
  amplitude and delay distortion, 1-16–1-17
  applications, 1-1–1-2
  components, classification, 1-2
  design process
    approximation step, 1-21–1-22
    implementation, 1-23
    realization step and imperfections, 1-22
  discrete- and continuous-time signal, 1-2
  ideal and practical filters, 1-15–1-16
  Laplace transform, 1-3–1-4
  minimum-phase filters
    amplitude response, 1-18
    phase response, 1-18–1-19
    zero-pole plots, 1-17–1-18
  nonminimum-phase transfer functions, 1-20–1-21
  realization
    active filters, 1-23–1-25
    biquads, 1-25–1-26
    passive *RLC* filters, 1-23
  section types
    allpass section, 1-28–1-29
    bandpass section, 1-27–1-28
    high-pass section, 1-27
    low-pass section, 1-26
    notch section, 1-28
  time-domain response
    impulse and step responses, 1-8
    inversion formula, 1-6–1-7
    overshoot, delay time, and rise time, 1-8–1-10
    partial-fraction, 1-7
  transfer function
    convolution integral, 1-4–1-5
    definition, 1-4
    methods, network analysis, 1-5–1-6
    stable and causal network, 1-6
Analog prototype filters
  bandpass filter
    bandpass-to-low-pass conversion, 19-30
    frequency response, 19-31
    LPF to BPF transformation, 19-29–19-30
    magnitude response specification, 19-28–19-29
    specification, 19-30–19-31
    transfer function, 19-31
  bandstop filter, 19-32
  design steps, 19-20
  high-pass filter
    analog and digital frequency, 19-27
    frequency response, 19-28–19-29
    inverse Chebyshev filter transfer function, 19-28
    LPF to HPF transformation, 19-27
    specification, 19-27–19-28
  low-pass filter
    bilinear transformation, 19-26
    impulse invariant method, 19-24–19-25
  transformation
    bilinear transformation, 19-23

impulse invariance method, 19-23–19-24
types, 19-20–19-22
Antisymmetrical impulse response, odd filter length
error function, 18-32
frequency response, 18-31–18-32
problem formulation, 18-33
Remez algorithm, 18-34
Antoniou CGIC biquad, *see* 2-OA CGIC biquad
Application-specific integrated circuit (ASIC)
programmable logic implementation, 21-11
special-purpose implementation, 21-8, 21-10
Approximation
approximation problem, 2-1–2-2
bandpass filter specifications, 2-7
Bessel–Thompson LPP approximation
gain and group delay characteristics, 2-22–2-23
loss function, 2-19
MFD and MFM approximation, 2-21
rational function, 2-20
recursion formula, 2-22
third-order Bessel filter, 2-22–2-23
Butterworth LPP approximation
definition, 2-8
Feldtkeller's equation, 2-9
gain and characteristic function, 2-8–2-9
$G(s)G(-s)$ poles, 2-10–2-11
loss function, 2-8–2-9
maximally flat magnitude (MFM) approximation, 2-9–2-10
second- and third-order Butterworth transfer function, 2-11
Chebyshev LPP approximation
complex number, 2-14
elliptic approximation, 2-23–2-24
equiripple behavior, 2-13
frequency response, 2-14
$G(s)G(-s)$ poles, 2-15–2-17
minimax error criterion, 2-12
pole location, 2-17–2-18
polynomial behavior, 2-12–2-13
ripple parameter, 2-14, 2-17
elliptic approximation
Chebyshev rational function, 2-26–2-27
elliptic and ordinary sine function, 2-28–2-29
elliptic rational functions, 2-31
filter rank ordering, 2-32
gain and characteristic functions, 2-24
gain plot, 2-31
Jacobian elliptic functions, 2-27
minimax error, 2-30–2-31
phase compensation, 2-32
rational approximation, 2-25
running integral, 2-27–2-28
sine transformation, 2-29–2-30
Weierstrass theorem, 2-23, 2-25–2-26
filter types, 2-3–2-5

B

Bamberger pyramids
2-D separable DWT, 25-24
image denoising, 25-26–25-28
Laplacian pyramid structure, 25-23–25-24
lowpass–highpass decomposition, 25-23
multiresolution (MR) process, 25-22
polar-separable representation, 25-22–25-23
texture analysis and segmentation, 25-25–25-26
Bandpass filters (BPF)
analog prototype filters
bandpass-to-low-pass conversion, 19-30
frequency response, 19-31
LPF to BPF transformation, 19-29–19-30
magnitude response specification, 19-28–19-29
specification, 19-30–19-31
transfer function, 19-31
approximation, 2-7
digital frequency transformation, 19-34–19-35
Sallen and Key filter, 11-8–11-9
Bandstop filters (BSF)
analog prototype filters, 19-32
digital frequency transformation, 19-35–19-36
Bartlett window
low-pass magnitude response, 18-10–18-11
spectrum, 18-10
Baseband communication, 26-28–26-29
Bayes minimum distance classifier, 25-25
Berka–Herpy biquad, 13-24–13-25
Bessel–Thompson low-pass prototype (LPP) approximation
gain and group delay characteristics, 2-22–2-23
loss function, 2-19
MFD and MFM approximation, 2-21
rational function, 2-20
recursion formula, 2-22
third-order Bessel filter, 2-22–2-23
Bilinear transformation
analog filter transformation, 23-2, 23-4
1-D analog transfer function, 23-18–23-19
1-D discrete transfer function, 23-21
nonessential singularity, 23-22
Biorthogonal filter bank, 24-16
Biquad multiloop feedback, 11-17
Biquadratic filter, 17-23–17-24
Blackman window
amplitude spectrum, 18-13
expression, 18-12
magnitude response, 18-13–18-14
Broadband matching network design
Butterworth networks
all-pass function, 10-15–10-16
Butterworth transducer power-gain, 10-15
equalizer back-end impedance, 10-16–10-17

final reactive element, 10-17
LC ladder network, 10-17–10-18
load impedance, 10-14
minimum-phase solution, 10-15
Chebyshev networks
all-pass function, 10-23
equalizer back-end impedance, 10-24
Laurent series expansion, 10-23
$RC\omega_c \sinh a<2 \sin \gamma_1$ and $L_{b1} \geq L$, 10-25
$RC\omega_c \sinh a<2 \sin \gamma_1$ and $L_{b1}<L$, 10-25
$RC\omega_c \sinh a \geq 2 \sin \gamma_1$ and $L_{b1}<L$, 10-24–10-25
$RC\omega_c \sinh a \geq 2 \sin \gamma_1$ and $L_{b1} \geq L$, 10-24
transducer power-gain, 10-22
coefficient constraints
normalized reflection coefficient, 10-5–10-6
passive impedance, 10-7–10-8
zero of transmission, 10-2–10-4
design procedure, 10-8–10-9
network configuration, 10-1–10-2
transmission and reflection coefficients, 10-1–10-2
Brune section
positive-real impedance, 6-9–6-10
two-port network, 6-8
type-A and type-B section, 6-8–6-9
type-E section, 6-7–6-8
Butterworth filters
factorized and normalized Butterworth polynomials, 19-13
magnitude response square, 19-12–19-13
transfer function, 19-11–19-12
Butterworth low-pass prototype (LPP) approximation
definition, 2-8
Feldtkeller's equation, 2-9
gain and characteristic function, 2-8–2-9
$G(s)G(-s)$ poles, 2-10–2-11
loss function, 2-8–2-9
maximally flat magnitude (MFM) approximation, 2-9–2-10
second- and third-order butterworth transfer function, 2-11
Butterworth networks
broadband matching network design
all-pass function, 10-15–10-16
Butterworth transducer power-gain, 10-15
equalizer back-end impedance, 10-16–10-17
final reactive element, 10-17
LC ladder network, 10-17–10-18
load impedance, 10-14
minimum-phase solution, 10-15
resistively terminated network design
element values, 9-6–9-7
input impedance, 9-5
input reflection coefficient, 9-4–9-5
LC ladder, 9-6
minimum-phase solution, 9-5
recurrence formula, 9-6
transducer power gain, 9-4

C

Cauer canonical form
LCM one-port network, 7-4
RC one-port network, 7-9
Cauer filters, *see* Elliptic filters
CCCS, *see* Current-controlled current sources
CCVS, *see* Current-controlled voltage sources
Cell Broadband Engine Architecture, 21-8
CGIC, *see* Current generalized immittance convertors
Chebyshev filters
magnitude response square, 19-14–19-15
normalized Chebyshev polynomials, 19-15–19-16
polynomial coefficients, 19-14
transfer function, 19-13–19-14
Chebyshev low-pass prototype (LPP) approximation
complex number, 2-14
elliptic approximation, 2-23–2-24
equiripple behavior, 2-13
frequency response, 2-14
$G(s)G(-s)$ poles, 2-15–2-17
minimax error criterion, 2-12
pole location, 2-17–2-18
polynomial behavior, 2-12–2-13
ripple parameter, 2-14, 2-17
Chebyshev networks
broadband matching network design
all-pass function, 10-23
equalizer back-end impedance, 10-24
Laurent series expansion, 10-23
$RC\omega_c \sinh a<2 \sin \gamma_1$ and $L_{b1} \geq L$, 10-25
$RC\omega_c \sinh a<2 \sin \gamma_1$ and $L_{b1}<L$, 10-25
$RC\omega_c \sinh a \geq 2 \sin \gamma_1$ and $L_{b1}<L$, 10-24–10-25
$RC\omega_c \sinh a \geq 2 \sin \gamma_1$ and $L_{b1} \geq L$, 10-24
transducer power-gain, 10-22
resistively terminated network design
element values, 9-10–9-11
input impedance, 9-10
input reflection coefficient, 9-9
minimum-phase solution, 9-9–9-10
transducer power-gain, 9-9
Circularly symmetric 2-D IIR filter
HP, BP, and BS filter realization configuration, 23-24–23-25
Nyquist point, 23-25
subfilter contour plot, 23-23–23-24
LP filter
1-D analog transfer function, 23-18–23-21
1-D discrete transfer function, 23-21–23-22
nonessential singularity elimination, 23-22–23-23

prescribed specification, 23-25–23-26
Coefficient sensitivity, 4-4–4-5
Color filter array (CFA)
Bayer pattern, 28-4
bicubic interpolation, 28-2, 28-4
designs, 28-2
mosaic pattern, 28-1
sampling
compression, 28-18
Fourier domain, 28-11
luminance channel, 28-10
optimal spectral sensitivity function, 28-19
super-resolution reconstruction, 28-17–28-18
Common-mode feedback (CMFB) circuit, 17-22–17-23
Conjugate quadrature filter bank (CQF), 24-16
Continuous-time integrated filters
g_m-C filters
cascade realization, 16-23–16-26
circuit symbols, 16-15
difference current, 16-16
first- and second-order sections, 16-22–16-23
gyrators, 16-20–16-22
integrators, 16-17–16-20
ladder simulation, 16-26–16-31
MOS device, 16-16
resistors, 16-15–16-16
small-signal equivalent circuit, 16-14–16-15
transconductance designs, 16-16–16-17
MOSFET-C method
balanced linear MOSFET conductance, 16-3–16-4
cascade realization, 16-9–16-11
equivalent resistor circuit, 16-4
first- and second-order sections, 16-7–16-9
integrator, 16-5–16-7
ladder simulation, 16-11–16-14
nonlinear drain current, 16-3
tuning process, 16-31–16-32
Continuous-time signal, 1-2
Cosine modulated filter bank, 24-43
Current-controlled current sources (CCCS), 4-18
Current-controlled voltage sources (CCVS), 4-18
Current generalized immittance converter (CGIC) biquads
Antoniou CGIC (2-OA CGIC biquad)
composite GIC biquad, 14-18, 14-19
configuration, 14-2–14-3
design and tuning procedure, 14-6–14-7
3G and 4G ports, 14-2
realization, 14-4–14-5
second-order transfer function, 14-3–14-4
sensitivity analysis, 14-4, 14-6
stability properties, 14-4
universal biquad, 14-11, 14-13–14-14
3-OA CGIC biquad
design and tuning procedure, 14-15–14-16
sixth-order elliptic BP filter design, 14-16–14-17
structure, 14-11, 14-14–14-15
Curvelet-99 transform, 27-20

D

Darlington type-D section
cascade connection, 6-12–6-13
impedance matrix, 6-13–6-14
positive-real impedance, 6-11–6-12
transmission matrix, 6-12–6-13
Daubechies wavelets
Bernstein polynomial, 24-18
conjugate quadrature filter bank (CQF), 24-16
Daubechies 8-tap symlet filters, 24-18–24-19
impulse and frequency responses, 24-16–24-18
$P_t(Z)$ factorization, 24-16
Device under test (DUT), 17-31
DFT, *see* Discrete Fourier transform
Diamond filters, 22-22–22-23, 25-8, 25-14
Difference equation, 20-15–20-16
Digital differentiators, 18-34–18-35
Directional filter banks (DFBs)
Bamberger directional filter bank (BDFB)
analysis filter, 25-10
analysis tree structure, 25-11
downsampling matrix, 25-11–25-12
eight-band BDFB analysis, 25-9–25-10
frequency band partition, 25-9
M-channel parallel structure, 25-10–25-11
wedge-shaped passband, 25-10–25-11
Bamberger pyramids
2-D separable DWT, 25-24
Laplacian pyramid structure, 25-23–25-24
lowpass–highpass decomposition, 25-23
multiresolution (MR) process, 25-22
polar-separable representation, 25-22–25-23
2-D maximally decimated filter bank, 25-7–25-8
2-D multirate system
alias-free 2-D decimation, 25-5–25-7
continuous time signal, 25-2
2-D decimation and interpolation, 25-4–25-5
2-D unimodular matrix, 25-7
2-D upsampler and interpolator, 25-7
fundamental parallepiped, 25-4
quincunx lattice, 25-3–25-4
2-D two-channel fan filter bank
BDFB design, ladder structure, 25-16–25-20
FFB design, 1-D quadrature mirror filter (QMF), 25-12–25-16
fingerprint enhancement and recognition, 25-28
finite-field DFB, 25-28–25-29
image denoising
additive white Gaussian noise and UDWT, 25-27–25-28

Bamberger pyramid, 25-27
Gaussian white noise, 25-26
wavelet denoising procedure, 25-26–25-27
iris recognition, 25-28
texture analysis and segmentation
Bamberger pyramid, 25-25–25-26
classification system, 25-25
multichannel method, 25-24–25-25
undecimated directional filter bank (UDFB)
decomposition, 25-22–25-23
implementation, 25-21–25-22
shift invariance, 25-20–25-21
UCFB and UFFB, 25-21–25-22
undecimated discrete wavelet transform (UDWT), 25-20
unimodular resampling matrix, 25-22
velocity selective filter bank (VSFB), 25-29–25-30
Discrete cosine transform (DCT), 24-43
Discrete Fourier transform (DFT), 22-10, 24-43
Discrete-space Fourier transform, 22-7
Discrete-time signal, 1-2
Discrete wavelet packet transform (DWPT), 27-27
Discrete wavelet transform (DWT), 24-8–24-9
1-D multirate filter banks
2-band filter bank
analysis, 24-3
downsampling and upsampling, 24-4–24-5
output expression, 24-3
reconstruction operation, 24-3–24-4
binary filter trees
decomposition levels, 24-6–24-7
size and bandwidth, 24-7
transformation, 24-7–24-8
discrete wavelet transform (DWT), 24-2
FIR filters and wavelets
antialiasing condition, 24-12
biorthogonal filter bank, 24-16
Daubechies wavelets, 24-16–24-19
high-pass filter, 24-14
LeGall 3,5-tap filter, 24-14–24-15
linear interpolation, 24-14
linear phase and balanced frequency response, 24-19–24-21
low-pass product filter, 24-13
number of zeros, 24-13–24-14
perfect reconstruction condition, 24-12
smoother wavelet, 24-21–24-24
Hilbert pairs
à trous algorithm, 24-43–24-44
common-factor dual-tree filter design, 24-45
dual-tree wavelet transform, 24-44–24-45
metrics for shift dependence, 24-50–24-52
Q-shift dual-tree filter design, 24-46–24-50
shift dependence and shift invariance, 24-43
IIR filter
all-pass filter design, 24-25–24-26
causal and anticausal filtering, 24-24
transformation-based design, 24-26–24-28
types, 24-24
lifting scheme
construction, 24-34–24-36
implementation, 24-37–24-39
M-band filter bank
lifting, 24-42–24-43
type 1 polyphase decomposition, 24-41–24-42
type 2 polyphase decomposition, 24-42
types, 24-43
multirate filtering, 24-5–24-6
nonlinear filter bank, 24-40–24-41
polyphase representation
analysis and synthesis outputs, 24-30
decomposition, 24-29–24-30
even- and odd-indexed coefficients, 24-29
linear phase structure, 24-32–24-33
orthogonal lattice structure, 24-32
total system polyphase matrix, 24-31–24-32
signal sparsity, 24-2
wavelets and scaling functions
analysis side equation, 24-9
convergence condition, 24-11
equivalent transfer function, 24-10–24-11
Fourier domain, 24-10
impulse and frequency responses, 24-8–24-9
piecewise constant function, 24-11
synthesis side equation, 24-9–24-10
vanishing moments (VM), 24-11
Dual-amplifier twin-*T* biquads
band-rejection filter, 13-6–13-7
Cauer low-pass and high-pass filter, 13-8–13-9
high-pass filter, 13-7–13-8
low-pass filter, 13-7
twin-*T* resonator, 13-5–13-6
voltage transfer ratios, 13-7
3-D wavelet packets
adaptive transform, 27-27
restoration algorithm, 27-27–27-28
thresholding, 27-26
wavelet denoising, 27-26–27-27
DWPT, *see* Discrete wavelet packet transform

E

Elliptic approximation
Chebyshev rational function, 2-26–2-27
elliptic and ordinary sine function, 2-28–2-29
elliptic rational functions, 2-31

filter rank ordering, 2-32
gain and characteristic functions, 2-24
gain plot, 2-31
Jacobian elliptic functions, 2-27
minimax error, 2-30–2-31
phase compensation, 2-32
rational approximation, 2-25
running integral, 2-27–2-28
sine transformation, 2-29–2-30
Weierstrass theorem, 2-23, 2-25–2-26
Elliptic filters
elliptic integral, 19-18
equiripples, 19-17
magnitude response square, 19-17, 19-19
pole and coefficient calculation, 19-18–19-19
rational function, 19-18
Equiripple FIR filters, 18-15–18-16
alternation theorem, 18-19
amplitude response, 18-17–18-18
antisymmetrical impulse response and odd filter length
error function, 18-32
frequency response, 18-31–18-32
problem formulation, 18-33
Remez algorithm, 18-34
arbitrary amplitude response, 18-35
cubic-interpolation search method, 18-25–18-26
digital differentiators, 18-34–18-35
error function, 18-16–18-17
frequency response, 18-16
multiband filter, 18-35, 18-37
noniterative/iterative methods, 18-15–18-16
piecewise-constant amplitude-response specification, 18-30
Remez exchange algorithm
exhaustive step-by-step search, 18-21–18-23
extremal initialization, 18-20–18-21
iterative multivariable algorithm, 18-20
maxima of error function, 18-21
superfluous potential external rejection, 18-23–18-24
selective step-by-step search method, 18-24–18-25
transfer function, 18-16
weighted-Chebyshev method, 18-16

F

Fan filter banks (FFBs), 25-8
Fast Fourier transform (FFT)
approximate minimax FIR filter, 22-13–22-14
window-based 2-D FIR filter design, 22-10
FDNR, *see* Frequency-dependent negative resistors
Field programmable gate array (FPGA)
GNURadio, 21-8
programmable logic implementation
FIR filter, 21-12–21-13
IIR filter, 21-13–21-14
Filter noise analysis, 11-27–11-29
Fingerprint enhancement and recognition, 25-28
Finite-impulse response (FIR) filters
code segment
ADSP-21020 architecture, 21-4–21-5
Motorola 56001 architecture, 21-6–21-7
TMS320C30 architecture, 21-3
TMS320C50 architecture, 21-5
2-D filter implementation, 22-24
equiripple FIR filters
alternation theorem, 18-19
amplitude response, 18-17–18-18
antisymmetrical impulse response and odd filter length, 18-31–18-34
arbitrary amplitude response, 18-35
cubic-interpolation search method, 18-25–18-26
digital differentiators, 18-34–18-35
error function, 18-16–18-17
frequency response, 18-16
multiband filter, 18-35, 18-37
noniterative/iterative methods, 18-15–18-16
piecewise-constant amplitude-response specification, 18-30
Remez exchange algorithm, 18-20–18-24
selective step-by-step search method, 18-24–18-25
transfer function, 18-16
weighted-Chebyshev method, 18-16
filter banks, 22-25–22-26
frequency response
antisymmetric impulse response and $N = even$, 18-5
antisymmetric impulse response and $N = odd$, 18-4–18-5
masking approach, 18-38–18-45
symmetric impulse response and $N = even$, 18-4
symmetric impulse response and $N = odd$, 18-3–18-4
linear phase property
difference equation, 18-2
impulse response, 18-3
phase and group delay functions, 18-2
phase response, 18-2–18-3
transfer function, 18-1–18-2
L_p norm, 22-11-22-12
multistage frequency-response masking approach
complexity minimization, 18-48–18-49
implementation form, 18-47
synthesis, 18-47–18-48
three-stage filter, 18-47
transfer function, 18-46–18-47
narrowband filter design
amplitude response, 18-51–18-52
Jing–Fam approach, 18-49, 18-55, 18-57–18-58

multiplier, minimization, 18-52–18-53
order of $F(z)$ and $G(z)$, 18-52
passband and stopband ripples, 18-56
single-stage design, 18-57
subfilter design, 18-51
synthesis, 18-50–18-51, 18-57–18-58
transfer function, 18-49, 18-51, 18-55–18-56
narrow transition band, 18-38
nonlinear-phase low-pass filter, 22-4–22-5
programmable logic implementation, 21-12–21-13
roundoff noise, 20-6–20-7
separable filter design, 22-16–22-17
special-purpose implementation
ASIC comparison, 21-10–21-11
Motorola 56200 architecture, 21-9–21-10
parallelism and pipelining, 21-9
180 MHz sampling rate, 21-9–21-10
wavelets
antialiasing condition, 24-12
biorthogonal filter bank, 24-16
Daubechies wavelets, 24-16–24-19
high-pass filter, 24-14
LeGall 3,5-tap filter, 24-14–24-15
linear interpolation, 24-14
linear phase and balanced frequency response, 24-19–24-21
low-pass product filter, 24-13
number of zeros, 24-13–24-14
perfect reconstruction condition, 24-12
smoother wavelet, 24-21–24-24
wideband filter design, 18-53–18-54
window-based filter design, 22-6–22-10
windowing techniques
Bartlett window, 18-10
Blackman window, 18-12–18-14
filter coefficient, 18-6
Hamming window, 18-11–18-12
Hanning window, 18-10–18-12
ideal low-pass filter response, 18-7
Kaiser window, 18-13–18-15
rectangular window, 18-7–18-9
zero locations, 18-5–18-6
zero-phase filters, 22-4–22-5
Finite wordlength effects
coefficient quantization error
alternate realization structure, 20-16–20-17
clustered root, 20-16
definition, 20-15
grid, 20-15–20-16
realizable pole locations, 20-16–20-17
transfer function, 20-15
fixed-point quantization error
sum of products, 20-2–20-3
types, 20-3–20-4
floating-point quantization error, 20-4–20-5
limit cycles
definition, 20-12
filter realization structure, 20-14
implementation sequence, 20-13
second-order filter, 20-12–20-13
number representation, 20-1–20-2
overflow oscillations, 20-14–20-15
realization, 20-17–20-18
roundoff noise
FIR filter, 20-6–20-7
fixed-point IIR filter, 20-7–20-10
floating-point IIR filter, 20-10–20-12
zero-mean white noise filter, 20-5
First-order *RC* network, 1-25
Fixed-point processors, 21-2
FLF, *see* Follow-the-leader feedback
Floating-point processors, 21-2
Follow-the-leader feedback (FLF) topology
feedback resistors, 15-11
first-order lowpass functions, 15-8
GIC bandpass sections, 15-11–15-12
lowpass-to-bandpass transformation, 15-8
matrix expression, 15-9
primary resonator block (PRB) design process, 15-10–15-11
second-order bandpass biquads, 15-7
summer and feedback factor implementation, 15-6–15-7
Foster canonical form
LCM one-port network, 7-3
RC one-port network, 7-8–7-10
Fourier slice theorem, 27-6–27-7
Fourier transform
analog filter, 1-16–1-17
Bartlett window, 18-10
Blackman window, 18-13
Hamming window, 18-11–18-12
Hanning window, 18-10–18-11
Rectangular window, 18-7–18-8
FPGA, *see* Field programmable gate array
Frequency-dependent negative resistors (FDNR), 15-27
Frequency-domain analysis
graphical construction
amplitude and phase responses, 1-13
frequency response evaluation, 1-13–1-14
gain and phase shift, 1-13
transfer function, 1-12–1-13
loss function, 1-14–1-15
sinusoidal response, 1-11–1-12
Frequency-response masking approach
complementary periodic filter pair, 18-40
error function, 18-43
$F(L\omega)$ design, 18-43
filter synthesis problem, 18-44
low-pass filter design, 18-40–18-42

passband and stopband ripples, 18-42
prototype transfer function, 18-40
subfilter order, 18-44–18-45
transfer function, 18-38–18-39
transition bandwidth, 18-44
zero-phase frequency response, 18-39–18-40
Frequency sampling, 22-10–22-11
Frequency transformations
bandpass transformation
imaginary frequency axis, 3-8–3-9
narrow-band approximation, 3-8
network transformation, 3-9–3-10
passband and stopband specifications, 3-8–3-9
rational function, 3-7
band-reject transformation
characterization, 3-10–3-11
frequency responses, 3-11
LPP transfer function, 3-12
network transformation, 3-12–3-13
frequency scaling
LP network transformation, 3-3–3-4
LPP transfer function, 3-2–3-3
high-pass transformation, 3-5–3-6
impedance scaling, 3-4
low-pass prototype, 3-1–3-2
Friend biquad, 12-12–12-13
Function sensitivity, 4-3–4-4

G

Gain-bandwidth
noninverting and inverting amplifier, 11-23–11-25
Sallen–Key second-order low-pass filter, 11-26–11-27
transfer function, 11-26
Generalized impedance converter (GIC)
dual-amplifier biquads
all-pass building block, 13-14–13-15
bandpass building block, 13-12–13-13
Cauer high-pass building block, 13-17–13-18
Cauer low-pass building block, 13-15–13-16
high-pass building block, 13-13–13-14
low-pass building block, 13-10
notch filter building block, 13-14–13-15
resonator, 13-9
time constant and conductance ratio, 13-11
transfer function, 13-12
voltage transfer ratio, 13-9–13-10
three-amplifier biquads, 13-18–13-19
g_m-C filters
cascade realization
capacitor values, 16-25–16-26
filter parameters, 16-24
low-pass filter structure, 16-25–16-26
low-pass g_m-C section, 16-24–16-25
circuit symbols, 16-15
difference current, 16-16
gyrators
definition, 16-20
inductive admittance, 16-21
inverting and noninverting transconductor, 16-20–16-21
passive equivalent circuit, 16-21–16-22
integrators
floating/grounded capacitor, 16-17–16-18
g_m-C–op amp integrator, 16-19
nominal correction, phase errors, 16-19–16-20
parasitic capacitors, 16-18–16-19
quality factor, 16-18
transfer function, 16-17
ladder simulations
element replacement methods, 16-26–16-29
signal-flow graph methods, 16-29–16-31
MOS device, 16-16
resistors, 16-15–16-16
small-signal equivalent circuit, 16-14–16-15
transconductor, 16-14
GNURadio, 21-7–21-8
Gorski-Popiel's method
inductance networks, 15-25–15-26
LC ladder realization, 15-26
sixth-order *LC* bandpass filter, 15-26–15-27
Graphical construction, frequency-domain analysis
amplitude and phase responses, 1-13
frequency response evaluation, 1-13–1-14
gain and phase shift, 1-13
transfer function, 1-12–1-13
Group delay function, 2-20–2-21
Gyration resistance, 20

H

Haar filters
all-pass filter, 24-25–24-26
4-level tree, 24-8–24-9
Half-plane symmetric filter, 23-14
Hamming window
amplitude spectrum, 18-11–18-12
2-D FIR filter design, 22-8–22-9
magnitude response, 18-12–18-13
Hanning window
amplitude spectrum, 18-10–18-11
expression, 18-10
magnitude response, 18-10, 18-12
High-order filters
cascade realization
Åckerberg–Mossberg circuit, 15-5–15-6
biquadratic function, 15-3
intermediate gain-scaled transfer functions, 15-4
*n*th-order transfer function, 15-2–15-3

sixth-order transfer function, 15-5
ladder simulations
dynamic range maximization, 15-18–15-23
element substitution, 15-23–15-27
signal-flow graph methods, 15-13–15-18
low-gain active filter, 11-16–11-17
multiple-loop feedback realizations
feedback resistors, 15-11
first-order lowpass functions, 15-8
GIC bandpass sections, 15-11–15-12
leapfrog topology, 15-12
lowpass-to-bandpass transformation, 15-8
matrix expression, 15-9
primary resonator block (PRB) design process, 15-10–15-11
second-order bandpass biquads, 15-7
summer and feedback factor implementation, 15-6–15-7
High-pass filters (HPF)
analog prototype filters
analog and digital frequency, 19-27
frequency response, 19-28–19-29
inverse Chebyshev filter transfer function, 19-28
LPF to HPF transformation, 19-27
specification, 19-27–19-28
configuration, 23-24–23-25
derivation, 23-23–23-24
digital frequency transformation, 19-33–19-34
1-D multirate filter banks, 24-14
Nyquist point, 23-25
Sallen and Key filter, 11-9–11-10
transfer function, 23-23–23-24
Hilbert pairs
à trous algorithm, 24-43–24-44
common-factor dual-tree filter design, 24-45
dual-tree wavelet transform, 24-44–24-45
metrics, shift dependence
aliasing energy ratio, 24-51
analysis and reconstruction, 24-50–24-51
dual-tree complex wavelet transform (DT-CWT), 24-51–24-52
shift invariance and shift dependence, 24-50
Q-shift dual-tree filter design
impulse response, 24-46
iterative energy minimization method, 24-48–24-49
zero-forcing method, 24-47
shift dependence and shift invariance, 24-43
HPF, *see* High-pass filters
Hurwitz polynomials, 5-7–5-8, 9-10

I

Image denoising, 25-26–25-28
Impulse response, 1-8
Independent component analysis (ICA), 27-3
Infinite impulse response (IIR) filters
allpass filter
block diagram, 19-10
cascade filter, 19-9–19-10
magnitude response, 19-8
phase response, 19-9
pole-zero reciprocal pair, 19-8–19-9
analog low-pass filter (LPF)
Butterworth filter, 19-11–19-13
Chebyshev filter, 19-13–19-16
elliptic filter, 19-17–19-19
inverse Chebyshev filter, 19-15–19-17
specification, 19-11
analog prototype filters
bandpass filter, 19-28–19-31
bandstop filter, 19-32
design steps, 19-20
high-pass filter, 19-27–19-29
low-pass filter, 19-24–19-26
transformation, 19-20–19-24
causality, 19-2–19-3
code segment
Motorola 56001 architecture, 21-7
TMS320C30 architecture, 21-3–21-4
TMS320C50 architecture, 21-5–21-6
computer-aided design
least squares ($\mathcal{L}_2$-norm) criterion, 19-36–19-40
weighted Chebyshev ($\mathcal{L}\infty$-norm) criterion, 19-40
digital frequency transformation
bandpass filter, 19-34–19-35
bandstop filter, 19-35–19-36
design process, 19-32–19-33
high-pass filter, 19-33–19-34
low-pass filter, 19-33
digital LPF specification, 19-11–19-12
direct form realizations
cascade second-order filter, 19-6
coefficient quantization, 19-7–19-8
parallel second-order filter, 19-7
system function, 19-5–19-6
1-D multirate filter banks
all-pass filter design, 24-25–24-26
causal and anticausal filtering, 24-24
transformation-based design
magnitude response, 24-28
phase response, 24-27–24-28
prototype linear phase low-pass filter, 24-27
types, 24-24
fixed-point IIR filter
first-order filter, 20-7
limit cycle, 20-13
normalized fixed-point roundoff noise variance, 20-9
quantization, noise source, 20-8
roundoff noise-to-signal ratio, 20-8–20-9
second-order filter, 20-8–20-9

state-space filter realization, 20-10
transfer function, 20-7–20-8
floating-point IIR filter
first-order filter, 20-10–20-11
limit cycle, 20-13
normalized floating-point roundoff noise variance, 20-12
roundoff noise-to-signal ratio, 20-11–20-12
second-order filter, 20-11–20-12
zero-mean white noise, 20-10
frequency response
complex function, 19-3–19-4
group delay, 19-5
magnitude square, 19-4
phase response, 19-5
lattice digital filters
injected numerator structure, 19-41–19-42
injector gains, 19-44–19-45
reflection coefficient, 19-42–19-44
tap gains, 19-44
tapped numerator structure, 19-41–19-42
third-order one-multiplier injected numerator filter, 19-42–19-43
minimum phase filter, 19-8
poles and zeros, 19-3
programmable logic implementation, 21-13–21-14
special-purpose implementation, 21-11
stability
optimization techniques, 19-40–19-41
second-order system, 19-3–19-4
system function and impulse response, 19-1–19-2
Inverse Chebyshev filters, 19-15–19-17
Iris recognition, 25-28
Iterative filter design algorithm, 22-13–22-14

J

Jing–Fam approach, 18-49, 18-55, 18-57–18-58

K

Kaiser window
definition, 18-15
magnitude response, 18-14–18-15
prolate spheroidal wave function, 18-14
spectral properties, 18-15
stopband attenuation, 18-13–18-14
Kirchhoff current law equation, 5-1

L

Ladder simulations
dynamic range maximization
active circuit, 15-22–15-23
feed-in resistors, 15-23
fourth-order elliptic lowpass ladder filter, 15-20–15-21
passive series branch, 15-19–15-20
passive shunt branch, 15-20
signal-level scaling, 15-18–15-19
transmittance, 15-21
voltage and current maxima, 15-21
element replacement methods
circuit capacitor value, 16–28–16-29
component values, 16-27
dual-input OTA, 16-27–16-28
third-order elliptic low-pass ladder, 16–28–16-29
transconductor-C simulation, 16-26–16-27
transfer function, 16–28
element substitution
Antoniou's general impedance converter (GIC), 15-24
Gorski-Popiel's method, inductor replacement, 15-25–15-27
impedance converter, 15-23–15-24
MOSFET-C method
elliptic LC low-pass filter, 16-12
implementation, 16-13–16-14
transfer function magnitude, 16-12
V–I relationship, 16-12–16-13
signal-flow graph methods
block diagram, 15-13–15-14
fourth-order all-pole lowpass ladder, 15-17–15-18
impedance- and signal-level scaling, 15-16
inverting lossy Miller integrator, 15-14
ladder structure, 15-13
noninverting lossy phase-lead integrator, 15-14
series and shunt ladder branch, 15-15–15-16
signal-flow graph (SFG) methods
fifth-order elliptic low-pass function, 16–29–16-30
third-order elliptic low-pass filter, 16–30–16-31
Ladder structures
analysis–synthesis ladder structure, 25-17–25-18
biorthogonal property, 25-19–25-20
closed-form Lagrange formula, 25-18
digital fan-shaped filter, 25-17
magnitude response, 25-18–25-19
regular biorthogonal wavelet generation, 25-18
two-channel biorthogonal analysis filter bank, 25-19
wavelet construction, 25-16
Laplace transform
analog filter characteristics, 1-3–1-4
analog IIR filter, 19-11
Laplacian statistics
filtering structure, 26-8–26-9
location estimation, 26-9–26-10
α-stable distributed samples, 26-10–26-11
weighted median (WM) filter, 26-9
Lattice digital filters
injected numerator structure, 19-41–19-42
injector gains, 19-44–19-45

reflection coefficient, 19-42–19-44
tap gains, 19-44
tapped numerator structure, 19-41–19-42
third-order one-multiplier injected numerator filter, 19-42–19-43
LC ladder
zero-producing step, 8-4–8-5
zero-shifting step, 8-2–8-4
LCM one-port network
admittance function, 7-3
driving-point immittance, 7-2
first and second Cauer canonical form, 7-4
first and second Foster canonical form, 7-3
input impedance, 7-1
reactance function, 7-2–7-3, 7-5–7-6
Leapfrog topology, 15-12
Learning vector quantization (LVQ) algorithm, 25-25
Least squares ($\mathcal{L}_2$-norm) criterion
adaptive weighted least square (WLS), 19-37–19-38
eigenfilter approach, 19-39–19-40
quadratic programming, 19-38
transfer function, IIR filter, 19-36
weighted square error, 19-36–19-37
LeGall 3,5-tap filter, 24-14–24-15

high-pass filter, 11-9–11-10
low-pass filter, 11-6–11-8
notch filter circuits, 11-10–11-11
second-order transfer functions
biquadratic transfer function, 11-3–11-4
high-pass and bandpass transfer functions, 11-3
low-pass filter, 11-2
tuning active filters, 11-6
Low-pass filters (LPF)
analog prototype filters
bilinear transformation, 19-26
impulse invariant method, 19-24–19-25
1-D analog transfer function
2-D zero-phase filter, 23-21
rotation angle, 23-20–23-21
subfilter stability and realization, 23-20
1-D discrete transfer function, 23-21–23-22
digital frequency transformation, 19-33

nonessential singularity elimination, 23-22–23-23
Sallen and Key filter, 11-6–11-8
Low-pass transfer function
bandpass transformation
bandpass network transformation, 3-9–3-10
bandpass transfer function, 3-7
imaginary frequency axis, 3-8
narrow-band approximation, 3-8
passband and stopband specifications, 3-8–3-9
band-reject transformation
band-rejection network transformation, 3-12–3-13
LPP transfer function, 3-12
transformation responses, 3-11–3-12
high-pass transformation
frequency range, 3-5–3-6
HP circuit, 3-6
imaginary axis, 3-5
network transformation, 3-6
LPF, *see* Low-pass filters

M

Magnitude truncation, 3
Maximally flat magnitude (MFM), 2-9–2-10
Maximum likelihood estimation
generalized Cauchy density
arg min and log functions, 26-13–26-14
error norm, 26-14–26-15
GCD function, 26-11–26-12
heavy-tailed distribution, 26-12
impulsive sequence, 26-12
minimization problem, 26-13
generalized Gaussian density
additive noise, 26-5
definition, 26-5–26-6
minimization problem, 26-6–26-7
M-band filter bank
lifting, 24-42–24-43
type 1 polyphase decomposition, 24-41–24-42
type 2 polyphase decomposition, 24-42
types, 24-43
McClellan transformation
Chebyshev polynomial, 22-17
frequency response, 22-17–22-21
nonlinear optimization problem, 22-21
window-based 2-D FIR filter design, 22-7–22-8
zero-phase filter, 22-17
M-estimation
filtering structure, 26-5
Gaussian statistics, linear filtering, 26-7–26-8
generalized Gaussian density, 26-5–26-7
additive noise, 26-5
definition, 26-5–26-6
minimization problem, 26-6–26-7
Laplacian statistics
filtering structure, 26-8–26-9
location estimation, 26-9–26-10
median filtering, 26-8–26-11
α-stable distributed samples, 26-10–26-11
weighted median (WM) filter, 26-9
MFM, *see* Maximally flat magnitude
Mikhael–Bhattacharyya biquad, 13-18
Minimal mean-square-error approximation, 23-38
Minimax algorithm
Charalambous minimax algorithm, 23-32–23-33
objective function, 23-31–23-32
Minimum-phase filters, 1-17–1-19
MOSFET-*C* method
balanced linear MOSFET conductance, 16-3–16-4
balanced symmetrical op amp, 16-4
cascade realization
aspect ratios, 16-11
gain constant, 16-10–16-11
high-order function, 16-9–16-10
*n*th-order transfer function, 16-10
equivalent resistor circuit, 16-4
first- and second-order sections
Tow–Thomas biquad, 16-7–16-8
transfer function, 16-8–16-9
integrators
active *RC* integrator, 16-5
differential MOSFET-*C* integrator, 16-5–16-6
equivalent circuit, 16-5
four-MOSFET configuration, 16-6
lossy integrator, 16-6–16-7
ladder simulations
elliptic *LC* low-pass filter, 16-12
implementation, 16-13–16-14
transfer function magnitude, 16-12
V–*I* relationship, 16-12–16-13
MOS transistor, 16-3
Mother wavelet, 24-8–24-11
Multiband filter, 18-35, 18-37
Multiple-amplifier biquads
all-pass-based biquads, 13-25–13-26
decoupled time constants
dual-amplifier bandpass filter, 13-2
dual op-amp bandpass filter section, 13-4–13-5
dual op-amp high-pass filter section, 13-4
dual op-amp low-pass filter section, 13-3
Sallen and Key bandpass circuit, 13-2
transfer voltage ratio, 13-2, 13-4
dual-amplifier twin-*T* biquads
twin-*T* band-rejection filter, 13-6–13-7
twin-*T* Cauer low-pass and high-pass filter, 13-8–13-9
twin-*T* high-pass filter, 13-7–13-8
twin-*T* low-pass filter, 13-7
twin-*T* resonator, 13-5–13-6
voltage transfer ratios, 13-7
GIC-derived dual-amplifier biquads
all-pass building block, 13-14–13-15

bandpass building block, 13-12–13-13
Cauer high-pass building block, 13-17–13-18
Cauer low-pass building block, 13-15–13-16
high-pass building block, 13-13–13-14
low-pass building block, 13-10
notch filter building block, 13-14–13-15
resonator, 13-9
time constant and conductance ratio, 13-11
transfer function, 13-12
voltage transfer ratio, 13-9–13-10
GIC-derived three-amplifier biquads, 13-18–13-19
single- to multiple-amplifier biquadratic filter, 13-1
state-variable-based biquads
Åkerberg–Mossberg biquad, 13-24–13-25
analog computer structure, 13-20–13-21
Berka–Herpy biquad, 13-24–13-25
low-pass transfer function, 13-21
noninverting integrator, 13-24
op-amp realization, Tow–Thomas filter, 13-22–13-23
output amplifier, 13-21–13-22
Tow–Thomas biquad, 13-23–13-24
Multiple-feedback (MFB) filters
all-pole designs
equal-capacitor design, 12-5
low-pass structure, 12-3–12-4
realization, 12-3–12-5
transfer ratio, 12-4–12-5
design
finite amplifier gain effects, 12-8–12-9
sensitivity, 12-8
tuning function, 12-9–12-10
MMFB structure
bandpass transfer function, 12-10–12-11
biquadratic structure, 12-12–12-13

N

Narrowband filter
amplitude response, 18-51–18-52
Jing–Fam approach, 18-49, 18-55, 18-57–18-58
multiplier, minimization, 18-52–18-53
order of $F(z)$ and $G(z)$, 18-52
passband and stopband ripples, 18-56
single-stage design, 18-57
subfilter design, 18-51
synthesis, 18-50–18-51, 18-57–18-58
transfer function, 18-49, 18-51, 18-55–18-56
NMOS transistor, switch resistance, 17-19–17-20
Nondiagonal nonsingular integer matrix, 22-22
Nonlinear filtering
image denoising
adaptive transform, 27-27
best basis selection, 27-16–27-17
brushlets and wave atoms, 27-20, 27-22
butterfly-based digital implementation, 27-9–27-12
continuous planelet transform, 27-23–27-24
continuous transform, 27-5–27-7
definition, 27-1
denoising algorithm, 27-25
discrete planelet transform (DPT), 27-24
discrete transform, 27-7–27-8
fixed/adaptive transform, 27-4
image data corruption, 27-1–27-2
inverse problem, 27-2
mapping function, 27-3
multiresolution Fourier transform, 27-19–27-20
multiscale polar cosine transform, 27-17–27-19, 27-22
nonlinear approximation, 27-12–27-16
planar feature extraction, 27-25–27-26
polar cosine packets, 27-16
radon-based digital implementation, 27-9
restoration algorithm, 27-27–27-28
ridgelet and curvelet transform, 27-20, 27-22
separable/nonseparable transform, 27-3–27-4
spatiotemporal denoising method, 27-2
standard images, 27-21
standard video sequences, 27-28–27-31
texture representation, 27-5
thresholding, 27-26
transform domain, 27-3
wavelet denoising, 27-26–27-27
statistical signal models
additive noise extraction, 26-27
baseband communication, 26-28–26-29
corrupted image sample, 26-2–26-3
definition, LM-estimation, 26-11
filtering structure, 26-5
Gaussian statistics, linear filtering, 26-7–26-8
generalized Cauchy density, 26-11–26-14
generalized Gaussian density, 26-5–26-7
highpass filtering, 26-29–26-31
Laplacian statistics, median filtering, 26-8–26-11
optimal estimation-based filter development, 26-2
power line communications (PLCs), 26-29–26-30

real-valued weights and optimization, 26-26–26-27
running meridian smoothers, 26-21–26-26
running myriad smoothers, 26-14–26-21
signal processing, 26-1–26-2
symmetric α-stable distributions, 26-28
Nonlinear-phase low-pass filter, 22-4–22-5
Nonminimum-phase transfer functions, 1-20–1-21
Norton equivalent, 9-1–9-2
Nyquist points, 23-25

O

On-chip spectrum/vector analyzer, 17-31
2-Opamp (OA) CGIC biquad
composite GIC biquad, 14-18, 14-19
configuration, 14-2–14-3
design
second-order BP filter, 14-8–14-9
second-order Butterworth LPF, 14-7–14-8
second-order HP filter, 14-9
sixth-order Chebyshev low-pass filter, 14-10–14-11
sixth-order elliptic bandpass filter, 14-11–14-12
and tuning procedure, 14-6–14-7
3*G* and 4*G* ports, 14-2
realization, 14-4–14-5
second-order transfer function, 14-3–14-4
sensitivity analysis, 14-4, 14-6
stability properties, 14-4
universal biquad, 14-11, 14-13–14-14
3-Opamp (OA) CGIC biquad
design and tuning procedure, 14-15–14-16
sixth-order elliptic BP filter design, 14-16–14-17
structure, 14-11, 14-14–14-15
Operational transconductance amplifier (OTA) filters, *see* g_m-*C* filters

P

Padukone–Mulawka–Ghausi biquad, 13-19
Parallel/series ladders
Cauer canonical form, 8-14–8-15
open-circuit voltage ratio, 8-15–8-16
RC α- and β-ladder, 8-12–8-13
realization, 8-13–8-14
scale factors, 8-12
transfer admittance level, 8-13–8-14
two ladder networks, 8-11
Parks–McClellan algorithm, 25-18
Passive cascade synthesis
Darlington type-D Section
cascade connection, 6-12
impedance matrix, 6-13–6-14
positive-real impedance, 6-11–6-12
transmission matrix, 6-12–6-13
index set, 6-4
Richards section, 6-10–6-11
two-port network, 6-1–6-2
type-E section
Brune section, 6-7–6-9
Darlington type-C section, 6-7
impedance and transmission matrix, 6-6–6-7
Passive immittances, one-port network
average electric and magnetic energy, 5-3
driving-point impedance, 5-2, 5-4
Hurwitz polynomial, 5-7–5-8
Kirchhoff current law equation, 5-1
positive-real function, 5-4–5-5
real rational function, 5-5–5-6
resistive, capacitive and inductive branch, 5-2–5-3
RLCM one-port network, 5-1–5-2
Sturm's theorem, 5-8
Passive RLC filters, 1-23
PLCs, *see* Power line communications
Polar cosine transform
best basis selection, 27-16–27-17
brushlets and wave atoms, 27-20, 27-22
butterfly-based digital implementation
Cartesian separable basis function, 27-10–27-11
forward and inverse transforms, 27-9–27-10
Fourier magnitude spectrum, 27-11–27-12
frequency spectrum, 27-10
continuous transform
Fourier slice theorem, 27-6–27-7
polar Fourier transform, 27-6
Radon transform, 27-6
real-to-complex ridge profile, 27-5
ridge function, 27-5–27-6
discrete transform, 27-7–27-8
multiresolution Fourier transform, 27-19–27-20
multiscale polar cosine transform
basis functions and frequency tiling, 27-18–27-19
construction, 27-17–27-18
denoising results, 27-22
nonlinear approximation
ghosting artifact, 27-14, 27-16
image patches, 27-12
PSNR curves, 27-12–27-14
reconstructions, 27-12, 27-14–27-15
polar cosine packets, 27-16
radon-based digital implementation, 27-9
ridgelet and curvelet transforms, 27-20, 27-22
standard images, 27-21
texture representation, 27-5
Polar Fourier transform, 27-6–27-7
Polar trigonometric transforms, 27-7
Polynomial filter, 2-11
Positive-real function, 5-4–5-5

Power line communications (PLCs), 26-29–26-30
Primary resonator block (PRB), 15-10–15-11
Programmable switched-capacitor filter
  block diagram representation, 17-29
  topology versatility, 17-29–17-30
  transfer function, 17-28–17-29
Programmable switched-capacitor oscillator
  BPF-based SC oscillator, 17-32–17-33
  finite-impulse-response (FIR) filter, 17-34
  four-level quasi-sinusoidal wave generator, 17-33–17-34
  high-quality-factor (*Q*-factor), 17-32–17-33
  linearity, 17-33
  measured frequency spectrum, 17-34–17-35
  sinewave oscillator, 17-32

Q

Q factors, *see* Quality factors
Quadrant fan filter, 23-9–23-10
Quadrature mirror filter (QMF), 25-12–25-16
Quality factors, 1-26
Quantization error
  coefficient quantization error
    alternate realization structure, 20-16–20-17
    clustered root, 20-16
    definition, 20-15
    grid, 20-15–20-16
    realizable pole locations, 20-16–20-17
    transfer function, 20-15
  fixed-point quantization error
    sum of products, 20-2–20-3
    types, 20-3–20-4
  floating-point quantization error, 20-4–20-5
Quasi-Newton algorithm, 23-29–23-30
Quincunx sampling matrix
  diamond and fan filter banks, 25-8
  nonsingular real matrix, 25-3–25-5
  quadrature mirror filter (QMF), 25-13–25-14

R

Raised-cosine window, *see* Hanning window
Rational function, 5-6–5-8
RC one-port networks
  continued-fraction expansion, 7-8–7-9
  first and second Cauer canonical form, 7-9
  first and second Foster canonical form, 7-8–7-10
  input impedance, 7-6–7-7
  RC impedance function, 7-7
Reactance function, 7-2–7-3, 7-5–7-6
Rectangular window
  causal and desired impulse response, 18-7
  definition, 18-7
  2-D FIR filter design, 22-9
  log–magnitude response, 18-8–18-9
  spectrum, 18-8
Relative coefficient sensitivity, 4-4
Relative sensitivity, 4-1–4-2
Remez exchange algorithm
  exhaustive step-by-step search, 18-21–18-23
  extremal initialization, 18-20–18-21
  iterative multivariable algorithm, 18-20
  maxima of error function, 18-21
  superfluous potential external rejection, 18-23–18-24
Resistively terminated network design
  Butterworth networks
    element values, 9-6–9-7
    input impedance, 9-5
    input reflection coefficient, 9-4–9-5
    LC ladder, 9-6
    minimum-phase solution, 9-5
    recurrence formula, 9-6
    transducer power gain, 9-4
  Chebyshev networks
    element values, 9-10–9-11
    input impedance, 9-10
    input reflection coefficient, 9-9
    minimum-phase solution, 9-9–9-10
    transducer power-gain, 9-9
  input and output reflection coefficients, 9-1
  maximum average power, 9-3
  Norton equivalent, 9-1–9-2
  sinusoidal steady state, 9-2
  Thévenin equivalent, 9-1–9-2
  transfer voltage ratio and impedance, 9-4
Richards function
  arbitrary positivereal constant, 6-2–6-3
  real nonnegative constant
    impedance matrix, 6-5–6-6
    index set, 6-4
    transmission matrix, 6-5
RLC load formulas
  Butterworth networks
    all-pass function, 10-15–10-16
    Butterworth transducer power-gain, 10-15
    equalizer back-end impedance, 10-16–10-17
    final reactive element, 10-17
    LC ladder network, 10-17–10-18
    load impedance, 10-14
    minimum-phase solution, 10-15
  Chebyshev networks
    all-pass function, 10-23
    equalizer back-end impedance, 10-24
    Laurent series expansion, 10-23
    $R C \omega_c \sinh a < 2 \sin \gamma_1$ and $L_{b1} \geq L$, 10-25
    $R C \omega_c \sinh a < 2 \sin \gamma_1$ and $L_{b1} < L$, 10-25
    $R C \omega_c \sinh a \geq 2 \sin \gamma_1$ and $L_{b1} < L$, 10-24–10-25
    $R C \omega_c \sinh a \geq 2 \sin \gamma_1$ and $L_{b1} \geq L$, 10-24
    transducer power-gain, 10-22
RLCM one-port network, 5-1–5-2
Robust nonlinear estimators/filters
  additive noise extraction, 26-27

baseband communication, 26-28–26-29
highpass filtering, 26-29–26-31
power line communications (PLCs), 26-29–26-30
symmetric α-stable distributions, 26-28
Root sensitivity
pole sensitivity, 4-5–4-7
semirelative root sensitivities, 4-5
Rotation-invariant classification system, 25-25

S

Sallen and Key filter
bandpass circuit, 11-8–11-9, 13-2
high-pass filter, 11-9–11-10
low-pass filter, 11-6–11-8
Second-order filters
biquadratic filters
biquadratic transfer function, 11-11–11-12
RC network realization, 11-14–11-15
single-amplifier low-gain realization, 11-12–11-13
two-amplifier low-gain biquad configuration, 11-14
Butterworth LPF, 14-7–14-8
positive-gain filter
bandpass circuit, 11-8–11-9
high-pass filter, 11-9–11-10
low-pass filter, 11-6–11-8
notch filter circuits, 11-10–11-11
Semirelative coefficient sensitivity, 4-4–4-5
Sensivity and selectivity
active RC filters, 4-19, 4-30
bounds, 4-18–4-19
cascaded realization, active filters
CAD methods, 4-24
operational amplifier, 4-26
polynomial coefficient, 4-23
Q-factor, 4-26–4-28
stages, 4-25–4-26
coefficient sensitivity, 4-4–4-5
comparative errors, 4-30–4-31
computations, adjoint network
branch impedance and branch admittance matrices, 4-21–4-22
port variable separation, 4-21
Tellegen theorem, 4-20
transfer function calculation, 4-22
definition, 4-1–4-2
doubly terminated matched lossless filters
Fettweis-Orchard theorem, 4-29–4-30
high-*Q* transfer function poles, 4-28
steady-state sinusoidal operation, 4-28–4-29
transducer function, 4-29
function sensitivity, 4-3–4-4
invariants
filter function, 4-16
frequency scaling, 4-17–4-18
homogeneous function, 4-15
impedance scaling, 4-17
passive RC circuits, 4-17
scaling operation, 4-15–4-16
limitations, 4-19
multiparameter sensitivities and sensitivity measures
average sensitivity index, 4-9, 4-11
multivariable statistical measure, 4-14
quadratic sensitivity index, 4-10, 4-12–4-13
sensitivity row vector, 4-9–4-10
worst-case sensitivity index, 4-10, 4-12–4-13
reduction methods, 4-22–4-23
root sensitivities
pole sensitivity, 4-5–4-7
semirelative root sensitivities, 4-5
statistical model, 4-7–4-8
Separable product filters
half-plane symmetric filter, 23-14
prescribed specification, 23-15–23-16
quadrantally symmetric filter, 23-12–23-13
transfer function, 23-11–23-12
Sinewave generator, 17-31–17-33
Single-amplifier multiple-feedback filters
all-pole designs
equal-capacitor design, 12-5
low-pass structure, 12-3–12-4
transfer ratio, 12-4–12-5
design
finite amplifier gain effects, 12-8–12-9
sensitivity, 12-8
tuning function, 12-9–12-10
modified multiple-loop feedback (MMFB) structure
bandpass transfer function, 12-10–12-11
biquadratic structure, 12-12–12-13
structures
all-pole realization, 12-3–12-5
double ladder multiple-feedback network, 12-2–12-3
infinite-gain single-amplifier structure, 12-1–12-2
voltage transfer function, 12-2
Singular-value decomposition (SVD)
Antoniou and Lu method
amplitude response matrix, 23-35–23-36
error compensation procedure, 23-39
error correction section, 23-36–23-39
Deng and Kawamata method
design procedure, 23-41–23-43
2-D filter realization, 23-43
matrix decomposition, 23-41
problem formulation, 23-34–23-35
Sinusoidal response
*N*th-order analog filter, 1-11
steady-state sinusoidal response, 1-11–1-12
Sixth-order Chebyshev low-pass filter, 14-10–14-11
Sixth-order elliptic BP filter
2-OA CGIC biquad, 14-11–14-12

3-OA CGIC biquad, 14-16–14-17
Slew rate, 11-27
Spatially adaptive wavelet thresholding (SAWT) algorithm, 25-27
Spectral transformation
complex transformation, 23-7–23-8
Constantinides transformation
application, 23-11
1-D digital filter design, 23-9–23-10
2-D discrete transfer function, 23-10
low-pass transfer function, 23-10–23-11
linear transformation
algebraic structure, 23-5
frequency response, multiplication table, 23-5–23-6
product of functions, 23-6–23-7
zero-phase filter, 23-7
quadrant fan filter, 23-9–23-10
symmetric fan filter, 23-8–23-9
Standard video sequences
computational complexity, 27-30
piecewise planar approximation, 27-31
SNR results, 27-28–27-29
Step response, 1-8
SVD, *see* Singular-value decomposition
Switched-capacitor filters
analog switches, 17-19–17-21
biquadratic filter, 17-23–17-24
channel mobile charge, 17-17
clock feedthrough, 17-15–17-16
continuous-time filter, 17-1
dynamic range, 17-17–17-18
first-order blocks
offset and gain compensated integrator, 17-6
reduced capacitance spread, 17-5–17-6
standard stray-insensitive integrator, 17-4–17-5
transfer function, 17-5
fully differential filter
charge redistribution analysis, 17-23
folded cascode amplifier and CMFB circuit, 17-22–17-23

Electrical Engineering

Upon its initial publication, *The Circuits and Filters Handbook* broke new ground. It quickly became **the** resource for comprehensive coverage of issues and practical information that can be put to immediate use. Not content to rest on his laurels, in addition to updating the second edition, editor Wai-Kai Chen divided it into tightly focused texts that made the information easily accessible and digestible. These texts have been revised, updated, and expanded so that they continue to provide solid coverage of standard practices and enlightened perspectives on new and emerging techniques.

Passive, Active, and Digital Filters provides an introduction to the characteristics of analog filters and a review of the design process and the tasks that need to be undertaken to translate a set of filter specifications into a working prototype. Highlights include discussions of the passive cascade synthesis and the synthesis of LCM and RC one-port networks; a summary of two-port synthesis by ladder development; a comparison of the cascade approach, the multiple-loop feedback topology, and ladder simulations; an examination of four types of finite wordlength effects; and coverage of methods for designing two-dimensional finite-extent impulse response (FIR) discrete-time filters. The book includes coverage of the basic building blocks involved in low- and high-order filters, limitations and practical design considerations, and a brief discussion of low-voltage circuit design.

Revised Chapters:

- Sensitivity and Selectivity
- Switched-Capacitor Filters
- FIR Filters
- IIR Filters
- VLSI Implementation of Digital Filters
- Two-Dimensional FIR Filters

New Chapters:

- 1-D Multirate Filter Banks
- Directional Filter Banks
- Nonlinear Filtering Using Statistical Signal Models
- Nonlinear Filtering for Image Denoising
- Video Demosaicking Filters

This volume will undoubtedly take its place as the engineer's first choice in looking for solutions to problems encountered when designing filters.

Index **IN-1**

Preface

The purpose of this book is to provide in a single volume a comprehensive reference work covering the broad spectrum of mathematics for circuits and filters; circuits elements, devices, and their models; and linear circuit analysis. This book is written and developed for the practicing electrical engineers in industry, government, and academia. The goal is to provide the most up-to-date information in the field.

Over the years, the fundamentals of the field have evolved to include a wide range of topics and a broad range of practice. To encompass such a wide range of knowledge, this book focuses on the key concepts, models, and equations that enable the design engineer to analyze, design, and predict the behavior of large-scale circuits. While design formulas and tables are listed, emphasis is placed on the key concepts and theories underlying the processes.

This book stresses fundamental theories behind professional applications and uses several examples to reinforce this point. Extensive development of theory and details of proofs have been omitted. The reader is assumed to have a certain degree of sophistication and experience. However, brief reviews of theories, principles, and mathematics of some subject areas are given. These reviews have been done concisely with perception.

The compilation of this book would not have been possible without the dedication and efforts of Professors Yih-Fang Huang and John Choma, Jr., and most of all the contributing authors. I wish to thank them all.

Wai-Kai Chen

Editor-in-Chief

Wai-Kai Chen is a professor and head emeritus of the Department of Electrical Engineering and Computer Science at the University of Illinois at Chicago. He received his BS and MS in electrical engineering at Ohio University, where he was later recognized as a distinguished professor. He earned his PhD in electrical engineering at the University of Illinois at Urbana–Champaign.

Professor Chen has extensive experience in education and industry and is very active professionally in the fields of circuits and systems. He has served as a visiting professor at Purdue University, the University of Hawaii at Manoa, and Chuo University in Tokyo, Japan. He was the editor-in-chief of the *IEEE Transactions on Circuits and Systems, Series I and II*, the president of the IEEE Circuits and Systems Society, and is the founding editor and the editor-in-chief of the *Journal of Circuits, Systems and Computers*. He received the Lester R. Ford Award from the Mathematical Association of America; the Alexander von Humboldt Award from Germany; the JSPS Fellowship Award from the Japan Society for the Promotion of Science; the National Taipei University of Science and Technology Distinguished Alumnus Award; the Ohio University Alumni Medal of Merit for Distinguished Achievement in Engineering Education; the Senior University Scholar Award and the 2000 Faculty Research Award from the University of Illinois at Chicago; and the Distinguished Alumnus Award from the University of Illinois at Urbana–Champaign. He is the recipient of the Golden Jubilee Medal, the Education Award, and the Meritorious Service Award from the IEEE Circuits and Systems Society, and the Third Millennium Medal from the IEEE. He has also received more than a dozen honorary professorship awards from major institutions in Taiwan and China.

A fellow of the Institute of Electrical and Electronics Engineers (IEEE) and the American Association for the Advancement of Science (AAAS), Professor Chen is widely known in the profession for the following works: *Applied Graph Theory* (North-Holland), *Theory and Design of Broadband Matching Networks* (Pergamon Press), *Active Network and Feedback Amplifier Theory* (McGraw-Hill), *Linear Networks and Systems* (Brooks/Cole), *Passive and Active Filters: Theory and Implements* (John Wiley), *Theory of Nets: Flows in Networks* (Wiley-Interscience), *The Electrical Engineering Handbook* (Academic Press), and *The VLSI Handbook* (CRC Press).

1.1 Introduction

It is only after the engineer masters' linear concepts—linear models and circuit and filter theory—that the possibility of tackling nonlinear ideas becomes achievable. Students frequently encounter linear methodologies, and bits and pieces of mathematics that aid in problem solution are stored away. Unfortunately, in memorizing the process of finding the inverse of a matrix or of solving a system of equations, the essence of the problem or associated knowledge may be lost. For example, most engineers are fairly comfortable with the concept of a vector space, but have difficulty in generalizing these ideas to the module level. Therefore, the intention of this section is to provide a unified view of key concepts in the theory of linear circuits and filters, to emphasize interrelated concepts, to provide a mathematical reference to the handbook itself, and to illustrate methodologies through the use of many and varied examples.

This chapter begins with a basic examination of vector spaces over fields. In relating vector spaces, the key ideas of linear operators and matrix representations come to the fore. Standard matrix operations are examined as are the pivotal notions of determinant, inverse, and rank. Next, transformations are shown to determine similar representations, and matrix characteristics such as singular values and eigenvalues are defined. Finally, solutions to algebraic equations are presented in the context of matrices and are related to this introductory chapter on mathematics as a whole.

Standard algebraic notation is introduced first. To denote an element s in a set S, use $s \in S$. Consider two sets S and T. The set of all ordered pairs (s, t) where $s \in S$ and $t \in T$ is defined as the Cartesian product set $S \times T$. A function f from S into T, denoted by $f : S \rightarrow T$, is a subset U of ordered pairs $(s, t) \in S \times T$ such that for every $s \in S$, one and only one $t \in T$ exists such that $(s, t) \in U$. The function evaluated at the element s gives t as a solution ($f(s) = t$), and each $s \in S$ as a first element in U appears exactly once.

A binary operation is a function acting on a Cartesian product set $S \times T$. When $T = S$, one speaks of a binary operation on S.

1.2 Vector Spaces over Fields

A field F is a nonempty set F and two binary operations, sum ($+$) and product, such that the following properties are satisfied for all $a, b, c \in F$:

1. Associativity: $(a + b) + c = a + (b + c)$; $(ab)c = a(bc)$
2. Commutativity: $a + b = b + a$; $ab = ba$
3. Distributivity: $a(b + c) = (ab) + (ac)$
4. Identities: (Additive) $0 \in F$ exists such that $a + 0 = a$
   (Multiplicative) $1 \in F$ exists such that $a1 = a$
5. Inverses: (Additive) For every $a \in F$, $b \in F$ exists such that $a + b = 0$
   (Multiplicative) For every nonzero $a \in F$, $b \in F$ exists such that $ab = 1$

Examples

- Field of real numbers R
- Field of complex numbers C
- Field of rational functions with real coefficients $R(s)$
- Field of binary numbers

The set of integers Z with the standard notions of addition and multiplication does not form a field because a multiplicative inverse in Z exists only for ± 1. The integers form a commutative ring. Likewise, polynomials in the indeterminate s with coefficients from F form a commutative ring $F[s]$. If field property 2 also is not available, then one speaks simply of a ring. An additive group is a nonempty set G and one binary operation $+$ satisfying field properties 1, 4, and 5 for addition, that is, associativity and the existence of additive identity and inverse. Moreover, if the binary operation $+$ is commutative (field property 2), then the additive group is said to be abelian. Common notation regarding inverses is that the additive inverse for $a \in F$ is $b = -a \in F$. In the multiplicative case $b = a^{-1} \in F$.

An F-vector space V is a nonempty set V and a field F together with binary operations $+$: $V \times V \to V$ and $\star$: $F \times V \to V$ subject to the following axioms for all elements $v, w \in V$ and $a, b \in F$:

1. V and $+$ form an additive abelian group
2. $a \star (v+w) = (a \star v)+(a \star w)$
3. $(a+b) \star v = (a \star v)+(b \star v)$
4. $(ab) \star v = a \star (b \star v)$
5. $1 \star v = v$

Examples

- Set of all n-tuples $(v_1, v_2, \ldots, v_n)$ for $n > 0$ and $v_i \in F$
- Set of polynomials of degree less than n with real coefficients ($F = R$)

Elements of V are referred to as vectors, whereas elements of F are scalars. Note that the terminology vector space V over the field F is used often. A module differs from a vector space in only one aspect; the underlying field in a vector space is replaced by a ring. Thus, a module is a direct generalization of a vector space.

When considering vector spaces of n-tuples, $+$ is vector addition defined element by element using the scalar addition associated with F. Multiplication ($\star$), which is termed scalar multiplication, also is defined

element by element using multiplication in F. The additive identity in this case is the zero vector (n-tuple of zeros) or null vector, and F^n denotes the set of n-tuples with elements in F, a vector space over F. A nonempty subset $\widetilde{V} \subset V$ is called a subspace of V if for each v, $w \in \widetilde{V}$ and every $a \in F$, $v + w \in \widetilde{V}$, and $a * v \in \widetilde{V}$. When the context makes things clear, it is customary to suppress the $*$, and write av in place of $a * v$.

A set of vectors $\{v_1, v_2, \ldots, v_m\}$ belonging to an F-vector space V is said to span the vector space if any element $v \in V$ can be represented by a linear combination of the vectors v_i. That is, scalars $a_1, a_2, \ldots, a_m \in F$ are such that

$$v = a_1 v_1 + a_2 v_2 + \cdots + a_m v_m \tag{1.1}$$

A set of vectors $\{v_1, v_2, \ldots, v_p\}$ belonging to an F-vector space V is said to be linearly dependent over F if scalars $a_1, a_2, \ldots, a_p \in F$, not all zero, exist such that

$$a_1 v_1 + a_2 v_2 + \cdots + a_p v_p = 0 \tag{1.2}$$

If the only solution for Equation 1.2 is that all $a_i = 0 \in F$, then the set of vectors is said to be linearly independent.

Examples

- (1, 0) and (0, 1) are linearly independent.
- (1, 0, 0), (0, 1, 0), and (1, 1, 0) are linearly dependent over R. To see this, simply choose $a_1 = a_2 = 1$ and $a_3 = -1$.
- $s^2 + 2s$ and $2s + 4$ are linearly independent over R, but are linearly dependent over $R(s)$ by choosing $a_1 = -2$ and $a_2 = s$.

A set of vectors $\{v_1, v_2, \ldots, v_n\}$ belonging to an F-vector space V is said to form a basis for V if it both spans V and is linearly independent over F. The number of vectors in a basis is called the dimension of the vector space, and is denoted as $\dim(V)$. If this number is not finite, then the vector space is said to be infinite dimensional.

Examples

- In an n-dimensional vector space, any n linearly independent vectors form a basis.
- Natural (standard) basis

$$e_1 = \begin{bmatrix} 1 \\ 0 \\ 0 \\ \vdots \\ 0 \\ 0 \end{bmatrix}, \quad e_2 = \begin{bmatrix} 0 \\ 1 \\ 0 \\ \vdots \\ 0 \\ 0 \end{bmatrix}, \quad e_3 = \begin{bmatrix} 0 \\ 0 \\ 1 \\ \vdots \\ 0 \\ 0 \end{bmatrix}, \ldots, \quad e_{n-1} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ \vdots \\ 1 \\ 0 \end{bmatrix}, \quad e_n = \begin{bmatrix} 0 \\ 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}$$

both spans F^n and is linearly independent over F.

Consider any basis $\{v_1, v_2, \ldots, v_n\}$ in an n-dimensional vector space. Every $v \in V$ can be represented uniquely by scalars $a_1, a_2, \ldots, a_n \in F$ as

$$v = a_1 v_1 + a_2 v_2 + \cdots + a_n v_n \tag{1.3}$$

$$= [v_1 \ v_2 \ \cdots \ v_n] \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_n \end{bmatrix} \tag{1.4}$$

$$= [v_1 \ v_2 \ \cdots \ v_n] a \tag{1.5}$$

Here, $a \in F^n$ is a coordinate representation of $v \in V$ with respect to the chosen basis. The reader will be able to discern that each choice of basis will result in another representation of the vector under consideration. Of course, in the applications, some representations are more popular and useful than others.

1.3 Linear Operators and Matrix Representations

First, recall the definition of a function f: $S \rightarrow T$. Alternate terminology for a function is mapping, operator, or transformation. The set S is called the domain of f, denoted by $D(f)$. The range of f, $R(f)$, is the set of all $t \in T$ such that $(s, t) \in U$ ($f(s) = t$) for some $s \in D(f)$.

Examples

Use $S = \{1, 2, 3, 4\}$ and $T = \{5, 6, 7, 8\}$.

- $\widetilde{U} = \{(1, 5), (2, 5), (3, 7), (4, 8)\}$ is a function. The domain is {1, 2, 3, 4} and the range is {5, 7, 8}.
- $\hat{U} = \{(1, 5), (1, 6), (2, 5), (3, 7), (4, 8)\}$ is not a function.
- $\overline{U} = \{(1, 5), (2, 6), (3, 7), (4, 8)\}$ is a function. The domain is {1, 2, 3, 4} and the range is {5, 6, 7, 8}.

If $R(f) = T$, then f is said to be surjective (onto). Loosely speaking, all elements in T are used up. If $f: S \rightarrow T$ has the property that $f(s_1) = f(s_2)$ implies $s_1 = s_2$, then f is said to be injective (one-to-one). This means that any element in $R(f)$ comes from a unique element in $D(f)$ under the action of f. If a function is both injective and surjective, then it is said to be bijective (one-to-one and onto).

Examples

- $\widetilde{U}$ is not onto because $6 \in T$ is not in $R(f)$. Also $\widetilde{U}$ is not one-to-one because $f(1) = 5 = f(2)$, but $1 \neq 2$.
- $\overline{U}$ is bijective.

Now consider an operator L: $V \rightarrow W$, where V and W are vector spaces over the same field F. L is said to be a linear operator if the following two properties are satisfied for all v, $w \in V$ and for all $a \in F$:

$$L(av) = aL(v) \tag{1.6}$$

$$L(v + w) = L(v) + L(w) \tag{1.7}$$

Equation 1.6 is the property of homogeneity and Equation 1.7 is the property of additivity. Together they imply the principle of superposition, which may be written as

$$L(a_1 v_1 + a_2 v_2) = a_1 L(v_1) + a_2 L(v_2) \tag{1.8}$$

for all v_1, $v_2 \in V$ and a_1, $a_2 \in F$. If Equation 1.8 is not satisfied, then L is called a nonlinear operator.

Examples

- Consider $V = C$ and $F = C$. Let $L: V \to V$ be the operator that takes the complex conjugate: $L(v) = \bar{v}$ for $v, \bar{v} \in V$. Certainly

$$L(v_1 + v_2) = \overline{v_1 + v_2} = \overline{v_1} + \overline{v_2} = L(v_1) + L(v_2)$$

  However,

$$L(a_1 v_1) = \overline{a_1 v_1} = \overline{a_1} L(v_1) \neq a_1 L(v_1)$$

  Then L is a nonlinear operator because homogeneity fails.

- For F-vector spaces V and W, let V be F^n and W be F^{n-1}. Examine $L: V \to W$, the operator that truncates the last element of the n-tuple in V, that is,

$$L((v_1, v_2, \ldots, v_{n-1}, v_n)) = (v_1, v_2, \ldots, v_{n-1})$$

  Such an operator is linear.

The null space (kernel) of a linear operator $L: V \to W$ is the set

$$\ker L = \{v \in V \text{ such that } L(v) = 0\} \tag{1.9}$$

Equation 1.9 defines a vector space. In fact, ker L is a subspace of V. The mapping L is injective if and only if ker $L = 0$; that is, the only solution in the right member of Equation 1.9 is the trivial solution. In this case, L is also called monic.

The image of a linear operator $L: V \to W$ is the set

$$\text{im } L = \{w \in W \text{ such that } L(v) = w \text{ for some } v \in V\} \tag{1.10}$$

Clearly, im L is a subspace of W, and L is surjective if and only if im L is all of W. In this case, L is also called epic.

A method of relating specific properties of linear mappings is the exact sequence. Consider a sequence of linear mappings

$$\cdots V \xrightarrow{L} W \xrightarrow{\tilde{L}} U \to \cdots \tag{1.11}$$

This sequence is said to be exact at W if im $L = \ker \tilde{L}$. A sequence is called exact if it is exact at each vector space in the sequence. Examine the following special cases:

$$0 \to V \xrightarrow{L} W \tag{1.12}$$

$$W \xrightarrow{\tilde{L}} U \to 0 \tag{1.13}$$

Sequence (Equation 1.12) is exact if and only if L is monic, whereas Equation 1.13 is exact if and only if $\tilde{L}$ is epic.

Further, let $L: V \to W$ be a linear mapping between finite-dimensional vector spaces. The rank of L, $\rho(L)$, is the dimension of the image of L. In such a case

$$\rho(L) + \dim(\ker L) = \dim V \tag{1.14}$$

Linear operators commonly are represented by matrices. It is quite natural to interchange these two ideas, because a matrix with respect to the standard bases is indistinguishable from the linear operator it represents. However, insight may be gained by examining these ideas separately. For V and W, n- and m-dimensional vector spaces over F, respectively, consider a linear operator L: $V \rightarrow W$. Moreover, let $\{v_1, v_2, \ldots, v_n\}$ and $\{w_1, w_2, \ldots, w_m\}$ be respective bases for V and W. Then L: $V \rightarrow W$ can be represented uniquely by the matrix $M \in F^{m \times n}$ where

$$M = \begin{bmatrix} m_{11} & m_{12} & \ldots & m_{1n} \\ m_{21} & m_{22} & \ldots & m_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ m_{m1} & m_{m2} & \ldots & m_{mn} \end{bmatrix} \tag{1.15}$$

The ith column of M is the representation of $L(v_i)$ with respect to $\{w_1, w_2, \ldots, w_m\}$. Element $m_{ij} \in F$ of Equation 1.15 occurs in row i and column j.

Matrices have a number of properties. A matrix is said to be square if $m = n$. The main diagonal of a square matrix consists of the elements m_{ii}. If $m_{ij} = 0$ for all $i > j$ ($i < j$), a square matrix is said to be upper (lower) triangular. A square matrix with $m_{ij} = 0$ for all $i \neq j$ is diagonal. Additionally, if all $m_{ii} = 1$, a diagonal M is an identity matrix. A row vector (column vector) is a special case in which $m = 1$ ($n = 1$). Also, $m = n = 1$ results essentially in a scalar.

Matrices arise naturally as a means to represent sets of simultaneous linear equations. For example, in the case of Kirchhoff equations, Chapter 7 shows how incidence, circuit, and cut matrices arise. Or consider a π network having node voltages v_i, $i = 1, 2$ and current sources i_i, $i = 1, 2$ connected across the resistors R_i, $i = 1, 2$ in the two legs of the π. The bridge resistor is R_3. Thus, the unknown node voltages can be expressed in terms of the known source currents in the manner

$$\frac{(R_1 + R_3)}{R_1 R_3} v_1 - \frac{1}{R_3} v_2 = i_1 \tag{1.16}$$

$$\frac{(R_2 + R_3)}{R_2 R_3} v_2 - \frac{1}{R_3} v_1 = i_2 \tag{1.17}$$

If the voltages, v_i, and the currents, i_i, are placed into a voltage vector $v \in R^2$ and current vector $i \in R^2$, respectively, then Equations 1.16 and 1.17 may be rewritten in matrix form as

$$\begin{bmatrix} i_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} \frac{(R_1+R_3)}{R_1 R_3} & -\frac{1}{R_3} \\ -\frac{1}{R_3} & \frac{(R_2+R_3)}{R_2 R_3} \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} \tag{1.18}$$

A conductance matrix G may then be defined so that $i = Gv$, a concise representation of the original pair of circuit equations.

1.4 Matrix Operations

Vector addition in F^n was defined previously as an element-wise scalar addition. Similarly, two matrices both M and N in $F^{m \times n}$ can be added (subtracted) to form the resultant matrix $P \in F^{m \times n}$ by

$$m_{ij} \pm n_{ij} = p_{ij}, \quad i = 1, 2, \ldots, m, \quad j = 1, 2, \ldots, n \tag{1.19}$$

Matrix addition, thus, is defined using addition in the field over which the matrix lies. Accordingly, the matrix, each of whose entries is $0 \in F$, is an additive identity for the family. One can set up additive inverses along similar lines, which, of course, turn out to be the matrices each of whose elements is the negative of that of the original matrix.

Recall how scalar multiplication was defined in the example of the vector space of n-tuples. Scalar multiplication can also be defined between a field element $a \in F$ and a matrix $M \in F^{m\times n}$ in such a way that the product aM is calculated element-wise:

$$aM = P \Leftrightarrow am_{ij} = p_{ij}, \quad i = 1, 2, \ldots, m, \quad j = 1, 2, \ldots, n \tag{1.20}$$

Examples

$$(F = R)\text{: } M = \begin{bmatrix} 4 & 3 \\ 2 & 1 \end{bmatrix}, \quad N = \begin{bmatrix} 2 & -3 \\ 1 & 6 \end{bmatrix}, \quad a = -0.5$$

- $M + N = P = \begin{bmatrix} 4+2 & 3-3 \\ 2+1 & 1+6 \end{bmatrix} = \begin{bmatrix} 6 & 0 \\ 3 & 7 \end{bmatrix}$
- $M - N = \tilde{P} = \begin{bmatrix} 4-2 & 3+3 \\ 2-1 & 1-6 \end{bmatrix} = \begin{bmatrix} 2 & 6 \\ 1 & -5 \end{bmatrix}$
- $aM = \hat{P} = \begin{bmatrix} (-0.5)4 & (-0.5)3 \\ (-0.5)2 & (-0.5)1 \end{bmatrix} = \begin{bmatrix} -2 & -1.5 \\ -1 & -0.5 \end{bmatrix}$

To multiply two matrices M and N to form the product MN requires that the number of columns of M equal the number of rows of N. In this case the matrices are said to be conformable. Although vector multiplication cannot be defined here because of this constraint, Chapter 2 examines this operation in detail using the tensor product. The focus here is on matrix multiplication. The resulting matrix will have its number of rows equal to the number of rows in M and its number of columns equal to the number of columns of N. Thus, for $M \in F^{m\times n}$ and $N \in F^{n\times p}$, $MN = P \in F^{m\times p}$. Elements in the resulting matrix P may be determined by

$$p_{ij} = \sum_{k=l}^{n} m_{ik} n_{kj} \tag{1.21}$$

Matrix multiplication involves one row and one column at a time. To compute the p_{ij} term in P, choose the ith row of M and the jth column of N. Multiply each element in the row vector by the corresponding element in the column vector and sum the result. Notice that in general, matrix multiplication is not commutative, and the matrices in the reverse order may not even be conformable. Matrix multiplication is, however, associative and distributive with respect to matrix addition. Under certain conditions, the field F of scalars, the set of matrices over F, and these three operations combine to form an algebra. Chapter 2 examines algebras in greater detail.

Examples

$$(F = R)\text{: } M = \begin{bmatrix} 4 & 3 \\ 2 & 1 \end{bmatrix}, \quad N = \begin{bmatrix} 1 & 3 & 5 \\ 2 & 4 & 6 \end{bmatrix}$$

- $MN = P = \begin{bmatrix} 10 & 24 & 38 \\ 4 & 10 & 16 \end{bmatrix}$

  To find p_{11}, take the first row of M, [4 3], and the first column of N, $\begin{bmatrix} 1 \\ 2 \end{bmatrix}$, and evaluate Equation 1.21: $4(1) + 3(2) = 10$. Continue for all i and j.

- NM does not exist because that product is not comformable.
- Any matrix $M \in F^{m\times n}$ multiplied by an identity matrix $I \in F^{n\times n}$ such that $MI \in F^{m\times n}$ results in the original matrix M. Similarly, $IM = M$ for I an $m \times m$ identity matrix over F. It is common to interpret I as an identity matrix of appropriate size, without explicitly denoting the number of its rows and columns.

The transpose $M^{\mathrm{T}} \in F^{n\times m}$ of a matrix $M \in F^{m\times n}$ is found by interchanging the rows and columns. The first column of M becomes the first row of M^{T}, the second column of M becomes the second row of M^{T}, and so on. The notations M^{T} and M' are also used. If $M = M^{\mathrm{T}}$ the matrix is called symmetric. Note that two matrices $M, N \in F^{m\times n}$ are equal if and only if all respective elements are equal: $m_{ij} = n_{ij}$ for all i, j. The Hermitian transpose $M_\star \in C^{n\times m}$ of $M \in C^{m\times n}$ is also termed the complex conjugate transpose. To compute $M_\star$, form M^{T} and take the complex conjugate of every element in M^{T}. The following properties also hold for matrix transposition for all $M, N \in F^{m\times n}$, $P \in F^{n\times p}$, and $a \in F$: $(M^{\mathrm{T}})^{\mathrm{T}} = M$, $(M+N)^{\mathrm{T}} = M^{\mathrm{T}} + N^{\mathrm{T}}$, $(aM)^{\mathrm{T}} = aM^{\mathrm{T}}$, and $(MP)^{\mathrm{T}} = P^{\mathrm{T}}\, M^{\mathrm{T}}$.

Examples

$$(F = C):\ M = \begin{bmatrix} j & 1-j \\ 4 & 2+j3 \end{bmatrix}$$

- $M^{\mathrm{T}} = \begin{bmatrix} j & 4 \\ 1-j & 2+j3 \end{bmatrix}$
- $M^{*} = \begin{bmatrix} -j & 4 \\ 1+j & 2-j3 \end{bmatrix}$

1.5 Determinant, Inverse, and Rank

Consider square matrices of the form $[m_{11}] \in F^{1\times 1}$. For these matrices, define the determinant as m_{11} and establish the notation $\det([m_{11}])$ for this construction. This definition can be used to establish the meaning of $\det(M)$, often denoted by $|M|$, for $M \in F^{2\times 2}$. Consider

$$M = \begin{bmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{bmatrix} \tag{1.22}$$

The minor of m_{ij} is defined to be the determinant of the submatrix which results from the removal of row i and column j. Thus, the minors of m_{11}, m_{12}, m_{21}, and m_{22} are m_{22}, m_{21}, m_{12}, and m_{11}, respectively. To calculate the determinant of this M, (1) choose any row i (or column j), (2) multiply each element m_{ik} (or m_{kj}) in that row (or column) by its minor and by $(-1)^{i+k}$ (or $(-1)^{k+j}$), and (3) add these results. Note that the product of the minor with the sign $(-1)^{i+k}$ (or $(-1)^{k+j}$) is called the cofactor of the element in question. If row 1 is chosen, the determinant of M is found to be $m_{11}(+m_{22}) + m_{12}(-m_{21})$, a well-known result. The determinant of 2×2 matrices is relatively easy to remember: multiply the two elements along the main diagonal and subtract the product of the other two elements. Note that it makes no difference which row or column is chosen in step 1.

A similar procedure is followed for larger matrices. Consider

$$\det(M) = \begin{vmatrix} m_{11} & m_{12} & m_{13} \\ m_{21} & m_{22} & m_{23} \\ m_{31} & m_{32} & m_{33} \end{vmatrix} \tag{1.23}$$

Expanding about column 1 produces

$$\det(M) = m_{11}\begin{vmatrix} m_{22} & m_{23} \\ m_{32} & m_{33} \end{vmatrix} - m_{21}\begin{vmatrix} m_{12} & m_{13} \\ m_{32} & m_{33} \end{vmatrix} + m_{31}\begin{vmatrix} m_{12} & m_{13} \\ m_{22} & m_{23} \end{vmatrix} \tag{1.24}$$

$$= m_{11}(m_{22}m_{33} - m_{23}m_{32}) - m_{21}(m_{12}m_{33} - m_{13}m_{32}) + m_{31}(m_{12}m_{23} - m_{13}m_{22}) \tag{1.25}$$

$$= m_{11}m_{22}m_{33} + m_{12}m_{23}m_{31} + m_{13}m_{21}m_{32} - m_{13}m_{22}m_{31} - m_{11}m_{23}m_{32} - m_{12}m_{21}m_{33} \tag{1.26}$$

An identical result may be achieved by repeating the first two columns next to the original matrix:

$$\begin{matrix} m_{11} & m_{12} & m_{13} & m_{11} & m_{12} \\ m_{21} & m_{22} & m_{23} & m_{21} & m_{22} \\ m_{31} & m_{32} & m_{33} & m_{31} & m_{32} \end{matrix} \tag{1.27}$$

Then, form the first three products of Equation 1.26 by starting at the upper left corner of Equation 1.27 with m_{11}, forming a diagonal to the right, and then repeating with m_{12} and m_{13}. The last three products are subtracted in Equation 1.26 and are formed by starting in the upper right corner of Equation 1.27 with m_{12} and taking a diagonal to the left, repeating for m_{11} and m_{13}. Note the similarity to the 2×2 case. Unfortunately, such simple schemes fail above the 3×3 case.

Determinants of $n \times n$ matrices for $n > 3$ are computed in a similar vein. As in the earlier cases, the determinant of an $n \times n$ matrix may be expressed in terms of the determinants of $(n-1) \times (n-1)$ submatrices; this is termed as Laplace's expansion. To expand along row i or column j in $M \in F^{n \times n}$, write

$$\det(M) = \sum_{k=l}^{n} m_{ik}\tilde{m}_{ik} = \sum_{k=l}^{n} m_{kj}\tilde{m}_{kj} \tag{1.28}$$

where the m_{ik} (m_{kj}) are elements of M. The $\tilde{m}_{ik}$ ($\tilde{m}_{kj}$) are cofactors formed by deleting the ith (kth) row and the kth (jth) column of M, forming the determinant of the $(n-1) \times (n-1)$ resulting submatrix, and multiplying by $(-1)^{i+k}$ ($(-1)^{k+j}$). Notice that minors and their corresponding cofactors are related by ± 1.

Examples

$$(F = R)\text{: } M = \begin{bmatrix} 0 & 1 & 2 \\ 3 & 4 & 5 \\ 2 & 3 & 6 \end{bmatrix}$$

- Expanding about row 1 produces

$$\det(M) = 0\begin{vmatrix} 4 & 5 \\ 3 & 6 \end{vmatrix} - 1\begin{vmatrix} 3 & 5 \\ 2 & 6 \end{vmatrix} + 2\begin{vmatrix} 3 & 4 \\ 2 & 3 \end{vmatrix}$$
$$= -(18 - 10) + 2(9 - 8) = -6$$

- Expanding about column 2 yields

$$\det(M) = -1\begin{vmatrix} 3 & 5 \\ 2 & 6 \end{vmatrix} + 4\begin{vmatrix} 0 & 2 \\ 2 & 6 \end{vmatrix} - 3\begin{vmatrix} 0 & 2 \\ 3 & 5 \end{vmatrix}$$
$$= -(18 - 10) + 4(0 - 4) - 3(0 - 6) = -6$$

- Repeating the first two columns to form Equation 1.27 gives

$$\begin{matrix} 0 & 1 & 2 & 0 & 1 \\ 3 & 4 & 5 & 3 & 4 \\ 2 & 3 & 6 & 2 & 3 \end{matrix}$$

  Taking the appropriate products,

$$0 \cdot 4 \cdot 6 + 1 \cdot 5 \cdot 2 + 2 \cdot 3 \cdot 3 - 1 \cdot 3 \cdot 6 - 0 \cdot 5 \cdot 3 - 2 \cdot 4 \cdot 2$$

  results in -6 as the determinant of M.

- Any square matrix with a zero row and/or zero column will have zero determinant. Likewise, any square matrix with two or more identical rows and/or two or more identical columns will have determinant equal to zero.

Determinants satisfy many interesting relationships. For any $n \times n$ matrix, the determinant may be expressed in terms of determinants of $(n-1) \times (n-1)$ matrices or first-order minors. In turn, determinants of $(n-1) \times (n-1)$ matrices may be expressed in terms of determinants of $(n-2) \times (n-2)$ matrices or second-order minors, etc. Also, the determinant of the product of two square matrices is equal to the product of the determinants:

$$\det(MN) = \det(M)\det(N) \tag{1.29}$$

For any $M \in F^{n \times n}$ such that $|M| \neq 0$, a unique inverse $M^{-1} \in F^{n \times n}$ satisfies

$$MM^{-1} = M^{-1}M = I \tag{1.30}$$

For Equation 1.29 one may observe the special case in which $N = M^{-1}$, then $(\det(M))^{-1} = \det(M^{-1})$. The inverse M^{-1} may be expressed using determinants and cofactors in the following manner. Form the matrix of cofactors

$$\tilde{M} = \begin{bmatrix} \tilde{m}_{11} & \tilde{m}_{12} & \cdots & \tilde{m}_{1n} \\ \tilde{m}_{21} & \tilde{m}_{22} & \cdots & \tilde{m}_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \tilde{m}_{n1} & \tilde{m}_{n2} & \cdots & \tilde{m}_{nn} \end{bmatrix} \tag{1.31}$$

The transpose of Equation 1.31 is referred to as the adjoint matrix or adj(M). Then,

$$M^{-1} = \frac{\tilde{M}^{\mathrm{T}}}{|M|} = \frac{\mathrm{adj}(M)}{|M|} \tag{1.32}$$

Examples

- Choose M of the previous set of examples. The cofactor matrix is

$$\begin{bmatrix} 9 & -8 & 1 \\ 0 & -4 & 2 \\ -3 & 6 & -3 \end{bmatrix}$$

  Because $|M| = -6$, M^{-1} is

$$\begin{bmatrix} -\frac{3}{2} & 0 & \frac{1}{2} \\ \frac{4}{3} & \frac{2}{3} & -1 \\ -\frac{1}{6} & -\frac{1}{3} & \frac{1}{2} \end{bmatrix}$$

  Note that Equation 1.32 is satisfied.

- $M = \begin{bmatrix} 2 & 1 \\ 4 & 3 \end{bmatrix}$, $\text{adj}(M) = \begin{bmatrix} 3 & -1 \\ -4 & 2 \end{bmatrix}$, $M^{-1} = \begin{bmatrix} \frac{3}{2} & -\frac{1}{2} \\ -2 & 1 \end{bmatrix}$

  In the 2×2 case, this method reduces to interchanging the elements on the main diagonal, changing the sign on the remaining elements, and dividing by the determinant.

- Consider the matrix equation in Equation 1.18. Because $\det(G) \neq 0$, whenever the resistances are nonzero, with R_1 and R_2 having the same sign, the node voltages may be determined in terms of the current sources by multiplying on the left of both members of the equation using G^{-1}. Then $G^{-1}i = v$.

The rank of a matrix M, $\rho(M)$, is the number of linearly independent columns of M over F, or using other terminology, the dimension of the image of M. For $M \in F^{m \times n}$ the number of linearly independent rows and columns is the same, and is less than or equal to the minimum of m and n. If $\rho(M) = n$, M is of full-column rank; similarly, if $\rho(M) = m$, M is of full-row rank. A square matrix with all rows (and all columns) linearly independent is said to be nonsingular. In this case, $\det(M) \neq 0$. The rank of M also may be found from the size of the largest square submatrix with a nonzero determinant. A full-rank matrix has a full-size minor with a nonzero determinant.

The null space (kernel) of a matrix $M \in F^{m \times n}$ is the set

$$\ker\ M = \{v \in F^n \text{ such that } Mv = 0\} \tag{1.33}$$

Over F, ker M is a vector space with dimension defined as the nullity of M, $\nu(M)$. The fundamental theorem of linear equations relates the rank and nullity of a matrix $M \in F^{m \times n}$ by

$$\rho(M) + \nu(M) = n \tag{1.34}$$

If $\rho(M) < n$, then M has a nontrivial null space.

Examples

- $M = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}$

  The rank M is 1 because only one linearly independent column of M is found. To examine the null space of M, solve $Mv = 0$. Any element in ker M is of the form $\begin{bmatrix} f_1 \\ 0 \end{bmatrix}$ for $f_1 \in F$. Therefore, $\nu(M) = 1$.

- $M = \begin{bmatrix} 1 & 4 & 5 & 2 \\ 2 & 5 & 7 & 1 \\ 3 & 6 & 9 & 0 \end{bmatrix}$

  The rank of M is 2 and the nullity is 2.

1.6 Basis Transformations

This section describes a change of basis as a linear operator. Because the choice of basis affects the matrix of a linear operator, it would be most useful if such a basis change could be understood within the context of matrix operations. Thus, the new matrix could be determined from the old matrix by matrix operations. This is indeed possible. This question is examined in two phases. In the first phase the linear operator maps from a vector space to itself. Then a basis change will be called a similarity transformation. In the second phase, the linear operator maps from one vector space to another, which is not necessarily the same as the first. Then a basis change will be called an equivalence transformation. Of course, the first situation is a special case of the second, but it is customary to make the distinction and to recognize the different terminologies. Philosophically, a fascinating special situation exists in which the second vector space, which receives the result of the operation, is an identical copy of the first vector space, from which the operation proceeds. However, in order to avoid confusion, this section does not delve into such issues.

For the first phase of the discussion, consider a linear operator that maps a vector space into itself, such as L: $V \rightarrow V$, where V is n-dimensional. Once a basis is chosen in V, L will have a unique matrix representation. Choose $\{v_1, v_2, \ldots, v_n\}$ and $\{\bar{v}_1, \bar{v}_2, \ldots, \bar{v}_n\}$ as two such bases. A matrix $M \in F^{n\times n}$ may be determined using the first basis, whereas another matrix $\overline{M} \in F^{n\times n}$ will result in the latter choice. According to the discussion following Equation 1.15, the ith column of M is the representation of $L(v_i)$ with respect to $\{v_1, v_2, \ldots, v_n\}$, and the ith column of $\overline{M}$ is the representation of $L(\bar{v}_i)$ with respect to $\{\bar{v}_1, \bar{v}_2, \ldots, \bar{v}_n\}$. As in Equation 1.4, any basis element v_i has a unique representation in terms of the basis $\{\bar{v}_1, \bar{v}_2, \ldots, \bar{v}_n\}$. Define a matrix $P \in F^{n\times n}$ using the ith column as this representation. Likewise, $Q \in F^{n\times n}$ may have as its ith column the unique representation of $\bar{v}_1$ with respect to $\{v_1, v_2, \ldots, v_n\}$. Either represents a basis change which is a linear operator. By construction, both P and Q are nonsingular. Such matrices and linear operators are sometimes called basis transformations. Notice that $P = Q^{-1}$.

If two matrices M and $\overline{M}$ represent the same linear operator L, they must somehow carry essentially the same information. Indeed, a relationship between M and $\overline{M}$ may be established. Consider $a_v, a_w, \bar{a}_v, \bar{a}_w \in F^n$ such that $Ma_v = a_w$ and $\overline{M}\bar{a}_v = \bar{a}_w$. Here, a_v denotes the representation of v with respect to the basis v_i, $\bar{a}_v$ denotes the representation of v with respect to the basis $\bar{v}_i$, and so forth. In order to involve P and Q in these equations, it is possible to make use of a sketch:

In this sketch, a vector at a given corner can be multiplied by a matrix on an arrow leaving the corner and set equal to the vector that appears at the corner at which that arrow arrives. Thus, for example, $a_w = Ma_v$ may be deduced from the top edge of the sketch. It is interesting to perform "chases" around such sketches. By way of illustration, consider the lower right corner. Progress around the sketch

counterclockwise so as to reach the lower left corner and set the result equal to that obtained by progressing clockwise to the lower left corner. In equations this is carried out as follows:

$$\bar{a}_w = Pa_w = PMa_v = PMQ\bar{a}_v = \overline{M}\bar{a}_v \tag{1.35}$$

Inasmuch as $\bar{a}_v \in F^n$ is arbitrary, it follows that

$$\overline{M} = PMP^{-1} \tag{1.36}$$

Sketches that have this type of property, namely the same result when the sketch is traversed from a starting corner to an finishing corner by two paths, are said to be commutative. It is perhaps more traditional to show the vector space F^n instead of the vectors at the corners. Thus, the sketch would be called a commutative diagram of vector spaces and linear operators. M and $\overline{M}$ are said to be similar because a nonsingular matrix $P \in F^{n\times n}$ is such that Equation 1.36 is true. The matrix P is then called a similarity transformation. Note that all matrix representations associated with the same linear operator, from a vector space to itself, are similar. Certain choices of bases lead to special forms for the matrices of the operator, as are apparent in the following examples.

Examples

- Choose L: $R^2 \rightarrow R^2$ as the linear operator that rotates a vector by 90°. Pick $\{v_1, v_2\}$ as the natural basis $\{[1 \quad 0]^T, [0 \quad 1]^T\}$ and $\{\bar{v}_1, \bar{v}_2\}$ as $\{[1 \quad 1]^T, [1 \quad 0]^T\}$. Then,

$$L(v_1) = [v_1 \quad v_2]\begin{bmatrix} 0 \\ 1 \end{bmatrix}$$
$$L(v_2) = [v_1 \quad v_2]\begin{bmatrix} -1 \\ 0 \end{bmatrix}$$
$$L(\bar{v}_1) = [\bar{v}_1 \quad \bar{v}_2]\begin{bmatrix} 1 \\ -2 \end{bmatrix}$$
$$L(\bar{v}_2) = [\bar{v}_1 \quad \bar{v}_2]\begin{bmatrix} 1 \\ -1 \end{bmatrix}$$

  so that

$$M = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}, \quad \overline{M} = \begin{bmatrix} 1 & 1 \\ -2 & -1 \end{bmatrix}$$

  To find the similarity transformation P, determine the representations of the basis vectors v_i in terms of the basis $\{\bar{v}_1, \bar{v}_2\}$. Then,

$$P = \begin{bmatrix} 0 & 1 \\ 1 & -1 \end{bmatrix}, \quad \bar{P} = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix}$$

  so that $PMP^{-1} = \overline{M}$.

- Suppose that $M \in F^{n\times n}$ is a representation of L: $V \rightarrow V$. Assume a $v \in F^n$ exists such that the vectors $\{v, Mv, \ldots, M^{n-1}v\}$ are linearly independent. Thus, these n vectors can be chosen as an alternate basis. (Section 1.7 discusses the characteristic equation of a matrix M.) Using the Cayley–Hamilton

theorem, which states that every matrix satisfies its own characteristic equation, it is always possible to write $M^n v$ as a linear combination of these alternate basis vectors

$$-\alpha_n v - \alpha_{n-1} Mv - \cdots - \alpha_1 M^{n-1} v$$

for $\alpha_i \in F$. The matrix representation of L with respect to the alternate basis given by this set of linearly independent vectors is

$$\overline{M} = \begin{bmatrix} 0 & 0 & \cdots & 0 & -\alpha_n \\ 1 & 0 & \cdots & 0 & -\alpha_{n-1} \\ 0 & 1 & \cdots & 0 & -\alpha_{n-2} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 0 & -\alpha_2 \\ 0 & 0 & \cdots & 1 & -\alpha_1 \end{bmatrix}$$

which is the transpose of what is known as the companion form.

For the second phase of the discussion, select a pair of bases, one for the vector space V and one for the vector space W, and construct the resulting matrix representation M of L: $V \rightarrow W$. Another choice of bases exists for V and W, with the property that the resulting matrix $\overline{M}$ representing L is of the form

$$\begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} \tag{1.37}$$

where I is $\rho(M) \times \rho(M)$. Such a matrix is said to be in normal form. It is possible to transform M into $\overline{M}$ with the assistance of three types of transformations which are called elementary: (1) interchange any two rows or any two columns, (2) scale any row or column by a nonzero element in F, and (3) add any F-multiple of any row (column) to any other row (column). It is apparent that each of the three transformations involving rows may be accomplished by multiplying M on the left by a nonsingular matrix. Column operations require a corresponding multiplication on the right. The secret to understanding elementary transformations is to recognize that each of them will carry one basis into another. Not as easy to see, but equally true, is that any transformation that carries one basis into another basis must be a product of such elementary transformations. The elementary column transformations are interpreted as changing the basis in the vector space from which the operator takes vectors, whereas the elementary row transformations correspond to changing the basis in the vector space into which the operator places its result. It stands to reason that a simultaneous adjustment of both sets of basis vectors could lead to some quite special forms for the matrices of an operator. Of course, a great deal of linear algebra and its applications is concerned with just such constructions and forms. Space does not permit a complete treatment here.

If a matrix M has been transformed into normal form, certain types of key information become available. For example, one knows the rank of M because $\rho(M)$ is the number of rows and columns of the identity in Equation 1.37. Perhaps more importantly, the normal form is easily factored in a fundamental way, and so such a construction is a natural means to construct two factors of minimal rank for a given matrix. The reader is cautioned, however, to be aware that computational linear algebra is quite a different subject than theoretical linear algebra. One common saying is that ''if an algorithm is straightforward, then it is not numerically desirable.'' This may be an exaggeration, but it is well to recognize the implications of finite precision on the computer. Space limitations prevent addressing numerical issues.

Many other thoughts can be expressed in terms of elementary basis transformations. By way of illustration, elementary basis transformations offer an alternative in finding the inverse of a matrix. For a nonsingular matrix $M \in F^{n \times n}$, append to M an $n \times n$ identity I to form the $n \times 2n$ matrix

$$\hat{M} = [M \quad I] \tag{1.38}$$

Perform elementary row transformations on Equation 1.38 to transform M into normal form. Then M^{-1} will appear in the last n columns of the transformed matrix.

Examples

$$(F = R)\text{: } M = \begin{bmatrix} 2 & 1 \\ 4 & 3 \end{bmatrix}$$

- Transform M into normal form. The process can be carried out in many ways. For instance, begin by scaling row 1 by $\frac{1}{2}$,

$$L_1 M = \begin{bmatrix} \frac{1}{2} & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 2 & 1 \\ 4 & 3 \end{bmatrix} = \begin{bmatrix} 1 & \frac{1}{2} \\ 4 & 3 \end{bmatrix}$$

  Clear the first element in row 2 by

$$L_2 L_1 M = \begin{bmatrix} 1 & 0 \\ -4 & 1 \end{bmatrix} \begin{bmatrix} 1 & \frac{1}{2} \\ 4 & 3 \end{bmatrix} = \begin{bmatrix} 1 & \frac{1}{2} \\ 0 & 1 \end{bmatrix}$$

  Finally, perform a column operation to produce $\overline{M}$:

$$L_2 L_1 M R_1 = \begin{bmatrix} 1 & \frac{1}{2} \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & -\frac{1}{2} \\ 0 & 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

  The rank of M is 2.

- Recall M^{-1} from previous examples. Form $\hat{M}$ and transform M into normal form by the following row operations:

$$L_1 \hat{M} = \begin{bmatrix} \frac{1}{2} & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 2 & 1 & 1 & 0 \\ 4 & 3 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 1 & \frac{1}{2} & \frac{1}{2} & 0 \\ 4 & 3 & 0 & 1 \end{bmatrix}$$

$$L_2 L_1 \hat{M} = \begin{bmatrix} 1 & 0 \\ -4 & 1 \end{bmatrix} \begin{bmatrix} 1 & \frac{1}{2} & \frac{1}{2} & 0 \\ 4 & 3 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 1 & \frac{1}{2} & \frac{1}{2} & 0 \\ 0 & 1 & -2 & 1 \end{bmatrix}$$

$$L_3 L_2 L_1 \hat{M} = \begin{bmatrix} 1 & -\frac{1}{2} \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & \frac{1}{2} & \frac{1}{2} & 0 \\ 0 & 1 & -2 & 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 & \frac{3}{2} & -\frac{1}{2} \\ 0 & 1 & -2 & 1 \end{bmatrix}$$

1.7 Characteristics: Eigenvalues, Eigenvectors, and Singular Values

A matrix has certain characteristics associated with it. Of these, characteristic values or eigenvalues may be determined through the use of matrix pencils. In general, a matrix pencil may be formed from two matrices M and $N \in F^{m \times n}$ and an indeterminate λ in the manner

$$[\lambda N - M] \in F[\lambda]^{n\times n} \tag{1.39}$$

In determining the eigenvalues of a square matrix $M \in F^{n\times n}$, one assumes the special case in which $N = I \in F^{n\times n}$.

Assume that M is a square matrix over the complex numbers. Then, $\lambda \in C$ is called an eigenvalue of M if some nonzero vector $v \in C^n$ exists such that

$$Mv = \lambda v \tag{1.40}$$

Any such $v \neq 0$ satisfying Equation 1.40 is said to be an eigenvector of M associated with λ. It is easy to see that Equation 1.40 can be rewritten as

$$(\lambda I - M)v = 0 \tag{1.41}$$

Because Equation 1.41 is a set of n linear homogeneous equations, a nontrivial solution ($v \neq 0$) exists if and only if

$$\Delta(\lambda) = \det(\lambda I - M) = 0 \tag{1.42}$$

In other words, $(\lambda I - M)$ is singular. Therefore, λ is an eigenvalue of M if and only if it is a solution of Equation 1.42. The polynomial $\Delta(\lambda)$ is the characteristic polynomial and $\Delta(\lambda) = 0$ is the characteristic equation. Moreover, every $n \times n$ matrix has n eigenvalues that may be real, complex, or both, where complex eigenvalues occur in complex–conjugate pairs. If two or more eigenvalues are equal they are said to be repeated (not distinct). It is interesting to observe that although eigenvalues are unique, eigenvectors are not. Indeed, an eigenvector can be multiplied by any nonzero element of C and still maintain its essential features. Sometimes this lack of uniqueness is resolved by selecting unit length for the eigenvectors with the aid of a suitable norm.

Recall that matrices representing the same operator are similar. One may question if these matrices indeed contain the same characteristic information. To answer this question, examine

$$\det(\lambda I - \overline{M}) = \det(\lambda PP^{-1} - PMP^{-1}) = \det(P(\lambda I - M)P^{-1}) \tag{1.43}$$

$$= \det(P)\det(\lambda I - M)\det(P^{-1}) = \det(\lambda I - M) \tag{1.44}$$

From Equation 1.44 one may deduce that similar matrices have the same eigenvalues because their characteristic polynomials are equal.

For every square matrix M with distinct eigenvalues, a similar matrix $\overline{M}$ is diagonal. In particular, the eigenvalues of M, and hence $\overline{M}$, appear along the main diagonal. Let $\lambda_1, \lambda_2, \ldots, \lambda_n$ be the eigenvalues (all distinct) of M and let $v_1, v_2, \ldots, v_n$ be corresponding eigenvectors. Then, the vectors $\{v_1, v_2, \ldots, v_n\}$ are linearly independent over C. Choose $P^{-1} = Q = [v_1\ v_2\ \cdots\ v_n]$ as the modal matrix. Because $Mv_i = \lambda_i v_i$, $\overline{M} = PMP^{-1}$ as before.

For matrices with repeated eigenvalues, a similar approach may be followed wherein $\overline{M}$ is block diagonal, which means that matrices occur along the diagonal with zeros everywhere else. Each matrix along the diagonal is associated with an eigenvalue and takes a specific form depending upon the characteristics of the matrix itself. The modal matrix consists of generalized eigenvectors, of which the aforementioned eigenvector is a special case; thus the modal matrix is nonsingular. The matrix $\overline{M}$ is the Jordan canonical form. Space limitations preclude a detailed analysis of such topics here; the reader is directed to Chen (1984) for further development.

Examples

$$(F = C):\ M = \begin{bmatrix} 1 & 4 \\ 2 & 3 \end{bmatrix}$$

- The characteristic polynomial is $\Delta(\lambda) = (\lambda - 1)(\lambda - 3) - 8 = (\lambda - 5)(\lambda + 1)$. The eigenvalues are $\lambda_1 = 5$, $\lambda_2 = -1$. To find the associated eigenvectors recall that for each λ_i, $(\lambda_i I - M)$ is singular, and write Equation 1.41

$$(\lambda_1 I - M)v_1 = \begin{bmatrix} 4 & -4 \\ -2 & 2 \end{bmatrix} \begin{bmatrix} v_{11} \\ v_{12} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

$$(\lambda_2 I - M)v_2 = \begin{bmatrix} -2 & -4 \\ -2 & -4 \end{bmatrix} \begin{bmatrix} v_{21} \\ v_{22} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

  Then, $v_{11} = v_{12}$ and $v_{21} = -2v_{22}$ so that $v_1 = [1 \quad 1]^T$ and $v_2 = [-2 \quad 1]^T$ are eigenvectors associated with λ_1 and λ_2, respectively.

- Because the eigenvalues of M are distinct, M may be diagonalized. For verification, choose $P^{-1} = [v_1\ v_2]$. Then,

$$\begin{aligned} \overline{M} = PMP^{-1} &= \frac{1}{3}\begin{bmatrix} 1 & 2 \\ -1 & 1 \end{bmatrix}\begin{bmatrix} 1 & 4 \\ 2 & 3 \end{bmatrix}\begin{bmatrix} 1 & -2 \\ 1 & 1 \end{bmatrix} \\ &= \frac{1}{3}\begin{bmatrix} 15 & 0 \\ 0 & -3 \end{bmatrix} = \begin{bmatrix} 5 & 0 \\ 0 & -1 \end{bmatrix} = \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix} \end{aligned}$$

In general, a matrix $M \in F^{m \times n}$ of rank r can be written in terms of its singular-value decomposition (SVD),

$$M = U\Sigma V^{\star} \tag{1.45}$$

For any M, unitary matrices U and V of dimension $m \times m$ and $n \times n$, respectively, form the decomposition; that is, $UU_{\star} = U_{\star}U = I$ and $VV_{\star} = V_{\star}V = I$. The matrix $\sum \in F^{m \times n}$ of the form

$$\begin{bmatrix} \sum_r & 0 \\ 0 & 0 \end{bmatrix} \tag{1.46}$$

for $\sum_r \in F^{r \times r}$, a diagonal matrix represented by

$$\begin{bmatrix} \sigma_1 & 0 & \cdots & 0 \\ 0 & \sigma_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \sigma_r \end{bmatrix} \tag{1.47}$$

The elements σ_i, called singular values, are related by $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_r > 0$, and the columns of U (V) are referred to as left (right) singular vectors. Although the unitary matrices U and V are not unique for a given M, the singular values are unique.

SVD is useful in the numerical calculation of rank. After performing an SVD, the size of the matrix $\sum_r$ may be decided. Additionally, the generalized inverse of a matrix M may be found by

$$M^{\dagger} = V \begin{bmatrix} \Sigma_r^{-1} & 0 \\ 0 & 0 \end{bmatrix} U^{\star} \tag{1.48}$$

It can be verified easily that $MM^{\dagger} M = M$ and $M^{\dagger} MM^{\dagger} = M^{\dagger}$. In the special case in which M is square and nonsingular,

$$M^{\dagger} = M^{-1} = V\Sigma^{-1} U^{\star} \tag{1.49}$$

1.8 On Linear Systems

Consider a set of n simultaneous algebraic equations, in m unknowns, written in the customary matrix form $w = Mv$ where

$$\begin{bmatrix} w_1 \\ w_2 \\ \vdots \\ w_n \end{bmatrix} = \begin{bmatrix} m_{11} & m_{12} & \dots & m_{1n} \\ m_{21} & m_{22} & \dots & m_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ m_{m1} & m_{m2} & \dots & m_{mn} \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ \vdots \\ v_m \end{bmatrix} \tag{1.50}$$

In the context of the foregoing discussion, Equation 1.50 represents the action of a linear operator. If the left member is a given vector, in the usual manner, then a first basic issue concerns whether the vector represented by the left member is in the image of the operator or not. If it is in the image, the equation has at least one solution; otherwise the equation has no solution. A second basic issue concerns the kernel of the operator. If the kernel contains only the zero vector, then the equation has at most one solution; otherwise more than one solution can occur, provided that at least one solution exists.

When one thinks of a set of simultaneous equations as a ''system'' of equations, the intuitive transition to the idea of a linear system is quite natural. In this case the vector in the left member becomes the input to the system, and the solution to Equation 1.50, when it exists and is unique, is the output of the system.

Other than being a description in terms of inputs and outputs, as above, linear systems may also be described in terms of sets of other types of equations, such as differential equations or difference equations. When that is the situation, the familiar notion of initial condition becomes an instance of the idea of state, and one must examine the intertwining of states and inputs to give outputs. Then, the idea of Equation 1.50, when each input yields a unique output, is said to define a system function.

If the differential (difference) equations are linear and have constant coefficients, the possibility exists of describing the system in terms of transforms, for example, in the s- or z-domain. This leads to fascinating new interpretations of the ideas of the foregoing sections, this time, for example, over fields of rational functions. Colloquially, such functions are best known as transfer functions.

Associated with systems described in the time-, s-, or z-domain, some characteristics of the system also aid in analysis techniques. Among the most basic of these are the entities termed poles and zeros, which have been linked to the various concepts of system stability. Both poles and zeros may be associated with matrices of transfer functions, and with the original differential or difference equations themselves. A complete and in-depth treatment of the myriad meanings of poles and zeros is a challenging undertaking, particularly in matrix cases. For a survey of the ideas, see Schrader and Sain (1989). However, a great many of the definitions involve such concepts as rank, pencils, eigenvalues, eigenvectors, special matrix forms, vector spaces, and modules—the very ideas sketched out in the sections preceding.

Algebraic methods are of growing importance in system theory. Of particular interest is the historical survey by Schrader and Wyman (2008) which describes the module-theoretic approach to zeros of a linear system and the application of these ideas to inverse systems and system design. The longstanding notion that zeros of a linear system become the poles of its inverse system is resolved using these methods. Additionally, for the first time, by employing module-theoretic approaches, a structural algebraic meaning is given to the principle that the number of zeros of a transfer function matrix equals the number of poles. Central to this result is the Fundamental Pole-Zero Exact Sequence, an exact sequence of finite-dimensional vector spaces over the same field, represented by

$$0 \to \mathcal{Z}(G) \to \frac{\mathcal{X}(G)}{\mathcal{W}(\ker G(z))} \to \mathcal{W}(\text{im } G(z)) \to 0$$

where

$\mathcal{Z}(G)$ is the global space of zeros of a transfer function matrix $G(z)$
$\mathcal{X}(G)$ is the global space of poles of $G(z)$
$\mathcal{W}()$ is the Wedderburn–Forney construction

The sequence is presented here to encourage further investigation into these powerful methods.

One very commonly known idea for representing solutions to Equation 1.50 is Cramer's rule. When $m = n$, and when M has an inverse, the use of Cramer's rule expresses each unknown variable individually by using a ratio of determinants. Choose the ith unknown v_i. Define the determinant M_i as the determinant of a matrix formed by replacing column i in M with w. Then,

$$v_i = \frac{M_i}{\det(M)} \tag{1.51}$$

It turns out that this very interesting idea makes fundamental use of the notion of *multiplying* vectors, which is not part of the axiomatic framework of the vector space. The reader may want to reflect further on this observation, with respect to the foregoing treatment of determinants. When the framework of vector spaces is expanded to include vector multiplication, as in the case of determinants, one gets to the technical subject of algebras. Chapter 2 returns to this concept.

The concepts presented previously allow for more detailed considerations in the solution of circuit and filter problems, using various approaches outlined in the remainder of this book. Chapter 2 discusses the multiplication of vectors by means of the foundational idea of bilinear operators and matrices. Chapters 3 through 5 on transforms—Fourier, z, and Laplace—provide the tools for analysis by allowing a set of differential or difference equations describing a circuit to be written as a system of linear algebraic equations. Moreover, each transform itself can be viewed as a linear operator, and thus becomes a prime example of the ideas of this chapter. The remaining chapters focus on graph–theoretical approaches to the solution of systems of algebraic equations. From this vantage point, one can see the entire Section I in the context of linear operators, their addition, and multiplication.

A brief treatment cannot deal with all the interesting questions and answers associated with linear operators and matrices. For a more detailed treatment of these standard concepts, see any basic algebra text, for example, Greub (1967).

2.1 Introduction

The key player in Chapter 1 was the F-vector space V, together with its associated notion of bases, when they exist, and linear operators taking one vector to another. The idea of basis is, of course, quite central to the applications because it permits a vector v in V to be represented by a list of scalars from F. Such lists of scalars are the quantities with which one computes. No doubt the idea of an F-vector space V is the most common and widely encountered notion in applied linear algebra. It is typically visualized, on the one hand, by long lists of axioms, most of which seem quite reasonable, but none of which is particularly exciting, and on the other hand by images of classical addition of force vectors, velocity vectors, and so forth. The notion seems to do no harm, and helps one to keep his or her assumptions straight. As such it is accepted by most engineers as a plausible background for their work, even if the ideas of matrix algebra are more immediately useful. Perhaps some of the least appreciated but most crucial of the vector space axioms are the four governing the scalar multiplication of vectors. These link the abelian group of vectors to the field of scalars. Along with the familiar distributive covenants, these four agreements intertwine the vectors with the scalars in much the same way that the marriage vows bring about the union of man and woman. This section brings forth a new addition to the marriage.

As useful as it is, the notion of an F-vector space V fails to provide for one of the most important ideas in the applications—the concept of multiplication of vectors. In a vector space one can add vectors and multiply vectors by scalars, but one cannot multiply vectors by vectors. Yet, there are numerous situations in which one faces exactly these operations. Consider, for instance, the cross and dot products from field theory. Even in the case of matrices, the ubiquitous and crucial matrix multiplication is available, when it is defined. The key to the missing element in the discussion lies in the terminology for

matrix operations, which will be familiar to the reader as the matrix algebra. What must occur in order for vector-to-vector multiplication to be available is for the vector space to be extended into an algebra.

Unfortunately, the word "algebra" carries a rather imprecise meaning from the most elementary and early exposures from which it came to signify the collection of operations done in arithmetic, at the time when the operations are generalized to include symbols or literals such as a, b, and c or x, y, and z. Such a notion generally corresponds closely with the idea of a field, F, as defined in Chapter 1, and is not much off the target for an environment of scalars. It may, however, come as a bit of a surprise to the reader that algebra is a technical term, in the same spirit as fields, vector spaces, rings, etc. Therefore, if one is to have available a notion of multiplication of vectors, then it is appropriate to introduce the precise notion of an algebra, which captures the desired idea in an axiomatic sense.

2.2 Algebras

Chapter 1 mentioned that the integers I and the polynomials $F[s]$ in s with coefficients in a field F were instances of a ring. In this section, it is necessary to carry the concept of ring beyond the example stage. Of course, a long list of axioms could be provided, but it may be more direct just to cite the changes necessary to the field axioms already provided in Section 1.2. To be precise, the axioms of a commutative ring differ from the axioms of a field only by the removal of the multiplicative inverse. Intuitively, this means that one cannot always divide, even if the element in question is nonzero. Many important commutative rings are found in the applications; however, this chapter is centered on rings, wherein one more axiom is removed—the commutativity of multiplication. The ring of $n \times n$ matrices with elements from a field is a classic and familiar example of such a definition. It may be remarked that in some references a distinction is made between rings and rings with identity, the latter having a multiplicative identity and the former not being so equipped. This treatment has no need for such a distinction, and hereafter the term "ring" is understood to mean ring with identity, or, as described above, a field with the specified two axioms removed.

It is probably true that the field is the most comfortable of axiomatic systems for most persons because it corresponds to the earliest and most persistent of calculation notions. However, it is also true that the ring has an intuitive and immediate understanding as well, which can be expressed in terms of the well-known phrase "playing with one arm behind one's back." Indeed, each time an axiom is removed, it is similar to removing one of the options in a game. This adds to the challenge of a game, and leads to all sorts of new strategies. Such is the case for algebras, as is clear from the next definition. What follows is not the most general of possible definitions, but probably that which is most common.

An algebra A is an F-vector space A, which is equipped with a multiplication a_1a_2 of vectors a_1 and a_2 in such a manner that it is also a ring. First, addition in the ring is simply addition of vectors in the vector space. Second, a special relationship exists between multiplication of vectors and scalar multiplication in the vector space. If a_1 and a_2 are vectors in A, and if f is a scalar in F, then the following identity holds:

$$f(a_1a_2) = (fa_1)a_2 = a_1(fa_2) \tag{2.1}$$

Note that the order of a_1 and a_2 does not change in the above equalities. This must be true because no axiom of commutativity exists for multiplication. The urge to define a symbol for vector multiplication is resisted here so as to keep things as simple as possible. In the same way the notation for scalar multiplication, as introduced in Chapter 1, is suppressed here in the interest of simplicity. Thus, the scalar multiplication can be associated either with the vector product, which lies in A, or with one or other of the vector factors. This is exactly the familiar situation with the matrix algebra.

Hidden in the definition of the algebra A above is the precise detail arising from the statement that A is a ring. Associated with that detail is the nature of the vector multiplication represented above with the juxtaposition a_1a_2. Because all readers are familiar with several notions of vector multiplication, the question arises as to just what constitutes such a multiplication. It turns out that a precise notion for

multiplication can be found in the idea of a bilinear operator. Thus, an alternative description of Section 2.3 is that of vector spaces equipped with vector multiplication. Moreover, one is tempted to inquire whether a vector multiplication exists that is so general in nature that all the other vector multiplications can be derived from it. In fact, this is the case, and the following section sets the stage for introducing such a multiplication.

2.3 Bilinear Operators

Suppose that there are three F-vector spaces: U, V, and W. Recall that $U \times V$ is the Cartesian product of U with V, and denotes the set of all ordered pairs, the first from U and the second from V. Now, consider a mapping b from $U \times V$ into W. For brevity of notation, this can be written b: $U \times V \rightarrow W$. The mapping b is a bilinear operator if it satisfies the following pair of conditions

$$b(f_1 u_1 + f_2 u_2, v) = f_1 b(u_1, v) + f_2 b(u_2, v) \tag{2.2}$$

$$b(u, f_1 v_1 + f_2 v_2) = f_1 b(u, v_1) + f_2 b(u, v_2) \tag{2.3}$$

for all f_1 and f_2 in F, for all u, u_1, and u_2 in U, and for all v, v_1, and v_2 in V. The basic idea of the bilinear operator is apparent from this definition. It is an operator with two arguments, having the property that if either of the two arguments is fixed, the operator becomes linear in the remaining argument. A moment's reflection will show that the intuitive operation of multiplication is of this type.

One of the important features of a bilinear operator is that its image need not be a subspace of W. This is in marked contrast with the image of a linear operator, whose image is always a subspace. This property leads to great interest in the manipulations associated with vector products. At the same time, it brings about a great deal of nontriviality. The best way to illustrate the point is with an example.

Example

Suppose that U, V, and W have bases $\{u_1, u_2\}$, $\{v_1, v_2\}$, and $\{w_1, w_2, w_3, w_4\}$, respectively. Then, vectors u in U and v in V can be represented in the following manner

$$u = f_1 u_1 + f_2 u_2 \tag{2.4}$$

$$v = g_1 v_1 + g_2 v_2 \tag{2.5}$$

where f_i and g_i are elements of F for $i = 1, 2$. Define a bilinear map by the action

$$b(u, v) = 2 f_1 g_1 w_1 + 3 f_1 g_2 w_2 + 3 f_2 g_1 w_3 + 2 f_2 g_2 w_4 \tag{2.6}$$

It is clear that every vector

$$h_1 w_1 + h_2 w_2 + h_3 w_3 + h_4 w_4 \tag{2.7}$$

in the image of b has the property that $9 h_1 h_4 = 4 h_2 h_3$. If the $\{h_i, i = 1, 2, 3, 4\}$ are given so as to satisfy the latter condition, consider the task of showing that this vector in W is a vector in the image of b. Suppose that $h_1 = 0$. Then either h_2 or h_3, is zero, or both are zero. If h_2 is zero, one may choose $f_1 = 0$, $f_2 = 1$, $g_1 = h_3/3$, and $g_2 = h_4/2$. If $h_3 = 0$, one may choose $g_1 = 0$, $g_2 = 1$, $f_1 = h_2/3$, and $f_2 = h_4/2$. An analogous set of constructions is available when $h_4 = 0$. For the remainder of the argument, it is assumed that neither h_1 nor h_2 is zero. Accordingly, none of the coordinates $\{h_i, i = 1, 2, 3, 4\}$ is zero. Without loss, assume that $f_1 = 1$. Then, g_1 is given by $h_1/2$, g_2 is found from $h_2/3$, and f_2 is constructed from $h_3/3g_1$, which is then $2h_3/3h_1$. It is easy to check that these choices produce the correct first three coordinates;

the last coordinate is $4h_3h_2/9h_1$, which by virtue of the property $9h_1h_4 = 4h_2h_3$ is equal to h_4 as desired. Thus, a vector in W is in the image of b if and only if the relation $9h_1h_4 = 4h_2h_3$ is satisfied. Next, it is shown that the vectors in this class are not closed under addition. For this purpose, simply select a pair of vectors represented by (1, 1, 9, 4) and (4, 9, 1, 1). The sum, (5, 10, 10, 5), does not satisfy the condition.

It is perhaps not so surprising that the image of b in this example is not a subspace of W. After all, the operator b is nonlinear, when both of its arguments are considered. What may be surprising is that a natural and classical way can be used to circumvent this difficulty, at least to a remarkable degree. The mechanism that is introduced in order to address such a question is the tensor. The reader should bear in mind that many technical personnel have prior notions and insights on this subject emanating from areas such as the theory of mechanics and related bodies of knowledge. For these persons, the authors wish to emphasize that the following treatment is algebraic in character and may exhibit, at least initially, a flavor different from that to which they may be accustomed. This difference is quite typical of the distinctive points of view that often can be found between the mathematical areas of algebra and analysis. Such differences are fortunate insofar as they promote progress in understanding.

2.4 Tensor Product

The notions of tensors and tensor product, as presented in this treatment, have the intuitive meaning of a very general sort of bilinear operator, in fact, the *most* general such operator. Once again, F-vector spaces U, V, and W are assumed. Suppose that b: $U \times V \rightarrow W$ is a bilinear operator. Then the pair (b, W) is said to be a tensor product of U and V if two conditions are met. The first condition is that W is the smallest F-vector space that contains the image of b. Using alternative terminology this could be expressed as W being the vector space generated by the image of b. The term "generated" in this expression refers to the formation of all possible linear combinations of elements in the image of b. The second condition relates b to an arbitrary bilinear operator $\breve{b}$: $U \times V \rightarrow X$ in which X is another F-vector space. To be precise, the second condition states that for every such $\breve{b}$, a linear operator $\breve{B}$: $W \rightarrow X$ exists with the property that

$$\breve{b}(u, v) = \breve{B}(b(u, v)) \tag{2.8}$$

for all pairs (u, v) in $U \times V$. Intuitively, this means that the arbitrary bilinear operator $\breve{b}$ can be factored in terms of the given bilinear operator b, which does not depend upon $\breve{b}$, and a linear operator $\breve{B}$ which does depend upon $\breve{b}$.

The idea of the tensor product is truly remarkable. Moreover, for any bilinear operator $\breve{b}$, the induced linear operator $\breve{B}$ is unique. The latter result is easy to see. Suppose that there are two such induced linear operators, e.g., $\breve{B}_1$ and $\breve{B}_2$. It follows immediately that

$$(\breve{B}_1 - \breve{B}_2)(b(u, v)) = 0 \tag{2.9}$$

for all pairs (u, v). However, the first condition of the tensor product assures that the image of b contains a set of generators for W, and thus that $(\breve{B}_1 - \breve{B}_2)$ must in fact be the zero operator. Therefore, once the tensor product of U and V is put into place, bilinear operations are in a one-to-one correspondence with linear operations. This is the essence of the tensor idea, and a very significant way to parameterize product operations in terms of matrices. In a certain sense, then, the idea of this chapter is to relate the fundamentally nonlinear product operation to the linear ideas of Chapter 1. That this is possible is, of course, classical; nonetheless, it remains a relatively novel idea for numerous workers in the applications. Intuitively, what happens here is that the idea of *product* is abstracted in the bilinear operator b, with all the remaining details placed in the realm of the induced linear operator $\breve{B}$.

When a pair (b, W) satisfies the two conditions above, and is therefore a tensor product for U and V, it is customary to replace the symbol b with the more traditional symbol $\otimes$. However, in keeping the notion

that $\otimes$ represents a product and not just a general mapping it is common to write $u \otimes v$ in place of the more correct, but also more cumbersome, $\otimes(u, v)$. Along the same lines, the space W is generally denoted $U \otimes V$. Thus, a tensor product is a pair $(U \otimes V, \otimes)$. The former is called the tensor product of U with V, and $\otimes$ is loosely termed the tensor product. Clearly, $\otimes$ is the most general sort of product possible in the present situation because all other products can be expressed in terms of it by means of linear operators $\breve{B}$. Once again, the colloquial use of the word "product" is to be identified with the more precise algebraic notion of bilinear operation. In this way the tensor product becomes a sort of "grandfather" for all vector products.

Tensor products can be constructed for arbitrary vector spaces. They are not, however, unique. For instance, if $U \otimes V$ has finite dimension, then W obviously can be replaced by any other F-vector space of the same dimension, and $\otimes$ can be adjusted by a vector space isomorphism. Here, the term "isomorphism" denotes an invertible linear operator between the two spaces in question. It can also be said that the two tensor product spaces $U \otimes V$ and W are isomorphic to each other. Whatever the terminology chosen, the basic idea is that the two spaces are essentially the same within the axiomatic framework in use.

2.5 Basis Tensors

Attention is now focused on the case in which U and V are finite-dimensional vector spaces over the field F. Suppose that $\{u_1, u_2, \ldots, u_m\}$ is a basis for U and $\{v_1, v_2, \ldots, v_n\}$ is a basis for V. Consider the following vectors

$$u_1 \otimes v_1 \quad u_1 \otimes v_2 \quad \cdots \quad u_1 \otimes v_n \quad u_2 \otimes v_1 \quad \cdots \quad u_m \otimes v_n \tag{2.10}$$

which can be represented in the manner $\{u_i \otimes v_j,\ i = 1, 2, \ldots, m;\ j = 1, 2, \ldots, n\}$. These vectors form a basis for the vector space $U \otimes V$. To understand the motivation for this, note that vectors in U and V, respectively, can be written uniquely in the following forms

$$u = \sum_{i=1}^{m} f_i u_i \tag{2.11}$$

$$v = \sum_{j=1}^{n} g_j v_j \tag{2.12}$$

Recall that $\otimes$, which is an alternate notation for b, is a bilinear operator. It follows then that

$$u \otimes v = \sum_{i=1}^{m} \sum_{j=1}^{n} f_i g_j u_i \otimes v_j \tag{2.13}$$

which establishes that the proposed basis vectors certainly span the image of $\otimes$, and thus that they span the tensor product space $U \otimes V$. It also can be shown that the proposed set of basis vectors is linearly independent. However, in the interest of brevity for this summary exposition, the details are omitted.

From this point onward, inasmuch as the symbol $\otimes$ has replaced b, it will be convenient to use b in place of $\breve{b}$ and B in place of $\breve{B}$. It is hoped that this leads to negligible confusion. Thus, in the sequel b refers simply to a bilinear operator and B to its induced linear counterpart.

Example

Consider the bilinear form b: $R^2 \times R^3 \rightarrow R$ with action defined by

$$b(f_1, f_2, g_1, g_2, g_3) = 2 f_2 g_3 \tag{2.14}$$

Observe that this can be put into the more transparent form

$$[f_1 \quad f_2]\begin{bmatrix}0 & 0 & 0\\ 0 & 0 & 2\end{bmatrix}\begin{bmatrix}g_1\\ g_2\\ g_3\end{bmatrix} \tag{2.15}$$

which, in turn, can be written in the compact notation $u^{\mathrm{T}}Mv$. Clearly, U has dimension two, and V has dimension three. Thus, $U \otimes V$ has a basis with six elements. The operator b maps into R, which has a basis with one element. All bases are chosen to be standard. Thus, an ith basis vector contains the multiplicative field element 1 in its ith row, and the additive field element 0 in its other rows. Therefore, the matrix of B has one row and six columns. To compute the entries, it is necessary to agree upon the order of the basis elements in $R^2 \otimes R^3$. It is customary to choose the natural ordering as introduced previously

$$u_1 \otimes v_1 \quad u_1 \otimes v_2 \quad u_1 \otimes v_3 \quad u_2 \otimes v_1 \quad u_2 \otimes v_2 \quad u_2 \otimes v_3 \tag{2.16}$$

The coordinate h_1 associated with the basis vector [1] in R, considered to be a vector space, is given by

$$h_1 = b(1, 0, 1, 0, 0) = 0 \tag{2.17}$$

when u and v are given by the respective first basis vectors in R^2 and R^3, respectively,

$$u = \begin{bmatrix}1\\ 0\end{bmatrix} \tag{2.18}$$

$$v = \begin{bmatrix}1\\ 0\\ 0\end{bmatrix} \tag{2.19}$$

Similarly, for the other five pairings in order, one obtains

$$h_1 = b(1, 0, 0, 1, 0) = 0 \tag{2.20}$$

$$h_1 = b(1, 0, 0, 0, 1) = 0 \tag{2.21}$$

$$h_1 = b(0, 1, 1, 0, 0) = 0 \tag{2.22}$$

$$h_1 = b(0, 1, 0, 1, 0) = 0 \tag{2.23}$$

$$h_1 = b(0, 1, 0, 0, 1) = 2 \tag{2.24}$$

in order. In view of these calculations, together with the definitions of matrices in Chapter 1, it follows that the matrix description of $B : R^2 \otimes R^3 \rightarrow R$ is given by

$$[B] = [0 \quad 0 \quad 0 \quad 0 \quad 0 \quad 2] \tag{2.25}$$

Observe that all the numerical information concerning B has been arrayed in $[B]$. It becomes increasingly clear then that such numerical entries define all possible bilinear forms of this type.

Example

In order to generalize the preceding example, one has only to be more general in describing the matrix of M. Suppose that

$$[M] = \begin{bmatrix} m_{11} & m_{12} & m_{13} \\ m_{21} & m_{22} & m_{23} \end{bmatrix} \tag{2.26}$$

so that the bilinear operator b has action

$$b(f_1, f_2, g_1, g_2, g_3) = \begin{bmatrix} f_1 & f_2 \end{bmatrix} \begin{bmatrix} m_{11} & m_{12} & m_{13} \\ m_{21} & m_{22} & m_{23} \end{bmatrix} \begin{bmatrix} g_1 \\ g_2 \\ g_3 \end{bmatrix} \tag{2.27}$$

Thus, it is easy to determine that

$$[B] = \begin{bmatrix} m_{11} & m_{12} & m_{13} & m_{21} & m_{22} & m_{23} \end{bmatrix} \tag{2.28}$$

The two examples preceding help in visualizing the linear operator B by means of its matrix. They do not, however, contribute to the understanding of the nature of the tensor product of two vectors. For that purpose, it is appropriate to carry the examples a bit further.

Example

The foregoing example presents the following representations

$$\begin{bmatrix} f_1 \\ f_2 \end{bmatrix} \tag{2.29}$$

for u and

$$\begin{bmatrix} g_1 \\ g_2 \\ g_3 \end{bmatrix} \tag{2.30}$$

for v. From the development of the ideas of the tensor product, it was established that $b(u, v) = B(u \otimes v)$. The construction of $u \otimes v$ proceeds according to definition in the manner

$$u \otimes v = \left(\sum_{i=1}^{2} f_i u_i \right) \otimes \left(\sum_{j=1}^{3} g_j v_j \right) \tag{2.31}$$

$$= \sum_{i=1}^{2} \sum_{j=1}^{3} f_i g_j u_i v_j \tag{2.32}$$

From this and the basis ordering chosen above, it is clear that the representation of $u \otimes v$ is given by

$$[u \otimes v] = [f_1 g_1 \quad f_1 g_2 \quad f_1 g_3 \quad f_2 g_1 \quad f_2 g_2 \quad f_2 g_3]^{\mathrm{T}} \tag{2.33}$$

The total picture for the tensor representation of $b(u, v)$, then, is

$$b(f_1,f_2,g_1,g_2,g_3)=\begin{bmatrix}f_1\\f_2\end{bmatrix}^{\top}\begin{bmatrix}m_{11}&m_{12}&m_{13}\\m_{21}&m_{22}&m_{23}\end{bmatrix}\begin{bmatrix}g_1\\g_2\\g_3\end{bmatrix} \tag{2.34}$$

$$=\begin{bmatrix}m_{11}&m_{12}&m_{13}&m_{21}&m_{22}&m_{23}\end{bmatrix}\left(\begin{bmatrix}f_1\\f_2\end{bmatrix}\otimes\begin{bmatrix}g_1\\g_2\\g_3\end{bmatrix}\right) \tag{2.35}$$

$$=\begin{bmatrix}m_{11}&m_{12}&m_{13}&m_{21}&m_{22}&m_{23}\end{bmatrix}\begin{bmatrix}f_1g_1\\f_1g_2\\f_1g_3\\f_2g_1\\f_2g_2\\f_2g_3\end{bmatrix} \tag{2.36}$$

The reader should have no difficulty in extending the notions of these examples to cases in which the dimensions of U and V differ from those used here. The extension to an X with dimension larger than 1 is similar in nature, and can be carried out row by row.

Example

Another sort of example, which is likely to be familiar to most readers, is the formation of the ordinary matrix product $m(P, Q) = PQ$ for compatible matrices P and Q over the field F. Clearly, the matrix product m is a bilinear operator. Thus, a linear operator M exists that has the property

$$m(P,Q)=M(P\otimes Q) \tag{2.37}$$

The matrix $P \otimes Q$ is known in the applications as the Kronecker product. If the basis vectors are chosen in the usual way, then its computation has the classical form. Thus, the Kronecker product of two matrices is seen to be the most general of all such products. Indeed, any other product, including the usual matrix product, can be found from the Kronecker product by multiplication with a matrix.

2.6 Multiple Products

It may happen that more than two vectors are multiplied together. Thus, certain famous and well-known field formulas include both crosses and dots. While the notion of multiple products is part and parcel of the concept of ring, so that no further adjustments need to be made there, one must undertake the question of how these multiple products are reflected back into the tensor concept. The purpose of this section, therefore, is to sketch the major ideas concerning such questions. A basic and natural step is the introduction of a generalization of bilinear operators.

For obvious reasons, not the least of which is the finite number of characters in the alphabet, it is now necessary to modify notation so as to avoid the proliferation of symbols. With regard to the foregoing discussion, the modification, which is straightforward, is to regard a bilinear operator in the manner b: $U_1 \times U_2 \to V$ in place of the previous $U \times V \to W$. Generalizing, consider p F-vector spaces U_i, $i = 1, 2, \ldots, p$. Let m: $U_1 \times U_2 \times \cdots \times U_p \to V$ be an operator that satisfies the following condition

$$\begin{aligned}m(u_1,u_2,\ldots,u_{i-1},f_iu_i+\breve{f}_i\breve{u}_i,u_{i+1},\ldots,u_p)&=f_im(u_1,u_2,\ldots,u_{i-1},u_i,u_{i+1},\ldots u_p)\\&\quad+\breve{f}_im(u_1,u_2,\ldots,u_{i-1},\breve{u}_i,u_{i+1},\ldots u_p)\end{aligned} \tag{2.38}$$

for $i = 1, 2, \ldots, p$, for all f_i and $\breve{f}_i$ in F, and for all u_i and $\breve{u}_i$ in U_i. Thus, m is said to be a p-linear operator. Observe in this definition that when $p - 1$ of the arguments of m are fixed, m becomes a linear operator in the remaining argument. Clearly, the bilinear operator is a special case of this definition, when $p = 2$. Moreover, the definition captures the intuitive concept of multiplication in a precise algebraic sense.

Next, the notion of tensor product is extended in a corresponding way. To do this, suppose that m and V satisfy two conditions. The first condition is that V is the smallest F-vector space that contains the image of m. Equivalently, V is the F-vector space generated by the image of m. Recall that the image of m is not equal to V, even in the bilinear case $p = 2$. The second condition is that

$$\breve{m}(u_1, u_2, \ldots, u_p) = \breve{M}(m(u_1, u_2, \ldots, u_p)) \tag{2.39}$$

where

$\breve{M}$: $V \rightarrow W$ is a linear operator
W is an F-vector space
$\breve{m}$: $U_1 \times U_2 \times \cdots \times U_p \rightarrow W$ is an arbitrary p-linear operator

If m satisfies these two conditions, the action of m is more traditionally written in the manner

$$m(u_1, u_2, \ldots, u_p) = u_1 \otimes u_2 \otimes \cdots \otimes u_p \tag{2.40}$$

and the space V is given by the notation

$$V = U_1 \otimes U_2 \otimes \cdots \otimes U_p \tag{2.41}$$

Once again, existence of the tensor product pair (m, V) is not a problem, and the same sort of uniqueness holds, that is, up to isomorphism.

It is now possible to give a major example of the multiple product idea. The general import of this example far exceeds the interest attached to more elementary illustrations. Therefore, it is accorded its own section. The reason for this will shortly become obvious.

2.7 Determinants

The body of knowledge associated with the theory of determinants tends to occupy a separate and special part of the memory which one reserves for mathematical knowledge. This theory is encountered somewhat indirectly during matrix inversion, and thus is felt to be related to the matrix algebra. However, this association can be somewhat misleading. Multiplication in the matrix algebra is really a multiplication of linear operators, but determinants are more naturally seen in terms of multiplication of vectors. The purpose of this section is to make this idea apparent, and to suggest that a natural way to correlate this body of knowledge is with the concept of an algebra constructed upon a given F-vector space. As such, it becomes a special case of the ideas previously introduced. Fitting determinants into the larger picture is then much less of a challenge than is usually the case, which can save precious human memory.

Consider at the outset a square array of field elements from F, denoted customarily by

$$D = \begin{pmatrix} d_{11} & d_{12} & \cdots & d_{1p} \\ d_{21} & d_{22} & \cdots & d_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ d_{p1} & d_{p2} & \cdots & d_{pp} \end{pmatrix} \tag{2.42}$$

The determinant of D will be denoted by $\det(D)$. It is assumed that all readers are comfortable with at least one of the algorithms for computing $\det(D)$. The key idea about $\det(D)$ is that it is a p-linear

operator on its columns or upon its rows. In fact, two of the three classical properties of determinants are tantamount precisely to this statement. The third property, which concerns interchanging columns or rows, is also of great interest here (see below).

Without loss of generality, suppose that det(D) is regarded as p-linear function of its columns. If the columns, in order, are denoted by $d_1, d_2, \ldots, d_p$, then it is possible to set up a p-linear operator

$$m(d_1, d_2, \ldots, d_p) = \det(D) \tag{2.43}$$

Accordingly, tensor theory indicates that this operator can be expressed in the manner

$$m(d_1, d_2, \ldots, d_p) = M(d_1 \otimes d_2 \otimes \cdots \otimes d_p) \tag{2.44}$$

It is interesting to inquire about the nature of the matrix [M].

In order to calculate [M], it is necessary to select bases U_i, $i = 1, 2, \ldots, p$. In this case it is possible to identify U_i for each i with a fixed space U of dimension p. Let $\{u_1, u_2, \ldots, u_p\}$ be a basis for U and represent this basis by the standard basis vectors $\{e_1, e_2, \ldots, e_p\}$ in F^p. Moreover, select a basis for F and represent it by the multiplicative unit 1 in F. Then the elements of [M] are found by calculating

$$\det(e_{i_1} \quad e_{i_2} \quad \cdots \quad e_{i_p}) \tag{2.45}$$

for all sequences $i_1 i_2 \ldots i_p$ in the increasing numerical order introduced earlier. Thus if $p = 3$, this set of sequences is 111, 112, 113, 121, 122, 123, 131, 132, 133, 211, 212, 213, 221, 222, 223, 231, 232, 233, 311, 312, 313, 321, 322, 323, 331, 332, 333.

Example

For the case $p = 3$ described previously, it is desired to calculate [M]. The first few calculations are given by

$$\det(e_1 \quad e_1 \quad e_1) = 0 \tag{2.46}$$

$$\det(e_1 \quad e_1 \quad e_2) = 0 \tag{2.47}$$

$$\det(e_1 \quad e_1 \quad e_3) = 0 \tag{2.48}$$

$$\det(e_1 \quad e_2 \quad e_1) = 0 \tag{2.49}$$

$$\det(e_1 \quad e_2 \quad e_2) = 0 \tag{2.50}$$

$$\det(e_1 \quad e_2 \quad e_3) = +1 \tag{2.51}$$

$$\det(e_1 \quad e_3 \quad e_1) = 0 \tag{2.52}$$

$$\det(e_1 \quad e_3 \quad e_2) = -1 \tag{2.53}$$

$$\det(e_1 \quad e_3 \quad e_3) = 0 \tag{2.54}$$

$$\det(e_2 \quad e_1 \quad e_1) = 0 \tag{2.55}$$

$$\det(e_2 \quad e_1 \quad e_2) = 0 \tag{2.56}$$

$$\det(e_2 \quad e_1 \quad e_3) = -1 \tag{2.57}$$

$$\vdots$$

Rather than providing the entire list in this form, it is easier to give the elements in the right members of the equations. Employing determinant theory, it follows that those sequences with repeated subscripts correspond to 0. Moreover, interchanging two columns changes the sign of the determinant, the third property mentioned previously. Thus, the desired results are

$$0,0,0,0,0,+1,0,-1,0,0,0,-1,0,0,0,+1,0,0,0,+1,0,-1,0,0,0,0,0 \tag{2.58}$$

Then, [*M*] is a row matrix having these numerical entries. It is 1×27.

Example

The preceding example indicates that the formation of the determinant in tensor notation results in the appearance of numerous multiplications by zero. This is inefficient. Moreover, if all the zero entries in [*M*] are dropped, the result is a product of the form

$$[+1 \quad -1 \quad -1 \quad +1 \quad +1 \quad -1] \begin{bmatrix} d_{11}d_{22}d_{33} \\ d_{11}d_{32}d_{23} \\ d_{21}d_{12}d_{33} \\ d_{21}d_{32}d_{13} \\ d_{31}d_{12}d_{23} \\ d_{31}d_{22}d_{13} \end{bmatrix} \tag{2.59}$$

easily seen to be the standard formula for classical calculation of the determinant. In view of this result, one immediately wonders what to do about all the dropped zeros. The following section shows how to do away with all the zeros. In the process, however, more things happen than might have been anticipated; as a result, an entirely new concept appears.

2.8 Skew Symmetric Products

The determinant is an instance of skew symmetry in products. Consider a *p*-linear operator m: $U_1 \times U_2 \times \cdots \times U_p \rightarrow V$ with the property that each interchange of two arguments changes the sign of the result produced by m. Thus, for example,

$$m(u_1,\ldots,u_{i-1},u_i,\ldots,u_{j-1},u_j,\ldots,u_p) = -m(u_1,\ldots,u_{i-1},u_j,\ldots,u_{j-1},u_i,\ldots,u_p) \tag{2.60}$$

If a list of k interchanges is performed, the sign is changed k times. Such an operator is described as skew symmetric.

Provided that only skew symmetric multiplications are of interest, the tensor construction can be streamlined. Let (m_{skewsym}, V) be a pair consisting of a skew symmetric *p*-linear operator and an *F*-vector space V. This pair is said to constitute a skew symmetric tensor product for the *F*-vector spaces U_1, $U_2,\ldots,U_p$, if two conditions hold. The reader can probably guess what these two conditions are. Condition 1 is that V is the *F*-vector space generated by the image of m_{skewsym}. Condition 2 is the property that for every skew symmetric *p*-linear operator $\breve{m}_{\text{skewsym}}$: $U_1 \times U_2 \times \cdots \times U_p \rightarrow W$, a linear operator $\breve{M}_{\text{skewsym}}$: $V \rightarrow W$ exists having the feature

$$\breve{m}_{\text{skewsym}}(u_1,u_2,\ldots,u_p) = \breve{M}_{\text{skewsym}}(m_{\text{skewsym}}(u_1,u_2,\ldots,u_p)) \tag{2.61}$$

If these two conditions hold for the pair (m_{skewsym}, V), then the custom is to write

$$m_{\text{skewsym}}(u_1,u_2,\ldots,u_p) = u_1 \wedge u_2 \wedge \cdots \wedge u_p \tag{2.62}$$

for the action of m_{skewsym} and

$$V = U_1 \wedge U_2 \wedge \cdots \wedge U_p \tag{2.63}$$

for the product of the vector spaces involved. Once again, this skew symmetric tensor product exists, and is unique in the usual way.

Now suppose that $U_i = U$, $i = 1, 2, \ldots, p$ and that $\{u_1, u_2, \ldots, u_p\}$ is a basis for U. It is straightforward to show that $u_{i_1} \wedge u_{i_2} \wedge \cdots \wedge u_{i_p}$ vanishes whenever two of its arguments are equal. Without loss, assume that $u_{i_j} = u_{i_k} = u$. If u_{i_j} and u_{i_k} are switched, the sign of the product must change. However, after the switch, the argument list is identical to the previous list. Because the only number whose value is unchanged after negation is zero, the conclusion follows. Accordingly, the basis $U_1 \wedge U_2 \wedge \cdots \wedge U_p$ is the family

$$\{u_{i_1} \wedge u_{i_2} \wedge \cdots \wedge u_{i_p}\} \tag{2.64}$$

where each $i_1\, i_2 \cdots i_p$ consists of p distinct nonzero natural numbers, and where the ordinary convention is to arrange the $\{i_k\}$ so as to increase from left to right. A moment's reflection shows that only one such basis element can exist, which is $u_1 \wedge u_2 \wedge \cdots \wedge u_p$. Thus, if $p = 4$, the basis element in question is $u_1 \wedge u_2 \wedge u_3 \wedge u_4$. If we return to the example of the determinant, and regard it as a skew symmetric p-linear operator, then the following representation

$$m_{\text{skewsym}}(d_1, d_2, \ldots, d_p) = M_{\text{skewsym}}(d_1 \wedge d_2 \wedge \cdots \wedge d_p) \tag{2.65}$$

is obtained. Next observe that each of the p columns of the array D can be written as a unique linear combination of the basis vectors $\{u_1, u_2, \ldots, u_p\}$ in the manner

$$d_j = \sum_{i=1}^{p} d_{ij} u_i \tag{2.66}$$

for $j = 1, 2, \ldots, p$. Then, it follows that $d_1 \wedge d_2 \wedge \cdots \wedge d_p$ is given by

$$\sum_{i_1=1}^{p} \sum_{i_2=1}^{p} \cdots \sum_{i_p=1}^{p} d_{i_1 1} d_{i_2 2} \cdots d_{i_p p} u_{i_1} \wedge u_{i_2} \wedge \cdots \wedge u_{i_p} \tag{2.67}$$

which is a consequence of the fact that $\wedge$ is a p-linear operator. The only nonzero terms in this p-fold summation are those for which the indices $\{i_k,\ k = 1, 2, \ldots, p\}$ are distinct. The reader will correctly surmise that these terms are the building blocks of $\det(D)$. Indeed,

$$d_1 \wedge d_2 \wedge \cdots \wedge d_p = \det(D) u_1 \wedge u_2 \wedge \cdots \wedge u_p \tag{2.68}$$

and, if U is R^p with the $\{u_i\}$ chosen as standard basis elements, then

$$d_1 \wedge d_2 \wedge \cdots \wedge d_p = \det(D) \tag{2.69}$$

because $u_1 \wedge u_2 \wedge \cdots \wedge u_p$ becomes 1 in F. Moreover, it is seen from this example how the usual formula for $\det(D)$ is altered if the columns of D are representations with respect to a basis other than the standard basis. In turn, this shows how the determinant changes when the basis of a space is changed. The main idea is that it changes by a constant that is constructed from the determinant whose columns are the corresponding vectors of the alternate basis. Finally, because this new basis is given by an

invertible linear transformation from the old basis, it follows that the determinant of the transformation is the relating factor.

It can now be observed that the change from a tensor product based upon $\otimes$ to a tensor product based upon $\wedge$ has indeed eliminated the zero multiplications associated with skew symmetry. However, and this could possibly be a surprise, it has reduced everything to one term, which is the coordinate relative to the singleton basis element in a tensor product space of dimension one. This may be considered almost a tautology, except for the fact that it produces a natural generalization of the determinant to arrays in which the number of rows is not equal to the number of columns. Without loss, assume that the number of columns is less than the number of rows.

Example

Consider, then, an array of field elements from F, with fewer columns than rows, denoted by

$$D = \begin{bmatrix} d_{11} & d_{12} & \cdots & d_{1p} \\ d_{21} & d_{22} & \cdots & d_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ d_{q1} & d_{q2} & \cdots & d_{qp} \end{bmatrix} \tag{2.70}$$

where $p < q$. The apparatus introduced in this section still permits the formation of a skew symmetric p-linear operation in the manner $d_1 \wedge d_2 \wedge \cdots \wedge d_p$. This is a natural generalization in the sense that the ordinary determinant is recovered when $p = q$. Moreover, the procedure of calculation is along the same lines as before, with the following representations

$$d_j = \sum_{i=1}^{q} d_{ij} u_i \tag{2.71}$$

for $j = 1, 2, \ldots, p$. Note that the upper limit on the summation has changed from p to q. The reader will observe, then, that $d_1 \wedge d_2 \wedge \cdots \wedge d_p$ can be found once again by the familiar step

$$\sum_{i_1=1}^{q} \sum_{i_2=1}^{q} \cdots \sum_{i_p=1}^{q} d_{i_1 1} d_{i_2 2} \cdots d_{i_p p} u_{i_1} \wedge u_{i_2} \wedge \cdots \wedge u_{i_p} \tag{2.72}$$

which is a consequence once again of the fact that $\wedge$ is a p-linear operator. In this case, however, there is more than one way to form nonzero products in the family

$$\{u_{i1} \wedge u_{i2} \wedge \cdots \wedge u_{ip}\} \tag{2.73}$$

in which $i_1\, i_2 \cdots i_p$ contains p distinct numbers, and where the traditional convention is to arrange the $\{i_k\}$ so that the numbers in each list are increasing, while the numbers which these sequences represent are also increasing. This verbiage is best illustrated quickly.

Example

Suppose that $p = 3$ and $q = 4$. Thus, the sequences $i_1 i_2 i_3$ of interest are 123, 124, 134, 234. It can be observed that each of these sequences describes a 3×3 subarray of D in which the indices are associated with rows. In a sense these subarrays lead to all the interesting 3×3 minors of D, inasmuch as all the others are either zero or negatives of these four. Some of these designated four minors could also be zero, but that would be an accident of the particular problem instead of a general feature.

Example

This example investigates in greater detail the idea of $q > p$. Suppose that $p = 2$ and $q = 3$. Further, let the given array be

$$D = \begin{pmatrix} d_{11} & d_{12} \\ d_{21} & d_{22} \\ d_{31} & d_{32} \end{pmatrix} \tag{2.74}$$

Choose the standard basis $\{e_1, e_2, e_3\}$ for $U = F^3$. Then,

$$d_1 = d_{11}e_1 + d_{21}e_2 + d_{31}e_3 \tag{2.75}$$

$$d_2 = d_{12}e_1 + d_{22}e_2 + d_{32}e_3 \tag{2.76}$$

from which one computes that

$$\begin{aligned} d_1 \wedge d_2 &= (d_{11}e_1 + d_{21}e_2 + d_{31}e_3) \wedge (d_{12}e_1 + d_{22}e_2 + d_{32}e_3) \\ &= (d_{11}d_{22} - d_{21}d_{12})e_1 \wedge e_2 \qquad (2.77) \\ &\quad + (d_{11}d_{32} - d_{31}d_{12})e_1 \wedge e_3 + (d_{21}d_{32} - d_{31}d_{22})e_2 \wedge e_3 \qquad (2.78) \end{aligned}$$

that evidently can be rewritten in the form

$$\begin{aligned} d_1 \wedge d_2 = &\det\begin{pmatrix} d_{11} & d_{12} \\ d_{21} & d_{22} \end{pmatrix} e_1 \wedge e_2 \\ &+ \det\begin{pmatrix} d_{11} & d_{12} \\ d_{31} & d_{32} \end{pmatrix} e_1 \wedge e_3 \\ &+ \det\begin{pmatrix} d_{21} & d_{22} \\ d_{31} & d_{32} \end{pmatrix} e_2 \wedge e_3 \end{aligned} \tag{2.79}$$

making clear the idea that the 2×2 minors of D become the coordinates of the expansion in terms of the basis $\{e_1 \wedge e_2, e_1 \wedge e_3, e_2 \wedge e_3\}$ for $R^3 \wedge R^3$.

2.9 Solving Linear Equations

An important application of Section 2.8 is to relate the skew symmetric tensor algebra to one's intuitive idea of matrix inversion. Consider the following linear equation

$$\begin{bmatrix} d_{11} & d_{12} & \cdots & d_{1p} \\ d_{21} & d_{22} & \cdots & d_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ d_{p1} & d_{p2} & \cdots & d_{pp} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_p \end{bmatrix} = \begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ c_p \end{bmatrix} \tag{2.80}$$

With the aid of the usual notation for columns of D, rewrite this equation in the manner

$$\sum_{i=1}^{p} x_i d_i = c \tag{2.81}$$

where c is a vector whose ith element is c_i. To solve for x_k, multiply both members of this equation by the quantity

$$d_1 \wedge d_2 \wedge \cdots \wedge d_{k-1} \wedge d_{k+1} \wedge \cdots \wedge d_p \tag{2.82}$$

which will be denoted by d_{k-}. This multiplication can be done either on the left or the right, and the vector product which is used is $\wedge$. Multiplying on the left provides the result

$$x_k d_{k-} \wedge d_k = d_{k-} \wedge c \tag{2.83}$$

Now if $\det(D)$ is not zero, then this equation solves for

$$x_k = (d_{k-} \wedge c)/(d_{k-} \wedge d_k) \tag{2.84}$$

and this is essentially Cramer's rule. Using this rule conventionally one performs enough interchanges so as to move c to the kth column of the array. If these interchanges are performed in an analogous way with regard to d_k in the denominator, the traditional form of the rule results. This approach to the result shows that the solution proceeds by selecting multiplication by a factor which annihilates all but one of the terms in the equation, where each term is concerned with one column of D.

This is simply a new way of viewing an already known result. However, the treatment of Section 2.8 suggests the possibility of extending the construction to the case in which are found more unknowns than equations. The latter procedure follows via a minor adjustment of the foregoing discussion, and thus it seems instructive to illustrate the steps by means of an example.

Example

Consider the problem corresponding to $q = 3$ and $p = 2$ and given by three equations in two unknowns as follows:

$$\begin{bmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} 7 \\ 8 \\ 9 \end{bmatrix} \tag{2.85}$$

Begin by rewriting the equation in the form

$$x_1 \begin{bmatrix} 1 \\ 3 \\ 5 \end{bmatrix} + x_2 \begin{bmatrix} 2 \\ 4 \\ 6 \end{bmatrix} = \begin{bmatrix} 7 \\ 8 \\ 9 \end{bmatrix} \tag{2.86}$$

To solve for x_2, multiply from the left with $[1\ 3\ 5]^{\mathrm{T}}$. This gives

$$x_2 \begin{bmatrix} 1 \\ 3 \\ 5 \end{bmatrix} \wedge \begin{bmatrix} 2 \\ 4 \\ 6 \end{bmatrix} = \begin{bmatrix} 1 \\ 3 \\ 5 \end{bmatrix} \wedge \begin{bmatrix} 7 \\ 8 \\ 9 \end{bmatrix} \tag{2.87}$$

which then implies

$$x_2 \begin{bmatrix} -2 \\ -4 \\ -6 \end{bmatrix} = \begin{bmatrix} -13 \\ -26 \\ -13 \end{bmatrix} \tag{2.88}$$

which implies that $x_2 = 13/2$. Next, consider a left multiplication by $[2 \quad 4 \quad 6]^T$. Therefore,

$$x_1 \begin{bmatrix} 2 \\ 4 \\ 6 \end{bmatrix} \wedge \begin{bmatrix} 1 \\ 3 \\ 5 \end{bmatrix} = \begin{bmatrix} 2 \\ 4 \\ 6 \end{bmatrix} \wedge \begin{bmatrix} 7 \\ 8 \\ 9 \end{bmatrix} \tag{2.89}$$

which then implies

$$x_1 \begin{bmatrix} 2 \\ 4 \\ 2 \end{bmatrix} = \begin{bmatrix} -12 \\ -24 \\ -12 \end{bmatrix} \tag{2.90}$$

which implies that $x_1 = -6$. It is easy to check that these values of x_1 and x_2 are the unique solution of the equation under study.

The reader is cautioned that the construction of the preceding example produces necessary conditions on the solution. If any of these conditions cannot be satisfied, no solution can be found. On the other hand, if solutions to the necessary conditions are found, we must check that these solutions satisfy the original equation. Space limitations prevent any further discussion of this quite fascinating point.

2.10 Symmetric Products

The treatment presented in Section 2.8 has a corresponding version for this section. Consider a p-linear operator m: $U_1 \times U_2 \times \cdots \times U_p \to V$ with the property that each interchange of two arguments leaves the result produced by m unchanged. Symbolically, this is expressed by

$$m(u_1, \ldots, u_{i-1}, u_i, \ldots, u_{j-1}, u_j, \ldots, u_p) = m(u_1, \ldots, u_{i-1}, u_j, \ldots, u_{j-1}, u_i, \ldots, u_p) \tag{2.91}$$

Such an operator is said to be symmetric.

If only symmetric multiplications are of interest, the tensor construction can once again be trimmed to fit. Let (m_{sym}, V) be a pair consisting of a symmetric p-linear operator and an F-vector space V. This pair is said to constitute a symmetric tensor product for the F-vector spaces $U_1, U_2, \ldots, U_p$ if two conditions hold. First, V is the F-vector space generated by the image of m_{sym}; and, second, for every symmetric p-linear operator $\breve{m}_{\text{sym}}$: $U_1 \times U_2 \times \cdots \times U_p \to W$, linear operator $\breve{M}_{\text{sym}}$: $V \to W$ exists such that

$$\breve{m}_{\text{sym}}(u_1, u_2, \ldots, u_p) = \breve{M}_{\text{sym}}(m_{\text{sym}}(u_1, u_2, \ldots, u_p)) \tag{2.92}$$

In such a case, one writes

$$m_{\text{sym}}(u_1, u_2, \ldots, u_p) = u_1 \vee u_2 \vee \cdots \vee u_p \tag{2.93}$$

to describe the action of m_{sym} and

$$V = U_1 \vee U_2 \vee \cdots \vee U_p \tag{2.94}$$

for the symmetric tensor product of the vector spaces involved. As before, this symmetric tensor product exists and is essentially unique.

Next, let $U_i = U$, $i = 1, 2, \ldots, p$, and $\{u_1, u_2, \ldots, u_p\}$ be a basis for U. Because the interchange of two arguments does not change the symmetric p-linear operator, the basis elements are characterized by the family

$$\{u_{i_1} \vee u_{i_2} \vee \cdots \vee u_{i_p}\} \tag{2.95}$$

where each $i_1 i_2 \ldots i_p$ consists of all combinations of p nonzero natural numbers, written in increasing order, and where the ordinary convention is to arrange the basis vectors so that the numbers $i_1 i_2 \ldots i_p$ increase. Unlike the skew symmetric situation, quite a few such basis vectors can, in general, exist. For instance, the first basis element is $u_1 \vee u_1 \vee \cdots \vee u_1$ with p factors and the last one is $u_p \vee u_p \vee \cdots \vee u_p$, again with p factors.

Example

Suppose that $p = 3$ and that the dimension of U is 4. The sequences $i_1 i_2 i_3$ of interest in the representation of symmetric p-linear products are 111, 112, 113, 114, 122, 123, 124, 133, 134, 144, 222, 223, 224, 233, 234, 244, 333, 334, 344, 444. Section 2.7 showed a related example which produced 27 basis elements for the tensor product space built upon $\otimes$. In this case, it would be 64. The same situation in Section 2.8 produced four basis elements for a tensor product space constructed with $\wedge$. Twenty basis elements are found for the tensor product space produced with $\vee$. Notice that $20 + 4 \neq 64$. This means that the most general space based on $\otimes$ is not just a direct sum of those based on $\wedge$ and $\vee$.

Example

For an illustration of the symmetric product idea, choose $U = R^2$ and form a symmetric bilinear form in the arrangement of a quadratic form $u^{\mathrm{T}} M u$:

$$m_{\mathrm{sym}}(f_1, f_2) = \begin{bmatrix} f_1 \\ f_2 \end{bmatrix}^{\mathrm{T}} \begin{bmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{bmatrix} \begin{bmatrix} f_1 \\ f_2 \end{bmatrix} \tag{2.96}$$

A word about the matrix M is in order. Because of the relationship

$$M = \frac{1}{2}(M + M^{\mathrm{T}}) + \frac{1}{2}(M - M^{\mathrm{T}}) \tag{2.97}$$

it is easy to see that M may be assumed to be symmetric without loss of generality, as the remaining term in this representation of m_{sym} (f_1, f_2) leads to a zero contribution in the result. Thus, one is concerned with a natural candidate for the symmetric tensor mechanism. The tensor construction begins by considering

$$\begin{bmatrix} f_1 \\ f_2 \end{bmatrix} \vee \begin{bmatrix} f_1 \\ f_2 \end{bmatrix} \tag{2.98}$$

Choose a standard basis $\{e_1, e_2\}$ for R^2. Then the expression introduced previously becomes

$$\sum_{i=1}^{2} \sum_{j=1}^{2} f_i f_j e_i \vee e_j \tag{2.99}$$

which becomes

$$f_1^2 e_1 \vee e_1 + 2 f_1 f_2 e_1 \vee e_2 + f_2^2 e_2 \vee e_2 \tag{2.100}$$

The result may be represented with the matrix

$$\begin{bmatrix} f_1^2 & 2 f_1 f_2 & f_2^2 \end{bmatrix}^{\mathrm{T}} \tag{2.101}$$

Because $p = 2$, the basis vectors of interest are seen to be $\{e_1 \vee e_1, e_1 \vee e_2, e_2 \vee e_2\}$. Inserted into the expression for m_{sym}, these produce the results m_{11}, $m_{12} = m_{21}$, m_{22}, respectively. Thus,

$$[M_{sym}] = [m_{11} \quad m_{12} \quad m_{22}] \tag{2.102}$$

Finally, the symmetric tensor expression for m_{sym} is

$$m_{sym}(f_1, f_2) = [m_{11} \quad m_{12} \quad m_{22}] \begin{bmatrix} f_1^2 \\ 2f_1 f_2 \\ f_2^2 \end{bmatrix} \tag{2.103}$$

Example

If M, as in the previous example, is real and symmetric, then it is known to satisfy the equation

$$ME = E\Lambda \tag{2.104}$$

where E is a matrix of eigenvectors of M, satisfying $E^T E = I$, and Λ is a diagonal matrix of eigenvalues $\{\lambda_i\}$, which are real. Then,

$$M = E\Lambda E^T \tag{2.105}$$

and the quadratic form $u^T M u$ becomes

$$u^T M u = [E^T u]^T \Lambda [E^T u] \tag{2.106}$$

$$= \sum_{i=1}^{p} \lambda_i [E^T u]_i \tag{2.107}$$

When one considers u to be an arbitrary vector in R^p, this quadratic form is nonnegative for all u if and only if the $\{\lambda_i\}$ are nonnegative and is positive for all nonzero u if and only if the $\{\lambda_i\}$ are positive. M is then nonnegative definite and positive definite, respectively.

Example

With reference to the preceding example, it is sometimes of interest to choose $U = C^p$, where the reader is reminded that C denotes the complex numbers. In this case a similar discussion can be carried out, with M as a complex matrix. The quadratic form must be set up a bit differently, with the structure $u^* M u$, in which superscript * denotes a combined transposition and conjugation. Also, without loss one can assume that $M^* = M$. A common instance of this sort of situation occurs when M is a function $M(s)$ of the Laplace variable s, which is under consideration on the axis $s = j\omega$.

2.11 Summary

The basic idea of this chapter is to examine the axiomatic framework for equipping an F-vector space V with a vector multiplication, and thus developing it into an algebra. As vector multiplication is manifestly a nonlinear operation, a very useful matrix theory can be developed for such multiplications. The treatment is based upon notions of algebraic tensor products from which all other multiplications can

be derived. The authors demonstrate that the determinant is nothing but a product of vectors, with a special skew symmetric character attached to it. Specializations of the tensor product to such cases, and to the analogous case of symmetric products, were discussed.

As a final remark, it should be mentioned that tensor products develop into a complete algebra of their own. Although space does not permit treatment here, note that the key idea is the definition

$$(v_1 \otimes \cdots \otimes v_p) \otimes (v_{p+1} \otimes \cdots \otimes v_q) = v_1 \otimes \cdots \otimes v_q \tag{2.108}$$

3.1 Introduction

The Laplace transform (LT) is the cornerstone of classical circuits, systems, and control theory. Developed as a means of rendering cumbersome differential equation solution simple algebraic problems, the engineer has transcended this original motivation and has developed an extensive toolbag of analysis and design methods based on the "*s*-plane." After a motivating differential equation (circuit) problem is presented, this chapter introduces the formal principles of the LT, including its properties and methods for forward and inverse computation. The transform is then applied to the analysis of circuits and systems, exploring such topics as the system function and stability analysis. Two appendices conclude the chapter, one of which relates the LT to other signal transforms to be covered in this book.

3.2 Motivational Example

3.2.1 Series RLC Circuit

Let us motivate our study of the LT with a simple circuit example. Consider the series RLC circuit shown in Figure 3.1, in which we leave the component values unspecified for the moment. With the input and output to the circuit taken to be the voltages x and y, respectively, the input–output dynamics of this circuit are found to be governed by a linear, constant-coefficient differential equation

$$x(t) = LC\frac{d^2y}{dt^2} + RC\frac{dy}{dt} + y(t) \tag{3.1}$$

This equation arises from a circuit example, but is typical of many second-order systems arising in mechanical, fluid, acoustic, biomedical, chemical, and other engineering models. We can, therefore, view the circuit as a "system," and the theory explored here as having broad applicability in modeling and analysis of systems.

Suppose we are asked to find the complete solution for the output voltage y, given input

$$x(t) = M_x e^{\sigma_x t}\cos(\omega_x t + \theta_x)u(t) \tag{3.2}$$

in which u denotes the unit step function,

$$u(t) \stackrel{\text{def}}{=} \{0,\ t < 0 \quad 1/2,\ t = 0 \quad 1,\ t > 0\} \tag{3.3}$$

For convenience and without loss of generality we assume that $M_x > 0$. The initial conditions (at time $t(0^-)$) on the circuit are given to be* $i(0^-) = i_0$ and $y(0^-) = y_0$ where y_0 and i_0 are known quantities.

3.2.2 Homogeneous Solution and the Natural Response

The homogeneous or complementary solution of the differential equation, say $\tilde{y}$, represents the natural, or unforced, response of the system. The natural response occurs because of the inequity between the initial conditions and the conditions imposed upon the system by the input at the instant it is applied. The system must adjust to these new conditions and will do so in accordance with its own physical properties (e.g., circuit values). For stable systems (see Section 3.4.3), the natural response will consist of transients, signals which decay exponentially with time. The unforced response will always be present unless the system is stable, and either the input was applied at time $t = -\infty$ (transient will have diminished in the infinite time interval prior to time zero) or the initial conditions on the system exactly nullify the "shock" of the input so that a transient adjustment is not necessary. The form of the natural response (homogeneous solution) is not dependent on the input (except for its use in determining changes around time $t = 0$), but rather on the inherent properties of the system.

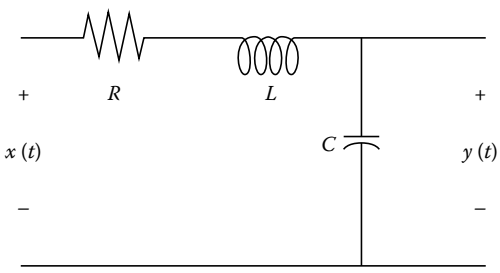

FIGURE 3.1 Series RLC circuit example.

* The notations 0^+ and 0^- indicate limits at $t = 0$ from the right and left, respectively. That $y(0^+) = y(0^-)$, for example, indicates continuity of $y(t)$ at $t = 0$.

The homogeneous solution is found by initially seeking the input-free response which may be written as

$$0 = (LC\mathcal{D}^2 + RC\mathcal{D} + 1)y(t) \quad \text{with } \mathcal{D}^i \stackrel{\text{def}}{=} \frac{\mathrm{d}^i}{\mathrm{d}t^i} \tag{3.4}$$

The characteristic equation is therefore

$$0 = (LCp^2 + RCp + 1) \tag{3.5}$$

Solving for the roots, we find

$$p_1, p_2 = \frac{-RC \pm \sqrt{R^2C^2 - 4LC}}{2LC} = -\frac{R}{2L} \pm \sqrt{\frac{R^2}{4L^2} - \frac{1}{LC}} \tag{3.6}$$

In general, p_1 and p_2 can be real and unequal (overdamped case), equal and real (critically damped case), or complex conjugates (underdamped case). Except in the critically damped case (in which $R^2C^2 = 4LC$ so that two identical real roots are found), the homogeneous solution takes the form.

$$\tilde{y}(t) = Ae^{p_1 t} + Be^{p_2 t} \tag{3.7}$$

with A and B to be specified at the end of the solution.

For the sake of discussion, assume the underdamped case in which the natural response will be oscillatory, corresponding to a complex-conjugate pair of roots of Equation 3.5. In this case we have $R^2C^2 < 4LC$ and $p_2 = p_1^*$. Let us define $p_h \stackrel{\text{def}}{=} p_1$, so the two roots are p_h and $= p_h^*$. The meaning of the subscript "h" will become clear later. Some manipulation of Equation 3.7 will simplify our future work. We have

$$\tilde{y}(t) = Ae^{p_h t} + Be^{p_h^* t} \tag{3.8}$$

We observe that A and B must be complex conjugates if $\tilde{y}$ is to be a real signal. Thus, we write

$$\tilde{y}(t) = Ae^{p_h t} + A^* e^{p_h t} \tag{3.9}$$

After some manipulation using Euler's relation, $e^{j\alpha} = \cos(\alpha) + j\,\sin(\alpha)$, we have

$$\begin{aligned} \tilde{y}(t) &= 2A_{\text{re}} e^{\sigma_h t} \cos(\omega_h t) - 2A_{\text{im}} e^{\sigma_h t} \sin(\omega_h t) \\ &= 2|A| e^{\sigma_h t} \cos(\omega_h t + \theta_A) \end{aligned} \tag{3.10}$$

where $A = A_{\text{re}} + jA_{\text{im}} = |A|\, e^{j\theta_A}$ and $p_h = \sigma_h + j\omega_h$. The numbers A_{re} and A_{im}, or, equivalently, $|A|$ and θ_A, are to be determined later.* Note that the number p_h is often called the complex frequency associated with the damped† sinusoid. The complex frequency is simply a convenient mathematical way to hold the damping and frequency information in one quantity. Later in the chapter we see that p_h is also a "pole" of the system being analyzed.

---

* In fact, because A_{re} and A_{im} are unknowns, we could replace $2A_{\text{re}}$, $2A_{\text{im}}$, and $2|A|$ with some simpler notations if desired.

† We use the term "damping" to refer to the real part of any complex frequency, "σ," with the understanding that two other cases are actually possible: If $\sigma = 0$ the signal is undamped, and if $\sigma > 0$, the signal is exponentially increasing.

3.2.3 Nonhomogeneous Solution and the Forced Response

The nonhomogeneous, or particular solution, say $\tilde{\tilde{y}}$, represents the system's forced, or driven, response. For certain prevalent types of inputs, the forced response represents an attempt to "track" the forcing function in some sense. If the natural response in a particular problem is transient and the forced response is not, then a "long time" (theoretically, $t \to \infty$) after the input is applied, only this "tracking" response will remain. In the present circuit example the forced response is uniquely present as $t \to \infty$ if $\sigma_h < 0$ (natural response exponentially decays) and $\sigma_x \geq 0$ (forcing function persists in driving the circuit for all time). Further, in the special case in which the forcing function is a periodic or constant signal (an undamped sinusoid, undamped complex exponential, or a constant (in each case $\sigma_x = 0$)), this "tracking" response, in the absence of any transients, is called the steady-state response of the system. Note that the forced response will be present for all $t > 0$, but may become uniquely evident only after the transient natural response dies out. Also, note that the forced response might never become evident if it is itself a transient ($\sigma_x < 0$), even though in this case the forced response will still represent an attempt to track the input.

For mathematical convenience in finding $\tilde{\tilde{y}}$, we let x be replaced by

$$\begin{aligned} x(t) &= M_x e^{\sigma_x(j\omega_x t + 0_x)} u(t) \\ &= [M_x e^{\sigma_x t}\cos(\omega_x t + \theta_x)] + [jM_x e^{\sigma_x t}\sin(\omega_x t + \theta_x)]u(t) \end{aligned} \tag{3.11}$$

Because of the linearity of the system, the real and imaginary parts of the solution $\tilde{\tilde{y}}$ will correspond to the real and imaginary parts of the complex x. Because we want the response to the real part (the cosine), we simply take the real part of the solution at the end.* It is extremely useful to rewrite Equation 3.11 as

$$x(t) = M_x e^{j\theta_x} e^{(\sigma_x + j\omega_x)t} u(t) = M_x e^{j\theta_x} e^{p_x t} u(t) \tag{3.12}$$

We shall call the complex number $\overline{X} = M_x e^{j\theta_x}$ a generalized phasor for the sinusoid, noting that the quantity is a conventional phasor (see, e.g., [5]) when $\sigma_x = 0$ (i.e., when x represents an undamped sinusoid). The complex frequency associated with the signal x is $p_x \stackrel{\text{def}}{=} \sigma_x + j\omega_x$.

Any signal that can be written as a sum of exponentials will be an eigensignal of a linear, time-variant (LTI) system such as the present circuit. The forced response of a system to an eigensignal is a scaled, time-shifted version of the eigensignal. This means that an eigensignal generally has its amplitude and phase altered by the system, but never its frequency! Many signals used in engineering analysis are eigensignals. This is the case with the present input x.

Because x is an eigensignal, the nonhomogeneous solution will be of the form

$$\tilde{\tilde{y}}(t) = |H(p_x)| M_x e^{\sigma_x t} e^{j(\omega_x t + \theta_x + \arg\{H(p_x)\})} = M_y e^{j\theta_y} e^{P_x t} \tag{3.13}$$

where $|H(p_x)|$ represents the amplitude scaling imposed upon a signal of complex frequency p_x, and arg $\{H(p_x)\}$ is the phase shift. For the moment, do not be concerned about the seemingly excessive notation $|H(p_x)|$ and $\arg\{H(p_x)\}$. The number $H(p_x) = |H(p_x)| e^{j\arg\{H(p_x)\}}$, called the eigenvalue of the system for complex frequency p_x, is a package containing the scaling and phase change induced upon a sinusoid or exponential input of complex frequency p_x. In Equation 3.13 we have implicitly defined $M_y \stackrel{\text{def}}{=} |H(p_x)| M_x$ and $\theta_y = \theta_x + \arg\{\mathrm{H(p_x)}\}$, noting that

$$\overline{Y} = M_y e^{j\theta_y} = H(p_x) M_x e^{j\theta_x} = H(p_x)\overline{X} \tag{3.14}$$

is the generalized phasor for the forced response $\tilde{\tilde{y}}$.

* Alternatively, we could also find the response $x^*(t)$, and average the two responses at each t.

Let us now put the expressions (Equations 3.12 and 3.13) into the differential equation (Equation 3.1) (ignoring the $u(t)$ because we are seeking a solution for $t > 0$)

$$M_x e^{j\theta_x} e^{p_x t} = p_x^2 LCM_y e^{j\theta_y} e^{p_x t} + p_x RCM_y e^{j\theta_y} e^{p_x t} + M_y e^{j\theta_y} e^{p_x t} \tag{3.15}$$

Dividing through by e^{pxt} (note this critical step),

$$M_x e^{j\theta_x} = p_x^2 LCM_y e^{j\theta_y} + p_x RCM_y e^{j\theta_y} + M_y e^{j\theta_y} \tag{3.16}$$

Isolating $M_y e^{j\theta_y}$ on the left side of Equation 3.16, we have

$$M_y e^{j\theta_y} = \frac{M_x e^{j\theta_x}}{LCp_x^2 + RCp_x + 1} \tag{3.17}$$

Because all quantities on the right are known, we can now solve for M_y and θ_y. For example (so that we can compare this result with future work), suppose we have system parameters

$$L = 2 \text{ H}, \quad C = 1 \text{ F}, \quad R = 1\ \Omega, \quad y_0 = \frac{1}{2} \text{ V}, \quad i_0 = 0 \text{ A} \tag{3.18}$$

and signal parameters

$$M_x = 3V, \quad \sigma_x = -0.1/\text{s}, \quad \omega_x = 1\,\text{rad/s} \quad \theta_x = \pi/4\,\text{rad} \tag{3.19}$$

Then we find $M_y e^{j\theta_y} = 2.076e^{-j(0.519\pi)}$.

Whatever the specific numbers, let us now assume that M_y and θ_y are known. We have

$$\tilde{\tilde{y}}(t) = M_y e^{j\theta_y} e^{(\sigma_x + j\omega_x)t} \tag{3.20}$$

Taking the real part,

$$\tilde{\tilde{y}}(t) = M_y e^{\sigma_x t} \cos(\omega_x t + \theta_y) \tag{3.21}$$

This nonhomogeneous solution is valid for $t > 0$

3.2.4 Total Solution

Combining the previous results, we obtain the complete solution for $t > 0$.

$$y(t) = \tilde{y}(t) + \tilde{\tilde{y}}(t) = 2|A|e^{\sigma_h t} \cos(\omega_h t + \theta_A) + M_y e^{\sigma_x t} \cos(\omega_x t + \theta_y) \tag{3.22}$$

We must apply the initial conditions to find the unknown numbers $|A|$ and θ_A. By a physical considerations we know $y(0^+) = y(0^-) = y_0$ and $i(0^+) = i(0^-) = i_0$, so

$$y(0) = y_0 = 2|A| \cos(\theta_A) + M_y \cos(\theta_y) \tag{3.23}$$

and

$$i(0) = i_0 = C\frac{dy}{dt}\bigg|_{t=0} = 2|A|C[\sigma_h \cos(\theta_A) - \omega_h \sin(\theta_A)] + M_y C[\sigma_h \cos(\theta_A) - \omega_h \sin(\theta_A)] \tag{3.24}$$

These two equations can be solved for $|A|$ and θ_A. For example, for the numbers given in Equations 3.18 and 3.19, using Equation 3.6 we find that $p_h = -1/4 + j\sqrt{7}/4$ and $A = 0.416e^{j(0.230\pi)}$. Whatever the specific numbers, let us assume that $|A|$ and θ_A are known. Then, putting all the known numbers back into Equation 3.23 gives a complete solution for $t > 0$.

3.2.5 Scrutinizing the Solution

The first term in the final solution, Equation 3.22, comprises the unforced response and corresponds to the homogeneous solution of the differential equation in conjunction with the information provided by the initial conditions. Notice that this response involves only parameters dependent upon the circuit components, e.g., σ_h and ω_h, and information provided by the initial conditions, $A = |A|e^{j\theta A}$. The latter term in Equation 3.22 is the forced response. We reemphasize that this part of the response, which corresponds to the nonhomogeneous solution to the differential equation, is of the same form as the forcing function x and that the system has only scaled and time-shifted (as reflected in the phase angle) the input.

It is important to understand that the natural or unforced response is not altogether unrelated to the forcing function. The adjustment that the circuit must make (using its own natural modes) depends on the discrepancy at time zero between the actual initial conditions on the circuit components and the conditions the input would "like" to impose on the components as the forcing begins. Accordingly, we can identify two parts of the natural solution, one due to the initial energy storage, the other to the "shock" of the input at time zero. We can see this in the example above by reconsidering Equations 3.23 and 3.24 and rewriting them as

$$y_0 = 2A_{\text{re}} + M_y \cos(\theta_y) \tag{3.25}$$

and

$$\frac{i_0}{C} = 2[A_{\text{re}}\sigma_h - A_{\text{im}}\omega_h] + M_y\left[\sigma_x \cos(\theta_y) - \omega_x \sin(\theta_y)\right] \tag{3.26}$$

Solving

$$A_{\text{re}} = \frac{y_0}{2} - \frac{M_y \cos(\theta_y)}{2} \tag{3.27}$$

$$A_{\text{im}} = \frac{\sigma_h y_0 - (i_0/C)}{2\omega_h} + \frac{M_y \cos(\theta_y)(\sigma_x - \sigma_h) - M_y \sin(\theta_y)\omega_x}{2\omega_h} \tag{3.28}$$

We see that each of the real and imaginary parts of the complex number A can be decomposed into a part depending on initial circuit conditions, y_0 and i_0, and a part depending on the system's interaction with the input at the initial instant. Accordingly, we may write

$$A = A_{\text{ic}} + A_{\text{input}} \tag{3.29}$$

where $A_{\text{ic}} = A_{\text{re,ic}} + jA_{\text{im,ic}}$ and $A_{\text{input}} = A_{\text{re,input}} + jA_{\text{im,input}}$. In polar form $A_{\text{ic}} = |A_{\text{ic}}|e^{j\theta A_{\text{ic}}}$ and $A_{\text{input}} = |A_{\text{input}}|e^{j\theta A_{\text{input}}}$. Therefore, the homogeneous solution can be decomposed into parts

$$\tilde{y}(t) = \tilde{y}_{\text{ic}}(t) + \tilde{y}_{\text{input}}(t) = 2|A_{ic}|e^{\sigma_h t}\cos(\omega_h t + \theta_{A_{\text{ic}}}) + 2\left|A_{\text{input}}\right|e^{\sigma_h t}\cos(\omega_h t + \theta_{A_{\text{input}}}) \tag{3.30}$$

Hence, we observe that a natural response may occur even if the initial conditions on the circuit are zero. The combined natural and forced response in this case, $\tilde{\tilde{y}}(t) + \tilde{y}_{\text{input}}(t)$, is called the zero-state response to indicate the state of zero energy storage in the system at time $t = 0$. On the other hand, the response to initial energy *only*, $\tilde{y}_{\text{ic}}$, is called the zero-input response for the obvious reason.

3.2.6 Generalizing the Phasor Concept: Onward to the Laplace Transform

To begin to understand the meaning of the LT, we reflect on the process of solving the circuit problem above. Although we could examine this solution deeply to understand the LT connections to both the natural and forced responses, it is sufficient for current purposes to examine only the forced solution.

Because the input to the system is an eigensignal previously, we could assume that the form of $\tilde{\tilde{y}}$ would be identical to that of x, with modifications only to the magnitude and phase. In noting that both x and $\tilde{\tilde{y}}$ would be of the form $Me^{j\theta}$, it seems reasonable that the somewhat tedious nonhomogeneous solution would eventually reduce to an algebraic solution to find M_y and θ_y from M_x and θ_x. All information needed and sought is found in the phasor quantities $\overline{X}$ and $\overline{Y}$ in conjunction with the system information. The critical step which converted the differential equation solution to an algebraic one comes in Equation 3.16 in which the superfluous term $e^{p_x t}$ is divided out of the equation.

Also observe that the ratio $H(p_x) = M_y e^{j\theta_y}/M_x e^{j\theta_x}$ depends only on system parameters and the complex frequency of the input, $p_x = \sigma_x + j\omega_x$. In fact, this ratio, when considered a function, e.g., H, of a general complex frequency, say, $s = \sigma + j\omega$, is called the system function for the circuit. In the present example, we see that

$$H(s) = \frac{1}{LCs^2 + RCs + 1} \tag{3.31}$$

The complex number $H(s)$, $s = \sigma + j\omega$, contains the scaling and delay (phase) information induced by the system on a signal with damping σ and frequency ω.

Let us now consider a slightly more general class of driving signals. Suppose we had begun the analysis above with a more complicated input of the form*

$$x(t) = \sum_{i=1}^{N} M_i e^{\sigma_i t} \cos(\omega_i t + \theta_i) \tag{3.32}$$

which, for convenience, would have been replaced by

$$x(t) = \sum_{i=1}^{N} M_i e^{j\theta_i} e^{(\sigma_i + j\omega_i)t} = \sum_{i=1}^{N} M_i e^{j\theta_i} e^{p_i t} \tag{3.33}$$

in the nonhomogeneous solution. It follows immediately from linearity that the solution could be obtained by entering each of the components in the input individually, and then combining the N solutions at the output. In each case we would clearly need to rid the analysis of the superfluous term of the form $e^{p_i t}$ by division. This information is equivalent to the form $e^{\sigma_i t}\cos(\omega_i t)$ which is known to automatically carry through to the output.

Now, recalling that $M_i e^{j\theta i}$ is the generalized phasor for the ith component in Equation 3.33, let us rewrite this expression as

* We omit the unit step u which appears in the input above because we are concerned only with the forced response for $t > 0$.

$$x(t) = \sum_{i=1}^{N} \overline{X}(p_i) e^{p_i t} \tag{3.34}$$

where $\overline{X}(p_i) \stackrel{\text{def}}{=} M_i e^{j\theta_i}$. Expression (Equation 3.34) is similar to a Fourier series (FS) (see Chapter 4), except that here (unless all $\sigma_i = 0$) the signal is only "pseudoperiodic" in that all of its sinusoidal components may be decaying or expanding in amplitude. The generalized phasors $\overline{X}(p_i)$ are similar to FS coefficients and contain all the information (amplitude and phase) necessary to obtain steady-state solutions. These phasors comprise frequency domain information as they contain packets of amplitude and phase information for particular complex frequencies.

With the concepts gleaned from this example, we are now prepared to introduce LT in earnest.

3.3 Formal Developments

3.3.1 Definitions of the Unilateral and Bilateral Laplace Transforms

Most signals used in engineering analysis and design of circuits and filters can be modeled as a sort of limiting case of Equation 3.34. Such a representation includes not just several complex frequency exponentials as in Equation 3.34, but an uncountably infinite number of such exponentials, one for every possible value of frequency ω. Each of these exponentials is weighted by a "generalized phasor" of infinitesimal magnitude. The exponential at complex frequency $s = \sigma + j\omega$, for example, is weighted by phasor $\overline{X}(\sigma + j\omega)\mathrm{d}\omega/2\pi$, where the differential dω assures the infinitesimal magnitude and the scale factor of 2π is included by convention. The uncountably infinite number of terms is "summed" by integration as follows:

$$x(t) = \int_{-\infty}^{\infty} \overline{X}(\sigma + j\omega) \frac{\mathrm{d}\omega}{2\pi} e^{(\sigma + j\omega)t} \tag{3.35}$$

The number σ in this representation is arbitrary as long as the integral exists. In fact, if the integral converges for any σ, then the integral exists for an uncountable infinite number of σ.

The complex function $\overline{X}(\sigma + j\omega)$ in Equation 3.35 is the LT for the signal $x(t)$. Based on the foregoing discussion, we can interpret the LT as a complex-frequency-dependent, uncountable infinite set of "phasor densities" containing all the magnitude and phase information necessary to find forced solutions for LTI systems. We use the word "density" here to indicate that the LT at complex frequency $\sigma + j\omega$ must be multiplied by the differential $\mathrm{d}\omega/2\pi$ to become properly analogous to a phasor. The LT, therefore has, for example, units volts per hertz. However, we find that the LT is much more than just a phasor-like representation, providing a rich set of analysis tools with which to design and analyze systems, including unforced responses, transients, and stability.

As in the preceding simpler examples, the solution of differential equations will be made easier by ridding the signals of superfluous complex exponentials of form $e^{(\sigma + j\omega)}$, that is, by working directly with LTs. Before doing so we change variables, to put Equation 3.35 into a more conventional form. Let s denote the general complex frequency $s \stackrel{\text{def}}{=} \sigma + j\omega$. Then

$$x(t) = \frac{1}{j2\pi} \int_{\sigma - j\infty}^{\sigma + j\infty} X(s) e^{st} \mathrm{d}s \tag{3.36}$$

where we have dropped the bar over the LT, X. This integral, which we have interpreted as an "expansion" of the signal x in terms of an uncountably infinite set of infinitesimal generalized phasors

and complex exponentials, offers a means for obtaining the signal x from the LT, X. Accordingly, Equation 3.36 is known as the inverse Laplace transform (inverse LT). The inverse LT operation is often denoted

$$x(t) = \mathcal{L}^{-1}\{X(s)\} \tag{3.37}$$

How one would evaluate such an integral and for what values of s it would exist are issues we shall address later.

In order to rid the signal x of the superfluous factors e^{st}, we can simply compute the LT. Without any rigorous attempt to derive the transform from Equation 3.36, it is believed that

$$X(s) = \int_{-\infty}^{\infty} \frac{x(t)}{e^{st}}\,\mathrm{d}t = \int_{-\infty}^{\infty} x(t)e^{-st}\,\mathrm{d}t \tag{3.38}$$

This is the bilateral, or two-sided, Laplace transform (BLT). The descriptor ''bilateral'' or ''two-sided'' is a reference to the fact that the signal may be nonzero in both positive and negative time. In contrast, the unilateral, or one-sided, Laplace transform (ULT) is defined as

$$X(s) = \int_{0^-}^{\infty} \frac{x(t)}{e^{st}}\,\mathrm{d}t = \int_{0^-}^{\infty} x(t)e^{-st}\,\mathrm{d}t \tag{3.39}$$

When a signal is zero all for $t < 0$, the ULT and BLT are identical. The same inverse LT, Equation 3.36, is applied in either case, with the understanding that the resulting time signal is zero by assumption in the ULT case. While the BLT can be used to treat a more general class of signals, we find that ULT has the advantage of allowing us to find the component of the natural response due to nonzero initial conditions. In other words, ULT is used to analyze signals that ''start'' somewhere, a time we conventionally call* $t = 0$.

These transformations are reminiscent of the process of dividing through by the complex exponential which was first encountered in the forced solution in the motivating circuit problem (see Equation 3.16).

3.3.2 Existence of the Laplace Transform

The variable $s = \sigma + j\omega$ is a complex variable over which the LT is calculated. The complex plane with σ along the abscissa and $j\omega$ on the ordinate, is called the s-plane. We find some powerful tools centered on the s-plane below. Note that the s-plane is not the LT, nor can the LT be ''plotted'' in the s-plane. The LT is a complex function of the complex variable s, and a plot of the LT would require another two dimensions ''over'' the s-plane. For this reason, we need to place some constraints on either s or $X(s)$ or both to create a plot. For example, we could use the LT to plot $|X(j\omega)|$ as a function of ω, by evaluating the magnitude of $X(s)$ along the $j\omega$-axis in the s-plane.† An illustration of these points is found in Figure 3.2.

We now address the question: For what values of s (i.e., ''where'' in the s-*p*lane) does the LT exist? Consider first a two-sided (in time) signal, *x*. x is assumed piecewise continuous in every finite interval of the real line. We assert that the BLT X ordinarily exists in the s-plane in a strip of the form

$$\sigma_+ < \mathrm{Re}\{s\} = \sigma < \sigma_- \tag{3.40}$$

as illustrated in Figure 3.3. In special cases the BLT may converge in the half-plane $\sigma_+ < \sigma$, or the half-plane $\sigma < \sigma_-$, or even in the entire s-plane.

---

* Note that if we apply the ULT to a signal $x(t)$ that ''starts'' in negative time, the result will be identical to that for the signal $x(t)\,u(t)$.

† This particular plot is equivalent to the magnitude spectrum of the signal that could be obtained using Fourier techniques discussed in Chapter 4.

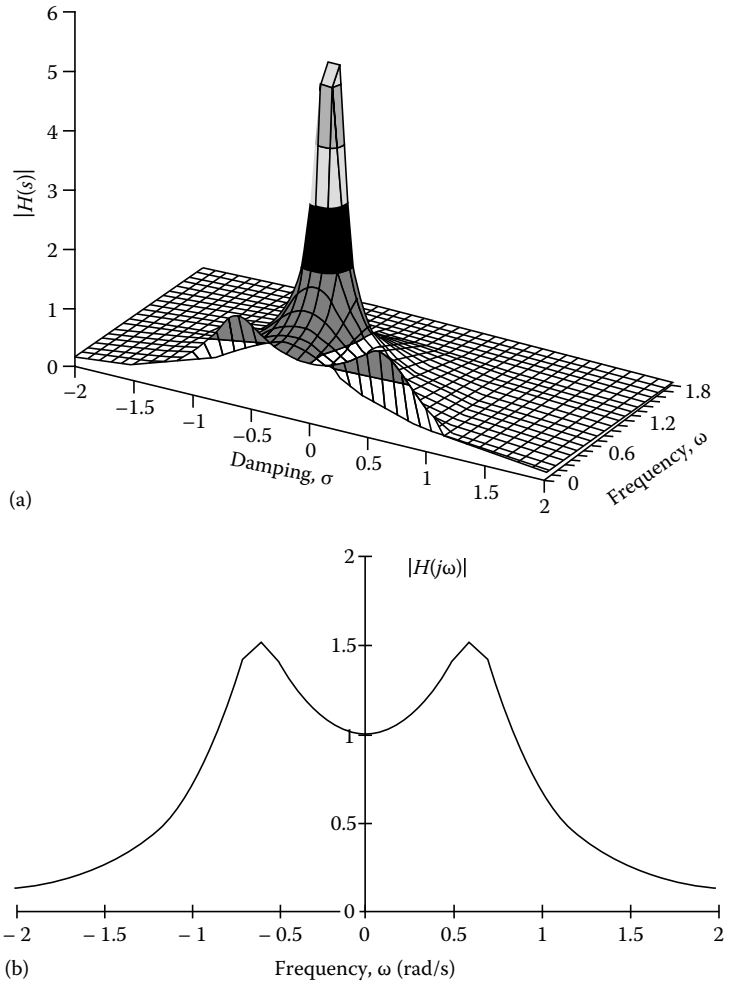

FIGURE 3.2 LT is called "H" instead of "X" in this figure for a reason to be discovered later. (a) A plot of $|H(s)|$ vs. s for the LT $H(s) = (0.5)/(s^2 + 0.5s + 0.5)$. Only the upper-half s-plane is shown ($\omega \geq 0$). Note that the peak occurs near the value $p_h = -1/4 + j\sqrt{7}/4$, as a root of the denominator of $H(s)$, which we shall later call a pole of the LT. The LT is theoretically infinite at $s = p_h$. (b) Evaluation of $|H(s)|$ along the $j\omega$-axis (corresponding to $\sigma = 0$) with the magnitude plotted as function of ω.

The boundary values σ_+ and σ_- are associated with the positive-time and negative-time portions of the signal, respectively. The minimum possible value of σ_+ and maximum possible value of σ_- are called the abscissas of absolute convergence. We henceforth use the notations σ_+ and σ_- to explicitly mean these extreme values. The vertical strip between but exclusive of, these abscissas is called the region of convergence (ROC) for the LT. In the special cases the ROC extends indefinitely from a single abscissa to the right ($\sigma_+ < \sigma$) or left ($\sigma < \sigma_-$) or covers the entire s-plane.

To verify that Equation 3.40 is a correct description of the ROC consider the positive-time part of x first. We maintain that $X(s)$ will exist on any s such that $\mathrm{Re}\{s\} = \sigma > \sigma_+$, if and only if (iff) a positive M exists such x is bounded by $Me^{\sigma_+ t}$ on $t \geq 0$,

$$|x(t)| < Me^{\sigma_+ t} \quad t \geq 0 \tag{3.41}$$

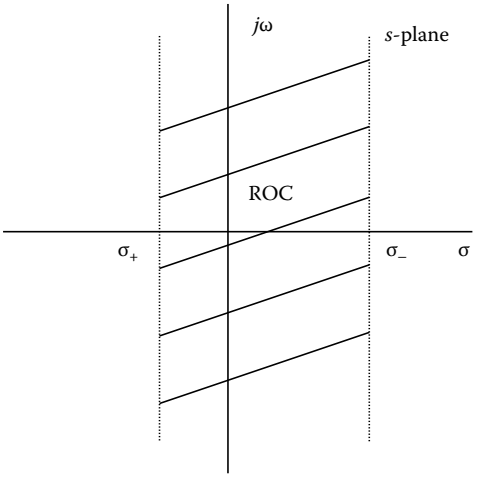

FIGURE 3.3 Except in special cases, the region of convergence for the BLT will be a vertical strip in the *s*-plane. This strip need not contain the *j*ω-axis as is the case in this illustration.

Under this condition (letting X_+ denote the LT of nonnegative-time part of x),

$$\begin{aligned}|X_+(s)| &= \left|\int_0^\infty x(t)e^{-st}\mathrm{d}t\right| \\ &\le \int_0^\infty |x(t)e^{-st}|\mathrm{d}t \\ &\le \int_0^\infty |x(t)|e^{-\sigma t}\mathrm{d}t < \int_0^\infty Me^{(\sigma_+-\sigma)t}\mathrm{d}t \\ &= \begin{cases} \dfrac{M}{\sigma-\sigma_+}, & \sigma > \sigma_+ \\ \infty, & \text{otherwise} \end{cases}\end{aligned} \tag{3.42}$$

If there is no finite, positive M such that Equation 3.30 holds, then the signal grows faster than $e^{-\sigma+t}$ and the LT integral (area under $x(t)e^{-\sigma+t}e^{j\omega t}$) will not converge for at least some value of s in the neighborhood of the vertical line $s=\sigma_+$. In this case, σ_+ is not a proper abscissa.

By similar means, we can argue that the negative-time part of x must be bounded as

$$|x(t)| < Me^{\sigma_- t}, \quad t < 0 \tag{3.43}$$

for some positive M, if the corresponding part of the LT, say X_-, is to converge at s such that $\mathrm{Re}\{s\}=\sigma<\sigma_-$. Similarly to Equation 3.42 it is shown that

$$\begin{aligned}|X_-(s)| &= \left|\int_{-\infty}^0 x(t)e^{-st}\mathrm{d}t\right| < \int_{-\infty}^0 Me^{(\sigma_--\sigma)t}\mathrm{d}t \\ &= \begin{cases} \dfrac{M}{\sigma_--\sigma}, & \sigma > \sigma_- \\ \infty, & \text{otherwise} \end{cases}\end{aligned} \tag{3.44}$$

and X_- will not converge in some left neighborhood of $\sigma=\sigma_-$ if the condition (Equation 3.43) is not met.

It should be clear from the discussion of the BLT that a ULT will ordinarily converge in the half-plane $\mathrm{Re}\{s\}=\sigma>\sigma_+$ iff a positive M exists such that Equation 3.41 is met. This follows immediately from the fact that the ULT of $x(t)$ is equivalent to the BLT of $x(t)u(t)$. The ''negative-time'' part of $x(t)$ yields $X_-(s)=0$ which converges everywhere in the s-plane. The ULT may also converge everywhere in the s-plane in special cases.

3.3.3 Example of Laplace Transform Computations and Table of Unilateral Laplace Transforms

A listing of commonly used ULTs with ROCs is given in Table 3.1. Each entry in the table can be verified by direct computation of the appropriate LT integral, or in many cases, properties of the LT can be exploited to make the computation easier. These properties are developed in Section 3.3.5.

TABLE 3.1 Table of ULT Pairs

Signal, $x(t)$	ULT, $X(s)$	ROC
$d(t)$	1	Entire s-plane
$\frac{d^k\delta}{dt^k}$	s^k	Entire s-plane
$u(t)$	$\frac{1}{s}$	$\{s : \sigma > 0\}$
$t^{n-1}u(t)$	$\frac{(n-1)!}{s^n}$	$\{s : \sigma > 0\}$
$e^{p_x t}u(t)$	$\frac{1}{(s-p_x)}$	$\{s : \sigma > \sigma_x\}$
$t^n e^{p_x t}\ u(t)$	$\frac{n!}{(s-p_x)^{n+1}}$	$\{s : \sigma > \sigma_x\}$
$\cos(\omega_x t + \theta_x)u(t)$	$\frac{s\cos(\theta_x) - \omega_x \sin(\theta_x)}{s^2 + \omega_x^2}$	$\{s : \sigma > 0\}$
$e^{\sigma_x t}\cos(\omega_x t + \theta_x)\ u(t)$	$\frac{(s-\sigma_x)\cos(\theta_x) - \omega_x \sin(\theta_x)}{(s-\sigma_x)^2 + \omega_x^2}$	$\{s : \sigma > \sigma_x\}$
$M_x t^{n-1} e^{\sigma_x t}\cos(\omega_x t + \theta_x)u(t)$	$\frac{E}{(s-p_x)^n} + \frac{E*}{(s-p_x*)^n}$; M_x real and positive, $E = \frac{M_x}{2}(n-1)!e^{j\theta_x}$	$\{s : \sigma > \sigma_x\}$

Note: In each entry, s is the general complex number $\sigma + j\omega$, and, where relevant, p_x is the specific complex number $\sigma_x + j\omega_x$.

It is rare to find a table of BLTs in engineering material because most of our work is done with the ULT. However, BLTs can often be found by summing the results of two ULTs in the following way. Suppose x is written as

$$x(t) = x_+(t) + x_-(t) \tag{3.45}$$

where x_+ and x_- are the causal and anticasual parts of the signal, respectively. To obtain X_+, we can use a ULT table. To obtain X_-, note the following easily demonstrated property of the BLT: If $\mathcal{L}\{y(t)\} = Y(s)$ with ROC $\{s$: Re$\{s\} > a\}$, then $\mathcal{L}\{y(-t)\} = Y(-s)$ with ROC $\{s$: Re$\{s\} > -a\}$. Therefore, we can find $\mathcal{L}\{x_-(-t)\}$ in a ULT table, and replace the argument s by $-s$ to obtain X_(s). The $X(s) = X_+(s) + X_-(s)$. This strategy is illustrated in Example 3.1. The ROC of the sum will ordinarily be the intersection of the individual LTs X_+ and X_-, but the total ROC may be larger than this if a pole–zero cancellation occurs (see Section 3.3.4).

Let us consider some examples which illustrate the direct forward computation of the LT and the process discussed in the preceding paragraph.

Example 3.1

Find the BLT and ULT for the signal

$$x(t) = Ae^{at}u(-t) + Be^{bt}u(t) \quad |A|,|B| < \infty \tag{3.46}$$

Note that A, B, a, and b may be complex.

Solution

In the bilateral case, we have

$$\begin{aligned} X(s) &= \int_{-\infty}^{0_-} Ae^{at}e^{-st} + \int_{-\infty}^{0_-} Be^{bt}e^{-st}\mathrm{d}t \\ &= \frac{Ae^{(a-s)t}}{a-s}\Big|_{-\infty}^{0-} + \frac{Be^{(b-s)t}}{b-s}\Big|_{0-}^{\infty} \\ &= \begin{bmatrix} -\dfrac{A}{s-a}, & \mathrm{Re\{s\}} < \mathrm{Re\{a\}} \\ \infty, & \text{otherwise} \end{bmatrix} \\ &\quad + \begin{bmatrix} \dfrac{B}{s-b}, & \mathrm{Re\{s\}} > \mathrm{Re\{b\}} \\ \infty, & \text{otherwise} \end{bmatrix} \end{aligned} \tag{3.47}$$

The ROC for this LT is $\{s\colon \mathrm{Re}\{b\} < \mathrm{Re}\{s\} < \mathrm{Re}\{a\}\}$. The LT does not exist for any s for which $\mathrm{Re}\{s\} \geq \mathrm{Re}\{a\}$ or $\mathrm{Re}\{s\} \leq \mathrm{Re}\{b\}$. Note also that when $\mathrm{Re}\{b\} \geq \mathrm{Re}\{a\}$, then no ROC can be found, meaning that the BLT does not exist anywhere for the signal.

The ULT follows immediately from the previous work. We have

$$X(s) = \int_{0_-}^{\infty} Be^{bt}e^{-st}\mathrm{d}t = \begin{cases} \dfrac{B}{s-b}, & \mathrm{Re\{s\}} > \mathrm{Re\{b\}} \\ \infty, & \text{otherwise} \end{cases} \tag{3.48}$$

The ROC in this case is $\{s\colon \mathrm{Re}\{s\} > \mathrm{Re}\{b\}\}$. We need not be concerned about the negative-time part of the signal (and the associated ROC) because the LT effectively zeros the signal on $t < 0$.

Note. The result of this example is worth committing to memory because it will reappear frequently.

Note that if we had found the ULT, Equation 3.48, for the casual part of x in a table (call it $X_+(s)$), then we could employ the trick suggested above to find the LT for the anticausal part. Let x_- denote the negative-time part: $x_-(t) = Ae^{at}u(-t)$. We know that the LT of $x_-(-t) = Ae^{-at}u(t)$ (a casual signal) is

$$X_-(-s) = \frac{A}{s+a}, \quad \text{with ROC } \{s\colon \mathrm{Re\{s\}} > -\mathrm{a}\} \tag{3.49}$$

Therefore,

$$X_-(s) = \frac{-A}{s-a}, \quad \text{with ROC } \{s\colon \mathrm{Re\{s\}} < \mathrm{a}\} \tag{3.50}$$

The overall BLT result is then $X(s) = X_+(s) + X_-(s)$ with ROC equal to the intersection of the individual results. This is consistent with the BLT found by direct integration.

The preceding simple example suggests that the BLT can treat a broader class of signals at the expense of greater required care in locating its ROC. A further and related complication of the BLT is the nonuniqueness of the transform with respect to the time signals. Consider Example 3.2.

Example 3.2

Find the BLT for the following signals:

$$x_1(t) = e^{bt}u(t) \quad \text{and} \quad x_2(t) = -e^{bt}u(-t) \tag{3.51}$$

Solution

From our work in Example 3.1, we find immediately that

$$X_1(s) = \frac{1}{s-b}, \quad \text{Re\{s\}} > \text{Re\{b\}} \quad \text{and}$$
$$X_2(s) = \frac{1}{s-b}, \quad \text{Re\{s\}} < \text{Re\{b\}} \tag{3.52}$$

Neither X_1 nor X_2 can be unambiguously associated with a time signal without knowledge of its ROC.

Another drawback of the BLT is its inability to handle initial conditions in problems like the one that motivated our discussion. For this, reason, and also because signals tend to be casual (occurring only in positive time) in engineering problems, the ULT is more widely used and we shall focus on it exclusively after treating one more important topic in Section 3.3.4. Before moving to Section 3.3.4, let us tackle a few more example computations.

Example 3.3

Find the ULT of the impulse function, $\delta(t)$ (see Section 3.6).

Solution

$$\Delta(s) = \int_{0^-}^{\infty} \delta(t) e^{-st} dt = 1 \quad \text{for all } s \tag{3.53}$$

The LT converges everywhere in the s-plane. We note that the lower limit 0^- is important here to yield the answer 1 (which will provide consistency of the theory) instead of 1/2.

Example 3.4

Find the ULT of the unit step function, $u(t)$ (see Equation 3.3).

Solution

$$U(s) = \int_{0^-}^{\infty} 1 e^{-st} dt = \frac{-e^{-st}}{s}\bigg|_{0^-}^{\infty} = \frac{1}{s} \quad \text{for Re}\{s\} > 0 \tag{3.54}$$

The ROC for this transform consists of the entire right-half s-plane exclusive of the $j\omega$-axis.

Example 3.5

Find the ULT of the damped ($\sigma_x < 0$), undamped ($\sigma_x = 0$), or expanding ($\sigma_x > 0$) sinusoid, $x(t) = M_x e^{\sigma_x t} \cos(\omega_x t \mid \theta_x)\, u(t)$.

Solution

Using Euler's relation, write x as

$$x(t) = \frac{M_x}{2} e^{\sigma_x t}\left[e^{j(\omega_x t + \theta_x)} + e^{-j(\omega_x t + \theta_x)}\right] = \frac{M_x}{2}\left[e^{j\theta_x} e^{p_x t} + e^{-j\theta_x} e^{p_x^* t}\right] \tag{3.55}$$

with $p_x \stackrel{\text{def}}{=} \sigma_x + j\omega_x$. Taking the LT,

$$\begin{aligned} X(s) &= \frac{M_x}{2}\int_{0-}^{\infty}\left[e^{j\theta_x}e^{p_x t} + e^{-j\theta_x}e^{p_x^* t}\right]e^{-st}\,\mathrm{d}t \\ &= \int_{0-}^{\infty}\frac{M_x}{2}e^{j\theta_x}e^{p_x t}e^{-st}\,\mathrm{d}t + \int_{0-}^{\infty}\frac{M_x}{2}e^{-j\theta_x}e^{p_x^* t}e^{-st}\,\mathrm{d}t \end{aligned} \tag{3.56}$$

Now using Equation 3.48 on each of the integrals

$$X(s) = \frac{(M_x/2)e^{j\theta_x}}{(s-p_x)} + \frac{(M_x/2)e^{-j\theta_x}}{(s-p_x^*)} \tag{3.57}$$

with the ROC associated with each of the terms being $\mathrm{Re}\{s\} > \mathrm{Re}\{p_x\} = \sigma_x$. Putting the fractions over a common denominator yields

$$\begin{aligned} X(s) &= \frac{M_x}{2}\left[\frac{(s-p_x^*)e^{j\theta_x} + (s-p_x)e^{-j\theta_x}}{(s-p_x)(s-p_x^*)}\right] \\ &= \frac{M_x}{2}\left[\frac{\left(se^{j\theta_x} + se^{-j\theta_x} - p_x^*e^{j\theta_x} - p_x e^{-j\theta_x}\right)}{s^2 - 2\mathrm{Re}\{p_x\}s + |p_x|^2}\right] \\ &= M_x\left[\frac{(s-\sigma_x)\cos(\theta_x) - \omega_x\sin(\theta_x)}{(s-\sigma_x)^2 + \omega_x^2}\right] \end{aligned} \tag{3.58}$$

The ROC of X is $\{s\colon \mathrm{Re}\{s\} > \sigma_x\}$.

Note. The chain of denominators in Equation 3.58 is worth noting because these relations occur frequently in LT work.

$$(s-p_x)(s-p_x^*) = s^2 - 2\mathrm{Re}\{p_x\}s + |p_x|^2 = s^2 - 2\sigma_x s + |p_x|^2 = (s-\sigma_x)^2 + \omega_x^2 \tag{3.59}$$

3.3.4 Poles and Zeros—Part I

"Pole–zero" analysis is among the most important uses of the LT in circuit and system design and analysis. We need to take a brief look at some elementary theory of functions of complex variables in order to carefully describe the meaning of a pole or zero. When we study methods of inverting the LT in a future section, this side trip will prove to be especially useful.

Let us begin with a general function, F, of a complex variable s. We stress that $F(s)$ may or may not be an LT. F is said to be analytic at $s = a$ if it is differentiable at a and in a neighborhood of a. For example, $F(s) = s - 1$ is analytic everywhere (or entire), but $G(s) = |s|$ is nowhere analytic because its derivative exists only at $s = 0$. On the other hand, a point p is an isolated singular point of F if the derivative F does not exist at p, but F is analytic in a neighborhood of p. The function $F(s) = e^{-s}/(s-1)$ has a singular point at $s = 1$. There is a circular analytic domain around any singular point, p, of F, say $\{s\colon |s-p| < p\}$, in which the function F can be represented by a Laurent series [3],

$$F(s) = \sum_{i=0}^{\infty} q_{i,p}(s-p)^i + \sum_{i=1}^{\infty}\frac{r_{i,p}}{(s-p)^i} \tag{3.60}$$

The second sum in Equation 3.60 is called the principle part of the function F at p. When the principle part of F at p contains terms up to order n, the isolated singular point p is called an nth-order pole of F.

Evidently from Equation 3.60, F tends to infinity at a pole and the order of infinity is n. For future reference, we note that the complex number $r_p \stackrel{\text{def}}{=} r_{1,p}$ is called the residue of F at $s = p$.

A zero of F is more simply defined as a value of s, say z, at which F is analytic and for which $F(z) = 0$. If all the derivatives up to the $(m-1)$st are also zero at z, but mth is nonzero, then z is called an mth-order zero of F. It can be shown that the zeroes of an analytic function F are isolated, except in trivial case $F(s) = 0$ for all s [3].

Most LTs encountered in signal and system problems are quotients of polynomials in s, say

$$X(s) = \frac{N(s)}{D(s)} \tag{3.61}$$

because of the signals employed in engineering work, and because (as we shall see later) rational LTs are naturally associated with LTI systems. N and D connote "numerator" and "denominator." In this case both N and D are analytic everywhere in the s-plane, and the poles and zeroes of X are easily found by factoring the polynomials N and D, to express X in the form

$$X(s) = C\left(\prod_{i=1}^{n_N}(s - z_i) \Big/ \prod_{i=1}^{n_D}(s - p_i)\right) \tag{3.62}$$

where

n_N is the number of simple factors in $N(s)$ (order of N in s)
n_D is the number of simple factors in $D(s)$ (order of D in s)
C is a constant
X is called a proper rational LT if $n_D > n_N$

After canceling all factors common to the numerator and denominator, if m terms $(s - z)$ are left in the numerator, then X has an mth order zero at $s = z$. Similarly, if n terms $(s - p)$ are left in the denominator, then X has an nth order pole at $s = p$.

Although the LT does not exist outside the ROC, all of the poles will occur at values of s outside the ROC. None, some, or all of the zeros may also occur outside the ROC. This does not mean that the LT is valid outside the ROC, but that its poles and zeroes may occur there. A pole is ordinarily indicated in the s-plane by the symbol $\times$; whereas a zero is marked with a small circle $\circ$.

Example 3.6

Find the poles and zeros of the LT

$$X(s) = \frac{3s^2 + 9s + 9}{(s+2)(s^2 + 2s + 2)} \tag{3.63}$$

Solution

Factoring the top and bottom polynomials to put X in form Equation 3.62, we have

$$X(s) = 3\frac{\left(s + \left(3 - j\sqrt{3}\right)/2\right)\left(s + \left(3 + j\sqrt{3}\right)/2\right)}{(s+2)(s+1+j)(s+1-j)} \tag{3.64}$$

There are first-order zeros at $s = (-3 + j\sqrt{3})/2$ and $s = (-3 - j\sqrt{3})/2$, and first order-poles at $s = -2$, $s = -1 + j$, and $s = -1 - j$. The pole–zero diagram appears in Figure 3.4.

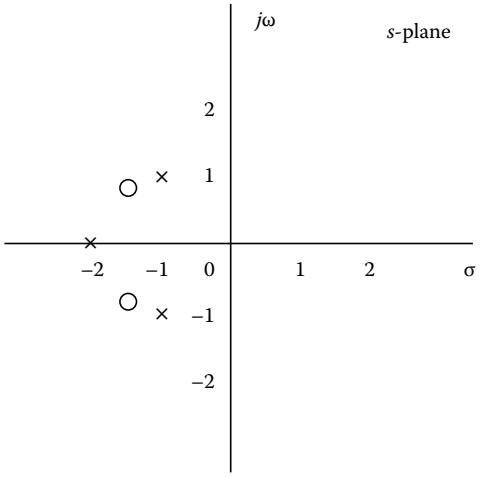

FIGURE 3.4 Pole–zero diagram for Example 3.6.

Two points are worth noting. First, complex poles and zeros will always occur in conjugate pairs, as they have here, if the LT corresponds to a real signal. Second, the denominator of Equation 3.64 also can be expressed as $(s+2)[(s+1)^2+1]$ (recall Equation 3.59). Comparing this form with the LT obtained in Example 3.5 suggests that the latter form might prove useful.

The purpose of introducing poles and zeros at this point in our discussion is to note the relationship of these singularities to the ROC. The preceding examples illustrate the following facts:

1. For a "right-sided" (nonnegative-time only) signal, x, the ROC of LT X (either ULT or BLT) is $\{s\colon \mathrm{Re}\{s\} > \mathrm{Re}\{p_+\} = \sigma_+\}$, where p_+ is the pole of X with maximum real part, namely, σ_+. If X has no poles, then the ROC is the entire s-plane.
2. For a "left-sided" (negative-time only) signal, x, the ROC of BLT X is $\{s\colon \mathrm{Re}\{s\} < \mathrm{Re}\{p_-\} = \sigma_-\}$, where p_- is the pole of X with minimum real part, namely, σ_-. If X has no poles, then the ROC is the entire s-plane.
3. For a "two-sided" signal x, the ROC of the BLT X is $\{s\colon \mathrm{Re}\{p_+\} = \sigma_+ < \mathrm{Re}\{s\} < \mathrm{Re}\{p_-\} = \sigma_-\}$ where p_+ is the pole of maximum real part associated with the right-sided part of x, and p_- is the pole of minimum real part associated with the left-sided part of x. If the right-sided signal has no pole, then the ROC extends indefinitely to the right in the s-plane. If the left-sided signal has no pole, then the ROC extends indefinitely to the left in the s-plane. Therefore, if neither part of the signal has a pole, then the ROC is the entire s-plane.

Let us revisit three of the previous examples to verify these claims. In Example 3.1, we found the ROC for the BLT to be $\{s\colon \mathrm{Re}\{b\} < \mathrm{Re}\{s\} < \mathrm{Re}\{a\}\}$. The only pole associated with the left-sided sequence is at $s = a$. The only pole associated with the right-sided signal occurs at $s = b$. Following rule 3 in the list above yields exactly the ROC determined by analytical means. The poles of X as well as the ROC are shown in Figure 3.5a.

In Example 3.4, we found the ROC to be the entire right-half s-plane, exclusive of the $j\omega$-axis. The single pole of $U(s) = 1/s$ occurs at $s = 0$. Figure 3.5b is consistent with rule 1.

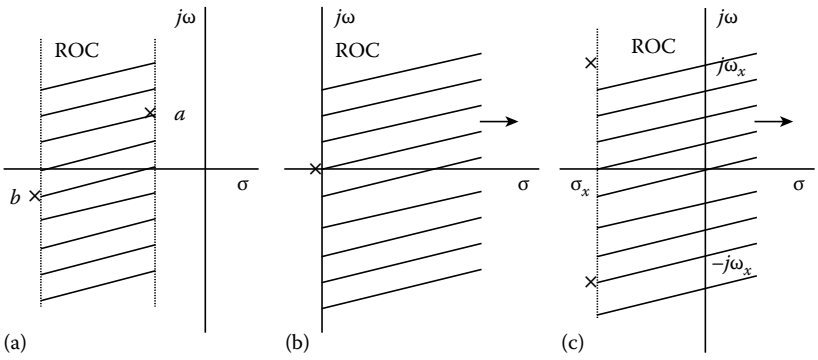

FIGURE 3.5 Pole–zero plots ROCs for the LTs of (a) Examples 3.1, (b) 3.4, and (c) 3.5.

The ULT of Example 3.5 has poles at $s = \sigma_x \pm j\omega_x$ and a zero at $s = \sigma_x + \omega_x \tan(\theta_x)$. Rule 1 therefore specifies that the ROC should be $\{s\colon \mathrm{Re}\{s\} > \mathrm{Re}\{\sigma_x \pm j\omega_x\} = \sigma_x\}$, which is consistent with the solution to Example 3.5. The pole–zero plot and ROC are illustrated in Figure 3.5c.

3.3.5 Properties of the Laplace Transform*

This section considers some properties of the LT which are useful in computing forward and inverse LTs, and in other manipulations occurring in signal and system design and analysis. A list of properties appears in Table 3.2.

In most cases, the verification of these properties follows in a straightforward manner from the definition of the transform. Consider the following examples. For convenience, we define the notation

$$x(t) \leftrightarrow X(s) \tag{3.65}$$

to mean that x and X are an LT pair, $X(s) = \mathcal{L}\{x(t)\}$.

TABLE 3.2 Operational Properties of the ULT

Description of Operation	Formal Operation	Corresponding LT
Linearity	$\alpha x(t) + \beta y(t)$	$\alpha X(s) + \beta Y(s)$
Time delay ($t_0 > 0$)	$x(t - t_0)u(t - t_0)$	$e^{-st_0} X(s)$
Exponential modulation in time (or complex frequency ("s") shift)	$e^{s_0 t} x(t)$	$X(s - s_0)$
Multiplication by t^k, $k = 1, 2, \ldots$	$t^k x(t)$	$(-1)^k \dfrac{\mathrm{d}^k X}{\mathrm{d}s^k}$
Time differentiation	$\dfrac{\mathrm{d}^k x}{\mathrm{d}t^k}$	$s^k X(s) - \displaystyle\sum_{i=0}^{k-1} s^i x^{(k-1-i)}(0^-)$
		$x^{(i)}(0^-) \stackrel{\text{def}}{=} \left.\dfrac{\mathrm{d}^i x}{\mathrm{d}t^i}\right\|_{t=0^-}$
Time integration	$\displaystyle\int_{-\infty}^{t} x(\lambda)\mathrm{d}(\lambda)$	$\dfrac{X(s)}{s} + \dfrac{x^{(-1)}(0^-)}{s}$
		$x^{(-1)}(0^-) \stackrel{\text{def}}{=} \left.\displaystyle\int_{-\infty}^{t} x(\lambda)\mathrm{d}(\lambda)\right\|_{t=0^-}$
Convolution	$\displaystyle\int_0^{\infty} x(\lambda) y(t - \lambda)\mathrm{d}\lambda$	$\boldsymbol{X(s)Y(s)}$
Correlation	$\displaystyle\int_0^{\infty} x(t) y(t + \tau)\mathrm{d}t$	$\boldsymbol{X(s)Y(-s)}$
Product (s-domain convolution)	$x(t)y(t)$	$\dfrac{1}{j2\pi}\displaystyle\int_{\sigma - j\infty}^{\sigma + j\infty} X(\lambda)Y(s - \lambda)\mathrm{d}\lambda$
Initial signal value (if time limit exists)	$\lim_{t \to 0^+} x(t)$	$\lim_{s \to \infty} sX(s)$
Final signal value (if time limit exists)	$\lim_{t \to \infty} x(t)$	$\lim_{s \to 0} sX(s)$
Time scaling	$x(\alpha t)$, $\alpha > 0$	$\dfrac{1}{\alpha} X\left(\dfrac{s}{\alpha}\right)$
Periodicity (period T)	$\displaystyle\sum_{i=0}^{\infty} x(t - iT)$	$\dfrac{X(s)}{(1 - e^{-sT})}$
	$x(t) = 0,\ t \notin [0, T]$	

Note: Throughout, X and Y are LTs of signals x and y, respectively; x and y are casual signals.

* Henceforth, this study restricts attention to the ULT and uses the acronym "LT" only.

Example 3.7

Verify the modulation property of the LT which states that if $x(t) \leftrightarrow X(s)$, then $e^{s0t}\, x(t) \leftrightarrow X(s - s_0)$.

Solution

By definition,

$$\begin{aligned}\mathcal{L}\{e^{s_0 t}x(t)\} &= \int_{0^-}^{\infty} e^{s_0 t}x(t)e^{-st}\,\mathrm{d}t \\ &= \int_{0^-}^{\infty} x(t)e^{-(s-s_0)}\,\mathrm{d}t = X(s - s_0)\end{aligned} \tag{3.66}$$

Example 3.8

Verify the periodicity property and find the LT for a square wave of period $T = 2$ and duty cycle 1/2.

Solution

Using the linearity and time-delay properties of the LT

$$\mathcal{L}\left\{\sum_{i=0}^{\infty} x(t - iT)\right\} = \sum_{i=0}^{\infty} X(s)e^{-siT} = X(s)\sum_{i=0}^{\infty} e^{-siT} = \frac{X(s)}{(1 - e^{-sT})} \tag{3.67}$$

Let us call the square wave $z(t)$ and its LT $Z(s)$. Now one period of z can be written as $x(t) = u(t) - u(t-1)$, $0 \le t < 2$ (see Figure 3.6). Using the delay property, therefore, $X(s) = (1/s) - (e^{-s}/s)$. Using Equation 3.67 with $T = 2$, we have

$$Z(s) = \frac{(1/s) - (e^{-s}/s)}{(1 - e^{-2s})} = \frac{(1 - e^{-s})}{s(1 - e^{-2s})} \tag{3.68}$$

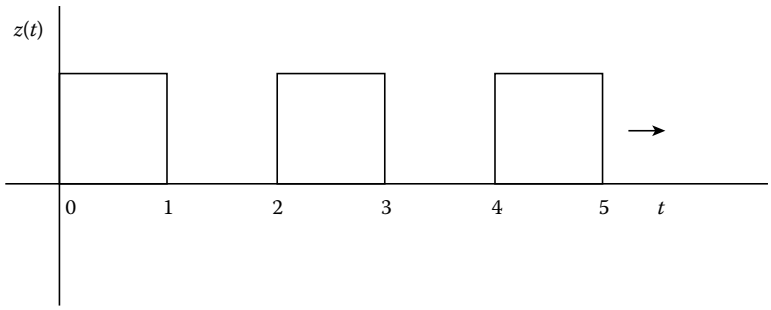

FIGURE 3.6 Square wave of Example 3.8.

Example 3.9

Verify the time-differentiation property of the LT which states that if $x(t) \leftrightarrow X(s)$, then $dx/dt \leftrightarrow sX(s) - x(0^-)$.

Solution

By definition, $\mathcal{L}\{dx/dt\} = \int_{0^-}^{\infty} (dx/dt)e^{-st}dt$. Integrating by parts yields

$$\mathcal{L}\left\{\frac{dx}{dt}\right\} = x(t)e^{-st}\Big|_{0^-}^{\infty} + s\int_{0^-}^{\infty} x(t)e^{-st}dt = sX(s) - x(0^-) \tag{3.69}$$

Example 3.10

Verify the initial value theorem of the LT which states that if $x(0^+) = \lim_{t\downarrow 0} x(t) < \infty$, then $\lim_{s\to\infty} sX(s) = x(0^+)$.

Solution

In case a discontinuity exists in x at $t = 0$, define the signal

$$y(t) = x(t) - c\delta(t) \tag{3.70}$$

where c is the amplitude shift at the discontinuity, $c = x(0^+) - x(0^-)$. Then y will be continuous at $t = 0$ (see Figure 3.7). Further,

$$\frac{dx}{dt} = \frac{dy}{dt} + c\delta(t) \tag{3.71}$$

so that using the time-differentiation property and the fact that $\mathcal{L}\{c\delta(t)\} = c$, we have

$$sX(s) - x(0^-) = \int_{0^-}^{\infty} \frac{dy}{dt}e^{-st}dt + c \tag{3.72}$$

Because $c = x(0^+) - x(0^-)$,

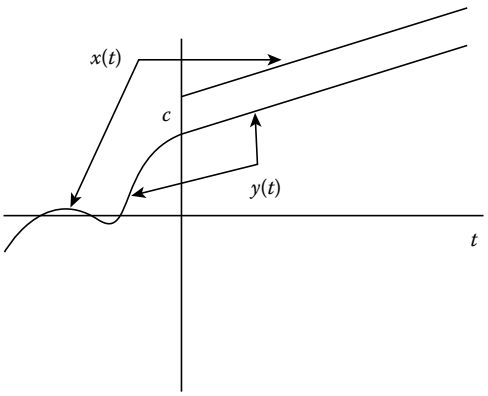

FIGURE 3.7 Signals x and y used in Example 3.10.

$$sX(s) = \int_{0^-}^{\infty} \frac{dy}{dt}e^{-st}dt + x(0^+) \tag{3.73}$$

Assuming that the LT of the signal y has a ROC (y is of exponential order), the integral in Equation 3.73 vanishes as $s \to \infty$. Finally, therefore, we obtain that $\lim_{s\to\infty} sX(s) = x(0^+)$.

Example 3.11

Verify the convolution property of the LT which states that if x and h are casual signals with $x(t) \leftrightarrow X(s)$, and $h(t) \leftrightarrow H(s)$, then

$$x(t) * h(t) = \int_{-\infty}^{\infty} x(\xi)h(t-\xi)\mathrm{d}\xi \leftrightarrow X(s)H(s) \tag{3.74}$$

Solution

Because $x(t) = 0$ for $t < 0$, we can write

$$\int_{-\infty}^{\infty} x(\xi)h(t-\xi)\mathrm{d}\xi = \int_{0^-}^{\infty} x(\xi)h(t-\xi)\mathrm{d}\xi \tag{3.75}$$

Now

$$\begin{aligned}\mathcal{L}\left\{\int_{-\infty}^{\infty} x(\xi)h(t-\xi)\mathrm{d}\xi\right\} &= \int_{0^-}^{\infty}\int_{0^-}^{\infty} x(\xi)h(t-\xi)e^{-st}\,\mathrm{d}\xi\mathrm{d}t \\ &= \int_{0^-}^{\infty}\int_{0^-}^{\infty} x(\xi)h(\beta)e^{-s\beta}e^{-s\xi}\,\mathrm{d}\beta\mathrm{d}\xi \\ &= \int_{0^-}^{\infty} x(\xi)e^{-s\xi}\mathrm{d}\xi \int_{0^-}^{\infty} x(\beta)e^{-s\beta}\,\mathrm{d}\beta \\ &= X(s)H(s)\end{aligned} \tag{3.76}$$

The causality of h is used in line (Equation 3.76) in setting the lower limit of integration over β to 0^-.

The operational properties are used to simplify forward and inverse transform computations and other manipulations involving transforms. To briefly illustrate, three examples follow.

Example 3.12

Using operational properties, rederive the LT for $x(t) = M_x \cos(\omega_x t + \theta_x)u(t)$, which was first considered in Example 3.5.

Solution

Write x as

$$x(t) = \frac{M_x}{2}e^{j\theta_x}e^{(\sigma_x+j\omega_x)t}u(t) + \frac{M_x}{2}e^{-j\theta_x}e^{(\sigma_x-j\omega_x)t}u(t) \tag{3.77}$$

The linearity property allows us to ignore the factors $M_x e^{\pm j\theta x}$ in the process of taking the transform, and returning them afterward. Recalling the previous result, Equation 3.48, we can write immediately

$$\mathcal{L}\left\{e^{(\sigma_x+j\omega_x)t}u(t)\right\} = \frac{1}{s-(\sigma_x+j\omega_x)}, \quad \mathrm{Re}\{s\} > \sigma_x \tag{3.78}$$

$$\mathcal{L}\left\{e^{(\sigma_x-j\omega_x)t}u(t)\right\} = \frac{1}{s-(\sigma_x-j\omega_x)}, \quad \mathrm{Re}\{s\} > \sigma_x \tag{3.79}$$

so

$$X(s) = \frac{M_x}{2} e^{j\theta_x} \frac{1}{s - (\sigma_x + j\omega_x)} + \frac{M_x}{2} e^{-j\theta_x} \frac{1}{s - (\sigma_x - j\omega_x)}, \quad \text{Re}\{s\} > \sigma_x \tag{3.80}$$

Placing the fractions over a common denominator yields the same result as that found using direct integration in Example 3.5.

Example 3.13

Find the time signals corresponding to the following LTs:

$$\begin{aligned} X(s) &= e^{-\pi s} \quad \text{for all } s \\ Y(s) &= \log(7) \frac{e^{-32s}}{s}, \quad \text{Re}\{s\} > 0 \\ Z(s) &= \frac{e^{\sqrt{2}s}}{s+5} + \frac{\sqrt{3}}{s-5}, \quad \text{Re}\{s\} > 5 \end{aligned} \tag{3.81}$$

Solution

Recognize that $X(s) = e^{-\pi s}\Delta(s)$, where $\Delta(s) = 1$ is the LT for the impulse function $\delta(t)$. Using the time-shift property, therefore, we have $x(t) = \delta(t - \pi)$.

Recognize that $Y(s) = \log(7)e^{-32s}\ U(s)$ where $U(s) = 1/s$ is the LT for the step function $u(t)$. Using linearity and the time-shift properties, therefore, $y(t) = \log(7)\ u(t - 32)$.

In finding z, linearity allows us to treat the two terms separately. Further, from Equation 3.48, we know that $\mathcal{L}^{-1}\{1/(s-5)\} = e^{5t}u(t)$ and $\mathcal{L}^{-1}\{1/(s-5)\} = e^{5t}u(t)$. Therefore, $x(t) = e^{-5(t+\sqrt{2})}u(t + \sqrt{2}) + \sqrt{3}e^{5t}u(t)$. Note that the first term has a ROC $\{s\text{: Re}\{s\} > -5\}$, while the second has ROC $\{s\text{: Re}\{s\} < 5\}$. The overall ROC is therefore consistent with these two components.

3.3.6 Inverse Laplace Transform

In principle, finding a time function corresponding to a given LT requires that we compute the integral in Equation 3.36:

$$x(t) = \frac{1}{j2\pi} \int_{\sigma - j\infty}^{\sigma + j\infty} X(s)e^{st}\,ds \tag{3.82}$$

Recall that σ is constant and taken to be in the ROC of X. Direct computation of this line integral requires a knowledge of the theory of complex variables. However, several convenient computational procedures are available that circumvent the need for a detailed understanding of the complex calculus. These measures are the focus of this section. The reader interested in more detailed information on complex variable theory is referred to [3]. ''Engineering'' treatments of this subject are also found in Ref. [10].

We first study the most challenging of the inversion methods, and the one that most directly solves the inversion integral above. The reader interested in quick working knowledge of LT inversion might wish to proceed immediately to Section 3.3.6.2.

3.3.6.1 Residue Theory

It is important to be able to compute residues of a function of a complex variable. Recall the Laurent series expansion of a complex function, say, F, which was introduced in Section 3.3.4, Equation 3.60. Also, recall that the coefficient $r_{1,p}$ is called the residue of F at p, and that we defined the simplified notation $r_p \stackrel{\text{def}}{=} r_{1,p}$ to indicate the residue because the subscript "1" is not useful outside the Laurent series. In the analytic neighborhood of singular point $s = p$ (an nth-order pole) we define the function

$$\varphi_p(s) = (s-p)^n F(s) = r_{1,p}(s-p)^{n-1} + r_{2,p}(s-p)^{n-2} + \cdots + r_{n,p} + \sum_{i=0}^{\infty} q_{i,p}(s-p)^{n+i} \tag{3.83}$$

in which it is important to note that $r_{n,p} \neq 0$. Because F is not analytic at $s = p$, φ_p is not defined, and is therefore not analytic, at $s = p$. We can, however, make φ_p analytic at p by simply defining $\varphi_p(p) \stackrel{\text{def}}{=} r_{n,p}$. In this φ_p is said to have a removable singular point (at p). Note that Equation 3.83 can be interpreted as the Taylor series expansion of φ_p about the point $s = p$. Therefore, the residue is apparently given by

$$r_p \stackrel{\text{def}}{=} r_{1,p} = \frac{\varphi_p^{(n-1)}(p)}{(n-1)!} \tag{3.84}$$

where $\varphi_p^{(i)}$ indicates the ith derivative of φ_p. When $n = 1$ (first-order pole), which is frequently the case in practice, this expression reduces to

$$r_p = \varphi_p(p) = \lim_{s \to p} (s-p)F(s) \tag{3.85}$$

The significance of the residues appears in the following key result (e.g., see Ref. [3]):

THEOREM 3.1: (Residue theorem)

Let C be a simple closed contour within and on which a function F is analytic except for a finite number of singularity points, $p_1, p_2, \ldots, p_k$ interior to C. If the respective residues at the singularities are $r_{p1}, r_{p2}, \ldots, r_{pk}$, then

$$\oint_C F(s)\mathrm{d}s = j2\pi(r_{p_1} + r_{p_2} + \cdots + r_{p_k}) \tag{3.86}$$

where the contour C is traversed in the counterclockwise direction.

The relevance of this theorem in our work is as follows: In principle, according to Equation 3.82, we want to integrate the complex function $F(s) = X(s)e^{st}$ on some vertical line in the ROC, for example, $c - j\infty$ to $c + j\infty$, where $c > \sigma_+$. Instead, suppose we integrate over the contour shown in Figure 3.8. By the residue theorem, we have

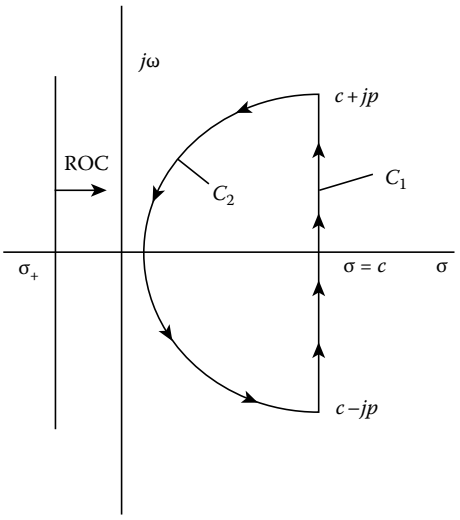

FIGURE 3.8 Contour in the s-plane for evaluating the inverse LT.

$$\oint_C X(e)e^{st}\,ds = j2\pi(r_{p_1} + r_{p_2} + \cdots + r_{p_k}) \tag{3.87}$$

where $r_{p_1}, r_{p_2}, \ldots, r_{p_k}$ are the k residues of the function $X(s)e^{st}$. The integral can be decomposed as

$$\oint_C X(s)e^{st}\,ds = \oint_{C_1} X(s)e^{st}\,ds + \oint_{C_2} X(s)e^{st}\,ds \tag{3.88}$$

where, as $\rho \to \infty$, C_1 approaches the line over which we wish to integrate according to Equation 3.82. It can be shown* that the integral over C_2 contributes nothing to the answer for $t > 0$, provided that X approaches zero uniformly† on C_2. Therefore,

$$\begin{aligned}\lim_{\rho\to\infty} \oint_C X(s)e^{st}\,ds &= \lim_{\rho\to\infty} \oint_{C_1} X(s)e^{st}\,ds \\ &= \lim_{\omega\to\infty} \frac{1}{j2\pi} \int_{c-j\omega}^{c+j\omega} X(s)e^{st}\,ds\end{aligned} \tag{3.89}$$

From Equation 3.87, we have

$$\frac{1}{j2\pi} \int_{\sigma-j\infty}^{\sigma+j\infty} X(s)e^{st}\,ds = r_{p_1} + r_{p_2} + \cdots + r_{p_k}, \quad t > 0 \tag{3.90}$$

Thus, recalling that the left side is the original inversion integral, we have

$$x(t) = \sum_{i=1}^{k} r_{p_i}, \quad t > 0 \tag{3.91}$$

where the r_{p_i} are the residues of $X(s)e^{st}$ at its k singular points.

Note that the residue method returns a time function only over the positive time range. We might expect a result beginning at $t = 0$ or $t = 0^-$ because we have defined the forward LT as an integral beginning at $t = 0^-$. The reason for this lower limit is so that an impulse function at the time origin will be transformed "properly." Another important place at which the initial condition "$x(0^-)$" appears is in the LT of a differentiated time function (see Table 3.2 and Example 3.9). Again, the condition is included to properly handle the fact that if x has a discontinuity at $t = 0$, its derivative should include an impulse and the LT of the derivative should include a corresponding constant. The residue cannot properly invert LTs of impulse functions (constants over the s-plane) because such LTs do not converge uniformly to zero over the semicircular part of the contour C_2. Such constants in the LT must be inverted in a more ad hoc way. If no apparent impulses occur and the residue method has provided x for $t > 0$, it is, in fact, possible, to assign an arbitrary finite value to $x(0)$. This is because one point in the time signal will not affect the LT, so the proper correspondence between x and X remains.‡ If it is necessary to assign a value to $x(0)$, the most natural procedure is to let $x(0) \stackrel{\text{def}}{=} x(0^+)$. Then when we

* A rigorous mathematical discussion appears in Ref. [3], while a particularly clear "engineering" discussion appears in Appendix B of Ref. [6].

† At the same rate regardless of the angle considered along C_2.

‡ In fact, any two signals that differ only on a set of measure zero (e.g., see Ref. [7]) will have the same LT.

write the final answer as $x(t) = [\text{time signal determined by residues}]\ u(t)$, the signal takes an implied value $x(0^+)/2$ at $t = 0$.

The preceding discussion emphasizes that, in general, successful application of the residue method depends on the uniform convergence of the LT to zero on the contour segment C_2. In principle each LT to be inverted must be checked against this criterion. However, this seemingly foreboding process is usually not necessary in linear signal and system analysis. The reason is that a practical LT ordinarily will take the form of a ratio of polynomials in s like (Equation 3.61). The check for proper convergence is a simple matter of assuring that the order of the denominator in s exceeds that of the numerator. When this not the case, a simply remedy exists which we illustrate in Example 3.15. Another frequent problem is the occurrence of an LT of form

$$X(s) = \frac{N(s)e^{st_0}}{D(s)}, \quad t_0 < 0 \tag{3.92}$$

where N and D are polynomials. The trick here is to recognize the factor e^{st_0} as corresponding to a time shift which can be taken care of at the end of the problem, once the rational part of the transform is inverted.

Finally, we remark that similar results apply to the bilateral LT. When the signal is two-sided in time, the casual part is obtained using the procedure above, but including only residues of poles known to be associated with the nonnegative-time part of the signal. The noncausal part of the signal is found by summing residues belonging to ''noncausal'' poles. Note that the association of poles with the casual and noncausal parts of the signal follows from a specification of the ROC. Poles belonging to the causal signal are to the left of the ROC, while noncausal poles are to the right.

Let us now illustrate the procedure with two examples.

Example 3.14

In Example 3.5, we showed that

$$\mathcal{L}\{M_x e^{\sigma_x t}\cos(\omega_x t + \theta_x)u(t)\} = M_x\left[\frac{(s-\sigma_x)\cos(\theta_x) - \omega_x \sin(\theta_x)}{(s-\sigma_x)^2 + \omega_x^2}\right] \tag{3.93}$$

with ROC $\{s\colon \mathrm{Re}\{s\} > \sigma_x\}$. Verify that this is correct by finding the inverse LT using residues. Call the signal x and LT X.

Solution

We can ignore the scalar M_x until the end due to linearity. Two poles are in the transform: $p_x = \sigma_x + j\omega_x$ and $p_x^* = \sigma_x + j\omega_x$ ($k = 2$ in the discussion above). These can be obtained by expanding the denominator and using the quadratic equation, but it is useful to remember the relationship between a quadratic polynomial written in this form and the conjugate roots (recall Equation 3.59). The residue for the pole at p_x is given by

$$\begin{aligned}\varphi_{px}(p_x) = X(s)e^{st}(s-p_x)\Big|_{s=p_x} &= \frac{[(s-\sigma_x)\cos(\theta_x) - \omega_x\sin(\theta_x)]e^{st}}{(s-p_x^*)}\Big|_{s=p_x} \\ &= \frac{[(p_x-\sigma_x)\cos(\theta_x) - \omega_x\sin(\theta_x)]e^{p_x t}}{(p_x - p_x^*)} \\ &= \frac{[(j\omega_x)\cos(\theta_x) - \omega_x\sin(\theta_x)]e^{(\sigma_x + j\omega_x)t}}{(2j\omega_x)}\end{aligned} \tag{3.94}$$

Similarly, we have for the pole at p_x^*, $\varphi_{p_x^*}(p_x^*) = [(-j\omega_x)\cos(\theta_x) - \omega_x \sin(\theta_x)]e^{(\sigma_x - j\omega_x)t}/(-2j\omega_x)$. For $t > 0$, therefore,

$$\frac{x(t)}{M_x} = \varphi_{p_x}(p_x) + \varphi_{p_x^*}(p_x^*)$$

$$= \frac{e^{\sigma_x t}[j\omega_x \cos(\theta_x)(e^{j\omega_x t} + e^{-j\omega_x t}) - \omega_x t \sin(\theta_x)(e^{j\omega_x t} - e^{-j\omega_x t})]}{2j\omega_x} \tag{3.95}$$

$$= e^{\sigma_x t}[\cos(\theta_x)\cos(\omega_x t) - \sin(\theta_x)\sin(\omega_x t)] = e^{\sigma_x t}\cos(\omega_x t + \theta_x) \tag{3.96}$$

and the transform is verified.

Example 3.15 illustrates the technique for handling polynomial quotients in which the order of the denominator does not exceed the numerator (X is not a proper rational LT).

Example 3.15

Find the causal time signal corresponding to LT

$$X(s) = \frac{N(s)}{D(s)} = \frac{Gs^2}{(s-p)^2}, \quad G, p \text{ are real} \tag{3.97}$$

Solution

To use the residue method, we must reduce the order of the numerator to at most unity. By dividing polynomial D and N using long division, we can express X as

$$X(s) = G + \frac{2Gps - Gp^2}{(s-p)^2} \stackrel{\text{def}}{=} X_1(s) + X_2(s) \tag{3.98}$$

First note that we can use linearity and invert the two terms separately. The first is simple because (see Table 3.1) $\mathcal{L}^{-1}\{X_1(s)\} = \mathcal{L}^{-1}\{G\} = G\delta(t)$. In the second term we find a pole of order $n = 2$ at $s = p$. To use Equation 3.84 to compute the residue, we require $\varphi_p(s) = X_2(s)e^{st}(s-p)^2 = [2Gps - Gp^2]e^{st}$. Then, for $t > 0$, the residue is

$$r_p = \frac{1}{1!}\frac{d\varphi_p}{ds}\bigg|_{s=p} = G[2pe^{pt} + 2p^2te^{pt} - p^2te^{pt}] = Gpe^{pt}[2 + pt] \tag{3.99}$$

Because r_p is the only residue, we have $x(t) = G\delta(t) + Gpe^{pt}[2 + pt]u(t)$.

Remark. If the order of the numerator *exceeds* the denominator by $k > 0$, the long division will result in a polynomial of the form $A_k s^k + A_{k-1}s^{k-1} + \cdots + A_0$. Consequently, the time domain signal will contain derivatives of the impulse function. In particular, if $k = 1$, and a "doublet" will be present in the time signal. (See Table 3.1 and Appendix A for more information.)

We can usually find several ways to solve inverse LT problems, residues often being among the most challenging. In this example, for instance, we could use Equation 3.98 to write

$$X(s) = G + \frac{2Gps}{(s-p)^2} - \frac{Gp^2}{(s-p)^2} = G + X_3(s) - X_4(s) \tag{3.100}$$

then use Table 3.1 to find $\mathcal{L}^{-1}\{G\} = G\delta(t)$ and $\mathcal{L}^{-1}\{X_4\} = x_4(t)$ [or use residues to find $x_4(t)$]. Noting that $X_3(s) = 2\ psX_4(s)$, we could then use the s-differentiation property (Table 3.2) to find x_3 from x_4. This alternative solution illustrates a general method that ordinarily is used regardless of the fundamental inversion technique. Linearity allows us to divide the problem into a sum of smaller, easier problems to invert, and then combine solutions at the end. The method presented next is probably the most popular, and clearly follows this paradigm.

3.3.6.2 Partial Fraction Expansion

The partial fraction expansion (PFE) method can be used to invert only rational LTs, with the exception that factors of the form e^{st_0} can be handled as discussed near Equation 3.92. As noted previously, this is not practically restricting for most engineering analyses. Partial fraction expansion is closely related to the residue method, a relationship evident via our examples.

As in the case of residues, a rational LT to be inverted must be proper, having a numerator polynomial whose order is strictly less than that of the denominator. If this is not the case, long division should be employed in the same manner as in the residue method (see Example 3.15).

Consider the LT $X(s) = N(s)/D(s)$. Suppose X has k poles, $p_1, p_2, \ldots, p_k$ and D is factored as

$$D(s) = (s - p_1)^{n_1}(s - p_2)^{n_2} \cdots (s - p_k)^{n_k} \tag{3.101}$$

where n_i is the order of the ith pole. (Note that $\Sigma_i^k = {}_1 n_i = n_D$.) Now if x is a real signal, the complex poles will appear in the conjugate pairs. It will sometimes be convenient to combine the corresponding factors into a quadratic following Equation 3.59,

$$(s - p)(s - p^*) = s^2 + \beta s + \gamma = s^2 - \mathrm{Re}\{p\}s + \left|p\right|^2 = s^2 - 2\sigma_p s + \left|p\right|^2 \tag{3.102}$$

for each conjugate pair. Assuming that the poles are ordered in Equation 3.101 so that the first k' are real and the last $2k''$ are complex ($k = k' + 2k''$), D can be written

$$\begin{aligned} D(s) = {} & (s - p_1)^{n_{re,1}}(s - p_2)^{n_{re,2}} \cdots (s - p_{k'})^{n_{re,k'}}(s^2 + \beta_1 s + \gamma_1)^{n_{c,1}} \\ & \times (s^2 + \beta_2 s + \gamma_2)^{n_{c,2}} \cdots (s^2 + \beta_{k''} s + \gamma_{k''})^{n_{c,k''}} \end{aligned} \tag{3.103}$$

Terms of the form $(s - p)$ are called simple linear factors, while those of form $(s^2 + \beta s + \gamma)$ are simple quadratic factors. When a factor is raised to a power greater than one, we say that there are repeated linear (or quadratic) factors. We emphasize that linear factors need not always be combined into quadratics when they represent complex poles. In other words, in the term $(s - p_i)^{ni}$, the pole p_i may be complex. Whether quadratics are used depends on the approach taken to solution.

The idea behind PFE is to decompose the larger problem into the sum of smaller ones. We expand the LT as

$$X(s) = \frac{N(s)}{D(s)} = \frac{N(s)}{\mathrm{factor}_1 \mathrm{factor}_2 \cdots \mathrm{factor}_{k'} \mathrm{factor}_{k'+1} \cdots \mathrm{factor}_{k'+k''}}$$

$$= \frac{N_1(s)}{\mathrm{factor}_1} + \frac{N_2(s)}{\mathrm{factor}_2} + \cdots + \frac{N_{k'}(s)}{\mathrm{factor}_{k'}} + \frac{N_{k'+1}(s)}{\mathrm{factor}_{k'+1}} \tag{3.104}$$

$$+ \frac{N_{k'+k''}(s)}{\mathrm{factor}_{k'+k''}} \tag{3.105}$$

Now, because of linearity, we can invert each of the partial functions in the sum individually, then add the results. Each of these ''small'' problems is easy and ordinarily can be looked up in a table or solved by memory.

We now consider a series of cases and examples.

Case 1: Simple linear factors. Let $X(s) = N(s)/D(s)$. Assume that the order of N is strictly less than the order of D. Without loss of generality (for the case under consideration), assume that the first factor in D is a simpler linear factor so that D can be written $D(s) = (s - p_1)D_{\text{other}}(s)$ where D_{other} is the product of all remaining factors. Then the PFE will take the form

$$\begin{aligned} X(s) &= \frac{N(s)}{D(s)} = \frac{N(s)}{(s-p_1)D_{\text{other}}(s)} \\ &= \frac{N_1(s)}{(s-p_1)} + [\text{other PFs corresponding to factors in } D_{\text{other}}(s)] \end{aligned} \tag{3.106}$$

Now note that

$$\begin{aligned} (s-p_1)X(s) &= \frac{N(s)}{D_{\text{other}}(s)} \\ &= N_1(s) + (s-p_1)[\text{other PFs corresponding to factors in } D_{\text{other}}(s)] \end{aligned} \tag{3.107}$$

Letting $s = p_1$ reveals that

$$N_1(p_1) = A_1 = \frac{N(p_1)}{D_{\text{other}}(p_1)} = [(s-p_1)X(s)]|_{s=p_1} \tag{3.108}$$

Note that the number A_1 is the residue of the pole at $s = p_1$. In terms of our residue notation

$$\varphi_{p_1}(s) = (s-p_1)X(s) = \frac{N(s)}{D_{\text{other}}(s)} \quad \text{and} \quad r_{p_1} = A_1 = \varphi_{p_1}(p_1) \tag{3.109}$$

Carefully note that we are computing residues of poles of $X(s)$, not $X(s)e^{st}$, in this case.

Example 3.16

Given LT

$$X(s) = \frac{s^2 + 3s}{(s+1)(s+2)(s+4)} \tag{3.110}$$

with ROC $\{s: \text{Re}\{s\} > -1\}$, find the corresponding time signal x.

Solution

Check that the order of the denominator exceeds that of the numerator. Because it does, we can proceed by writing

$$X(s) = \frac{A_1}{(s+1)} + \frac{A_2}{(s+2)} + \frac{A_3}{(s+4)} \tag{3.111}$$

Using the previous method, we find that

$$A_1 = \left.\frac{s^2 + 3s}{(s+2)(s+4)}\right|_{s=-1} = -\frac{2}{3} \tag{3.112}$$

In a similar manner, we find that $A_2 = 1$ and $A_3 = 2/3$. Therefore,

$$X(s) = -\frac{2/3}{(s+1)} + \frac{1}{(s+2)} + \frac{2/3}{(s+4)} \tag{3.113}$$

Now, using linearity and Table 3.1 (or recalling Equation 3.48), we can immediately write

$$x(t) = \left[-\frac{2}{3}e^{-t} + e^{-2t} + \frac{2}{3}e^{-4t}\right]u(t) \tag{3.114}$$

Case 2: Simple quadratic factors. When $D(s)$ contains a simple quadratic factor, the LT can be expanded as

$$\begin{aligned} X(s) &= \frac{N(s)}{D(s)} = \frac{N(s)}{(s^2 - \beta s + \gamma)D_{\text{other}}(s)} \\ &= \frac{Bs + C}{(s^2 - \beta s + \gamma)} + [\text{other PFs corresponding to factors in } D_{\text{other}}(s)] \end{aligned} \tag{3.115}$$

The usefulness of this form is illustrated next.

Example 3.17

Find the time signal x corresponding to LT

$$X(s) = \frac{(s+4)}{(s+2)(s^2+6s+34)}, \quad ROC\{s: \text{Re}\{s\} > -3\} \tag{3.116}$$

Solution

The order of D exceeds the order of N, so we may proceed. The roots of the quadratic term are $p, p* = (-6 \pm \sqrt{36 - 136}/2 = -3 \pm j5)$, so we leave it as a quadratic. (If the roots were real, we would use the simple linear factor approach.) Expand the LT into PFs

$$X(s) = \frac{A}{(s+2)} + \frac{Bs + C}{(s^2 + 6s + 34)} \tag{3.117}$$

Using the method for simple linear factors, we find that $A = 1/13$. Now multiply both sides of Equation 3.117 by $D(s) = (s+2)\ (s^2 + 6s + 34)$ to obtain

$$(s+4) = \frac{1}{13}(s^2 + 6s + 34) + (Bs + C)(s+2) \tag{3.118}$$

Equating like powers of s on the two sides of the equation yields $B = -1/13$ and $C = -1/13$, so

$$X(s) = \frac{1/13}{(s+2)} + \frac{[(-1/13)s + (9/13)]}{(s^2 + 6s + 34)} \tag{3.119}$$

The first fraction has become familiar by now and corresponds to time function $(1/13)e^{-2t}\ u(t)$. Let us focus on the second fraction. Note that (recall Equation 3.59)

$$s^2 + 6s + 34 = (s - p)(s - p^*) = (s + 3 - j5)(s + 3 + j5) = (s+3)^2 + 5^2 \tag{3.120}$$

The second fraction, therefore, can be written as

$$-\frac{1}{13}\left[\frac{(s+3)}{(s+3)^2+5^2}-\frac{12}{(s+3)^2+5^2}\right]$$
$$=-\frac{1}{13}\left[\frac{(s+3)}{(s+3)^2+5^2}-\frac{(12/5)5}{(s+3)^2+5^2}\right] \tag{3.121}$$

The terms in brackets correspond to a cosine and sine, respectively, according to Table 3.1. Therefore,

$$X(t)=\left[\frac{1}{13}e^{-2t}-\frac{1}{13}e^{-3t}\cos(5t)+\frac{12}{5(13)}e^{-3t}\sin(5t)\right]u(t) \tag{3.122}$$

Simple quadratic factors need not be handled by the above procedure, but can be treated as simple linear factors, as illustrated by Example 3.18.

Example 3.18

Repeat the previous problem using simple linear factors.

Solution

Expand X into simple linear PFs

$$X(s)=\frac{A}{(s+2)}+\frac{E}{(s-p)}+\frac{E^*}{(s-p^*)},\quad p=-3+j5 \tag{3.123}$$

Note that the PFE coefficients corresponding to complex-conjugate pole pairs will themselves be complex conjugates. In order to derive a useful general relationship, we ignore the specific numbers for the moment. Using the familiar inverse transform, we can write

$$x(t)=[Ae^{-2t}+Ee^{pt}+E^*e^{p^*t}]u(t) \tag{3.124}$$

Letting $E=|E|e^{j\theta E}$ and $p=\sigma_p+j\omega_p$, we have

$$Ee^{pt}+E^*e^{p^*t}=|E|e^{j\theta_E}e^{(\sigma_p+j\omega_p)t}+|E|e^{-j\theta_E}e^{(\sigma_p+j\omega_p)t}=2|E|e^{\sigma_p t}\cos(\omega_p t+\theta_E) \tag{3.125}$$

This form should be noted for use with complex-conjugate pairs.

Using the method for finding simple linear factor coefficients, we find that $A=1/13$. Also

$$E=X(s)\ (s-p)|_{s=p}=\left.\frac{(s+4)}{(s+2)(s-p^*)}\right|_{s=p}=\frac{(p+4)}{(p+2)(j2\mathrm{Im}\{p\})}$$
$$=\frac{(1+j5)}{(-1+j5)(j10)}=0.1e^{-j0.626\pi} \tag{3.126}$$

Therefore, the answer can be written as

$$x(t)=\left[\frac{1}{13}e^{-2t}+0.2e^{-3t}\cos(5t-0.626\pi)\right]u(t) \tag{3.127}$$

This solution is shown to be consistent with that of the previous example using the trigonometric identity $\cos(\alpha+\beta)=\cos(\alpha)\cos(\beta)-\sin(\alpha)\sin(\beta)$.

Case 3: Repeated linear factors. When $D(s)$ contains a repeated linear factor, for example, $(s-p)^n$ the LT must be expanded as

$$X(s) = \frac{N(s)}{D(s)} = \frac{N(s)}{(s-p)^n D_{\text{other}}(s)} = \frac{A_n}{(s-p)^n} + \frac{A_{n-1}}{(s-p)^{n-1}} + \cdots + \frac{A_1}{(s-p)} + [\text{other PFs corresponding to factors in } D_{\text{other}}(s)] \tag{3.128}$$

The PFE coefficients of the n fractions are found as follows. Define

$$\varphi_p(s) = (s-p)^n X(s) \tag{3.129}$$

Then

$$A_{n-i} = \frac{1}{i!}\frac{d^i}{ds^i}\varphi_p\bigg|_{s=p} \tag{3.130}$$

The similarity of these computations to residues is apparent, but only A_1 can be interpreted as the residue of pole p. We illustrate this method by example.

Example 3.19

Find the time signal x corresponding to LT $X(s) = (s+4)/(s+1)^3$.

Solution

The order of D exceeds the order of N, so we may proceed. X has a third-order pole at $s=-1$, so we expand X as

$$X(s) = \frac{(s+4)}{(s+1)^3} = \frac{A_3}{(s+1)^3} + \frac{A_2}{(s+1)^2} + \frac{A_1}{(s+1)} \tag{3.131}$$

Let $\varphi_{-1}(s) = (s+1)^3\, X(s) = (s+4)$. Then

$$A_3 = \varphi_{-1}(-1) = 3, \quad A_2 = \frac{d\varphi_{-1}}{ds}\bigg|_{s=-1} = 1, \quad \text{and} \quad A_1 = \frac{1}{2}\frac{d^2\varphi_{-1}}{ds^2}\bigg|_{s=-1} = 0 \tag{3.132}$$

So

$$X(s) = \frac{3}{(s+1)^3} + \frac{1}{(s+1)^2} \tag{3.133}$$

Using Table 3.1, we have

$$x(t) = \left[\frac{3}{2}t^2 e^{-t} + te^{-t}\right]u(t) \tag{3.134}$$

Case 4: Repeated quadratic factors. When $D(s)$ contains a repeated quadratic factor, e.g., $(s^2+\beta s+\gamma)^n$, the LT may be either inverted by separating the quadratic into repeated linear factors (one nth-order factor for each of the complex roots; see Equation 3.155), then treated using the method of Case 3, or it can be expanded as

$$X(s) = \frac{N(s)}{D(s)} = \frac{N(s)}{(s^2 + \beta s + \gamma)^n D_{\text{other}}(s)}$$
$$= \sum_{i=0}^{n-1} \frac{(B_{n-i}s + C_{n-i})}{(s^2 + \beta s + \gamma)^n} + [\text{other PFs corresponding to factors in } D_{\text{other}}(s)] \quad (3.135)$$

The PFE coefficients of the n factions are found algebraically as we illustrate by example.

Example 3.20

Find the time signal x corresponding to $X(s) = 4s^2/(s^2 + 1)^2\,(s + 1)$ [10].

Solution

Recognize the factor $(s^2 + 1)^2$ as an $n = 2$ order quadratic factor with $\beta = 0$ and $\gamma = 1$. We know from our previous work that $\beta = -2\,\text{Re}\{p\}$, where p and p^* are the poles associated with the quadratic factor, in this case $\pm j$. In turn, the real part of p provides the damping term in front of the sinusoid represented by the quadratic factor. In this case, therefore, we should expect one of the terms in the time signal to be a pure sinusoid.

Write X as

$$X(s) = \frac{(B_2 s + C_2)}{(s^2 + 1)^2} + \frac{(B_1 s + C_1)}{(s^2 + 1)} + \frac{A}{(s + 1)} \quad (3.136)$$

Using the familiar technique for simple linear factors, we find that $A = 1$. Now multiplying both sides of Equation 3.136 by $(s^2 + 1)^2\,(s + 1)$, we obtain $4s^2 = (B_2 s + C_2)(s + 1) + (B_1 s + C_1)(s^2 + 1)(s + 1) + (s^2 + 1)^2$. Equating like powers of s, we obtain $B_2 = -1$, $C_2 = 1$, $B_1 = 2$, and $C_1 = -2$. Hence,

$$X(s) = \frac{1}{(s + 1)} + \frac{(2s - 2)}{(s^2 + 1)^2} + \frac{(s - 1)}{(s^2 + 1)} \quad (3.137)$$

We can now use Tables 3.1 and 3.2 to invert the three fractions. Note that the third term will yield an undamped sinusoid as predicted. Also note that the middle term is related to the third by differentiation. This fact can be used in obtaining the inverse.

3.4 Laplace Transform Analysis of Linear Systems

Let us return to the example circuit problem, which originally motivated our discussion, and discover ways in which the LT can be used in system analysis. Three fundamental means are available for using the LT in such problems. The most basic is the use of LT theory to solve the differential equation governing the circuit dynamics. The differential equation solution methods are quite general and apply to linear, constant coefficient differential equations arising in any context. The second method involves the use of the "system function," an LT-based representation of an LTI system, which embodies all the relevant information about the system dynamics. Finally, we preview "LT equivalent circuits," an LT method that is primarily used for circuit analysis, and is treated more completely in Chapter 20.

3.4.1 Solution of the System Differential Equation

Consider a system is governed by a linear, constant coefficient differential equation of the form

$$\sum_{\ell=0}^{n_D} a_\ell \frac{d^\ell}{dt^\ell} y(t) = \sum_{\ell=0}^{n_N} b_\ell \frac{d^\ell}{dt^\ell} x(t) \quad (3.138)$$

with appropriate initial conditions given. (The numbers n_N and n_D should be considered fixed integers for now, but are later seen to be consistent with similar notation used in the discussion of rational LTs.) Using the linearity and time-differentiation properties of the LT, we can transform both sides of the equation to obtain

$$\sum_{\ell=0}^{n_D} a_\ell \left[s^\ell Y(s) - \sum_{i=0}^{\ell-1} y^{(i)}(0^-) s^{\ell-i-1} \right] = \sum_{\ell=0}^{n_N} b_\ell \left[s^\ell X(s) - \sum_{i=0}^{\ell-1} x^{(i)}(0^-) s^{\ell-i-1} \right] \tag{3.139}$$

where $y^{(i)}$ and $x^{(i)}$ are the ith derivatives of y and x. Rearranging, we have

$$Y(s) = \frac{X(s) \sum_{\ell=0}^{n_N} b_\ell s^\ell - \sum_{\ell=0}^{n_N} b_\ell \sum_{i=0}^{\ell-1} x^{(i)}(0^-) s^{\ell-i-1} + \sum_{\ell=0}^{n_D} a_\ell \sum_{i=0}^{\ell-1} y^{(i)}(0^-) s^{\ell-i-1}}{\sum_{\ell=0}^{n_D} a_\ell s^\ell} \tag{3.140}$$

Given the input signal x and all necessary initial conditions on x and y, all quantities on the right side of Equation 3.140 are known and can be combined to yield Y. Our knowledge of LT inversion will then, in principle, allow us to deduce y. This process often turns an unwieldy differential equation solution into simpler algebraic operations. The price paid for this simplification, however, is that the process of inverting Y to obtain y is sometimes challenging.

Recall that in the motivating example, a similar conversion of the (nonhomogeneous) differential equation solution to algebraic operations occurred (recall Equation 3.16 and surrounding discussion), as the superfluous term e^{pxt} was divided out of the equation. Except for the lack of attention paid to initial conditions, what remains in Equation 3.16 is tantamount to an LT equation of form Equation 3.139, as shown below. The homogeneous solution and related initial conditions were not included in the earlier discussion to avoid obfuscating the main issue. The reader was encouraged to think of the LT as a process of "dividing" the "e^{st}" term out of the signals before starting the solution. We can now clearly see this fundamental connection between the differential equation and LT solutions.

Example 3.21

Return to the motivating example in Section 3.2 and solve the problem using LT analysis.

Solution

Recall the differential equation governing the circuit, Equation 3.1, $x(t) = LC(d^2 y/dt^2) + RC(dy/dt) + y(t)$. The initial conditions are $y(0^-) = y_0$ and $i(0^-) = i_0$. Recall also that for convenience we seek the solution for $x(t) = M_x e^{j\theta_x} e^{(\sigma + j\omega_x)t} u(t) = M_x e^{j\theta_x} e^{p_x t} u(t)$ recognizing that the "correct" solution will be the real part of that obtained.

Taking the LT of each side of the differential equation, we have

$$X(s) = LC[s^2 Y(s) - sy(0^-) - y^{(1)}(0^-)] + RC[sY(s) - y(0^-)] + Y(s) \tag{3.141}$$

or

$$Y(s) = \frac{X(s)}{(LCs^2 + RCs + 1)} + \frac{(sLC - RC)y(0^-) + LCy^{(1)}(0^-)}{(LCs^2 + RCs + 1)} \tag{3.142}$$

Dividing both numerator and denominator of each fraction by LC, and inserting the LT $X(s) = M_x e^{j\theta x}/(s - p_x)$ and the initial conditions [recall that $Cy^{(1)} = i(t) \Rightarrow Cy^{(1)}(0^-) = i_0$], we have

$$Y(s) = \frac{M_x e^{j\theta_x}/LC}{(s - p_x)[s^2 + (R/L)s + 1]} + \frac{[s - (R/L)]y_0 + i_0/C}{[s^2 + (R/L)s + 1]} \tag{3.143}$$

Using PFE, this can be written

$$Y(s) = \frac{\dfrac{M_x e^{j\theta_x}/LC}{\left[p_x^2 + (R/L)p_x + 1\right]}}{(s - p_x)} + \frac{\dfrac{M_x e^{j\theta_x}/LC}{(p_h - p_x)}}{(s - p_h)} + \frac{\left(\dfrac{M_x e^{j\theta_x}/LC}{(p_h - p_x)}\right)^*}{(s - p_h^*)} + \frac{[s - (R/L)]y_0 + i_0/C}{(s - p_h)(s - p_h^*)} \tag{3.144}$$

where p_h and $p_h{}^\star$ are the system poles. We have expanded the first fraction in Equation 3.143 using simpler linear factors involving the poles p_x, p_h, and $p_h{}^\star$.The latter two poles correspond to the system (roots of $(s^2 + (r/L)s + 1)$), and the resulting terms in Equation 3.144 are part of the natural response. The first pole, p_x, is attributable to the forcing function, and the resulting term in Equation 3.144 will yield the forced response in the time domain. Finally, the last term in Equation 3.144, which arises from the last term in Equation 3.143, is also part of the natural response. The separation of the natural response into these three LT terms harkens back to the time-domain discussion about the distinct contributions of the input and initial conditions to the natural response. The last term is clearly related to initial conditions and the circuit's natural means of dissipating that energy. The former, terms, which will also yield a damped sinusoid of identical complex frequency to that of the third term, are clearly "caused" by the input.

Remark. The reader may wonder why the first fractions in Equations 3.17 and 3.144, both of which represent the forced response, are not identical. After all, we have been encouraged to view the LT as a kind of generalized phasor representation. Recall, however, that the LT at a particular s must be thought of as a "phasor density." If an eigensignal of the system represents one complex frequency, e.g., $s = p_x$, the LT is infinitely dense at that point in the s-plane, corresponding to the existence of a pole there. If the signal does have a conventional phasor representation such as $\overline{Y} = M_y e^{j\theta_y}$, then this phasor will be related to the LT as

$$\bar{Y} = Y(s)\frac{\mathrm{d}s}{2\pi}\bigg|_{s=p_x} = \lim_{s \to p_x} Y(s)(s - p_x) \tag{3.145}$$

which we recognize as the residue of the LT Y at the pole p_x. The reader can easily verify this assertion using Equation 3.143. This discussion is closely related to the interconnection between the FS coefficients (which are similar to conventional sinusoidal phasors) and the Fourier transform (FT). These signal representations are discussed in Chapter 4.

3.4.2 System Function

Definition 3.1: In our motivating example an input sinusoid with generalized phasor $M_x e^{j\theta x}$ produced an output sinusoid with generalized phasor $M_y e^{j\theta y}$. We discovered that the ratio of phasors was dependent only upon system parameters and the complex frequency, p_x. We noted that when considered as a function of the general complex frequency, s, this ratio is called the system function. That is, the system function is a complex function, H, of complex frequency, s, such that if a damped sinusoid

of complex frequency $s = p_x$ and with generalized phasor $\overline{X} = M_x e^{j\theta_x}$ is used as input to the system, the forced response will be a sinusoid of complex frequency p_x and with generalized phasor

$$M_y e^{j\theta_y} = H(p_x) M_x e^{j\theta_x} \tag{3.146}$$

3.4.2.1 Preview of Magnitude and Phase Responses

It is often important to know how a system will respond to a pure sinusoid of radian frequency, e.g., ω_x. In particular, we would like to know the amplitude and phase changes imposed on the sinusoid by the system. In terms of the definition just given, we see that this information is contained in the system function evaluated at frequency $p_x = j\omega_x$. In particular, $^*H(j\omega_x)^*$ represents the magnitude factor and arg $\{H(j\omega_x)\}$ the phase change at this frequency. When plotted as functions of general frequency ω, the real functions $^*H(j\omega)^*$ and arg $\{H(j\omega_x)\}$ are called the magnitude (or sometimes frequency) response, and phase response of the system, respectively. The complex function $H(j\omega)$ will be seen to be the FT of the impulse response (see Appendix B and Chapter 4) and is sometimes called the transfer function for the system. Returning to Figure 3.2b, the reader will discover that we have plotted the magnitude response for the series RLC circuit of Section 3.2 with numerical values given in Equation 3.18.

The magnitude and phase responses of the system can be obtained graphically from the pole–zero diagram. Writing $H(s)$ similarly to Equation 3.62,
$H(s) = \mathcal{C} \prod_{i=1}^{n_N} (s - z_i) / \prod_{i=1}^{n_D} (s - p_i)$. Therefore,

$$\begin{aligned} |H(j\omega)| &= \mathcal{C} \frac{\prod_{i=1}^{n_N} |j\omega - z_i|}{\prod_{i=1}^{n_D} |j\omega - p_i|} \quad \text{and} \\ \arg\{H(j\omega)\} &= \sum_{i=1}^{n_N} \arg\{(j\omega - z_i)\} - \sum_{i=1}^{n_D} \arg\{(j\omega - p_i)\} \end{aligned} \tag{3.147}$$

where we have assumed $\mathcal{C} > 0$ (if not, add π radians to arg$\{H(j\omega_x)\}$). By varying ω the desired plots are obtained as illustrated in Figure 3.9.

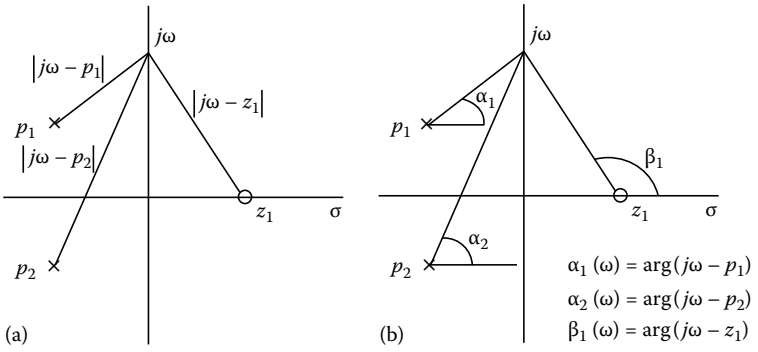

FIGURE 3.9 Pole–zero plot for an example system function, $H(s) = C(s - z_1)/(s - p_1)(s - p_2)$. (a) To obtain the magnitude response $|H(s\omega)|$ at frequency ω, the product of lengths from all zeroes to $s = j\omega$ is divided by the product of lengths from all poles to $s = j\omega$. The result must be multiplies by the gain term $|C|$. (b) To obtain the phase response $\{H(j\omega_x)\}$ at frequency ω, the sum of angles from all poles to $s = j\omega$ is subtracted from the sum of angles from all zeroes to $s = j\omega$. An additional π radians is added if $C < 0$.

Definition 3.2: More generally, the system function, $H(s)$, for an LTI system can be defined as the ratio of the LT, for example, $Y(s)$, of the output, resulting from any input with LT, for example, $X(s)$, when the system is initially at rest (zero initial conditions). In other words, H is the ratio of the LT of the zero-state response to the LT of the input,

$$H(s) \stackrel{\text{def}}{=} \frac{Y(s)}{X(s)} \text{when all initial conditions are zero} \tag{3.148}$$

While the latter definition is more general, the two definitions are consistent when the input is an eigensignal, as we show by example.

Example 3.22

Show that the two definitions of the system function described previously are consistent for the RLC circuit of Section 3.2.

Solution

Replacing the specific frequency p_x by a general complex frequency s in the initial example using phasor analysis, we found that (recall Equation 3.31) $H(s) = 1/(LCs^2 + RCs + 1)$. On the other hand, using more formal LT analysis on the same problem, we derived Equation 3.142. Forming the ratio $Y(s)/X(s)$ where both initial conditions are set to zero, yields an identical result.

Finally, another very useful definition of the system is as follows.

Definition 3.3: The output of LTI system to an impulse excitation, $x(t) = \delta(t)$ (see Section 3.6, Appendix A), when all initial conditions are zero, is called the impulse response of the system. The impulse response is usually denoted $h(t)$. The system function can be defined as the LT of the impulse response $H(s) = \mathcal{L}\{h(t)\}$.

The consistency of this definition with the first two is easy to demonstrate. Let H denote the system function for the system, regardless of how it might be related to $h(t)$. From Definition 3.2, we have $H(s) = Y(s)/X(s)$ for any valid LTs X and Y. Let $x(t) = \delta(t)$, in which $X(s) = 1$. By definition, $y(t) = h(t)$, so $\mathcal{L}\{h(t)\} = \mathcal{L}\{y(t)\} = H(s)X(s) = H(s)$.

This interpretation of H enables us to find the impulse response of the system, a task which is not always easy in the time domain because of the pitfalls of working with impulse functions.

Example 3.23

Find the impulse response, h, for the circuit of Section 3.2.

Solution

Using various means we showed that the system function is $H(s) = 1/(LCs^2 + RCs + 1)$. Let us find h by computing $h(t) = \mathcal{L}^{-1}\{H(s)\}$. Using the quadratic equation, we find the roots of the denominator (poles of the system) to be (cf., Equation 3.6)

$$p_1, p_2 = \frac{-RC \pm \sqrt{R^2C^2 - 4LC}}{2LC} = -\frac{R}{2L} \pm \sqrt{\frac{R^2}{4L^2} - \frac{1}{LC}} \tag{3.149}$$

Assume that these poles are complex conjugates and call them p_h, p_h^*, where

$$p_h = -\frac{R}{2L} + j\sqrt{\frac{1}{LC} - \frac{R^2}{4L^2}} \stackrel{\text{def}}{=} \sigma_h + j\omega_h \tag{3.150}$$

Comparing to our initial work on finding the homogeneous solution of the differential equation, we see that these system poles are the roots of the characteristic equation. The reason for using subscript "h" in our early work should now be clear. In terms of Equation 3.150 we can rewrite H as

$$H(s) = \frac{1/LC}{(s-\sigma_h)^2 + \omega_h^2} \tag{3.151}$$

(recall Equation 3.59). Now using Table 3.1: $\mathcal{L}\{e^{\sigma_b t}\cos(\omega_b t + \theta_b)\} = [(s-\sigma_b)\cos(\theta_b) - \omega_b \sin(\theta_b)]/[(s-\sigma_h)^2 + \omega_h^2]$. Letting $\theta_h = \pi/2$ and using linearity, we have

$$h(t) = -\frac{1}{LC\omega_h} e^{\sigma_h t}\cos\left(\omega_h t + \frac{\pi}{2}\right)u(t) = \frac{1}{LC\omega_h} e^{\sigma_h t}\sin(\omega_h t)u(t) \tag{3.152}$$

We could also note that $|p_h| = \sqrt{1/LC}$ and write the initial scale factor as $|p_h|^2/\omega_h$.

We see clearly that the impulse response is closely related to the natural responses of a system, which in turn are tied to the homogeneous solution of the differential equation. These transient responses depend only on properties of the system, and not on properties of the input signal (beyond the initial instant of excitation). The form of the homogeneous differential equation solution is specified by the number and values of the roots of the characteristic equation. These roots are, thus, the poles of the system function H. The system function offers an extremely valuable tool for the design and analysis of systems. We now turn to this important topic.

3.4.3 Poles and Zeros—Part II: Stability Analysis of Systems

We return to the issue of poles and zeroes, this time with attention restricted to rational LTs. In particular, we focus on the poles and zeroes of a system function and their effects on the performance of the system.

3.4.3.1 Natural Modes

The individual time responses corresponding to the poles of H are often called natural modes of the system. These modes are indicators of the physical properties of the system (e.g., circuit values), which in turn determine the natural way in which the system will dissipate, store, amplify, or respond to energy of various frequencies. Consider two general cases. Suppose H has a real pole of order n at $s = p$, so that it can be written

$$H(s) = \sum_{i=1}^{n} \frac{A_i}{(s-p)^i} + [\text{other terms}] \tag{3.153}$$

We know from previous work, therefore, that (see Table 3.1) h has corresponding modal components,

$$h(t) = \sum_{i=1}^{n} \frac{A_i}{(i-1)!} t^{i-1} e^{pt} u(t) + [\text{other terms}] \tag{3.154}$$

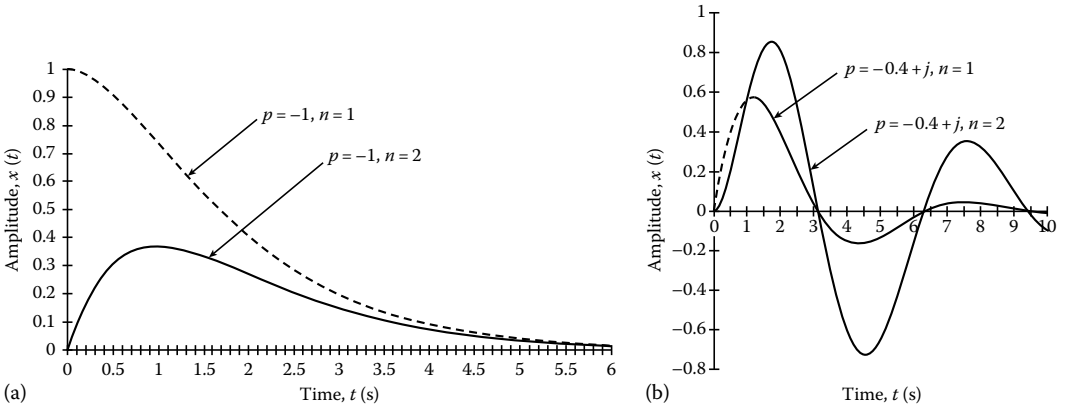

FIGURE 3.10 Modal components in the impulse response corresponding to (a) a real pole of orders $n = 1$ and $n = 2$ at $s = p$, and (b) a complex pole pair of orders $n = 1$ and $n = 2$ and $s = p, p^{\star}$.

When $|p| < 0$, the modal components due to pole p will decay exponentially with time (modulated by the terms t^{i-1}). When $|p| > 0$, these modal components will increase exponentially with time (modulated by the terms t^{i-1}). When $p = 0$, the term will either remain bounded if $n = 1$, or terms will increase with power n as t increases. These cases are illustrated in Figure 3.10a.

Next, let H have a complex pole pair of order n at $s = p, p^{\star}$, so that it can be written

$$H(s) = \sum_{i=1}^{n} \left[\frac{E_i}{(s-p)^i} + \frac{E_i^{\star}}{(s-p^{\star})^i} \right] + [\text{other terms}] \tag{3.155}$$

Using Table 3.1, we see that h has a corresponding modal component

$$h(t) = \sum_{i=1}^{n} \frac{2|E_i|}{(i-1)!} t^{i-1} e^{\sigma_p t} \cos(\omega_p t + \theta_{E_i}) u(t) + [\text{other terms}] \tag{3.156}$$

where $p = \sigma_p + j\omega_p$, and $\theta_{E_i} = \arg\{E_i\}$. In this case, when $|p| < 0$, the sinusoidal components will decay exponentially with time (modulated by the terms t^{i-1}); when $|p| > 0$, these terms will increases exponentially with time (modulated by the terms t^{i-1}); and when $p = 0$, the terms due to p will either represent a constant or increasing sinusoid, depending on the value of n. These cases are illustrated in Figure 3.10b.

3.4.3.2 BIBO Stability

We digress momentarily to discuss the concept of stability. To avoid some unnecessary complications, we restrict the discussion to causal systems, and, as usual, to the unilateral LT. There are various ways to define stability, but the most frequent and useful definition for an LTI system is that of BIBO stability. A system is said to be bounded-input–bounded-output (BIBO) stable iff every bounded input produces a bounded output. Formally, any bounded input, for example, x such that $|x(t)| \leq B_x < \infty$ for all t, must result in an output, y, for which $B_y < \infty$ exists so that $|y(t)| \leq B_y$ for all t.

A necessary and sufficient condition for BIBO stability of an LTI system is that its impulse response be absolutely integrable

$$\int_0^\infty |h(t)|\mathrm{d}t < \infty \tag{3.157}$$

This is easy to show. First, assume $|x(t)| < B_x$ for all t. Then, form the convolution integral

$$|y(t)| = \left| \int_0^\infty x(t-\lambda)h(\lambda)\mathrm{d}\lambda \right| \tag{3.158}$$

Now, using the Schwarz inequality (see Ref. [7]), we have

$$|y(t)| \leq \int_0^\infty \left\| x(t-\lambda) \right\| h(\lambda)|\mathrm{d}\lambda \leq B_x \int_0^\infty |h(\lambda)|\mathrm{d}\lambda \tag{3.159}$$

Consequently, it is sufficient that Equation 3.157 be true for $B_y < \infty$ to exist. On the other hand, suppose that condition (Equation 3.157) were not true, but the system were BIBO stable. For a fixed t, consider the input

$$x(t-\lambda) = \begin{cases} 1, & h(\lambda) > 0 \\ -1, & h(\lambda) < 0 \\ 0, & h(\lambda) = 0 \end{cases} \tag{3.160}$$

For this input, the output at time t is

$$y(t) = \int_0^\infty \left| h(\lambda) \right| \mathrm{d}\lambda \tag{3.161}$$

which is not bounded according to assumption. Therefore, we encounter a contradiction showing that the condition (Equation 3.157) is also necessary for BIBO stability.

3.4.3.3 Stability and Natural Modes

Now we tie the stability analysis to the discussion of modal components above. We assert that a ''causal LTI system with proper rational system function H will be BIBO stable iff all of its poles are in the left-half s-plane.'' That this is true is easily seen. If any pole is in the right-half s-plane, we know that h will contain at least one mode that will increase without bound. Therefore, Equation 3.157 cannot hold and the system is not BIBO stable. Conversely, if all poles are in the left-half s-plane, Equation 3.157 will hold. The case in which one or more simple poles fall exactly on the $s = j\omega$-axis (and none in the right-half s-plane) is called marginal BIBO stability. In this case Equation 3.157 does not hold, so the system is not strictly BIBO stable. However, the system does theoretically produce bounded outputs for some inputs. Finally, note that we show by example below Example 3.24(a) that an improper rational system function cannot represent a BIBO stable system.

Based on our earlier discussion of LT ROCs, an equivalent way to state the BIBO stability condition is as follows: ''A causal, LTI system is BIBO stable iff the ROC of its system function H includes the $s = j\omega$-axis in the s-plane.'' We recall that the failure to include the $j\omega$- axis would imply at least one pole of H in the right-half s-plane.

Let us conclude this discussion by considering some examples.

Example 3.24

Comment on the BIBO stability of the following systems:

$$\text{(a)}\quad H(s)=\frac{N(s)}{D(s)}=\frac{(1/2)s^3}{s^2+2s+1}=\frac{(1/2)s^3}{(s+1)^2}$$

$$\text{(b)}\quad H(s)=\frac{(s-3)}{s^2+5s+4}$$

$$\text{(c)}\quad H(s)=\frac{(s-3)}{(s^2+5s+4)(s^2-2s-3)}$$

$$\text{(d)}\quad H(s)=\frac{6}{\left[(s+3)^2+25\right](s+8)}$$

$$\text{(e)}\quad H(s)=\frac{s}{s^2+4}$$

Solution

(a) H is not a proper rational fraction because the order of $N(s)>$ order of $D(s)$. We illustrate that such a system is not BIBO stable. Dividing D into N, we can write

$$H(s)=\frac{1}{2}s-1+\frac{3/2}{s(s^2+2s+1)} \tag{3.162}$$

Suppose we enter $x(t)=u(t)$ as a (bounded) input. Then

$$Y(s)=H(s)X(s)=\frac{H(s)}{s}=\frac{1}{2}-\frac{1}{s}+\frac{3/2}{s(s^2+2s+1)} \tag{3.163}$$

Therefore,

$$y(t)=\frac{1}{2}\delta(t)-u(t)+\left[\text{terms resulting from}\frac{3/2}{s(s^2+2s+1)}\right] \tag{3.164}$$

The output is unbounded in response to a bounded input and the system is therefore not BIBO stable. "A similar result will occur whenever H is not proper."

(b) H has poles at $s=-1,-4$, and zero at $s=3$. The system is BIBO stable. Note that the right-half plane zero has no adverse effect on stability.

(c) $H(s)=N(s)/D(s)$ has a second-order pole at $s=-1$, and a simple pole at $s=-4$. Both N and D have roots $s=3$, thus neither a pole nor zero is found there (they cancel). The system is therefore BIBO stable.

Remark. The response to nonzero initial conditions of a system which has one or more "cancelled poles" in the right-half s-plane will increase without bound, and therefore could be considered "unstable" in some sense, even though it is BIBO stable. The reader is invited to show that the present system will respond in this undesirable manner to nonzero initial conditions. A system is said to be asymptotically stable if it is BIBO stable and its response to initial conditions approaches zero as $t\to\infty$. We see that asymptotic stability implies BIBO stability but the converse is not true.

(d) Recalling Equation 3.59, we find H has poles $s=-3\pm j5$ and $s=-8$. No finite zeros are included. The system is BIBO stable and will have both an oscillatory mode and a damped exponential mode.

(e) H has poles at $s=\pm j2$ which are on the $j\omega$-axis. The system is marginally BIBO stable.

Example 3.25

Return to the series RLC circuit of Section 3.2 and discuss the system's stability as R varies for a fixed L and C. Assume that $R < 2\sqrt{L/C}$.

Solution

In light of Equation 3.149, the upper bound on R means that the poles of the system will always be complex conjugates, e.g., p_h, p_h^* (h is oscillatory). From Equation 3.150 we see that the poles of the system can be written in polar form as

$$p_h, p_h^* = \sqrt{\sigma_h^2 + \omega_h^2}\, e^{\pm j \tan^{-1}(\omega_h/\sigma_h)} = \frac{1}{\sqrt{LC}} e^{\pm j \tan^{-1}(\omega_h/\sigma_h)} \tag{3.165}$$

For fixed L and C, the poles remain on a circle of radius $1/\sqrt{LC}$ in the s-plane. Having established this fact, recall the Cartesian form of p_h given in Equation 3.149 and note that as $R \to 0, p_h \to j\sqrt{1/LC}$. On other hand, as $R \to 2\sqrt{LC}, p_h \to -\sqrt{1/LC}$ (see Figure 3.11). Therefore, the poles remain in the left-half s-plane over the specified range for R, except when $R = 0$, in which case the poles are exactly on the $j\omega$-axis at $s = \pm j(1/\sqrt{LC})$. Therefore, the system is BIBO stable, except when $R = 0$, in which case it is marginally stable. Only if R were to take negative values would the circuit go unstable. This is not realistic unless active circuit elements are present which effectively present negative resistance. The reader is encouraged to explore what happens as R continues to increase beyond the given upper bound.

3.4.4 Laplace-Domain Phasor Circuits

After completing a sufficient number of circuit problems involving differential equations like Example 3.21, certain patterns would become apparent in a Laplace-transformed differential equation like Equation 3.141. These patterns occur precisely because of the invariant relationships between currents and voltages across lumped parameter components. For example, because the current and voltage

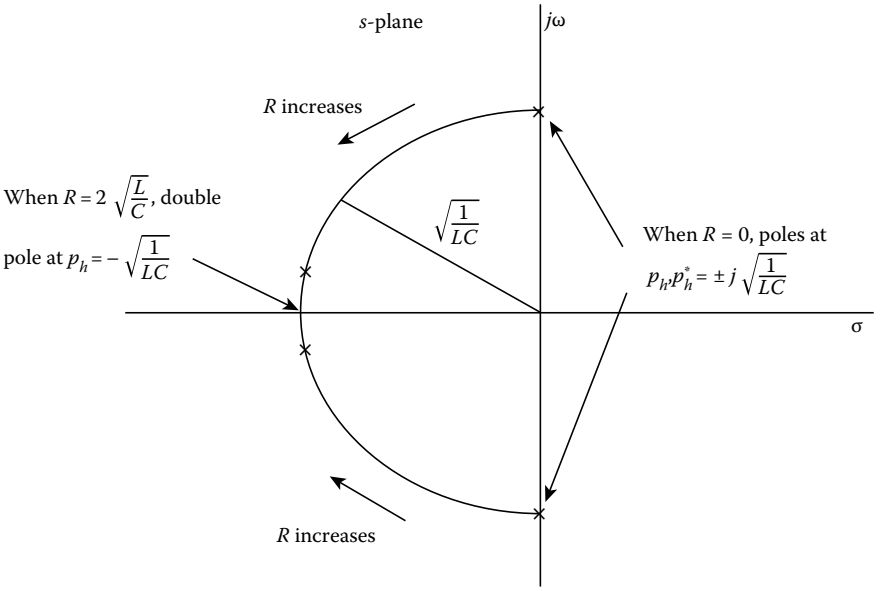

FIGURE 3.11 Locus of the poles as R varies in Example 3.25.

through an inductor are related as $v_L(t) = L(\mathrm{d}i_L/\mathrm{d}t)$, whenever this relationship is encountered and transformed in a circuit problem, it becomes $V_L(s) = sLI_L(s) - Li_L(0^-)$. This relationship may be written without recourse to the time domain by treating $V_L(s)$ and $I_L(s)$ as a ''DC voltage'' and a ''DC current,'' by replacing the inductor with a ''resistor'' with value sL, by adding a voltage source in series with value $Li_L(0^-)$ having proper polarity, a small DC circuit problem.

In general, we can make ''Laplace'' substitutions for each component in a circuit, then use ''DC'' analysis to write the Laplace-transformed differential equation directly. The appropriate substitutions and variations for both mesh and nodal analysis are discussed in detail in Chapter 12 of *Feedback, Nonlinear, and Distributed Circuits*, along with more advanced frequency-domain uses of such LT replacements. After studying that material, the reader may wish to provide closure to the present discussion by solving the following problem.

Example 3.26

Derive the Laplace-transformed differential equation (Equation 3.141) using Laplace circuit equivalents.

3.5 Conclusions and Further Readings

The LT is a powerful tool in the analysis and design of linear, time-invariant circuits and systems. In this exposition we have developed the LT by appealing to the manner in which it turns differential equation solutions into simple algebraic problems. We have focused not only on the technique for exploiting this advantage, but also the reasons that this happens. Along the way we have discovered some useful properties of the LT, as well as the meaning of poles and zeros. We also discussed numerous techniques for recovering the time signal from the LT, noting that this sometime difficult task is the price paid for alleviating the difficulties of time-domain solution. In the latter part of the chapter we turned our attention to the analysis of systems, in particular the meaning and derivation of the system function. This study led to the understanding of the relationship between the system function and impulse response, and between the pole locations of the system function and stability of the system.

Most of our work has focused on the ULT, although the BLT was carefully discussed at the outset. The advantage of the ULT is that it provides a way to incorporate initial condition information, a very important property in many design and analysis problems, particularly because the initial conditions play an important role in the transient response of the system. On the other hand, the BLT can handle a much broader class of signals, a feature that is often advantageous in theoretical and formal developments. The ROC of the LT in the s-plane becomes much more important for the BLT as the LT itself is not unique without it. Accordingly, we spent a significant amount of effort studying the ROC.

The LT is closely related to the Fourier and z-transforms (ZTs), which are the subjects of subsequent chapters. Section 3.7, Appendix B previews these ideas.

Finally, we note that several LT topics have not been treated here. These topics, such as the analysis of feedback systems and state-space models, deal principally with control theory and applications and are therefore outside of the scope of this book. Many fine books on signals and systems are available to which the reader can turn to explore these subjects. Some of these texts are referenced below. Many excellent books on circuit analysis and filter design, too numerous to cite here, are also available.

3.6 Appendix A: The Dirac Delta (Impulse) Function

The Dirac delta, or impulse, function, $\delta(t)$, is defined as the function with the following properties: If signal x is continuous at t_0 (''where the impulse is located in time''), then

$$\int_a^b x(t)\delta(t - t_0)\mathrm{d}t = \begin{cases} 0, & t_0 \notin [a,b] \\ x(t_0), & t_0 \in (a,b) \end{cases} \tag{3.166}$$

Two special cases are noted:

1. Note that Equation 3.166 does not cover the case in which the impulse is located exactly at one of the limits of integration. In such cases whether x is continuous at t_0.
   The integral takes the value $\frac{1}{2}x(t_0^+)$ if t_0 is the lower limit, $t_0 = a$.
   The integral takes the value $\frac{1}{2}x(t_0^-)$ if t_0 is the upper limit, $t_0 = b$.
2. The only case not explicitly covered is one in which x is discontinuous at t_0 and t_0 is not a limit of integration. In this case the integral takes the value $\frac{1}{2}[x(t_0^-) + x(t_0^+)]$ if $t_0 \in (a, b)$, and 0 otherwise. Note that this answer is also valid if x is continuous at t_0, but it is unnecessarily complicated.

Note what happens in the special case in which $x(t) = 1$, $a = -\infty$, $b = t$, and $t_0 = 0$. From the definition, we can write

$$\int_{-\infty}^{t} \delta(\lambda)\mathrm{d}\lambda = \begin{cases} 0, & t < 0 \\ 1, & 5t > 0 \\ \dfrac{1}{2}, & t = 0 \end{cases} \tag{3.167}$$

We see that

$$\int_{-\infty}^{t} \delta(\lambda)\mathrm{d}\lambda = u(t) \tag{3.168}$$

Therefore, except at $t = 0$,

$$\frac{\mathrm{d}u}{\mathrm{d}t} = \delta(t) \tag{3.169}$$

What emerges here is a very strange function. We see from Equation 3.168 that δ must be zero everywhere except at $t = 0$ because, apparently we accumulate area at only that point. The area under that one point is unity because the integral takes a jump from 0 to 1 as t crosses zero. Because δ has zero width and unity total area, it must have infinite amplitude (at that one point!). To indicate the delta function, therefore, we draw ''arrows'' as shown in Figure 3.12. It is sometimes mathematically useful to indicate a delta function with area other than unity. In this case we simply label the arrow with a number called the ''weight'' of the impulse. Note that it makes no sense to draw taller and shorter arrows for

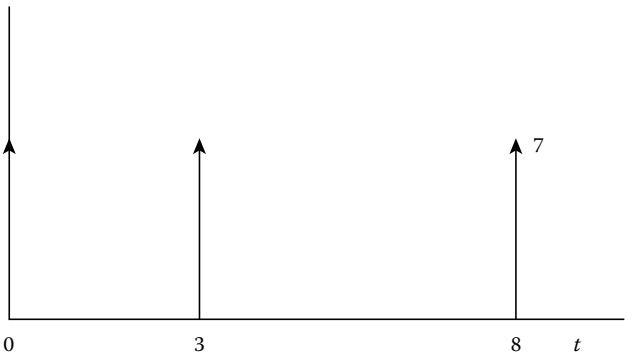

FIGURE 3.12 Impulse functions $\delta(t)$, $\delta(t-3)$, and $7\delta(t-8)$.

different weights, although this is sometimes done in textbooks, because the weight does not indicate the "height" of the function (∞!), but instead, its area!

Finally, note that computing integrals with delta functions in them is very easy because one need only follow the rules of the definition. For example,

$$\int_{-18}^{\infty} e^{\pi(\lambda-4)}\delta(\lambda-6)\mathrm{d}\lambda = e^{2\pi} \tag{3.170}$$

and

$$\int_{0}^{2} 3u(t)\delta(t)\mathrm{d}t = 3\frac{u(0^+)}{2} = \frac{3}{2} \tag{3.171}$$

Remark. The kth derivative of the impulse (usually $k \leq 2$) occasionally appears in LT work. The notation

$$\delta^{(k)}(t) \stackrel{\text{def}}{=} \frac{\mathrm{d}^k\delta}{\mathrm{d}t^k} \tag{3.172}$$

is often used to denote this signal. The signal $\delta^{(1)}(t)$ is called a doublet and is plotted as shown in Figure 3.13.

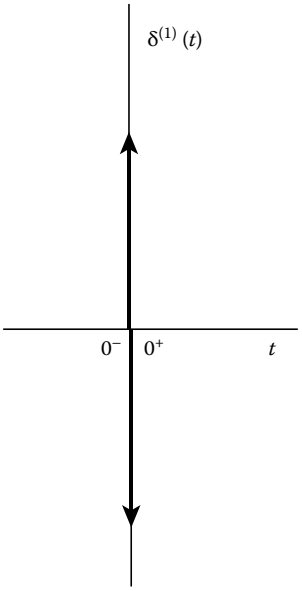

FIGURE 3.13 Doublet.

3.7 Appendix B: Relationships among the Laplace, Fourier, and z-Transforms

The transforms previewed here are most frequently defined and discussed for two-sided signals. Therefore, it is most natural to base this discussion on the BLT, as defined in Equation 3.38.

The FT, X_F, of a signal x is defined by the integral

$$X_F(\omega) = \int_{-\infty}^{\infty} x(t)e^{j\omega t}\mathrm{d}t \tag{3.173}$$

Upon comparison with Equation 3.38, it is apparent that the FT evaluated at radian frequency ω is equivalent to the BLT of x evaluated at $s = j\omega$ in the s-plane. The FT can, therefore, be obtained over all ω by evaluating the BLT, e.g., X_L along the $j\omega$-axis:

$$X_F(\omega) = X_L(s)\big|_{s=j\omega} \tag{3.174}$$

Evidently, the FT will only exist for a signal x if its BLT has an ROC that includes the $j\omega$-axis.

One very important class of signals whose BLT ROCs include the entire left-half s-plane, but not the $j\omega$-axis, is the periodic signals. For this purpose, the FS can be used to expand the signal on a set of discrete, harmonically related, basis functions (either complex exponentials or sinusoids). The complex version is

$$x(t) = \sum_{\ell=-\infty}^{\infty} c_\ell e^{j\ell\omega_0 t} \tag{3.175}$$

where $\omega_0 = 2\pi/T_0$ is the fundamental radian frequency, with T_0 the period of the waveform. The complex numbers c_ℓ, $\ell = \ldots, -1, 0, 1, 2, \ldots$ are the FS coefficients computed as

$$c_\ell = \frac{1}{T_0} \int_{T_0} x(t) e^{-j\ell\omega_0 t} \mathrm{d}t \tag{3.176}$$

where the integral is taken over any period of the waveform.

Comparing Equations 3.176 and 3.173, we see that the FS coefficients are equivalent to (scaled) samples of the FT of one period of x, where the samples are taken at frequencies $\ell\omega_0$. If we have a periodic waveform, therefore, we can always represent it by samples of the FT of one period. Similarly, if we have "short" signal and want to represent it using only frequency samples, we can let it be periodic and represent it using the FS coefficients. In this case, we simply need to recall that the signal is not truly periodic and work with only one period.

Conversely, the FT may be represented using only samples of the time waveform by artificially letting the FT become periodic, then letting the time samples play the role of the FS coefficients. In this case, we in effect, let the BLT become periodic along the $j\omega$-axis. This "backward FS" is what is known as the discrete-time Fourier transform (DTFT). The DTFT is discussed in Chapter 4 along with the discrete Fourier transform, a Fourier-type transform which is discrete and periodic in both time and frequency. For the latter, the connections to the BLT are too obtuse to describe in brief terms here.

Finally, if we let the BLT become periodic in ω with some fixed period along each σ line, the BLT can also be represented by discrete-time samples. This is similar to writing a "FS" which changes for each σ. This discrete-time Laplace transform (DTLT) could, in principle, be used in the design and analysis of discrete-time systems in much the same way the BLT is used incontinuous-time work. For historical reasons and for mathematical convenience, however, the ZT is almost universally used. The ZT is obtained from the DTLT using the mapping $e^{sT} \to z$, where T is the sample period on the time signal. As a consequence of this mapping, "strips" in the s-plane map into annuli in the z-plane. Therefore, the ROC of a ZT takes the form of an annulus and the unit circle in the z-plane plays the role of the $j\omega$-axis in the s-plane.

These ideas will become clearer and more precise through the study of successive Chapters 4 and 5. The reader is also encouraged to see Ref. [2] for an elementary approach to discrete FTs.

4.1 Introduction

The Fourier transform is a mathematical tool that is used to expand signals into a spectrum of sinusoidal components to facilitate the signal representation and the analysis of system performance. In certain applications, the Fourier transform is used for spectral analysis, and while in others it is used for spectrum shaping that adjusts the relative contributions of different frequency components in the filtered result. In certain applications, the Fourier transform is used for its ability to decompose the input signal into uncorrelated components, so that signal processing can be more effectively implemented on the

individual spectral components. Different forms of the Fourier transform, such as the continuous-time (CT) Fourier series, the CT Fourier transform, the discrete-time (DT) Fourier transform (DTFT), the discrete Fourier transform (DFT), and the fast Fourier transform (FFT), are applicable in different circumstances. The goal of this section is to clearly define the various Fourier transforms, to discuss their properties, and to illustrate how each form is related to the others in the context of a family tree of Fourier signal processing methods.

Classical Fourier methods such as the Fourier series and the Fourier integral are used for CT signals and systems, i.e., systems in which the signals are defined at all values of t on the continuum $-\infty < t < \infty$. A more recently developed set of discrete Fourier methods, including the DTFT and the DFT, are extensions of basic Fourier concepts for DT signals and systems. A DT signal is defined only for integer values of n in the range $-\infty < n < \infty$. The class of DT Fourier methods is particularly useful as a basis for digital signal processing (DSP) because it extends the theory of classical Fourier analysis to DT signals and leads to many effective algorithms that can be directly implemented on general computers or special-purpose DSP devices.

4.2 Classical Fourier Transform for Continuous-Time Signals

A CT signal $s(t)$ and its Fourier transform $S(j\omega)$ form a transform pair that are related by the following equations for any $s(t)$ for which the integral (Equation 4.1a) converges:

$$S(j\omega) = \int_{-\infty}^{\infty} s(t)e^{-j\omega t}dt \tag{4.1a}$$

$$s(t) = \frac{1}{2\Pi}\int_{-\infty}^{\infty} S(j\omega)e^{j\omega t}d\omega \tag{4.1b}$$

In most literatures, Equation 4.1a is simply called the *Fourier transform*, whereas Equation 4.1b is called the *Fourier integral*. The relationship $S(j\omega) = F\{s(t)\}$ denotes the Fourier transformation of $s(t)$, where $F\{\cdot\}$ is a symbolic notation for the integral operator, and where ω is the continuous frequency variable expressed in rad/s. A transform pair $s(t) \leftrightarrow S(j\omega)$ represents a one-to-one invertible mapping as long as $s(t)$ satisfies conditions which guarantee that the Fourier integral converges.

In the following discussion, the symbol $\delta(t)$ is used to denote a *CT impulse function* that is defined to be zero for all $t \neq 0$, undefined for $t = 0$, and has unit area when integrated over the range $-\infty < t < \infty$. From Equation 4.1a, it is found that $F\{\delta(t - t_0)\} = e^{-j\omega t_0}$ due to the well-known shifting property of $\delta(t)$. Similarly, from Equation 4.1b we find that $F^{-1}\{2\pi\delta(\omega - \omega_0)\} = e^{j\omega_0 t}$, so that $\delta(t - t_0) \leftrightarrow e^{-j\omega t_0}$ and $e^{j\omega_0 t} \leftrightarrow 2\pi\delta(\omega - \omega_0)$ are Fourier transform pairs. Using these relationships, it is easy to establish the Fourier transforms of $\cos(\omega_0 t)$ and $\sin(\omega_0 t)$, as well as many other useful waveforms, many of which are listed in Table 4.1.

The CT Fourier transform is useful in the analysis and design of CT systems, i.e., systems that process CT signals. Fourier analysis is particularly applicable to the design of CT filters, which are characterized by Fourier magnitude and phase spectra, i.e., by $|H(j\omega)|$ and $\arg H(j\omega)$, where $H(j\omega)$ is commonly called the frequency response of the filter.

4.2.1 Properties of the Continuous-Time Fourier Transform

The CT Fourier transform has many properties that make it useful for the analysis and design of linear CT systems. Some of the more useful properties are summarized in this section, while a more complete

1. Linearity (a and b are complex constants)	$F\{af_1(t) + bf_2(t)\} = aF\{f_1(t)\} + bF\{f_2(t)\}$
2. Time-shifting	$F\{f(t-t_0)\} = e^{-j\omega t_0}F\{f(t)\}$
3. Frequency-shifting	$e^{j\omega_0 t}F^{-1}\{F\{j(\omega-\omega_0)\}$
4. Time-domain convolution	$F\{f_1(t)^* f_2(t)\} = F\{f_1(t)\}\cdot F\{f_2(t)\}$
5. Frequency-domain convolution	$F\{f_1(t)\cdot f_2(t)\} = \frac{1}{2\Pi}F\{f_1(t)\}^* F\{f_2(t)\}$
6. Time-differentiation	$-j\omega F(j\omega) = F\{d(f(t))/dt\}$
7. Time-integration	$F\left\{\int_{-\infty}^{t} f(\tau)d\tau\right\} = \frac{1}{j\omega}F(j\omega) + \pi F(0)\delta(\omega)$

The above properties are particularly useful in CT system analysis and design, especially when the system characteristics are easily specified in the frequency domain, as in linear filtering. Note that properties (1), (6), and (7) are useful for solving differential or integral equations. Property (4) (time-domain

convolution) provides the basis for many signal processing algorithms, since many systems can be specified directly by their impulse or frequency response. Property (3) (frequency-shifting) is useful for analyzing the performance of communication systems where different modulation formats are commonly used to shift spectral energy among different frequency bands.

4.2.2 Sampling Models for Continuous- and Discrete-Time Signals

The relationship between the CT and the DT domains is characterized by the operations of sampling and reconstruction. If $s_a(t)$ denotes a signal $s(t)$ that has been uniformly sampled every T seconds, then the mathematical representation of $s_a(t)$ is given by

$$S_a(t) = \sum_{n=-\infty}^{n=\infty} s(t)\delta(t - nT) \tag{4.2a}$$

where $\delta(t)$ is the CT impulse function defined previously. Since the only places where the product $s(t)\delta(t - nT)$ is not identically equal to zero are at the sampling instances, $s(t)$ in Equation 4.2a can be replaced with $s(nT)$ without changing the overall meaning of the expression. Hence, an alternate expression for $s_a(t)$ that is often useful in Fourier analysis is

$$S_a(t) = \sum_{n=-\infty}^{n=\infty} s(nT)\delta(t - nT) \tag{4.2b}$$

The CT sampling model $s_a(t)$ consists of a sequence of CT impulse functions uniformly spaced at intervals of T seconds and weighted by the values of the signal $s(t)$ at the sampling instants, as depicted in Figure 4.1. Note that $s_a(t)$ is not defined at the sampling instants because the CT impulse function itself is not defined at $t = 0$. However, the values of $s(t)$ at the sampling instants are imbedded as "area under the curve" of $s_a(t)$, and as such represent a useful mathematical model of the sampling process. In the DT domain, the sampling model is simply the sequence defined by taking the values of $s(t)$ at the sampling instants, i.e.,

$$s[n] = s(t)|_{t=nT} \tag{4.3}$$

In contrast to $s_a(t)$, which is not defined at the sampling instants, $s[n]$ is well defined at the sampling instants, as illustrated in Figure 4.2. From this discussion, it is now clear that $s_a(t)$ and $s[n]$ are different but equivalent models of the sampling process in the CT and DT domains, respectively. They are both useful for signal analysis in their corresponding domains. It will be shown later that their equivalence is established by the fact that they have equal spectra in the Fourier domain, and that the underlying CT

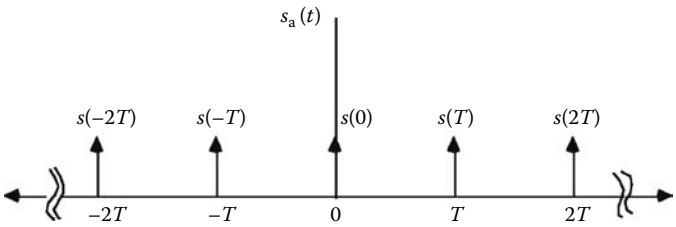

FIGURE 4.1 CT model of a sampled CT signal.

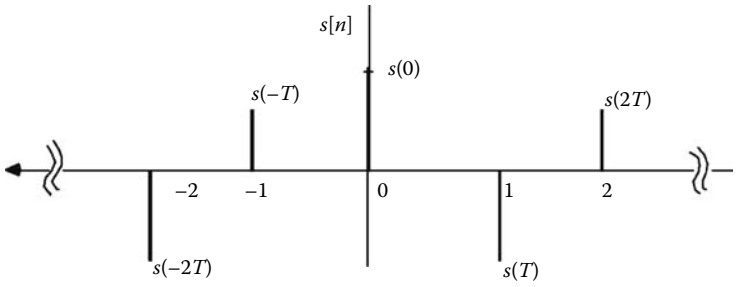

FIGURE 4.2 DT model of a sampled CT signal.

signal from which $s_a(t)$ and $s[n]$ are derived can be recovered from either sampling representation provided that a sufficiently high sampling rate is used in the sampling operation.

4.2.3 Fourier Spectrum of a Continuous-Time Sampled Signal

The operation of uniformly sampling a CT signal $s(t)$ at every T seconds is characterized by Equation 4.2a and b, where $\delta(t)$ is the CT time impulse function defined earlier:

$$s_a(t) = \sum_{n=-\infty}^{\infty} s_a(t)\delta(t - nT) = \sum_{n=-\infty}^{\infty} s_a(nT)\delta(t - nT)$$

Since $s_a(t)$ is a CT signal, it is appropriate to apply the CT Fourier transform to obtain an expression for the spectrum of the sampled signal:

$$F\{s_a(t)\} = F\left\{\sum_{n=-\infty}^{\infty} s_a(nT)\delta(t - nT)\right\} = \sum_{n=-\infty}^{\infty} s_a(nT)[e^{j\omega T}]^{-n} \tag{4.4}$$

Since the expression on the right-hand side of Equation 4.4 is a function of $e^{j\omega T}$, it is customary to express the transform as $F(e^{j\omega T}) = F\{s_a(t)\}$. If ω is replaced with a normalized frequency $\omega' = \omega/T$, so that $-\pi < \omega' < \pi$, then the right side of Equation 4.4 becomes identical to the DTFT that is defined directly for the sequence $s[n] = s_a(nT)$.

4.2.4 Generalized Complex Fourier Transform

The CT Fourier transform characterized by Equation 4.1 can be generalized by considering the variable $j\omega$ to be the special case of $u = \sigma + j\omega$ with $\sigma = 0$, writing Equation 4.1 in terms of u, and interpreting u as a complex frequency variable. The resulting complex Fourier transform pair is given by Equation 4.5a and b (Bracewell 1986):

$$s(t) = \frac{1}{2\Pi j}\int_{\sigma - j\infty}^{\sigma + j\infty} S(u)e^{jut}du \tag{4.5a}$$

$$S(u) = \int_{-\infty}^{\infty} s(t)e^{-jut}dt \tag{4.5b}$$

The set of all values of u for which the integral of Equation 4.5b converges is called the region of convergence (ROC). Since the transform $S(u)$ is defined only for values of u within the ROC, the path of integration in Equation 4.5a must be defined so the entire path lies within the ROC. In some literature this transform pair is called the bilateral Laplace transform because it is the same result obtained by including both the negative and positive portions of the time axis in the classical Laplace transform integral. The complex Fourier transform (bilateral Laplace transform) is not often used in solving practical problems, but its significance lies in the fact that it is the most general form that represents the place where Fourier and Laplace transform concepts merge together. Identifying this connection reinforces the observation that Fourier and Laplace transform concepts share common properties because they result from placing different constraints on the same parent form.

4.3 Fourier Series Representation of Continuous-Time Periodic Signals

The classical Fourier series representation of a periodic time-domain signal $s(t)$ involves an expansion of $s(t)$ into an infinite series of terms that consist of sinusoidal basis functions, each weighted by a complex constant (Fourier coefficient) that provides the proper contribution of that frequency component to the complete waveform. The conditions under which a periodic signal $s(t)$ can be expanded in a Fourier series are known as the *Dirichlet conditions*. They require that in each period $s(t)$ has a finite number of discontinuities, a finite number of maxima and minima, and satisfies the absolute convergence criterion of Equation 4.6 (VanValkenburg 1974):

$$\int_{-T/2}^{T/2} |s(t)|\mathrm{d}t < \infty \tag{4.6}$$

It is assumed throughout the following discussion that the Dirichlet conditions are satisfied by all functions that will be represented by a Fourier series.

4.3.1 Exponential Fourier Series

If $s(t)$ is a CT periodic signal with period T the exponential Fourier series expansion of $s(t)$ is given by

$$s(t) = \sum_{n=-\infty}^{\infty} a_n \mathrm{e}^{jn\omega_0 t} \tag{4.7a}$$

where $\omega_0 = 2\pi/T$. The a_ns are the complex Fourier coefficients given by

$$a_n = \frac{1}{T} \int_{-T/2}^{T/2} s(t)\mathrm{e}^{-jn\omega_0 t}\mathrm{d}t, \quad -\infty < n < \infty \tag{4.7b}$$

For every value of t where $s(t)$ is continuous the right side of Equation 4.7a converges to $s(t)$. At values of t where $s(t)$ has a finite jump discontinuity, the right side of Equation 4.7a converges to the average of $s(t^-)$ and $s(t^+)$, where

$$s(t^-) = \lim_{\varepsilon \to 0} (t - \varepsilon) \quad \text{and} \quad s(t^+) = \lim_{\varepsilon \to 0} (t + \varepsilon).$$

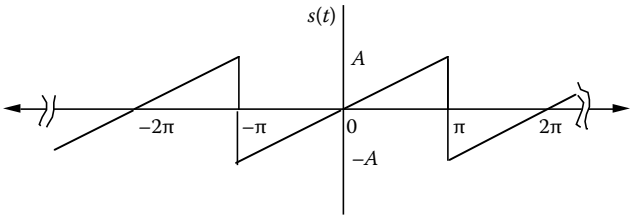

FIGURE 4.3 Periodic CT signal used in Fourier series Example 1.

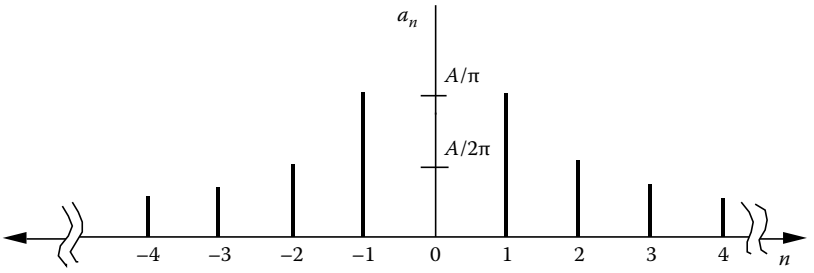

FIGURE 4.4 Magnitude of the Fourier coefficients for Example 1.

For example, the Fourier series expansion of the sawtooth waveform (Example 1) illustrated in Figure 4.3 is characterized by $T = 2\pi$, $\omega_0 = 1$, $a_0 = 0$, and $a_n = a_{-n} = A\ \cos(n\pi)/(jn\pi)$ for $n = 1, 2, \ldots$. The coefficients of the exponential Fourier series given by Equation 4.7b can be interpreted as a spectral representation of $s(t)$, since the a_nth coefficient represents the contribution of the $(n\omega_0)$th frequency component to the complete waveform. Since the a_ns are complex valued, the Fourier domain (spectral) representation has both magnitude and phase spectra. For example, the magnitudes of the a_ns are plotted in Figure 4.4 for the sawtooth waveform of Figure 4.3. The fact that the a_ns constitute a discrete set is consistent with the fact that a periodic signal has a spectrum that contains only integer multiples of the fundamental frequency ω_0. The equation pair given by Equation 4.7a and b can be interpreted as a transform pair that is similar to the CT Fourier transform for periodic signals. This leads to the observation that the classical Fourier series can be interpreted as a special transform that provides a one-to-one invertible mapping between the discrete-spectral domain and the CT domain.

4.3.2 Trigonometric Fourier Series

Although the complex form of the Fourier series expansion is useful for complex periodic signals, the Fourier series can be more easily expressed in terms of real-valued sine and cosine functions for real-valued periodic signals. In the following discussion it is assumed that the signal $s(t)$ is real-valued. When $s(t)$ is periodic and real-valued, it is convenient to replace the complex exponential Fourier series with a *trigonometric expansion* that contains $\sin(\omega_0 t)$ and $\cos(\omega_0 t)$ terms with corresponding real-valued coefficients (VanValkenburg 1974). The trigonometric form of the Fourier series for a real-valued signal $s(t)$ is given by

$$s(t) = \sum_{n=0}^{\infty} b_n \cos(n\omega_0) + \sum_{n=1}^{\infty} c_n \sin(n\omega_0) \tag{4.8a}$$

where $\omega_0 = 2\pi/T$. In Equation 4.8a the b_ns and c_ns are real-valued Fourier coefficients determined by

$$b_0 = \frac{1}{T}\int_{-T/2}^{T/2} s(t)\mathrm{d}t$$
$$b_n = \frac{2}{T}\int_{-T/2}^{T/2} s(t)\cos(n\omega_0 t)\mathrm{d}t, \quad n = 1, 2, \ldots \tag{4.8b}$$

and

$$c_n = \frac{2}{T}\int_{-T/2}^{T/2} s(t)\sin(n\omega_0 t)\mathrm{d}t, \quad n = 1, 2, \ldots$$

An arbitrary real-valued signal $s(t)$ can be expressed as a sum of even and odd components, $s(t) = s_{\text{even}}(t) + s_{\text{odd}}(t)$, where $s_{\text{even}}(t) = s_{\text{even}}(-t)$ and $s_{\text{odd}}(t) = -s_{\text{odd}}(-t)$, and where $s_{\text{even}}(t) = [s(t) + s(-t)]/2$ and $s_{\text{odd}}(t) = [s(t) - s(-t)]/2$. For the trigonometric Fourier series, it can be shown that $s_{\text{even}}(t)$ is represented by the (even) cosine terms in the infinite series, $s_{\text{odd}}(t)$ is represented by the (odd) sine terms, and b_0 is the DC level of the signal. Therefore, if it can be determined by inspection that a signal has a DC level, or if it is even or odd, then the correct form of the trigonometric series can be chosen to simplify the analysis. For example, it is easily seen that the signal shown in Figure 4.5 (Example 2) is an even signal with a zero DC level, and therefore, can be accurately represented by the cosine series with $b_n = 2A\ \sin(\pi n/2)/(\pi n/2)$, $n = 1, 2, \ldots$ as shown in Figure 4.6. In contrast note that the sawtooth waveform used in the previous example is an odd signal with zero DC level, so that it can be completely

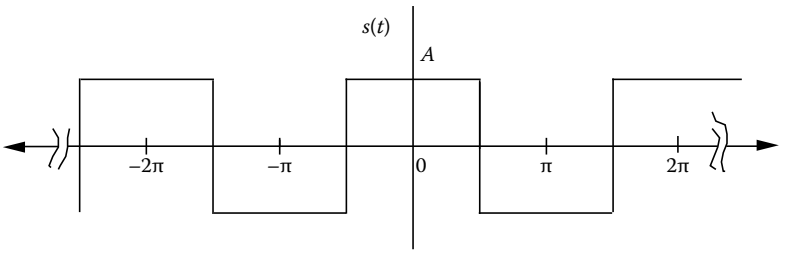

FIGURE 4.5 Periodic CT signal used in Fourier series Example 2.

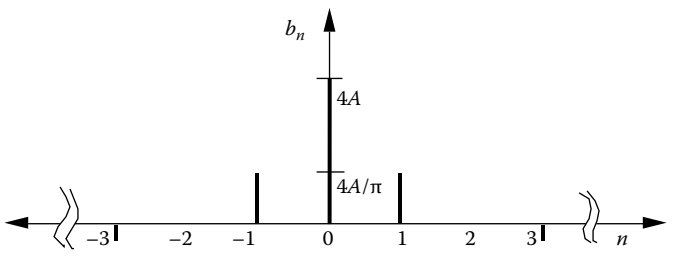

FIGURE 4.6 Fourier coefficients for example of Figure 4.5.

specified by the sine terms of the trigonometric series. This result can be demonstrated by pairing each positive frequency component from the exponential series with its conjugate partner, i.e., $c_n = \sin(n\omega_0 t) = a_n e^{jn\omega_0 t} + a_{-n} e^{-jn\omega_0 t}$, whereby it is found that $c_n = 2A\cos(n\pi)/(n\pi)$ for this example. In general, it is found that $a_n = (b_n - jc_n)/2$ for $n = 1, 2, \ldots$, $a_0 = b_0$, and $a_{-n} = a_n^*$. The trigonometric Fourier series is common in the signal processing literature because it replaces complex coefficients with real ones and often results in a simpler and more intuitive interpretation of the results.

4.3.3 Convergence of the Fourier Series

The Fourier series representation of a periodic signal is an approximation that exhibits mean squared convergence to the true signal. If $s(t)$ is a periodic signal of period T, and $s'(t)$ denotes the Fourier series approximation of $s(t)$, then $s(t)$ and $s'(t)$ are equal in the mean square sense if

$$\text{mse} = \int_{-T/2}^{T/2} |s(t) - s'(t)|^2 \, dt = 0 \tag{4.9}$$

Even if Equation 4.9 is satisfied, *mean square error* (MSE) convergence does not guarantee that $s(t) = s'(t)$ at every value of t. In particular, it is known that at values of t where $s(t)$ is discontinuous, the Fourier series converges to the average of the limiting values to the left and right of the discontinuity. For example, if t_0 is a point of discontinuity, then $s'(t_0) = [s(t_0^-) + s(t_0^+)]/2$, where $s(t_0^-)$ and $s(t_0^+)$ were defined previously (note that at points of continuity, this condition is also satisfied by the very definition of continuity). Since the Dirichlet conditions require that $s(t)$ have at most a finite number of points of discontinuity in one period, the set S_t such that $s(t) \neq s'(t)$ within one period contains a finite number of points, and S_t is a set of measure zero in the formal mathematical sense. Therefore $s(t)$ and its Fourier series expansion $s'(t)$ are *equal almost everywhere*, and $s(t)$ can be considered identical to $s'(t)$ for analysis in most practical engineering problems.

The condition of convergence almost everywhere is satisfied only in the limit as an infinite number of terms are included in the Fourier series expansion. If the infinite series expansion of the Fourier series is truncated to a finite number of terms, as it must always be in practical applications, then the approximation will exhibit an oscillatory behavior around the discontinuity, known as the *Gibbs phenomenon* (VanValkenburg 1974). Let $s'_N(t)$ denote a truncated Fourier series approximation of $s(t)$, where only the terms in Equation 4.7a from $n = -N$ to $n = N$ are included if the complex Fourier series representation is used, or where only the terms in Equation 4.8a from $n = 0$ to $n = N$ are included if the trigonometric form of the Fourier series is used. It is well known that in the vicinity of a discontinuity at t_0 the Gibbs phenomenon causes $s'_N(t)$ to be a poor approximation to $s(t)$. The peak magnitude of the Gibbs oscillation is 13% of the size of the jump discontinuity $s(t_0^-) - s(t_0^+)$ regardless of the number of terms used in the approximation. As N increases, the region that contains the oscillation becomes more concentrated in the neighborhood of the discontinuity, until, in the limit as N approaches infinity, the Gibbs oscillation is squeezed into a single point of mismatch at t_0. The Gibbs phenomenon is illustrated in Figure 4.7 where an ideal low-pass frequency response is approximated by impulse response function that has been limited to having only N nonzero coefficients, and hence the Fourier series expansion contains only a finite number of terms.

An important property of the Fourier series is that the exponential basis functions $e^{jn\omega_0 t}$ (or $\sin(n\omega_0 t)$ and $\cos(n\omega_0 t)$ for the trigonometric form) for $n = 0, \pm 1, \pm 2, \ldots$ (or $n = 0, 1, 2, \ldots$ for the trigonometric form) constitute an *orthonormal set*, i.e., $t_{nk} = 1$ for $n = k$, and $t_{nk} = 0$ for $n \neq k$, where

$$t_{nk} = \frac{1}{T} \int_{-T/2}^{T/2} (e^{-jn\omega_0 t})(e^{jk\omega_0 t}) \, dt$$

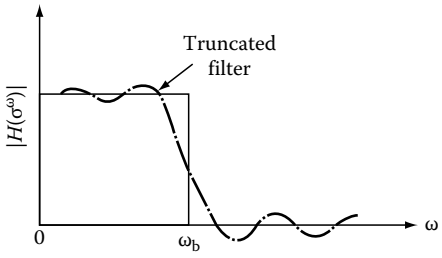

FIGURE 4.7 Gibbs phenomenon in a low-pass digital filter caused by truncating the impulse response to N terms.

As terms are added to the Fourier series expansion, the orthogonality of the basis functions guarantees that the approximation error decreases in the mean square sense, i.e., that MSE_N decreases monotonically as N is increased, where

$$\text{MSE}_N = \int_{-T/2}^{T/2} \left| s(t) - s'_N(t) \right|^2 \mathrm{d}t$$

Therefore, when applying Fourier series analysis including more terms always improves the accuracy of the signal representation.

4.3.4 Fourier Transform of Periodic Continuous-Time Signals

For a periodic signal $s(t)$, the CT Fourier transform can then be applied to the Fourier series expansion of $s(t)$ to produce a mathematical expression for the "line spectrum" that is characteristic of periodic signals:

$$F\{s(t)\} = F\left\{ \sum_{n=-\infty}^{\infty} a_n \mathrm{e}^{jn\omega_0 t} \right\} = 2\pi \sum_{n=-\infty}^{\infty} a_n \delta(\omega - \omega_0) \tag{4.10}$$

The spectrum is shown in Figure 4.8. Note the similarity between the spectral representation of Figure 4.8 and the plots of the Fourier coefficients in Figures 4.4 and 4.6, which were heuristically interpreted as a line spectrum. Figures 4.4 and 4.6 are different from Figure 4.8 but they are equivalent representations of the Fourier line spectrum that is characteristic of periodic signals.

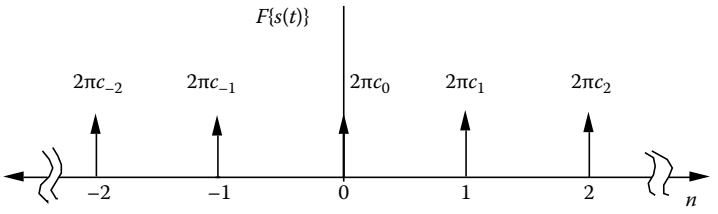

FIGURE 4.8 Spectrum of the Fourier representation of a periodic signal.

4.4 Discrete-Time Fourier Transform

The DTFT is obtained directly in terms of the sequence samples $s[n]$ by taking the relationship obtained in Equation 4.4 to be the definition of the DTFT. Letting $T = 1$ so that the sampling period is removed from the equations and the frequency variable is replaced with a normalized frequency $\omega' = \omega T$, the DTFT pair is defined by Equation 4.11. In order to simplify notation, it is not customary to distinguish between ω and ω', but rather to rely on the context of the discussion to determine whether ω refers to the normalized ($T = 1$) or the unnormalized ($T \neq 1$) frequency variable.

$$S(e^{j\omega'}) = \sum_{n=-\infty}^{\infty} s[n]e^{-j\omega' n} \tag{4.11a}$$

$$s[n] = \frac{1}{2\Pi} \int_{-\Pi}^{\Pi} S(e^{j\omega'})e^{jn\omega'} d\omega' \tag{4.11b}$$

The spectrum $S(e^{j\omega'})$ is periodic in ω' with period 2π. The fundamental period in the range $-\pi < \omega' \leq \pi$, referred to as the baseband, is the useful frequency range of the DT system because frequency components in this range can be represented unambiguously in sampled form (without aliasing error). In much of the signal processing literature the explicit primed notation is omitted from the frequency variable. However, the explicit primed notation will be used throughout this section because there is a potential for confusion when so many related Fourier concepts are discussed within the same framework.

By comparing Equations 4.4 and 4.11a, and noting that $\omega' = \omega T$, it is seen that

$$F\{s_a(t)\} = \text{DTFT}\{s[n]\}$$

where $s[n] = s_a(t)|_{t=nT}$. This demonstrates that the spectrum of $s_a(t)$ as calculated by the CT Fourier transform is identical to the spectrum of $s[n]$ as calculated by the DTFT. Therefore although $s_a(t)$ and $s[n]$ are quite different sampling models, they are equivalent in the sense that they have the same Fourier domain representation. A list of common DTFT pairs is presented in Table 4.3. Just as the CT Fourier transform is useful in CT signal system analysis and design, the DTFT is equally useful for DT system analysis and design.

In the same way that the CT Fourier transform was found to be a special case of the complex Fourier transform (or bilateral Laplace transform), the DTFT is a special case of the *bilateral z-transform* with $z = e^{j\omega' t}$. The more general bilateral z-transform is given by

$$S(z) = \sum_{n=-\infty}^{\infty} s[n]z^{-n} \tag{4.12a}$$

$$s[n] = \frac{1}{2\pi j} \oint_c S(z)z^{n-1} dz \tag{4.12b}$$

where C is a counter clockwise contour of integration which is a closed path completely contained within the ROC of $S(z)$. Recall that the DTFT was obtained by taking the CT Fourier transform of the CT sampling model $s_a(t)$. Similarly, the bilateral z-transform results by taking the bilateral Laplace transform of $s_a(t)$. If the lower limit on the summation of Equation 4.12a is taken to be $n = 0$, then Equation 4.12a and b becomes the one-sided z-transform, which is the DT equivalent of the one-sided Laplace transform for CT signals.

TABLE 4.3 Some Basic Discrete Time Fourier Transform Pairs

4.4.1 Properties of the Discrete-Time Fourier Transform

Since the DTFT is a close relative of the classical CT Fourier transform, it should come as no surprise that many properties of the DTFT are similar to those of the CT Fourier transform. In fact, for many of the properties presented earlier, there is an analogous property for the DTFT. The following list parallels the list that was presented earlier for the CT Fourier transform, to the extent that the same properties exist (a more complete list of DTFT properties is given in Table 4.4). Note that $F\{\cdot\}$ denotes the DT Fourier transform operation, $F^{-1}\{\cdot\}$ denotes the inverse DT Fourier transform operation, and "$\star$" denotes the DT convolution operation defined as

$$f_1[n]\star f_2[n] = \sum_{k=-\infty}^{+\infty} f_1[n] f_2[n-k]$$

1. Linearity (a and b are complex constants)	$\text{DTFT}\{af_1[n] + bf_2[n]\} = a \cdot \text{DTFT}\{f_1[n]\} + b \cdot \text{DTFT}\{f_2[n]\}$
2. Index-shifting	$\text{DTFT}\{f[n - n_0]\} = e^{-j\omega n_0}\ \text{DTFT}\{f[n]\}$
3. Frequency-shifting	$e^{j\omega_0 n} f[n] = \text{DTFT}^{-1}\{F(j\omega - \omega_0)\}$
4. Time-domain convolution	$\text{DTFT}\{f_1[n]\star f_2[n]\} = F\{f_1[n]\} \cdot F\{f_2[n]\}$
5. Frequency-domain convolution	$\text{DTFT}\{f_1[n] \cdot f_2[n]\} = \frac{1}{2\Pi}\text{DTFT}\{f_1[n]\} * \text{DTFT}\{f_2[n]\}$
6. Frequency-differentiation	$nf[n] = \text{DTFT}^{-1}\{dF(j\omega)/d\omega\}$

Note that the time-differentiation and time-integration properties of the CT Fourier transform do not have analogous counterparts in the DTFT because time-domain differentiation and integration are not

defined for DT signals. When working with DT systems practitioners must often manipulate difference equations in the frequency domain. For this purpose the properties of linearity and index-shifting are very important. As with the CT Fourier transform, time-domain convolution is also important for DT systems because it allows engineers to work with the frequency response of the system in order to achieve proper shaping of the input spectrum, or to achieve frequency selective filtering for noise reduction or signal detection.

4.4.2 Relationship between the CT and DT Spectra

Since DT signals often originate by sampling a CT signal, it is important to develop the relationship between the original spectrum of the CT signal and the spectrum of the DT signal that results. First, the CT Fourier transform is applied to the CT sampling model, and the properties are used to produce the following result:

$$F\{s_a(t)\} = F\left\{s_a(t)\sum_{n=-\infty}^{\infty}\delta(t-nT)\right\} = \frac{1}{2\pi}S_a(j\omega)F\left\{\sum_{n=-\infty}^{\infty}\delta(t-nT)\right\} \tag{4.13}$$

Since the sampling function (summation of shifted impulses) on the right-hand side of Equation 4.13 is periodic with period T it can be replaced with a CT Fourier series expansion and the frequency-domain convolution property of the CT Fourier transform can be applied to yield two equivalent expressions for the DT spectrum:

$$S(e^{j\omega T}) = \frac{1}{T}\sum_{n=-\infty}^{\infty} S_a(j[\omega - n\omega_s]) \quad \text{or} \quad S(e^{j\omega'}) = \frac{1}{T}\sum_{n=-\infty}^{\infty} S_a(j[\omega' - n2\pi/T]) \tag{4.14}$$

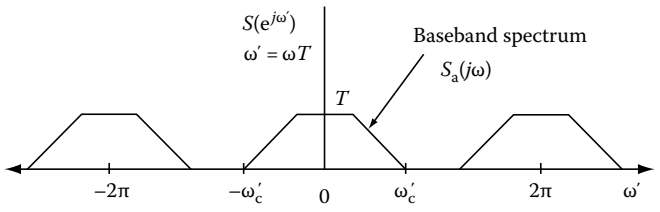

FIGURE 4.9 Relationship between the CT and DT spectra.

In Equation 4.14 $\omega_s = (2\pi/T)$ is the sampling frequency and $\omega' = \omega T$ is the normalized DT frequency axis expressed in radians. Note that $S(e^{j\omega T}) = S(e^{j\omega'})$ consists of an infinite number of replicas of the CT spectrum $S(j\omega)$, positioned at intervals of $(2\pi/T)$ on the ω axis (or at intervals of 2π on the ω' axis), as illustrated in Figure 4.9. Note that if $S(j\omega)$ is band-limited with a bandwidth ω_c, and if T is chosen sufficiently small so that $\omega_s > 2\omega_c$, then the DT spectrum is a copy of $S(j\omega)$ (scaled by $1/T$) in the baseband. The limiting case of $\omega_s = 2\omega_c$ is called the *Nyquist sampling frequency*. Whenever a CT signal is sampled at or above the Nyquist rate, no aliasing distortion occurs (i.e., the baseband spectrum does not overlap with the higher order replicas) and the CT signal can be exactly recovered from its samples by extracting the baseband spectrum of $S(e^{j\omega'})$ with an ideal low-pass filter that recovers the original CT spectrum by removing all spectral replicas outside the baseband and scaling the baseband by a factor of T.

4.5 Discrete Fourier Transform

To obtain the DFT the continuous-frequency domain of the DTFT is sampled at N points uniformly spaced around the unit circle in the z-plane, i.e., at the points $\omega_k = (2\pi k/N)$, $k = 0,\ 1, \ldots, N-1$. The result is the DFT transform pair defined by Equation 4.15a and b:

$$S[k] = \sum_{n=0}^{N-1} s[n] e^{-j\frac{2\pi kn}{N}}, \quad k = 0, 1, \ldots, N-1 \tag{4.15a}$$

$$s[k] = \frac{1}{N} \sum_{k=0}^{N-1} S[k] e^{j\frac{2\pi kn}{N}}, \quad n = 0, 1, \ldots, N-1 \tag{4.15b}$$

The signal $s[n]$ is either a finite length sequence of length N, or it is a periodic sequence with period N. Regardless of whether $s[n]$ is a finite length or periodic sequence, the DFT treats the N samples of $s[n]$ as though they are one period of a periodic sequence. This is a peculiar feature of the DFT, and one that must be handled properly in signal processing to prevent the introduction of artifacts.

4.5.1 Properties of the DFT

Important properties of the DFT are summarized in Table 4.5. The notation $([k])_N$ denotes k modulo N, and $R_N[n]$ is a rectangular window such that $R_N[n] = 1$ for $n = 0, \ldots, N-1$, and $R_N[n] = 0$ for $n < 0$ and $n \geq N$. The transform relationship given by Equation 4.15a and b is also valid when $s[n]$ and $S[k]$ are periodic sequences, each of period N. In this case n and k are permitted to range over the complete set of real integers, and $S[k]$ is referred to as the discrete Fourier series (DFS). In some cases, the DFS is developed as a distinct transform pair in its own right (Jenkins 1986). Whether or not the DFT and the DFS are considered identical or distinct is not important in this discussion. The important point to be

TABLE 4.5 Properties of the Discrete Fourier Transform (DFT)

Finite-Length Sequence (Length N)	N-Point DFT (Length N)
1. $x[n]$	$X[k]$
2. $x_1[n]$, $x_2[n]$	$X_1[k]$, $X_2[k]$
3. $ax_1[n] + bx_2[n]$	$aX_1[k] + bX_2[k]$
4. $X[n]$	$Nx[((-k))_N]$
5. $x[(\,(n-m))_N]$	$W_N^{km}X[k]$
6. $W_N^{-\ell n}x[n]$	$X[((k-\ell))_N]$
7. $\sum_{m=0}^{N-1} x_1(m)x_2[((n-m))_N]$	$X_1[k]X_2[k]$
8. $x_1[n]x_2[n]$	$\frac{1}{N}\sum_{\ell=0}^{N-1} X_1(\ell)X_2[((k-\ell))_N]$
9. $x^*[n]$	$X^*[(\,(-k))_N]$
10. $x^*[((-n))_N]$	$X^*[k]$
11. $\mathcal{R}e\{x[n]\}$	$X_{ep}[k] = \frac{1}{2}\{X[((k))_N] + X^*[((-k))_N]\}$
12. $j\mathcal{I}\mathrm{m}\{x[n]\}$	$X_{op}[k] = \frac{1}{2}\{X[((k))_N] - X^*[((-k))_N]\}$
13. $x_{ep}[n] = \frac{1}{2}\{x[n] + x^*[((-n))_N]\}$	$\mathcal{R}\mathrm{e}\ \{X[k]\}$
14. $x_{op}[n] = \frac{1}{2}\{x[n] - x^*[((-n))_N]\}$	$j\mathcal{I}\mathrm{m}\ \{X[k]\}$
Properties 15–17 apply only when $x[n]$ is real.	
15. Symmetry properties	$\begin{cases} X[k] & = X^*[((-k))_N] \\ Re\{X[k]\} & = Re\{X[((-k))_N]\} \\ \mathcal{I}\mathrm{m}\{X[k]\} & = -\mathcal{I}\mathrm{m}\{X[((-k))_N]\} \\ \lvert X[k]\rvert & = \lvert X[((-k))_N]\rvert \\ \measuredangle\{X[k]\} & = -\measuredangle\{X[((-k))_N]\} \end{cases}$
16. $x_{ep}[n] = \frac{1}{2}\{x[n] + x[((-n))_N]\}$	$\mathcal{R}\mathrm{e}\{X[k]\}$
17. $x_{op}[n] = \frac{1}{2}\{x[n] - x[((-n))_N]\}$	$j\mathcal{I}\mathrm{m}\{X[k]\}$

emphasized here is that the DFT treats $s[n]$ as though it were a single period of a periodic sequence, and all signal processing done with the DFT will inherit the consequences of this assumed periodicity.

Most of the properties listed in Table 4.5 for the DFT are similar to those of the Z-transform and the DTFT, although there are important differences. For example, Property (5) (time-shifting property), holds for circular shifts of the finite length sequence $s[n]$, which is consistent with the notion that the DFT treats $s[n]$ as one period of a periodic sequence. Also, the multiplication of two DFTs results in the *circular convolution* of the corresponding DT sequences, as specified by Property (7). This latter property is quite different from *the linear convolution* property of the DTFT. Circular convolution is simply a linear convolution of the periodic extensions of the finite sequences being convolved, where each of the finite sequences of length N defines the structure of one period of the periodic extensions.

For example, suppose it is desired to implement a digital filter with finite impulse response (FIR) $h[n]$. The output in response to $s[n]$ is

$$y[n] = \sum_{k=0}^{N-1} h[k]s[n-k] \tag{4.16}$$

which is obtained by transforming $h[n]$ and $s[n]$ into $H[k]$ and $S[k]$ using the DFT, multiplying the transforms point-wise to obtain $Y[k] = H[k]S[k]$, and then using the inverse DFT to obtain $y[n] = \mathrm{DFT}^{-1}\{Y[k]\}$. If $s[n]$ is a finite sequence of length M, then the results of the circular convolution

implemented by the DFT will correspond to the desired linear convolution if and only if the block length of the DFT, N_{DFT}, is chosen sufficiently large so that $N_{\mathrm{DFT}} > N + M - 1$ and both $h[n]$ and $s[n]$ are padded with zeros to form blocks of length N_{DFT}.

4.5.2 Fast Fourier Transform Algorithms

The DFT is typically implemented in practice with one of the common forms of the FFT algorithm. The FFT is not a Fourier transform in its own right, but rather it is simply a computationally efficient algorithm that reduces the complexity of the computing DFT from Order $\{N^2\}$ to Order $\{N \log_2 N\}$. When N is large, the computational savings provided by the FFT algorithm is so great that the FFT makes real-time DFT analysis practical in many situations which would be entirely impractical without it. There are numerous FFT algorithms, including decimation-in-time (D-I-T) algorithms, decimation-in-frequency (D-I-F) algorithms, bit-reversed algorithms, normally ordered algorithms, mixed-radix algorithms (for block lengths that are not powers-of-2 [PO2]), prime factor algorithms, and Winograd algorithms (Blahut 1985). The D-I-T and the D-I-F radix-2 FFT algorithms are the most widely used in practice. Detailed discussions of various FFT algorithms can be found in Brigham (1974) and Oppenheim and Schafer (1975).

The FFT is easily understood by examining the simple example of $N = 8$. There are numerous ways to develop the FFT algorithm, all of which deal with a nested decomposition of the summation operator of Equation 4.20a. The development presented here is called an *algebraic* development of the FFT because it follows straightforward algebraic manipulation. First, each of the summation indices (k, n) in Equation 4.15a is expressed as explicit binary integers, $k = k_2 4 + k_1 2 + k_0$ and $n = n_2 4 + n_1 2 + n_0$, where k_i and n_i are bits that take on the values of either 0 or 1. If these expressions are substituted into Equation 4.20a, all terms in the exponent that contain the factor $N = 8$ can be deleted because $e^{-j2\pi l} = 1$ for any integer l. Upon deleting such terms and regrouping the remaining terms, the product nk can be expressed in either of two ways:

$$nk = (4k_0)n_2 + (4k_1 + 2k_0)n_1 + (4k_2 + 2k_1 + k_0)n_0 \tag{4.17a}$$

$$nk = (4n_0)k_2 + (4n_1 + 2n_0)k_1 + (4n_2 + 2n_1 + n_0)k_0 \tag{4.17b}$$

Substituting Equation 4.17a into Equation 4.15a leads to the D-I-T FFT, whereas substituting Equation 4.25b leads to the D-I-F FFT. Only the D-I-T FFT is discussed further here. The D-I-F and various related forms are treated in detail in Oppenheim and Schafer (1975).

The D-I-T FFT decomposes into $\log_2 N$ stages of computation, plus a stage of bit reversal,

$$x_1[k_0, n_1, n_0] = \sum_{n_2=0}^{n_2=1} s[n_2, n_1, n_0] W_8^{4k_0 n_2} \text{ (stage 1)} \tag{4.18a}$$

$$x_2[k_0, k_1, n_0] = \sum_{n_1=0}^{n_1=1} x_1[k_0, n_1, n_0] W_8^{4k_1 + 2k_0)n_1} \text{ (stage 2)} \tag{4.18b}$$

$$x_3[k_0, k_1, k_2] = \sum_{n_0=0}^{n_0=1} x_2[k_0, k_1, n_0] W_8^{4k_2 + 2k_1 + k_0)n_0} \text{ (stage 3)} \tag{4.18c}$$

$$s(k_2, k_1, k_0) = x_3(k_2, k_1, k_2) \text{ (bit reversal)} \tag{4.18d}$$

In each summation above, one of the n_is is summed out of the expression, while at the same time a new k_i is introduced.

The notation is chosen to reflect this. For example, in stage 3, n_0 is summed out, k_2 is introduced as a new variable, and n_0 is replaced by k_2 in the result. The last operation, called bit reversal, is necessary to

correctly locate the frequency samples $X[k]$ in the memory. It is easy to show that if the samples are paired correctly, an in-place computation can be done by a sequence of butterfly operations. The term in-place means that each time a butterfly is to be computed, a pair of data samples is read from memory, and the new data pair produced by the butterfly calculation is written back into the memory locations where the original pair was stored, thereby overwriting the original data. An in-place algorithm is designed so that each data pair is needed for only one butterfly, and so the new results can be immediately stored on top of the old in order to minimize memory requirements.

For example, in stage 3 the $k=6$ and $k=7$ samples should be paired, yielding a "butterfly" computation that requires one complex multiply, one complex add, and one subtract.

$$x_3(1,1,0) = x_2(1,1,0) + W_8^3 x_2(1,1,1) \tag{4.19a}$$

$$x_3(1,1,1) = x_2(1,1,0) - W_8^3 x_2(1,1,1) \tag{4.19b}$$

Samples $x_2(6)$ and $x_2(7)$ are read from the memory, the butterfly is executed on the pair, and $x_3(6)$ and $x_3(7)$ are written back to the memory, overwriting the original values of $x_2(6)$ and $x_2(7)$. In general, there are $N/2$ butterflies per stage and $\log_2 N$ stages, so the total number of butterflies is $[N/2]\log_2 N$. Since there is at most one complex multiplication per butterfly, the total number of multiplications is bounded by $(N/2)\log_2 N$ (some of the multiplies involve factors of unity and should not be counted).

Figure 4.10 shows the signal flow graph of the D-I-T FFT algorithm for $N=8$. This algorithm is referred to as an in-place FFT with normally ordered input and bit-reversed output samples. Minor variations that include bit-reversed inputs and normally ordered outputs, and non-in-place algorithms with normally ordered inputs and outputs are also possible. Also, when N is not a "power-of-2" (PO2), a mixed-radix algorithm can be used to reduce the computation. The mixed-radix FFT is most efficient when N is highly composite, i.e., when N can be expressed as $N = p_1^{r_1} p_2^{r_2} \cdots p_L^{r_L}$, where the p_is are small

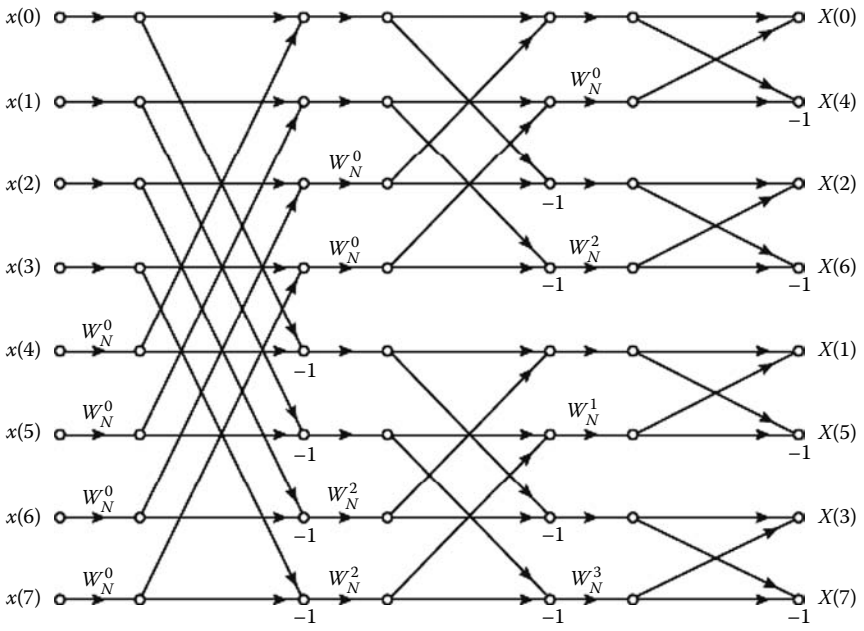

FIGURE 4.10 D-I-T FFT algorithm with normally ordered inputs and bit-reversed outputs.

prime numbers and the r^is are positive integers. It can be shown that the order of complexity of the mixed-radix FFT is Order $\{N(r_1(p_1 - 1) + r_2(p_2 - 1) + \cdots + r_L(p^L - 1)\}$. Because of the lack of uniformity of structure among stages, this algorithm has not received much attention for hardware implementation. However, the mixed-radix FFT is often used in software applications, especially for processing data recorded in laboratory experiments where it is not convenient to restrict the block lengths to be PO2. Many advanced FFT algorithms, such as higher-radix forms, the mixed-radix form, the prime-factor algorithm, and the Winograd algorithm, are described in Blahut (1985). Algorithms specialized for real-valued data reduce the computational cost by a factor-of-2.

4.6 Family Tree of Fourier Transforms

Figure 4.11 illustrates the functional relationships among the various forms of CT and DT Fourier transforms that have been discussed in the previous sections. The family of CT Fourier transforms is shown on the left side of Figure 4.11, whereas the right side of the figure shows the hierarchy of DT Fourier transforms. Note that the most general, and consequently the most powerful, Fourier transform is the classical complex Fourier transform (or equivalently, the bilateral Laplace transform). Note also that the complex Fourier transform is identical to the bilateral Laplace transform, and it is at this level that the classical Laplace transform techniques and Fourier transform techniques become identical. Each special member of the CT Fourier family is obtained by impressing certain constraints on the general

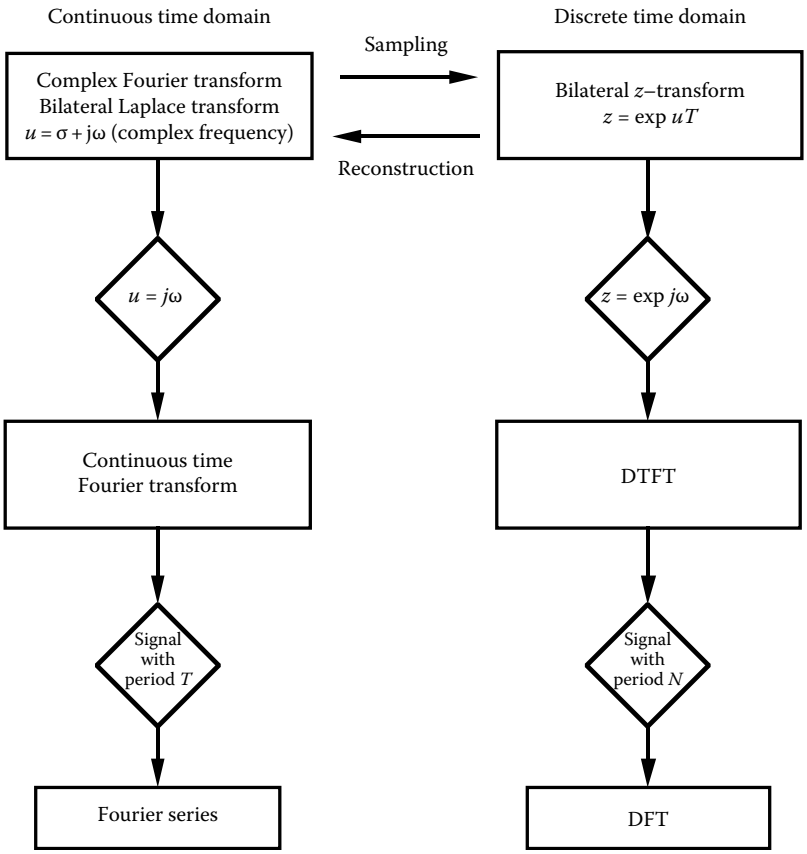

FIGURE 4.11 Functional relationships among various forms of the Fourier transform.

form, thereby producing special transforms that are simpler and more useful in practical problems where the constraints are met.

In Figure 4.11 it is seen that the bilateral z-transform is analogous to the complex Fourier transform, the unilateral z-transform is analogous to the classical (one-sided) Laplace transform, the DTFT is analogous to the classical Fourier (CT) transform, and the DFT is analogous to the classical (CT) Fourier series.

4.6.1 Walsh–Hadamard Transform

The Walsh–Hadamard transform (WHT) is a computationally attractive orthogonal transform that is structurally related to the DFT, and which can be implemented in practical applications without multiplication, and with a computational complexity for addition that is on the same order of complexity as that of an FFT. The t_{mk}th element of the WHT matrix $\mathbf{T}_{\text{WHT}}$ is given by

$$t_{mk} = \frac{1}{\sqrt{N}} \prod_{\ell=0}^{p-1} (-1)^{b_1(m) b_{p-1-\ell(k)}}, \quad m \text{ and } k = 0, \ldots, N-1$$

where $b_\ell(m)$ is the ℓth order bit in the binary representation of m, and $N = 2^p$. The WHT is defined only when N is a PO2. Note that the columns of $\mathbf{T}_{\text{WHT}}$ form a set of orthogonal basis vectors whose elements are all 1s or -1s, so that the calculation of the matrix–vector product $\mathbf{T}_{\text{WHT}}\, X$ can be accomplished with only additions and subtractions. It is well known that $\mathbf{T}_{\text{WHT}}$ of dimension $(N \times N)$, for N a PO2, can be computed recursively according to

$$\mathbf{T}_k = \begin{bmatrix} \mathbf{T}_{k/2} & \mathbf{T}_{k/2} \\ \mathbf{T}_{k/2} & -\mathbf{T}_{k/2} \end{bmatrix} \quad \text{for} \quad K = 4, \ldots, N \text{ (even) and } \mathbf{T}_2 = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$$

The above relationship provides a convenient way of quickly constructing the Walsh–Hadamard matrix for any arbitrary (even) size N.

Due to structural similarities between the DFT and the WHT matrices, the WHT transform can be implemented using a modified FFT algorithm. The core of any FFT program is a butterfly calculation that is characterized by a pair of coupled equations that have the following form:

$$X_{i+1}(\ell, m) = X_i(\ell, m) + e^{j\theta(\ell,m,k,s)} X_i(k, s)$$
$$X_{i+1}(\ell, m) = X_i(\ell, m) - e^{j\theta(\ell,m,k,s)} X_i(k, s)$$

If the exponential factor in the butterfly calculation is replaced by a "1," so the "modified butterfly" calculation becomes

$$X_{i+1}(\ell, m) = X_i(\ell, m) + X_i(k, s)$$
$$X_{i+1}(\ell, m) = X_i(\ell, m) - X_i(k, s)$$

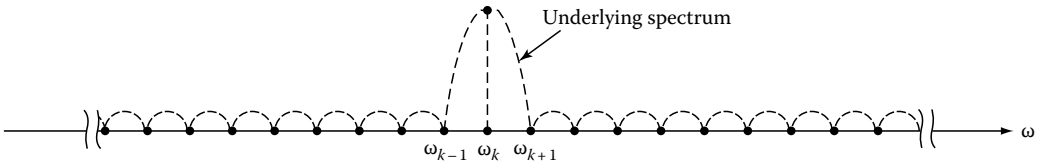
the modified FFT program will in fact perform a WHT on the input vector. This property not only provides a quick and convenient way to implement the WHT, but it also establishes clearly that in addition to the WHT requiring no multiplication, the number of additions required has order of complexity of $(N/2)\log_2 N$, i.e., the same as the that of the FFT.

The WHT is used in many applications that require signals to be decomposed in real time into a set of orthogonal components. A typical application in which the WHT has been used in this manner is in code division multiple access (CDMA) wireless communication systems. A CDMA system requires spreading

of each user's signal spectrum using a PN sequence. In addition to the PN spreading codes, a set of length-64 mutually orthogonal codes, called the Walsh codes, are used to ensure orthogonality among the signals for users received from the same base station. The length $N = 64$ Walsh codes can be thought of as the orthogonal column vectors from a (64×64) Walsh–Hadamard matrix, and the process of demodulation in the receiver can be interpreted as performing a WHT on the complex input signal containing all the modulated user's signals so they can be separated for accurate detection.

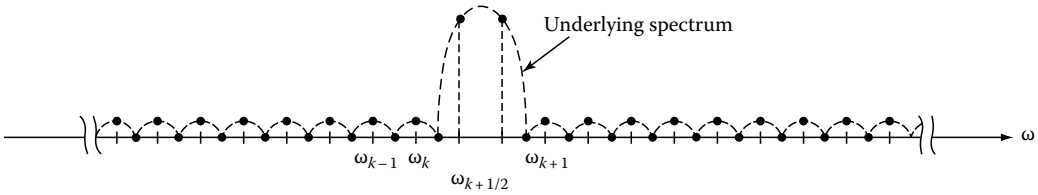
4.7 Selected Applications of Fourier Methods

4.7.1 DFT (FFT) Spectral Analysis



An FFT program is often used to perform spectral analysis on signals that are sampled and recorded as part of laboratory experiments, or in certain types of data acquisition systems. There are several issues to be addressed when spectral analysis is performed on (sampled) analog waveforms that are observed over a finite interval of time.

Windowing: The FFT treats the block of data as though it were one period of a periodic sequence. If the underlying waveform is not periodic, then harmonic distortion may occur because the periodic waveform created by the FFT may have sharp discontinuities at the boundaries of the blocks. This effect is minimized by removing the mean of the data (it can always be reinserted) and by windowing the data so the ends of the block are smoothly tapered to zero. A good rule of thumb is to taper 10% of the data on each end of the block using either a cosine taper or one of the other common windows (e.g., Hamming, Von Hann, Kaiser windows, etc.). An alternate interpretation of this phenomenon is that the finite length observation has already windowed the true waveform with a rectangular window that has large spectral sidelobes. Hence, applying an additional window results in a more desirable window that minimizes frequency-domain distortion.



Zero-padding: An improved spectral analysis is achieved if the block length of the FFT is increased. This can be done by (1) taking more samples within the observation interval, (2) increasing the length of the observation interval, or (3) augmenting the original data set with zeros. First, it must be understood that the finite observation interval results in a fundamental limit on the spectral resolution, even before the signals are sampled. The CT rectangular window has a $(\sin x)/x$ spectrum, which is convolved with the true spectrum of the analog signal. Therefore, the frequency resolution is limited by the width of the mainlobe in the $(\sin x)/x$ spectrum, which is inversely proportional to the length of the observation interval. Sampling causes a certain degree of aliasing, although this effect can be minimized by using a sufficiently high sampling rate. Therefore, lengthening the observation interval increases the fundamental resolution limit, while taking more samples within the observation interval minimizes aliasing distortion and provides a better definition (more sample points) on the underlying spectrum.

Padding the data with zeros and computing a longer FFT does give more frequency-domain points (improved spectral resolution), but it does not improve the fundamental limit, nor does it alter the effects of aliasing error. The resolution limits are established by the observation interval and the sampling rate. No amount of zero padding can improve these basic limits. However, zero padding is a useful tool for providing more spectral definition, i.e., it enables one to get a better look at the (distorted) spectrum that results once the observation and sampling effects have occurred.

Leakage and the picket-fence effect: An FFT with block length N can accurately resolve only frequencies $w_k = (2\pi/N)k$, $k = 0, \ldots, N-1$ that are integer multiples of the fundamental $w_1 = (2\pi/N)$. An analog waveform that is sampled and subjected to spectral analysis may have frequency components between the harmonics. For example, a component at frequency $w_{k+1/2} = (2\pi/N)(k + 1/2)$ will appear scattered throughout the spectrum. The effect is illustrated in Figure 4.12 for a sinusoid that is observed through a rectangular window and then sampled a N points. The "picket-fence effect" means that not all

(a) FFT of a windowed sinusoid with frequency $\omega_k = 2\pi k/N$

(b) Leakage for a nonharmonic sinusoidal component

FIGURE 4.12 Illustration of leakage and the picket-fence effects.

frequencies can be seen by the FFT. Harmonic components are seen accurately, but other components "slip through the picket fence" while their energy is "leaked" into the harmonics. These effects produce artifacts in the spectral domain that must be carefully monitored to assure that an accurate spectrum is obtained from FFT processing.

4.7.2 FIR Digital Filter Design

A common method for designing FIR digital filters is by the use of windowing and FFT analysis. In general, window designs can be carried out with the aid of a hand calculator and a table of well-known window functions. Let $h[n]$ be the impulse response that corresponds to some desired frequency response, $H(e^{j\omega})$. If $H(e^{j\omega})$ has sharp discontinuities then $h[n]$ will represent an infinite impulse response (IIR) function. The objective is to time-limit $h[n]$ in such a way as to not distort $H(e^{j\omega})$ any more than necessary. If $h[n]$ is simply truncated, a ripple (Gibbs phenomenon) occurs around the discontinuities in the spectrum, resulting in a distorted filter, as was earlier illustrated in Figure 4.7.

Suppose that $w[n]$ is a window function that time-limits $h[n]$ to create an FIR approximation, $h'[n]$; i.e., $h'[n] = w[n]h[n]$. Then if $W(e^{j\omega})$ is the DTFT of $w[n]$, $h'[n]$ will have a Fourier transform given by $H'(e^{j\omega}) = W(e^{j\omega}) \star H(e^{j\omega})$, Where $\star$. denotes convolution. From this it can be seen that the ripples in $H(e^{j\omega})$ result from the sidelobes of $W(e^{j\omega})$. Ideally, $W(e^{j\omega})$ should be similar to an impulse so that $H'(e^{j\omega})$ is approximately equal to $H(e^{j\omega})$.

Special case: Let $h[n] = \cos n\omega_0$, for all n. Then $h[n] = w[n]\cos n\omega_0$, and

$$H'(e^{j\omega}) = (1/2)W(e^{j(\omega+\tilde{\omega})}) + (1/2)W(e^{j(\omega+\tilde{\omega})}) \tag{4.20}$$

as illustrated in Figure 4.13. For this simple class, the center frequency of the passband is controlled by ω_0, and both the shape of the passband and the sidelobe structure are strictly determined by the choice of the window. While this simple class of FIRs does not allow for very flexible designs, it is a simple technique for determining quite useful low-pass, bandpass, and high-pass FIR filters.

General case: Specify an ideal frequency response, $H(e^{j\omega})$, and choose samples at selected values of w. Use a long inverse FFT of length N' to find $h'[n]$, an approximation to $h[n]$, where if N is the desired length of the final filter, then $N' \gg N$. Then use a carefully selected window to truncate $h'[n]$ to obtain $h[n]$ by

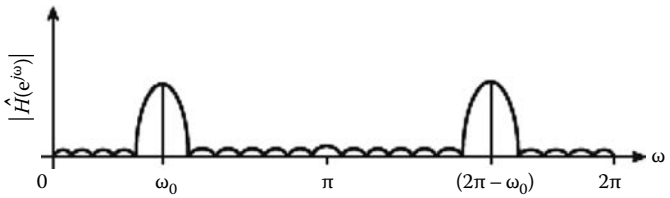


FIGURE 4.13 Design of a simple bandpass FIR filter by windowing.

letting $h[n] = w[n]h'[n]$. Finally, use an FFT of length N' to find $H'(e^{j\omega})$. If $H'(e^{j\omega})$ is a satisfactory approximation to $H(e^{j\omega})$, the design is finished. If not, choose a new $H(e^{j\omega})$, or a new $w[n]$ and repeat. Throughout the design procedure, it is important to choose $N' = kN$, with k an integer that is typically in the range $[4, \ldots, 10]$. Since this design technique is a trial-and-error procedure, the quality of the result depends to some degree on the skill and experience of the designer.

4.7.3 Fourier Block Processing in Real-Time Filtering Applications

In some practical applications, either the value of M is too large for the memory available, or $s[n]$ may not actually be finite in length, but rather a continual stream of data samples that must be processed by a filter at real time rates. Two well-known algorithms are available that partition $s[n]$ into smaller blocks and process the individual blocks with a smaller-length DFT (1) overlap-save partitioning and (2) overlap-add partitioning. Each of these algorithms is summarized below (Burrus 1985; Jenkins 2002).

1. *Overlap-save processing*: In this algorithm, N_{DFT} is chosen to be some convenient value with $N_{\text{DFT}} > N$. The signal $s[n]$, is partitioned into blocks which are of length N_{DFT} and which overlap by $N-1$ data points. Hence, the kth block is $s_k[n] = s[n + k(N_{\text{DFT}} - N + 1)]$, $n = 0, \ldots, N_{\text{DFT}} - 1$. The filter impulse response $h[n]$ is augmented with $N_{\text{DFT}} - N$ zeros to produce

$$h_{\text{pad}}[n] = \begin{cases} h[n], & n = 0, \ldots, N-1 \\ 0, & n = N, \ldots, N_{\text{DFT}} - 1 \end{cases} \tag{4.21}$$

   The DFT is then used to obtain $Y_{\text{pad}}[n] = \text{DFT}\{h_{\text{pad}}[n]\} \cdot \text{DFT}\{s_k[n]\}$, and $y_{\text{pad}}[n] = \text{IDFT}\{Y_{\text{pad}}[n]\}$. From the $y_{\text{pad}}[n]$ array the values that correctly correspond to the linear convolution are saved; values that are erroneous due to wrap-around error caused by the circular convolution of the DFT are discarded. The kth block of the filtered output is obtained by

$$y_k[n] = \begin{cases} y_{\text{pad}}[n], & n = 0, \ldots, N-1 \\ 0, & n = N, \ldots, N_{\text{DFT}} - 1 \end{cases} \tag{4.22}$$

   For the overlap-save algorithm, each time a block is processed there are $N_{\text{DFT}} - N + 1$ points saved and $N-1$ points discarded. Each block moves forward by $N_{\text{DFT}} - N + 1$ data points and overlaps the previous block by $N-1$ points.
2. *Overlap-add processing*: This algorithm is similar to the previous one except that the kth input block is defined to be

$$s_k[n] = \begin{cases} s[n], & n = 0, \ldots, L-1 \\ 0, & n = L, \ldots, N_{\text{DFT}} - 1 \end{cases} \tag{4.23}$$

   where $L = N_{\text{DFT}} - N + 1$. The filter function $h_{\text{pad}}[n]$ is augmented with zeros, as before, to create $h_{\text{pad}}[n]$, and the DFT processing is executed as before. In each block $y_{\text{pad}}[n]$ that is obtained at the

output, the first $N-1$ points are erroneous, the last $N-1$ points are erroneous, and the middle $N_{\mathrm{DFT}}-2(N-1)$ points correctly correspond to the linear convolution. However, if the last $N-1$ points from block k are overlapped with the first $N-1$ points from block $k+1$ and added pairwise, correct results corresponding to linear convolution are obtained from these positions, too. Hence, after this addition, the number of correct points produced per block is $N_{\mathrm{DFT}}-N+1$, which is the same as that for the overlap-save algorithm. The overlap-add algorithm requires approximately the same amount of computation as the overlap-save algorithm, although the addition of the overlapping portions of blocks is extra. This feature, together with the extra delay of waiting for the next block to be finished before the previous one is complete, has resulted in more popularity for the overlap-save algorithm in practical applications.

Block filtering algorithms make it possible to efficiently filter continual data streams in real time because the FFT algorithm can be used to implement the DFT, thereby minimizing the total computation time and permits reasonably high overall data rates. However, block filtering generates data in bursts, i.e., there is a delay during which no filtered data appears, and then suddenly an entire block is generated. In real-time systems, buffering must be used. The block algorithms are particularly effective for filtering very long sequences of data that are prerecorded on magnetic tape or disk.

4.7.4 Fourier Domain Adaptive Filtering

A transform domain adaptive filter (TDAF) is a generalization of the well-known least mean squares (LMS) adaptive filter in which the input signal is passed through a linear transformation in order to decompose it into a set of orthogonal components and to optimize the adaptive step size for each component and thereby maximize the learning rate of the adaptive filter (Jenkins et al. 1996). The LMS algorithm is an approximation to the steepest descent optimization strategy. For a length N FIR filter with the input expressed as a column vector $x(n)=[x(n), x(n-1),\ldots, x(n-N+1)]^{\mathrm{T}}$, the filter output $y(n)$ is expressed as

$$y(n)=\mathbf{w}^{\mathrm{T}}(n)\mathbf{x}(n)$$

where $\mathbf{w}(n)=[w_0(n), w_1(n),\ldots, w_{N-1}(n)]^{\mathrm{T}}$ is the time varying vector of filter coefficients (tap weights), and the superscript "T" denotes vector transpose. The output error is formed as the difference between the filter output and a training signal $d(n)$, i.e., $e(n)=d(n)-y(n)$. Strategies for obtaining an appropriate $d(n)$ vary from one application to another. In many cases the availability of a suitable training signal determines whether an adaptive filtering solution will be successful in a particular application. The ideal cost function is defined by the MSE criterion, $E\{|e(n)|^2\}$. The LMS algorithm is derived by approximating the ideal cost function by the instantaneous squared error, resulting in $J_{\mathrm{LMS}}(n)=|e(n)|^2$. While the LMS seems to make a rather crude approximation at the very beginning, the approximation results in an unbiased estimator. In many applications the LMS algorithm is quite robust and is able to converge rapidly to a small neighborhood of the Wiener solution.

When a steepest descent optimization strategy is combined with a gradient approximation formed using the LMS cost function $J_{\mathrm{LMS}}(n)=|e(n)|^2$, the conventional LMS adaptive algorithm results:

$$\begin{aligned}\mathbf{w}(n+1)&=\mathbf{w}(n)+\mu e(n)\mathbf{x}(n)\\ e(n)&=d(n)-y(n)\\ y(n)&=\mathbf{x}(n)^{\mathrm{T}}\mathbf{w}(n)\end{aligned}\tag{4.24}$$

The convergence behavior of the LMS algorithm, as applied to a direct form FIR filter structure, is controlled by the autocorrelation matrix $\mathbf{R}_{\mathrm{x}}$ of the input process, where

$$\mathbf{R}_{\mathrm{x}}\equiv E[\mathbf{x}^{*}(n)\mathbf{x}^{\mathrm{T}}(n)]\tag{4.25}$$

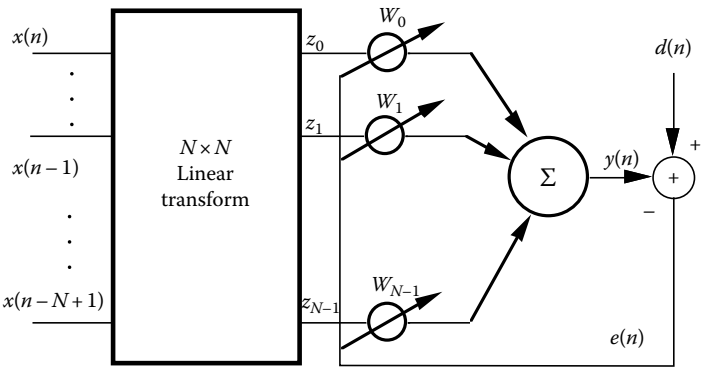

FIGURE 4.14 TDAF structure.

The autocorrelation matrix $\mathbf{R}_x$ is usually positive definite, which is one of the conditions necessary to guarantee convergence to the Wiener solution. Another necessary condition for convergence is $0 < m < 1/l_{max}$, where l_{max} is the largest eigenvalue of $\mathbf{R}_x$. It is well established that the convergence of this algorithm is directly related to the eigenvalue spread of $\mathbf{R}_x$. The eigenvalue spread is measured by the condition number of $\mathbf{R}_x$, defined as $k = l_{max}/l_{min}$, where l_{min} is the minimum eigenvalue of $\mathbf{R}_x$. Ideal conditioning occurs when $k = 1$ (white noise); as this ratio increases, slower convergence results. The eigenvalue spread (condition number) depends on the spectral distribution of the input signal, and is related to the maximum and minimum values of the input power spectrum. From this line of reasoning it becomes clear that white noise is the ideal input signal for rapidly training an LMS adaptive filter. The adaptive process is slower and requires more computation for input signals that are colored.

The TDAF structure is shown in Figure 4.14. The input $x(n)$ and the desired signal $d(n)$ are assumed to be zero mean and jointly stationary. The input to the filter is a vector of N current and past input samples, defined in the previous section and denoted as $\mathbf{x}(n)$. This vector is processed by a unitary transform, such as the DFT. Once the filter Order N is fixed, the transform is simply an $N \times N$ matrix T, which is in general complex, with orthonormal rows. The transformed outputs form a vector $\mathbf{v}(n)$ which is given by

$$\mathbf{v}(n) = [v_0(n), v_1(n), \ldots, v_{N-1}(n)]^T = \mathbf{T}\mathbf{x}(n)$$

With an adaptive tap vector defined as $w(n) = [w_0(n), w_1(n), \ldots, w_{N-1}(n)]^T$, the filter output is given by

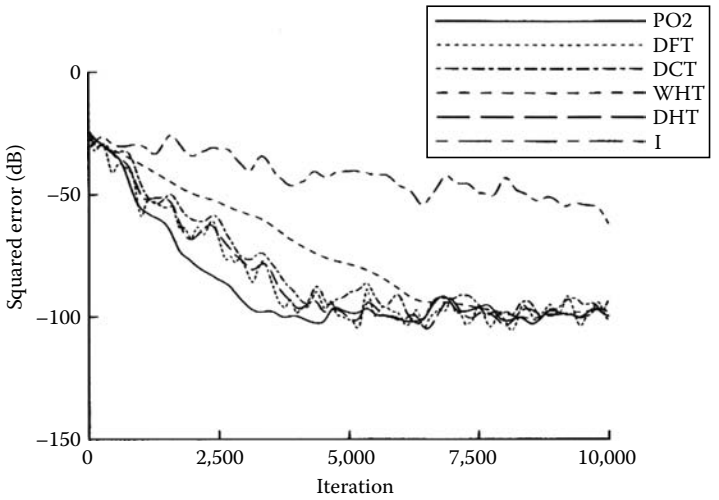
$$y(n) = \mathbf{w}^T(n)\mathbf{v}(n) = \mathbf{W}^T(n)\mathbf{T}\mathbf{x}(n) \tag{4.26}$$

The instantaneous output error is then formed and used to update the adaptive filter taps using a modified form of the LMS algorithm (Jenkins 1996):

$$\begin{aligned} &\mathbf{W}(n+1) = \mathbf{W}(n) + \mu e(n)\boldsymbol{\Lambda}^{-2}\mathbf{v}^*(n) \\ &\boldsymbol{\Lambda}^2 \equiv \text{diag}\left[\sigma_1^2, \sigma_1^2, \ldots, \sigma_N^2\right] \end{aligned} \tag{4.27}$$

where

$$\sigma_i^2 = E\left[|v_i(n)|^2\right]$$



The power estimates σ_i^2 can be developed online by computing an exponentially weighted average of past samples according to

$$\sigma_i^2(n) = \alpha\sigma_i^2(n-1) + |v_i(n)|^2, \quad 0 < a < 1 \tag{4.28}$$

If σ_i^2 becomes too small due to an insufficient amount of energy in the *i*th channel, the update mechanism becomes ill-conditioned due to a very large effective step size. In some cases, the process will become unstable and register overflow will cause the adaptation to catastrophically fail. So the algorithm given by Equation 4.27 should have the update mechanism disabled for the *i*th orthogonal channel if σ_i^2 falls below a critical threshold.

The motivation for using the TDAF adaptive system instead of a simpler LMS-based system is to achieve rapid convergence of the filters coefficients when the input signal is not white, while maintaining a reasonably low computational complexity requirement. The optimal decorrelating transform is composed of the orthonormal eigenvectors of the input autocorrelation matrix, and is known as the Karhunen–Loe'ye transform (KLT). The KLT is signal dependent and usually cannot be easily computed in real time. Throughout the literature the DFT, the discrete cosine transform (DCT), and the WHT have received considerable attention as possible candidates for use in the TDAF.

Figure 4.15 shows learning characteristics for computer generated TDAF examples using six different orthogonal transforms to decorrelate the input signal. The examples presented are for system

Transform	Effective Input Correlation Matrix Eigenvalue Ratio

FIGURE 4.15 Comparison of (smoothed) learning curves for five different transforms operating on a colored noise input signal with condition number 681 fault in any of the coefficients. When *R* redundant coefficients are added as many as *R* coefficients can fail to adjust without any adverse effect on the filter's ability to achieve the minimum MSE condition.

identification experiments, where the desired signal was derived by passing the input through an 8-tap FIR filter that is the "unknown system" to be identified. The filter input was generated by filtering white pseudonoise with a 32-tap linear phase FIR coloring filter to produce an input autocorrelation matrix with a condition number (eigenvalue ratio) of 681. Examples were then produced using the DFT, the DCT, the WHT, discrete Hartley transform (DHT), and a specially designed computationally efficient (PO2) transform. The condition numbers that result from transform processing with each of these transforms are also shown in Figure 4.15. Note that all of the transforms used in this example are able to reduce the input condition number and greatly improve convergence rates, although some transforms are seen to be more effective than others for the coloring chosen for these examples.

4.7.5 Adaptive Fault Tolerance via Fourier Domain Adaptive Filtering

Adaptive systems adjust their parameters to minimize a specified error criterion under normal operating conditions. Fixed errors or hardware faults would prevent the system to minimize the error criterion, but at the same time the system will adapt the parameters such that the best possible solution is reached. In adaptive fault tolerance (AFT), the inherent learning ability of the adaptive system is used to compensate for failure of the adaptive coefficients. This mechanism can be used with specially designed structures whose redundant coefficients have the ability to compensate for the adjustment failures of other coefficients (Jenkins et al. 1996).

The FFT-based transform domain fault tolerant adaptive filter (FTAF) is described by the following equations:

$$\begin{aligned} \mathbf{x}[n] &= [\mathrm{x}_{\mathrm{in}}[n],00\cdots 0] \\ \mathbf{x}_{\mathrm{T}}[n] &= \mathbf{T}\mathbf{x}[n] \\ y[n] &= \mathbf{w}_{\mathrm{T}}^{t}[n]\mathbf{x}_{\mathrm{T}}[n] \end{aligned} \tag{4.29}$$

where $\mathbf{x}_{\mathrm{in}}[n] = [x[n], x[n-1], \ldots, x[n-N+1]]$ is the vector of the current input and $N-1$ past inputs samples, $x[n]$ is $x_{\mathrm{in}}[n]$ zero-padded with R zeros, T is the $M \times M$ DFT matrix where $M = N+R$, $\mathbf{w}_T[n]$ is the vector of M adaptive coefficients in the transform domain, and $d[n]$ is the desired response. The FFT-based transform domain FTAF is similar to a standard TDAF except that the input data vector is zero-padded with R zeros before it is multiplied by the transform matrix. Since the input data vector is zero-padded, the transform domain FTAF maintains a length N impulse response and has R redundant coefficients in the transform domain. When used with the zero padding strategy described above, this structure possesses a property called *full fault tolerance*, where each redundant coefficient is sufficient to compensate for a single "stuck at" fault condition in any of the coefficients. When R redundant coefficients are added as many as R coefficients can fail without any adverse effect on the filter's ability to achieve the minimum MSE condition.

An example of a transform domain FTAF with one redundant filter tap ($R = 1$) is demonstrated below for the identification of a 64-tap FIR low-pass "unknown" system. The training signal is Gaussian white noise with a unit variance and a noise floor of -60 dB. A fixed fault is introduced at iteration 3000 by setting an arbitrary filter coefficient to a random fixed value. Simulated learning curves are shown in Figure 4.16 in which both demonstrated that the redundant tap allows the filter to reconverge after the occurrence of the fault, although the postfault convergence rate slowed somewhat due to an increased condition number of the postfault autocorrelation matrix (Jenkins 1996).

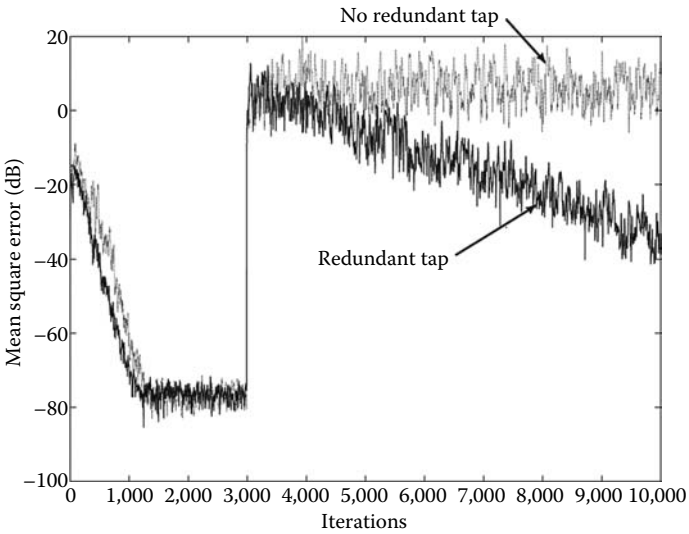

FIGURE 4.16 Learning curve demonstrating postfault behavior both with and without a redundant tap.

4.8 Summary

Numerous Fourier transform concepts have been presented for both CT and DT signals and systems. Emphasis was placed on illustrating how various forms of the Fourier transform relate to one another, and how they are all derived from more general complex transforms, the complex Fourier (or bilateral Laplace) transform for CT, and the bilateral z-transform for DT. It was shown that many of these transforms have similar properties that are inherited from their parent forms, and that there is a parallel hierarchy among Fourier transform concepts in the CT and DT domains. Both CT and DT sampling models were introduced as a means of representing sampled signals in these two different domains and it was shown that the models are equivalent by virtue of having the same Fourier spectra when transformed into the Fourier domain with the appropriate Fourier transform. It was shown how Fourier analysis properly characterizes the relationship between the spectra of a CT signal and its DT counterpart obtained by sampling, and the classical reconstruction formula was obtained as a result of this analysis. Finally, the DFT, the backbone for much of modern DSP, was obtained from more classical forms of the Fourier transform by simultaneously discretizing the time and frequency domains. The DFT, together with the remarkable computational efficiency provided by the FFT algorithm, has contributed to the resounding success that engineers and scientists have had in applying DSP to many practical scientific problems.

5.1 Introduction

When analyzing linear systems, one of the problems we often encounter is that of solving linear, constant-coefficient differential equations. A tool used for solving such equations is the Laplace transform. At the same time, to aid the analysis of linear systems, we extensively use Fourier-domain methods. With the advent of digital computers, it has become increasingly necessary to deal with discrete-time signals, or, sequences. These signals can be either obtained by sampling a continuous-time signal, or they could be inherently discrete. To analyze linear discrete-time systems, one needs a discrete-time counterpart of the Laplace transform (LT). Such a counterpart is found in the z-transform, which similarly to the LT, can be used to solve linear constant-coefficient difference equations. In other words, instead of solving these equations directly, we transform them into a set of algebraic equations first, and then solve in this transformed domain. On the other hand, the z-transform can be seen as a generalization of the discrete-time Fourier transform (FT)

$$X(e^{j\omega}) = \sum_{n=-\infty}^{+\infty} x[n]e^{-j\omega n} \tag{5.1}$$

This expression does not always converge, and thus, it is useful to have a representation which will exist for these nonconvergent instances. Furthermore, the use of the z-transform offers considerable notational

simplifications. It also allows us to use the extensive body of work on complex variables to aid in analyzing discrete-time systems.

The z-transform, as pointed out by Jury in his classical text [3], is not new. It can be traced back to the early eighteenth century and the times of DeMoivre, who introduced the notion of the generating function, extensively used in probability theory

$$\Gamma(z) = \sum_{n=-\infty}^{+\infty} p[n]z^n \tag{5.2}$$

where $p[n]$ is the probability that the discrete random variable **n** will take a value n [8]. By comparing Equations 5.2 and 5.3, we can see that the generating function $\Gamma(1/z)$ is the z-transform of the sequence $p[n] = p\{\mathbf{n} = n\}$. After these initial efforts, and due to the fast development of digital computers, a renewed interest in the z-transform occurred in the early 1950s, and z-transform has been used for analyzing discrete-time systems ever since.

This section is intended as a brief introduction to the theory and application of the z-transform. For a rigorous mathematical treatment of the transform itself, the reader is referred to the book by one of the pioneers in the development of analysis of sampled data systems, Jury [3], and the references therein. For a more succinct account of the z-transform, its properties and use in discrete-time systems, consult, for example, Ref. [7]. A few other texts which contain parts on the z-transform include Refs. [1,2,5,6,10].

5.2 Definition of the *z*-Transform

Suppose we are given a discrete-time sequence $x[n]$, either inherently discrete time, or obtained by sampling a continuous-time signal $x_c(t)$, so that $x[n] = x_c(nT)$, $n \in \mathbb{Z}$, where T is the sampling period. Then the two-sided z-transform of $x[n]$ is defined as

$$X(z) = \sum_{n=-\infty}^{+\infty} x[n]z^{-n} \tag{5.3}$$

Here, z is a complex variable, and depending on its magnitude and the sequence $x[n]$, the above sum may or may not converge. The region in the z-plane where the sum does converge is called the region of convergence (ROC), and is discussed in more detail later.

Observe that in Equation 5.3, n ranges from $-\infty$ to $+\infty$. That is why the z-transform defined in this way is called two-sided. One could define a one-sided z-transform, where n would range from 0 to $+\infty$. Obviously, the two definitions are equivalent only if the signal itself is one-sided, that is, if $x[n] = 0$, for $n < 0$. The advantage of using the one-sided z-transform is that it is useful in solving linear constant-coefficient difference equations with nonzero initial conditions and in the study of sampled-data feedback systems, discussed later. However, from now on, we deal mostly with the two-sided z-transform (see also Chapter 3 where the one-sided LT is used).

A power series given in Equation 5.3 is a Laurent series, and thus for it to converge uniformly, it has to be absolutely summable, that is, the following must hold:

$$\sum_{n=-\infty}^{n=+\infty} |x[n]|z|^{-n} < \infty \tag{5.4}$$

where $|z|$ is the magnitude of the complex variable z, i.e., $z = |z|\ e^{j\arg z}$. We can now see that if the z-transform converges for $z = z_1$, it will converge for all z such that $|z| = |z_1|$; that is, for all z on the circle $|z| = |z_1|$. In general, therefore, the ROC will be an annular region in the z-plane, and will be of the form

$$0 \le R_- < |z| < R_+ \le \infty \tag{5.5}$$

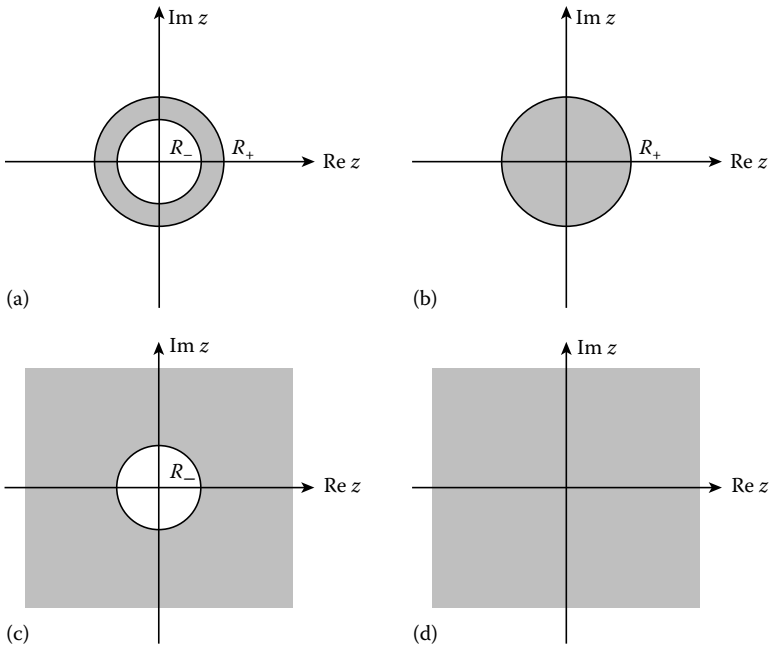

FIGURE 5.1 ROC of the z-transform. (a) General case: $0 \leq R_- < |z| < R_+ \leq \infty$. (b) ROC is the inside of the circle $|z| < R_+$ ($z = 0$ might be excluded). (c) ROC is the outside of the circle $R_- < |z|$ ($z = \infty$ might be excluded). (d) ROC is the whole z-plane (except possibly $z = 0$ or $z = \infty$).

Here, R_- could be zero, and R_+ could be infinity, so that all of the cases given in Figure 5.1 are possible. Note that the points $z = 0$, or $z = \infty$ could be included in the region of convergence.

A very important notion when talking about the ROC of the z-transform is that of the unit circle, because it makes the connection to the discrete-time FT. The unit circle is defined as the set of points in the z-plane for which $|z| = 1$. Let us evaluate the z-transform of a sequence on the unit circle. Because $|z| = 1$, it can be expressed as $z = e^{j\omega}$, where $\omega = \arg z$. Thus,

$$X(z)|_{|z|=1} = X(e^{j\omega}) = \sum_{n=-\infty}^{+\infty} x[n]e^{-j\omega n} \tag{5.6}$$

Note that here we use $X(e^{j\omega})$ instead of $X(\omega)$ to make it explicit that this is a function of $e^{j\omega}$. As can be seen from the equation, the z-transform evaluated on the unit circle is equivalent to the discrete-time FT given in Equation 5.1. This immediately justifies the statement from the beginning of the section that the *z-transform* can be seen as a generalization of the FT. In other words, instances occur when the FT does not converge, while the z-transform does. One such instance is the unit-step function $u[n]$:

$$u[n] = \begin{cases} 1, & n \geq 0, \\ 0, & \text{otherwise} \end{cases}$$

The sum

$$U(e^{j\omega}) = \sum_{n=-\infty}^{+\infty} u[n]e^{-j\omega n} = \sum_{n=0}^{+\infty} e^{-j\omega n}$$

is not absolutely summable and thus its FT does not converge, while

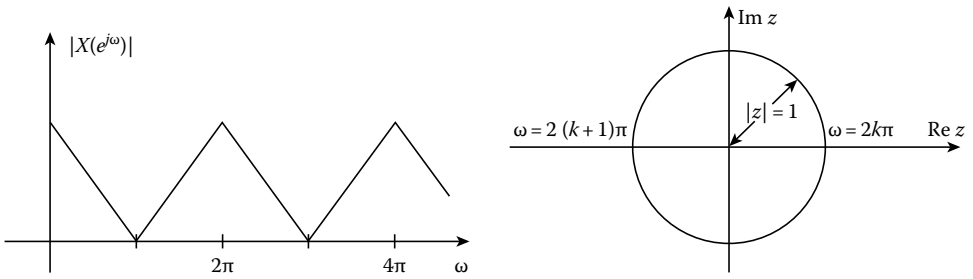

FIGURE 5.2 Warping of the linear frequency axis of the discrete-time FT into the unit circle of the z-transform. For example, the point (Re z, Im z) = (1, 0) on the unit circle corresponds to points $\omega = 2k\pi$ on the ω-axis.

$$U(z) = \sum_{n=-\infty}^{+\infty} u[n]z^{-n} = \sum_{n=0}^{+\infty} z^{-n}$$

converges for $|z| > 1$. As a consequence, if the ROC includes the unit circle, then the discrete-time FT of a given sequence will exist, otherwise it will not.

The unit circle captures the periodicity of the discrete-time FT. If we start evaluating the z-transform on the unit circle at the point (Re z, Im z) = (1, 0) corresponding to $\omega = 0$, going through (Re z, Im z) = (0, j), (Re z, Im z) = (−1, 0) which corresponds to $\omega = \pi$, and (Re z, Im z) = (0, $-j$), back to (Re z, Im z) = (1, 0) corresponding to $\omega = 2\pi$, we have evaluated one period of the FT and have returned to the same point. Thus, we are effectively warping the linear frequency axis into the unit circle (Figure 5.2).

We also mentioned that the z-transform is the discrete-time counterpart of the LT. Consider the function

$$x_{cs}(t) = \sum_{n=-\infty}^{+\infty} x_c(nT)\delta(t - nT) \tag{5.7}$$

or, the sampled version of the original continuous time function $x_c(t)$. Here, T is the sampling period, and $\delta(t)$ is the Dirac function. Taking the LT of $x_{cs}(t)$, we obtain

$$X_{cs}(s) = \sum_{n=-\infty}^{+\infty} x_c(nT)e^{-nTs} \tag{5.8}$$

If we now replace e^{sT} by z, we obtain the z-transform. Now, observe that $X_{cs}(s)$ in Equation 5.8 is periodic, because

$$\begin{aligned} X_{cs}\left(s + j\frac{2\pi}{T}\right) &= \sum_{n=-\infty}^{+\infty} x_c(nT)e^{-nT[s+j(2\pi)/T]} \\ &= \sum_{n=-\infty}^{+\infty} x_c(nT)e^{-nTs}e^{-j2\pi n} \\ &= X_{cs}(s) \end{aligned} \tag{5.9}$$

This means that $X_{cs}(s)$ is periodic along constant lines $\sigma = \sigma_{const}$ (parallel to the $j\omega$-axis). This further means that any line parallel to the $j\omega$-axis maps into a circle in the z-plane. It is easy to see that the $j\omega$-axis itself would map into the unit circle, while the left (or right) half-planes would map into the inside (or outside) of the unit circle, respectively.

Finally, let us say a few words about a very important class of signals, those whose z-transform is a rational function of z. They arise from systems that can be represented by linear constant-coefficient difference equations and are the signals with which we deal mostly in practice. If we represent such signals by

$$X(z) = \frac{N(z)}{D(z)} \tag{5.10}$$

then the zeroes of the numerator $N(z)$ are called zeroes of $X(z)$, while the zeroes of the denominator $D(z)$ are called poles of $X(z)$ (more precisely, a pole z_p will be a point at which $\lim_{z \to z_p} X(z)$ does not exist). How the poles can determine the region of convergence is the subject of a discussion later in this chapter.

5.3 Inverse *z*-Transform

We have seen that specifying the ROC when taking the z-transform of a sequence is an integral part of the process. For example, consider the following sequences: $x[n] = u[n]$ and $y[n] = -u[-n-1]$, where $u[n]$ is the unit-step function. Taking their z-transforms, we obtain

$$X(z) = \frac{1}{1 - z^{-1}}, \quad |z| > 1 \tag{5.11}$$

$$Y(z) = \frac{1}{1 - z^{-1}}, \quad |z| < 1 \tag{5.12}$$

They are identical except for their ROCs (Figure 5.3). This tells us that without the ROC, our z-transform is not complete, and that if we are given $1/(1 - z^{-1})$ as the z-transform of a sequence, the inverse is not uniquely specified unless we know the ROC.

We examine two ways of finding the inverse z-transform: first, and the formal one, by contour integration, and second, by partial fraction expansion. Note that the latter can be used only when $X(z)$ is a rational function of z; however, because most of the time we are dealing with rational functions of z, the partial fraction expansion method is used more often. We also mention two other informal techniques for determining the inverse z-transform.

5.3.1 Contour Integration

The formal inversion process for the z-transform is given by contour integration. It is obtained by taking the expression for the z-transform given by Equation 5.3 and multiplying both sides by $(1/2\pi j)z^{k-1}$. Then the result is integrated counterclockwise along a closed contour C in the z-plane containing the origin, leading to

$$\oint_C \frac{1}{2\pi j} X(z) z^{k-1} dz = \oint_C \frac{1}{2\pi j} z^{k-1} \sum_{n=-\infty}^{+\infty} x[n] z^{-n} dz \tag{5.13}$$

We choose the contour of integration to lie within the ROC, which will allow us to interchange the order of integration and summation on the right side of Equation 5.13. This leads to

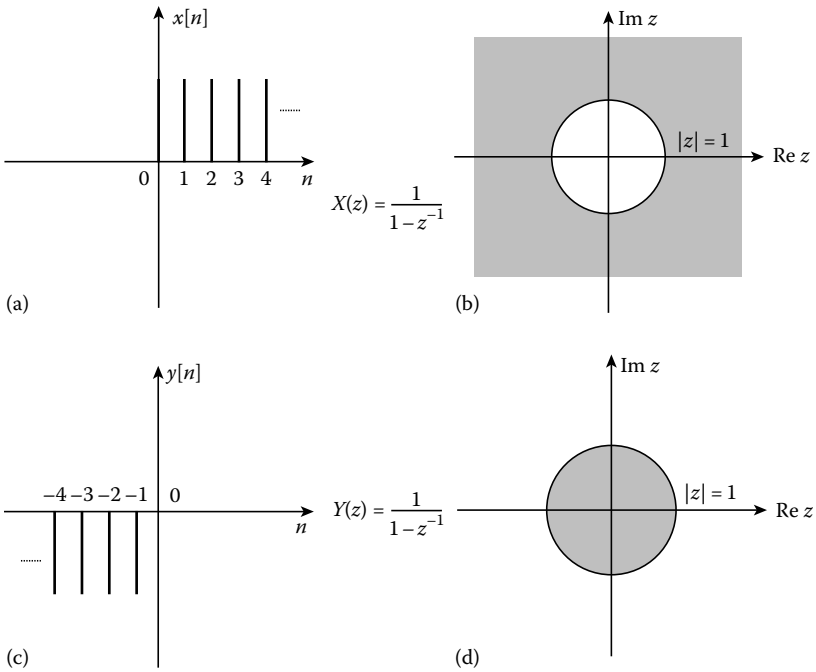

FIGURE 5.3 Two different sequences giving rise to the same z-transforms $1/(1-z^{-1})$ except for their ROCs. (a) Sequence $x[n]=u[n]$ and (b) its ROC $|z|>1$. (c) Sequence $y[n]=-u[-n-1]$ and (d) its ROC $|z|<1$.

$$\frac{1}{2\pi j}\oint_C X(z)z^{k-1}\mathrm{d}z=\sum_{n=-\infty}^{+\infty}x[n]\left(\frac{1}{2\pi j}\oint_C z^{-n+k-1}\mathrm{d}z\right) \tag{5.14}$$

The integral in parentheses on the right side of Equation 5.14 can be evaluated using Cauchy's integral formula, which states that if the contour of integration C contains the origin, and integration is performed counterclockwise, then

$$\frac{1}{2\pi j}\oint_C z^k\mathrm{d}z=\begin{cases}1, & k=-1,\\ 0, & \text{otherwise}\end{cases} \tag{5.15}$$

Substituting Equation 5.15 in Equation 5.14, we see that the integral is nonzero only for $n=k$, and thus Equation 5.14 can be rewritten as

$$\frac{1}{2\pi j}\oint_C X(z)z^{k-1}\mathrm{d}z=x[k] \tag{5.16}$$

Equation 5.16 is the inversion formula for the z-transform. To evaluate it for general functions can be quite difficult. However, in cases in which $X(z)$ is a rational function of z, we can make use of Cauchy's formula. It tells us that

$$\frac{1}{2\pi j}\oint_C \frac{F(z)}{z-z_\mathrm{p}}\mathrm{d}z=\begin{cases}F(z_\mathrm{p}), & z_\mathrm{p}\text{ inside }C,\\ 0, & \text{otherwise}\end{cases} \tag{5.17}$$

where C is a simple closed path and $F'(z)$, the derivative of $F(z)$, exists on and inside C. If we have a pole of multiplicity r enclosed in the contour C, and $F(z)$ and its $(r+1)$ derivatives exist in and on C, then

$$\frac{1}{2\pi j}\oint_C \frac{F(z)}{(z-z_p)^r}\mathrm{d}z = \begin{cases} \frac{1}{(r-1)!}\frac{\mathrm{d}^{r-1}}{\mathrm{d}z^{r-1}}F(z)|_{z=z_p}, & z_p \text{ inside } C, \\ 0, & \text{otherwise} \end{cases} \tag{5.18}$$

Equations 5.17 and 5.18 are called *residues*. Use Equations 5.17 and 5.18, and if we express

$$X(z)z^{k-1} = \frac{F(z)}{(z-z_p)^r} \tag{5.19}$$

where $F(z)$ has no poles at $z = z_p$, then Cauchy's residue theorem says that

$$x[k] = \frac{1}{2\pi j}\oint_C X(z)z^{k-1}\mathrm{d}z = \sum_i R_i \tag{5.20}$$

where R_i are residues of $X(z)z^{k-1}$ at the poles inside the contour C. The poles outside the contour do not contribute to the sum. If no poles are inside the contour of integration for a certain k, then $x[k]$ is zero for that k. Do not ignore the fact that the contour of integration C must lie within the ROC.

In some instances, it may be quite cumbersome to evaluate Equation 5.20, for example, when we have a multiple-order pole at $z = 0$, whose order depends on k. In that case we can rewrite Equation 5.20 as

$$x[k] = \sum_i R_i'$$

where

R_i' is the residue of $X(1/z)z{-}k{-}1$ at the poles inside the contour C'
C' is a circle of radius $1/s$ if C is a circle of radius s

For more details, see Ref. [7].

5.3.2 Partial Fraction Expansion

Another method of obtaining the inverse z-transform is by using partial fraction expansion. Note, however, that the partial fraction expansion method can be applied only to rational functions. Thus, suppose that $X(z)$ can be represented as in Equation 5.10. We can then rewrite it as

$$X(z) = \frac{N_0}{D_0}\cdot\frac{\prod_{i=1}^{N}(1-n_i z^{-1})}{\prod_{i=1}^{D}(1-d_i z^{-1})} \tag{5.21}$$

where

n_i are the nontrivial zeroes of $N(z)$
d_i are the zeroes of $D(z)$

The partial fraction expansion of $X(z)$ can be written as

$$X(z) = \sum_{i=0}^{N-D} A_i z^{-i} + \sum_{i=1}^{D_s}\frac{B_i}{(1-d_i z^{-1})} + \sum_{i=1}^{D_m}\sum_{m=1}^{p_i}\frac{C_{mi}}{(1-d_i z^{-1})^m} \tag{5.22}$$

Here, if $N \geq D$, A_i can be obtained by long division of the numerator by the denominator; otherwise, that first sum in Equation 5.22 disappears. In the second sum D_s denotes the number of single poles d_i of $X(z)$, and the coefficients B_i can be obtained as

$$B_i = \left(1 - d_i z^{-1}\right) X(z)\big|_{z=d_i} \tag{5.23}$$

The third sum (double sum) represents the part with multiple poles. D_m is the number of multiple poles d_i, and p_i are their respective multiplicities. The coefficients C_{mi} can be obtained as

$$C_{mi} = \frac{1}{(p_i - m)!(-d_i)^{pi-m}} \frac{\mathrm{d}^{pi-m}}{\mathrm{d}z^{pi-m}} [(1 - d_i z)^{pi} X(z^{-1})]\big|_{z=d_i^{-1}} \tag{5.24}$$

Once we have the expression (Equation 5.22), we can recognize each term as the z-transform of a known sequence. For example, $B_i/(1 - d_i z^{-1})$ will be the z-transform of either $B_i d_i^n u[n]$ or $-B_i d_i^n u[-n-1]$, depending on whether $|z| > |d_i|$, or $|z| < |d_i|$.

5.3.3 Other Methods for Obtaining the Inverse z-Transform

Although the two methods presented previously will work in most cases, sometimes it can be more convenient to use simpler techniques.

One of these is the inspection method [7]. It consists of learning to recognize some often-used z-transform pairs. For example, if we are given $3/(1 - z^{-1})$ with the ROC $|z| < 1$, from Equation 5.21 we can recognize it as the z-transform of $-3u[-n-1]$. In this process the tables of z-transform pairs are an invaluable tool. An extensive list of z-transform pairs can be found in Ref. [3].

Another technique can be used if we are given a z-transform in the form of a power series expansion:

$$X(z) = \cdots + x[-1]z + x[0] + x[1]z^{-1} + \cdots$$

Then, we can identify each term with the appropriate power of z. For example, the coefficient with z^{-k} will be $x[k]$.

5.4 Properties of the z-Transform

Although we can always obtain a z-transform of a sequence by directly applying its definition as given in Equation 5.3, it is useful to have a list of properties at hand to help calculate a particular z-transform or inverse z-transform more easily. We divide these properties into two categories: properties of the ROC, and properties of the z-transform itself. In what follows R_x will denote the ROC of the signal $x[n]$, while R_{x_-} and R_{x_+} will denote its lower/upper bounds, respectively (as given in Equation 5.5).

5.4.1 Region of Convergence

The ROC is an integral part of the z-transform of a sequence. Thus, this section goes into more detail on some of the points touched upon earlier. These properties and the order in which they are presented follow those in Ref. [7]; therefore, for more details, see Ref. [7].

First, we said that the ROC is an annular region in the z-plane, i.e., $0 \leq R_- < |z| < R_+ \leq \infty$. This follows from the fact that if the z-transform converges for $z = z_1$, it will converge for all z such that $|z| = |z_1|$, that is, for all z on the circle $|z| = |z_1|$. Then, if we put $|z| = 1$ in Equation 5.3, we obtain Equation 5.6, or the discrete-time FT. Therefore, it is obvious that the FT of $x[n]$ converges iff the z-transform of $x[n]$ converges for $|z| = 1$, that is, iff the ROC of the z-transform contains the unit circle.

Another useful property is that the ROC cannot contain any poles. This stems from the fact that if it did, the z-transform at the pole would be infinite and would not converge.

Consider now what happens if the sequence is of finite duration—it is zero except in a finite interval $-\infty < N_1 \leq n \leq N_2 < +\infty$. If all the values are finite, then the sequence is clearly absolutely summable and the z-transform will converge everywhere, except possibly at points $z = 0$ or $z = \infty$. Using the same type of arguments one can conclude that if the sequence is right-sided (it is zero for $n < N_1 < +\infty$), then the ROC will be the annular region outside of the finite pole of $X(z)$ of the largest magnitude. Similarly, if the sequence is left-sided (it is zero for $n > N_2 > -\infty$), then the ROC will be the annular region inside the finite pole of $X(z)$ of the smallest magnitude. As a result, if a sequence is neither left- nor right-sided, the ROC will be an annular region bounded on the interior and the exterior by a pole.

5.4.2 Properties of the Transform

The sequences $x[n]$, $y[n], \ldots$ will have associated z-transforms $X(z)$, $Y(z), \ldots$, with ROCs R_x, $R_y, \ldots$, in which each ROC will have its associated lower and upper bounds, as given in Equation 5.5.

5.4.2.1 Linearity

$$ax[n] + by[n] \leftrightarrow aX(z) + bY(z) \quad \text{ROC} \supset R_x \cap R_y \tag{5.25}$$

To prove this, apply the definition given in Equation 5.5. Note that the resulting ROC is at least as large as the intersection of the two starting ROCs. For example, if both $X(z)$ and $Y(z)$ are rational functions of z, and by adding $aX(z)$ to $bY(z)$ we introduce a zero that cancels one of the poles, the resulting ROC is larger than the intersection. If, on the other hand, no pole/zero cancelation exists, the resulting ROC is exactly the intersection.

5.4.2.2 Shift in Time

$$x[n - i] \leftrightarrow z^{-i}X(z) \quad \text{ROC} = R_x \tag{5.26}$$

The proof is straightforward and follows by the change of variables $k = n - i$ in Equation 5.5. Note that the resulting ROC could gain or lose a few poles at $z = 0$ or $z = \infty$.

5.4.2.3 Time Reversal

$$x[-n] \leftrightarrow X\left(\frac{1}{z}\right) \quad \frac{1}{R_{x_+}} < |z| < \frac{1}{R_{x_-}} \tag{5.27}$$

Again, the proof is straightforward and follows by the change of variables $k = -n$ in Equation 5.5.

5.4.2.4 Multiplication by an Exponential Sequence

One can easily show that the following holds:

$$a^n x[n] \leftrightarrow X\left(\frac{z}{a}\right) \quad |a|R_{x_-} < |z| < |a|R_{x_+} \tag{5.28}$$

Because z/a is the variable in the transform domain, we can see that all the poles of the original $X(z)$ have been scaled by a.

5.4.2.5 Multiplication by a Ramp

This property could also be called "differentiation of $X(z)$":

$$nx[n] \leftrightarrow -z\frac{dX(z)}{dz}, \quad \text{ROC} = R_x \tag{5.29}$$

To demonstrate this, differentiate both sides of Equation 5.3 with respect to z and then multiply by $-z$ to obtain Equation 5.29.

5.4.2.6 Convolution in Time

In transform domain convolution becomes simply the product of the two sequences. If we denote convolution by *

$$x[n]^*y[n] = \sum_{k=-\infty}^{+\infty} x[k]y[n-k] = \sum_{k=-\infty}^{+\infty} y[k]x[n-k] \tag{5.30}$$

then

$$x[n]^*y[n] \leftrightarrow X(z)\cdot Y(z), \quad \text{ROC} \supset R_x \cap R_y \tag{5.31}$$

Although the proof is not difficult, we write it here, because this is one of the most useful properties. Thus, take the convolution in Equation 5.30, multiply it by z^{-n} and sum over n

$$\begin{aligned}\sum_{n=-\infty}^{+\infty}\sum_{k=-\infty}^{+\infty} x[k]y[n-k]z^{-n} &= \sum_{k=-\infty}^{+\infty} x[k]\sum_{n=-\infty}^{+\infty} y[n-k]z^{-n} \\ &= \sum_{k=-\infty}^{+\infty} x[k]\sum_{p=-\infty}^{+\infty} y[p]z^{-(p+k)} \\ &= \sum_{k=-\infty}^{+\infty} x[k]z^{-k}\sum_{p=-\infty}^{+\infty} y[p]z^{-p} \\ &= X(z)Y(z)\end{aligned}$$

where we have used change of variables $p = n - k$. As in the case of linearity, if it happens that a pole residing at the border of one of the ROCs is canceled by a zero from the other transform, then the resulting ROC will be larger than the intersection of the individual ROCs; otherwise, it will be exactly their intersection.

5.4.3 Convolution in z-Domain

Convolution in z-domain is given by (for more details, refer to Ref. [3] or [7])

$$x[n]\cdot y[n] \leftrightarrow \frac{1}{2\pi j}\oint_C X(\lambda)Y\left(\frac{z}{\lambda}\right)\lambda^{-1}d\lambda \quad R_{x_-}R_{y_-} < |z| < R_{x_+}R_{y_+} \tag{5.32}$$

where C is a closed contour in the intersection of the ROCs of $X(\lambda)$ and $Y(z/\lambda)$, and integration is performed counterclockwise. This property is the generalization of the periodic convolution property of the FT. Suppose that the contour C is the unit circle and $\lambda = e^{j\omega}$, $z = e^{j\theta}$. Also, observe that $d\lambda = je^{j\omega}\,d\omega$, and that if λ goes around the unit circle, ω ranges from $-\pi$ to π. Then,

$$\frac{1}{2\pi j}\oint_C X(\lambda)Y\left(\frac{z}{\lambda}\right)\lambda^{-1}d\lambda = \frac{1}{2\pi}\int_{-\pi}^{\pi} X(e^{j\omega})Y[e^{j(\theta-\omega)}]d\omega$$

This equation states that the product of two sequences has as its FT the periodic convolution of their FTs.

5.4.3.1 Conjugation

If we are given a complex sequence $x^*[n]$, then its z-transform pair is

$$x^*[n] \leftrightarrow X^*(z^*) \quad \text{ROC} = R_x \tag{5.33}$$

5.4.3.2 Real Part

This property and the next one use the conjugation property given in Equation 5.33. Thus, if we express

$$\text{Re}\{x[n]\} = \frac{x[n] + x^*[n]}{2}$$

then by Equation 5.33 and the linearity of the z-transform

$$\text{Re}\{x[n]\} \leftrightarrow \frac{1}{2}[X(z) + X^*(z^*)] \quad \text{ROC} \supset R_x \tag{5.34}$$

5.4.3.3 Imaginary Part

Similarly to the previous property, if we express

$$\text{Im}\{x[n]\} = \frac{x[n] - x^*[n]}{2j}$$

then by Equation 5.33 and the linearity of the z-transform

$$\text{Im}\{x[n]\} \leftrightarrow \frac{1}{2j}[X(z) - X^*(z^*)] \quad \text{ROC} \supset R_x \tag{5.35}$$

5.4.3.4 Parseval's Relation

Parseval's relation is widely used in various transform domains, usually to find the energy of a signal. We start here with its more general formulation, and then reduce it to its usual form

$$\sum_{n=-\infty}^{+\infty} x[n]y^*[n] = \frac{1}{2\pi j}\oint_C X(\lambda)Y^*\left(\frac{1}{\lambda^*}\right)\lambda^{-1}d\lambda \tag{5.36}$$

where C is a closed contour in the intersection of the ROCs of $X(\lambda)$ and $Y^*(1/\lambda^*)$, and integration is performed counterclockwise. Again, for the proof, we refer the reader to Ref. [3] or [7].

Suppose now that $y[n] = x[n]$. Then Equation 5.36 reduces to

$$\sum_{n=-\infty}^{+\infty} |x[n]|^2 = \frac{1}{2\pi j}\oint_C X(\lambda)X^*\left(\frac{1}{\lambda^*}\right)\lambda^{-1}d\lambda \tag{5.37}$$

If both $x[n]$ and $y[n]$ converge on the unit circle, i.e., their FTs exist, then, we can choose $\lambda = e^{j\omega}$ and Equation 5.36 becomes

$$\sum_{n=-\infty}^{+\infty} x[n]y^{\star}[n] = \frac{1}{2\pi j}\oint_{C} X(e^{j\omega})Y^{\star}(e^{j\omega})e^{-j\omega}\mathrm{d}(e^{j\omega})$$
$$= \frac{1}{2\pi}\int_{-\pi}^{\pi} X(e^{j\omega})Y^{\star}(e^{j\omega})\mathrm{d}\omega$$

which is the usual Parseval's relation in Fourier domain.

5.4.3.5 Initial Value Theorem

If $x[n]$ is causal (it is 0 for $n < 0$), then

$$x[0] = \lim_{z\to\infty} X(z) \tag{5.38}$$

5.4.3.6 Final Value Theorem

If the poles of $X(z)$ are all inside the unit circle, then

$$\lim_{n\to\infty} x[n] = \lim_{z\to 1}[(1 - z^{-1})X(z)] \tag{5.39}$$

5.5 Role of the *z*-Transform in Linear Time-Invariant Systems

The class of systems dealt with mostly are linear time-invariant systems. We discuss here the role of the z-transform in such systems. Recall that if we are given a system with input $x[n]$ and output $y[n]$, described by an operator $H[\cdot]$

$$y[n] = H[x[n]]$$

and $H[\cdot]$ is defined to be linear and time invariant, then

1. If inputs $x_1[n]$ and $x_2[n]$ produce outputs $y_1[n]$ and $y_2[n]$, then the input $ax_1[n]+bx_2[n]$ will produce the output $ay_1[n] + by_2[n]$.
2. If the input $x[n]$ produces output $y[n]$, then the input $x[n-k]$ will produce the output $y[n-k]$.

We recall a few properties of discrete linear time-invariant systems. For more details, refer to Refs. [4,7].

Note first that $x[n]$ can be written as a superposition of unit samples as

$$x[n] = \sum_{k=-\infty}^{+\infty} x[k]\delta[n-k] \tag{5.40}$$

If this is the input and we want to find the corresponding output, then

$$\begin{aligned} y[n] &= H[x[n]] \\ &= H\left[\sum_{k=-\infty}^{+\infty} x[k]\delta[n-k]\right] \\ &= \sum_{k=-\infty}^{+\infty} x[k]H[\delta[n-k]] \\ &= \sum_{k=-\infty}^{+\infty} x[k]h[n-k] \end{aligned} \tag{5.41}$$

Here, $h[n]$ is called the unit-sample response, defined as the response of the system to the unit sample $\delta[n]$. Equation 5.41 is a convolution sum, thus it can be written as

$$y[n] = x[n]^* h[n] \tag{5.42}$$

One of the most important properties of the z-transform is that the convolution in time has a product as its transform-domain pair. Therefore, using Equation 5.31, we can write Equation 5.42 in z-domain as

$$Y(z) = X(z)H(z) \tag{5.43}$$

Here, $H(z)$ is called the system transfer function

$$H(z) = \sum_{n=-\infty}^{+\infty} h[n]z^{-n} \tag{5.44}$$

We may also obtain this transfer function in another manner, if we assume that the systems we are dealing with are those that can be described by linear constant-coefficient difference equations (much in the same way as continuous-time systems that can be represented by linear constant-coefficient differential equations). Along the way, the use of z-transform greatly simplifies analysis of such systems and the solutions to these equations reduce to solutions of algebraic equations. Hence, suppose that our system can be described by the following linear constant-coefficient difference equation:

$$\sum_{k=0}^{D} b_k y[n-k] = \sum_{k=0}^{N} a_k x[n-k] \tag{5.45}$$

This equation has many solutions. We assume that the system is causal and moreover, we assume that the initial conditions are satisfied so that the system is linear and time invariant. With these factors in mind, we can write the expression for the output of the system as

$$y[n] = -\sum_{k=1}^{D} \frac{b_k}{b_0} y[n-k] + \sum_{k=0}^{N} \frac{a_k}{b_0} x[n-k] \tag{5.46}$$

This means that the output at time n depends on the outputs from D previous instants as well as from the input at time n and at N previous instants. Taking the z-transform of both sides of Equation 5.45 and using the linearity and shift in time properties of the z-transform, we obtain

$$Y(z) = \frac{\sum_{k=0}^{N} a_k z^{-k}}{\sum_{k=0}^{D} b_k z^{-k} X(z)} \tag{5.47}$$

Finally, using Equation 5.43 we can identify $H(z)$ here as

$$H(z) = \frac{\sum_{k=0}^{N} a_k z^{-k}}{\sum_{k=0}^{D} b_k z^{-k}} \tag{5.48}$$

The function $H(z)$ is often referred to as a filter. If the denominator is a delay, i.e., $b_i\, z^{-i}$, such a filter will be a finite impulse response filter (FIR), as opposed to the infinite impulse response filter (IIR). Taking the inverse z-transform of Equation 5.48 we may obtain the unit-sample response of the system $h[n]$.

Finally, let us see how one might obtain the frequency response of the system. Evaluate Equation 5.44 on the unit circle (assuming that the ROC of $H(z)$ contains the unit circle)

$$H(z)|_{|z|=1} = H(e^{j\omega}) = \sum_{n=-\infty}^{+\infty} h[n]e^{-j\omega n} \tag{5.49}$$

Therefore, the frequency response of the system is the system transfer function evaluated on the unit circle:

$$H(e^{j\omega}) = H(z)|_{z=e^{j\omega}} \tag{5.50}$$

A consequence of this is that a linear time-invariant system is bounded-input–bounded-output stable (i.e., bounded input produces bounded output), iff the ROC of the transfer function $H(z)$ contains the unit circle.

We mentioned earlier that we are using the double-sided z-transform, while the one-sided z-transform is most useful when solving linear constant-coefficient difference equations with nonzero initial conditions. To transform such an equation into an algebraic equation, we used the linearity and shift in time properties of the double-sided z-transform. We would like to be able to do the same with the one-sided z-transform; however, we must re-derive the shift in time property in order to do that. Therefore, assume we are given a sequence $x[n-i]$ as in Equation 5.26.

Taking its one-sided z-transform, we obtain

$$\begin{aligned}\sum_{n=0}^{+\infty} x[n-i]z^{-n} &= \sum_{p=-i}^{+\infty} x[p]z^{-(p+i)} \\ &= \sum_{p=-i}^{-1} x[p]z^{-(p+i)} + z^{-i}\sum_{p=0}^{+\infty} x[p]z^{-p} \\ &= x[-i] + \cdots + x[-1]z^{-(i-1)} + z^{-i}X(z)\end{aligned} \tag{5.51}$$

To solve Equation 5.45, we can take the one-sided z-transform of both sides and use the linearity and shift in time properties to obtain

$$\sum_{k=0}^{D} b_k \left[\sum_{p=-k}^{-1} y[p]z^{-(p+k)} + z^{-k}Y(z)\right] = \sum_{k=0}^{N} a_k \left[\sum_{p=-k}^{-1} x[p]z^{-(p+k)} + z^{-k}X(z)\right] \tag{5.52}$$

The output $y[n]$ for $n \geq 0$ can be obtained as the inverse z-transform of

$$Y(z) = \left(\frac{\sum_{k=0}^{N} a_k z^{-k}}{\sum_{k=0}^{D} b_k z^{-k}}\right)X(z) + \left[\frac{\sum_{k=0}^{N} a_k \sum_{p=-k}^{-1} x[p]z^{-(p+k)} - \sum_{k=0}^{D} b_k \sum_{p=-k}^{-1} y[p]z^{-(p+k)}}{\sum_{k=0}^{D} b_k z^{-k}}\right] \tag{5.53}$$

To solve for $Y(z)$ we need to know initial conditions $y[n]$, for $n = -D, \ldots, -1$, and for $x[n]$ for $n = -N, \ldots, -1$. Note that if $x[n]$ is causal, and the initial conditions are all zero, the above solution is the same as the one when the double-sided z-transform is used; i.e., it reduces to the first term on the right side of Equation 5.53.

5.6 Variations on the *z*-Transform

5.6.1 Multidimensional *z*-Transform

Although the two-dimensional and multidimensional z-transforms are related to the one-dimensional z-transform, they are not straightforward generalizations of it. We give here a brief overview of the two-dimensional z-transform. For more details on it and the multidimensional z-transform, see Refs. [1,2].

The two-dimensional z-transform of a sequence $x[n_1, n_2]$ is given by

$$X(z_1, z_2) = \sum_{n_1=-\infty}^{+\infty} \sum_{n_2=-\infty}^{+\infty} x[n_1, n_2] z_1^{-n_1} z_2^{-n_2} \tag{5.54}$$

Here, z_1 and z_2 are complex variables and the region in the four-dimensional (z_1, z_2) space in which the previous double sum converges is called the ROC. In one dimension, the ROC is an annular region in the z-plane, while here it is called the Reinhardt domain. The analog of the unit circle in one dimension is the unit bicircle for $|z_1| = 1$ and $|z_2| = 1$. On the unit bicircle, the two-dimensional z-transform becomes the two-dimensional discrete-time FT.

Properties of the two-dimensional z-transform are similar to those of the one-dimensional z-transform, and they can be found in Refs. [1,2]. Here, we list just two. First, for separable signals, the following holds:

$$x[n_1]y[n_2] \leftrightarrow X(z_1)Y(z_2) \tag{5.55}$$

where (z_1, z_2) is the ROC, if z_1 is in R_x and z_2 is in R_y. The differentiation property is as follows:

$$n_1 n_2 x[n_1, n_2] \leftrightarrow z_1 z_2 \frac{\partial^2}{\partial z_1 \partial z_2} X[z_1, z_2], \quad \text{ROC} = R_x \tag{5.56}$$

In analyzing two-dimensional systems it is useful to identify singularities. Given a two-dimensional linear shift-invariant system with an associated constant-coefficient difference equation

$$\sum_{k_1=0}^{D_1} \sum_{k_2=0}^{D_2} b_{k_1 k_2}\ y[n_1 - k_1, n_2 - k_2] = \sum_{k_1=0}^{N_1} \sum_{k_2=0}^{N_2} a_{k_1 k_2}\ x[n_1 - k_1, n_2 - k_2] \tag{5.57}$$

we can find the equivalent transfer function as

$$H(z_1, z_2) = \left(\frac{\sum_{k_1=0}^{N_1} \sum_{k_2=0}^{N_2} a_{k_1 k_2} z_1^{-k_1} z_2^{-k_2}}{\sum_{k_1=0}^{D_1} \sum_{k_2=0}^{D_2} b_{k_1 k_2} z_1^{-k_1} z_2^{-k_2}} \right) = \frac{N(z_1, z_2)}{D(z_1, z_2)} \tag{5.58}$$

Then, the zero of $H(z_1, z_2)$ is a point at which $A(z_1, z_2) = 0$ and $B(z_1, z_2) \neq 0$, while a pole is a point at which $B(z_1, z_2) = 0$. Note, however, that both zeroes and poles are continuous surfaces rather than a discrete set of points, as in one dimension. Note, also, that unlike in one dimension, no fundamental theorem of algebra tells us how to factorize a multidimensional polynomial into its factors, and thus, it is not easy to isolate poles and zeroes.

5.6.2 Modified *z*-Transform

The original, one-sided *z*-transform was developed to deal only with the signal at is sampling instants, and discard the rest. In many systems, particularly in mixed analog-digital systems, it is important to conserve the information about the signal between the sampling instants. Jury, among others, used the modified ***z***-transform [3] to take care of this problem. The idea is to delay the continuous-time function $x_c(t)$ by a fictitious delay $(1-\Delta)T$, where Δ varies from 0 to 1 (Figure 5.4) in order to get all the values of $x_i(t)$ for $t=(n-1+\Delta)T$, $0 \le \Delta \le 1$, $n \in \mathbb{Z}$; T is the sampling period. Then, the modified *z*-transform is defined as follows:

$$X_c(z,\Delta) = \sum_{n=-\infty}^{+\infty} x_c[(n-1+\Delta)T]z^{-n}, \quad 0 \le \Delta \le 1 \tag{5.59}$$

or, using the change of variable $k=n-1$,

$$X_c(z,\Delta) = z^{-1} \sum_{k=-\infty}^{+\infty} x_c[(k+\Delta)T]z^{-k}, \quad 0 \le \Delta \le 1 \tag{5.60}$$

It is easy to see that the *z*-transform as defined in Equation 5.3 can be obtained as a special case of the modified *z*-transform as

$$X_c(z) = |X_c(z,\Delta)|_{\Delta=1} \tag{5.61}$$

Similar to the *z*-transform, the modified *z*-transform possesses a number of useful properties. For these, the reader is referred to Ref. [3].

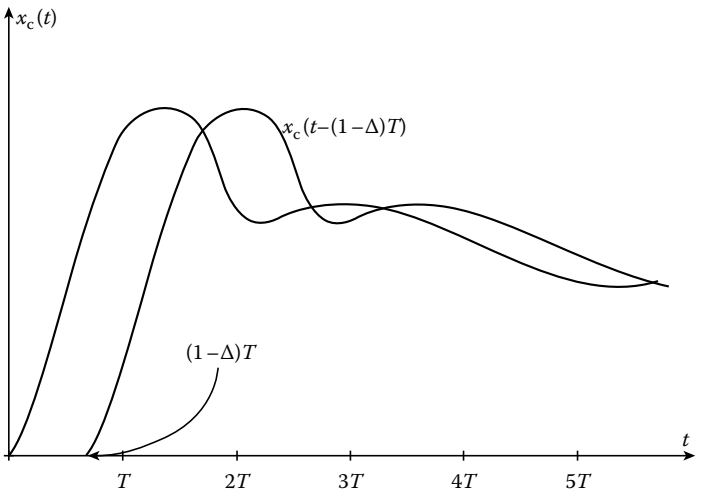

FIGURE 5.4 Modified *z*-transform takes into account values of the function between sampling instants by creating a fictitious delay $(1-\Delta)T$.

5.6.3 Chirp z-Transform Algorithm

This is a brief discussion of an algorithm for computing the z-transform of a finite-length sequence, much as was done in the case of the DFT. Suppose we wanted to compute the z-transform on a circle concentric to the unit circle. We could use the DFT algorithm, with some minor modifications. However, the chirp z-transform algorithm used in radar systems [9] can be more efficient and allows one to compute the z-transform of a finite-length sequence on a spiral contour in the z-plane. The samples we compute are equally spaced in angle over some portion of the spiral. The algorithm employs the DFT as well, and has the complexity of

$$(N + M - 1)\log_2(N + M - 1)$$

where

N is the number of nonzero values of the sequence $x[n]$, i.e., $x[0], \ldots, x[N-1]$
M is the number of points at which we evaluate the z-transform, z_k, $k = 1, \ldots, M$

5.7 Concluding Remarks

This chapter developed the basics of the z-transform. We demonstrated that it is a generalization of the discrete-time FT, and have explored the relationships between the two. We also discussed the connection to the LT. The inverse z-transform was presented, using both contour integration and partial fraction expansion. Although the partial fraction expansion method is easier, it can be used only for rational functions of z. We explored a number of properties of the ROC of the z-transform, as well as important properties of the transform itself. Finally, we showed how the z-transform is used in solving linear constant-coefficient difference equations. To conclude the section, we discussed the modified z-transform and the multidimensional z-transform. We also briefly mentioned the chirp z-transform algorithm, used for computing a few points of the z-transform of a finite-length sequence. For more details on these topics, refer to Refs. [1–3,5–7,9,10].

Acknowledgments

I thank Professor Eli Jury for his encouragement and technical insight while writing this manuscript, as well as an anonymous reviewer for his useful remarks.

6.1 Introduction

Transform techniques such as the Fourier and Laplace transforms and the z-transform have long been used in a wide variety of scientific and engineering disciplines [1,2]. In a number of applications in which we require a joint time–frequency picture, it is necessary to consider other types of transforms or time–frequency representations. Many such methods have evolved. The wavelet transform (WT) technique [3–5] in particular has some unique advantages over other kinds of time–frequency representations such as the short-time Fourier transform (STFT). For historical developments as well as many technical details and original material, see Ref. [5]. This chapter describes some of these representations and explains the advantages of the wavelet transform, as well as the reason for its recent popularity.

A subclass of wavelet transforms [6] has an intimate connection with the theory of digital filter banks [7–10]. Filter banks have been known to the signal processing community for over three decades (see Ref. [7] and references therein). It is this relation that makes it possible to construct in a systematic way a wide family of wavelets with several desirable properties such as compact support (i.e., finite duration), smoothness, good time–frequency localization, and basis orthonormality (all these terms will be explained later).

The connection between wavelets and filter banks finds beautiful mathematical expression in the theory of multiresolution [11]. This enables us to compute the wavelet transform coefficients using the so-called fast wavelet transform (FWT), which is essentially a tree-structured filter bank. In addition to the practical value, many deep results from several disciplines find a unified home in the theory and development of the wavelet transform. This includes signal processing, circuit theory, communications, and mathematics. Our emphasis here is on this unification, and the beautiful big picture that it provides. Other tutorials on wavelets with different choices of emphasis can be found in Refs. [7,12–14].

6.1.1 Scope and Outline

The literature on wavelets is enormous, and an attempt to do justice to everything would prove futile. Even a list of references that is fair to all contributors would be too long. We, therefore, restrict discussions to basic, core material. Sections 6.2 through 6.5 provide an overview, with the presentation given at a level that can be comprehended by most engineers. The more advanced results on wavelets, which brought them great attention in recent years, are presented in Sections 6.9 through 6.13. At the heart of these results lie several powerful mathematical tools, which are usually not familiar to engineers, and so we present a fairly extensive math review in three sections (Sections 6.6 through 6.8). We suggest that the reader go through this review material once and then use it primarily as a reference.

The advanced Sections 6.9 through 6.13 are organized such that the main points, summarized as theorems for convenience of reference, can be appreciated even without the mathematical background

material in Sections 6.6 through 6.8. The mathematical sections do, however, facilitate a deeper understanding. It is our hope that these sections will bring most readers to a point where they can pursue wavelet literature without difficulty.

Why Wavelets?
A commonly asked question is "Why wavelets?," that is, "what are the advantages offered by wavelets over other types of transform techniques such as, the Fourier transform?" The answer to this question is fairly sophisticated, and also depends on the level at which we address the question. Several discussions addressing this question are scattered throughout this chapter. A convenient listing of the locations of these discussions is given in Section 6.14 under "Why Wavelets?"

6.1.2 General Notations and Acronyms

1. Boldfaced quantities represent matrices and vectors.
2. Notations $\mathbf{A}^{\mathrm{T}}$, $\mathbf{A}^{\star}$, and $\mathbf{A}^{\dagger}$ represent, respectively, the transpose, conjugate, and transpose–conjugate of the matrix $\mathbf{A}$.
3. Accent tilde is defined as follows: $\tilde{\mathbf{H}}(z) = \mathbf{H}^{\dagger}(1/z^{\star})$; thus, if $\mathbf{H}(z) = \mathbf{\Sigma}_n \mathbf{h}(n) z^{-n}$, then $\tilde{\mathbf{H}}(z) = \sum_n \mathbf{h}^{\dagger}(-n) z^{-n}$. On the unit circle $\tilde{\mathbf{H}}(z) = \mathbf{H}^{\dagger}(z)$.
4. *Acronyms*. BIBO (bounded-input–bounded-output); FIR (finite impulse response); IIR (infinite impulse response); LTI (linear time invariant); PR (perfect reconstruction); STFT (short-time Fourier transform); WT (wavelet transform).
5. For LTI systems, "stability" stands for BIBO stability.
6. $\delta(n)$ denotes the unit pulse or discrete time impluse, defined such that $\delta(0) = 1$ and $\delta(n) = 0$ otherwise. This should be distinguished from the Dirac delta function [2], which is denoted as $\delta_a(t)$.
7. *Figures*. Sampled versions of continuous time signals are indicated with an arrow on the top (e.g., Figure 6.10a). The sampled versions are impulse trains of the form $\mathbf{\Sigma}_n c(n) \delta_a(t-n)$, and are functions of continuous t.

6.2 Signal Representation Using Basis Functions

The electrical engineer is very familiar with the Fourier transform (FT) and its role in the study of LTI systems or filters. For example, the frequency response of an LTI system is the FT of its impulse response. The FT is also used routinely in the design and analysis of circuits. As a reminder, the FT of a signal $x(t)$ is given by the familiar integral $X(\omega) = \int_{-\infty}^{\infty} x(t) e^{-j\omega t} \mathrm{d}t$ and the inverse transform by*

$$x(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} X(\omega) e^{j\omega t} \mathrm{d}\omega \tag{6.1}$$

From this equation, we can say that $x(t)$ has been expressed as a linear superposition (or linear combination) of an infinite number of functions $g_{\omega}(t) \stackrel{\Delta}{=} e^{j\omega t}$. Because the frequency ω is a continuous variable, uncountably many functions $g_{\omega}(t)$ are superimposed. Electrical engineers, in particular signal processors and communications engineers, are also familiar with two special classes of signals which can be regarded as a superposition of countably many functions:

$$x(t) = \sum_{n=-\infty}^{\infty} \alpha_n g_n(t) \tag{6.2}$$

* At the moment, it is not necessary to worry about the existence, invertibility, and the type (e.g., L^1 or L^2) of the FT. We return to the mathematical subtleties in Section 6.6.

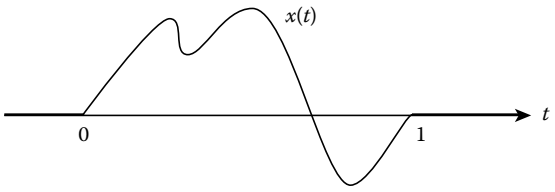

FIGURE 6.1 Finite duration signal, with support $0 \le t \le 1$.

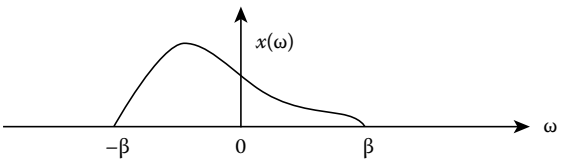

FIGURE 6.2 Fourier transform of a signal band-limited to $|\omega| < \beta$.

where α_n are scalars (possibly complex) uniquely determined by $x(t)$. These two examples are time-limited signals for which we can find a Fourier series (FS), and band-limited signals that can be reconstructed from uniformly spaced samples by weighting them with shifted sinc functions (see the following paragraph).

First consider a time-limited signal $x(t)$ with duration $0 \le t \le 1$ (Figure 6.1). Under some mild conditions such a signal can be represented in the form of Equation 6.2 with $g_n(t) = e^{j2\pi nt}$. The expression 6.2 is then the FS of $x(t)$, and α_n are the Fourier coefficients. (In contrast we say that Equation 6.1 is the Fourier integral of $x(t)$.) The transform domain signal $\{\alpha_n\}$ is a sequence, and the transform domain variable is discrete, namely, the frequencies $\omega_n \stackrel{\Delta}{=} 2\pi n$. Because $e^{j2\pi nt}$ is periodic in t with period one, the right-hand side of Equation 6.2 is periodic, and it represents $x(t)$ only in $0 \le t \le 1$. It is sometimes convenient to replace the complex functions $e^{j2\pi nt}$ with the set of real functions $1, \sqrt{2}\cos(2\pi nt), \sqrt{2}\sin(2\pi nt), n > 0$, especially in circuit analysis.

Next, consider a band-limited signal $x(t)$ with FT $X(\omega)$ as demonstrated in Figure 6.2. If we sample the signal at the Nyquist rate 2β rad/s (i.e., sampling period $T = \pi/\beta$), then multiple copies of the FT are generated [2], and we can recover $x(t)$ from the samples by use of an ideal low-pass filter $F((\omega)$ (Figure 6.3). The impulse response of the filter is the sinc function $f(t) = \sin \beta t/\beta t$ so that the reconstruction formula is

$$x(t) = \sum_{n=-\infty}^{\infty} x(nT) f(t - nT) = \sum_{n=-\infty}^{\infty} x(nT) \frac{\sin \beta(t - nT)}{\beta(t - nT)}, \quad T = \pi/\beta \tag{6.3}$$

Comparing to Equation 6.2 we see that the transform domain coefficients α_n can be regarded as the samples $x(nT)$, whereas the functions $g_n(t)$ are the shifted sinc functions.

If a signal is time limited or band limited, we can express it as a countable linear combination of a set of fundamental functions (called basis functions, in fact an orthonormal basis; see below). If the signal is more arbitrary, i.e., not limited in time or bandwidth, can we still obtain such a countable linear combination? Suppose we restrict $x(t)$ to be a finite energy signal (i.e., $\int |x(t)|^2 dt < \infty$; also called L^2 signals, see below). Then this is possible. In fact, we can find an unusual kind of basis called the wavelet basis, fundamentally different from the Fourier basis. Representation of $x(t)$ using this basis has,

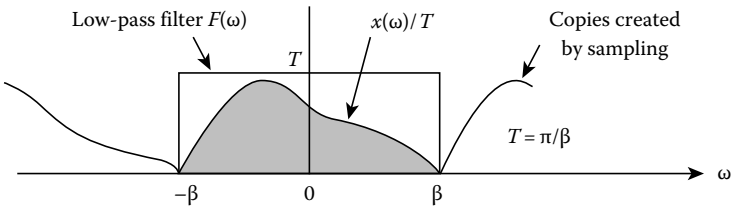

FIGURE 6.3 Use of low-pass filter $F(\omega)$ to recover $x(t)$ from its samples.

in some applications, some advantages over the Fourier representation or the short-time (windowed) Fourier representation. Wavelet bases also exist for many other classes of signals, but this discussion is limited to the L^2 class of signals.

The most common kind of wavelet representation takes the form

$$x(t) = \sum_{k=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} c_{kn} \underbrace{2^{k/2}\psi(2^k t - n)}_{\psi_{kn}(t)} \tag{6.4}$$

The functions $\psi_{kn}(t)$ are typically (but not necessarily) linearly independent and form a basis for finite energy signals. The basis is very special in the sense that all the functions $\psi_{kn}(t)$ are derived from a single function $\psi(t)$ called the wavelet, by two operations: dilation ($t \rightarrow 2^k t$) and time shift ($t \rightarrow t - 2^{-k} n$). The advantage of such a basis is that it allows us to capture the details of a signal at various scales, while providing time-localization information for these ''scales.'' Examples in future sections clarify this idea.

Why Worry about Signal Representations?

A common feature of all the previous discussions is that we have taken a signal $x(t)$ and found an equivalent representation in terms of the transform domain quantity $\{\alpha_n\}$ in Equation 6.2, or $\{c_{kn}\}$ in Equation 6.4. If our only aim is to compute α_n from $x(t)$ and then recompute $x(t)$ from α_n, that would be a futile exercise. The motivation in practice is that the transform domain quantities are better suited in some sense. For example, in audio coding, decomposition of a signal into frequency components is motivated by the fact that the human ear perceives higher frequencies with less frequency resolution. We can use this information. We can also code the high-frequency components with relatively less precision, thereby enabling data compression. In this way, we can take into account perceptual information during compression. Also, we can account for the fact that the error allowed by the human ear (due to quantization of frequency components) depends on the frequency masking property of the ear, and perform optimum-bit allocation for a given bit rate. Other applications of signal representations using wavelets include numerical analysis, solution of differential equations, and many others [5,15,16].

The main point, in any case, is that we typically perform certain manipulations with the transform domain coefficients α_n (or c_{kn} in Equation 6.4) before we recombine them to form an approximation of $x(t)$. Therefore, we really only have

$$\hat{x}(t) = \sum_n \hat{\alpha}_n g_n(t) \tag{6.5}$$

where $\{\hat{\alpha}_n\}$ approximates $\{\alpha_n\}$. This discussion gives rise to many questions: how best to choose the basis functions $g_n(t)$ for a given application? How to choose the compressed signal $\{\hat{\alpha}_n\}$ so that for a given data rate the reconstruction error is minimized? What, indeed, is the best way to define the reconstruction error?

These questions are deep and complicated and will take us too far afield. Our goal is to point out the basic advantages (sometimes) offered by the WT over other kinds of transforms (e.g., the FT).

6.2.1 Ideal Bandpass Wavelet

Consider a bandpass signal $x(t)$ with FT as shown in Figure 6.4. Such signals arise in communication applications. The bandedges of the signal are ω_1 and ω_2 (and $-\omega_1$ and ((ω_2 on the negative side, which is natural if $x(t)$ is real). Viewed as a low-pass signal, the total bandwidth (counting negative frequencies also) is $2\omega_2$, but viewed as a bandpass signal, the total bandwidth is only 2β where $\beta = \omega_2 - \omega_1$. Does it mean that we can sample it at the rate 2β rad/s (which is the Nyquist rate for the low-pass case)?

In the low-pass case, sampling at Nyquist rate was enough to ensure that the copies of the spectrum created by the sampling did not overlap (Figure 6.3). In the bandpass case, we have two sets of such copies; one created by the positive half of the frequency $\omega_1 \leq \omega \leq \omega_2$ and the other by the negative

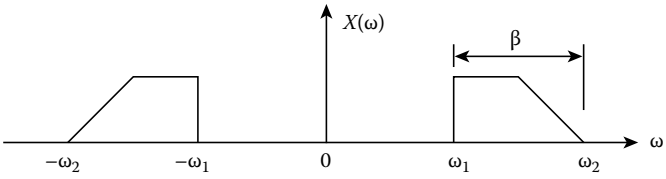

FIGURE 6.4 Fourier transform of a bandpass signal.

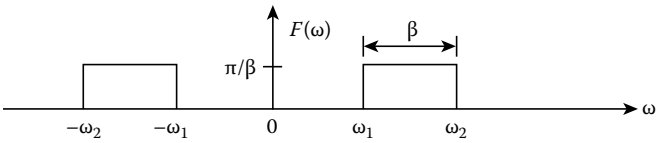

FIGURE 6.5 Bandpass filter to be used in the reconstruction of the bandpass signal from its samples.

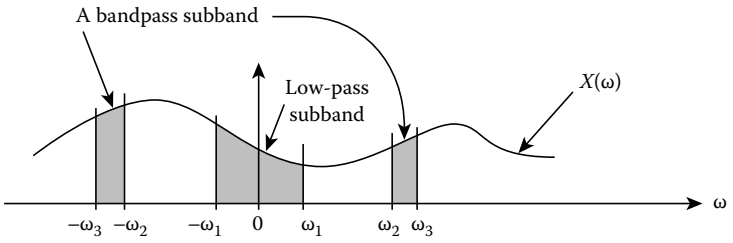

FIGURE 6.6 Splitting a signal into frequency subbands.

half $-\omega_2 \le \omega \le -\omega_1$. This makes the problem somewhat more complicated. It can be shown that, for sampling at the rate 2β, no overlap of images exists iff one of the edges, ω_1 or ω_2, is a multiple of 2β. This is called the bandpass sampling theorem. The reconstruction of $x(t)$ from the samples proceeds exactly as in the low-pass case, except that the reconstruction filter $F(\omega)$ is now a bandpass filter (Figure 6.5), occupying precisely the signal bandwidth. The first part of Equation 6.3, therefore, is still valid, i.e., $x(t) = \Sigma_n\, x(nT)\, f(t - nT)$, where $T = \pi/\beta$ again, but the sinc function is replaced with the bandpass impulse response $f(t)$.

Given a signal $x(t)$, imagine now that we have split its frequency axis into subbands in some manner (Figure 6.6). Letting $y_k(t)$ denote the kth subband signal, we can write $x(t) = \Sigma_k y_k(t)$. This can be visualized as passing $x(t)$ through a bank of filters $\{H_k(\omega)\}$ (Figure 6.7a), with responses as in Figure 6.7b. Note that each subband region is symmetric with respect to zero frequency, and therefore supports positive as well as negative frequencies. If the subband region $\omega_\kappa \le |\omega| < \omega_{k+1}$ satisfies the bandpass sampling condition, then the bandpass signal $y_k(t)$ can be expressed as a linear combination of its samples as before. Thus, $x(t) = \sum_k y_k(t) = \sum_k \sum_n y_k(nT_k) f_k(t - nT_k)$, where $T_k = \pi/\beta_k$. Here, $f_k(t)$ is the impulse response of the reconstruction filter (or synthesis filter) $F_k(\omega)$ shown in Figure 6.7c. Figure 6.7a also illustrates this reconstruction schematic.

Figure 6.8 shows the set of synthesis filters $\{F_k(\omega)\}$ for two examples of frequency splitting arrangement, namely uniform splitting and nonuniform (octave) splitting. We will see later that the uniform splitting arrangement gives an example of the STFT representation (Sections 6.3 and 6.9). In this section, we are interested in octave splitting. The bandedges of the filters here are $\omega_k = 2^k\pi$ ($k = \ldots -1, 0, 1, 2, \ldots$). The bandedges are such that $y_k(t)$ is a signal satisfying the bandpass sampling theorem. It has

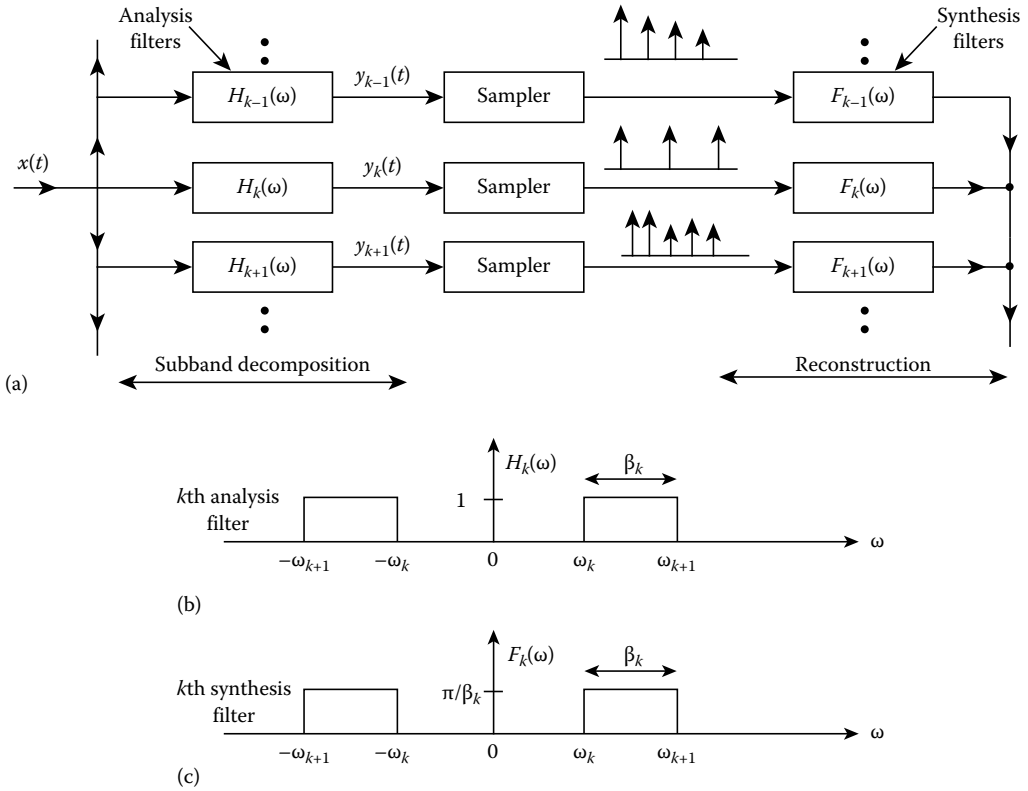

FIGURE 6.7 (a) Splitting a signal into subband signals, sampling, and then recombining; (b) response of the kth analysis filter; and (c) response of kth synthesis filter.

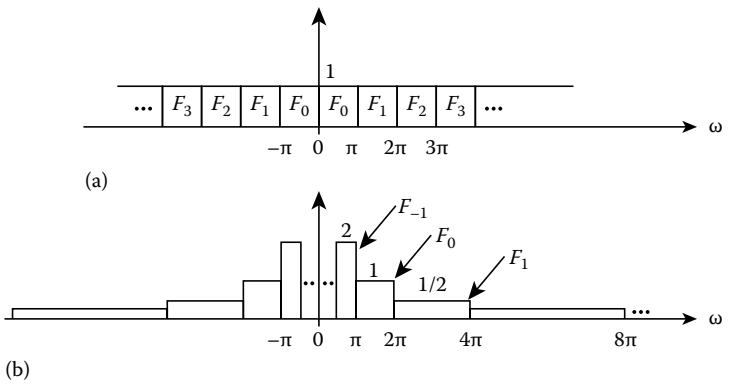

FIGURE 6.8 Two possible schemes to decompose a signal into frequency bands: (a) uniform splitting and (b) octave-band splitting. The responses shown are those of synthesis filters.

$\beta_\kappa = 2^k\pi$, according to the notation of Figure 6.7. It can be sampled at period $T_k = \pi/\beta_k = 2^{-k}$ without aliasing, and we can reconstruct it from samples as

$$y_k(t) = \sum_{n=-\infty}^{\infty} y_k(2^{-k}n) f_k(t - 2^{-k}n) \tag{6.6}$$

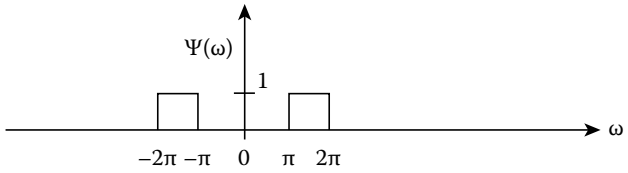

FIGURE 6.9 Fundamental bandpass function that generates a bandpass wavelet.

As k increases, the bandwidths of the filters increase so the sample spacing $T_k = 2^{-k}$ becomes finer. Because $x(t) = \Sigma_k y_k(t)$ we see that $x(t)$ can be expressed as

$$x(t) = \sum_{k=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} y_k(2^{-k}n) f_k(t - 2^{-k}n) \tag{6.7}$$

Our definition of the filters shows that the frequency responses are scaled versions of each other, i.e., $F_k(\omega) = 2^{-k}\ \psi(2^{-k}\omega)$, with $\psi(\omega)$ as in Figure 6.9. The impulse responses are therefore related as $f_k(t) = \psi(2^k t)$, and we can rewrite Equation 6.7 as

$$x(t) = \sum_{k=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} y_k(2^{-k}n) \psi(2^{-k}t - n) \tag{6.8}$$

We will write this as $x(t) = \Sigma_k \Sigma_n C_{kn}\ \psi_{kn}(t)$ by defining $c_{kn} = 2^{-k/2} y_k(2^{-k}n)$ and

$$\psi_{kn}(t) = 2^{k/2}\psi(2^k t - n) = 2^{k/2}\psi(2^k(t - 2^{-k}n)) \tag{6.9}$$

Then the functions $y_{kn}(t)$ will have the same energy $\int |\psi_{kn}(t)|^2\ \mathrm{d}t$ for all k, n. From the analysis/synthesis filter bank point of view (Figure 6.7) this is equivalent to making $H_k(\omega) = F_k(\omega)$ and rescaling, as shown in Figure 6.10. With filters so rescaled, the wavelet coefficients c_{kn} are just samples of the outputs of the analysis filters $H_k(\omega)$.

The function $\psi(2^k t)$ is a dilated version of $\psi(t)$ (squeezed version if $k > 0$ and stretched version if $k < 0$). The dilation factor 2^k is a power of 2, so this is said to be a dyadic dilation. The function $\psi(2^k(t - 2^{-k}n))$ is a shifted version of the dilated version. Thus, we have expressed $x(t)$ as a linear combination of shifted versions of (dyadic) dilated versions of a single function $\psi(t)$. The shifts $2^{-k}n$, are in integer multiples of 2^{-k}, where k governs the dilation. For completeness, note that the impulse response $\psi(t)$ corresponding to the function in Figure 6.9 is given by

$$\psi(t) = \frac{\sin(\pi t/2)}{\pi t/2} \cos(3\pi t/2) \quad \text{(ideal bandpass wavelet)} \tag{6.10}$$

This is plotted in Figure 6.11.

In Equation 6.8 we obtained a wavelet representation for $x(t)$ (compare to Equation 6.4). The function $\psi(t)$ is called the ideal bandpass wavelet, also known as the Littlewood–Paley wavelet. We now introduce some terminology for convenience and then return to more detailed definitions and discussions of the WT.

6.2.2 L^2 Spaces, Basis Functions, and Orthonormal Bases

Most of our discussions are restricted to the class of L^2 functions or square integrable functions, i.e., functions $x(t)$ for which $\int |x(t)|^2\ \mathrm{d}t$ exists and has a finite value. The norm, or L^2 norm, of such functions, denoted $\|x(t)\|_2$, is defined as $\|x(t)\|_2 = (\int |x(t)|^2 \mathrm{d}t)^{1/2}$. The notation $L^2[a, b]$ stands for L^2 functions that

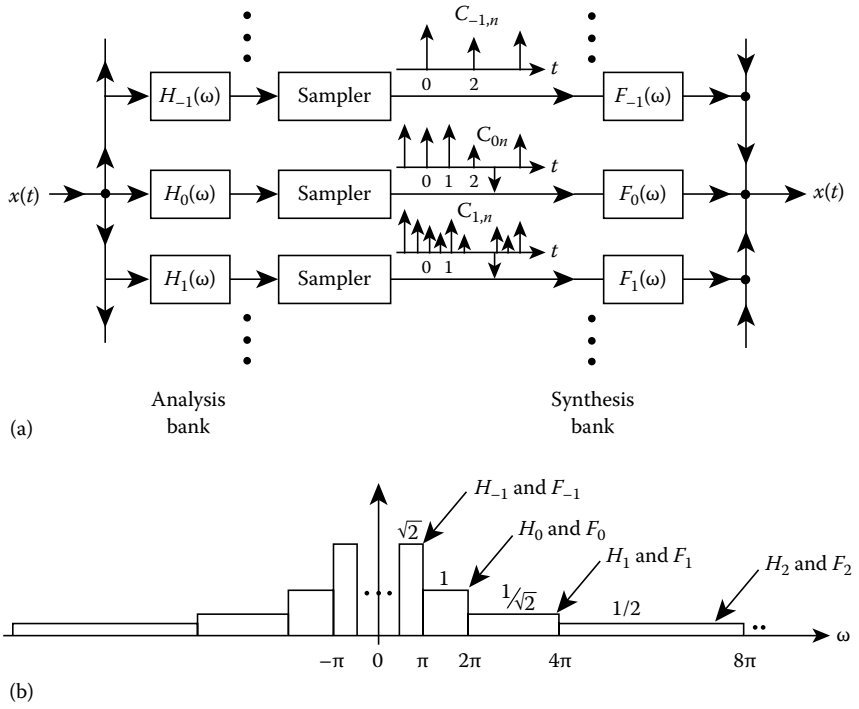

FIGURE 6.10 Octave-band splitting scheme. (a) The analysis bank, samplers, and synthesis bank and (b) the filter responses.

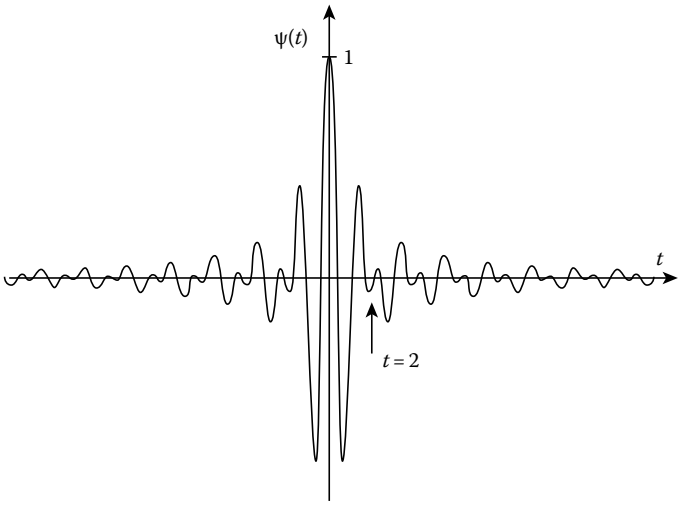

FIGURE 6.11 Ideal bandpass wavelet.

are zero outside the interval $a \leq t \leq b$. The set $L^2(R)$ is the class of L^2 functions supported on the real line $-\infty < t < \infty$. We often abbreviate $L^2(R)$ as L^2.

The class of L^2 functions forms a (normed) linear vector space, i.e., any finite linear combination of functions in L^2 is still in L^2. In fact, it forms a special linear space such that a countable basis exists. That is, a sequence of linearly independent functions $\{g_n(t)\}$ exists in L^2 such that any L^2 function $x(t)$ can be

expressed as $x(t) = \sum_n \alpha_n g_n(t)$, for a unique set of $\{\alpha_n\}$. We say that $g_n(t)$ are the basis functions. L^2 spaces have orthonormal bases. For such a basis, the basis functions satisfy

$$\langle g_k(t), g_m(t)\rangle = \delta(k-m) \tag{6.11}$$

where the notation $\langle f(t), g(t)\rangle \triangleq \int f(t)g^*(t)dt$ denotes the inner product between $f(t)$ and $g(t)$. For an orthonormal basis, the coefficients α_n in the expansion $x(t) = \sum_{n=-\infty}^{\infty} \alpha_n g_n(t)$ can thus be computed using the exceptionally simple relation

$$\alpha_n = \langle x(t), g_n(t)\rangle \tag{6.12}$$

Two examples of orthonormal basis were shown previously. The first is the FS expansion of a time-limited signal ($0 \le t \le 1$). Here, the basis functions $\{e^{j2\pi nt}\}$ are clearly orthonormal, with integrals going from 0 to 1. The second example is the expansion Equation 6.3 of a band-limited signal; it can be shown that the shifted versions $f(t - nT)$ of the sinc functions form an orthonormal basis for band-limited signals (integrals going from $-\infty$ to ∞).

Orthogonal Projections

Suppose we consider a subset $\{g_{n_k}(t)\}$ of the orthonormal basis $\{g_n(t)\}$. Let $\mathcal{S}$ denote the subspace generated by $\{g_{n_k}(t)\}$ (an accurate statement would be that $\mathcal{S}$ is the "closure of the span of $\{g_{n_k}(t)\}$"; see Section 6.7). Consider the linear combination $y(t) = \sum_k \alpha_{n_k} g_{n_k}(t)$ where the α_{n_k} are evaluated as above, i.e., $\alpha_{n_k} = \langle x(t), g_{n_k}(t)\rangle$ for some signal $x(t)$. Then, $y(t) \in \mathcal{S}$, and it can be shown that among all functions in $\mathcal{S}$, $y(t)$ is the unique signal closest to $x(t)$ (i.e, $\|x(t) - y(t)\|_2$ is the smallest). We say that $y(t)$ is the orthogonal projection of $x(t)$ onto the subspace $\mathcal{S}$, and write

$$y(t) = P_{\mathcal{S}}[x(t)] \tag{6.13}$$

6.2.3 Wavelet Transforms

If a signal $x(t)$ is in L^2, then its FT $X(\omega)$ exists in the L^2 sense (Section 6.6). We will see in Section 6.6 that the discussion which resulted in Equation 6.8 is applicable for any signal $x(t)$ in L^2. Equation 6.8 means that the signal can be expressed as a linear combination of the form

$$x(t) = \sum_{k=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} c_{kn} \underbrace{2^{k/2}\psi(2^k t - n)}_{\psi_{kn}(t)} \tag{6.14}$$

where $\psi(t)$ is the impulse response (Figure 6.11) of the bandpass function $\psi(\omega)$ in Figure 6.9.* Because the frequency responses for two different values of k do not overlap, the functions $\psi_{kn}(t)$ and $\psi_{mi}(t)$ are orthogonal for $k \neq m$ (use Parseval's relation). For a given k, the functions $\psi_{kn}(t)$ are shifted versions of the impulse responses of the bandpass filter $F_k(\omega)$. From the ideal nature of this bandpass filter, we can show that $\psi_{kn}(t)$ and $\psi_{km}(t)$ are also orthonormal for $n \neq m$. Thus, the set of functions $\{\psi_{kn}(t)\}$, with k and n ranging over all integers, forms an orthonormal basis for the class of L^2 functions, i.e., any L^2 function can be expressed as in Equation 6.14 and furthermore,

$$\langle \psi_{kn}(t), \psi_{mi}(t)\rangle = \delta(k-m)\delta(n-i) \tag{6.15}$$

Because of this orthonormality, the coefficients c_{kn} are computed very easily as

$$c_{kn} = \langle x(t), \psi_{kn}(t)\rangle = \int_{-\infty}^{\infty} x(t)2^{k/2}\psi^*(2^k t - n)dt \tag{6.16}$$

* The above equality and the convergence of the summation should be interpreted in the L^2 sense; see Section 6.6.

Defining

$$\eta(t) = \psi^*(-t) \tag{6.17}$$

this takes the form

$$c_{kn} = \langle x(t), \eta^*_{kn}(-t)\rangle = \int_{-\infty}^{\infty} x(t)2^{k/2}\eta(n - 2^k t)\mathrm{d}t \tag{6.18}$$

resembling a convolution.

Wavelet Transform Definitions
A set of basis functions $\psi_{kn}(t)$ derived from a single function $\psi(t)$ by dilations and shifts of the form

$$\psi_{kn}(t) = 2^{k/2}\psi(2^k t - n) \tag{6.19}$$

is said to be a wavelet basis, and $\psi(t)$ is called the wavelet function. The coefficients c_{kn} are the wavelet transform coefficients. The formula (Equation 6.16) that performs the transformation from $x(t)$ to c_{kn} is the wavelet transform of the signal $x(t)$. Equation 6.14 is the wavelet representation or the inverse wavelet transform. While this is only a special case of more general wavelet decompositions outlined at the end of this section, it is perhaps the most popular and useful.

Note that the kth dilated version $\psi(2^k\, t)$ has the shifted versions $\psi(2^k\, t - n) = \psi(2^k(t - 2^{-k}n))$, so the amount of shift is in integer multiples of 2^{-k}. Thus, the stretched versions are shifted by larger amounts and squeezed versions by smaller amounts. Even though we developed these ideas based on an example, the above definitions still hold generally for any orthonormal wavelet basis. For the ideal bandpass wavelet, the function $\psi(t)$ is real and symmetric (Equation 6.10) so that $\eta(t) = \psi(t)$. For more general orthonormal wavelets, we have the relation $\eta(t) = \psi^*\,(-t)$. We say that $\eta(t)$ is the analyzing wavelet (because of Equation 6.18) and $\psi(t)$ the synthesis wavelet (because of Equation 6.14). For the nonorthonormal case we still have the transform and inverse transform equations as above, but the relation between $\psi(t)$ and $\eta(t)$ is not as simple as $\eta(t) = \psi^*\,(-t)$.

Before exploring the properties and usefulness of wavelets let us turn to a distinctly different example. This shows that unlike the Fourier basis functions $\{e^{j2\pi nt}\}$, the wavelet basis functions can be designed by the user. This makes them more flexible, interesting, and useful.

6.2.4 Haar Wavelet Basis

An orthonormal basis for L^2 functions was found by Haar [5] as early as 1910, which satisfies the definition of a wavelet basis given above. That is, the basis functions $\psi_{kn}(t)$ are derived from a single function $\psi(t)$ using dilations and shifts as in Equation 6.19. To explain this system, first, consider a signal $x(t) \in L^2[0, 1]$. The Haar basis is built from two functions called $\phi(t)$ and $\psi(t)$, as described in Figure 6.12. The basis function $\phi(t)$ is a constant in $[0, 1]$. The basis function $\psi(t)$ is constant on each half interval, and its integral is zero. After this, the remaining basis functions are obtained from $\psi(t)$ by dilations and shifts as indicated. It is clear from the figure that any two of these functions are mutually orthogonal. We have an orthonormal set, and it can be shown that this set of functions is an orthonormal basis for $L^2[0, 1]$. However, this is not exactly a wavelet basis yet because of the presence of $\phi(t)$.*

If we eliminate the requirement that $x(t)$ be supported or defined only on $[0, 1]$ and consider $L^2(R)$ functions then we can still obtain an orthonormal basis of the above form by including the shifted versions $\{\psi(2^k\, t - n)\}$ for all integer values of n, as well as the shifted versions $\{\phi(t - n)\}$.

An alternative to the use of $\{\phi(t - n)\}$ would be to use stretched (i.e., $\psi(2^k\, t)$, $k < 0$) as well as squeezed (i.e., $\psi(2^k\, t)$, $k > 0$) versions of $\psi(t)$. The set of functions can thus be written as in Equation 6.19, which

* We see in Section 6.10 that the function $\phi(t)$ arises naturally in the context of the fundamental idea of multiresolution.

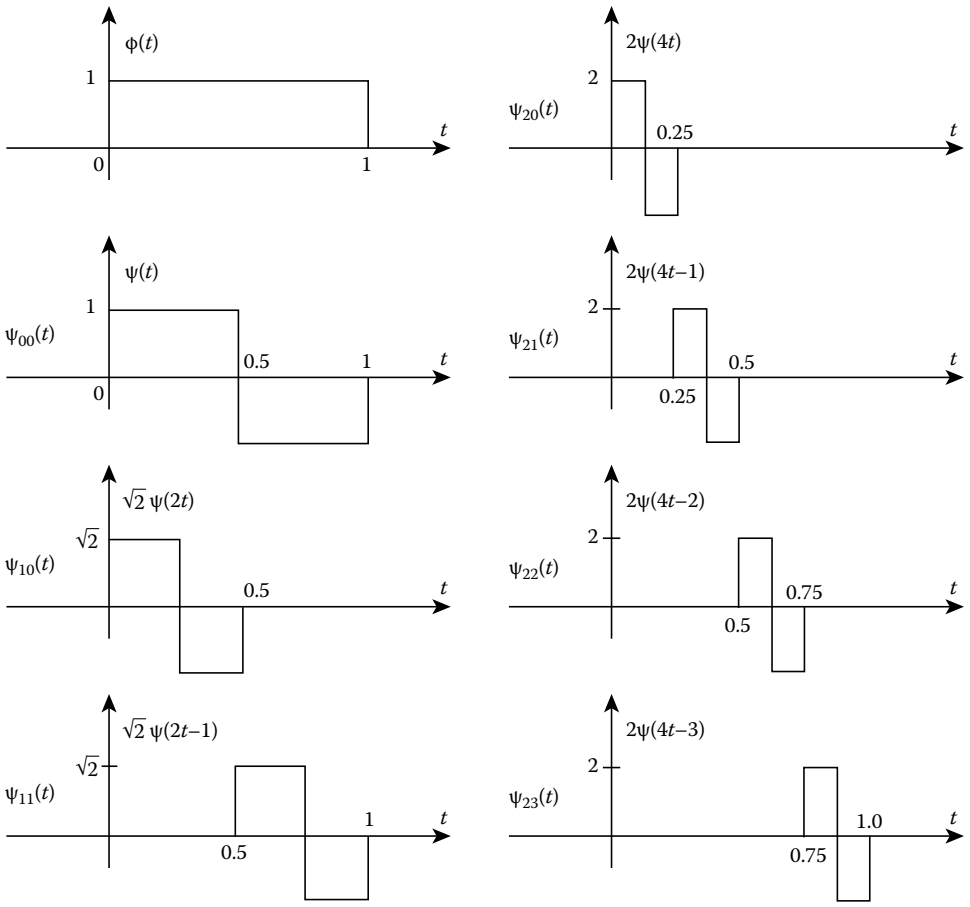

FIGURE 6.12 Examples of basis functions in the Haar basis for $L^2[0, 1]$.

has the form of a wavelet basis. It can be shown that this forms an orthonormal basis for $L^2(R)$. The FT of the Haar wavelet $\psi(t)$ is given by

$$\Psi(\omega) = je^{-j\omega/2}\frac{\sin^2(\omega/4)}{\omega/4} \quad \text{(Haar wavelet)} \tag{6.20}$$

The Haar wavelet has limited duration in time, whereas the ideal bandpass wavelet (Equation 6.10), being band limited, has infinite duration in time.

6.2.5 Basic Properties of Wavelet Transforms

Based on the definitions and examples provided so far, we can already draw some very interesting conclusions about wavelet transforms, and obtain a preliminary comparison to the FT.

1. Concept of scale: The functions $\psi_{kn}(t)$ are useful to represent increasingly finer "variations" in the signal $x(t)$ at various levels. For large k, the function $\psi_{kn}(t)$ looks like a "high frequency signal." This is especially clear from the plots of the Haar basis functions. (For the bandpass wavelets, see below.) Because these basis functions are not sinusoids, we do not use the term "frequency" but rather the term "scale." We say that the component $\psi_{kn}(t)$ represents a finer scale for larger k.

Accordingly k (sometimes $1/k$) is called the scale variable. Thus, the function $x(t)$ has been represented as a linear combination of component functions that represent variations at different scales. For instance, consider the Haar basis. If the signal expansion (Equation 6.14) has a relatively large value of $c_{4,2}$ this means that the component at scale $k = 4$ has large energy in the interval $[2/2^4, 3/2^4]$ (Figure 6.14).

2. Localized basis: The preceding comment shows that if a signal has energy at a particular scale concentrated in a slot in the time domain, then the corresponding c_{kn} has large value, i.e., $\psi_{kn}(t)$ contributes more to $x(t)$. The wavelet basis, therefore, provides localization information in time domain as well as in the scale domain. For example, if the signal is zero everywhere except in the interval $[2/2^4, 3/2^4]$ then the subset of the Haar basis functions which do not have their support in this interval are simply absent in this expansion.

Note that the Haar wavelet has compact support, that is, the function $\psi(t)$ is zero everywhere outside a closed bounded interval ($[0, 1]$ here). While the above discussions are motivated by the Haar basis, many of them are typically true, with some obvious modifications, for more general wavelets. Consider, for example, the ideal bandpass wavelet (Figure 6.11) obtained from the bandpass filter $\Psi(\omega)$ in Figure 6.9. In this case the basis functions do not have compact support, but are still locally concentrated around $t = 0$. Moreover, the basis functions for large k represent "fine" information, or the frequency component around the center frequency of the filter $F_k(\omega)$ (Figure 6.10). The Haar wavelet and the ideal bandpass wavelet are two extreme examples (one is time limited and the other band-limited). Many intermediate examples can be constructed.

6.2.6 Filter Bank Interpretation and Time–Frequency Representation

We know that the wavelet coefficients c_{kn} for the ideal bandpass wavelet can be viewed as the sampled version of the output of a bandpass filter (Figure 6.10a). The same is true for any kind of WT. For this recall, the Equation 6.18 for the wavelet coefficients. This can be interpreted as the set of sampled output sequences of a bank of filters $H_k(\omega)$, with impulse response $h_k(t) = 2^{k/2}\, h_o(2^k t)$, where $h_o(t) = \eta(t)$. Thus the wavelet transform can be interpreted as a nonuniform continuous time analysis filter bank, followed by samplers. The Haar basis and ideal bandpass wavelet basis are two examples of the choice of these bandpass filters.

The wavelet coefficients c_{kn} for a given scale k are therefore obtained by sampling the output $y_k(t)$ of the bandpass filter $H_k(\omega)$, as indicated in Figure 6.13a. The first subscript k (the scale variable) represents the filter number. As k increases by 1, the center frequency ω_k increases by a factor of 2. The wavelet coefficients c_{kn} at scale k are merely the samples $y_k(2^{-k}n)$. As k increases, the filter bandwidth increases, and thus the samples are spaced by a proportionately finer amount 2^{-k}. The quantity $c_{kn} = y_k(2^{-k}n)$ measures the "amount" of the "frequency component" around the center frequency ω_k of the analysis filter $H_k(\omega)$, localized in time around $2^{-k}n$.

In wavelet transformation, the transform domain is represented by the two integer variables k and n. This means that the transform domain is two dimensional (the time–frequency domain), and is discretized. We say that c_{kn} is a time–frequency representation of $x(t)$. Section 6.3 explains that this is an improvement over another time–frequency representation, the STFT, introduced many years ago in the signal-processing literature.

Synthesis Filter Bank and Reconstruction

The inner sum in Equation 6.14 can be interpreted as follows: For each k, convert the sequence c_{kn} into an impulse train* $\Sigma_n c_{kn}\delta_a(t - 2^{-k}n)$ and pass it through a bandpass filter $F_k(\omega) = 2^{-k/2}\Psi(2^{-k}\omega)$ with impulse response $f_k(t) = 2^{k/2}\Psi(2^k t)$. The outer sum merely adds the outputs of all these filters. Figure 6.13a shows this interpretation. Therefore, the reconstruction of the signal $x(t)$ from the wavelet

* $\delta_a(t)$ is the Dirac delta function [2]. It is used here only as a schematic. The true meaning is that the output of $f_k(t)$ is $\Sigma_n c_{kn} f_k(t - 2^{-k}n)$.

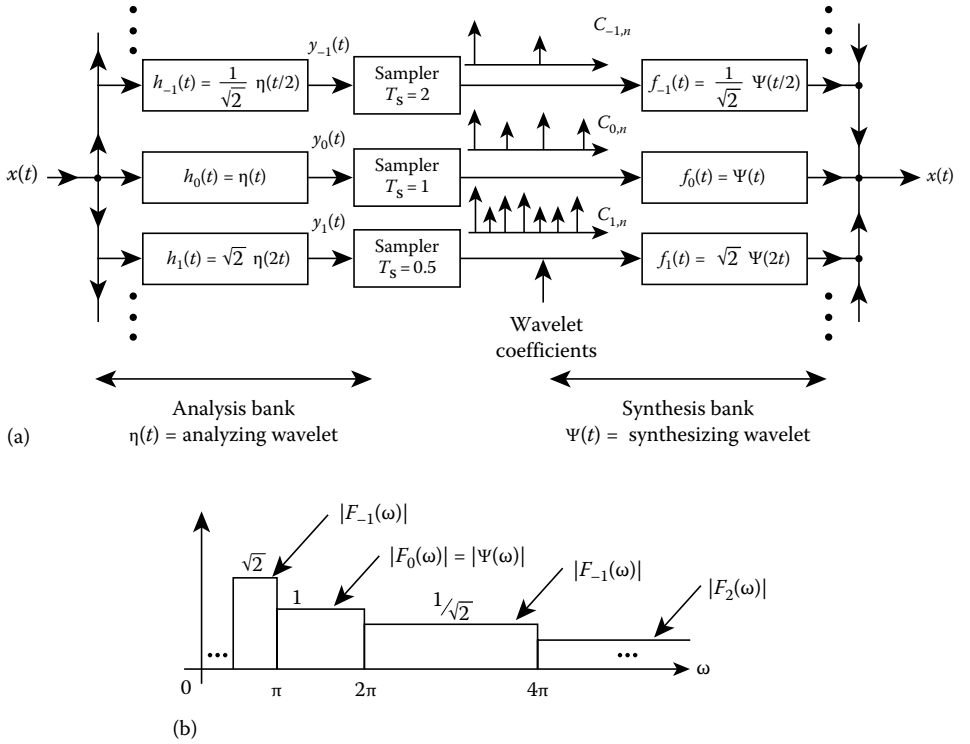

FIGURE 6.13 (a) Representing the dyadic WT as an analysis bank followed by samplers, and the inverse transform as a synthesis bank. For the orthonormal case, $\psi(t) = \eta^*(-t)$, and $f_k(t) = h_k{}^*(-t)$. (b) Filter responses for the example in which $\psi(t)$ is the ideal bandpass wavelet.

coefficients c_{kn} is equivalent to the implementation of a nonuniform continuous time synthesis filter bank, with synthesis filters $f_k(t) = 2^{k/2} f_0(2^k t)$ generated by dilations of a single filter $f_0(t) \stackrel{\Delta}{=} \psi(t)$.

As mentioned earlier, the analyzing wavelet $\eta(t)$ and the synthesis wavelet $\psi(t)$ are related by $\eta(t) = \psi^*(-t)$ in the orthonormal case. Thus, the analysis and synthesis filters are related as $h_k(t) = f_k^*(-t)$; i.e., $H_k(\omega) = F_k^*(\omega)$. For the special case of the ideal bandpass wavelet (Equation 6.10), $\psi(t)$ is real and symmetric so that $f_k(t) = f_k^*(-t)$; i.e., $h_k(t) = f_k(t)$. Figure 6.13 summarizes the relations described in the preceding paragraphs.

Design of Wavelet Functions

Because all the filters in the analysis and synthesis banks are derived from the wavelet function $\psi(t)$, the quality of the frequency responses depends directly on $\Psi(\omega)$. In the time domain the Haar basis has poor smoothness (it is not even continuous), but it is well localized (compactly supported). Its FT $\psi(\omega)$, given in Equation 6.20, decays only as $1/\omega$ for large ω. The ideal bandpass wavelet, on the other hand, is poorly localized in time, but has very smooth behavior. In fact, because it is band limited, $\psi(t)$ is infinitely differentiable, but it decays only as $1/t$ for large t. Thus, the Haar wavelet and the ideal bandpass wavelet represent two opposite extremes of the possible choices.

We could carefully design the wavelet $\psi(t)$ such that it is reasonably well localized in time domain, while at the same time sufficiently smooth or "regular." The term regularity is often used to quantify the degree of smoothness. For example, the number of times we can differentiate the wavelet $\psi(t)$ and the degree of continuity (so-called Hölder index) of the last derivative are taken as measures of regularity. We return to this in Sections 6.11 through 6.13, where we also present systematic procedures for design of the function $\psi(t)$. This can be designed in such a way that $\{2^{k/2}\psi(2^k t - n)\}$ forms an orthonormal basis with

prescribed decay and regularity properties. It is also possible to design $\psi(t)$ such that we obtain other kinds of structures rather than an orthonormal basis, e.g., a Riesz basis or a frame (Sections 6.7 and 6.8).

6.2.7 Wavelet Basis and Fourier Basis

Returning to the Fourier basis $g_k(t) = \{e^{j2\pi kt}\}$ for functions supported on [0, 1], we see that $g_k(t) = g_1(kt)$, so that all the functions are dilated versions (dilations being integers rather than powers of integers) of $g_1(t)$. However, *these do not have the localization property of wavelets*. To understand this, note that $e^{j2\pi kt}$ has unit magnitude everywhere, and sines and cosines are nonzero almost everywhere. Thus, if we have a function $x(t)$ that is identically zero in a certain time slot (e.g., Figure 6.14), then in order for the infinite series $\sum_n \alpha_n e^{j2\pi nt}$ to represent $x(t)$, extreme cancellation of terms must occur in that time slot. In contrast, if a compactly supported wavelet basis is used, it provides localization information as well as information about "frequency contents" in the form of scales. The "transform domain" in traditional FT is represented by a single continuous variable ω. In the wavelet transform, where the transform coefficients are c_{kn}, the transform domain is represented by two integers k and n.

It is also clear that WT provides a great deal of flexibility because we can choose $\psi(t)$. With FTs, on the other hand, the basis functions (sines and cosines) are pretty much fixed (see, however, Section 6.3 on STFT).

6.2.8 Most General Form of Wavelet Transformation

The most general form of wavelet transform is given by

$$X(a,b)\frac{1}{\sqrt{|a|}}\int_{-\infty}^{\infty} x(t)\psi\left(\frac{t-b}{a}\right)\mathrm{d}t \tag{6.21}$$

where a and b are real. This is called the continuous wavelet transform (CWT) because a and b are continuous variables. The transform domain is a two-dimensional domain (a, b). The restricted version of this, in which a and b take a discrete set of values $a = c^{-k}$ and $b = c^{-k}n$ (where k and n vary over the set of all integers), is called the discrete wavelet transform (DWT). The further special case, in which $c = 2$, i.e., $a = 2^{-k}$ and $b = 2^{-k}n$, is the WT discussed so far (Equation 6.16) and is called the dyadic DWT. Expansions of the form given in Equation 6.14 are also called wavelet series expansions by analogy with the FS expansion (a summation rather than an integral).

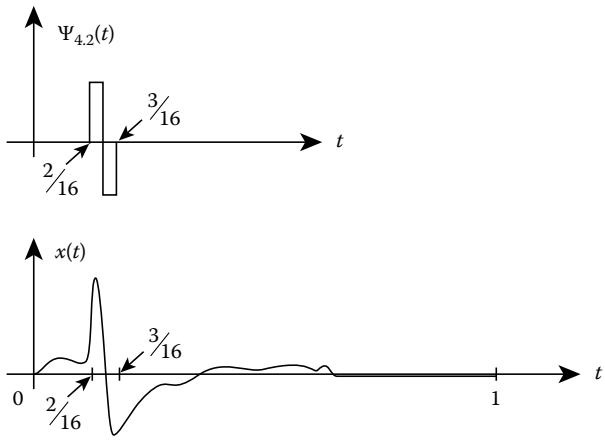

FIGURE 6.14 Example of an $L^2[0,1]$ signal $x(t)$ for which the Haar component $\psi_{4,2}(t)$ dominates.

For fixed a, Equation 6.21 is a convolution. Thus, if we apply the input signal $x(t)$ to a filter with impulse response $\psi(-t/a)/\sqrt{|a|}$, its output, evaluated at time b, will be $X(a, b)$. The filter has frequency response $\sqrt{|a|}\psi(-a\omega)$. If we imagine that $\psi(\omega)$ has a good bandpass response with center frequency ω_0, then the above filter is bandpass with center frequency $-a^{-1}\omega_0$; i.e., the wavelet transform $X(a, b)$, which is the output of the filter at time b, represents the "frequency content" of $x(t)$ around the frequency $-a^{-1}\omega_0$ "around" time b. Ignoring the minus sign (because $\psi(t)$ and $x(t)$ are typically real anyway), we see that the variable a^{-1} is analogous to frequency. In wavelet literature, the quantity $|a|$ is usually referred to as the scale rather than inverse frequency.

For reasons that cannot be explained with our limited exposure thus far, the wavelet function $\psi(t)$ is restricted to be such that $\int\psi(t)\mathrm{d}t = 0$. For the moment, notice that is equivalent to $\Psi(0) = 0$, which is consistent with the bandpass property of $\psi(t)$. In Section 6.10, where we generate wavelets systematically using multiresolution analysis, we see that this condition follows naturally from theoretical considerations.

6.3 Short-Time Fourier Transform

In many applications, we must accommodate the notion of frequency that evolves or changes with time. For example, audio signals are often regarded as signals with a time-varying spectrum, e.g., a sequence of short-lived pitch frequencies. This idea cannot be expressed with the traditional FT because $X(\omega)$ for each ω depends on $x(t)$ for all t.

The STFT was introduced as early as 1946 by Gabor [5] to provide such a time–frequency picture of the signal. Here, the signal $x(t)$ is multiplied with a window $v(t-\tau)$ centered or localized around time τ (Figure 6.15) and the FT of $x(t)\ v(t-\tau)$ computed as

$$X(\omega, \tau) = \int_{-\infty}^{\infty} x(t)v(t-\tau)e^{-j\omega t}\mathrm{d}t \tag{6.22}$$

This is then repeated for shifted locations of the window, i.e., for various values of τ. That is, we compute not just one FT, but infinitely many. The result is a function of both time τ and frequency ω. If this must be practical we must make two changes: compute the STFT only for discrete values of ω, and use only a discrete a number of window positions τ. In the traditional STFT both ω and τ are discretized on uniform grids:

$$\omega = k\omega_s, \quad \tau = nT_s \tag{6.23}$$

The STFT is thus defined as

$$X_{\mathrm{STFT}}(k\omega_s, nT_s) = \int_{-\infty}^{\infty} x(t)v(t-nT_s)e^{-jk\omega_s t}\mathrm{d}t, \tag{6.24}$$

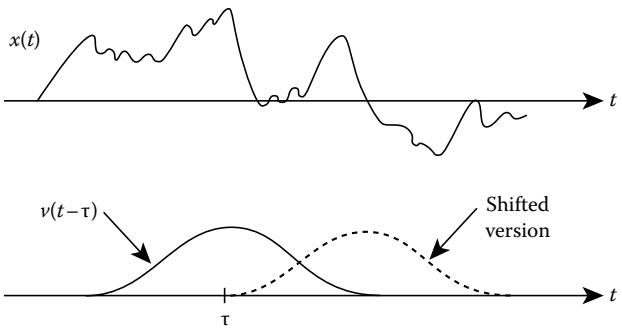

FIGURE 6.15 Signal $x(t)$ and the sliding window $v(t-\tau)$.

which we abbreviate as $X_{\text{STFT}}(k, n)$ when there is no confusion. Thus the time domain is mapped into the time–frequency domain. The quantity $X_{\text{STFT}}(k\omega_s, nT_s)$ represents the FT of $x(t)$ around time nT_s and around frequency $k\omega_s$. This, in essence, is similar to the WT: in both cases the transform domain is a two-dimensional discrete domain.

We compare wavelets and STFT on several grounds, giving a filter bank view and comparing time–frequency resolution and localization properties. Section 6.9 provides a comparison on deeper grounds: for example, when can we reconstruct a signal $x(t)$ from the STFT coefficients $X_{\text{STFT}}(k, n)$? Can we construct an orthonormal basis for L^2 signals based on the STFT? The advantage of WTs over the STFT will be clear after these discussions.

6.3.1 Filter Bank Interpretation

The STFT evaluated for some frequency ω_k can be rewritten as

$$X_{\text{STFT}}(\omega_k, \tau) = e^{-j\omega_k\tau} \int_{-\infty}^{\infty} x(t)v(t-\tau)e^{-j\omega_k(t-\tau)}\,dt \tag{6.25}$$

This integral looks like a convolution of $x(t)$ with the filter impulse response

$$h_k(t) \stackrel{\Delta}{=} v(-t)e^{j\omega_k t} \tag{6.26}$$

If $v(-t)$ has a FT looking like a low-pass filter then $h_k(t)$ looks like a bandpass filter with center frequency ω_k (Figure 6.16). Thus, $X_{\text{STFT}}(\omega_k, \tau)$ is the output of this bandpass filter at time τ, downshifted in frequency by ω_k. The result is a low-pass signal $y_k(t)$ whose output is sampled uniformly at time $\tau = nT_s$. For every frequency ω_k so analyzed, one such filter channel exists. With the frequencies uniformly located at $\omega_k = k\omega_s$, we get the analysis filter bank followed by downshifters and samplers as shown in Figure 6.17.

The STFT coefficients $X_{\text{STFT}}(k\omega_s, nT_s)$, therefore, can be regarded as the uniformly spaced samples of the outputs of a bank of bandpass filters $H_k(\omega)$, all derived from one filter $h_0(t)$ by modulation:

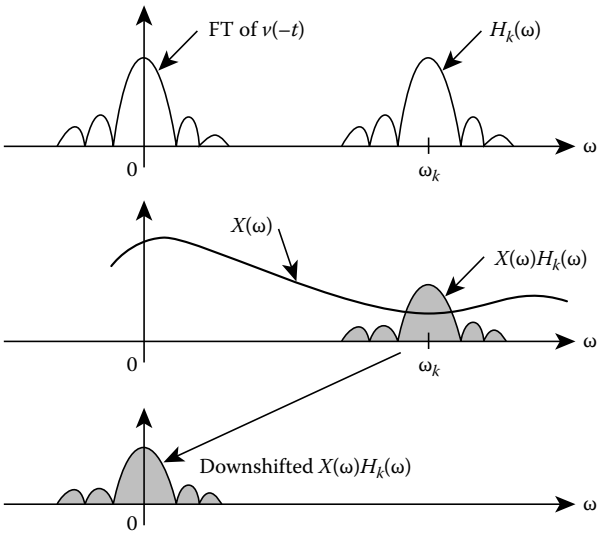

FIGURE 6.16 STFT viewed as a bandpass filter followed by a downshifter.

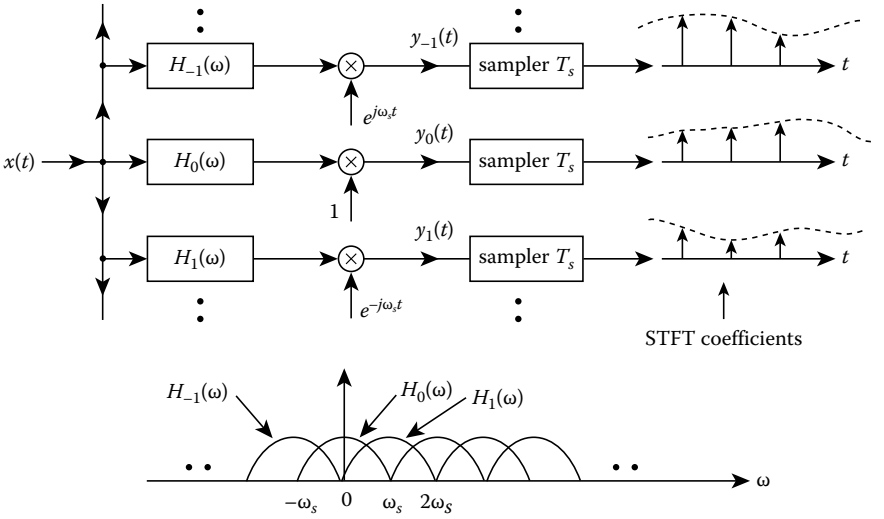

FIGURE 6.17 STFT viewed as an analysis bank of uniformly shifted filters.

$h_k(t) = e^{jk\omega st}\, h_0(t)$; i.e., $H_k(\omega) = H_0(\omega - k\omega_s)$. (The filters are one sided in frequency so they have complex coefficients in the time domain, but ignore these details for now.) The output of $H_k(\omega)$ represents a portion of the FT $X(\omega)$ around the frequency $k\omega_s$. The downshifted version $y_k(t)$ is therefore a low-pass signal. In other words, it is a slowly varying signal, whose evolution as a function of t represents the evolution of FT $X(\omega)$ around frequency $k\omega_s$. By sampling this slowly varying signal, we can therefore compress the transform domain information.

If the window is narrow in the time domain, then $H_k(\omega)$ has large bandwidth. That is, a good time resolution and poor frequency resolution are obtained. If the window is wide, the opposite is true. Thus, if we try to capture the local information in time by making a narrow window, we get a fuzzy picture in frequency. Conversely, in the limit, as the filter becomes extremely localized in frequency, the window is very broad and STFT approaches the ordinary FT. That is, the time–frequency information collapses to the all-frequency information of ordinary FT. We see that time–frequency representation is inherently a compromise between time and frequency resolutions (or localizations). This is related to the uncertainty principle: as windows get narrow in time they have to get broad in frequency, and vice versa.

Optimal Time–Frequency Resolution: The Gabor Window

What is the best frequency resolution one can obtain for a given time resolution? For a given duration of the window $v(t)$ how small can the duration of $V(\omega)$ be? If we define duration according to common sense, we are already in trouble because if $v(t)$ has finite duration then $V(\omega)$ has infinite duration. A more useful definition of duration is called the root mean square (RMS) duration. The RMS time duration D_t and the RMS frequency duration D_f for the window $v(t)$ are defined such that

$$D_t^2 = \frac{\int t^2 |v(t)|^2 \mathrm{d}t}{\int |v(t)|^2 \mathrm{d}t}, \quad D_f^2 = \frac{\int \omega^2 |V(\omega)|^2 \mathrm{d}\omega}{\int |V(\omega)|^2 \mathrm{d}\omega} \tag{6.27}$$

Intuitively, D_t cannot be arbitrarily small for a specified D_f. The uncertainty principle says that $D_t D_f \geq 0.5$. Equality holds iff $v(t)$ has the shape of a Gaussian, i.e., $v(t) = Ae^{-\alpha t^2}$, $\alpha > 0$. Thus, best joint time–frequency resolution is obtained by using the Gaussian window. This is also intuitively acceptable for the reason that the Gaussian is its own FT (except for scaling of variables and so forth). Gabor used the Gaussian window as early as 1946. Because it is of infinite duration, a truncated approximation is used in practice. The STFT based on the Gaussian is called the Gabor transform. A limitation of the

Gabor transform is that it does not give rise to an orthonormal signal representation; in fact, it cannot even provide a ''stable basis.'' (Sections 6.7 and 6.9 explain the meaning of this.)

6.3.2 Wavelet Transform versus Short-Time Fourier Transform

The STFT works with a fixed window $v(t)$. If a high-frequency signal is being analyzed, many cycles are captured by the window, and a good estimate of the FT is obtained. If a signal varies very slowly with respect to the window, however, then the window is not long enough to capture it fully. From a filter bank viewpoint, notice that all the filters have identical bandwidths (Figure 6.17). This means that the frequency resolution is uniform at all frequencies, i.e., the ''percentage resolution'' or accuracy is poor for low frequencies and becomes increasingly better at high frequencies. The STFT, therefore, does not provide uniform percentage accuracy for all frequencies; the computational resources are somehow poorly distributed.

Compare this with the WT, which is represented by a nonuniform filter bank (Figure 6.8b). Here, the frequency resolution gets poorer as the frequency increases, but the fractional resolution (i.e., the filter bandwidth $\Delta\omega_k$ divided by the center frequency ω_k) is constant for all k (the percentage accuracy is uniformly distributed in frequency). In the time domain this is roughly analogous to having a large library of windows; narrow windows are used to analyze high-frequency components and very broad windows are used to analyze low-frequency components. In electrical engineering language the filter bank representing WT is a constant Q filter bank, or an octave band filter bank. Consider, for example, the Haar wavelet basis. Here, the narrow basis functions $\psi_{2,n}(t)$ of Figure 6.12 are useful to represent the highly varying components of the input, and are correspondingly narrower (have shorter support than the functions $\psi_{1,n}(t)$).

A second difference between the STFT and the WTs is the sampling rates at the outputs of the bandpass filters. These are identical for the STFT filters (since all filters have the same bandwidth). For the wavelet filters, these are proportional to the filter bandwidths, hence nonuniform (Figure 6.10a). This is roughly analogous to the situation that the narrower windows move in smaller steps compared to the wider windows. Compare again with Figure 6.12 where $\psi_{2,n}(t)$ are moved in smaller steps as compared to $\psi_{1,n}(t)$ in the process of constructing the complete set of basis functions. The nonuniform (constant Q) filter stacking (Figure 6.8b) provided by wavelet filters is also naturally suited for analyzing audio signals and sometimes even as components in the modeling of the human hearing system.

Time–Frequency Tiling

The fact that the STFT performs uniform sampling of time and frequency whereas the WT performs nonuniform sampling is represented by the diagram shown in Figure 6.18. Here, the vertical lines represent time locations at which the analysis filter bank output is sampled, and the horizontal lines represent the center frequencies of the bandpass filters. The time–frequency tiling for the STFT is a simple rectangular grid, whereas for the WT it has a more complicated appearance.

Example 6.1

Consider the signal $x(t) = \cos(10\pi t) + 0.5\cos(5\pi t) + 0.5\cos(5\pi t) + 1.2\delta_a(t - 0.07) + 1.2\delta_a(t + 0.07)$. It has impulses at $t = \pm 0.07$ in the time domain. Two impulses (or lines) are found in the frequency domain, at $\omega_1 = 5\pi$ and $\omega_2 = 10\pi$. The function is illustrated in Figure 6.19 with impulses replaced by narrow pulses. The aim is to try to compute the STFT or WT such that the impulses in time as well as those in frequency are resolved. Figure 6.20a through c shows the STFT plot for three widths of the window $v(t)$ and Figure 6.20d shows the wavelet plot. The details of the window $v(t)$ and the wavelet $\psi(t)$ used for this example are described next, but first let us concentrate on the features of these plots.

The STFT plots are time–frequency plots, whereas the wavelet plots are (a^{-1}, b) plots, where a and b are defined by Equation 6.21. As explained in Section 6.2, the quantity a^{-1} is analogous to frequency in

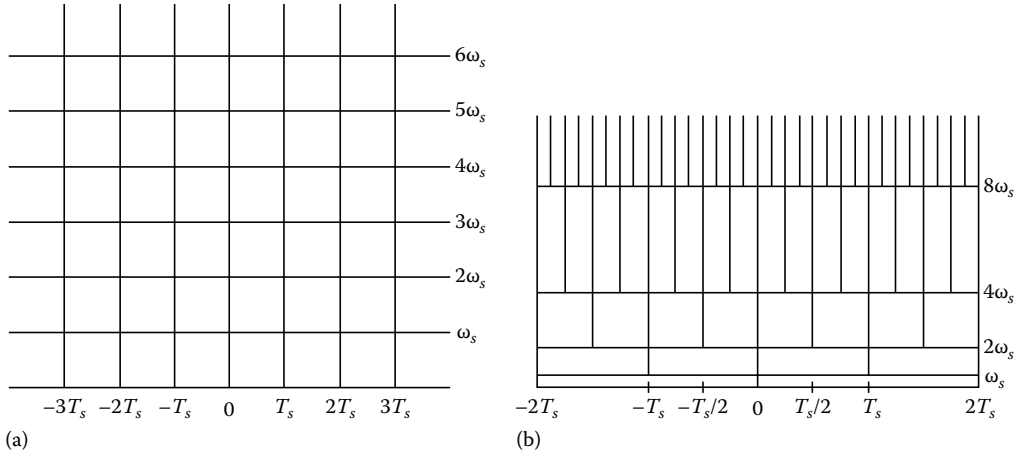

FIGURE 6.18 Time–frequency tiling schemes for (a) the STFT and (b) the WT.

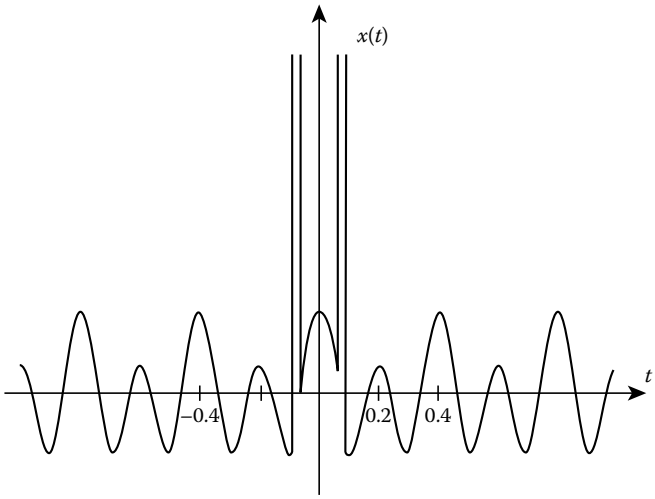

FIGURE 6.19 Signal to be analyzed by STFT and WT.

the STFT, and b is analogous to time in the STFT. The brightness of the plots in Figure 6.20 is proportional to the magnitude of the STFT or WT, so the transform is close to zero in the dark regions. We see that for a narrow window with width equal to 0.1, the STFT resolves the two impulses in time reasonably well, but the impulses in frequency are not resolved. For a wide window with width equal to 1.0, the STFT resolves the lines in frequency very well, but not the time domain impulses. For an intermediate window width equal to 0.3, the resolution is poor in both time and frequency. The wavelet transform plot (Figure 6.20d), on the other hand, simultaneously resolves both time and frequency very well. We can clearly see the locations of the two impulses in time, as well as the two lines in frequency.

The STFT for this example was computed using the Hamming window [2] defined as $v(t) = c[0.54 + 0.46\cos(\pi t/D)]$ for $-D \le t \le D$ and zero outside. The widths indicated in the figure correspond to $D = 0.1$, 1.0, and 0.3 (although the two-sided width is twice this). The wavelet transform was computed by using an example of the Morlet wavelet [5]. Specifically,

$$\psi(t) = e^{-t^2/16}(e^{j\pi t} - \alpha)$$

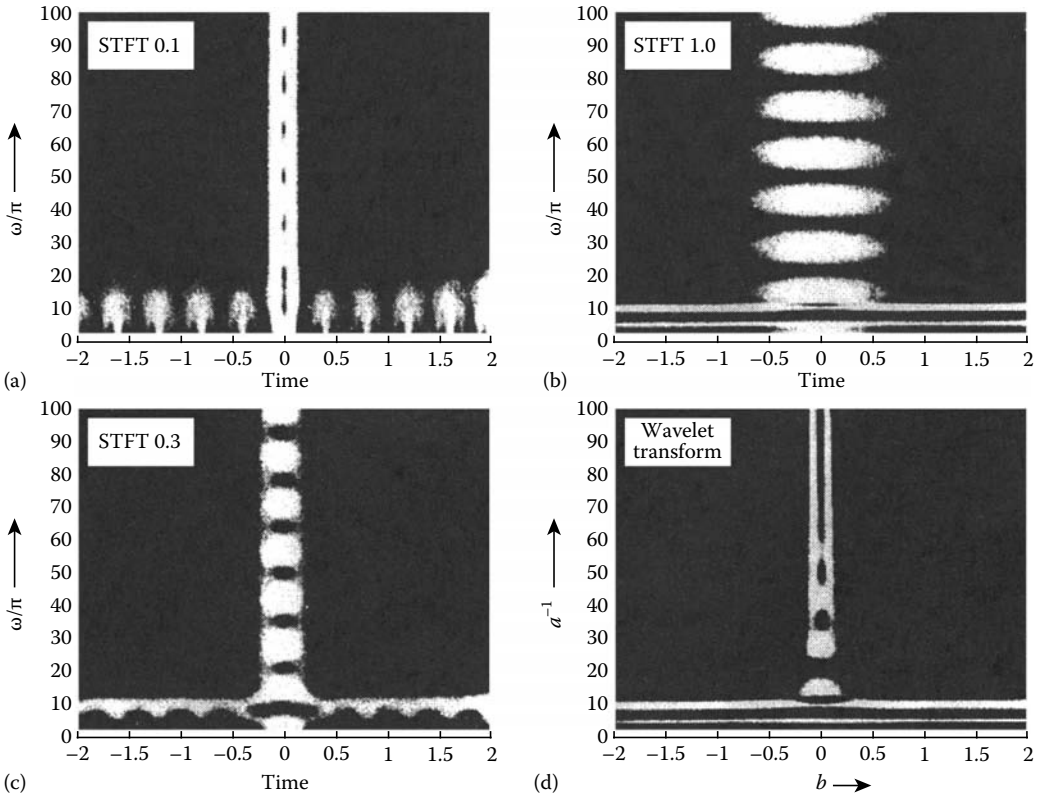

FIGURE 6.20 (a)–(c) STFT plots with window widths of 0.1, 1.0, and 0.3, respectively, and (d) WT plot.

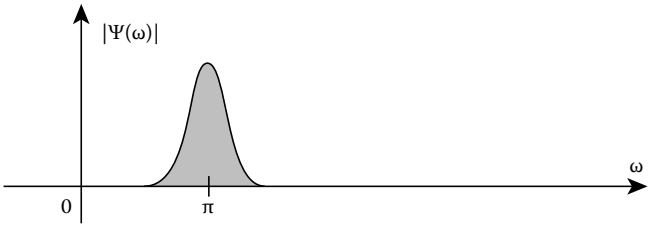

FIGURE 6.21 FT magnitude for the Morlet wavelet.

First, let us understand what this wavelet function is doing. The quantity $e^{-t^2/16}$ is the Gaussian (except for a constant scalar factor) with Fourier transform $4\sqrt{\pi}, e^{-4\omega^2}$ which is again Gaussian, concentrated near $\omega = 0$. Thus, $e^{-t^2/16}\ e^{j\pi t}$ has an FT concentrated around $\omega = \pi$. Ignoring the second term α in the expression for $\psi(t)$, we see that the wavelet is a narrowband bandpass filter concentrated around π (Figure 6.21).* If we set $a = 1$ in Equation 6.21, then $X(1, b)$ represents the frequency contents around π. Thus, the frequencies $\omega_1 = 5\pi$ and $\omega_2 = 10\pi$ in the given signal $x(t)$ show up around points $a^{-1} = 5$ and $a^{-1} = 10$ in the WT plot, as seen from Figure 6.20d. In the STFT plots, we have shown the frequency axis

* The quantity α in the expression of $\psi(t)$ ensures that $\int \psi(t)\ dt = 0$ (Section 6.2). Because α is very small, it does not significantly affect the plots in Figure 6.20.

as ω/π so that the frequencies ω_1 and ω_2 show up at 5 and 10, making it easy to compare the STFT plots with the wavelet plot.

Mathematical Issues to Be Addressed

While the filter bank viewpoint places wavelets and STFT on unified ground, several mathematical issues remain unaddressed. It is this deeper study that brings forth further subtle differences, giving wavelets a definite advantage over the STFT.

Suppose we begin from a signal $x(t) \in L^2$ and compute the STFT coefficients $X(k\omega_s, nT_s)$. How should we choose the sampling periods T_s and ω_s of the time and frequency grids so that we can reconstruct $x(t)$ from the STFT coefficients? (Remember that we are not talking about band-limited signals, and no sampling theorem is at work.) If the filters $H_k(\omega)$are ideal one-sided bandpass filters with bandwidth ω_s, the downshifted low-pass outputs $y_k(t)$ (Figure 6.16) can be sampled separately at the Nyquist rate ω_s or higher. This then tells us that $T_s \leq 2\pi/\omega_s$, that is,

$$\omega_s T_s \leq 2\pi \tag{6.28}$$

However, the use of ideal filters implies an impractical window $v(n)$.

If we use a practical window (e.g., one of finite duration), how should we choose T_s in relation to ω_s so that we can reconstruct $x(t)$ from the STFT coefficients $X(k\omega_s, nT_s)$? Is this a stable reconstruction? That is, if we make a small error in some STFT coefficient does it affect the reconstructed signal in an unbounded manner? Finally, does the STFT provide an orthonormal basis for L^2? These questions are deep and interesting, and require more careful treatment. We return to these in Section 6.9.

6.4 Digital Filter Banks and Subband Coders

Figure 6.22a shows a two-channel filter bank with input sequence $x(n)$ (a discrete-time signal). $G_a(z)$ and $H_a(z)$ are two digital filters, typically low-pass and high-pass. $x(n)$ is split into two subband signals, $x_0(n)$ and $x_1(n)$, which are then downsampled or decimated (see the following paragraphs for definitions). The total subband data rate, counting both subbands, is equal to the number of samples per unit time in the original signal $x(n)$. Digital filter banks provide a time–frequency representation for discrete time signals, similar to the STFT and WT for continuous time signals. The most common engineering application of the digital filter bank is in subband coding, which is used in audio, image, and video compression.

Neither subband coding nor such a time–frequency representation is the main point of our discussion here. We are motivated by the fact that a deep mathematical connection exists between this digital filter

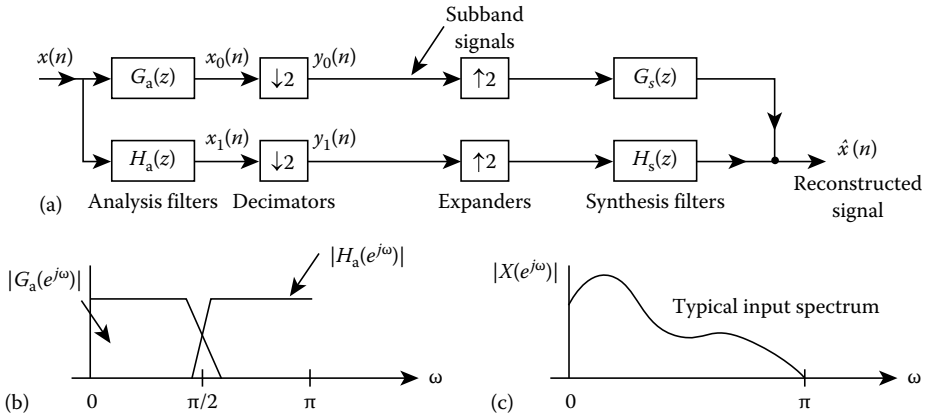

FIGURE 6.22 (a) The two-channel digital filter bank, (b) typical filter responses, and (c) typical input spectrum.

bank and the continuous time WT. This fundamental relation, discovered by Daubechies [6], is fully elaborated in Sections 6.10 through 6.13. This relation is what makes the WT so easy to design and attractive to implement in practice. Several detailed references on the topic of multirate systems and digital filter banks are available [7], and a detailed treatment can be found in Chapter 24 of Passive, *Active, and Digital Filters*, so we will be brief.

The Multirate Signal Processing Building Blocks: The building blocks in the digital filter bank of Figure 6.22a are digital filters, decimators, and expanders. The M-fold decimator or downsampler (denoted $\downarrow M$) is defined by the input–output relation $y(n) = x(Mn)$. The corresponding z-domain relation is $Y(z) = (1/M)\sum_{k=0}^{M-1} X(z^{1/M}e^{-j2\pi k/M})$. This relation is sometimes abbreviated by the notation $Y(z) = X(z)|_{\downarrow M}$ or $Y(e^{j\omega}) = X(e^{j\omega})|_{\downarrow M}$. The M-fold expander or upsampler (denoted $\uparrow M$) is defined by

$$y(n) = \begin{cases} x(n/M), & n = \text{multiple of } M, \\ 0, & \text{otherwise} \end{cases} \tag{6.29}$$

The transform domain relation for the expander is $Y(z) = X(z^M)$, i.e., $Y(e^{j\omega}) = X(e^{jM\omega})$.

6.4.1 Reconstruction from Subbands

In many applications, it is desirable to reconstruct $x(n)$ from the decimated subband signals $y_k(n)$ (possibly after quantization). For this, we pass $y_k(n)$ through expanders and combine them with the synthesis filters $G_s(z)$ and $H_s(z)$. The system is said to have the perfect reconstruction (PR) property if $\hat{x}(n) = cx(n - n_0)$ for some $c \neq 0$ and some integer n_0. The PR property is not satisfied for several reasons. First, subband quantization and bit allocation are present, which are the keys to data compression using subband techniques. However, because our interest here lies in the connection between filter banks and wavelets, we will not be concerned with subband quantization. Second, because the filters $G_a(z)$ and $H_a(z)$ are not ideal, aliasing occurs due to decimation. Using the above equations for the decimator and expander building blocks, we can obtain the following expression for the reconstructed signal: $\hat{X}(z) = T(z)X(z) + A(z)X(-z)$, where $T(z) = 0.5[G_a(z)G_s(z) + H_a(z)H_s(z)]$ and $A(z) = 0.5[G_a(-z)G_s(z) + H_a(-z)H_s(z)]$. The second term having $X(-z)$ is the aliasing term due to decimation. It can be eliminated if the filters satisfy

$$G_a(-z)G_s(z) + H_a(-z)H_s(z) = 0 \quad \text{(alias cancellation)} \tag{6.30}$$

We can then obtain PR [$\hat{x}(z) = 0.5X(z)$] by setting

$$G_a(z)G_s(z) + H_a(z)H_s(z) = 1 \tag{6.31}$$

A number of authors have developed techniques to satisfy the PR conditions. In this chapter we are interested in a particular technique to satisfy Equations 6.30 and 6.31, the conjugate quadrature filter (CQF) method, which was independently reported by Smith and Barnwell in 1984 [18] and by Mintzer in 1985 [19]. Vaidyanathan [20] showed that these constructions are examples of a general class of M channel filter banks satisfying a property called orthonormality or paraunitariness. More references can be found in Ref. [7]. The two-channel CQF solution was later rediscovered in the totally different contexts of multiresolution analysis [11] and compactly supported orthonormal wavelet construction [6]. These are discussed in subsequent sections.

Conjugate Quadrature Filter Solution

Suppose the low-pass filter $G_a(z)$ is chosen such that it satisfies the condition

$$\tilde{G}_a(z)G_a(z) + \tilde{G}_a(-z)G_a(-z) = 1 \quad \text{for all } z \tag{6.32}$$

If we now choose the high-pass filter $H_a(z)$ and the two synthesis filters as

$$H_a(z) = z^{-1}\tilde{G}_a(-z), \quad G_s(z) = \tilde{G}_a(z), \quad H_s(z) = \tilde{H}_a(z) \tag{6.33}$$

then Equations 6.30 and 6.31 are satisfied, and $\hat{x}(n) = 0.5x(n)$. In the time domain the above equations become

$$h_a(n) = -(-1)^n g_a^*(-n+1), \quad g_s(n) = g_a^*(-n), \quad h_s(n) = h_a^*(-n) \tag{6.34}$$

The synthesis filters are time-reversed conjugates of the analysis filters. If we design a filter $G_a(z)$ satisfying the single condition (Equation 6.32) and determine the remaining three filters as described previously, then the system has the PR property. A filter $G_a(z)$ satisfying Equation 6.32 is said to be power symmetric. Readers familiar with half-band filters will notice that the condition (Equation 6.32) says simply that $\tilde{G}_a(z)G_a(z)$ is half-band. To design a PR CQF system, we first design a low-pass half-band filter $G(z)$ with $G(e^{j\omega}) \geq 0$, and then extract a spectral factor $G_a(z)$. That is, find $G_a(z)$ such that $G(z) = \tilde{G}_a(z)G_a(z)$. The other filters can be found from Equation 6.33.

6.4.2 Polyphase Representation

The polyphase representation of a filter bank provides a convenient platform for studying theoretical questions and also helps in the design and implementation of PR filter banks. According to this representation the filter bank of Figure 6.22a can always be redrawn as in Figure 6.23a, which in turn can be redrawn as Figure 6.23b using standard multirate identities. Here, $\mathbf{E}(z)$ and $\mathbf{R}(z)$ are the "polyphase matrices," determined uniquely by the analysis and synthesis filters, respectively.

If we impose the condition $\mathbf{R}(z)\mathbf{E}(z) = \mathbf{I}$, that is

$$\mathbf{R}(z) = \mathbf{E}^{-1}(z) \tag{6.35}$$

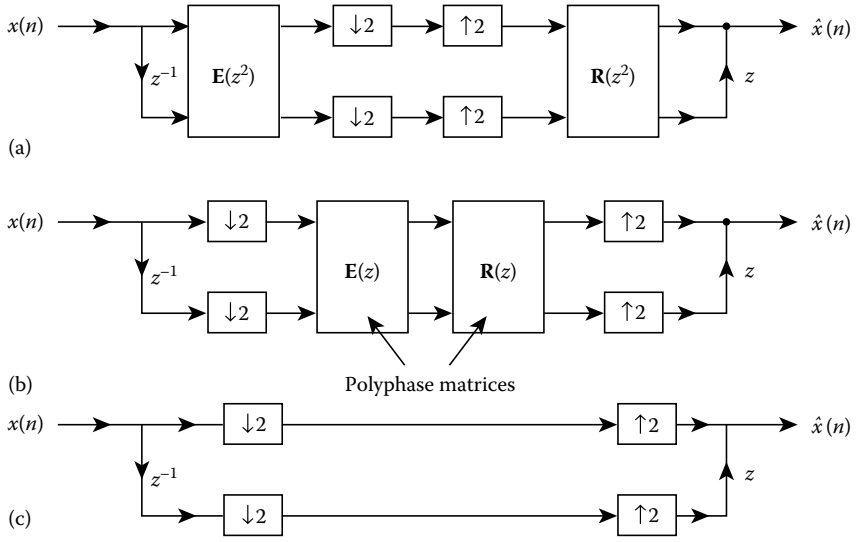

FIGURE 6.23 (a) The polyphase form of the filter bank, (b) further simplification, and (c) equivalent structure when $\mathbf{R}(z) = \mathbf{E}^{-1}(z)$.

the system reduces to Figure 6.23c, which is a perfect reconstruction system with $\hat{x}(n) = x(n)$. Equation 6.35 will be called the PR condition. Notice that insertion of arbitrary scale factors and delays to obtain $\mathbf{R}(z) = cz^{-K}\mathbf{E}^{-1}(z)$ does not affect the PR property.

6.4.3 Paraunitary Perfect Reconstruction System

A transfer matrix* $\mathbf{H}(z)$ is said to be paraunitary if $\mathbf{H}(e^{j\omega})$ is unitary; that is, $\mathbf{H}^{\dagger}(e^{j\omega})\mathbf{H}(e^{j\omega}) = \mathbf{I}$ (more generally $\mathbf{H}^{\dagger}(e^{j\omega})\mathbf{H}(e^{j\omega}) = c\mathbf{I}$, $c > 0$, for all ω). In all practical designs, the filters are rational transfer functions so that the paraunitary condition implies $\tilde{\mathbf{H}}(z)\mathbf{H}(z) = \mathbf{I}$ for all z, where the notation $\tilde{\mathbf{H}}(z)$ was explained in Section 6.1. Note that $\tilde{\mathbf{H}}(z)$ reduces to transpose conjugation $\mathbf{H}^{\dagger}(e^{j\omega})$ on the unit circle. A filter bank in which $\mathbf{E}(z)$ is paraunitary and $\mathbf{R}(z) = \tilde{\mathbf{E}}(z)$ enjoys the PR property $\hat{x}(n) = cx(n)$, $c \neq 0$. We often say that the analysis filter pair $\{G_a(z), H_a(z)\}$ is paraunitary instead of saying that the corresponding polyphase matrix is paraunitary.

The paraunitary property has played a fundamental role in electrical network theory [1,21], and has a rich history (see references in Chapters 6 and 14 of Ref. [7]). Essentially, the scattering matrices of lossless (LC) multiports are paraunitary, i.e., unitary on the imaginary axis of the s-plane.

Properties of Paraunitary Filter Banks

Define the matrices $\mathbf{G}_a(z)$ and $\mathbf{G}_s(z)$ as follows:

$$\mathbf{G}_a(z) = \begin{bmatrix} G_a(z) & G_a(-z) \\ H_a(z) & H_a(-z) \end{bmatrix}, \quad \mathbf{G}_s(z) = \begin{bmatrix} G_s(z) & H_s(z) \\ G_s(-z) & H_s(-z) \end{bmatrix} \tag{6.36}$$

Notice that these two matrices are fully determined by the analysis filters and synthesis filters, respectively. If $\mathbf{E}(z)$ and $\mathbf{R}(z)$ are paraunitary with $\tilde{\mathbf{E}}(z)\ \mathbf{E}(z) = 0.5\mathbf{I}$ and $\tilde{\mathbf{R}}(z)\ \mathbf{R}(z) = 0.5\mathbf{I}$, it can be shown that

$$\tilde{\mathbf{G}}_a(z)\mathbf{G}_a(z) = \mathbf{I}, \quad \tilde{\mathbf{G}}_s(z)\mathbf{G}_s(z) = \mathbf{I} \tag{6.37}$$

In other words, the matrices $\mathbf{G}_a(z)$ and $\mathbf{G}_s(z)$ defined previously are paraunitary as well.

Half-Band Property and Power Symmetry Property: The paraunitary property $\mathbf{G}_a(z)\tilde{\mathbf{G}}_a(z) = \mathbf{I}$ is also equivalent to $\mathbf{G}_a(z)\tilde{\mathbf{G}}_a(z) = \mathbf{I}$, which implies

$$\tilde{G}_a(z)G_a(z) + \tilde{G}_a(-z)G_a(-z) = 1 \tag{6.38}$$

In other words, $G_a(z)$ is a power symmetric filter. A transfer function $G(z)$ satisfying $G(z) + G(-z) = 1$ is called a half-band filter. The impulse response of such $G(z)$ satisfies $g(2n) = 0$ for all $n \neq 0$ and $g(0) = 0.5$. We see that the power symmetry property of $G_a(z)$ says that $\tilde{\mathbf{G}}_a(z)G_1(z)$ is a half-band filter. In terms of frequency response the power symmetry property of $G_a(z)$ is equivalent to

$$|G_a(e^{j\omega})|^2 + |G_a(-e^{j\omega})|^2 = 1 \tag{6.39}$$

Imagine that $G_a(z)$ is a real-coefficient low-pass filter so that $|G_a(e^{j\omega})|^2$ has symmetry with respect to zero frequency. Then $|G_a(e^{j\omega})|^2$ is as demonstrated in Figure 6.24, and the power symmetry property means that the two plots in the figure add up to unity. In this figure ω_p and ω_s are the bandedges, and δ_1 and δ_2 are the peak passband ripples of $G_a(e^{j\omega})$ (for definitions of filter specifications see Refs. [2] or [7]). Notice

* Transfer matrices are essentially transfer functions of multi-input multi-output systems. A review is found in Chapter 13 of Ref. [7].

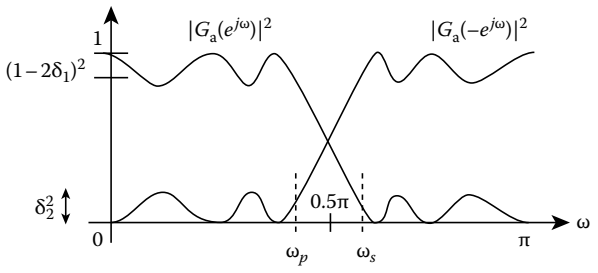

FIGURE 6.24 Magnitude responses $|G_a(e^{j\omega})|^2$ and $|G_a(e^{j\omega})|^2$ for a real-coefficient power symmetric filter $G_a(z)$.

in particular that power symmetry of $G_a(z)$ implies that a symmetry relation exists between the passband and stopband specifications of $G_a(e^{j\omega})$. This is given by $\omega_s = \pi - \omega_p$, $\delta_2{}^2 = 1 - (1 - 2\delta_1)^2$.

Relation between Analysis Filters: The property $\tilde{\mathbf{G}}_a(z)\mathbf{G}_a(z) = \mathbf{I}$ implies a relation between $G_a(z)$ and $H_a(z)$, namely $H_a(z) = e^{j\theta}z^N \tilde{G}_a(-z)$, where θ is arbitrary and N is an arbitrary odd integer. Let $N = -1$ and $\theta = 0$ for future simplicity. Then

$$H_a(z) = z^{-1}\tilde{G}_a(-z) \tag{6.40}$$

In particular, we have $|H_a(e^{j\omega})| = |G_a(-e^{j\omega})$. Combining with the power symmetry property (Equation 6.39), we see that the two analysis filters are power complementary:

$$|G_a(e^{j\omega})|^2 + |H_a(e^{j\omega})|^2 = 1 \tag{6.41}$$

for all ω. With $G_a(z) = \Sigma_n g_a(n)z^{-n}$ and $H_a(z) = \Sigma_n h_a(n)z^{-n}$ we can rewrite Equation 6.40 as

$$h_a(n) = -(-1)^n g_a^\star(-n+1) \tag{6.42}$$

Relation between Analysis and Synthesis Filters: If we use the condition $\mathbf{R}(z) = \tilde{\mathbf{E}}(z)$ in the definitions of $\mathbf{G}_s(z)$ and $\mathbf{G}_a(z)$ we obtain $\mathbf{G}_s(z) = \tilde{\mathbf{G}}_a(z)$, from which we conclude that the synthesis filters are given by $G_s(z) = \tilde{G}_a(z)$ and $H_s(z) = \tilde{H}_a(z)$. We can also rewrite these in the time domain; summarizing all this, we have

$$G_s(z) = \tilde{G}_a(z), \quad H_s(z) = \tilde{H}_a(z), \quad g_s(n) = g_a^\star(-n), \quad h_s(n) = h_a^\star(-n) \tag{6.43}$$

The synthesis filter coefficients are time-reversed conjugates of the analysis filters. Their frequency responses are conjugates of the analysis filter responses. In particular, $|G_s(e^{j\omega})| = |G_a(e^{j\omega})|$ and $|H_s(e^{j\omega})| = |H_a(e^{j\omega})|$. In view of the preceding relations, the synthesis filters have all the properties of the analysis filters. For example, $G_s(e^{j\omega})$ is power symmetric, and the pair $\{G_s(e^{j\omega}), H_s(e^{j\omega})\}$ is power complementary. Finally, $H_s(z) = z\tilde{G}_s(-z)$, instead of Equation 6.40.

Relation to Conjugate Quadrature Filter Design: The preceding discussions indicate that in a paraunitary filter bank the filter $G_a(z)$ is power symmetric, and the remaining filters are derived from $G_a(z)$ as in Equations 6.40 and 6.43. This is precisely the CQF solution for PR, stated at the beginning of this section.

Summary of Filter Relations in a Paraunitary Filter Bank

If the filter bank of Figure 6.22a is paraunitary, then the polyphase matrices $\mathbf{E}(z)$ and $\mathbf{R}(z)$ (Figure 6.23) satisfy $\tilde{\mathbf{E}}(z)\ \mathbf{E}(z) = 0.5\mathbf{I}$ and $\tilde{\mathbf{R}}(z)\ \mathbf{R}(z) = 0.5\mathbf{I}$ Equivalently, the filter matrices $\mathbf{G}_a(z)$ and $\mathbf{G}_s(z)$ and satisfy $\tilde{\mathbf{G}}_a(z)\mathbf{G}_a(z) = \mathbf{I}$ and $\tilde{\mathbf{G}}_s(z)\mathbf{G}_s(z) = \mathbf{I}$. A number of properties follow from these:

1. All four filters, $G_a(z)$, $H_a(z)$, $G_s(z)$, and $H_s(z)$ are power symmetric. This property is defined, for example, by the relation given in Equation 6.38. This means that the filters are spectral factors of half-band filters; for example, $\tilde{G}_s(z)G_s(z)$ is half band.
2. The two analysis filters are related as in Equation 6.40, so the magnitude responses are related as $|H_a(e^{j\omega})| = |G_a(-e^{j\omega})|$. The synthesis filters are time-reversed conjugates of the analysis filters as shown by Equation 6.43. In particular, $G_s(e^{j\omega}) = G_a^\star(e^{j\omega})$ and $H_s(e^{j\omega}) = H_a^\star(e^{j\omega})$.
3. The analysis filters form a power complementary pair, i.e., Equation 6.41 holds. The same is true for the synthesis filters.

4. Any two-channel paraunitary system satisfies the CQF equations (Equations 6.32 and 6.33) (except for delays, constant scale factors, etc.). Conversely, any CQF design is a paraunitary filter bank.
5. The design procedure for two-channel paraunitary (i.e., CQF) filter banks is as follows: design a zero-phase, low-pass, half-band filter $G(z)$ with $G(e^{j\omega}) \geq 0$ and then extract a spectral factor $G_a(z)$. That is, find $G_a(z)$ such that $G(z) = \tilde{G}_a(z)G_a(z)$. Then choose the remaining three filters as in Equation 6.33, or equivalently, as in Equation 6.34.

6.4.4 Parametrization of Paraunitary Filter Banks

Factorization theorems exist for matrices, which allow the expression of paraunitary matrices as a cascade of elementary paraunitary blocks. For example, let $\mathbf{H}(z) = \sum_{n=0}^{L} \mathbf{h}(n)z^{-n}$ be a 2×2 real causal FIR transfer matrix (thus, $\mathbf{h}(n)$ are 2×2 matrices with real elements). This is paraunitary iff it can be expressed as $\mathbf{H}(z) = \mathbf{R}_N\, \Lambda(z)\mathbf{R}_{N-1} \ldots \mathbf{R}_1(z)\Lambda z\mathbf{R}_0\mathbf{H}_0$ where

$$\mathbf{R}_m = \begin{bmatrix} \cos\theta_m & \sin\theta_m \\ -\sin\theta_m & \cos\theta_m \end{bmatrix}, \quad \mathbf{\Lambda}(z) = \begin{bmatrix} 1 & 0 \\ 0 & z^{-1} \end{bmatrix}, \quad \mathbf{H}_0 = \begin{bmatrix} \alpha & 0 \\ 0 & \pm\alpha \end{bmatrix} \tag{6.44}$$

where α and θ_m are real. For a proof see Ref. [7]. The unitary matrix $\mathbf{R}_m$ is called a rotation operator or the Givens rotation. The factorization gives rise to a cascaded lattice structure that guarantees the paraunitary property structurally. This is useful in the design as well as the implementation of filter banks, as explained in Ref. [7]. Thus, if the polyphase matrix is computed using the cascaded structure, $G_a(z)$ is guaranteed to be power symmetric, and the relation $H_a(z) = z^{-1}\tilde{G}_a(-z)$ between the analysis filters automatically holds. Further results on factorizations are described in Chapter 24 of *Passive, Active, and Digital Filters*.

6.4.5 Maximally Flat Solutions

The half-band filter $G(z) \triangleq \tilde{G}_a(z)G_a(z)$ can be designed in many ways. One can choose to have equiripple designs or maximally flat designs [2]. An early technique for designing FIR maximally flat filters was proposed by Herrmann in 1971 [7]. This method gives closed form expressions for the filter coefficients and can be adapted easily for the special case of half-band filters. Moreover, the design automatically guarantees the condition $G(e^{j\omega}) \geq 0$, which in particular implies zero phase.

The family of maximally flat half-band filters designed by Herrmann is demonstrated in Figure 6.25. The transfer function has the form

$$G(z) = z^K \left(\frac{1+z^{-1}}{2}\right)^{2K} \sum_{n=0}^{K-1} (-z)^n \binom{K+n-1}{n} \left(\frac{1-z^{-1}}{2}\right)^{2n} \tag{6.45}$$

The filter has order $4K-2$. On the unit circle we find $2K$ zeroes, and all of these zeroes are concentrated at the point $z = -1$ (i.e., at $\omega = \pi$). The remaining $2K-2$ zeroes are located in the z-plane such that $G(z)$ has the half-band property described earlier (i.e., $G(z) + G(-z) = 1$).

Section 6.13 explains that if the CQF bank is designed by starting from Herrmann's maximally flat half-band filter, then it can be used to design continuous time wavelets with arbitrary regularity (i.e., smoothness) properties.

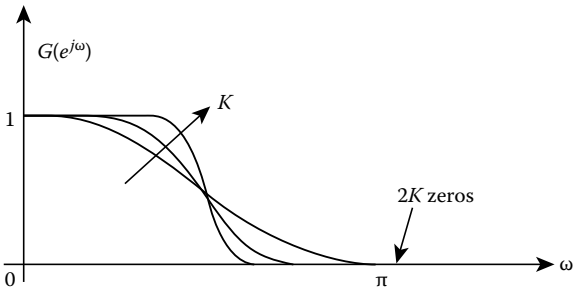

FIGURE 6.25 Maximally flat half-band filter response with $2K$ zeroes at π.

6.4.6 Tree-Structured Filter Banks

The idea of splitting a signal $x(n)$ into two subbands can be extended by splitting a subband signal further, as demonstrated in Figure 6.26a. In this example the low-pass subband is split repeatedly. This is called a tree-structured filter bank. Each node of the tree is a two-channel analysis filter bank.

The synthesis bank corresponding to Figure 6.26a is illustrated in Figure 6.26b. We combine the signals in pairs in the same manner that we split them. It can be demonstrated that if $\{G_a(z), H_a(z), G_s(z), H_s(z)\}$ is a PR system (i.e., satisfies $\hat{x}(n) = x(n)$ when connected in the form Figure 6.22a), then the tree-structured analysis/synthesis system of Figure 6.26 has PR $\hat{x}(n) = x(n)$.

The tree-structured system can be redrawn in the form shown in Figure 6.27. For example, if we have a tree structure similar to Figure 6.26 with three levels, we have $M = 4$, $n_0 = 2$, $n_1 = 4$, $n_2 = 8$, and $n_3 = 8$. If we assume that the responses of the analysis filters $G_a(e^{j\omega})$ and $H_a(e^{j\omega})$ are as in Figure 6.28a, the

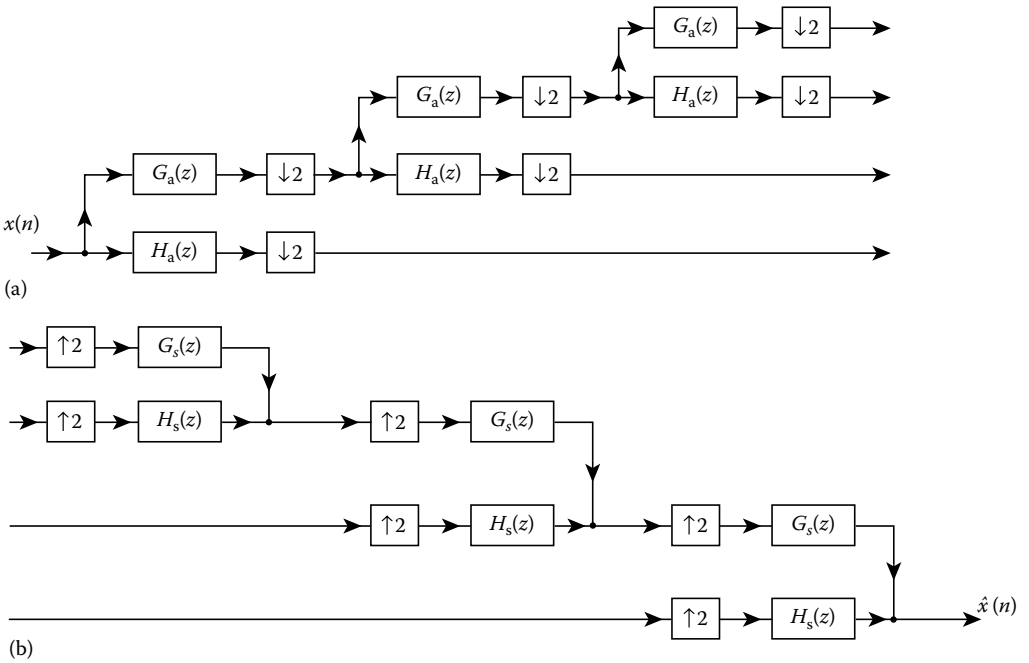

FIGURE 6.26 Tree-structured filter banks: (a) analysis bank and (b) synthesis bank.

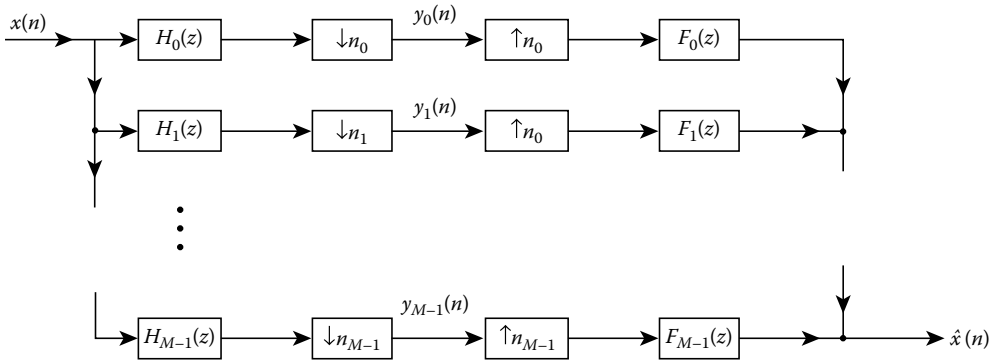

FIGURE 6.27 General nonuniform digital filter bank.

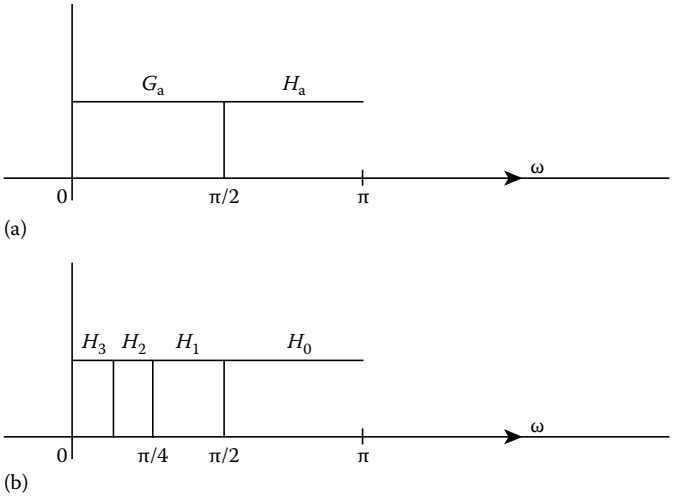

FIGURE 6.28 Example of responses: (a) $G_a(z)$ and $H_a(z)$ and (b) tree-structured analysis bank.

responses of the analysis filters $H_k(e^{j\omega})$ are as shown in Figure 6.28b. Note that this resembles the wavelet transform (Figure 6.8b). The outputs of different filters are subsampled at different rates exactly as for wavelets. Thus, the tree-structured filter bank bears a close relationship to the WT. Sections 6.10 through 6.13 present the precise mathematical connection between the two, and the relation to multiresolution analysis.

6.4.7 Filter Banks and Basis Functions

Assuming PR $\hat{x}(n) = x(n)$, we can express $x(n)$ as

$$x(n) = \sum_{k=0}^{M-1} \sum_{m=-\infty}^{\infty} y_k(m) \underbrace{f_k(n - n_k m)}_{\eta_{km}(n)} \tag{6.46}$$

where

$y_k(n)$ are the decimated subband signals
$f_k(n)$ are the impulse response of $F_k(z)$

Thus, the system is analogous to the filter bank systems which represented the continuous time STFT and WT in Sections 6.2 and 6.3. The collection of subband signals $y_k(m)$ can be regarded as a time–frequency representation for the sequence $x(n)$. As before, k denotes the frequency index and m the time index in the transform domain. If we have a PR filter bank, we can recover $x(n)$ from this time–frequency representation using Equation 6.46. The doubly indexed family of discrete time sequences $\{\eta_{km}(n)\}$ can be regarded as "basis functions" for the representation of $x(n)$.

To make things mathematically accurate, let $x(n) \in l^2$ (i.e., $\boldsymbol{\Sigma}_n |x(n)|^2$ is finite). If the two-channel filter bank $\{G_a(z), H_a(z), G_s(z), H_s(z)\}$, which makes up the tree structure of Figure 6.26 is paraunitary, it can be shown that $\eta_{km}(n)$ is an orthonormal basis for l^2. Orthonormality means

$$\sum_{n=-\infty}^{\infty} \eta_{k_1 m_1}(n) \eta^*_{k_2 m_2}(n) = \delta(k_1 - k_2)\delta(m_1 - m_2) \tag{6.47}$$

Notice that the basis functions (sequences) are not derived from a single function. Instead, they are derived from a finite number of filters $\{f_k(n)\}$ by time shifts of a specific form. The wavelet basis $\{2^{k/2}\,\psi\,(2^k t - n)\}$, on the other hand, is derived from a *single* wavelet function $\psi(t)$. We say that $\{\eta_{km}(n)\}$ is a *filter bank* type of basis for the space of l^2 sequences.

6.5 Deeper Study of Wavelets, Filter Banks, and Short-Time Fourier Transforms

We already know what the WT is and how it compares with the STFT, at least qualitatively. We are also familiar with time–frequency representations and digital filter banks. It is now time to fill in several important details, and generally be more quantitative. For example, we would like to mention some major technical limitations of the STFT which are not obvious from its definition, and explain that wavelets do not have this limitation.

For example, if the STFT is used to obtain an orthonormal basis for L^2 signals, the time–frequency RMS durations of the window $v(t)$ should satisfy $D_t\,D_f = \infty$. That is, either the time or the frequency resolution is very poor (Theorem 6.5). Also, if we have an STFT system in which the time–frequency sampling product $\omega_s T_s$ is small enough to admit redundancy (i.e., the vectors are not linearly independent as they would be in an orthonormal basis), the previous difficulty can be eliminated (Section 6.9).

The Gabor transform, while admittedly a tempting candidate because of the optimal time–frequency resolution property ($D_t D_f$ minimized), has a disadvantage. For example, if we want to recover the signal $x(t)$ from the STFT coefficients, the reconstruction is *unstable* in the so-called critically sampled case (Section 6.9). That is, a small error in the STFT coefficients can lead to a large error in reconstruction.

The WT does not suffer from the above limitations of the STFT. Sections 6.11 through 6.13 show how to construct orthonormal wavelet bases with good time and frequency resolutions. We also show that we can start from a paraunitary digital filter bank and construct orthonormal wavelet bases for $L^2(R)$ very systematically (Theorem 6.13). Moreover, this can be done in such a way that many desired properties (e.g., compact support, orthonormality, good time–frequency resolution, smoothness, and so forth) can be incorporated during the construction (Section 6.13). Such a construction is placed in evidence by the theory of multiresolution, which gives a unified platform for wavelet construction and filter banks (Theorems 6.6. and 6.7).

At this point, the reader may want to preview the above-mentioned theorems in order to get a flavor of things to come. However, to explain these results quantitatively, it is very convenient to review a number of mathematical tools. The need for advanced tools arises because of the intricacies associated with basis functions for infinite dimensional spaces, i.e., spaces in which the set of basis functions is an infinite set. (For finite dimensional spaces an understanding of elementary matrix theory would have been sufficient.) For example, a representation of the form $x(t) = \Sigma c_n f_n(t)$ in an infinite dimensional space could be *unstable* in the sense that a small error in the transform domain $\{c_n\}$ could be amplified in an unbounded manner during reconstruction. A special type of basis called the *Riesz basis* does not have this problem (orthonormal bases are special cases of these). Also, the so-called frames (Section 6.8) share many good properties of the Riesz bases but may have redundant vectors (i.e., not a linearly independent set of vectors). For example, the concept of frames arises in the comparison of wavelets and the STFT. General STFT frames have an advantage over STFT bases. Frames also come into consideration when the connection between wavelets and paraunitary digital filter banks is explained in Section 6.11. When describing the connection between wavelets and nonunitary filter banks, one again encounters Riesz bases and the idea of biorthogonality.

Because it is difficult to find all the mathematical background material in one place, we review a carefully selected set of topics in the next few sections. These are very useful for a deeper understanding of wavelets and STFT. The material in Section 6.6 is fairly standard (Lebesgue integrals, L^p spaces, L^1 and L^2 FTs). The material in Sections 6.7 and 6.8 (Riesz bases and frames) are less commonly known among

engineers, but play a significant role in wavelet theory. The reader may want to go through these review sections (admittedly dense), once during first reading and then use them as a reference. Following this review, we return to our discussions of wavelets, STFT, and filter banks.

6.6 Space of L^1 and L^2 Signals

We developed the wavelet representation in Section 6.2 based on the framework of a bank of bandpass filters. To make everything mathematically meaningful it becomes necessary to carefully specify the types of signals, types of FTs, etc. For example, the concept of ideal bandpass filtering is appealing to engineers, but a difficulty arises. An ideal bandpass filter $H(\omega)$ is not stable, that is, $\int |h(t)| \mathrm{d}t$ does not exist [2]. In other words $h(t)$ does not belong to the space L^1 (see below).

Why should this matter if we are discussing theory? The frequency domain developments based on Figure 6.2, which finally give rise to the time domain expression (Equation 6.8), implicitly rely on the convolution theorem (convolution in time implies multiplication in frequency). However, the convolution theorem is typically proved only for L^1 signals and bounded L^2 signals; it is not valid for arbitrary signals. Therefore, care must be exercised when using these familiar engineering notions in a mathematical discussion.

6.6.1 Lebesgue Integrals

In most engineering discussions, we think of the integrals as Riemann integrals, but in order to handle several convergence questions in the development of Fourier series, convolution theorems, and wavelet transforms, it is necessary to use Lebesgue integration. Lebesgue integration theory has many beautiful results which are not true for the Riemann integral under comparable assumptions about signals. This includes theorems that allow us to interchange limits, integrals, and infinite sums freely.

All integrals in this chapter are Lebesgue integrals. A review of Lebesgue integration is beyond the scope of this chapter, although many excellent references, for example, [22], are available. A few elementary comparisons between Riemann and Lebesgue integrals are given next.

1. If $x(t)$ is Riemann integrable on a bounded interval $[a, b]$ then it is also Lebesgue integrable on $[a, b]$. The converse is not true, however. For example, if we define $x(t) = -1$ for all rationals and $x(t) = 1$ for all irrationals in $[0, 1]$ then $x(t)$ is not Riemann integrable in $[0, 1]$, but it is Lebesgue integrable, and $\int_0^1 x(t)\mathrm{d}t = 1$.
2. A similar statement is not true for the unbounded interval $(-\infty, \infty)$. For the unbounded interval $(-\infty, \infty)$ the Riemann integral is defined only as a limit called the improper integral.* Consider the sinc function defined as: $s(t) = \sin t/t$ for $t \neq 0$, and $s(0) = 1$. This has an improper Riemann integral $= \pi$, but is not Lebesgue integrable.
3. If $x(t)$ is Lebesgue integrable, so is $|x(t)|$. The same is not true for Riemann integrals, as demonstrated by the sinc function $s(t)$ of the preceding paragraph.
4. If $|x(t)|$ is Lebesgue integrable, so is $x(t)$ as long as it is measurable.† This, however, is not true for Riemann integrals. If we define $x(t) = -1$ for all rationals and 1 for all irrationals in $[0, 1]$, it is not Riemann integrable in $[0, 1]$ although $|x(t)|$ is.
5. If $x(t)$ is (measurable and) bounded by nonnegative Lebesgue integrable function $g(t)$ (i.e., $|x(t)| \leq g(t)$), then $x(t)$ is Lebesgue integrable.

---

* Essentially, we consider $\int_{-a}^{b} x(t)\mathrm{d}t$ and let a and b go to ∞ *separately*. This limit, the improper Riemann integral, should not be confused with Cauchy principal value, which is the limit of $\int_{-a}^{a} x(t)\mathrm{d}t$ as $a \to \infty$. The function $x(t) = t$ has Cauchy principal value $= 0$, but the improper Riemann integral does not exist.

† The notion of measurable function is very subtle. Any continuous function is measurable, and any Lebesgue integrable function is measurable. In fact, examples of nonmeasurable functions are so rare and so hard to construct that practically no danger exists that we will run into one. We take measurability for granted and never mention it.

Sets of Measures Zero

A subset $\mathcal{S}$ of real numbers is said to have measure zero if, given $\varepsilon > 0$, we can find a countable union $\cup_i I_i$ of open intervals I_i (intervals of the form (a_i, b_i), i.e., $a_i < x < b_i$) such that $\mathcal{S} \subset \cup_i I_i$ and the total length of the intervals is less than ε. For example, the set of all integers (in fact, any countable set of real numbers, e.g., rationals) has measure zero. Uncountable sets of real numbers exist that have measure zero, a famous example being the Cantor set [22].

When something is said to be true "almost everywhere" (abbreviated a.e.) or "for almost all t," it means that the statement holds everywhere, except possibly on a set of measure zero. For example, if $x(t) = y(t)$ everywhere except for integer values of t, then $x(t) = y(t)$ a.e. An important fact in Lebesgue integration theory is that if two Lebesgue integrable functions are equal a.e., then their integrals are equal. In particular, if $x(t) = 0$ a.e., the Lebesgue integral $\int x(t)\mathrm{d}t$ exists and is equal to zero.

Convergence Theorems

What makes the Lebsegue integral so convenient is the existence of some powerful theorems which allow us to interchange limits with integrals and summations under very mild conditions. These theorems have been at the center of many beautiful results in Fourier and wavelet transform theory.

Let $\{g_k(t)\}$, $1 \le k \le \infty$ be a sequence of Lebesgue integrable functions. In general, this sequence may not have a limit, and even if it did, the limit may not be integrable. Under some further mild postulates, we can talk about limits and their integrals. In what follows we often say "$g(t)$ is a pointwise limit a.e., of the sequence $\{g_k(t)\}$," or "$g_k(t)$ converges to $g(t)$ a.e." This means that for any chosen value of t (except possibly in a set of measure zero), we have $g_k(t) \to g(t)$ as $k \to \infty$.

Monotone Convergence Theorem: *Suppose* $\{g_k(t)\}$ *is* nondecreasing a.e., (*i.e., for almost all values of t,* $g_k(t)$ *is nondecreasing in k) and* $\int g_k(t)\mathrm{d}t$ *is a* bounded sequence. *Then* $\{g_k(t)\}$ *converges* a.e., *to a Lebesgue integrable function* $g(t)$ *and* $\lim_k \int g_k(t)\mathrm{d}t = \int \lim_k g_k(t)\mathrm{d}t$, i.e., $\lim_k \int g_k(t)\mathrm{d}t = \int g(t)\mathrm{d}t$. *That is, we can* interchange the limit with the integral.

Dominated Convergence Theorem: *Suppose* $\{g_k(t)\}$ *is dominated by a nonnegative Lebesgue integrable function* $f(t)$, *i.e.,* $|g_k(t)| \le f(t)$ a.e., *and* $\{g_k(t)\}$ *converges to a limit* $g(t)$ a.e. *Then the limit* $g(t)$ *is Lebesgue integrable and* $\lim_k \int g_k(t)\mathrm{d}t = \int \lim_k g_k(t)\mathrm{d}t$, i.e., $\lim_k \int g_k(t)\mathrm{d}t = \int g(t)\mathrm{d}t$. *That is, we can interchange the limit with the integral.*

Levi's Theorem: *Suppose* $\int \sum_{k=1}^{m} |g_k(t)|\mathrm{d}t$ *is a bounded sequence in* m. Then $\int \sum_{k=1}^{\infty} g_k(t)\mathrm{d}t = \sum_{k=1}^{\infty} \int g_k(t)\mathrm{d}t$. *This means, in particular, that* $\sum_{k=1}^{\infty} g_k(t)$ *converges* a.e., *to a Lebesgue integrable function. This theorem permits us to interchange infinite sums with the integrals.*

Fatou's Lemma: *Let* (a) $g_k(t) \ge 0$ a.e., (b) $g_k(t) \to g(t)$ a.e., and (c) $\int g_k(t)\,\mathrm{d}t \le A$ *for some* $0 < A < \infty$. *Then the limit* $g(t)$ *is Lebesgue integrable and* $\int g(t) \le A$. (Stronger versions of this result exist [23], but we shall not require them here.)

6.6.2 L^p Signals

Let p be an integer such that $1 \le p < \infty$. A signal $x(t)$ is said to be an L^p signal if it is measurable, and if $\int |x(t)|^p\,\mathrm{d}t$ exists. We define the L^p norm of $x(t)$ as $\|x(t)\|_p = \left[\int |x(t)|^p \mathrm{d}t\right]^{1/p}$. For fixed p, the set of L^p signals forms a vector space. It is a normed linear vector space, with norm defined previously. The term "linear" means that if $x(t)$ and $y(t)$ are in L^p, then $\alpha x(t) + \beta y(t)$ is also in L^p for any complex α and β. Because any two signals $x(t)$ and $y(t)$ that are equal a.e., cannot be distinguished (i.e., $\|x(t) - y(t)\|_p = 0$), each element in L^p is in reality "a set of functions that are equal a.e." Each such set becomes an "equivalence class" in mathematical language. For $p = 2$ the quantity $\|x(t)\|_p^2$ is equal to the energy of $x(t)$, as defined in signal processing texts. Thus, an L^2 signal is a finite-energy (or square-integrable) signal. For $p = \infty$ the above definitions do not make sense, and we simply define L^∞ to be the space of essentially bounded signals. A signal $x(t)$ is said to be essentially bounded if there exists a number $B < \infty$ such that $|x(t)| \le B$ a.e. We often omit the term "essential" for simplicity; it arises because of the a.e. in

the inequality. The norm $\|x(t)\|_\infty$ is taken as essential supremum of $|x(t)|$ over all t. That is, $\|x(t)\|_\infty$ is the smallest number such that $|x(t)| \le \|x(t)\|_\infty$ a.e.

L^1, L^2, and L^∞ functions are particularly interesting for engineers. Note that neither L^1 nor L^2 contains the other. However, bounded L^1 functions are in L^2, and L^2 functions on bounded intervals are in L^1. That is

$$L^1 \cap L^\infty \subset L^2 \quad \text{and} \quad L^2[a,b] \subset L^1[a,b] \tag{6.48}$$

Thus, L^2 is already bigger than bounded L^1 functions. Moreover,

$$x(t) \in L^1 \cap L^\infty \Rightarrow x(t) \in L^p \quad \text{for all } p > 1$$

This follows because $|x(t)|^p \le |x(t)|\ \|x(t)\|_\infty^{p-1}$.Thus, $|x(t)|^p$ is (measurable and) bounded by a Lebesgue integrable function (because $|x(t)|$ is integrable), and is therefore integrable.

Orthonormal Signals in L^2

The inner product $\langle x(t), y(t)\rangle = \int x(t)y^*(t)\mathrm{d}t$ always exists for any $x(t)$ and $y(t)$ in L^2. Thus, the product of two L^2 functions is an L^1 function. If $\langle x(t), y(t)\rangle = 0$ we say that $x(t)$ and $y(t)$ are orthogonal. Clearly, $\|x(t)\|_2^2 = \langle x(t), x(t)\rangle$. Consider a sequence $\{g_n(t)\}$ of signals such that any pair of these are orthogonal, and $\|g_n(t)\|_2 = 1$ for all n. This is said to be an orthonormal sequence. The following two results are fundamental.

THEOREM 6.1

Let $\{g_n(t)\}$, $1 \le n \le \infty$ be an orthonormal sequence in L^2. Define $c_n = \langle x(t), g_n(t)\rangle$ for some $x(t) \in L^2$. Then the sum $\boldsymbol{\Sigma}_n|c_n|2$ converges, and $\boldsymbol{\Sigma}_n|c_n|^2 \le \|x(t)\|^2$.

THEOREM 6.2: (Riesz–Fischer Theorem)

Let $\{g_n(t)\}$, $1 \le n \le \infty$ be an orthonormal sequence in L^2 and let $\{c_n\}$ be a sequence of complex numbers such that $\boldsymbol{\Sigma}_n|c_n|^2$ converges. Then there exists $x(t) \in L^2$ such that $c_n = \langle x(t), g_n(t)\rangle$, and $x(t) = \boldsymbol{\Sigma}_n c_n g_n(t)$ (with equality interpreted in the L^2 sense; see below).

The space L^2 is more convenient to work with than L^1. For example, inner product and the concept of orthonormality are undefined in L^1. Moreover (see following section), the FT in L^2 has more time–frequency symmetry than in L^1. In Section 6.7, we will define unconditional bases, which have the property that any rearrangement continues to be a basis. It turns out that any orthonormal basis in L^2 is unconditional, whereas the L^1 space does not even have an unconditional basis.

Equality and Convergence in L^p Sense

Let $x(t)$ and $y(t)$ be L_P functions ($p < \infty$). Then $\|x(t) - y(t)\|_p = 0$ iff $x(t) = y(t)$ a.e. For example, if $x(t)$ and $y(t)$ differ only for every rational t we still have $\|x(t) - y(t)\|_p = 0$. Whenever $\|x(t) - y(t)\|_p = 0$, we say that $x(t) = y(t)$ in L^p sense. Now consider a statement of the form

$$x(t) = \sum_{n=1}^{\infty} c_n g_n(t) \tag{6.49}$$

for $p < \infty$, where $g_n(t)$ and $x(t)$ are in L^p. This means that the sum converges to $x(t)$ in the L^p sense; that is, $\|x(t) - \Sigma_{n=1}^{N} c_n g_n(t)\|_p$ goes to zero as $N \to \infty$. If we modify the limit $x(t)$ by adding some number to $x(t)$ for all rational t, the result is still a limit of $\Sigma_{n=1}^{N} c_n g_n(t)$ in the L^p sense. L^p limits are unique only the a.e. sense. We omit the phrase "in the L^p sense" whenever it is clear from the context.

l^p Spaces

Let p be an integer with $1 \le p \le \infty$. The collection of all sequences $x(n)$ such that $\Sigma_n |x(n)|^p$ converges to a finite value is denoted l^p. This is a linear space with norm $\|x(n)\|_p$ defined so that $\|x(n)\|_p = (\Sigma_n |x(n)|^p)^{1/p}$. Unlike L^p spaces, l^p spaces satisfy the following inclusion rule:

$$l^1 \subset l^2 \subset l^3 \ldots l^\infty \tag{6.50}$$

The spaces l^1 and l^2 are especially interesting in circuits and signal processing. If $h(n) \in l^1$, $\Sigma_n |h(n)| < \infty$. This is precisely the condition for the BIBO stability of a linear time invariant system with impulse response $h(n)$ [2].

Continuity of Inner Products

If $\{x_n(t)\}$ is a sequence in L^2 and has an L^2 limit $x(t)$, then, for any $y(t) \in L^2$,

$$\lim_{n\to\infty} \langle x_n(t), y(t)\rangle = \left\langle \lim_{n\to\infty} x_n(t), y(t)\right\rangle = \langle x(t), y(t)\rangle \tag{6.51}$$

with the second limit interpreted in the L^2 sense. Thus, limits can be interchanged with inner product signs. Similarly, infinite summation signs can be interchanged with the inner product sign, that is, $\sum_{n=1}^{\infty} \langle \alpha_n x_n(t), y(t)\rangle = \left\langle \sum_{N=1}^{\infty} \alpha_n x_n(t), y(t)\right\rangle$, provided the second summation is regarded as an L^2 limit. These follow from the fundamental property that *inner products are continuous* [23].

Next, suppose $\{x_n(t)\}$ is a sequence of functions L^p for some integer $p \ge 1$, and suppose $x_n(t) \to x(t)$ in the L^p sense. Then $\|x_n(t)\|_p \to \|x(t)\|_p$ as well. We can rephrase this as

$$\lim_{n\to\infty} \|x_n(t)\|_p = \left\| \lim_{n\to\infty} x_n(t)\right\|_p = \|x(t)\|_p \tag{6.52}$$

Thus, the limit sign can be interchanged with the norm sign, where the limit in the second expression is in the L^p sense. This follows because

$$\left| \|x_n(t)\|_p - \|x(t)\|_p \right| \le \|x_n(t) - x(t)\|_p \to 0 \text{ as } n \to \infty.$$

6.6.3 Fourier Transforms

The Fourier transform is defined for L^1 and L^2 signals in different ways. The properties of these two types of FT are significantly different. In the signal processing literature, in which we ultimately seek engineering solutions (such as filter approximation with rational transfer functions), this distinction often is not necessary. However, when we try to establish that a certain set of signals is a basis for a certain class, we must be careful, especially if we use tools such as the FT, convolution theorem, etc. (as we implicitly did in Section 6.2). Detailed references for this section include Refs. [15,22,23].

L^1 Fourier Transform

Given a signal $x(t) \in L^1$, its FT $X(\omega)$ (the L^1 FT) is defined in a manner that is familiar to engineers:

$$X(\omega) = \int_{-\infty}^{\infty} x(t) e^{-j\omega t} dt \tag{6.53}$$

The existence of this integral is assured by the fact that $x(t)$ is in L^1.* In fact, the preceding integral exists iff $x(t) \in L^1$. The L^1 FT has the following properties:

1. $X(\omega)$ is a continuous function of ω.
2. $X(\omega) \to 0$ as $|\omega| \to \infty$. This is called the Riemann–Lebesgue lemma.
3. $X(\omega)$ is bounded, and $\|x(\omega)\| \leq \|x(t)\|_1$.

In engineering applications, we often draw the ideal low-pass filter response ($F(\omega)$ in Figure 6.3) and consider it to be the FT of the impulse response $f(t)$, but this frequency response is discontinuous and already violates property 1. This is because $f(t)$ is not in L^1 and $F(\omega)$ is not the L^1-FT of $f(t)$. That $f(t)$ is not in L^1 is consistent with the fact that the ideal filter is not BIBO stable (i.e., a bounded input may not produce bounded output because $\int|f(t)|\,dt$ is not finite).

Inverse Fourier Transform: The FT $X(\omega)$ of an L^1 signal generally is not in L^1. For example, if $x(t)$ is the rectangular pulse, then $X(\omega)$ is the sinc function which is not absolutely integrable. Thus, the familiar inverse transform formula

$$x(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} X(\omega) e^{j\omega t} d\omega \tag{6.54}$$

does not make sense in general. However, because $X(\omega)$ is continuous and bounded, it is integrable on any bounded interval, so $\int_{-c}^{c} X(\omega)e^{j\omega t}d\omega/2\pi$ exists for any finite c. This quantity may even have a limit as $c \to \infty$, even if the Lebesgue integral or improper Rieman integral, does not exist. Such a limit (the Cauchy principal value) does represent the original function $x(t)$ under some conditions. Two such cases are outlined next.

Case 1: Thus, suppose $x(t) \in L^1$ and suppose that is of bounded variation in an interval $[a, b]$; that is, it can be expressed as the difference of two nondecreasing functions [22]. Then, we can show that the above Cauchy principal value exists, and

$$\frac{x(t^+) + x(t^-)}{2} = \lim_{c\to\infty} \frac{1}{2\pi} \int_{-c}^{c} X(\omega) e^{j\omega t} d\omega \tag{6.55}$$

for every $t \in (a, b)$. The notations $x(t^-)$ and $x(t^+)$ are the left-hand limit and the right-hand limit respectively, of $x(\cdot)$ at t; for functions of bounded variation, these limits can be shown to exist. If $x(\cdot)$ is continuous at t, then $x(t^-) = x(t^+) = x(t)$, and above reduces to the familiar inversion formula.

Case 2: Suppose now that $x(t) \in L^1$ and $X(\omega) \in L^1$ as well. Then, the integral $y(t) \triangleq \int_{-\infty}^{\infty} X(\omega)e^{j\omega t}d\omega/2\pi$ exists as a Lebesgue integral, and $y(t) = x(t)$ a.e. [23]. In particular, if $x(\cdot)$ is continuous at t, $x(t) = \int_{-c}^{c} X(\omega)e^{j\omega t}d\omega/2\pi$.

If $x(t)$ and $X(\omega)$ are both in L^1 they are both in L^2 as well. This is shown as follows: because $x(t) \in L^1$ implies that $X(\omega)$ is bounded. We see that $X(\omega) \in L^1 \cap L^\infty$. So $X(\omega) \in L^p$ for all integer p (see Section 6.6.2). In particular, $X(\omega) \in L^2$, so $x(t) \in L^2$ as well (by Parseval's relation; see below).

L^2 Fourier Transform

The L^1 Fourier transform lacks the convenient property of time–frequency symmetry. For example, even though $x(t)$ is in L^1, $X(\omega)$ may not in L^1. Also, even though $x(t)$ may not be continuous, $X(\omega)$ is necessarily continuous. The space L^2 is much easier to work with. Not only can we talk about inner products and orthonormal bases, perfect symmetry also exists between time and frequency domains. We must define L^2-FT differently because the usual definition (Equation 6.53) is meaningful only for L^1

* Because $x(t)$ is Lebesgue integrable (hence, measurable), the product $x(t)e^{-j\omega t}$ is measurable, and it is bounded by the integrable function $|x(t)|$. Thus, $x(t)e^{-j\omega t}$ is integrable.

signals. Suppose $x(t) \in L^2$ and we truncate it to the interval $[-n, n]$. This truncated version is in L^1 because of Equation 6.48, and its L^1 FT exists:

$$X_n(\omega) = \int_{-n}^{n} x(t)e^{-j\omega t}\,dt \tag{6.56}$$

It can be shown that $X_n(\omega)$ is in L^2 and that the sequence $\{X_n(\omega)\}$ has a limit in L^2. That is, there exists an L^2 function $X(\omega)$ such that

$$\lim_{n\to\infty} \|X_n(\omega) - X(\omega)\|_2 = 0 \tag{6.57}$$

This limit $X(\omega)$ is defined to be the L^2 FT of $x(t)$. Some of the properties are listed next:

1. $X(\omega)$ is in L^2, and we can compute $x(t)$ from $X(\omega)$ in an entirely analogous manner, namely the L^2 limit of $\int_{-n}^{n} X(\omega)e^{j\omega t}d\omega/2\pi$.
2. If $x(t)$ is in L^1 and L^2, then the above computation gives the same answer as the L^1-FT Equation 6.53 a.e. For example, consider the rectangular pulse $x(t) = 1$ in $[-1, 1]$ and zero otherwise. This is in L^1 and L^2, and the FT using either definition is $X(\omega) = 2\sin\omega/\omega$. This answer is in L^2, but not in L^1. The inverse L^2-FT of $X(\omega)$ is the original $x(t)$.
3. If $x(\omega) \in L^2$ and $x(\omega) \in L^1$ then the Lebesgue integral $\int_{-\infty}^{\infty} X(\omega)e^{j\omega t}d\omega/2\pi$ exists, and equals $x(t)$ a.e.
4. Parseval's relation holds, i.e., $\sqrt{2\pi}\|x(t)\|_2 = \|X(\omega)\|_2$. Thus, the FT is a linear transformation from L^2 to L^2, which preserves norms except the scale factor $\sqrt{2\pi}$. (Note that this would not make sense if $x(t)$ were only in L^1.) In particular, it is a bounded transformation because the norm $\|X(\omega)\|_2$ in the transform domain is bounded by the norm $\|x(t)\|_2$ in the original domain.
5. Unlike the L^1-FT, the L^2-FT $X(\omega)$ need not be continuous. For example, the impulse response of an ideal low-pass filter (sinc function) is in L^2 and its FT is not continuous.
6. Let $\{f_n(t)\}$ be a sequence in L^2 and let $x(t) = \Sigma_n c_n f_n(t)$ be a convergent summation (in the L^2 sense). With upper case letters denoting the L^2-FTs, $x(\omega) = \Sigma_n c_n F_n(\omega)$. This result is obvious for finite summations because of the linearity of the FT. For infinite summations, this follows from the property that the L^2-FT is a continuous mapping from L^2 to L^2. (This in turn follows from the result that it is a bounded linear transformation). The continuity allows us to move the FT operation inside the infinite summation.

Thus, complete symmetry exists between the time and frequency domains. The L^2-FT is a one-to-one mapping from L^2 onto L^2. Moreover, because $\sqrt{2\pi}\|x(t)\|_2 = \|X(\omega)\|_2$, it is a norm preserving mapping—one says that the L^2-FT is an isometry from L^2 to L^2.

l^1 Fourier Transform

If a sequence $x(n) \in l^1$ its discrete-time FT $X(e^{j\omega}) = \Sigma_n x(n)e^{-j\omega n}$ exists, and is the l^1-FT of $x(n)$. It can be demonstrated that $X(e^{j\omega})$ is a continuous function of ω and that $|X(e^{j\omega})|$ is bounded.

6.6.4 Convolutions

Suppose $h(t) \in L^1$ and $h(t) \in L^p$ for some p in $1 \le p \le \infty$. The familiar convolution integral defined by $(x^* h)(t) = \int x(\tau)h(t-\tau)d\tau$ exists for almost all t [23]. If we define a function $y(t)$ to be $x \cdot h$ where it exists and to be zero elsewhere, the result is, in fact, an L^p function. We simply say that the convolution of an L^1, function with an L^p function gives an L^p function. By recalling that an LTI system is stable (i.e., BIBO stable), iff its impulse response is in L^1, we have the following examples:

1. If an L^1 signal is input to a stable LTI system, the output is in L^1. Because the convolution of two L^1 signals is in L^1, the cascade of two stable LTI systems is stable, a readily accepted fact in engineering.
2. If an L^2 signal (finite energy input) is input to a stable LTI system, the output is in L^2.
3. If an L^∞ signal is input to a stable LTI system, the output is in L^∞ (i.e., bounded inputs produce bounded outputs).

If $x(t)$ and $h(t)$ are both in L^1, their convolution $y(t)$ is in L^1, and all three signals have L^1-FT. The convolution theorem [23] says that theses three are related as $Y(\omega) = H(\omega)\, X(\omega)$. When signals are not necessarily in L^1 we cannot in general write this, even if convolution might itself be well defined.

Convolution Theorems for L^2 Signals

For all our discussions in the preceding sections, the signals were restricted to be in L^2, but not necessarily in L^1. In fact, even the filters are often only in L^2. For example, ideal bandpass filters (Figure 6.8) are unstable, and therefore only in L^2. For arbitrary L^2 signals $x(t)$ and $h(t)$, the convolution theorem does not hold. We therefore need to better understand L^2 convolution.

Assume that $x(t)$ and $h(t)$ are both in L^2. Their convolution $y(t) = \int x(\tau)h(t-\tau)\mathrm{d}\tau$ exists for all t, as the integral is only an inner product in L^2. Using Schwartz inequality [23], we also have $|y(t)| \leq \|x(t)\|_2 \, \|h(t)\|_2$, that is, $y(t) \in L^\infty$. Suppose the filter $h(t)$ has the further property that the frequency response $H(\omega)$ is bounded, i.e., $|H(\omega)| \leq B$ a.e., for some $B < \infty$. Then we can show that $y(t) \in L^2$, and that the convolution theorem holds ($Y(\omega) = H(\omega)X(\omega)$). To prove this, note that

$$y(t) = \int x(\tau)h(t-\tau)\mathrm{d}\tau = \frac{1}{2\pi}\int X(\omega)H(\omega)e^{j\omega t}\mathrm{d}\omega \tag{6.58}$$

from Parseval's relation which holds for L^2 signals [23]. If $|H(\omega)| \leq B$, then $|X(\omega)H(\omega)|^2 \leq B^2|X(\omega)|^2$. Therefore, $|X(\omega)H(\omega)|^2$ is bounded by the integrable function $|X(\omega)|^2$, and is therefore integrable. Thus, $X(\omega)H(\omega) \in L^2$, and the preceding equation establishes that $y(t) \in L^2$. The equation also shows that $y(t)$ and $H(\omega)X(\omega)$ form an L^2-FT pair, so $Y(\omega) = H(\omega)X(\omega)$.

Bounded L^2 Filters

Filters for which $h(t) \in L^2$ and $H(\omega)$ bounded are called bounded L^2 filters. The preceding discussion shows that bounded L^2 filters admit the convolution theorem, although arbitrary L^2 filters do not. Another advantage of bounded L^2 filters is that a cascade of two bounded L^2 filters, $h_1(\mathrm{t})$ and $h_2(\mathrm{t})$, is a bounded L^2 filter, just as a cascade of two stable filters would be stable. To see this, note that the cascaded impulse response is the convolution $h(t) = (h_1 * h_2)(t)$. By the preceding discussion, $h(t) \in L^2$, and moreover, $H(\omega) = H_1(\omega)H_2(\omega)$. Clearly, $H(\omega)$ is still bounded. Bounded L^2 filters are therefore very convenient to work with. Fortunately, all filters in the discussion of wavelets and filter banks are bounded L^2 filters, even though they may not be BIBO stable (as are the ideal bandpass filters in Figure 6.8). We summarize the preceding discussions as follows.

THEOREM 6.3: (Convolution of L^2 functions)

We say that $h(t)$ is a bounded L^2 filter if $h(t) \in L^2$ and $|H(\omega)| \leq B < \infty$ a.e.

1. *Let $x(t) \in L^2$ and let $h(t)$ be a bounded L^2 filter. Then $y(t) = (x * h)(t)$ exists for all t and $y(t) \in L^2$. Moreover, $Y(\omega) = H(\omega)X(\omega)$.*
2. *If $h_1(t)$ and $h_2(t)$ are bounded L^2 filters, then their cascade $h(t) = (h_1 * h_2)(t)$ is a bounded L^2 filter and $H(\omega) = H_1(\omega)H_2(\omega)$.*

6.7 Riesz Basis, Biorthogonality, and Other Fine Points

In a finite dimensional space, such as the space of all N-component Euclidean vectors, the ideas of basis and orthonormal basis are easy to appreciate. When we extend these ideas to infinite dimensional spaces (i.e., where the basis $\{g_n(t)\}$ has infinite number of functions), a number of complications and subtleties arise. Our aim is to point these out. References for this section include Refs. [5,15,24].

Readers familiar Hilbert spaces will note that the L^2 space is a Hilbert space; all our developments here are valid for any Hilbert space $\mathcal{H}$. Elements in $\mathcal{H}$ (vectors) are typically denoted *x, y,* etc. When we deal with Hilbert space L^2, the vectors are functions and are denoted as $x(t)$, $y(t)$, etc., for clarity. Similarly, for the special case of Euclidean vectors we use boldface, e.g., $\mathbf{x}$, $\mathbf{y}$, etc. The reader not familiar with Hilbert spaces can assume that all discussions are in L^2 and that x is merely a simplification of the notation $x(t)$.

6.7.1 Finite Dimensional Vector Spaces

We first look at the finite dimensional case and then proceed to the infinite dimensional case. Consider an $N \times N$ matrix $\mathbf{F} = [\mathbf{f}_1\ \mathbf{f}_2 \ldots \mathbf{f}_N]$. We assume that this is nonsingular, that is, the columns $\mathbf{f}_n$ are linearly independent. These column vectors form a basis for the N-dimensional Euclidean space $\mathcal{C}^N$ of complex N-component vectors. This space is an example of a finite dimensional Hilbert space, with inner product defined as $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{y}^\dagger = \sum_{n=1}^{N} x_n x_n^\star$. The norm $\|\mathbf{x}\|$ induced by this inner product is defined as $\|\mathbf{x}\| \sqrt{\langle \mathbf{x}, \mathbf{x} \rangle}$. Thus, $\|\mathrm{x}\|^2 = \mathbf{x}^\dagger \mathbf{x} = \sum_{n=1}^{N} |x_n|^2$.

Any vector $\mathrm{x} \in \mathcal{C}^N$ can be expressed as $\mathbf{x} = \mathbf{\Sigma}_{n=1}^{N} c_n \mathbf{f}_n$ for some uniquely determined set of scalars c_n. We can abbreviate this as $\mathbf{x} = \mathbf{Fc}$, where $\mathbf{c} = [c_1\ c_2 \ldots c_N]^{\mathrm{T}}$. The matrix $\mathbf{F}$ can be regarded as a linear transformation from $\mathcal{C}^N$ to $\mathcal{C}^N$. The nonsingularity of $\mathbf{F}$ means that for every $\mathbf{x} \in \mathcal{C}^N$ we can find a unique $\mathbf{c}$ such that $\mathbf{x} = \mathbf{Fc}$.

6.7.1.1 Boundedness of F and Its Inverse

In practice, we have further requirement that if the norm $\|\mathbf{c}\|$ is "small" then $\|\mathbf{x}\|$ should also be "small," and vice versa. This requirement implies, for example, that if a small error occurs in the transmission or estimate of the vector $\mathbf{c}$, the corresponding error in x is also small. From the relation $\mathbf{x} = \mathbf{Fc}$ we obtain

$$\|\mathbf{x}\|^2 = \mathbf{x}^\dagger \mathbf{x} = \mathbf{c}^\dagger \mathbf{F}^\dagger \mathbf{F} \mathbf{c} \tag{6.59}$$

Letting λ_{M} and λ_{m} denote the maximum and minimum eigenvalues of $\mathbf{F}^\dagger \mathbf{F}$, it then follows that $\|\mathbf{x}\|^2 \geq \lambda_{\mathrm{m}} \|\mathbf{c}\|^2$ and that $\|\mathbf{x}\|^2 \leq \lambda_{\mathrm{M}} \|\mathbf{c}\|^2$. That is

$$\lambda_{\mathrm{m}} \|\mathbf{c}\|^2 \leq \|\mathbf{x}\|^2 \leq \lambda_{\mathrm{M}} \|\mathbf{c}\|^2 \tag{6.60}$$

with $0 < \lambda_{\mathrm{m}} \leq \lambda_{\mathrm{M}} < \infty$, where $0 < \lambda_{\mathrm{m}}$ follows from the nonsingularity of $\mathbf{F}$. Thus, the transformation $\mathbf{F}$, which converts $\mathbf{c}$ into $\mathbf{x}$, has an amplification factor bounded by λ_{M} in the sense that $\|\mathbf{x}\|^2 \leq \lambda_{\mathrm{M}} \|\mathbf{c}\|^2$. Similarly, the inverse transformation $\mathbf{G} = \mathbf{F}^{-1}$, which converts $\mathbf{x}$ into $\mathbf{c}$, has amplification bounded by $1/\lambda_{\mathrm{m}}$. Because λ_{M} is finite, we say that F is a bounded linear transformation, and because $\lambda_{\mathrm{m}} \neq 0$, we see that the inverse transformation is also bounded.

Using $\mathbf{x} = \mathbf{\Sigma}_n c_n \mathbf{f}_n$ and $\|\mathrm{c}\|^2 = \mathbf{\Sigma}_n |c_n|^2$ we can rewrite the preceding inequality as

$$A \sum_n |c_n|^2 \leq \left\| \sum_n c_n \mathbf{f}_n \right\|^2 \leq B \sum_n |c_n|^2 \tag{6.61}$$

where

$A = \lambda_m > 0$

$B = \lambda_M < \infty$, and all summations are for $1 \leq n \leq N$

Readers familiar with the idea of a Riesz basis in infinite dimensional Hilbert spaces will notice that the above is in the form that agrees with that definition. We will return to this issue later.

Biorthogonality

With $\mathbf{F}^{-1}$ denoted as $\mathbf{G}$, let $\mathbf{g}_n^\dagger$ denote the rows of $\mathbf{G}$:

$$\mathbf{G} = \begin{bmatrix} \mathbf{g}_1^\dagger \\ \mathbf{g}_2^\dagger \\ \vdots \\ \mathbf{g}_N^\dagger \end{bmatrix}, \quad \mathbf{F} = [\mathbf{f}_1\ \mathbf{f}_2 \ldots \mathbf{f}_N] \tag{6.62}$$

The property $\mathbf{GF} = \mathbf{I}$ implies $\mathbf{g}_k^\dagger \mathbf{f}_n = \delta(k-n)$:

$$\langle \mathbf{f}_n, \mathbf{g}_k \rangle = \delta(k-n) \tag{6.63}$$

for $1 \le k, n \le N$. Equivalently, $\langle \mathbf{g}_k\ \mathbf{f}_n \rangle = \delta(k-n)$.

Two sets of vectors, $\{\mathbf{f}_n\}$ and $\{\mathbf{g}_k\}$, satisfying Equation 6.63 are said to be **biorthogonal**. Because $\mathbf{c} = \mathbf{F}^{-1}\ \mathbf{x} = \mathbf{Gx}$ we can write the elements of $\mathbf{c}$ as $c_n = \mathbf{g}_n^\dagger \mathbf{x} = \langle \mathbf{x}, \mathbf{g}_n \rangle$. Then $\mathbf{x} = \sum_n c_n \mathbf{f}_n = \sum_n \langle \mathbf{x}, \mathbf{g}_n \rangle \mathbf{f}_n$. Next, $\mathbf{G}^\dagger$ is a nonsingular matrix, therefore, we can use its columns $\mathbf{g}_n$, instead of the columns of $\mathbf{F}$, to obtain a similar development, and express the arbitrary vector $\mathbf{x} \in \mathcal{C}^N$ as $\mathbf{x} = \boldsymbol{\Sigma}_n \langle \mathbf{x}, \mathbf{f}_n \rangle \mathbf{g}_n$. Summarizing, we have

$$\mathbf{x} = \sum_n \langle \mathbf{x}, \mathbf{g}_n \rangle \mathbf{f}_n = \sum_n \langle \mathbf{x}, \mathbf{f}_n \rangle \mathbf{g}_n \tag{6.64}$$

where the summations are for $1 \le n \le N$. By using the expressions $c_n = \langle \mathbf{x}, \mathbf{g}_n \rangle$ and $\mathbf{x} = \boldsymbol{\Sigma}_n c_n \mathbf{f}_n$, we can rearrange the inequality Equation 6.61 into $B^{-1}\ \|\mathbf{x}\|^2 \le \boldsymbol{\Sigma}_n\ |\langle \mathbf{x}, \mathbf{g}_n \rangle|^2 \le A^{-1} \|\mathbf{x}\|^2$. With the columns $\mathbf{g}_n$ of $\mathbf{G}^\dagger$, instead of the columns of $\mathbf{F}$, used as the basis for $\mathcal{C}^N$, we obtain similarly

$$A\|\mathbf{x}\|^2 \le \sum_n |\langle \mathbf{x}, \mathbf{f}_n \rangle|^2 \le B\|\mathbf{x}\|^2 \tag{6.65}$$

where $1 \le n \le N$, and $A = \lambda_m$, $B = \lambda_M$ again. Readers familiar with the idea of a frame in an infinite dimensional Hilbert space will recognize that the above inequality defines a frame $\{\mathbf{f}_n\}$.

Orthonormality

The basis $\mathbf{f}_n$ is said to be orthonormal if $\langle \mathbf{f}_k, \mathbf{f}_n \rangle = \delta(k-n)$, i.e., $\mathbf{f}_n^\dagger \mathbf{f}_k = \delta(k-n)$. Equivalently, $\mathbf{F}$ is unitary, i.e., $\mathbf{F}^\dagger\ \mathbf{F} = \mathrm{I}$. In this case the rows of the inverse matrix G are the quantities $\mathbf{f}_n{}^\dagger$. But $\mathbf{F}^\dagger\ \mathbf{F} = \mathbf{I}$, and we have $\lambda_m = \lambda_M = 1$ or $A = B = 1$. With this, Equation 6.60 becomes $\|\mathbf{c}\| = \|\mathbf{x}\|$, or $\boldsymbol{\Sigma}_n |c_n|^2 = \|\boldsymbol{\Sigma}_n c_n \mathbf{f}_n\|^2$. This shows that Equation 6.61 is a generalization of the orthonormal situation. Similarly, biorthogonality (Equation 6.63) is a generalization of orthonormality.

Basis in Infinite Dimensional Spaces

When the simple idea of a basis in a finite dimensional space (e.g., the Euclidean space $\mathcal{C}^N$) is extended to infinite dimensions, several new issues arise which make the problem nontrivial. Consider the sequence of functions $\{f_n\}$, $1 \le n \le \infty$ in a Hilbert space $\mathcal{H}$. Because of the infinite range of n, linear combinations of the form $\sum_{n=1}^{\infty} c_n f_n$ must now be considered. The problem that immediately arises is one of convergence. For arbitrary sequences c_n this sum does not converge, so the statement "all linear combinations" must be replaced with something else.*

* Our review uses $1 \le n \le \infty$ to be consistent with standard math texts, but all the crucial results hold for doubly infinite sequences and summations, i.e., for the case $-\infty \le n \le \infty$. This is what we need in the case of Fourier and wavelet bases; see, for example, Equations 6.3 and 6.4.

Closure of Span

First define the set of all finite linear of the form $\sum_{n=1}^{\infty} c_n f_n$, where N varies over all integers ≥ 1. This is called the span of $\{f_n\}$. Now suppose $\mathbf{x} \in \mathcal{H}$ is a vector not necessarily in the span of $\{f_n\}$, but can be approximated as closely as we wish by vectors in the span. In other words, given an $\varepsilon > 0$ we can find N and the sequence of constants c_{nN} such that

$$\left\| x - \sum_{n=1}^{N} c_{nN} f_n \right\| < \varepsilon \tag{6.66}$$

where $\|x\|$ is the norm defined as $\|x\| = \sqrt{\langle x, x \rangle}$. If we append all such vectors x to the span of $\{f_n\}$ we get the closure of the span of $\{f_n\}$.* Note that c_{nN}, in general, depends on ε because N depends on ε.

Completeness

A sequence of vectors $\{f_n\}$ is said to be complete in $\mathcal{H}$ if the closure of the linear span of $\{f_n\}$ equals $\mathcal{H}$. Therefore, any $x \in \mathcal{H}$ can be approximated, as closely as we wish, by finite linear combinations of f_n in the sense of Equation 6.66. This is also expressed by saying that the linear span of $\{f_n\}$ is dense in $\mathcal{H}$. Completeness of $\{f_n\}$ in a Hilbert space is equivalent to the statement that the only vector orthogonal to all f_n is the zero vector.

Infinite Summations

When we write $x = \sum_{n=1}^{\infty} c_n f_n$, we mean that the infinite summation converges to x in the norm of $\mathcal{H}$. In other words, given $\varepsilon > 0$, there exists n_0 such that

$$\left\| x - \sum_{n=1}^{N} c_n f_n \right\| < \varepsilon \quad \text{for all } N \geq n_0 \tag{6.67}$$

This statement is stronger than saying that x is in the closure of the linear span of $\{f_n\}$. The latter statement only requires Equation 6.66, where N and hence c_{nN} depends on ε. In Equation 6.67, $\{c_n\}$ is a fixed sequence.

Linear Independence

Let $\{f_n\}$, $n = 1, 2, \ldots$ be a sequence of vectors in an infinite dimensional Hilbert space $\mathcal{H}$. Unlike in a finite dimensional space, one must distinguish between several types of linear independence.

Type 1: $\{f_n\}$ has *finite linear independence if* $\sum_{n=1}^{N} c_n f_n = 0$, for any finite N implies $c_n = 0$, $1 \leq n \leq N$.

Type 2: $\{f_n\}$ is ω-*independent if* $\sum_{n=1}^{\infty} c_n f_n = 0$ implies $c_n = 0$ for all n (where the infinite sum is interpreted as explained above).

Type 3: $\{f_n\}$ is *minimal* if none of the f_m is in the closure of the span of the remaining set of f_n.

Type 3 independence implies type 2, which in turn implies type 1. Thus, type 3 is the strongest kind of linear independence. The reason that it is stronger than type 2 is that type 2 implies we cannot have $f_m = \mathbf{\Sigma}_{n \neq m} c_n f_n$. However, for a type 2 independent sequence $\{f_n\}$, it is possible that we can make

$$\left\| f_m - \sum_{\substack{n=1 \\ n \neq m}}^{N} c_{nN} f_n \right\| < \varepsilon \tag{6.68}$$

* The term "closure" has its origin from the theory of metric spaces, more generally, topological vector spaces. We do not require the deeper, more general meaning here.

for any given $\varepsilon > 0$ by choosing N and c_{nN} properly.* Type 3 linear independence prohibits even this. The comments following Example 6.3 make this distinction more clear (see p. 6–42 and 6–43).

Basis or Schauder Basis

A sequence of vectors $\{f_n\}$ in $\mathcal{H}$ is a Schauder basis for $\mathcal{H}$ if any $x \in \mathcal{H}$ can be expressed as $x = \sum_{n=1}^{\infty} c_n f_n$, and the sequence of scalars $\{c_n\}$ is unique for a given x. The second condition can be replaced with the statement that $\{f_n\}$ is ω-independent. A subtle result for Hilbert spaces [24] is that a Schauder basis automatically satisfies minimality (i.e., type 3 independence).

A Schauder basis is ω-independent and complete in the sense defined above. Conversely, ω-independence and completeness do not imply that $\{f_n\}$ is a Schauder basis; completeness only means that we may approximate any vector as closely as we wish in the sense of Equation 6.66, where c_{kN} depend on N. In this chapter "independence" (or linear independence) stands for ω-independence. Similarly "basis" stands for Schauder basis unless qualified otherwise.

Riesz Basis

Any basis $\{\mathbf{f}_n\}$ in a finite dimensional space satisfies Equation 6.61, which in turn ensures that the transformation from x to $\{c_n\}$ and that from $\{c_n\}$ to $\mathbf{x}$ are stable. For a basis in an infinite dimensional space, Equation 6.61 is not automatically guaranteed, as shown by the following example.

Example 6.2

Let $\{e_n\}$, $1 \le n \le \infty$ be an orthonormal basis in a Hilbert space $\mathcal{H}$, and define the sequence $\{f_n\}$ by $f_n = e_n/n$. Then we can show that f_n is still a basis, i.e., it satisfies the definition of a Schauder basis. Suppose we pick $x = \varepsilon e_k$ for some k. Then, $x = \sum_n c_n f_n$, with $c_k = \varepsilon k$, and $c_n = 0$ for all other n. Thus, $\sum_n |c_n|^2 = \varepsilon^2 k^2$ and grows as k increases, although $\|x\| = \varepsilon$ for all k. That is, a "small" error in x can become amplified in an unbounded manner. Recall that this could never happen in the finite dimensional case because $A > 0$ in Equation 6.61. For our basis $\{f_n\}$, we can indeed show that no $A > 0$ satisfies Equation 6.61. To see this let $c_n = 0$ for all n, except that $c_k = 1$. Then, $\sum_n c_n f_n = f_k = e_k/k$ and has norm $1/k$. So Equation 6.61 reads $A \le 1/k^2 \le B$ for all $k \ge 1$. This is not possible with $A > 0$.

If $\{e_n\}$, $1 \le n \le \infty$ is an orthonormal basis in an infinite dimensional Hilbert space $\mathcal{H}$, then any vector $x \in \mathcal{H}$ can be expressed uniquely as $x = \sum_{n=1}^{\infty} c_n e_n$ where

$$\|x\|^2 = \sum_{n=1}^{\infty} |c_n|^2$$

This property automatically ensures the stability of the transformations from x to $\{c_n\}$ and vice versa. The Riesz basis is defined such that this property is made more general.†

Definition of a Riesz Basis: A sequence $\{f_n\}$, $1 \le n \le \infty$ in a Hilbert space $\mathcal{H}$ is a Riesz basis if it is *complete* and constants A and B exist such that $0 < A \le B < \infty$ and

$$A \sum_{n=1}^{\infty} |c_n|^2 \le \left\| \sum_{n=1}^{\infty} c_n f_n \right\|^2 \le B \sum_{n=1}^{\infty} |c_n|^2 \tag{6.69}$$

for all choice of c_n satisfying $\sum_n |c_n|^2 < \infty$.

---

* As we make ε increasingly smaller, we may need to change N and *all coefficients* c_{kN}. Therefore, this does not imply $f_m = \Sigma_{n \ne m} c_n f_n$ for fixed $\{c_n\}$.

† For readers familiar with bounded linear transformations in Hilbert spaces, we state that a basis is a Riesz basis iff it is related on an orthonormal basis via a bounded linear transformation with bounded inverse.

In a finite dimensional Hilbert space, A and B come from the extreme eigenvalues of a nonsingular matrix $\mathbf{F}^{\dagger}\mathbf{F}$, so automatically $A > 0$ and $B < \infty$. In other words, any basis in a finite dimensional space is a Riesz basis. As Example 6.2 shows, this may not be the case in infinite dimensions.

Unconditional Basis

It can be shown that the Riesz basis is an unconditional basis, that is, any reordering of $\{f_n\}$ is also a basis (and the new c_n are the correspondingly reordered versions). This is a nontrivial statement; an arbitrary (Schauder) basis is not necessarily unconditional. In fact, the space of L^1 functions (which is a Banach space, not a Hilbert space) does not have an unconditional basis.

Role of the Constants A and B

1. *Strongest linear independence*: The condition $A > 0$ means, in particular, that $\mathbf{\Sigma}_n c_n f_n \neq 0$ unless c_n is zero for all n. This is just ω-independence. Actually the condition $A > 0$ means that the vectors $\{f_n\}$ are independent in the strongest sense (type 3), that is, $\{f_n\}$ is minimal. To see this, assume this is not the case by supposing some vector f_m is in the closure of the span of the others. Then, given arbitrary $\varepsilon > 0$ we can find N and c_{nN} satisfying Equation 6.66 with $x = f_m$. Defining $c_n = -c_{nN}$ for $n \neq m$ and $c_m = 1$, Equation 6.69 implies $A(1 + \mathbf{\Sigma}_{n \neq m} |c_{nN}|^2) \leq \varepsilon^2$. Because ε is arbitrary, this is not possible for $A > 0$.
2. *Distance between vectors:* The condition $A > 0$ also implies that no two vectors in $\{f_n\}$ can become "arbitrarily close." To see this, choose $c_k = -c_m = 1$ for some k, m and $c_n = 0$ for all other n. Then Equation 6.69 gives $2A \leq \|f_k - f_m\|^2 \leq 2B$. Thus, the distance between any two vectors is at least $\sqrt{2A}$, at most $\sqrt{2B}$.
3. *Bounded basis:* A Riesz basis is a bounded basis in the sense that $\|f_n\|$ cannot get arbitrarily large. In fact, by choosing $c_n = 0$ for all but one value of n, we can see that $0 < A \leq \|f_n\|^2 \leq B < \infty$. That is, the norms of the vectors in the basis cannot become arbitrarily small or large. Note that the basis in Example 6.2 violates this, because $\|f_n\| = 1/n$. Therefore, Example 6.2 is only a Schauder basis and not a Riesz basis.
4. *Stability of basis*. The condition $A > 0$ yields $\mathbf{\Sigma}_n |c_n|^2 \leq A^{-1} \|x\|^2$, where $x = \mathbf{\Sigma}_n c_n f_n$. This means that the transformation from the vector x to the sequence $\{c_n\}$ is bounded, so a small error in x is not amplified in an unbounded manner. Similarly, the inequality $\|x\|^2 \leq B \mathbf{\Sigma}_n |c_n|^2$ shows that role of B is to ensure that the inverse transformation from c_n to x is bounded. Summarizing, the transformation from x to $\{c_n\}$ is numerically stable (i.e., small errors not severely amplified) because $A > 0$, and the reconstruction of x from $\{c_n\}$ is numerically stable because $B < \infty$.
5. *Orthonormality:* For a Riesz basis with $A = B = 1$ the condition (Equation 6.69) reduces to $\mathbf{\Sigma}_n |c_n|^2 = \|\mathbf{\Sigma}_n c_n f_n\|^2$. It can be shown that such a Riesz is as simply an orthonormal basis. The properties listed above show that the Riesz basis is as good as orthonormal basis in most applications. Any Riesz basis can be obtained from an orthonormal basis by means of a bounded linear transformation with a bounded linear inverse.

Example 6.3: Mishaps with a System That Is Not a Riesz Basis

Let us modify Example 6.2 to $f_n = (e_n/n) + e_1$, $n \geq 1$, where $\{e_n\}$ is an orthonormal basis. As $n \to \infty$ the vectors f_n move arbitrarily closer together (although $\|f_n\|$ approaches unity from above). Formally, $f_n - f_m = (e_n/n) - (e_m/m)$, so $\|f_n - f_m\|^2 = (1/n^2) + (1/m^2)$, which goes to zero as n, $m \to \infty$. Thus there does not exist $A > 0$ satisfying Equation 6.69 (because of comment 2 above). This, then, is not a Riesz basis; in fact, this is not even a Schauder basis (see below). This example also has $B = \infty$. To see this let $c_n = 1/n$, then $\mathbf{\Sigma}_n |c_n|^2$ converges, but $\|\mathbf{\Sigma}_{n=1}^{N} c_n f_n\|^2$ does not converge as $N \to \infty$ (as we can verify), so Equation 6.69 is not satisfied for finite B. Such mishaps cannot occur with a Riesz basis.

In this example, $\{f_n\}$ is not minimal (which is type 3 independence). Note that $|f_1 - f_n|$ gets arbitrarily small as n increases to infinity, therefore, f_1 is in the closure of the span of $\{f_n\}$, $n \neq 1$. However, $\{f_n\}$ is ω-independent; no sequence $\{c_n\}$ exists such that $\|\mathbf{\Sigma}_{n=1}^{N} c_n f_n\| \to 0$ as $N \to \infty$. In

any case, the fact that $\{f_n\}$ is not minimal (i.e., not independent in the strongest sense) shows that it is not even a Schauder basis.

6.7.2 Biorthogonal Systems, Riesz Bases, and Inner Products

When discussing finite dimensional Hilbert spaces, we found that given a basis $\mathbf{f}_n$ (columns of a nonsingular matrix) we can express any vector $\mathbf{x}$ as a linear combination $\mathbf{x} = \boldsymbol{\Sigma}_n \langle \mathbf{x}, \mathbf{g}_n \rangle \mathbf{f}_n$, where $\mathbf{g}_n$ is such that the biorthogonality property $\langle \mathbf{f}_m, \mathbf{g}_n \rangle = \delta(m-n)$ holds. A similar result is true for infinite dimensional Hilbert spaces.

THEOREM 6.4: Biorthogonality and Riesz Basis

Let $\{f_n\}$ be a basis in a Hilbert space $\mathcal{H}$. Then, there exists a unique sequence $\{g_n\}$ biorthogonal to $\{f_n\}$, that is,

$$\langle f_m, g_n \rangle = \delta(m-n) \quad \text{(biorthogonality)} \tag{6.70}$$

Moreover, the unique expansion of any $x \in \mathcal{H}$ in terms of the basis $\{f_n\}$ is given by

$$x = \sum_{n=1}^{\infty} \langle x, g_n \rangle f_n \tag{6.71}$$

It is also true that the biorthogonal sequence $\{g_n\}$ is a basis and that $x = \boldsymbol{\Sigma}_{n=1}^{\infty} \langle x, f_n \rangle g_n$. Moreover, if $\{f_n\}$ is a Riesz basis, then $\boldsymbol{\Sigma}_n |\langle x, g_n \rangle|^2$ and $\boldsymbol{\Sigma}_n |\langle x, f_n \rangle|^2$ are finite, and we have

$$A\|x\|^2 \leq \sum_{n=1}^{\infty} |\langle x, f_n \rangle|^2 \leq B\|x\|^2 \tag{6.72}$$

where A and B are the same constants as in the definition (Equation 6.69) of a Riesz basis.

This beautiful result resembles the finite dimensional version, where f_n corresponds to the column of a matrix and g_n corresponds to the rows (conjugated) of the inverse matrix. In this sense we can regard the biorthogonal pair of sequences $\{f_n\}$, $\{g_n\}$ as inverses of each other. Both are bases for $\mathcal{H}$. A proof of the above result can be obtained by combining the ideas on pages 28–32 of Ref. [24]. The theorem implies, in particular, that if $\{f_n\}$ is a Riesz basis, then any vector in the space can be written in the form $\boldsymbol{\Sigma}_{n=1}^{\infty} c_n f_n$, where $c_n \in l^2$.

Summary of Riesz Basis

The Riesz basis $\{f_n\}$ in a Hilbert space is a complete set of vectors, linearly independent in the strongest sense (i.e., type 3 or minimal). It is a bounded basis with bounded inverse. Any two vectors are separated by at least $\sqrt{2A}$, that is, $\|f_n - f_m\|^2 \geq 2A$. The norm of each basis vector is bounded as $\|f_n\| \leq \sqrt{B}$. In the expression $x = \sum_n c_n f_n$ the computation of x from c_n as well as the computation of c_n from x are numerically stable because $B < \infty$ and $A > 0$, respectively. A Riesz basis with $A = B = 1$ is an orthonormal basis. In fact, any Riesz basis can be obtained from an orthonormal basis via a bounded linear transformation with a bounded inverse. Given any basis $\{f_n\}$ in a Hilbert space, a unique biorthogonal sequence $\{g_n\}$ exists such that we can express any $x \in \mathcal{H}$ as $x = \boldsymbol{\Sigma}_{n=1}^{\infty} \langle x, g_n \rangle f_n$ as well as $x = \boldsymbol{\Sigma}_{n=1}^{\infty} \langle x, f_n \rangle g_n$; if this basis is also a Riesz basis, then $\boldsymbol{\Sigma}_n |\langle x, f_n \rangle|^2$ and $\boldsymbol{\Sigma}_n |\langle x, g_n \rangle|^2$ are finite. If $\{f_n\}$ is a Riesz basis, then any vector $x \in \mathcal{H}$ can be written in the form $x = \boldsymbol{\Sigma}_{n=1}^{\infty} c_n f_n$, where $c_n \in l^2$.

6.8 Frames in Hilbert Spaces

A frame in a Hilbert space $\mathcal{H}$ is a sequence of vectors $\{f_n\}$ with certain special properties. While a frame is not necessarily a basis, it shares some properties of a basis. For example, we can express any vector $x \in \mathcal{H}$

as a linear combination of the frame elements, i.e., $x = \Sigma_n c_n f_n$. However, frames generally have redundancy—the frame vectors are not necessarily linearly independent, even in the weakest sense defined in Section 6.7. The Riesz basis (hence, any orthonormal basis) is a special case of frames. The concept of a frame is useful when discussing the relation between wavelets, STFTs, and filter banks. Frames were introduced by Duffin and Schaeffer [25], and used in the context of wavelets and STFT by Daubechies [5]. Excellent tutorials can be found in Refs. [12,24].

6.8.1 Definition of a Frame

A sequence of vectors $\{f_n\}$ in a (possibly infinite dimensional) Hilbert space $x \in \mathcal{H}$ is a frame if there exist constants A and B with $0 < A \leq B < \infty$ such that for any $x \in \mathcal{H}$ we have

$$A\|x\|^2 \leq \sum_{n=1}^{\infty} |\langle x, f_n \rangle|^2 \leq B\|x\|^2 \tag{6.73}$$

The constants A and B are called frame bounds.

In Section 6.7, we saw that a Riesz basis, which by definition satisfies Equation 6.69 and also satisfies Equation 6.72, which is precisely the frame definition. A Riesz basis is, therefore, also a frame, but it is a special case of a frame, where the set of vectors is minimal.

Any frame is complete. That is, if a vector $x \in \mathcal{H}$ is orthogonal to all elements in $\{f_n\}$, then $x = 0$, otherwise $A > 0$ is violated. Thus, any $x \in \mathcal{H}$ is in the closure of the span of the frame. In fact, we will see that more is true; for example, we can express $x = \Sigma c_n f_n$, although $\{c_n\}$ may not be unique. The frame elements are not necessarily linearly independent, as demonstrated by examples below. A frame, then, is not necessarily a basis. Compare Equation 6.73 with the Riesz basis definition (Equation 6.69), where the left inequality forced the vectors f_n to be linearly independent (in fact, minimal). The left inequality for a frame only ensures completeness, not linear independence.

6.8.2 Representing Arbitrary Vectors in Terms of Frame Elements

We will see that, given a frame $\{f_n\}$ we can associate with it another sequence $\{g_n\}$ called the dual frame, such that any element $x \in \mathcal{H}$ can be represented as $x = \Sigma_{n=1}^{\infty} \langle x, g_n \rangle f_n$. We also can write $x = \Sigma_{n=1}^{\infty} \langle x, f_n \rangle g_n$. This representation in terms of $\{f_n\}$ and $\{g_n\}$ resembles the biorthogonal system discussed in Section 6.7, but some differences are pointed out later.

Stability of Computations

To obtain the representation $x = \sum_{n=1}^{\infty} \langle x, f_n \rangle g_n$ we compute (at least conceptually) the coefficients $\langle x, f_n \rangle$ for all n. This computation is a linear transformation from $\mathcal{H}$ to the space of sequences. The inverse transform computes x from this sequence by using the formula $x = \sum_{n=1}^{\infty} \langle x, f_n \rangle g_n$. The condition $B < \infty$ in the frame definition ensures that the transformation from x to $\langle x, f_n \rangle$ is bounded. Similarly, the condition $A > 0$ ensures that the inverse transformation, from $\langle x, f_n \rangle$ to x is bounded. The conditions $A > 0$ and $B < \infty$, therefore, ensure stability; small errors in one domain are not arbitrarily amplified in the other domain. A similar advantage was pointed out earlier for the Riesz basis—for arbitrary bases in infinite dimensional spaces such an advantage cannot be claimed (Example 6.4).

If we wish to use the dual representation $x = \sum_{n=1}^{\infty} \langle x, g_n \rangle f_n$ instead of $x = \sum_{n=1}^{\infty} \langle x, f_n \rangle g_n$, we must compute $\langle x, g_n \rangle$, etc.; the roles of A and B are taken up by $1/B$ and $1/A$, respectively, and similar discussions hold. This is summarized in Figure 6.29.

6.8.3 Exact Frames, Tight Frames, Riesz Bases, and Orthonormal Bases

The resemblance between a Riesz basis and a frame is striking. Compare Equation 6.69 with Equation 6.73. One might wonder what the precise relation is. Thus far, we know that a Riesz basis is a frame.

To go deeper, we need a definition: a frame $\{f_n\}$ which ceases to be a frame if any element f_k is deleted is said to be an exact frame. Such a frame has no redundancy. A frame with $A = B$ is said to be a tight frame. The defining property reduces to $\|x\|^2 = A^{-1}\,\mathbf{\Sigma}_n |\langle x, f_n\rangle|^2$, resembling Parseval's theorem for an orthonormal basis. A frame is *normalized* if $\|f_n\| = 1$ for all n. The following facts concerning exact frames and tight frames are fundamental:

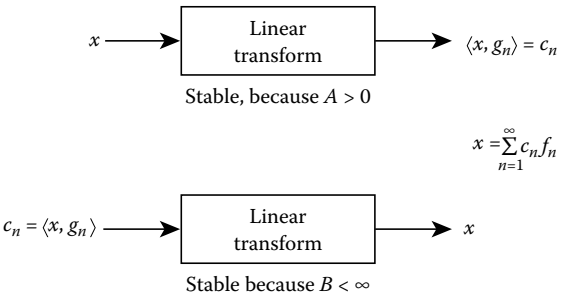

FIGURE 6.29 Representation of x using frame elements $\{f_n\}$. The transformation from x to $\{c_n\}$ and vice versa are stable.

1. A tight frame with $A = B = 1$ and $\|f_n\| = 1$ for all n (i.e., a normalized tight frame with frame bound = 1) is an orthonormal basis [5].
2. $\{f_n\}$ is an exact frame iff it is a Riesz basis [24]. Moreover, if a frame is not exact then it cannot be a basis [12]. *Thus, if a frame is a basis, it is certainly a Riesz basis.*
3. Because an orthonormal basis is a Riesz basis, a normalized tight frame with frame bound equal to 1 is automatically an exact frame.

Some examples follow that serve to clarify the preceding concepts and definitions. In these examples, the sequence $\{e_n\}$, $n \geq 1$ is an orthonormal basis for $\mathcal{H}$. Thus, $\{e_n\}$ is a tight frame with $A = B = 1$, and $\|e_n\| = 1$.

Example 6.4

Let $f_n = e_n/n$ as in Example 6.2. Then $\{f_n\}$ is still a (Schauder) basis for $\mathcal{H}$, but it is not a frame. In fact, this satisfies Equation 6.73 only with $A = 0$; i.e., the inverse transformation (reconstruction) from $\langle x, f_n\rangle$ to x is not bounded. To see why $A = 0$, note that if we let $x = e_k$ for some $k > 0$ then $\|x\| = 1$, whereas $\mathbf{\Sigma}_n |\langle x, f_n\rangle|^2 = 1/k^2$. The first inequality in the frame definition becomes $A \leq 1/k^2$, which cannot be satisfied for all k unless $A = 0$. In this example a finite B works because $|\langle x, f_n \rangle| = |\langle x, e_n \rangle|/n$ for each n. Therefore, $\mathbf{\Sigma}_n |\langle x, f_n\rangle|^2 \leq \mathbf{\Sigma}_n |\langle x, e_n\rangle|^2 = \|x\|^2$.

Example 6.5

Suppose we modify the above example as follows: define $f_n = (e_n/n) + e_1$. We know that this is no longer a basis (Example 3). We now have $B = \infty$ in the frame definition, so this is not a frame. To verify this, let $x = e_1$ so $\|x\| = 1$. Then $\langle x, f_n\rangle = 1$ for all $n > 1$, so $\mathbf{\Sigma}_n |\langle x, f_n \rangle|^2$ does not converge to a finite value.

Example 6.6

Consider the sequence of vectors $\{e_1, e_1, e_2, e_2, \ldots\}$. This is a tight frame with frame bounds $A = B = 2$. Note that, even though the vectors are normalized and the frame is tight, this is not an orthonormal basis. This has a redundancy of two in the sense that each vector is repeated twice. This frame is not even a basis, therefore, it is not a Riesz basis.

Example 6.7

Consider the sequence of vectors $\{e_1, (e_2/\sqrt{2}), (e_2/\sqrt{2}), (e_3/\sqrt{3}), (e_3/\sqrt{3}), (e_3/\sqrt{3}), \ldots\}$. Again, redundancy occurs, so it is not a basis. It is a tight frame with $A = B = 1$, but not an exact frame, and clearly not a basis. It has redundancy (repeated vectors).

Frame Bounds and Redundancy

For a tight frame with unit norm vectors f_n, the frame bound measures the redundancy. In Example 6.6 the redundancy is two (every vector repeated twice), and indeed $A = B = 2$. In Example 6.7, where we still have redundancy, the frame bound $A = B = 1$ does not indicate it. The frame bound of a tight frame measures redundancy only if the vectors f_n have unit norm as in Example 6.6.

6.8.4 Frame Operator, Dual Frame, and Biorthogonality

The frame operator $\mathcal{F}$ associated with a frame $\{f_n\}$ in a Hilbert space $\mathcal{H}$ is a linear operator defined as

$$\mathcal{F}x = \sum_{n=1}^{\infty} \langle x, f_n \rangle f_n \tag{6.74}$$

The summation can be shown to be convergent by using the definition of the frame. The frame operator $\mathcal{F}$ takes a vector $x \in \mathcal{H}$ and produces another vector in $\mathcal{H}$. The norm of $\mathcal{F}$ x is bounded as follows:

$$A\|x\| \leq \|\mathcal{F}x\| \leq B\|x\| \tag{6.75}$$

The frame operator is a bounded linear operator (because $B < \infty$; hence, it is a continuous operator [12]. Its inverse is also a bounded linear operator because $A > 0$).

From Equation 6.74 we obtain $\langle \mathcal{F}x, x \rangle = \Sigma_n |\langle x, f_n \rangle|^2$ by interchanging the inner product with the infinite summation. This is permitted by the continuity of the operator $\mathcal{F}$ and the continuity of inner products (Section 6.6). Because $\{f_n\}$ is complete, the right-hand side is positive for $x \neq 0$. Thus, $\langle \mathcal{F}x, x \rangle > 0$ unless $x = 0$, that is, $\mathcal{F}$ is a positive definite operator. The realness of $\langle \mathcal{F}x, x \rangle$ also means that $\mathcal{F}$ is self-adjoint, or $\langle \mathcal{F}x, y \rangle = \langle x, \mathcal{F}y \rangle$ for any $x, y \in \mathcal{H}$.

The importance of the frame operator arises from the fact that if we define $g_n = \mathcal{F}^1 f_n$, any $x \in \mathcal{H}$ can be expressed as

$$x = \sum_{n=1}^{\infty} \langle x, g_n \rangle f_n = \sum_{n=1}^{\infty} \langle x, f_n \rangle g_n \tag{6.76}$$

The sequence $\{g_n\}$ is itself a frame in $\mathcal{H}$ called the dual frame. It has frame bounds B^{-1} and A^{-1}. Among all representations of the form $x = \Sigma_n c_n f_n$, the representation $x = \Sigma_n \langle x, g_n \rangle f_n$ possesses the special property that the energy of the coefficients is minimized, i.e., $\Sigma_n |\langle x, g_n \rangle|^2 \leq \Sigma_n |c_n|^2$ with equality iff $c_n = \langle x, g_n \rangle$ for all n [12]. As argued earlier, the computation of $\langle x, f_n \rangle$ from x and the inverse computation of x from $\langle x, f_n \rangle$ are numerically stable operations because $B < \infty$ and $A > 0$, respectively.

For the special case of a tight frame ($A = B$), the frame operator is particularly simple. We have $\mathcal{F}x = Ax$, and so $g_n = \mathcal{F}^{-1} f_n = f_n / A$. Any vector $x \in \mathcal{H}$ can be expressed as

$$x = \frac{1}{A} \sum_{n=1}^{\infty} \langle x, f_n \rangle f_n \quad \text{(tight frames)} \tag{6.77}$$

Notice also that Equation 6.73 gives

$$\sum_{n=1}^{\infty} |\langle x, f_n \rangle|^2 = A\|x\|^2 \quad \text{(tight frames)} \tag{6.78}$$

For a tight frame with $A = 1$, these equations resemble the representation of x using an orthonormal basis, even though such a tight frame is not necessarily a basis because of possible redundancy (Example 6.7).

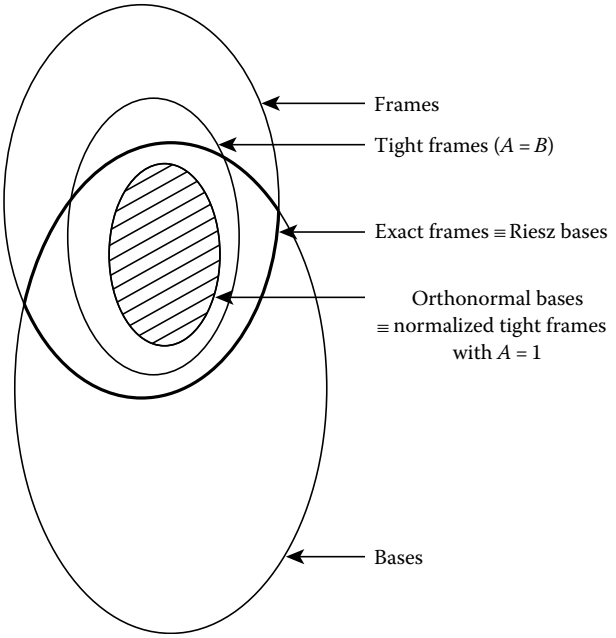

FIGURE 6.30 Venn diagram showing the relation between frames and bases in a Hilbert space.

Exact Frames and Biorthogonality

For the special case of an exact frame (i.e., a Riesz basis) the sequence $\{f_n\}$ is minimal, and it is biorthogonal to the dual frame sequence $\{g_n\}$. This is consistent with our observation at the end of Section 6.7.

Summary of Frames

A sequence of vectors $\{f_n\}$ in a Hilbert space $\mathcal{H}$ is a frame if there exist constants $A > 0$ and $B < \infty$ such that Equation 6.73 holds for every vector $x \in \mathcal{H}$. Frames are complete (because $A > 0$), but not necessarily linearly independent. The constants A and B are called the frame bounds. A frame is *tight* if $A = B$. A tight frame with $A = B = 1$ and with normalized vectors ($\|f_n\| = 1$) is an orthonormal basis. For a tight frame with $\|f_n\| = 1$, the frame bound A measures redundancy. Any vector $x \in \mathcal{H}$ can be expressed in either of the two ways shown in Equation 6.76. Here, $g_n = \mathcal{F}^{-1} f_n$, where $\mathcal{F}$ is the frame *operator* defined in Equation 6.74. The frame operator is a bounded linear operator and is self-adjoint (in fact, positive). The sequence $\{g_n\}$ is the dual frame and has frame bounds B^{-1} and A^{-1}. For a tight frame the frame representation reduces to Equation 6.77. A frame is *exact* if deletion of any vector f_m destroys the frame property. A sequence $\{f_n\}$ is an exact frame iff it is a Riesz basis. An exact frame $\{f_n\}$ is biorthogonal to the dual frame $\{g_n\}$.

Figure 6.30 is a Venn diagram, which shows the classification of frames and bases and the relationship between these.

6.9 Short-Time Fourier Transform: Invertibility, Orthonormality, and Localization

In Section 6.8, we saw that a vector x in an infinite dimensional Hilbert space (e.g., a function $x(t)$ in L^2) can be expanded in terms of a sequence of vectors $\{f_n\}$ called a frame, that is $x = \sum_{n=1}^{\infty} \langle x, g_n \rangle f_n$. One of the most important features of frames is that the construction of the expansion coefficients $\langle x, g_n \rangle$ from x as well as the reconstruction of x from these coefficients are numerically stable operations

because $A > 0$ and $B < \infty$ (Section 6.8). Riesz and orthonormal bases, which are special cases of a frame (Figure 6.30), also share this numerical stability.

In Section 6.3, we attempted to represent an L^2 function in terms of the STFT. The STFT coefficients are constructed using the integral (Equation 6.24). Denote for simplicity

$$g_{kn}(t) = v^*(t - nT_s)e^{jk\omega_s t} \tag{6.79}$$

The computation of the STFT coefficients can be written as

$$X_{\text{STFT}}(k\omega_s, nT_s) = \langle x(t), g_{kn}(t)\rangle \tag{6.80}$$

This is a linear transformation which converts $x(t)$ into a two-dimensional sequence because k and n are integers. Our hope is to be able to reconstruct $x(t)$ using an inverse linear transformation (inverse STFT) of the form

$$x(t) = \sum_{k=-\infty}^{\infty}\sum_{n=-\infty}^{\infty} X_{\text{STFT}}(k\omega_s, nT_s)f_{kn}(t) \tag{6.81}$$

We know that this can be done in a numerically stable manner if $\{g_{kn}(t)\}$ is a frame in L^2 and $\{f_{kn}(t)\}$ is the dual frame. The fundamental questions, then, are under what conditions does $\{g_{kn}(t)\}$ constitute a frame? Under what further conditions does this become a Riesz basis, better still, an orthonormal basis? With such conditions, what are the time–frequency localization properties of the resulting STFT? The answers depend on the window $v(t)$ and the sample spacings ω_s and T_s.

We first construct a very simple example which shows the existence of orthonormal STFT bases, and indicate a fundamental disadvantage in the example. We then state the answers to the above general questions without proof. Details can be found in Refs. [5,12,16].

Example 6.8: Orthonormal Short-Time Fourier Transform Basis

Suppose $v(t)$ is the rectangular window shown in Figure 6.31, applied to an L^2 function $x(t)$. The product $x(t)v(t)$ therefore has finite duration. If we sample its FT at the rate $\omega_s = 2\pi$ we can recover $x(t)v(t)$ from these samples (this is like a Fourier series of the finite duration waveform $x(t)v(t)$). Shifting the window by successive integers (i.e., $T_s = 1$), we can in this way recover successive pieces of $x(t)$ from the STFT, with sample spacing $\omega_s = 2\pi$ in the frequency domain. Thus, the choice $T_s = 1$ and $\omega_s = 2\pi$ (so, $\omega_s T_s = 2\pi$) leads to an STFT $X_{\text{STFT}}(k\omega_s, nT_s)$, from which we can reconstruct $x(t)$ for all t. The quantity $g_{kn}(t)$ becomes

$$g_{kn}(t) = v(t - n)e^{jk\omega_s t} = v(t - n)e^{j2\pi kt} \tag{6.82}$$

Because the successive shifts of the window do not overlap, the functions $g_{kn}(t)$ are orthonormal for different values of n. The functions are also orthonormal for different values of k. Summarizing, the rectangular window of Figure 6.31, with the time–frequency sampling durations $T_s = 1$ and $\omega_s = 2\pi$, produces an orthonormal STFT basis for L^2 functions.

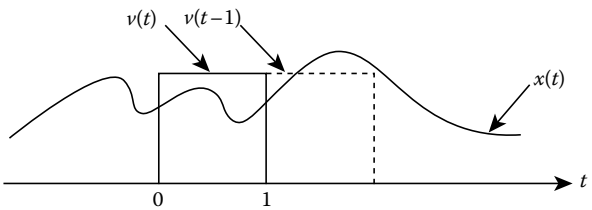

FIGURE 6.31 Rectangular window in STFT.

This example is reminiscent of the Nyquist sampling theorem in the sense that we can reconstruct $x(t)$ from (time–frequency) samples, but the differences are that $x(t)$ is an L^2 signal, not necessarily

band-limited. Note that T_s and ω_s cannot be arbitrarily interchanged (even if $\omega_s T_s = 2\pi$ is preserved). Thus, if we had chosen $T_s = 2$ and $\omega_s = \pi$ (preserving the product $\omega_s T_s$) we would not have obtained a basis because two successive positions of the window would be spaced too far apart and we would miss 50% of the signal $x(t)$.

6.9.1 Time–Frequency Sampling Density for Frames and Orthonormal Bases

Let us assume that $v(t)$ is normalized to have unit energy, i.e., $\int |v(t)|^2 \, dt = 1$ so that $\| g_{kn}(t) \| = 1$ for all k, n. If we impose the condition that $g_{kn}(t)$ be a frame, then it can be shown that the frame bounds satisfy the condition

$$A \leq \frac{2\pi}{\omega_s T_s} \leq B \tag{6.83}$$

regardless of how $v(t)$ is chosen. As an orthonormal basis is a tight frame with $A = B = 1$, an STFT orthonormal basis must therefore have $\omega_s T_s = 2\pi$.

It can further be shown that if $\omega_s T_s > 2\pi$, $\{g_{kn}(t)\}$ cannot be a frame. For $\omega_s T_s < 2\pi$, we can find frames (but not orthonormal basis) by appropriate choice of window $v(t)$. The critical time–frequency sampling density is $(\omega_s T_s)^{-1} = (2\pi)^{-1}$. If the density is smaller we cannot have frames, and if it is larger we cannot have orthonormal basis, only frames.

6.9.1.1 Orthonormal Short-Time Fourier Transform Bases Have Poor Time–Frequency Localization

If we wish to have an orthonormal STFT basis, the time–frequency density is constrained so that $\omega_s T_s = 2\pi$. Under this condition suppose we choose $v(t)$ appropriately to design such a basis. The time–frequency localization properties of this system can be judged by computing the mean square durations D_t^2 and D_f^2 defined in Equation 6.27 It has been shown by Balian and Low [5,16] that one of these is necessarily infinite no matter how $v(t)$ is designed. Thus, an orthonormal STFT basis always satisfies $D_t D_f = \infty$. That is, either the time localization or the frequency resolution is very poor. This is summarized in the following theorem.

THEOREM 6.5

Let the window $v(t)$ be such that $\{g_{kn}(t)\}$ in Equation 6.79 is an orthonormal basis for L^2 (which means, in particular, that $\omega_s T_s = 2\pi$). Define the RMS durations D_t and D_f for the window $v(t)$ as usual (Equation 6.27). Then, either $D_t = \infty$ or $D_f = \infty$.

Return now to Example 6.8, where we constructed an orthonormal STFT basis using the rectangular window of Figure 6.31. Here, $T_s = 1$ and $\omega_s = 2\pi$ so that $\omega_s T_s = 2\pi$. The window $v(t)$ has finite mean square duration D_t^2. Its FT $V(\omega)$ has magnitude $|V(\omega)| = |\sin(\omega/2)/(\omega/2)|$ so that $\int \omega^2 |V(\omega)|^2 \, d\omega$ is not finite. This demonstrates the result of Theorem 6.5. One can try to replace the window $v(t)$ with something for which $D_t D_f$ is finite, but this cannot be done without violating orthonormality.

6.9.1.2 Instability of the Gabor Transform

Gabor constructed the STFT using the Gaussian window $v(t) = ce^{-t^2/2}$. In this case the sequence of functions $\{g_{kn}(t)\}$ can be shown to be complete in L^2 (in the sense defined in Section 6.7) as long as $\omega_s T_s \leq 2\pi$. However, if $\omega_s T_s = 2\pi$ the system is not a frame because it can be shown that $A = 0$ in Equation 6.73. Thus, the reconstruction of $x(t)$ from $X_{STFT}(k\omega_s, nT_s)$ is unstable if $\omega_s T_s = 2\pi$ (Section 6.8), even though $\{g_{kn}(t)\}$ is complete. Although the Gabor transform has the ideal time–frequency

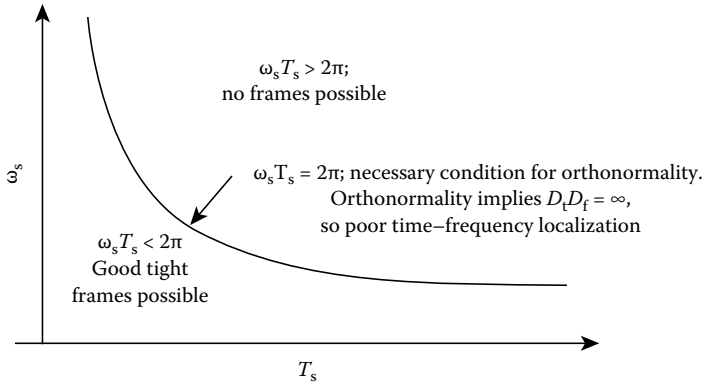

FIGURE 6.32 Behavior of STFT representation for various regions of time–frequency sampling product $\omega_s T_s$. The curve $\omega_s T_s = 2\pi$ is critical; see text.

localization (minimum D_t D_f), it cannot provide a *stable basis*; hence, it is certainly not an orthonormal basis, whenever $\omega_s T_s = 2\pi$.

Because orthonormal STFT basis is not possible if $\omega_s T_s \neq 2\pi$, this shows that an orthonormal basis can never be achieved with the Gabor transform (Gaussian windowed STFT), no matter how we choose ω_s and T_s. The Gabor example also demonstrates the fact that even if we successfully construct a complete set of functions (not necessarily a basis) to represent $x(t)$, it may not be useful because of the instability of reconstruction. If we construct Riesz bases (e.g., orthonormal bases) or more generally frames, this disadvantage disappears. For example, with the Gabor transform if we let $\omega_s T_s < 2\pi$ then all is well. We obtain a frame (so $A > 0$ and $B < \infty$ in Equation 6.73); we have stable reconstruction and good time–frequency localization, but not orthonormality. Figure 6.32 summarizes these results pertaining to the time–frequency product $\omega_s T_s$ in the STFT.

A major advantage of the WT over the STFT is that it is free from the above difficulties. For example, we can obtain an orthonormal basis for L^2 with excellent time–frequency localization (finite, controllable $D_t D_f$). We will also see how to constrain such a wavelet $\psi(t)$ to have the additional property of regularity or smoothness. Regularity is a property which is measured by the continuity and differentiability of $\psi(t)$. More precisely, it is quantified by the Hölder index (defined in Section 6.13). In the next few sections where we construct wavelets based on paraunitary filter banks, we will see how to achieve all this systematically.

6.10 Wavelets and Multiresolution

Sections 6.11 through 6.13 show how to construct compactly supported wavelets systematically to obtain orthonormal bases for L^2. The construction is such that excellent time–frequency localization is possible. Moreover, the smoothness or regularity of the wavelets can be controlled. The construction is based on the two-channel paraunitary filter bank described in Section 6.4. In that section, we denoted the synthesis filters as $G_s(z)$ and $H_s(z)$, with impulse response $g_s(n)$ and $h_s(n)$, respectively.

All constructions are based on obtaining the wavelet $\psi(t)$ and an auxiliary function $\phi(t)$, called the scaling function, from the impulse response sequences $g_s(n)$ and $h_s(n)$. We do this by using time domain recursions of the form

$$\phi(t) = 2\sum_{n=-\infty}^{\infty} g_s(n)\phi(2t-n), \quad \psi(t) = 2\sum_{n=-\infty}^{\infty} h_s(n)\phi(2t-n) \tag{6.84}$$

called dilation equations. Equivalently, in the frequency domain

$$\Phi(\omega) = G_s(e^{j\omega/2})\Phi(\omega/2), \quad \Psi(\omega) = H_s(e^{j\omega/2})\Phi(\omega/2) \tag{6.85}$$

If $\{G_s(z), H_s(z)\}$ is a paraunitary pair with further mild conditions (e.g., that the low-pass filter $G_s(e^{j\omega})$ has a zero at π and no zeroes in $[0, \pi/3]$) the preceding recursions can be solved to obtain $\psi(t)$, which gives rise to an orthonormal wavelet basis $\{2^{k/2}\psi(2^k t - n)\}$ for L^2. By constraining $G_s(e^{j\omega})$ to have a sufficient number of zeroes at π we can further control the Hölder index (or regularity) of $\psi(t)$ (Section 6.13).

Our immediate aim is to explain the occurrence of the function $\phi(t)$, and the curious recursions (Equation 6.84) called the dilation equations or two-scale equations. These have origin in the beautiful theory of multiresolution for L^2 spaces [4,11]. Because multiresolution theory lays the foundation for the construction of the most practical wavelets to date, we give a brief description of it here.

6.10.1 Idea of Multiresolution

Return to Figure 6.13a, where we interpreted the wavelet transformation as a bank of continuous time analysis filters followed by samples, and the inverse transformation as a bank of synthesis filters. Assume for simplicity the filters are ideal bandpass. Figure 6.13b is a sketch of the frequency responses. The bandpass filters $F_k(\omega) = 2^{-k/2}\psi(\omega/2^k)$ become increasingly narrow as k decreases (i.e., as k becomes more and more negative). Instead of letting k be negative, suppose we keep only $k \geq 0$ and include a low-pass filter $\Phi(\omega)$ to cover the low frequency region. Then, we get the picture of Figure 6.33. This is analogous to Figure 6.12, where we used the pulse function $\phi(t)$ instead of using negative k in $\psi(2^k t - n)$.

Imagine for a moment that $\Phi(\omega)$ is an ideal low-pass filter with cutoff $\pm\pi$. Then we can represent any L^2 function $F(\omega)$ with support restricted to $\pm\pi$ in the form $F(\omega) = \sum_{n=-\infty}^{\infty} a_n \Phi(\omega)e^{-j\omega n}$. This is simply the FS expansion of $F(\omega)$ in $[-\pi, \pi]$, and it follows that $\sum_n |a_n|^2 < \infty$ (Theorem 6.1). In the time domain, this means

$$f(t) = \sum_{n=-\infty}^{\infty} a_n \phi(t - n) \tag{6.86}$$

Let us denote by V_0 the closure of the span of $\{\phi(t-n)\}$. Thus, V_0 is the class of L^2 signals that are band-limited to $[-\pi, \pi]$. Because $\phi(t)$ is the sinc function, the shifted functions $\{\phi(t-n)\}$ form an orthonormal basis for V_0.

Consider now the subspace $W_0 \subset L^2$ of bandpass functions band-limited to $\pi < |\omega| \leq 2\pi$. The bandpass sampling theorem (Section 6.2) allows us to reconstruct such a bandpass signal $g(t)$ from its samples $g(n)$ by using the ideal filter $\Psi(\omega)$. Denoting the impulse response of $\Psi(\omega)$ by $\psi(t)$ we see

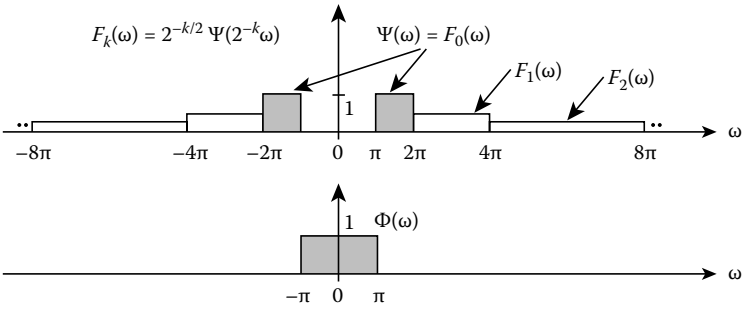

FIGURE 6.33 Low-pass function $\Phi(\omega)$, bandpass function $\Psi(\omega)$, and stretched bandpass filters $F_k(\omega)$.

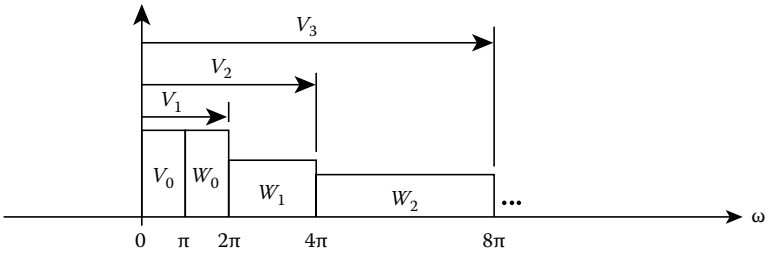

FIGURE 6.34 Toward multiresolution analysis. The spaces $\{V_k\}$ and $\{W_k\}$ spanned by various filter responses.

that $\{\psi(t-n)\}$ spans W_0. It can be verified that $\{\psi(t-n)\}$ is an orthonormal basis for W_0. Moreover, as $\Psi(\omega)$ and $\Phi(\omega)$ do not overlap, it follows from Parseval's theorem that W_0 is orthogonal to V_0.

Next, consider the space of all signals of the form $f(t)+g(t)$, where $f(t) \in V_0$ and $g(t) \in W_0$. This space is called the direct sum (in this case, orthogonal sum) of V_0 and W_0, and is denoted as $V_1 = V_0 \oplus W_0$. It is the space of all L^2 signals band limited to $[-2\pi, 2\pi]$. We can continue in this manner and define the spaces V_k and W_k for all k. Then, V_k is the space of all L^2 signals band limited to $[-2^k\pi, 2^k\pi]$, and W_k is the space of L^2 functions band limited to $2^k\pi < |\omega| \leq 2^{k+1}\pi$. The general recursive relation is $V_{k+1} = V_k \oplus W_k$. Figure 6.34 demonstrates this for the case in which the filters are ideal bandpass. Only the positive half of the frequency axis is shown for simplicity.

It is clear that we could imagine V_0 itself to be composed of subspaces V_{-1} and W_{-1}. Thus, $V_0 = V_{-1} \oplus W_{-1}$, $V_{-1} = V_{-2} \oplus W_{-2}$, and so forth. In this way, we have defined a sequence of spaces $\{V_k\}$ and $\{W_k\}$ for all integers k such that the following conditions are true:

$$V_{k+1} = V_k \oplus W_k, \quad W_k \perp W_m, \quad k \neq m \tag{6.87}$$

where $\perp$ means "orthogonal," i.e., the functions in W_k are orthogonal to those in W_m. It is clear that $V_k \subset V_{k+1}$.

We will see later that even if the ideal filters $\Phi(\omega)$ and $\Psi(\omega)$ *are replaced with nonideal approximations*, we can sometimes define sequences of subspaces V_k and W_k satisfying the above conditions. The importance of this observation is that *whenever* $\Psi(\omega)$ *and* $\Phi(\omega)$ are such that we can construct such a subspace structure, the impulse response $\psi(t)$ of the filter $\Psi(\omega)$ can be used to generate an orthonormal wavelet basis. Although this might appear to be too complicated and convoluted, we will see that the construction of the function $\phi(t)$ is quite simple and elegant, and simplifies the construction of orthonormal wavelet bases. A realization of these ideas based on paraunitary filter banks is presented in Section 6.11. It is now time to be more precise with definitions as well as statements of the results.

6.10.2 Definition of Multiresolution Analysis

Consider a sequence of closed subspaces $\{V_k\}$ in L^2, satisfying the following six properties:

1. *Ladder property*: $\cdots V_{-2} \subset V_{-1} \subset V_0 \subset V_1 \subset V_2 \cdots$.
2. $\bigcap_{k=-\infty}^{\infty} V_k = \{0\}$.
3. Closure of $\bigcup_{k=-\infty}^{\infty} V_k$ is equal to L^2.
4. *Scaling property*: $x(t) \in V_k$ iff $x(2t) \in V_{k+1}$. Because this implies "x(t) $\in V_0$ iff $x(2^k t) \in V_k$," all the spaces V_k are scaled versions of the space V_0. For $k > 0$, V_k is a *finer space* than V_0.
5. *Translation invariance*: If $x(t) \in V_0$, then $x(t-n) \in V_0$; that is, the space V_0 is invariant to translations by integers. By the previous property, this means that V_k is invariant to translations by $2^{-k}n$.

6. *Special orthonormal basis*: A function $\phi(t) \in V_0$ exists such that the integer shifted versions $\{\phi(t-n)\}$ form an orthonormal basis for V_0. Employing property 4, this means that $\{2^{k/2}\phi(2^k t-n)\}$ is an orthonormal basis for V_k. The function $\phi(t)$ is called the scaling function of multiresolution analysis.

Comments on the Definition

Notice that the scaling function $\phi(t)$ determines V_0, hence all V_k. We say that $\phi(t)$ generates the entire multiresolution analysis $\{V_k\}$. The sequence $\{V_k\}$ is said to be a ladder of subspaces because of the inclusion property $V_k \subset V_{k+1}$. The technical terms closed and closure, which originate from metric space theory, have simple meanings in our context because L^2 is a Hilbert space. Thus, the subspace V_k is "closed" if the following is true: whenever a sequence of functions $\{f_n(t)\} \in V_k$ converges to a limit $f(t) \in L^2$ (i.e., $\|f(t)-f_n(t)\| \to 0$ as $n \to \infty$), the limit $f(t)$ is in V_k itself. In general, an infinite union of closed sets is not closed, which is why we need to take "closure" in the third property on page 187. The third property simply means that any element $x(t)L^2$ can be approximated arbitrary closely (in the L^2 norm sense) by an element in $\bigcup_{k=-\infty}^{\infty} V_k$.

General Meaning of W_k

In the general setting of the previous definition, the subspace W_k is defined as the orthogonal complement of V_k with respect to V_{k+1}. Thus, the relation $V_{k+1} = V_k \oplus W_k$, which was valid in the ideal bandpass case (Figure 6.34), continues to hold.

Haar Multiresolution

A simple example of multiresolution in which $\Phi(\omega)$ is not ideal low-pass is the Haar multiresolution, generated by the function $\phi(t)$ in Figure 6.35a. Here, V_0 is the space of all functions that are piecewise constants on intervals of the form $[n, n+1]$. We will see later that the function $\psi(t)$ associated with this example is as in Figure 6.35b—the space W_0 is spanned by $\{\psi(t-n)\}$. The space V_k contains functions that are constants in $[2^{-k}\, n,\ 2^{-k}\,(n+1)]$. Figure 6.35c and d shows examples of functions belonging to V_0 and V_1. For this example, the six properties in the definition of multiresolution are particularly clear (except perhaps property 3, which also can be proved).

The multiresolution analysis generated by the ideal bandpass filters (Figures 6.33 and 6.34) is another simple example, in which $\phi(t)$ is the sinc function. We see that the two elementary orthonormal wavelet examples (Haar wavelet and the ideal bandpass wavelet) also generate a corresponding multiresolution analysis. The connection between wavelets and multiresolution is deeper than this, and is elaborated in the following section.

Derivation of the Dilation Equation

Because $\{\sqrt{2}\phi(2t-n)\}$ is an orthonormal basis for V_1 (see p. 6-53), and because $\phi(t) \in V_0 \subset V_1, \phi(t)$ can be expressed as a linear combination of the functions $\{\sqrt{2}\phi(2t-n)\}$:

$$\phi(t) = 2\sum_{n=-\infty}^{\infty} g_s(n)\phi(2t-n) \qquad (6.88)$$

(dilation equation)

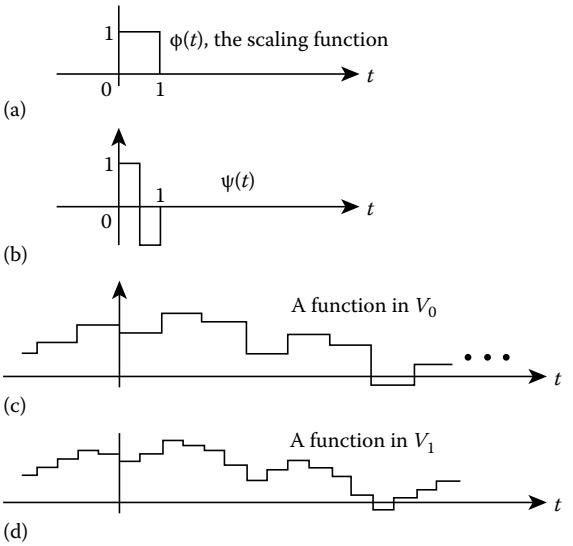

FIGURE 6.35 Harr multiresolution example. (a) The scaling function $\phi(t)$ that generates multiresolution, (b) the function $\psi(t)$ that generates W_0, (c) example of a member of V_0, and (d) example of a member of V_1.

Thus, the dilation equation arises naturally out of the multiresolution condition. For example, the Haar scaling function $\phi(t)$ satisfies the dilation equation

$$\phi(t) = \phi(2t) + \phi(2t-1) \tag{6.89}$$

The notation $g_s(n)$ and the factor 2 in the dilation equation might appear arbitrary now, but are convenient for future use. Orthonormality of $\{\phi(t-n)\}$ implies that $\|\phi(t)\| = 1$, and that $\{\sqrt{2}\phi(2t-n)\}$ are orthonormal. Therefore, $\Sigma_n |g_s(n)|^2 = 0.5$ from Equation 6.88.

Example 6.9: Nonorthonormal Multiresolution

Consider the triangular function shown in Figure 6.36a. This has $\|\phi(t)\| = 1$ and satisfies the dilation equation

$$\phi(t) = \phi(2t) + 0.5\phi(2t-1) + 0.5\phi(2t+1) \tag{6.90}$$

as demonstrated in Figure 6.36b. With V_k denoting the closure of the span of $\{2^{k/2}\phi(2^k t - n)\}$ it can be shown that the spaces $\{V_k\}$ satisfy all the conditions in the multiresolution definition, except one. Namely, $\{\phi(t-n)\}$ does not form an orthonormal basis (for example, compare $\phi(t)$ and $\phi(t-1)$). We will see later (Example 6.10) that it does form a Riesz basis and that it can be converted into an orthonormal basis by orthonormalization. This example is a special case of a family of scaling functions called spline functions [15].

We will see below that starting from an orthonormal multiresolution system (in particular from the function $\phi(t)$) one can generate an orthonormal wavelet basis for L^2. The wavelet bases generated from splines $\phi(t)$ after orthonormalization are called spline wavelets [15]. These are also called the Battle–Lemarié family of wavelets. The link between multiresolution analysis and wavelets is explained quantitatively in Section 6.10.3.

Multiresolution Approximation of L^2 Functions

Given a multiresolution analysis, we know that $\bigcap_{k=-\infty}^{\infty} V_k = \{0\}$ and that the closure of $\bigcup_{k=-\infty}^{\infty} V_k = L^2$. From this it can be shown that the W_k make up the entire L^2 space, that is

$$L^2 = \bigoplus_{k=-\infty}^{\infty} W_k \tag{6.91a}$$

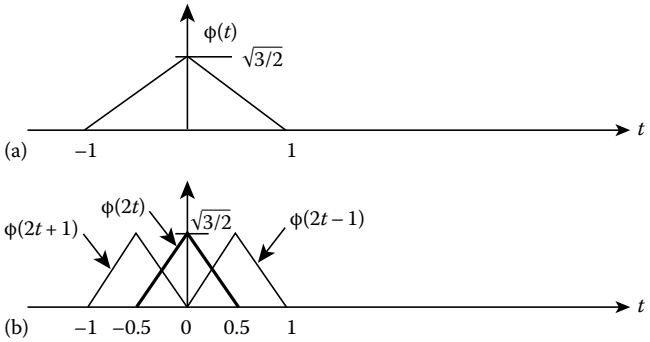

FIGURE 6.36 Example of a scaling function $\phi(t)$ generating nonorthogonal multiresolution. (a) The scaling function and (b) demonstrating the dilation equation.

We can approximate an arbitrary L^2 function $x(t)$ to a certain degree of accuracy by projecting it onto V_k for appropriate k. Thus, let $x_k(t)$ be this orthogonal projection (Section 6.2). Suppose we increase k to $k+1$. Because $V_{k+1} = V_k \oplus W_k$ and W_k is orthogonal to V_k, we see that the new approximation $x_{k+1}(t)$ (projection onto the finer space V_{k+1}) is given by $x_{k+1}(t) = x_k(t) + y_k(t)$, where $y_k(t)$ is in W_k.

Thus, when we go from scale k to scale $k+1$ we go to a larger space $V_{k+1} \supset V_k$, which permits a finer approximation. This is nicely demonstrated in the two extreme examples mentioned previously. For the example with ideal filters (Figures 6.33 and 6.34), the process of passing from scale k to $k+1$ is like admitting higher frequency components, which are orthogonal to the existing low-pass components. For the Haar example (Figure 6.35) where $\psi(t)$ and $\phi(t)$ are square pulses, when we pass from k to $k+1$ we permit finer pulses (i.e., highly localized finer variations in the time domain). For this example, Figure 6.35c and d demonstrates the projections $x_k(t)$ and $x_{k+1}(t)$ at two successive resolutions. The projections are piecewise-constant approximations of an L^2 signal $x(t)$.

By repeated application of $V_{k+1} = V_k \oplus W_k$, we can express V_0 as

$$V_0 = \bigoplus_{k=-\infty}^{-1} W_k \tag{6.91b}$$

which, together with Equation 6.91a, yields

$$L^2 = V_0 \oplus W_0 \oplus W_1 \oplus W_2 \oplus \cdots \tag{6.91c}$$

This has a nice interpretation based on Figure 6.34. The L^2 signal $x(t)$ has been decomposed into orthogonal components belonging to V_0 (low-pass component), W_0 (bandpass component), W_1 (bandpass with higher bandwidth and center frequency), etc.

We can find an infinite number of multiresolution examples by choosing $\phi(t)$ appropriately. It is more important now to obtain systematic techniques for constructing such examples. The quality of the example is governed by the quality of $\psi(t)$ and $\phi(t)$—the time localization and frequency resolution they can provide, the smoothness (regularity) of these functions, and the ease with which we can implement these approximations.

6.10.3 Relation between Multiresolution and Wavelets

Suppose $\phi(t) \in L^2$ generates an orthonormal multiresolution $\{V_k\}$, as defined in Section 6.10.2. We know $\phi(t) \in V_0$ and that $\{\phi(t-n)\}$ is an orthonormal basis for V_0. Moreover, $\phi(t)$ satisfies the dilation Equation 6.88, and the sequence $\{g_s(n)\} \in \ell^2$ defines the filter $G_s(e^{j\omega})$.

Now consider the finer space $V_1 = V_0 \oplus W_0$, where W_0 is orthonormal to V_0. If $f(t) \in W_0$ then $f(t) \in V_1$, so it is a linear combination of $\sqrt{2}\phi(2t-n)$ (property 6; see definitions). Using this and the fact that W_0 is orthogonal to V_0, we can show that $F(\omega)$ (the L^2-*FT* of $f(t)$) has a special form. This is given by

$$F(\omega) = e^{j\omega/2} G_s^\star(-e^{j\omega/2}) \Phi(\omega/2) H(e^{j\omega})$$

where $H(e^{j\omega})$ is 2π-periodic. The special case of this with $H(e^{j\omega}) = 1$ is denoted $\Psi(\omega)$; that is

$$\Psi(\omega) = e^{j\omega/2} G_s^\star(-e^{j\omega/2}) \Phi(\omega/2) \tag{6.92}$$

The above definition of $\Psi(\omega)$ is equivalent to

$$\psi(t) = 2 \sum_{n=-\infty}^{\infty} (-1)^{n+1} g_s^\star(-n-1) \phi(2t-n) \quad \text{[dilation equation for } \psi(t)\text{]} \tag{6.93}$$

The function $\psi(t)$ satisfying this equation has some useful properties. First, it is in L^2. This follows from Theorem 6.2 (Riesz–Fisher Theorem), because $\sum_n |g_s(n)|^2$ is finite. It can be shown that $\psi(t-n) \in W_0$ and that $\{\psi(t-n)\}$ is an orthonormal basis for W_0. This implies that $\{2^{k/2}\psi(2^k\, t-n)\}$ is an orthonormal basis for W_k because $f(t) \in W_0$ iff $f\,(2^k t) \in W_k$, which is a property induced by the scaling property (property 4 in the definition of multiresolution). In view of Equation 6.91 we conclude that the sequence $\{2^{k/t}\,\psi(2^k\, t-n)\}$, with k and n varying over all integers, forms a basis for L^2. Summarizing we have the following result:

THEOREM 6.6: (Multiresolution and Wavelets)

Let $\phi(t) \in L^2$ generate an orthonormal multiresolution, i.e., a ladder of spaces $\{V_k\}$ satisfying the six properties in the definition of multiresolution; $\{\phi(t-n)\}$ is an orthonormal basis for V_0. Then, $\phi(t)$ satisfies the dilation Equation 6.88 for some $g_s(n)$ with $\Sigma_n\,|g_s(n)\,|^2 = 0.5$. Define the function $\psi(t)$ according to the dilation Equation 6.93. Then, $\psi(t) \in W_0 \subset L^2$, and $\{\psi(t-n)\}$ is an orthonormal basis for W_0. Therefore, $\{2^{k/2}\,\psi(2^k\, t-n)\}$ is an orthonormal basis for W_k, just as $\{2^{k/2}\,\phi(2^k\, t-n)\}$ is an orthonormal basis for V_k (for fixed k). Moreover, with k and n varying over all integers, the doubly indexed sequence $\{2^{k/2}\,\psi(2^k\, t-n)\}$ is an orthonormal wavelet basis for L^2.

Thus to construct a wavelet basis for L^2 we have only to construct an orthonormal basis $\{\phi(t-n)\}$ for V_0. Everything else follows from that. All proofs can be found in Refs. [5,11,15].

6.10.4 Relation between Multiresolution Analysis and Paraunitary Filter Banks

Denoting

$$h_s(n) = (-1)^{n+1} g_s^*(-1-n), \quad \text{i.e., } H_s(e^{j\omega}) = e^{j\omega} G_s^*(-e^{j\omega})$$

we see that $\phi(t)$ and $\psi(t)$ satisfy the two dilation equations in Equation 6.84. By construction, $\psi(t) \in W_0$ and $\phi(t) \in V_0$. The fact that W_0 and V_0 are mutually orthogonal subspaces can be used to show that $H_s(e^{j\omega})$ and $G_x(e^{j\omega})$ satisfy

$$G_s^*(e^{j\omega})H_s(e^{j\omega}) + !G_s^*(-e^{j\omega})H_s(-e^{j\omega}) = 0 \tag{6.94}$$

Also, orthonormality of $\{\phi(t-n)\}$ leads to the power complementary property

$$\left|G_s\left(e^{j\omega}\right)\right|^2 + \left|G_s\left(-e^{j\omega}\right)\right|^2 = 1 \tag{6.95}$$

In other words, $G_s(e^{j\omega})$ is a power symmetric filter. That is, the filter $|G_s(e^{j\omega})|^2$ is a half-band filter. Using $H_s(e^{j\omega}) = e^{j\omega}G_s(-e^{j\omega})$, we also have

$$\left|H_s\left(e^{j\omega}\right)\right|^2 + \left|H_s\left(-e^{j\omega}\right)\right|^2 = 1 \tag{6.96}$$

A compact way to express the above three equations is by defining the matrix

$$\mathbf{G}_s(e^{j\omega}) = \begin{bmatrix} G_s(e^{j\omega}) & H_s(e^{j\omega}) \\ G_s(-e^{j\omega}) & H_s(-e^{j\omega}) \end{bmatrix}$$

The three properties in Equations 6.94 through 6.96 are equivalent to $\mathbf{G}_s^{\dagger}(e^{\ j\omega})\mathbf{G}_s(e^{j\omega}) = \mathbf{I}$; i.e., the matrix $\mathbf{G}_s(e^{j\omega})$ is unitary for all ω. This matrix was defined in Section 6.4 in the context of paraunitary digital

filter banks. Thus, the filters $G_s(e^{j\omega})$ and $H_s(e^{j\omega})$ constructed from a multiresolution setup constitute a paraunitary (CQF) synthesis bank.

Thus, orthonormal multiresolution automatically gives rise to paraunitary filter banks. Starting from a multiresolution analysis we obtained two functions $\phi(t)$ and $\psi(t)$. These functions generate orthonormal bases $\{\phi(t-n)\}$ and $\{\psi(t-n)\}$ for the orthogonal subspaces V_0 and W_0. The functions $\phi(t)$ and $\psi(t)$ generated in this way satisfy the dilation equations (Equation 6.84). Defining the filters $G_s(z)$ and $H_s(z)$ from the coefficients $g_s(n)$ and $h_s(n)$ in an obvious way, we find that these filters form a paraunitary pair.

This raises the following fundamental question: If we start from a paraunitary pair $\{G_s(z), H_s(z)\}$ and define the functions $\phi(t)$ and $\psi(t)$ by (successfully) solving the dilation equations, do we obtain an orthonormal basis $\{\phi(t-n)\}$ for multiresolution, and a wavelet basis $\{2^{k/2}\,\psi(2^k\,t-n)\}$ for the space of L^2 functions? The answer, fortunately, is in the affirmative, subject to some minor requirements which can be trivially satisfied in practice.

6.10.4.1 Generating Wavelet and Multiresolution Coefficients from Paraunitary Filter Banks

Recall that the subspaces V_0 and W_0 have the orthonormal bases $\{\phi(t-n)\}$ and $\{\psi(t-n)\}$, respectively. By the scaling property, the subspace V_k has the orthonormal basis $\{\phi_{kn}(t)\}$, and similarly the subspace W_k has the orthonormal basis $\{\psi_{kn}(t)\}$, where, as usual, $\phi_{kn}(t) = 2^{k/2}\phi\ (2^k\ t-n)$ and $\psi_{kn}(t) = 2^{k/2}\ \psi(2^k t-n)$. The orthogonal projections of a signal $x(t) \in L^2$ onto V_k and W_k are given, respectively, by

$$\begin{aligned} P_k[x(t)] &= \sum_{n=-\infty}^{\infty} \langle x(t), \phi_{kn}(t)\rangle \phi_{kn}(t) \quad \text{and} \\ Q_k[x(t)] &= \sum_{n=-\infty}^{\infty} \langle x(t), \psi_{kn}(t)\rangle \psi_{kn}(t) \end{aligned} \tag{6.97}$$

(Section 6.2). Denote the scale-k projection coefficients as $d_k(n) = \langle x(t), \phi_{kn}(t)\rangle$ and $c_k(n) = \langle x(t), \psi_{kn}(t)\rangle$ for simplicity. (The notation c_{kn} was used in earlier sections, but $c_k(n)$ is convenient for the present discussion.) We say that $d_k(n)$ are the multiresolution coefficients at scale k and $c_k(n)$ are the wavelet coefficients at scale k.

Assume that the projection coefficients $d_k(n)$ are known for some scale, e.g., $k=0$. We will show that $d_k(n)$ and $c_k(n)$ for the coarser scales, i.e., $k=-1, -2, \ldots$ can be generated by using a paraunitary analysis filter bank $\{G_a(e^{j\omega}), H_a(e^{j\omega})\}$, corresponding to the synthesis bank $\{G_s(e^{j\omega}), H_s(e^{j\omega})\}$ (Section 6.4). We know $\phi(t)$ and $\psi(t)$ satisfy the dilation equations (Equation 6.84). By substituting the dilation equations into the right-hand sides of $\phi_{kn}(t) = 2^{k/2}\ \phi(2^k\ t-n)$ and $\psi_{kn}(t) = 2^{k/2}\ \psi(2^k\ t-n)$, we obtain

$$\begin{aligned} \phi_{kn}(t) &= \sqrt{2}\ \sum_{m=-\infty}^{\infty} g_s(m-2n)\phi_{k+1,\,m}(t) \quad \text{and} \\ \psi_{kn}(t) &= \sqrt{2}\ \sum_{m=-\infty}^{\infty} h_s(m-2n)\phi_{k+1,\,m}(t) \end{aligned} \tag{6.98}$$

A computation of the inner products $d_k(n) = \langle x(t), \phi_{kn}(t)\rangle$ and $c_k(n) = \langle x(t), \psi_{kn}(t)\rangle$ yields

$$\begin{aligned} d_k(n) &= \sum_{m=-\infty}^{\infty} \sqrt{2} g_a(2n-m) d_{k+1}(m) \\ c_k(n) &= \sum_{m=-\infty}^{\infty} \sqrt{2} h_a(2n-m) d_{k+1}(m) \end{aligned} \tag{6.99}$$

where $g_a(n) = g_s^*(-n)$ and $h_a(n) = h_s^*(-n)$ are the analysis filters in the paraunitary filter bank.

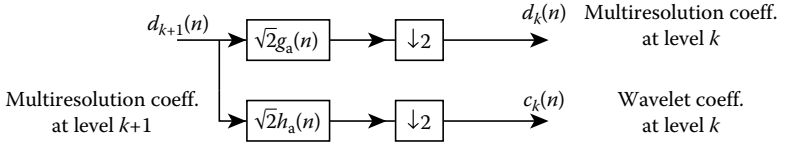

FIGURE 6.37 Generating the wavelet and multiresolution coefficients at level k from level $k+1$.

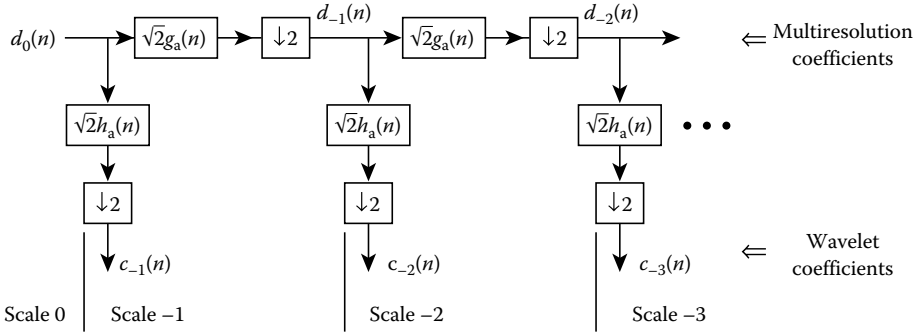

FIGURE 6.38 Tree-structured analysis bank generating wavelet coefficients $c_k(n)$ and multiresolution coefficients $d_k(n)$ recursively.

The beauty of these equations is that they look like discrete-time convolutions. Thus, if $d_{k+1}(n)$ is convolved with the impulse response $\sqrt{2}g_a(n)$ and the output decimated by 2, the result is the sequence $d_k(n)$. A similar statement follows for $c_k(n)$. The above computation can therefore be interpreted in filter bank form as in Figure 6.37. Because of the PR property of the two-channel system (Figure 6.22), it follows that we can reconstruct the projection coefficients $d_{k+1}(n)$ from the projection coefficients $d_k(n)$ and $c_k(n)$.

6.10.4.2 Fast Wavelet Transform

Repeated application of this idea results in Figure 6.38, which is a tree-structured paraunitary filter bank (Section 6.4) with analysis filters $\sqrt{2}g_a(n)$and$\sqrt{2}h_a(n)$ at each stage. Thus, given the projection coefficients $d_0(n)$ for V_0, we can compute the projection coefficients $d_k(n)$ and $c_k(n)$ for the coarser spaces V_{-1}, W_{-1}, V_{-2}, W_{-2},.... This scheme is sometimes referred to as the fast wavelet transform (FWT). Figure 6.39 shows a schematic of the computation. In this figure each node (heavy dot) represents a decimated paraunitary analysis bank $\{\sqrt{2}g_a(n), \sqrt{2}h_a(n)\}$. The subspaces W_m and V_m are indicated in the figure rather than the projection coefficients.

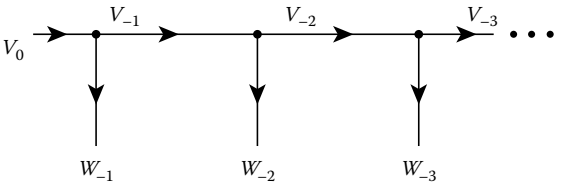

FIGURE 6.39 Schematic of the tree-structured filter bank, which generates the coefficients of the projections onto V_k and W_k.

Computation of the Initial Projection Coefficient: Everything depends on the computation of $d_0(n)$. Note that $d_0(n) = \langle x(t), \phi(t-n)\rangle$, which can be written as the integral $d_0(n) = \int x(t)\phi^*(t-n)\mathrm{d}t$. An elaborate computation of this integral is avoided in practice. If the scale $k=0$ is fine enough—if $x(t)$ does not change much within the duration where $\phi(t)$ is significant—we can approximate this integral with the sample value $x(n)$; i.e., $d_0(n) \approx x(n)$. Improved approximations of $d_0(n)$ have been suggested by other authors, but are not reviewed here.

6.10.5 Continuous Time Filter Banks and Multiresolution

The preceding discussions show the deep connection between orthonormal multiresolution analysis and discrete-time paraunitary filter banks. As shown by Equation 6.91c, any L^2 signal $x(t)$ can be written as a sum of its projections onto the mutually orthogonal spaces V_0, W_0, W_1, etc.:

$$x(t) = \sum_n d_0(n)\phi(t-n) + \sum_{k=0}^{\infty}\sum_n c_k(n)2^{k/2}\psi(2^k t - n)$$

This decomposition itself can be given a simple filter bank interpretation, with continuous time filters and samplers. For this, first note that the V_0 component $\sum_n d_0(n)\phi(t-n)$ can be regarded as the output of a filter with impulse response $\phi(t)$, with the input chosen as the impulse train $\sum_n d_0(n)\delta_a(t-n)$. Similarly, the W_k component $\sum_n c_k(n)2^{k/2}\psi(2^k t - n)$ is the output of a filter with impulse response $f_k(t) = 2^{k/2}\psi(2^k t)$, in response to the input $\sum_n c_k(n)\delta_a(t - 2^{-k}n)$. This interpretation is shown by the synthesis bank of Figure 6.40a.

The projection coefficients $d_0(n)$ and $c_k(n)$ can also be interpreted nicely. For example, we have $d_0(n) = \langle x(t), \phi(t-n)\rangle$ by orthonormality. This inner product can be explicitly written out as

$$d_0(n) = \int x(t)\phi^\star(t-n)\mathrm{d}t$$

The integral can be interpreted as a convolution of $x(t)$ with $\phi^\star(-t)$. Consider the output of the filter with impulse response $\phi^\star(-t)$, with the input chosen as $x(t)$. This output, sampled at time n, gives $d_0(n)$.

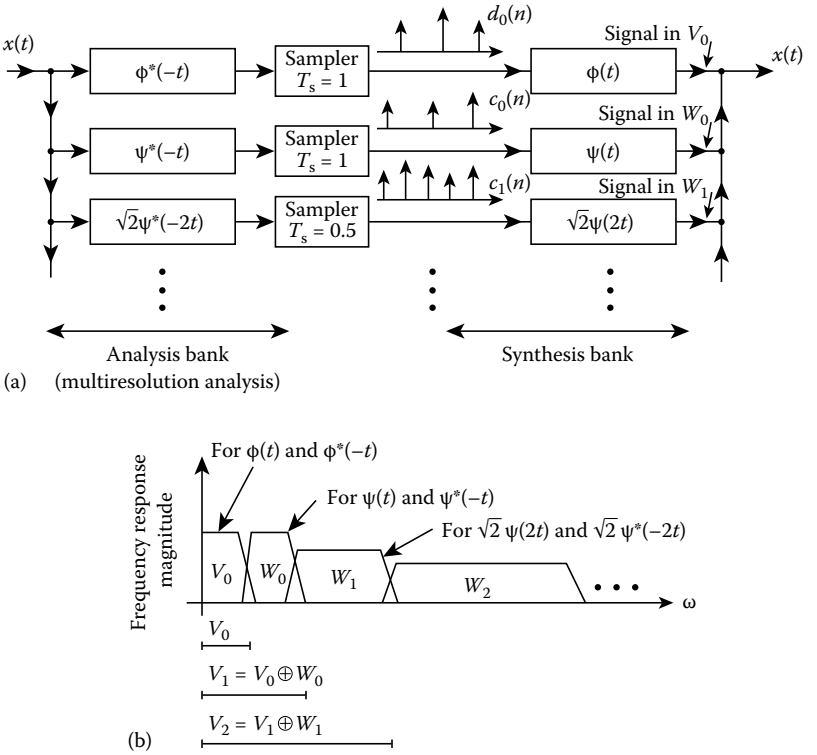

FIGURE 6.40 (a) Multiresolution analysis and resynthesis in filter bank form and (b) typical frequency responses.

Similarly, $c_k(n)$ can be interpreted as the output of the filter $h_k(t) = 2^{k/2}\psi^*(-2^k\ t)$, sampled at the time $2^{-k}n$. The analysis bank of Figure 6.40a illustrates this interpretation. Thus, the projection coefficients $d_0(n)$ and $c_k(n)$ are the sampled versions of the outputs of an analysis filter bank.

Notice that all the filters in the filter bank are determined by the scaling function $\phi(t)$ and the wavelet function $\psi(t)$. Every synthesis filter $f_k(t)$ is the time-reversed conjugate of the corresponding analysis filter $h_k(t)$, that is, $f_k(t) = h^*{}_k(-t)$ (a consequence of orthonormality). In terms of frequency responses this means $F_k(\omega) = H_k{}^*(\omega)$. For completeness of the picture, Figure 6.40b shows typical frequency response magnitudes of these filters.

6.10.6 Further Manifestations of Orthonormality

The orthonormality of the basis functions $\{\phi(t-n)\}$ and $\{\psi(t-n)\}$ have further consequences, summarized below. A knowledge of these will be useful when we generate the scaling function $\phi(t)$ and the wavelet function $\psi(t)$ systematically in Section 6.11 from paraunitary filter banks.

6.10.6.1 Nyquist Property and Orthonormality

With $\phi(t) \in L^2$, the autocorrelation function $R(t) = \int \phi(t)\phi^*(t-\tau)dt$ exists for all τ because this is simply an inner product of two elements in L^2. Clearly, $R(0) = |\phi(t)|^2 = 1$. Further, the orthonormality property $\langle \phi(t), \phi(t-n)\rangle = \delta(n)$ can be rewritten as $R(n) = \delta(n)$. Thus, $R(\tau)$ has periodic zero crossings at nonzero integer values of τ (Figure 6.41). This is precisely the *Nyquist property* familiar to communication engineers. The autocorrelation of the scaling function $\phi(t)$ is a Nyquist function. The same holds for the wavelet function $\psi(t)$.

Next, using Parseval's identity for L^2-FTs, we obtain $\langle \phi(t), \phi(t-n)\rangle = \int \Phi(\omega)\Phi(\omega)e^{j\omega n}d\omega/2\pi = \delta(n)$. If we decompose the integral into a sum of integrals over intervals of length 2π and use the 2π-periodicity of $e^{j\omega n}$, we obtain, after some simplification:

$$\sum_{k=-\infty}^{\infty} |\Phi(\omega + 2\pi k)|^2 = 1 \quad \text{a.e.} \tag{6.100}$$

This is the Nyquist condition, now expressed in the frequency domain. The term a.e., almost everywhere, arises from the fact that we have drawn a conclusion about an integrand from the value of the integral. Thus, $\{\phi(t-n)\}$ is orthonormal iff the preceding equation holds. A similar result follows for $\Psi(\omega)$, so orthonormality of $\{\psi(t-n)\}$ is equivalent to

$$\sum_{k=-\infty}^{\infty} |\Psi(\omega + 2\pi k)|^2 = 1 \quad \text{a.e.} \tag{6.101}$$

6.10.6.2 Case in Which Equalities Hold Pointwise

If we assume that all FTs are continuous, then equalities in the Fourier domain actually hold pointwise. This is the most common situation; in all examples here, the following are true: the filters $G_s(e^{j\omega})$ and

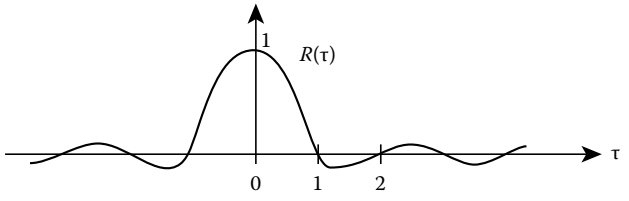

FIGURE 6.41 Example of an autocorrelation of the scaling function $\phi(t)$.

$H_s(e^{j\omega})$ are rational (FIR or IIR), so the frequency responses are continuous functions of ω, and $\phi(t)$ and $\psi(t)$ are not only in L^2, but also in L^1; i.e., $\phi(t)$, $\psi(t) \in L^1 \cap L^2$. Thus, $\Phi(\omega)$ and $\Psi(\omega)$ are continuous functions (Section 6.6).

With the dilation equation $\Phi(\omega) = G_s(e^{j\omega/2})\Phi(\omega/2)$ holding pointwise, we have $\Phi(0) = G_s(e^{j0})\Phi(0)$. In all our applications $\Phi(0) \neq 0$ (it is a low-pass filter), so $G_s(e^{j0}) = 1$. The power symmetry property

$$\left|G_s(e^{j\omega})\right|^2 + \left|G_s(-e^{j\omega})\right|^2 = 1$$

then implies $G_s(e^{j\pi}) = 0$. Because the high-pass synthesis filter is $H_s(e^{j\omega}) = e^{j\omega}G_s^*(-e^{j\omega})$ we conclude $H_s(e^{j0}) = 0$ and $H_s(e^{j\pi}) = -1$. Thus,

$$G_s(e^{j0}) = 1, \quad G_s(e^{j\pi}) = 0, \quad H_s(e^{j0}) = 0, \quad H_s(e^{j\pi}) = -1 \tag{6.102}$$

In particular, the low-pass impulse response $g_s(n)$ satisfies $\Sigma_n g_s(n) = 1$. Because we already have $\Sigma_n |g_s(n)|^2 = 0.5$ (Theorem 6.6), we have both of the following:

$$\sum_{n=-\infty}^{\infty} g_s(n) = 1 \quad \text{and} \quad \sum_{n=-\infty}^{\infty} |g_s(n)|^2 = 0.5 \tag{6.103}$$

From the dilation equation $\Phi(\omega) = G_s(e^{j\omega/2})\Phi(\omega/2)$, we obtain $\Phi(2\pi k) = G_s(e^{j\pi k})\Phi(\pi k)$. By using the fact that $G_s(e^{j\pi}) = 0$, and after elementary manipulations, we can show that

$$\Phi(2\pi k) = 0, \quad k \neq 0 \tag{6.104}$$

In other words, $\Phi(\omega)$ is itself a Nyquist function of ω. If Equation 6.100 is *assumed to hold pointwise*, the above implies that $|\Phi(0)| = 1$. Without loss of generality we will let $\Phi(0) = 1$, i.e., $\int(\phi(t)dt = 1$. The dilation equation for the wavelet function $\Psi(\omega)$ in Equation 6.85 shows that $\Psi(0) = 0$ (because $H_s(e^{j0}) = 0$ by Equation 6.102). That is, $\int\psi(t)dt = 0$. Summarizing, the scaling and wavelet functions satisfy

$$\begin{aligned} &\int_{-\infty}^{\infty} \phi(t)dt = 1, \quad \int_{-\infty}^{\infty} \psi(t)dt = 0 \quad \text{and} \\ &\int_{-\infty}^{\infty} |\phi(t)|^2 dt = \int_{-\infty}^{\infty} |\psi(t)|^2 dt = 1 \end{aligned} \tag{6.105}$$

where property 3 follows from orthonormality. These integrals make sense because of the assumption $\phi(t) \in L^1 \cap L^2$. Another result that follows from $\Phi(2\pi k) = \delta(k)$ is that

$$\sum_{n=-\infty}^{\infty} \phi(t-n) = 1 \quad \text{a.e.} \tag{6.106}$$

Thus, the basis functions of the subspace V_0 add up to unity. Return to the Haar basis and notice how beautifully everything fits together.

6.10.7 Generating Wavelet and Multiresolution Basis by Design of $\phi(t)$

Most of the well-known wavelet basis families of recent times were generated by first finding a scaling function $\phi(t)$ such that it is a valid generator of multiresolution, and then generating $\psi(t)$ from $\phi(t)$. The first step, therefore, is to identify the conditions under which a function $\phi(t)$ will be a valid scaling function (i.e., it will generate a multiresolution). Once this is done and we successfully identify the coefficients $g_s(n)$ in the dilation equation for $\phi(t)$, we can identify the wavelet function $\psi(t)$ using the

second dilation equation in Equation 6.84. From Theorem 6.6, we know that if $\psi(t)$ is computed in this way, then $\{2^{k/2}\,\psi(2^k t - n)\}$ is an orthonormal wavelet basis for L^2. The following results can be deduced from the many detailed results presented in Ref. [5].

THEOREM 6.7: (Orthonormal Multiresolution)

Let $\phi(t)$ *satisfy the following conditions:* $\phi(t) \in L^1 \bigcap L^2$, $\int \phi(t)\,dt \neq 0$ (*i.e.*, $\Phi(0) \neq 0$), $\phi(t) = 2\boldsymbol{\Sigma}_n g_s(n)\,\phi(2t - n)$ *for some* $\{g_s(n)\}$, *and* $\{\phi(t - n)\}$ *is an orthonormal sequence. Then the following are true*:

1. $\phi(t)$ *generates a multiresolution. That is, if we define the space* V_k *to be the closure of the span of* $\{2^{k/2}\,\phi(2^k t - n)\}$, *then the set of spaces* $\{V_k\}$ *satisfies the six conditions in the definition of multiresolution.*
2. *Define* $\psi(t) = 2\boldsymbol{\Sigma}_n (-1)^{n+1}\, g_s^*(-n-1)\,\phi\,(2t - n)$. *Then,* $\psi(t)$ *generates an orthonormal wavelet basis for* L^2 *; that is,* $\{2^{k/2}\psi(2^k t - n)\}$, *with k and n varying over all integers, is an orthonormal basis for* L^2. *In fact, for fixed k, the functions* $\{2^{k/2}\psi(2^k t - n)\}$ *from an orthonormal basis for the subspace* W_k *(defined following the definition of multiresolution analysis).*

Comments: In many examples, $\phi(t) \in L^2$, and it is compactly supported. Then it is naturally in L^1 as well, so the assumption $\phi(t) \in L^2 \cap L^1$ is not too restrictive. Because $L^1 \cap L^2$ is dense in L^2, the previous construction still gives a wavelet basis for L^2. Notice also that the orthonormality of $\{\phi(t - n)\}$ implies orthonormality of $\{\sqrt{2}\phi(2t - n)\}$. The recursion $\phi(t) = 2\Sigma_n g_s(n)\phi(2t - n)$, therefore, is a Fourier series for $\phi(t)$ in L^2. Thus the condition $\boldsymbol{\Sigma}_n\, |g_s(n)|^2 = 0.5$ is automatically implied. This is not explicitly stated as part of the conditions in the theorem.

Orthonormalization

We know that orthonormality of $\{\phi(t - n)\}$ is equivalent to

$$\sum_{k=-\infty}^{\infty} |\Phi(\omega + 2\pi k)|^2 = 1 \tag{6.107}$$

Suppose now that this is not satisfied, but the weaker condition

$$a \leq \sum_{k=-\infty}^{\infty} |\Phi(\omega + 2\pi k)|^2 \leq b \tag{6.108}$$

holds for some $a > 0$ and $b < \infty$. Then, it can be shown that, we can at least obtain a Riesz basis (Section 6.7) of the form $\{\phi(t - n)\}$ for V_0. We can also normalize it to obtain an orthonormal sequence $\{\hat{\phi}(t - n)\}$ from which an orthonormal wavelet basis can be generated in the usual way. The following theorem summarizes the main results.

THEOREM 6.8

Let $\phi(t) \in L^1 \cap L^2$, $\int \phi(t)dt \neq 0$ (*i.e.*, $\Phi(0) \neq 0$), *and* $\phi(t) = 2\Sigma_n g_s(n)\phi(2t - n)$ *with* $\Sigma_n |g_s(n)|^2 < \infty$. *Instead of the orthonormality condition* (*Equation* 6.107), *let Equation* 6.108 *hold for some* $a > 0$ *and* $b < \infty$. *Then the following are true:*

1. $\{\phi(t - n)\}$ *is a Riesz basis for the closure* V_0 *of its span.*
2. $\phi(t)$ *generates a multiresolution. That is, if we define the space* V_k *to be the closure of the span of* $\{2^{k/2}\phi(2^k t - n)\}$ *the set of spaces* $\{V_k\}$ *satisfies the six conditions in the definition of multiresolution.*

If we define a new function $\hat{\phi}(t)$ in terms of its FT as

$$\hat{\Phi}(\omega) = \frac{\Phi(\omega)}{\left(\sum_k |\Phi(\omega + 2\pi k)|^2\right)^{0.5}} \tag{6.109}$$

then $\hat{\phi}(t)$ generates an orthonormal multiresolution, and satisfies a dilation equation similar to Equation 6.84. Using this we can define a corresponding wavelet function $\hat{\psi}(t)$ in the usual way. That is, if $\hat{\phi}(t) = 2\boldsymbol{\Sigma}_n g_s(n)\hat{\phi}(2t-n)$, choose $\hat{\psi}(t) = 2\boldsymbol{\Sigma}_n h_s(n)\hat{\phi}(2t-n)$, where $h_s(n) = (-1)^{n+1} g_s^*(-n-1)$. This wavelet $\hat{\psi}(t)$ generates an orthonormal wavelet basis for L^2. Note that the basis is not necessarily compactly supported if we start with compactly supported $\phi(t)$. An example is given in Figure 6.46b later.

Example 6.10: Battle–Lemarié Orthonormal Wavelets from Splines

In Example 6.9, we considered a triangular $\phi(t)$ (Figure 6.36), which generates a nonorthonormal multiresolution. In this example, we have

$$\Phi(\omega) = \sqrt{\frac{3}{2}}\left(\frac{\sin(\omega/2)}{(\omega/2)}\right)^2 \tag{6.110}$$

and it can be shown that

$$\sum_{k=-\infty}^{\infty} |\Phi(\omega + 2\pi k)|^2 = \frac{2 + \cos\omega}{2} \tag{6.111}$$

The inequality Equation 6.108 is satisfied with $a = 1/2$ and $b = 3/2$. Thus, we have a Riesz basis $\{\phi(t-n)\}$ for V_0. From this scaling function, we can obtain the normalized function $\hat{\Phi}(\omega)$ as above and then generate the wavelet function $\hat{\psi}(t)$ as explained earlier. This gives an orthonormal wavelet basis for L^2. $\hat{\phi}(t)$ does not, however, have compact support (unlike $\phi(t)$). Thus, the wavelet function $\hat{\psi}(t)$ generating the orthonormal wavelet basis is not compactly supported either.

6.11 Orthonormal Wavelet Basis from Paraunitary Filter Banks

The wisdom gained from the multiresolution viewpoint (Section 6.10) tells us a close connection exists between wavelet bases and two-channel digital filter banks. In fact, we obtained the equations of a paraunitary filter bank just by imposing the orthonormality condition on the multiresolution basis functions $\{\phi(t-n)\}$. This section presents the complete story. Suppose we start from a two-channel digital filter bank with the paraunitary property. Can we derive an orthonormal wavelet basis from this? To be more specific, return to the dilation equations (Equation 6.84) or equivalently Equation 6.85. Here, $g_s(n)$ and $h_s(n)$ are the impulse response coefficients of the two synthesis filters $G_s(e^{j\omega})$ and $H_s(e^{j\omega})$ in the digital filter bank. Given these two filters, can we "solve" for $\phi(t)$ and $\psi(t)$? If so, does this $\psi(t)$ generate an orthonormal basis for L^2 space? This section answers some of these questions. Unlike any other section, we also indicate a sketch of the proof for each major result, in view of the importance of these in modern signal processing theory.

Recall first that under some mild conditions (Section 6.10) we can prove that the filters must satisfy Equations 6.102 and 6.103, if we need to generate wavelet and multiresolution bases successfully. We impose these at the outset. By repeated application of the dilation equation, we obtain $\Phi(\omega) = G_s(e^{j\omega/2})$ $G_s(e^{j\omega/4})\Phi(\omega/4)$. Further indefinite repetition yields an infinite product. Using the condition $\Phi(0) = 1$, which we justified earlier, we obtain the infinite products

$$\Phi(\omega) = \prod_{k=1}^{\infty} G_s(e^{j\omega/2^k}) = G_s(e^{j\omega/2}) \prod_{k=2}^{\infty} G_s(e^{j\omega/2^k}) \tag{6.112a}$$

$$\Psi(\omega) = H_s(e^{j\omega/2}) \prod_{k=2}^{\infty} G_s(e^{j\omega/2^k}) \tag{6.112b}$$

The first issue to be addressed is the convergence of the infinite products above. For this we need to review some preliminaries on infinite products [22,23].

Ideal Bandpass Wavelet Rederived from the Digital Filter Bank: Before we address the mathematical details, let us consider a simple example. Suppose the pair of filters $G_s(e^{j\omega})$ and $H_s(e^{j\omega})$ are ideal brickwall low-pass and high-pass filters in Figure 6.28a. Then we can verify, by making simple sketches of a few terms in Equation 6.112, that the above infinite products yield the functions $\Phi(\omega)$ and $\psi(\omega)$ shown in Figure 6.33. That is, the ideal bandpass wavelet is indeed related to the ideal paraunitary filter bank by means of the above infinite product.

6.11.1 Convergence of Infinite Products

To define convergence of a product of the form $\prod_{k=1}^{\infty} a_k$, consider the sequence $\{p_n\}$ of partial products $p_n = \prod_{k=1}^{\infty} a_k$. If this converges to a (complex) number A with $0 < |A| < \infty$, we say that the infinite product converges to A. Convergence to zero should be defined more carefully to avoid degenerate situations (e.g., if $a_1 = 0$, then $p_n = 0$ for all n regardless of the remaining terms a_k, $k > 1$). We use definition in Ref. [22]. The infinite product is said to converge to zero iff $a_k = 0$ for a finite nonzero number of values of k, and if the product with these a_k deleted converges to a nonzero value.

6.11.1.1 Useful Facts about Infinite Products

1. Whenever $\prod_{k=1}^{\infty} a_k$ converges, it can be shown $a_k \to 1$ as $k \to \infty$. For this reason it is convenient to write $a_k = 1 + b_k$.
2. We say that $\prod_{k=1}^{\infty}(1 + b_k)$ converges absolutely if $\prod_{k=1}^{\infty}(1 + |b_k|)$ converges. Absolute convergence of $\prod_{k=1}^{\infty}(1 + b_k)$ implies its convergence.
3. It can be shown that the product $\prod_{k=1}^{\infty}(1 + |b_k|)$ converges iff the sum $\sum_{k=1}^{\infty}|b_k|$ converges. That is, $\prod_{k=1}^{\infty}(1 + b_k)$ converges absolutely iff $\sum_{k=1}^{\infty} b_k$ converges absolutely.

Example 6.11

The product $\prod_{k=1}^{\infty}(1 + k^{-2})$ converges because $\sum_{k=1}^{\infty} 1/k^2$ converges. Similarly, $\prod_{k=1}^{\infty}(1 - k^{-2})$ converges because it converges absolutely, by the preceding example. The product $\prod_{k=1}^{\infty}(1 + k^{-1})$ does not converge because $\sum_{k=1}^{\infty} 1/k$ diverges. Products such as $\prod_{k=1}^{\infty}(1/k^2)$ do not converge because the terms do not approach unity as $k \to \infty$.

6.11.1.2 Uniform Convergence

A sequence $\{p_n(z)\}$ of functions of the complex variable z converges *uniformly* to a function $p(z)$ on a set $\mathcal{S}$ in the complex plane if the convergence rate is the same everywhere in $\mathcal{S}$. More precisely, if we are given $\varepsilon > 0$ we can find N such that $|p_n(z) - p(z)| < \varepsilon$ for every $z \in \mathcal{S}$, as long as $n \geq N$. The crucial thing is that N depends only on ε and not on z, as long as $z \in \mathcal{S}$. A similar definition applies for functions of real variables.

We say that an infinite product of functions $\prod_{k=1}^{\infty} a_k(z)$ converges at a point z if the sequence of partial products $p_n(z) = \prod_{k=1}^{n} a_k(z)$ converges as described previously. If this convergence of $p_n(z)$ is uniform in a set $\mathcal{S}$, we say that infinite product converges uniformly on $\mathcal{S}$. Uniform convergence has similar advantages, as in the case of infinite summations. For example, if each of the functions $a_k(\omega)$ is continuous on the real interval $[\omega_1, \omega_2]$, then uniform convergence of the infinite product $A(\omega) = \prod_{k=1}^{\infty} a_k(\omega)$ on $[\omega_1, \omega_2]$ implies that the limit $A(\omega)$ is continuous on $[\omega_1, \omega_2]$. We saw above that convergence of infinite products can be related to that of infinite summations. The following theorem [23] makes the connection between uniform convergence of summations and uniform convergence of products.

THEOREM 6.9

Let $b_k(z)$, $k \geq 1$ be a sequence of bounded functions of the complex variable z, such that $\sum_{k=1}^{\infty} |b_k(z)|$ converges uniformly on a compact set $\mathcal{S}$ in the complex z plane. Then, the infinite product $\prod_{k=1}^{\infty}(1 + b_k(z))$ converges uniformly on $\mathcal{S}$. This product is zero for some z_0 iff $1 + b_k(z_0) = 0$ for some k.*

Uniform convergence and analyticity: We know that if a sequence of continuous functions converges uniformly to a function, then the limit is also continuous. A similar result is true for analytic functions. If a sequence $\{f_n(s)\}$ of analytic functions converges uniformly to a function $f(s)$, then $f(s)$ is analytic as well. For a more precise statement of this result see Theorem 10.28 in Ref. [23].

6.11.2 Infinite Product Defining the Scaling Function

Return now to the infinite product (Equation 6.112a). As justified in Section 6.10, assume $G_s(e^{j\omega})$ to be continuous, $G_s(e^{j0}) = 1$, and $\Phi(0) \neq 0$. Note that $G_s(e^{j0}) = 1$ is necessary for the infinite product to converge (because convergence of $\prod_k a_k$ implies that $a_k \to 1$; apply this for $\omega = 0$). The following convergence result is fundamental.

THEOREM 6.10: Convergence of the Infinite Product

Let $G_s(e^{j\omega}) = \sum_{n=-\infty}^{\infty} g_s(n)e^{-j\omega n}$. Assume that $G_s(e^{j0}) = 1$ and $\Sigma_n|ng_s(n)| < \infty$. Then

1. *The infinite product* (*Equation* 6.112a) *converges pointwise for all* ω. *In fact, it converges absolutely for all* ω, *and uniformly on compact sets (i.e., closed bounded sets, such as sets of the form* $[\omega_1,\omega_2]$).
2. *The quantity $G_s(e^{j\omega})$ as well as the limit $\Phi(\omega)$ of the infinite product* (*Equation* 6.112a) *are continuous functions of* ω.
3. *$G_s(e^{j\omega})$ is in L^2.*

Because the condition $\Sigma_n|ng_s(n)| < \infty$ implies $\Sigma_n|g_s(n)| < \infty$, the filter $G_s(e^{j\omega})$ is restricted to be stable, but the above result holds whether $g_s(n)$ is FIR or IIR.

***Sketch of Proof*:** Theorem 6.9 allows us to reduce the convergence of the product to the convergence of an infinite sum. For this we must write $G_s(e^{j\omega})$ in the form $1 - F(e^{j\omega})$ and consider the summation $\sum_{k=1}^{\infty} |F(e^{j\omega/2^{\kappa}})|$. Because, $G_s(e^{j0}) = 1 = \Sigma_n g_s(n)$, we can write $G_s(e^{j\omega}) = 1 - (1 - G_s(e^{j\omega})) = 1 - \Sigma_n g_s(n)(1 - e^{-j\omega n})$. However, $|\Sigma_n g_s(n)(1 - e^{-j\omega n})| \leq 2\Sigma_n|g_s(n) \sin(\omega n/2)| \leq |\omega|\Sigma_n| ng_s(n)|$(use $|\sin x/x| \leq 1$). $\Sigma_n|ng_s(n)|$ is assumed to converge, thus we have $|\Sigma_n g_s(n)(1 - e^{-j\omega n})| \leq c|\omega|$. Using this and the fact that $\sum_{k=1}^{\infty} 2^{-k}$ converges, we can complete the proof of part 1 (by applying Theorem 6.9). $\Sigma_n|ng_s(n)| < \infty$ implies in particular that $g_s(n) \in \ell^1$ therefore, its $\ell^1 - \text{FT}$ $G_s(e^{j\omega})$ is continuous (Section 6.6). The continuity $G_s(e^{j\omega})$, together with uniform convergence of the infinite product, implies that the pointwise limit $\Phi(\omega)$ is also continuous. Finally, because $\ell^1 \subset \ell^2$ (Section 6.6), we have $g_s(n) \in \ell^2$, that is, $G_s(e^{j\omega}) \in L^2[0, 2\pi]$ as well.

6.11.3 Orthonormal Wavelet Basis from Paraunitary Filter Bank

We now consider the behavior of the infinite product $\prod_{k=1}^{\infty} G_s(e^{j\omega/2^k})$, when $G_s(e^{j\omega})$ comes from a paraunitary filter bank. The paraunitary property implies that $G_s(e^{j\omega})$ is power symmetric. If we impose some further mild conditions on $G_s(e^{j\omega})$, the scaling function $\phi(t)$ generates an orthonormal

* For us, a compact set means any closed bounded set in the complex plane or on the real line. Examples are all points on and inside a circle in the complex plane, and the closed interval [a, b] on the real line.

multiresolution basis $\{\phi(t-n)\}$. We can then obtain an orthonormal wavelet basis $\{\psi_{kn}(t)\}$ (Theorems 6.6 and 6.7). The main results are given in Theorems 6.11 through 6.15.

First, we define the truncated partial products $P_n(\omega)$. Because $G_s(e^{j\omega})$ has period 2π, the term $G_s(e^{j\omega/2k})$ has period $2^{k+1}\,\pi$. For this reason the partial product $\prod_{k=1}^{n} G_s(e^{j\omega/2^k})$ has period $2^{n+1}\pi$, and we can regard the region $[-2^n\pi, 2^n\pi]$ to be the fundamental period. Let us truncate the partial product to this region, and define

$$P_n(\omega) = \begin{cases} \prod_{k=1}^{n} G_s(e^{j\omega/2^k}), & \text{for } -2^n\pi \le \omega \le 2^n\pi, \\ 0, & \text{otherwise} \end{cases} \tag{6.113}$$

This quantity will be useful later. We will see that this is in $L^2(R)$, and we can discuss $p_n(t)$, its inverse L^2-FT.

THEOREM 6.11

Let $G_s(e^{j\omega})$ be as in Theorem 6.10. In addition let it be power symmetric; in other words, $|G_s(e^{j\omega})|^2 + G_s(-e^{j\omega})|^2 = 1$. Notice in particular that this implies $G_s(e^{j\pi}) = 0$, because $G_s(e^{j0}) = 1$. Then the following are true:

1. $\int_0^{2\pi} |G_s(e^{j\omega})|^2 d\omega/2\pi = 0.5$.
2. *The truncated partial product $P_n(\omega)$ is in L^2, and $\int_{-\infty}^{\infty} |P_n(\omega)|^2 d\omega/2\pi = 1$ for all n. Further, the inverse L^2-FT, denoted as $p_n(t)$, gives to an orthonormal sequence $\{p_n(t-k)\}$, i.e., $\langle p_n(t-k), p_n(t-i)\rangle = \delta(k-i)$ for any $n \ge 1$.*
3. *The limit $\Phi(\omega)$ of the infinite product (Equation 6.112a) is in L^2; hence, it has an inverse L^2-FT, $\phi(t) \in L^2$. Moreover, $\|\phi(t)\|_2 \le 1$.*

Sketch of Proof: Part 1 follows by integrating both sides of $|G_s(e^{j\omega})|^2 + |G_s(-e^{j\omega})|^2 = 1$. The integral in part 2 is $\int_0^{2^{n+1}\pi} \prod_{k=1}^{n} |G_s(e^{j\omega/2^k})|^2 d\omega/2\pi$, which we can split into two terms such as $\int_0^{2^n\pi} + \int_{2_n\pi}^{2^{n+1}\pi}$. Using the 2π periodicity and the power symmetric property of $G_s(e^{j\omega})$, we obtain $\int |P_n|^2\, d\omega = \int |P_{n-1}|^2 d\omega$. Repeated application of this, together with part 1, yields $\int_{-\infty}^{\infty} |P_n(\omega)|^2 d\omega/2\pi = 1$. The proof of orthonormality of $\{p_n(t-k)\}$ follows essentially similarly by working with the modified integral $\int_{-\infty}^{\infty} |P_n(\omega)|^2 e^{j\omega(k-i)} d\omega/2\pi$, and using the half-band property of $|G_s(e^{j\omega})|^2$.

The third part is the most subtle, and uses Fatou's lemma for Lebesgue integrals (Section 6.6). For this, define $g_n(\omega) = |P_n(\omega)|^2$. Then, $\{g_n(\omega)\}$ is a sequence of nonnegative integrable functions such that $g_n(\omega) \to |\Phi(\omega)|^2$ pointwise for each ω. Because $\int g_n(\omega) d\omega = 2\pi$ (from part 2), Fatou's lemma assures us that $|\Phi(\omega)|^2$ is integrable with integral $\le 2\pi$. This proves part 3.

It is most interesting that the truncated partial products $P_n(\omega)$ give rise to orthonormal sequences $\{p_n(t-k)\}$. This orthonormality is induced by the paraunitary property, more precisely the power symmetry property of $G_s(e^{j\omega})$. This is consistent with the fact that the filter bank type of basis introduced in Section 6.4 is an orthonormal basis for ℓ^2 whenever the filter bank is paraunitary.

As the scaling function $\Phi(\omega)$ is the pointwise limit of $\{P_n(\omega)\}$ as $n \to \infty$, this leads to the hope that $\{\phi(t-k)\}$ is also an orthonormal sequence, so that we can generate a multiresolution and then a wavelet basis as in Theorems 6.6 and 6.7. This, however, is not always true. The crux of the reason is that $\Phi(\omega)$ is only the pointwise limit of $\{P_n(\omega)\}$, and not necessarily the L^2 limit. The distinction is subtle (see below). The pointwise limit property means that for any fixed ω, the function $P_n(\omega)$ approaches $\Phi(\omega)$. The L^2 limit property means that $\int |P_n(\omega) - \Phi(\omega)|^2 d\omega \to 0$. Neither of these limit properties implies the other; neither is stronger than the other. It can be shown that it is the L^2 limit that propagates the orthonormality property, and this is what we want.

THEOREM 6.12

Let $\{p_n\ (t-k)\}$ *be an orthonormal sequence for each n. That is* $\langle p_n(t-k), p_n(t-i)\rangle = \delta\ (k-i)$. *Suppose* $p_n(t) \to \phi(t)$ *in the* L^2 *sense. Then* $\{\phi(t-k)\}$ *is an orthonormal sequence.*

Proof: If we take limits as $n \to \infty$, we can write

$$\lim_{n\to\infty} \langle p_n(t-k),\, p_n(t-i)\rangle = \left\langle \lim_{n\to\infty} p_n(t-k),\ \lim_{n\to\infty} p_n(t-i)\right\rangle \tag{6.114}$$

This movement of the "limit" sign past the inner product sign is allowed (by continuity of inner products, Section 6.6), provided the limits in the second expression are L^2 limits. By the conditions of the theorem, the left side of the above equation is $\delta(k-i)$, whereas the right side is $\langle \phi(t-k), \phi(t-i)\rangle$. So the result follows.

6.11.3.1 L^2 Convergence versus Pointwise Convergence

The fact that L^2 limits are not necessarily pointwise limits is obvious from the fact that differences at a countable set of points do not affect integrals. The fact that pointwise limits are not necessarily L^2 limits is demonstrated by the sequence of L^2 functions $\{f_n(t)\}$, with $f_n(t)$ as in Figure 6.42. Note that $f_n(t) \to 0$ pointwise for each t, that is, the pointwise limit is $f(t) \equiv 0$. Hence, $\| f_n(t) - f(t) \| = \| f_n(t)\| = 1$ for all n, so $\| f_n(t) - f(t)\|$ does not go to zero as $n \to \infty$ and thus, $f(t)$ is not the L^2 limit of $f_n(t)$. Notice in this example that $1 = \lim_{n\to\infty} \int |f_n(t)|^2\, dt \neq \int \lim_{n\to\infty} |f_n(t)|^2\, dt = 0$. This is consistent with the fact that the Lebesgue dominated convergence theorem cannot be applied here—no integrable function dominates $|f_n(t)|^2$ for all n. In this example, the sequence $\{f_n(t)\}$ does not converge in the L^2 sense. In fact, $\|f_n(t) - f_m(t)\|^2 = 2$ for $n \neq m$. Thus, $\{f_n\}$ is not a Cauchy sequence [22] in L^2.

Some facts pertaining to pointwise and L^2 convergences: It can be shown that if $f_n(t) \to f(t)$ in L^2 sense and $f_n(t) \to g(t) \in L^2$ pointwise as well, then $f(t) = g(t)$ a.e. In particular, $\|f(t) - g(t)\| = 0$ and $\|f(t)\| = \|g(t)\|$. It also can be shown that if $f_n(t) \to f(t)$ in L^2 sense, then $\|f_n(t)\| \to \|f(t)\|$. Finally, if $f_n(t) \to f(t) \in L^2$ pointwise a.e., and $\|f_n(t)\| \to \|f(t)\|$ then $f_n(t) \to f\,(t)$ in L^2 sense as well [23].

THEOREM 6.13: Orthonormal Wavelet Basis

Let the filter $G_s(e^{j\omega}) = \sum_{n=-\infty}^{\infty} g_s(n) e^{-j\omega n}$ *satisfy the following properties*:

1. $G_s(e^{j0}) = 1$
2. $\Sigma_n |n g_s(n)| < \infty$
3. $|G_s(e^{j\omega})|^2 + |G_s(-e^{j\omega})|^2 = 1$ (power symmetry)
4. $G_s(e^{j\omega}) \neq 0$ for $\omega \in [-0.5\pi, 0.5\pi]$

Then the infinite product (*Equation* 6.112a) *converges to a limit* $\Phi(\omega) \in L^2$, *and its inverse FT* $\phi(t)$ *is such that* $\{\phi(t-n)\}$ *is an orthonormal sequence. Defining the wavelet function* $\psi(t)$ *as usual, i.e., as in Equation* 6.93, *the sequence* $\{2^{k/2}\, \psi(2^k\, t - n)\}$ (*with k and n varying over all integers*) *forms an orthonormal wavelet basis for* L^2.

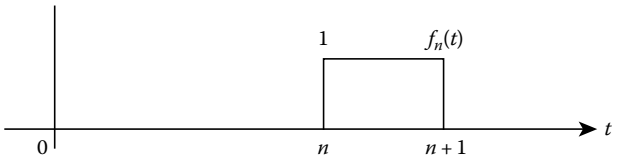

FIGURE 6.42 Sequence $\{f_n(t)\}$ with a pointwise limit is not a limit in the L^2 sense.

Sketch of Proof: We will show that the sequence $\{P_n(\omega)\}$ of partial products converges to $\Phi(\omega)$ in the L^2 sense, i.e., $\int|P_n(\omega)-\Phi(\omega)|^2 d\omega \to 0$, so that $p_n(t) \to \phi(t)$ in L^2 sense. The desired result then follows in view of Theorems 6.11 and 6.12. The key tool in the proof is the dominated convergence theorem for Lebesgue integrals (Section 6.6). First, the condition $G(e^{j\omega}) \neq 0$ in $[-0.5\pi, 0.5\pi]$ implies that $\Phi(\omega) \neq 0$ in $[-\pi, \pi]$. Because $|\Phi(\omega)|^2$ is continuous (Theorem 6.10) it has a minimum value $c^2 > 0$ in $[-\pi, \pi]$. Now the truncated partial product $P_n(\omega)$ can always be written as $P_n(\omega) = \Phi(\omega)/\Phi(\omega/2^n)$ in its region of support. Because $|\Phi(\omega/2^n)|^2 \geq c^2$ in $[-2^n\pi, 2^n\pi]$, we have $|P_n(\omega)|^2 \leq |\Phi(\omega)|^2/c^2$ for all ω. Define $Q_n(\omega) = |P_n(\omega) - \Phi(\omega)|^2$. Then using $|P_n(\omega)|^2 \leq |\Phi(\omega)|^2/c^2$ we can show that $Q_n(\omega) \leq \alpha|\Phi(\omega)|^2$ for some constant α. Because the right-hand side is integrable, and because $Q_n(\omega) \to 0$ pointwise (Theorem 6.10) we can use the dominated convergence theorem (Section 6.6) to conclude that $\lim_n \int Q_n(\omega)d\omega = \int \lim_n Q_n(\omega)\, d\omega = 0$. This completes the proof.

6.11.3.2 Computing the Scaling and Wavelet Functions

Given the coefficients $g_s(n)$ of the filter $G(e^{j\omega})$, how do we compute the scaling function $\Phi(t)$ and the wavelet function $\psi(t)$? Because we can compute $\psi(t)$ using $\psi(t) = 2\sum_{n=-\infty}^{\infty}(-1)^{n+1}g_s^*(-n-1)\phi(2t-n)$, the key issue is the computation of $\phi(t)$. In the preceding theorems $\phi(t)$ was defined only as an inverse L^2–FT of the infinite product $\Phi(\omega)$ given in Equation 6.112a. Because an L^2 function is determined only in the a.e. sense, this way of defining $\phi(t)$ itself does not fully determine $\phi(t)$. Recall, however, that the infinite product for $\Phi(\omega)$ was only a consequence of the more fundamental equation, the dilation equation $\phi(t) = 2\sum_{n=-\infty}^{\infty} g_s(n)\phi(2t-n)$. In practice $\phi(t)$ is computed using this equation, which is often a finite sum (Section 6.12). The procedure is recursive; we assume an initial solution for the function $\phi(t)$, substitute it into the right-hand side of the dilation equation, thereby recomputing $\phi(t)$, and then repeat the process. Details of this and discussions on convergence of this procedure can be found in Refs. [5,15,26].

6.11.3.3 Lawton's Eigenfunction Condition for Orthonormality [5]

Equation 6.100 is equivalent to the orthonormality of $\{\phi(t-n)\}$. Let $S(e^{j\omega})$ denote the left-hand side of Equation 6.100, which evidently has period 2π in ω. Using the frequency domain version of the dilation equation (Equation 6.85), it can be shown that the scaling function $\phi(t)$ generated from $G_S(e^{j\omega})$ is such that

$$|G_s(e^{j\omega})|^2 S(e^{j\omega})\big|_{\downarrow 2} = 0.5S(e^{j\omega}) \tag{6.115}$$

where the notation $\downarrow 2$ indicates decimation (Section 6.4). Thus, the function $S(e^{j\omega})$ can be regarded as an eigenfunction (with eigenvalue = 0.5) of the operator $\mathcal{F}$, which performs filtering by $|G_s(e^{j\omega})|^2$ followed by decimation.

Now consider the case in which the digital filter bank is paraunitary, so that $G_S(e^{j\omega})$ is power symmetric (i.e., satisfies Equation 6.95). The power symmetric condition can be rewritten in the form $|G_s(e^{j\omega})|^2\big|_{\downarrow 2} = 0.5$. Thus, in the power symmetric case the identity function is an eigenfunction of the operator F. If the only eigenfunction of the operation F is the identity function, it then follows that $S(e^{j\omega}) = 1$; i.e., Equation 6.100 holds and $\{\phi(t-n)\}$ is orthonormal.

The FIR Case: Section 6.12 shows that restricting $G_s(z)$ to be FIR ensures that $\phi(t)$ has finite duration. For the FIR case, Lawton and Cohen independently showed that the previous eigenfunction condition also works in the other direction. That is, if $\{\phi(t-n)\}$ has to be orthonormal, then the trignometric polynomial $S(e^{j\omega})$ satisfying Equation 6.115 must be unique up to a scale factor.* Details can be found in Ref. [5].

* A finite sum of the form $\sum_{n=N_1}^{N_2} p_n e^{j\omega n}$ is said to be a trignometric polynomial. If $G_s(e^{j\omega})$ is FIR, it can be demonstrated that the left-hand side of Equation 6.100 is not only periodic in ω, but is in fact a trignometric polynomial.

6.11.3.4 Examples and Counter-Examples

We already indicated after the introduction of Equation 6.112 that the example of the ideal bandpass wavelet can be generated formally by starting from the ideal brickwall paraunitary filter bank. We now discuss some other examples.

Example 6.12: Haar Basis from Filter Banks

A filter bank of the form Figure 6.22a with filters

$$G_a(z) = \frac{1+z^{-1}}{2} \quad H_a(z) = \frac{z^{-1}-1}{2} \quad G_s(z) = \frac{1+z^{-1}}{2} \quad H_s(z) = \frac{1-z^{-1}}{2}$$

is paraunitary. The magnitude responses of the synthesis filters, $|G_s(e^{j\boldsymbol{\omega}})| = |\cos(\boldsymbol{\omega}/2)|$ and $|H_s(e^{j\boldsymbol{\omega}})| = |\sin(\boldsymbol{\omega}/2)|$, are shown in Figure 6.43a. $G_s(z)$ satisfies all the conditions of Theorem 6.13. In this case we can evaluate the infinite products for $\boldsymbol{\Phi}(\boldsymbol{\omega})$ and $\boldsymbol{\psi}(\boldsymbol{\omega})$ explicitly by using the identity $\prod_{m=1}^{\infty} \cos(2^{-m}\boldsymbol{\omega}) = \sin \boldsymbol{\omega}/\boldsymbol{\omega}$. The resulting $\boldsymbol{\phi}(t)$ and $\boldsymbol{\psi}(t)$ are as shown in Figure 6.43b and c. These are precisely the functions that generate the Haar orthonormal basis.

Example 6.13: Paraunitary Filter Bank That Does Not Give Orthonormal Wavelets

Consider the filter bank with analysis filters $G_a(z) = (1+z^{-3})/2$, $H_a(z) = -(1-z^{-3})/2$, and synthesis filters $G_s(z) = (1+z^{-3})/2$, $H_s(z) = (1-z^{-3})/2$. Because this is obtained from the preceding example by the substitution $z \rightarrow z^3$, it remains paraunitary and satisfies the PR property. $G_s(z)$ satisfies all the properties of Theorem 6.13, except the fourth condition. With $\boldsymbol{\phi}(t)$ and $\boldsymbol{\psi}(t)$ obtained from $G_s(e^{j\boldsymbol{\omega}})$ using the usual dilation equations, the functions $\{\boldsymbol{\phi}(t-n)\}$ are *not orthonormal*. In addition, the wavelet functions $\{2^{k/2}\,\boldsymbol{\psi}(2^k\,t-n)\}$ do not form an orthonormal basis. These statements can be verified from the sketches of the functions $\boldsymbol{\phi}(t)$ and $\boldsymbol{\psi}(t)$ shown in Figure 6.44. Clearly, $\boldsymbol{\phi}(t)$ and $\boldsymbol{\phi}(t-1)$ are not orthogonal, and $\boldsymbol{\psi}(t)$ and $\boldsymbol{\psi}(t-2)$ are not orthogonal. In this example, $\|P_n(\boldsymbol{\omega})\| = 1$ for all n, whereas $\|\boldsymbol{\Phi}(\boldsymbol{\omega})\| = 1/\sqrt{3}$. The limit of $\|P_n(\boldsymbol{\omega})\|$ does not agree with $\|\boldsymbol{\Phi}(\boldsymbol{\omega})\|$, and our conclusion is that $\boldsymbol{\Phi}(\boldsymbol{\omega})$ is not the L^2 limit of $P_n(\boldsymbol{\omega})$. The L_2 limit of $P_n(\boldsymbol{\omega})$ does not exist in this example.

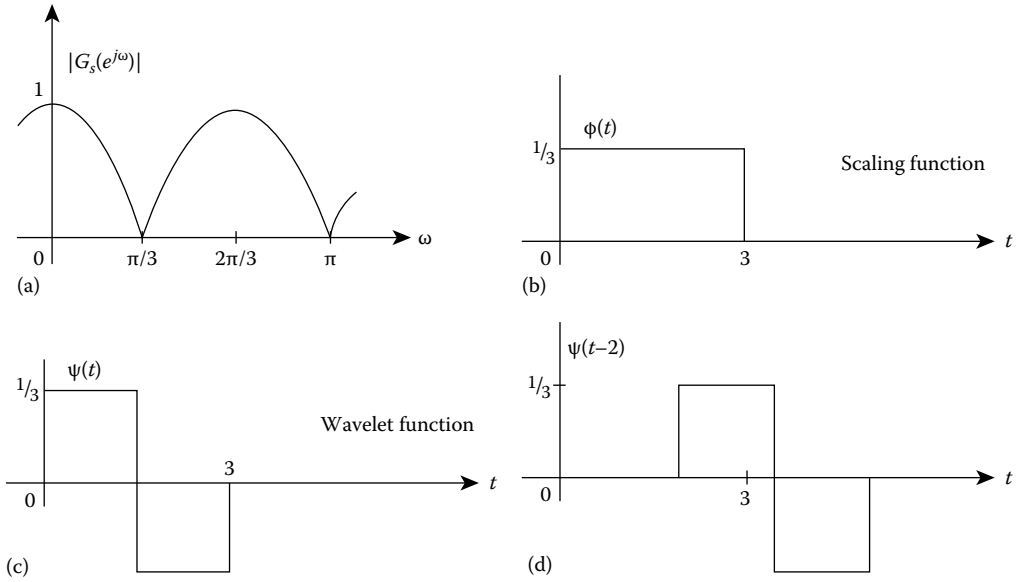

FIGURE 6.44 Paraunitary filter bank generating nonorthonormal $\{\phi(t-n)\}$. (a) The synthesis filter response, (b) the scaling function, (c) the wavelet function, and (d) a shifted version.

Thus, a paraunitary filter bank may not generate an orthonormal wavelet basis if the fourth condition in Theorem 6.13 is violated. However, this is hardly of concern in practice, because any reasonable low-pass filter designed for a two-channel filter bank will be free from zeroes in the region $[-0.5\pi, 0.5\pi]$. In fact, a stronger result was proved by Cohen, who derived necessary and sufficient conditions for an FIR paraunitary filter bank to generate an orthonormal wavelet basis. One outcome of Cohen's analysis is that the fourth condition in Theorem 6.13 can be replaced by the even milder condition that $G_s(e^{j\omega})$ not be zero in $[-\pi/3, \pi/3]$. In this sense, the condition for obtaining an orthonormal wavelet basis is trivially satisfied in practice. The case in which the fourth condition fails is primarily of theoretical interest; an attractive result in this context is Lawton's tight frame theorem.

6.11.4 Wavelet Tight Frames

Although the wavelet functions $\{2^{k/2}\psi(2^k t - n)\}$ generated from a paraunitary filter bank may not form an orthonormal basis when the fourth condition of Theorem 6.13 is violated, the functions always form a tight frame for L^2. Thus, any L^2 function can be expressed as an infinite linear combination of the functions $\{2^{k/2}\psi(2^k t - n)\}$. More precisely, we have the following result due to Lawton [5].

THEOREM 6.14: Tight Frames from Paraunitary Filter Banks

Let $G_s(e^{j\omega}) = \sum_{n=0}^{N} g_s(n)e^{-j\omega n}$ be a filter satisfying the following properties:

1. $G_s(e^{j0}) = 1$
2. $|G_s(e^{j\omega})|^2 + |G_s(-e^{j\omega})|^2 = 1$ (*power symmetry*)

Then, $\phi(t) \in L^2$. *Defining the wavelet function* $\psi(t)$ *as in Equation* 6.93, *the sequence* $\{2^{k/2}\psi(2^k t - n)\}$ (*with k and n varying over all integers*) *forms a tight frame for* L^2, *with frame bound unity* (i.e., $A = B = 1$; *see Section* 6.8).

Thus, the functions $\psi_{kn}(t)$ in Example 6.13 constitute a tight frame for L^2. From Section 6.8, we know that this tight frame property means that any $x(t) \in L^2$ can be expressed as

$$x(t) = \sum_{k=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} \langle x(t), \psi_{kn}(t) \rangle \psi_{kn}(t) \tag{6.116}$$

where $\psi_{kn}(t) = 2^{k/2}\ \psi(2^k\ t - n)$. This expression is pretty much like an expansion into an orthonormal basis. We can find the wavelet coefficients $c_{kn} = \langle x(t), \psi_{kn}(t) \rangle$ exactly as in the orthonormal case. We also know that frames offer stability of reconstruction. Thus, in every respect this resembles an orthonormal basis, the only difference being that the functions are not linearly independent (redundancy exists in the wavelet tight frame $\{\psi_{kn}(t)\}$).

6.12 Compactly Supported Orthonormal Wavelets

Section 6.11 showed how to construct an orthonormal wavelet basis for L^2 space by starting from a paraunitary filter bank. Essentially, we defined two infinite products $\Phi(\omega)$ and $\Psi(\omega)$ starting from the digital low-pass filter $G_s(e^{j\omega})$. Under some mild conditions on $G_s(e^{j\omega})$, the products converge (Theorem 6.10). Under the further condition that $G_s(e^{j\omega})$ be power symmetric and nonzero in $[-0.5, 0.5]$, we saw that $\{\phi(t-k)\}$ forms an orthonormal set, and the corresponding $\{2^{k/2}\ \psi(2^k\ t-n)\}$ forms an orthonormal wavelet basis for L^2 (Theorem 6.13). If we further constrain $G_s(e^{j\omega})$ to be FIR, that is, $G_s(z) = \sum_{n=0}^{N} g_s(n) z^{-n}$, then the scaling function $\phi(t)$ and the wavelet function $\psi(t)$ have finite duration [5,6].

THEOREM 6.15

Let $G_s(z) = \sum_{n=0}^{N} g_s(n) z^{-n}$, with $G_s(e^{j0}) = 1$ and $H_s(e^{j\omega}) = e^{j\omega}\ G_s^{\star}(-e^{j\omega})$. Define the infinite products as in Equation 6.112a and b, and assume that the limits $\Phi(\omega)$ and $\Psi(\omega)$ are L^2 functions, for example, by imposing power symmetry condition on $G_s(z)$ as in Theorem 6.11. Then $\phi(t)$ and $\psi(t)$ (the inverse L^2-FTs) are compactly supported, with support in $[0, N]$.

The time decay of the wavelet $\psi(t)$ is therefore excellent. In particular, all the basis functions $\{2^{k/2}\ \psi(2^k\ t-n)\}$ are compactly supported. By further restricting the low-pass filter $G_s(z)$ to have a sufficient number of zeroes at $\omega = \pi$, we also ensure (Section 6.13) that the FT $\Psi(\omega)$ has excellent decay (equivalently $\psi(t)$ is regular or smooth in the sense to be quantified in Section 6.13).

The rest of this section is devoted to the technical details of the above result. The reader not interested in these details can move to Section 6.13 without loss of continuity. The theorem might seem ''obvious'' at first sight, and indeed a simple engineering argument based on Dirac delta functions can be given (p. 521 of Ref. [7]). However, the correct mathematical justification relies on a number of deep results in function theory. One of these is the celebrated Paley–Wiener theorem for band-limited functions.

Paley–Wiener Theorem: A beautiful result in the theory of signals is that if an L^2 function $f(t)$ is band-limited, that is, $F(\omega) = 0$, $|\omega| \geq \sigma$, then $f(t)$ is the ''real-axis restriction of an entire function.'' We say that a function $f(s)$ of the complex variable s is entire if it is analytic for all s. Examples are polynomials in s, exponentials such as e^s, and simple combinations of these. The function $f(t)$ obtained from $f(s)$ for real values of $s (s = t)$ is the real-axis restriction of $f(s)$.

Thus, if $f(t)$ is a band-limited signal then an entire function $f(s)$ exists such that its real-axis restriction is $f(t)$. In particular, therefore, a band-limited function $f(t)$ is continuous and infinitely differentiable with respect to the time variable t. The entire function $f(s)$ associated with band-limited function has the further

property $|f(s)| \leq ce^{\sigma|s|}$ for some c > 0. We express this by saying that $f(s)$ is exponentially bounded or of the exponential type. What is even more interesting is that the converse of this result is true: if $f(s)$ is an entire function of the exponential type, and the real-axis restriction $f(t)$ is in L^2, then $f(t)$ is band-limited. By interchanging the time and frequency variables, we can obtain similar conclusions for time-limited signals; this is what we need in the discussion of the time-limited (compactly supported) wavelets.

THEOREM 6.16: (Paley–Wiener)

Let $W(s)$ be an entire function such that for all s, we have $|W(s)| \leq c \exp(A|s|)$ for some c, $A > 0$, and the real-axis restriction $W(\omega)$ is in L^2. Then, there exists a function $w(t)$ in L^2 such that $W(s) = \int_{-A}^{A} w(t)e^{-jts}dt$.

A proof can be found in Ref. [23]. Thus, $w(t)$ can be regarded as a compactly supported function support in $[-A, A]$. Recall Equation 6.48 that $L^2[-A, A] \subset L^1[-A, A]$ so $w(t)$ is in $L^1[-A, A]$ and $L^2[-A, A]$. Therefore, $W(\omega)$ is the L^1-FT of $w(t)$, and agrees with the L^2-FT a.e.

Our aim is to show that the infinite product for $\Phi(\omega)$ satisfies the conditions of the Paley–Wiener theorem, and therefore that $\phi(t)$ is compactly supported. A modified version of the previous result is more convenient for this. The modification allows the support to be more general, namely $[-A_1, A_2]$, and permits us to work with the imaginary part of s instead of the absolute value.

THEOREM 6.17: (Paley–Wiener, Modified)

Let $W(s)$ be an entire function such that

$$|W(s)| \leq \begin{cases} c_1 \exp(A_1|\text{Im } s|), & \text{Im } s \geq 0 \\ c_2 \exp(A_2|\text{Im } s|), & \text{Im } s \leq 0 \end{cases} \tag{6.117}$$

for some $c_1, c_2, A_1, A_2 > 0$, and such that the real-axis restriction $W(\omega)$ is in L^2. Then a function $w(t)$ exists in L^2 such that $W(s) = \int_{-A_2}^{A_1} w(t)e^{-jts}dt$. We can regard $W(\omega)$ as the FT of the function $w(t)$ supported in $[-A_2, A_1]$.

This result can be made more general; the condition given in Equation 6.117 can be replaced with one in which the right-hand sides have the form $P_i(s) \exp(A_i|\text{Im } s|)$, where $P_i(s)$ are polynomials. We are now ready to sketch the proof that $\phi(t)$ and $\Psi(t)$ have the compact support $[0, N]$.

1. Using the fact that $G_s(z)$ is FIR and that $G_s(e^{j0}) = 1$, show that the product $\prod_{k=1}^{\infty} G_s(e^{js/2^k})$ converges uniformly on any compact set of the complex s-plane. (For real s, namely $s = \omega$, this holds even for the IIR case as long as $\sum_n |ng_s(n)|$ converges. This was shown in Theorem 6.10.)
2. Uniformity of convergence of the product guarantees that is limit $\Phi(s)$ is an entire function of the complex variable s (Theorem 10.28 [23]).
3. The FIR nature of $G_s(z)$ allows us to establish the exponential bound Equation 6.117 for $\Phi(s)$ with $A_2 = 0$ and $A_1 = N$. This shows that $\phi(t)$ is compactly supported in $[0, N]$. Because $\Psi(t)$ is obtained from the dilation Equation 6.93, the same result follows for $\Psi(t)$ as well.

6.13 Wavelet Regularity

From the preceding section, we know that if we construct the power symmetric FIR filter $G_s(z)$ properly, we can get an orthonormal multiresolution basis $\{\phi(t-n)\}$, and an orthonormal wavelet basis

$\{2^{k/2}\psi(2^k t - n)\}$ for L^2. Both of these bases are compactly supported. These are solutions to the two-scale dilation equations

$$\phi(t) = 2\sum_{n=0}^{N} g_s(n)\phi(2t - n) \tag{6.118}$$

$$\psi(t) = 2\sum_{n=0}^{N} h_s(n)\phi(2t - n) \tag{6.119}$$

where $h_s(n) = (-1)^{n+1} g_s^*(-n-1)$. In the frequency domain we have the explicit infinite product expressions (Equation 6.112) connecting the filters $G_s(z)$ and $H_s(z)$ to the L^2-FTs $\Phi(\omega)$ and $\Psi(\omega)$.

Figure 6.45a shows two cases of a ninth-order FIR filter $G_s(e^{j\omega})$ used to generate the compactly supported wavelet. The resulting wavelets are shown in Figure 6.45b and c. In both cases all conditions of Theorem 6.13 are satisfied so we obtain orthonormal wavelet bases for L^2. The filter $G_s(e^{j\omega})$ has more zeroes at π for case 2 than for case 1. The corresponding wavelet looks much smoother or "regular"; this is an example of a Daubechies wavelet. By designing $G_s(z)$ to have a sufficient number of zeroes at π, we can make the wavelet "as regular as we please." A quantitative discussion of the connection between the number of zeroes at π and the smoothness of $\psi(t)$ is given in the following discussions.

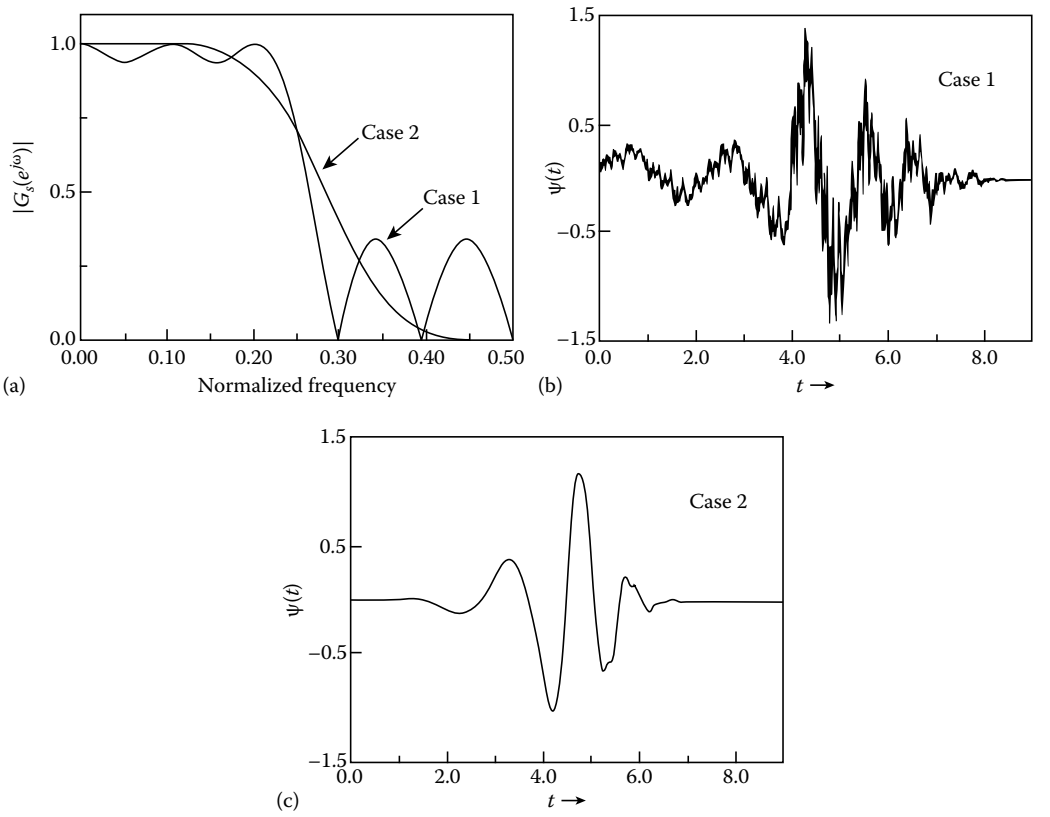

FIGURE 6.45 Demonstrating the importance of zeroes at π. (a) The response of the FIR filter $G_s(z)$ for two cases, and (b) and (c) the corresponding wavelet functions.

Quantitatively, the idea is that if $G_s(e^{j\omega})$ has a large number of zeroes at π, the function $\Phi(\omega)$ given by the infinite product (Equation 6.112a) decays "fast," as $\omega \to \infty$. This fast asymptotic decay in the frequency domain implies that the time function $\phi(t)$ is "smooth." Because $\psi(t)$ is derived from $\phi(t)$ using a finite sum (Equation 6.119), the smoothness of $\phi(t)$ is transmitted to $\psi(t)$. We will the make ideas more quantitative in the next few sections.

Why Regularity?

The point made above was that if we design an FIR paraunitary filter bank with the additional constraint that the low-pass filter $G_s(e^{j\omega})$ should have a sufficient number of zeroes at π, the wavelet basis functions $\Psi_{kn}(t)$ are sufficiently smooth. The smoothness requirement is perhaps the main new component brought into the filter bank theory from the wavelet theory. Its importance can be understood in a number of ways.

Consider the expansion $x(t) = \Sigma_{k,n}\, c_{k,n}\, \Psi_{kn}(t)$. Suppose we truncate this to a finite number of terms, as is often done in practice. If the basis functions are not smooth, the error can produce perceptually annoying effects in applications such as audio and image coding, even though the L^2 norm of the error may be small.

Next, consider a tree-structured filter bank. An example is shown in Figure 6.26. In the syntheses bank, the first path can be regarded as an effective interpolation filter, or an expander (e.g., $\uparrow 8$ in Figure 6.26b) followed by a filter of the form $G_s(e^{j\omega})G_s\,(e^{2j\omega})G_s\,(e^{4j\omega})\cdots G_s\,(e^{2^L\, j\omega})$. The same finite product can be obtained by truncating to $L+1$ terms the infinite product defining $\Phi(\omega)$ (Equation 6.112), and making a change of variables. Similarly, the remaining paths can be related to interpolation filters which are various truncated versions of the infinite product defining $\Psi(\omega)$ in Equation 6.112. Imagine we use the tree-structured system in subband coding. The quantization error in each subband is filtered through an interpolation filter. If the impulse response of the interpolation filter is not smooth enough (e.g., if it resembles Figure 6.45b), the filtered noise tends to show severe perceptual effects, for example, in image reconstruction. This explains, qualitatively, the importance of having "smooth impulse responses" for the synthesis filters.

6.13.1 Smoothness and Hölder Regularity Index

We are familiar with the notion of continuous functions. We say that $f(t)$ is continuous at t_0 if, for any $\varepsilon > 0$, we can find a $\delta > 0$ such that $|f(t) - f(t_0)| < \varepsilon$ for all t satisfying $|t - t_0| < \delta$. A stronger type of continuity, called Hölder continuity, is defined as follows: $f(t)$ is Hölder continuous in a region $\mathcal{S}$ if $|f(t_0) - f(t_1)| \le c|t_0 - t_1|^{\beta}$ for some $c, \beta > 0$, for all $t_0, t_1 \in \mathcal{S}$. This implies, in particular, continuity in the ordinary sense. If $\beta > 1$ the above would imply that $f(t)$ is constant on $\mathcal{S}$. For this reason, we have the restriction $0 < \beta \le 1$. As β increases from 0 to 1, the function becomes increasingly "smoother." The constant β is called the **Lipschitz constant** of the function $f(t)$.

Suppose the function $f(t)$ is n times differentiable in some region $\mathcal{S}$ and the nth derivative $f^{(n)}(t)$ is Hölder continuous with Lipschitz constant β. Define $\alpha = n + \beta$. We say that $f(t)$ belongs to the class C^{α}. The coefficient α is called the Hölder regularity index of $f(t)$. For example, $C^{3,4}$ is the class of functions that are three times differentiable and the third derivatives are Hölder continuous with Lipschitz constant equal to 0.4.

The Hölder regularity index α is taken as a quantitative measure of regularity or smoothness of the function $\psi(t)$. We sometimes say $\psi(t)$ has regularity α. Qualitatively speaking, a function with a large Hölder index is regarded as more "smooth" or "well-behaved." Because the dilation equations in the FIR case are finite summations, the Hölder indices of $\phi(t)$ and $\psi(t)$ are identical.

Some functions are differentiable an infinite number of times. That is, they belong to C^{∞}. Examples are e^t, sin t, and polynomials. C^{∞} functions even exist that are compactly supported (i.e., have finite duration; they will not be discussed here).

6.13.2 Frequency-Domain Decay and Time-Domain Smoothness

We can obtain time-domain smoothness of a certain degree by imposing certain conditions on the FT $\Psi(\omega)$. This is made possible by the fact that the rate of decay of $\Psi(\omega)$ as $\omega \to \infty$ (i.e., the asymptotic decay) governs the Hölder regularity index α of $\psi(t)$. Suppose $\Psi(\omega)$ decays faster than $(1+|\omega|)^{-(1+\alpha)}$:

$$|\Psi(\omega)| \leq \frac{c}{(1+|\omega|)^{1+\alpha+\varepsilon}} \quad \text{for all } \omega \tag{6.120}$$

for some $c > 0$, $\varepsilon > 0$. Then, $\Psi(\omega)(1+|\omega|)^{\alpha}$ is bounded by the integrable function $c/(1+|\omega|)^{1+\varepsilon}$, and is therefore (Lebesgue) integrable. Using standard Fourier theory it can be shown that this implies $\psi(t) \in C^{\alpha}$. In the wavelet construction of Section 6.11, which begins with a digital filter bank, the above decay of $\psi(\omega)$ can be accomplished by designing the digital filter $G_s(e^{j\omega})$ such that it has a sufficient number of zeroes at $\omega = \pi$.

Thus, the decay in the frequency domain translates into regularity in the time domain. Similarly, one can regard time-domain decay as an indication of smoothness in frequency. When comparing two kinds of wavelets, we can usually compare them in terms of time-domain regularity (frequency domain decay) and time-domain decay (frequency domain smoothness). An extreme example is one in which $\psi(t)$ is band limited. This means that $\Psi(\omega)$ is zero outside the passband, and so the "decay" is the best possible. Correspondingly, the smoothness of $\psi(t)$ is excellent; in fact, $\psi(t) \in C^{\infty}$. However, the decay of $\psi(t)$ may not be excellent (certainly it cannot be time limited if it is band limited).

Return to the two familiar wavelet examples, the Haar wavelet (Figure 6.12) and the bandpass wavelet (Figures 6.9 and 6.11). We see that the Haar wavelet has poor decay in the frequency domain because $\Psi(\omega)$ decays only as ω^{-1}. Correspondingly, the time-domain signal $\psi(t)$ is not even continuous, hence, not differentiable.* The bandpass wavelet, on the other hand, is band limited, so the decay in frequency is excellent. Thus, $\psi(t) \in C^{\infty}$, but it decays slowly, behaving similarly to t^{-1} for large t. These two examples represent two extremes of orthonormal wavelet bases for L^2.

The game, therefore, is to construct wavelets that have good decay in time as well as good regularity in time. An extreme hope is where $\psi(t) \in C^{\infty}$, and has compact support as well. It can be shown that such $\psi(t)$ can never give rise to an orthonormal basis, so we must strike a compromise between regularity in time and decay in time.

6.13.2.1 Regularity and Decay in Early Wavelet Constructions

In 1982, Stromberg showed how to construct wavelets in such a way that $\psi(t)$ has exponential decay, and at the same time has arbitrary regularity (i.e., $\psi(t) \in C^k$ for any chosen integer k). In 1985, Meyer constructed wavelets with band-limited $\psi(t)$ (so $\psi(t) \in C^{\infty}$ as for the bandpass wavelet), but he also showed how to design this $\psi(t)$ to decay faster than any chosen inverse polynomial, as $t \to \infty$. Figure 6.46a shows an example of a Meyer wavelet; a detailed description of this wavelet can be found in Ref. [5]. In both of the above constructions the wavelets gave rise to orthonormal bases for L^2.

In 1987 and 1988, Battle and Lemarié independently constructed wavelets with similar properties as Stromberg's wavelets, namely, $\psi(t) \in C^k$ for arbitrary k, and $\psi(t)$ decays exponentially. Their construction is based on spline functions and an orthonormalization step, as described in Section 6.10. The resulting wavelets, while not compactly supported, decay exponentially and generate orthonormal bases. Figure 6.46b shows an example of the Battle–Lemarié wavelet.

Table 6.1 gives a summary of the main features of these early wavelet constructions (first three entries). When these examples were constructed, the relation between wavelets and digital filter banks was not known. The constructions were not systematic or unified by a central theory. Moreover, it was not clear whether one could get a compactly supported (i.e., finite duration) wavelet $\psi(t)$, which at the same time

* It is true that $\psi(t)$ is differentiable almost everywhere, but the discontinuities at the points $t = 0$, 0.5, 1.0 will be very noticeable if we take linear combinations such as $\Sigma_{k,n} c_{kn}\, \psi_{kn}(t)$.

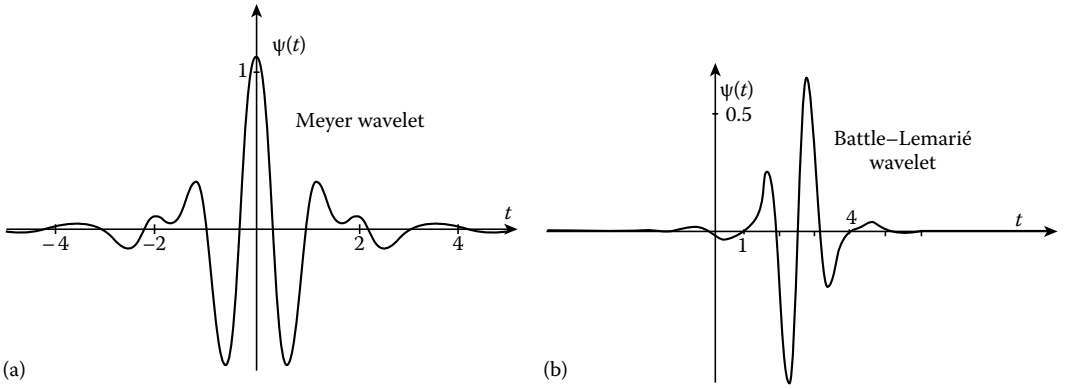

FIGURE 6.46 (a) An example of Meyer wavelet, and (b) an example of Battle–Lemarié wavelet.

TABLE 6.1 Summary of Several Types of Wavelet Bases for $L^2(R)$

Type of Wavelet	Decay of $\psi(t)$ in Time	Regularity of $\psi(t)$ in Time	Type of Wavelet Basis
Stromberg (1982)	Exponential	$\psi(t) \in C^k$; k can be chosen arbitrarily large	Orthonormal
Meyer (1985)	Faster than any chosen inverse polynomial	$\psi(t) \in C^\infty$ (band limited)	Orthonormal
Battle–Lemarié (1987, 1988) (splines)	Exponential	$\psi(t) \in C^k$; k can be chosen arbitrarily large	Orthonormal
Daubechies (1988)	Compactly supported	$\psi(t) \in C^\alpha$;. α can be chosen as large as we please	Orthonormal

had arbitrary regularity (i.e., $\psi(t) \in C^k$ for any chosen k), and generated an orthonormal wavelet basis. This was made possible for the first time when the relation between wavelets and digital filter banks was observed by Daubechies in Ref. [6]. Simultaneously and independently, Mallat invented the multiresolution framework and observed the relation between his framework, wavelets, and paraunitary digital filter banks (the CQF bank, Section 6.4). These discoveries have made the wavelet construction easy and systematic, as described in Sections 6.11 and 6.12. The way to obtain arbitrary wavelet regularity with this scheme is described next.

6.13.3 Time-Domain Decay and Time-Domain Regularity

We now state a fundamental limitation which arises when trying to impose regularity and decay simultaneously [5].

THEOREM 6.18: Vanishing Moments

Let $\{2^{k/2}\,\psi(2^k t - n)\}$, $-\infty \le k, n \le \infty$ *be an orthonormal set in* L^2. *Suppose the wavelet* $\psi(t)$ *satisfies the following properties:*

1. $|\psi(t)| \le c(1 + |t|)^{-(m+1+\varepsilon)}$ *for some integer* m *and some* $\varepsilon > 0$; *that is, the wavelet decays faster than* $(1 + |t|)^{-(m+1)}$.
2. $\psi(t) \in C^m$ (*i.e.,* $\psi(t)$ *differentiable* m *times*), *and the* m *derivatives are bounded.*

Then, the first m *moments of* $\psi(t)$ *are zero, that is,* $\int t^i \psi(t) \mathrm{d}t = 0 \quad \text{for} \quad 0 \le i \le m$.

Impossibility of Compact Support, Infinite Differentiability, and Orthonormality: Suppose we have an orthonormal wavelet basis such that $\psi(t)$ is compactly supported, and infinitely differentiable (i.e., $\psi(t) \in C\infty$). Then all the conditions of Theorem 6.18 are satisfied. So the moments of $\psi(t)$ are zero, and therefore $\psi(t) = 0$ for all t violating the unit-norm property of $\psi(t)$. Thus, we cannot design compactly supported orthonormal wavelets which are infinitely differentiable; only a finite Hölder index can be accomplished. A similar observation can be made even when $\psi(t)$ is not compactly supported as long as it decays faster than any inverse polynomial (e.g., exponential decay).

The vanishing moment condition $\int t^i \, ^{\psi}(t)dt = 0$, $0 \le i \le m$ implies that the L^2-FT $\Psi(\omega)$ has $m+1$ zeroes at $\omega = 0$. This follows by using standard theorems on the L^1-FT [23].* Thus, the first m derivatives of $\Psi(\omega)$ vanish at $\omega = 0$. This implies a certain degree of flatness at $\omega = 0$. Summarizing, we have the following result.

THEOREM 6.19: Flatness in Frequency and Regularity in Time

Suppose we have a compactly supported $\psi(t)$ generating an orthonormal wavelet basis $\{2^{k/2}\ \Psi(2^k t - n)\}$, and let $\psi(t) \in C^m$, with m derivatives bounded. Then, $\psi(\omega)$ has $m+1$ zeroes at $\omega = 0$.

Return now to the wavelet construction technique described in Section 6.11. We started from a paraunitary FIR filter bank (Figure 6.22a) and obtained the scaling function $\phi(t)$ and wavelet function $\psi(t)$ as in Equations 6.118 and 6.119. The FIR nature implies that $\psi(t)$ has compact support (Section 6.12). With the mild conditions of Theorem 6.13 satisfied, we have an orthonormal wavelet basis for L^2. We see that if the wavelet $\psi(t)$ has Hölder index α, it satisfies all the conditions of Theorem 6.19, where m is the integer part of α. Thus, $\psi(\omega)$ has $m+1$ zeroes at $\omega = 0$, but because $\Phi(0) \neq 0$ (Section 6.10), we conclude from the dilation equation $\Psi(\omega) = H_s(e^{j\omega/2})\Phi(\omega/2)$ that the high-pass FIR filter $H_s(z)$ has $m+1$ zeroes at $\omega = 0$ (i.e., at $z = 1$). Using the relation $H_s(e^{j\omega}) = e^{j\omega}\ G_s.\ (-e^{j\omega})$, we conclude that $G_s(e^{j\omega})$ has $m+1$ zeroes at $\omega = \pi$; that is, the low-pass FIR filter $G_s(z)$ has the form $G_s(z) = (1+z^{-1})^{m+1}\ F(z)$, where $F(z)$ is FIR. Summarizing, we have the theorem below.

THEOREM 6.20: Zeroes at π and Regularity

Suppose we wish to design a compactly supported orthonormal wavelet basis for L^2 by designing an FIR filter $G_s(z)$ satisfying the conditions of Theorem 6.13. *If $\psi(t)$ must have the Hölder regularity index α then it is necessary that $G_s(z)$ have the form $G_s(z) = (1+z^{-1})^{m+1}\ F(z)$, where $F(z)$ is FIR, and m is the integer part of α.*

One zero at π is essential. From Theorem 6.10, we know that we must have $G_s(e^{j0}) = 1$, for the infinite product (Equation 6.112a) to converge. Theorem 6.13 imposes further conditions that enable us to obtain an orthonormal wavelet basis for L^2. One of these conditions is the power symmetric property $|G_s(e^{j\omega})|^2 + |G_s(-e^{j\omega})|^2 = 1$. Together with $G_s(e^{j0}) = 1$, this implies $G_s(e^{j\pi}) = 0$. Thus, it is necessary to have at least one zero for $G_s(e^{j\omega})$ at π. The filter that generates the Haar basis (Example 6.12) has exactly one zero at π, but the Haar wavelet $\psi(t)$ is not even continuous. If we desire increased regularity (continuity, differentiability, etc.), we need to put additional zeroes at π, as the above theorem shows.

Design techniques for paraunitary filter banks do not automatically yield filters which have zeroes at π. This condition must be incorporated separately. The maximally flat filter bank solution (Section 6.4) does satisfy this property, and in fact even allows us to specify the number of zeroes at π.

* Because $\psi(t) \in L^2$ and has compact support, $\psi(t) \in L^1$ as well.

6.13.4 Wavelets with Specified Regularity

The fundamental connection between digital filter banks and continuous time wavelets, elaborated in the preceding sections, allows us to construct the scaling function $\phi(t)$ and the wavelet function $\psi(t)$ with specified regularity index α. If $G_s(z)$ has a certain number of zeroes at π, this translates into the Hölder regularity index α. What really matters is not only the number of zeroes at π, but also the order of the FIR filter $G_s(z)$.

For a given order N of the filter $G_s(z)$, suppose we wish to put as many of its zeroes as possible at π. Let this number be K. What is the largest possible K? Not all N zeroes can be at π because we have imposed the power symmetric condition on $G_s(z)$. The best we can do is to put all the unit circle zeroes at π. The power symmetric condition says that $G(z) \triangleq G_s(z)G_s(z)$ is a half-band filter. This filter has order $2N$, with $2K$ zeroes at π. Because we wish to maximize K for fixed N, the solution for $G(z)$ is the maximally flat FIR filter (Figure 6.25), given in Equation 6.45. As the filter in Equation 6.45 has $2K$ zeroes at π and order $2N = 4K - 2$, we conclude that $K = (N+1)/2$. For example, if $G_s(z)$ is a fifth-order power symmetric filter it can have at most three zeroes at π.

The 20% Regularity Rule

Suppose $G_s(z)$ has been designed to be FIR power symmetric of order N, with the number K of zeroes at π adjusted to be maximum (i.e., $K = (N+1)/2$). It can be shown that the corresponding scaling and wavelet functions have a Hölder regularity index $\alpha \approx 0.2\,K$. This estimate is poor for small K, but improves as K grows. Thus, every additional zero at π contributes to $\approx$20% improvement in regularity.

For $K = 4$ (i.e., seventh-order $G_s(z)$), we have $\alpha = 1.275$, which means that the wavelet $\psi(t)$ is once differentiable and the derivative is Hölder continuous with Lipschitz constant 0.275. For $K = 10$ (19th-order $G_s(z)$) we have $\alpha = 2.9$, so the wavelet $\psi(t)$ is twice differentiable and the second derivative has Hölder regularity index 0.9.

Design Procedure: The design procedure is therefore very simple. For a specified regularity index α, we can estimate K and hence $N = 2K - 1$. For this K, we compute the coefficients of the FIR half-band maximally flat filter $G(z)$ using Equation 6.45. From this, we compute a spectral factor $G_s(z)$ of the filter $G(z)$. Tables of the filter coefficients $g_s(n)$ for various values of N can be found in Ref. [5]. From the coefficients $g_s(n)$ of the FIR filter $G_s(z)$, the compactly supported scaling and wavelet functions are fully determined via the dilation equations. These wavelets are called Daubechies wavelets and were first generated in Ref. [6]. Figure 6.45c is an example, generated with a ninth-order FIR filter $G_s(z)$, where response is shown as case 2 in Figure 6.45a.

The above regularity estimates, based on frequency domain behavior, give a single number α, which represents the regularity of $\psi(t)$ for all t. It is also possible to define pointwise or local regularity of the function $\psi(t)$ so that its smoothness can be estimated as a function of time t. These estimation methods, based on time domain iterations, are more sophisticated, but give a detailed view of the behavior of $\psi(t)$. Detailed discussions on obtaining various kinds of estimates for regularity can be found in Refs. [5,26].

6.14 Concluding Remarks

We introduced the WT and studied its connection to filter banks and STFTs. A number of mathematical concepts such as frames and Riesz bases were reviewed and used later for a more careful study of wavelets. We introduced the idea of multiresolution analysis and explained the connections both to filter banks and wavelets. This connection was then used to generate orthonormal wavelet bases from paraunitary filter banks. Such wavelets have compact support when the filter bank is FIR. The regularity or smoothness of the wavelet was quantified in terms of the Hölder exponent. We showed that we can achieve any specified Hölder exponent for compactly supported wavelets by restricting the low-pass filter of the FIR paraunitary filter bank to be a maximally flat power symmetric filter, with a sufficient number of zeroes at π.

6.14.1 Why Wavelets?

Discussions comparing wavelets with other types of time–frequency transforms appear at several places in this chapter. Here is a list of these discussions:

1. Section 6.2 discusses basic properties of wavelets and gives an elementary comparison of wavelet basis with the Fourier basis.
2. Section 6.3 compares the WT with the STFT and shows the time–frequency tilings for both cases (Figures 6.18 and 6.20).
3. Section 6.9 gives a deeper comparison with the STFT in terms of stability properties of the inverse, existence of frames, etc.
4. Section 6.13 presents a comparison to the traditional filter bank design approach. In traditional designs, the appearance of zero(es) at π is not considered important. At the beginning of Section 6.13.1, we discuss the importance of these zeroes in wavelets as well as in tree-structured filter banks.

6.14.2 Further Reading

The literature on wavelet theory and applications is enormous. This chapter is only a brief introduction, concentrating on one-dimensional orthonormal wavelets. Many results can be found on the topics of multidimensional wavelets, biorthogonal wavelets, and wavelets based on IIR filter banks. Two special issues of the *IEEE Transactions* have appeared on the topic thus far [27,28]. Multidimensional wavelets are treated by several authors in the edited volume of Ref. [15], and the filter bank perspective can be found in the work by Kovačevi´cand Vetterli [27]. Advanced results on multidimensional wavelets can be found in Ref. [29]. Advanced results on wavelets constructed from *M*-channel filter banks can be found in the chapter by Gopinath and Burrus in the edited volume of Ref. [15], and in the work by Steffen et al. [28]. The reader can also refer to the collections of chapters in Refs. [15,16], and the many references therein.

Acknowledgments

The authors are grateful to Dr. Ingrid Daubechies, Princeton University, Princeton, New Jersey, for many useful e-mail discussions on wavelets. This work was supported in part by Office of Naval Research grant N00014-93-1-0231, Rockwell International, and Tektronix, Inc.

7.1 Introduction

Graph theory had its beginning in Euler's solution of what is known as the Konigsberg Bridge problem. Kirchhoff developed the theory of trees in 1847 as a tool in the study of electrical networks. This was the first application of graph theory to a problem in physical science. Electrical network theorists have since played a major role in the phenomenal advances of graph theory that have taken place. A comprehensive treatment of these developments may be found in Ref. [1]. In this chapter, we develop most of those results which form the foundation of graph theoretic study of electrical networks.

Our development of graph theory is self-contained, except for the definitions of standard set-theoretic operations and elementary results from matrix theory. We wish to note that the ring sum of two sets S_1 and S_2 refers to the set consisting of all those elements which are in S_1 or in S_2 but not in both S_1 and S_2.

7.2 Basic Concepts

A graph $G = (V, E)$ consists of two sets: a finite set $V = (v_1, v_2, \ldots, v_n)$ of elements called vertices and a finite set $E = (e_1, e_2, \ldots, e_m)$ of elements called edges. Each edge is identified with a pair of vertices. If the edges of G are identified with ordered pairs of vertices, then G is called a directed or an oriented graph. Otherwise G is called an undirected or a nonoriented graph. Graphs are amenable for pictorial representations. In a pictorial representation each vertex is represented by a dot and each edge is represented by a line segment joining the dots associated with the edge. In directed graphs, we assign an orientation or direction to each edge. If the edge is associated with the ordered pair (v_i, v_j), then this edge is oriented from v_i to v_j. If an edge e connects vertices v_i and v_j, then it is denoted by $e = (v_i, v_j)$. In a directed graph, (v_i, v_j) refers to an edge directed from v_i to v_j. An undirected graph and a directed graph are shown in Figure 7.1. Unless explicitly stated, the term "graph" may refer to an undirected graph or to a directed graph.

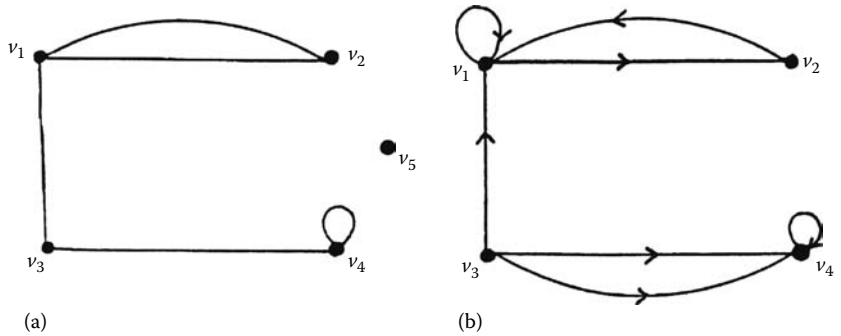

FIGURE 7.1 (a) An undirected graph; (b) a directed graph.

The vertices v_i and v_j associated with an edge are called the end vertices of the edge. All edges having the same pair of end vertices are called parallel edges. In a directed graph, parallel edges refer to edges connecting the same pair of vertices v_i and v_j oriented in the same direction from v_i to v_j or from v_j to v_i. For instance, in the graph of Figure 7.1a, the edges connecting v_1 and v_2 are parallel edges. In the directed graph of Figure 7.1b the edges connecting v_3 and v_4 are parallel edges. However, the edges connecting v_1 and v_2 are not parallel edges because they are not oriented in the same direction. If the end vertices of an edge are not distinct, then the edge is called a self-loop. The graph of Figure 7.1a has one self-loop and the graph of Figure 7.1b has two self-loops.

An edge is said to be incident on its end vertices. In a directed graph the edge (v_i, v_j) is said to be incident out of v_i and is said to be incident into v_j. Vertices v_i and v_j are adjacent if an edge connects v_i and v_j.

The number of edges incident on a vertex v_i is called the degree of v_i and is denoted by $d(v_i)$. In a directed graph $d_{\text{in}}(v_i)$ refers to the number of edges incident into vertex v_i, and it is called the in-degree of v_i. $d_{\text{out}}(v_i)$ refers to the number of edges incident out of vertex v_i, and it is called the out-degree of v_i. If $d(v_i) = 0$, then v_i is called an isolated vertex. If $d(v_i) = 1$, then v_i is called a pendant vertex. A self-loop at a vertex v_i is counted twice while computing $d(v_i)$. As an example, in the graph of Figure 7.1a, $d(v_1) = 3$, $d(v_4) = 3$, and v_5 is an isolated vertex. In the directed graph of Figure 7.1b $d_{\text{in}}(v_1) = 3$, $d_{\text{out}}(v_1) = 2$.

Note that in a directed graph, for every vertex v_i,

$$d(v_i) = d_{\text{in}}(v_i) + d_{\text{out}}(v_i)$$

THEOREM 7.1

1. *The sum of the degrees of the vertices of a graph G is equal to 2m, where m is the number of edges of G.*
2. *In a directed graph with m edges, the sum of the in-degrees and the sum of the out-degrees are both equal to m.*

Proof

1. Because each edge is incident on two vertices, it contributes 2 to the sum of the degrees of G. Hence, all edges together contribute $2m$ to the sum of the degrees.
2. Proof follows if we note that each edge is incident out of exactly one vertex and incident into exactly one vertex.

THEOREM 7.2

The number of vertices of odd degree in any graph is even.

Proof: By Theorem 7.1, the sum of the degrees of the vertices is even. Thus, the sum of the odd degrees must be even. This is possible only if the number of vertices of odd degree is even.

Consider a graph $G = (V, E)$. The graph $G' = (V', E')$ is a subgraph of G if $V' \subseteq V$ and $E' \subseteq E$. If every vertex in V' is an end vertex of an edge in E', then G' is called the induced subgraph of G on E'. As an example, a graph G and two subgraphs of G are shown in Figure 7.2.

In a graph G, a path P connecting vertices v_i and v_j is an alternating sequence of vertices and edges starting at v_i and ending at v_j with all vertices except v_i and v_j being distinct. In a directed graph, a path P connecting vertices v_i and v_j is called a directed path from v_i to v_j if all the edges in P are oriented in the same direction as we traverse P from v_i toward v_j. If a path starts and ends at the same vertex, it is called a circuit.* In a directed graph, a circuit in which all the edges are oriented in the same direction is called a directed circuit. It is often convenient to represent paths and circuits by the sequence of edges representing them.

For example, in the undirected graph of Figure 7.3a P: e_1, e_2, e_3, e_4 is a path connecting v_1 and v_5 and C: e_1, e_2, e_3, e_4, e_5, e_6 is a circuit. In the directed graph of Figure 7.3b P: e_1, e_2, e_7, e_5 is a directed path and C: e_1, e_2, e_7, e_6 is a directed circuit. Note that e_7, e_5, e_4, e_1, e_2 is a circuit in this directed graph, although it is not a directed circuit.

Two vertices v_i and v_j are said to be connected in a graph G if a path in G connects v_i and v_j. A graph G is connected if every pair of vertices in G is connected; otherwise, it is a disconnected graph. For example, the graph G in Figure 7.4a is connected, but the graph in Figure 7.4b is not connected.

A connected subgraph $G' = (V', E')$ of a graph $G = (V, E)$ is a component of G if adding to G' an edge $e \in E - E'$ results in a disconnected graph. Thus, a connected graph has exactly one component. For example, the graph in Figure 7.4b is not connected and has two components.

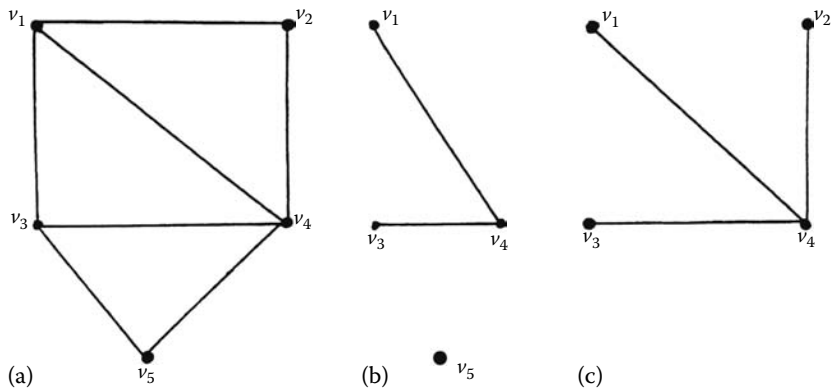

FIGURE 7.2 (a) Graph G; (b) subgraph of G; (c) an edge-induced subgraph of G.

* In electrical network theory literature, the term "loop" is also used to refer to a circuit.

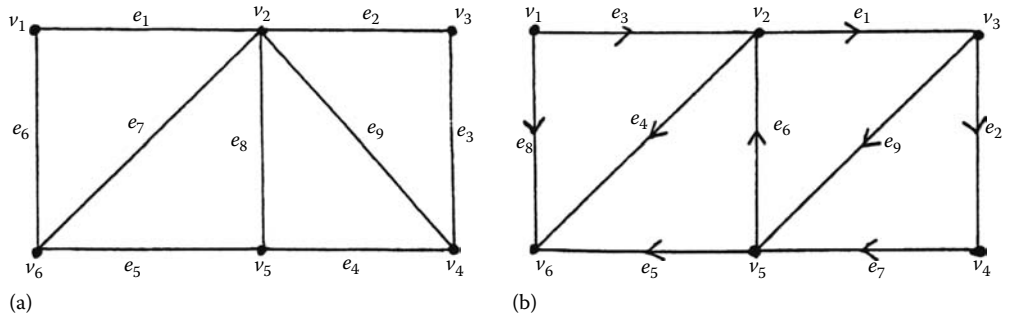

FIGURE 7.3 (a) An undirected graph; (b) a directed graph.

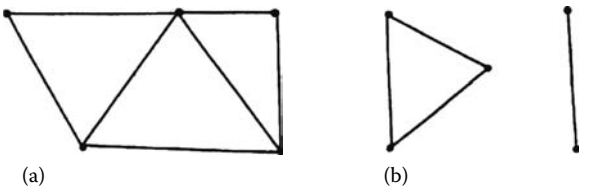

FIGURE 7.4 (a) A connected graph; (b) a disconnected graph.

A tree is a graph that is connected and has no circuits. Consider a connected graph G. A subgraph of G is a spanning tree* of G if the subgraph is a tree and contains all the vertices of G. A tree and a spanning tree of the graph of Figure 7.5a are shown in Figure 7.5b and c, respectively.

The edges of a spanning tree T are called the branches of T. Given a spanning tree of a connected graph G, the cospanning tree* relative to T is the subgraph of G induced by the edges that are not present in T. For example, the cospanning tree relative to the spanning tree T of Figure 7.5c consists of the edges e_3, e_6, and e_7. The edges of a cospanning tree are called chords.

A subgraph of a graph G is a k-tree of G if the subgraph has exactly k components and has no circuits. For example, a 2-tree of the graph of Figure 7.5a is shown in Figure 7.5d. If a graph has k components, then a forest of G is a spanning subgraph that has k components and no circuits. Thus, each component of the forest is a spanning tree of a component of G. A graph G and a forest of G are shown in Figure 7.6.

Consider a directed graph G. A spanning tree T of G is called a directed spanning tree with root v_i if T is a spanning tree of G, and $d_{\text{in}}(v_i) = 0$ and $d_{\text{in}}(v_j) = 1$ for all $v_j \neq v_i$. A directed graph G and a directed spanning tree with root v_1 are shown in Figure 7.7.

It can easily be verified that, in a tree, exactly one path connects any two vertices.

THEOREM 7.3

A tree on n vertices has $n - 1$ edges.

Proof: Proof is by induction on the number of vertices of the tree. Clearly, the result is true if a tree has one or two vertices. Assume that the result is true for trees on $n \geq 2$ or fewer vertices. Consider now a

* In electrical network theory literature, the terms "tree" and "cotree" are usually used to mean spanning tree and cospanning tree, respectively.

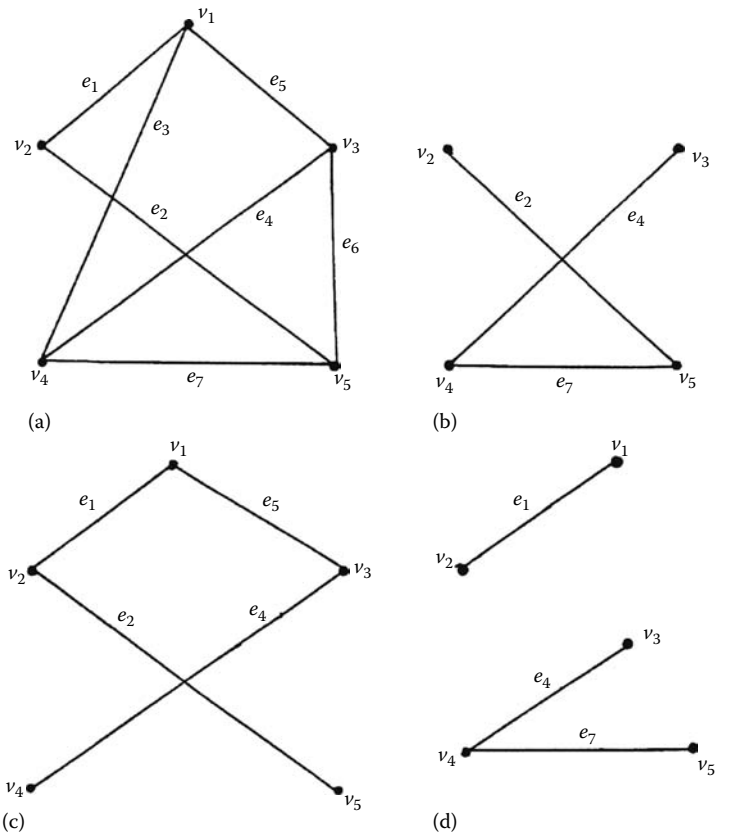

FIGURE 7.5 (a) Graph G; (b) a tree of graph G; (c) a spanning tree of G; (d) a 2-tree of G.

tree T on $n+1$ vertices. Pick an edge $e=(v_i, v_j)$ in T. Removing e from T would disconnect it into exactly two components T_1 and T_2. Both T_1 and T_2 are trees. Let n_1 and m_1 be the number of vertices and the number of edges in T_1, respectively. Similarly n_2 and m_2 are defined. Then, by the induction hypothesis

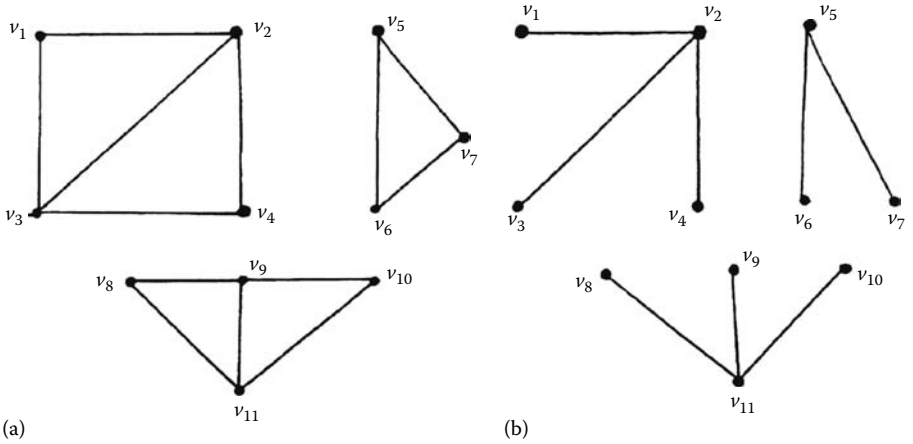

FIGURE 7.6 (a) Graph G; (b) a forest of G.

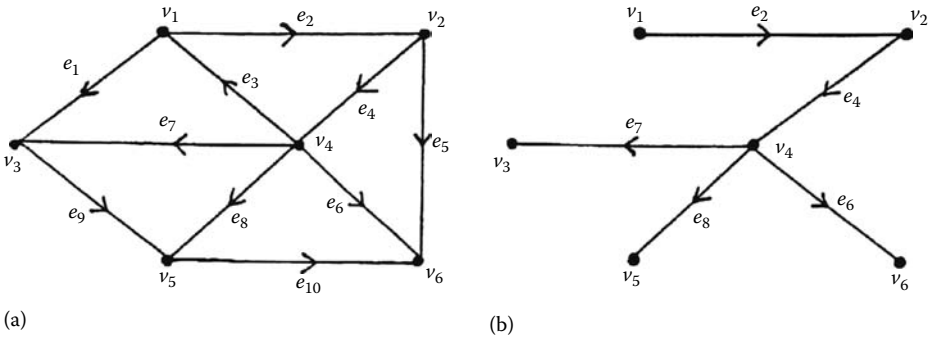

FIGURE 7.7 (a) Directed graph G; (b) a directed spanning tree of G with root v_1.

$$m_1 = n_1 - 1$$

and

$$m_2 = n_2 - 1$$

Thus, the number m of edges in T is given by

$$\begin{aligned} m &= m_1 + m_2 + 1 \\ &= (n_1 - 1) + (n_2 - 1) + 1 \\ &= n_1 + n_2 - 1 \\ &= n - 1 \end{aligned}$$

This completes the proof of the theorem.

If a connected graph G has n vertices, m edges, and k components, then the rank ρ and nullity μ of G are defined as follows:

$$\rho(G) = n - k \tag{7.1}$$

$$\mu(G) = m - n + k \tag{7.2}$$

Clearly, if G is connected, then any spanning tree of G has $\rho = n - 1$ branches and $\mu = m - n + 1$ chords.

We conclude this section with the following theorems. Proof of these theorems may be found in Ref. [2].

THEOREM 7.4

A tree on $n \geq 2$ vertices has at least two pendant vertices.

THEOREM 7.5

A subgraph of an n-vertex connected graph G is a spanning tree of G if and only if the subgraph has no circuits and has $n - 1$ edges.

THEOREM 7.6

If a subgraph G' of a connected graph G has no circuits then there exists a spanning tree of G that contains G'.

7.3 Cuts, Circuits, and Orthogonality

We introduce here the notions of a cut and a cutset and develop certain results which bring out the dual nature of circuits and cutsets.

Consider a connected graph $G = (V, E)$ with n vertices and m edges. Let V_1 and V_2 be two mutually disjoint nonempty subsets of V such that $V = V_1 \approx V_2$. Thus, $V_2 = \overline{V}_1$, the complement of V_1 in V. V_1 and V_2 are also said to form a partition of V. Then the set of all those edges which have one end vertex in V_1 and the other in V_2 is called a cut of G and is denoted by $\langle V_1, V_2 \rangle$. As an example, a graph G and a cut $\langle V_1, V_2 \rangle$ of G are shown in Figure 7.8.

The graph G' which results after removing the edges in a cut will have at least two components and so will not be connected. G' may have more than two components. A cutset S of a connected graph G is a minimal set of edges of G such that removal of S disconnects G into exactly two components. Thus, a cutset is also a cut. Note that the minimality property of a cutset implies that no proper subset of a cutset is a cutset.

Consider a spanning tree T of a connected graph G. Let b be a branch of T. Removal of the branch b disconnects T into exactly two components, T_1 and T_2. Let V_1 and V_2 denote the vertex sets of T_1 and T_2, respectively. Note that V_1 and V_2 together contain all the vertices of G. We can verify that the cut $\langle V_1, V_2 \rangle$ is a cutset of G and is called the fundamental cutset of G with respect to branch b of T. Thus, for a given connected graph G and a spanning tree T of G, we can construct $n - 1$ fundamental cutsets, one for each branch of T. As an example, for the graph shown in Figure 7.8, the fundamental cutsets with respect to the spanning tree $T = [e_1, e_2, e_6, e_8]$ are

Branch e_1: (e_1, e_3, e_4)
Branch e_2: (e_2, e_3, e_4, e_5)
Branch e_6: (e_6, e_4, e_5, e_7)
Branch e_8: (e_8, e_7)

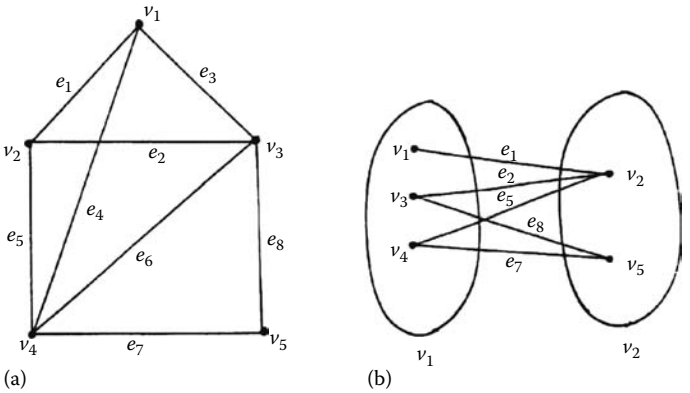

FIGURE 7.8 (a) Graph G; (b) cut $\langle V_1, V_2 \rangle$ of G.

Note that the fundamental cutset with respect to branch b contains b. Furthermore, the branch b is not present in any other fundamental cutset with respect to T.

Next, we identify a special class of circuits of a connected graph G. Again, let T be a spanning tree of G. Because exactly one path exists between any two vertices of T, adding a chord c to T produces a unique circuit. This circuit is called the fundamental circuit of G with respect to chord c of T. Note again that the fundamental circuit with respect to chord c contains c, and the chord c is not present in any other fundamental circuit with respect to T. As an example, the set of fundamental circuits with respect to the spanning tree $T = (e_1, e_2, e_6, e_8)$ of the graph shown in Figure 7.8 is

Chord e_3: (e_3,e_1,e_2)
Chord e_4: (e_4,e_1,e_2,e_6)
Chord e_5: (e_5,e_2,e_6)
Chord e_7: (e_7,e_8,e_6)

We now present a result that is the basis of what is known as the orthogonality relationship.

THEOREM 7.7

A circuit and a cutset of a connected graph have an even number of common edges.

Proof: Consider a circuit C and a cutset $S = \langle V_1, V_2 \rangle$ of G. The result is true if C and S have no common edges. Suppose that C and S possess some common edges. Let us traverse the circuit C starting from a vertex, e.g., v_1 and V_1. Because the traversing should end at v_1, it is necessary that every time we encounter an edge of S leading us from V_1 to V_2 an edge of S must lead us from V_2 back to V_1. This is possible only if S and C have an even number of common edges.

The above result is the foundation of the theory of duality in graphs. Several applications of this simple result are explored in different parts of this chapter.

A comprehensive treatment of the duality theory and its relationship to planarity may be found in Ref. [2]. The following theorem establishes a close relationship between fundamental circuits and fundamental cutsets.

THEOREM 7.8

1. *The fundamental circuit with respect to a chord of a spanning tree T of a connected graph consists of exactly those branches of T whose fundamental cutsets contain the chord.*
2. *The fundamental cutset with respect to a branch of a spanning tree T of a connected graph consists of exactly those chords of T whose fundamental circuits contain the branch.*

Proof: Let C be the fundamental circuit of a connected graph G with respect to a chord c of a spanning tree T of G. Let C contain, in addition to the chord c, the branches $b_1, b_2, \ldots, b_k$ of T. Let S_i be the fundamental cutset with respect to branch b_i.

We first show that each S_i, $1 \leq i \leq k$ contains c. Note that b_i is the only branch common to S_i and C, and c is the only chord in C. Because by Theorem 7.7, S_i and C must have an even number of common edges, it is necessary that S_i contains c.

Next, we show that no other fundamental cutset of T contains c. Suppose the fundamental cutset S_{k+1} with respect to some branch b_{k+1} of T contains c. Then c will be the only edge common to S_{k+1} and C, contradicting Theorem 7.7. Thus the chord c is present only in those cutsets defined by the branches $b_1, b_2, \ldots, b_k$.

The proof for item 2 of the theorem is similar to that of item 1.

7.4 Incidence, Circuit, and Cut Matrices of a Graph

The incidence, circuit, and cut matrices are coefficient matrices of Kirchhoff's equations which describe an electrical network. We develop several properties of these matrices that have proved useful in the study of electrical networks. Our discussions are mainly in the context of directed graphs. The results become valid in the case of undirected graphs if addition and multiplication are in $GF(2)$, the field of integers modulo 2. (Note that $1 + 1 = 0$ in this field.)

7.4.1 Incidence Matrix

Consider a connected directed graph G with n vertices and m edges and have no self-loop. The all-vertex incidence matrix $A_c = [a_{ij}]$ of G has n rows, one for each vertex, and m columns, one for each edge. The element a_{ij} of A_c is defined as follows:

$$a_{ij} = \begin{cases} 1, & \text{if the } j\text{th edge is incident out of the } i\text{th vertex} \\ -1, & \text{if the } j\text{th edge is incident into the } i\text{th vertex} \\ 0, & \text{if the } j\text{th edge is not incident on the } i\text{th vertex} \end{cases}$$

A row of A_c will be referred to as an incidence vector. As an example, for the directed graph shown in Figure 7.9, the matrix A_c is

$$A_c = \begin{array}{c} \\ v_1 \\ v_2 \\ v_3 \\ v_4 \\ v_5 \end{array} \begin{array}{c} \begin{array}{ccccccc} e_1 & e_2 & e_5 & e_6 & e_3 & e_4 & e_7 \end{array} \\ \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 1 & -1 \\ -1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & -1 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 & -1 & 0 & 1 \end{bmatrix} \end{array}$$

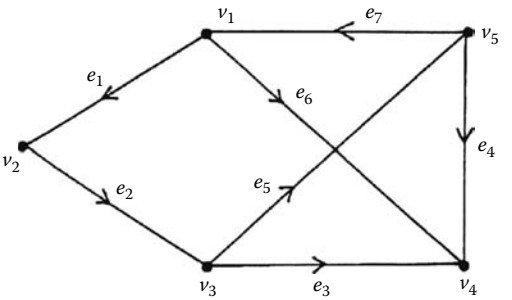

FIGURE 7.9 Directed graph.

From the definition of A_c it should be clear that each column of this matrix has exactly two nonzero entries, one $+1$ and one -1, and therefore, we can obtain any row of A_c from the remaining rows. Thus,

$$\text{rank}(A_c) \leq n - 1 \tag{7.3}$$

An $(n-1)$ rowed submatrix of A_c is referred to as an incidence matrix of G. The vertex which corresponds to the row of A_c that is not in A is called the reference vertex of A.

THEOREM 7.9

The determinant of an incidence matrix of a tree is ± 1.

Proof: Proof is by induction on the number m of edges in the tree. We can easily verify that the result is true for any tree with $m \leq 2$ edges. Assume that the result is true for all trees having $m \geq 2$ or fewer edges. Consider a tree T with $m+1$ edges. Let A be the incidence matrix of T with reference vertex v_r. Because, by Theorem 7.4, T has at least two pendant vertices, we can find a pendant vertex $v_i \neq v_r$. Let (v_i, v_j) be the only edge incident on v_i. Then, the remaining edges form a tree T_1. Let A_1 be the incidence matrix of T_1 with vertex v_r as reference. Now let us rearrange the rows and columns of A so that the first $n-2$ rows correspond to the vertices in T_1 (except v_r) and the first $n-1$ columns correspond to the edges of T_1. Then, we have

$$A = \begin{bmatrix} A_1 & A_3 \\ 0 & \pm 1 \end{bmatrix}$$

So

$$\det A = \pm(\det A_1) \tag{7.4}$$

A_1 is the incidence matrix of T_1 and T_1 has m edges, it follows from the induction hypothesis that det $A_1 = \pm 1$. Hence the theorem.

Because a connected graph has at least one spanning tree, it follows from the above theorem that any incidence matrix A of a connected graph has a nonsingular submatrix of order $n-1$. Therefore,

$$\text{rank}(A_c) \geq n - 1 \tag{7.5}$$

Combining Equations 7.3 and 7.5 yields the following theorem.

THEOREM 7.10

The rank of any incidence matrix of a connected directed graph G is equal to $n-1$, the rank of G.

7.4.2 Cut Matrix

Consider a cut $\langle V_a, \overline{V}_a \rangle$ in a connected directed graph G with n vertices and m edges. Recall that $\langle V_a, \overline{V}_a \rangle$ consists of all those edges connecting vertices in V_a to those in $\overline{V}_a$. This cut may be assigned on orientation from V_a to $\overline{V}_a$ or from $\overline{V}_a$ to V_a. Suppose the orientation of $\langle V_a, \overline{V}_a \rangle$ is from V_a to $\overline{V}_a$. Then the orientation of an edge (v_i, v_j) is said to agree with the cut orientation if $v_i \in V_a$, and $v_j \in \overline{V}_a$.

The cut matrix $Q_c = [q_{ij}]$ of G has m columns, one for each edge, and has one row for each cut. The element q_{ij} is defined as follows:

$$q_{ij} = \begin{cases} 1, & \text{if the } j\text{th edge is in the } i\text{th cut and its orientation agrees with the cut orientation} \\ \pm 1, & \text{if the } j\text{th edge is in the } i\text{th cut and its orientation does not agree with the cut orientation} \\ 0, & \text{if the } j\text{th edge is not in the } i\text{th cut} \end{cases}$$

Each row of Q_c is called a cut vector.

The edges incident on a vertex form a cut. Thus, it follows that the matrix A_c is a submatrix of Q_c. Next we identify another important submatrix of Q_c.

Recall that each branch of a spanning tree T of a connected graph G defines a fundamental cutset. The submatrix of Q_c corresponding to the $n-1$ fundamental cutsets defined by T is called the fundamental cutset matrix Q_f of G with respect to T.

Let $b_1, b_2, \ldots, b_{n-1}$ denote the branches of T. Let us assume that the orientation of a fundamental cutset is chosen so as to agree with that of the defining branch. Suppose we arrange the rows and the columns of Q_f so that the ith column corresponds to branch b_i, and the ith row corresponds to the fundamental cutset defined by b_i. Then, the matrix Q_f can be displayed in a convenient form as follows:

$$Q_f = [U | Q_{fc}] \tag{7.6}$$

where U is the unit matrix of order $n-1$ and its columns correspond to the branches of T.

As an example, the fundamental cutset matrix of the graph in Figure 7.9 with respect to the spanning tree

$$T = (e_1, e_2, e_5, e_6) \text{ is}$$

$$Q_f = \begin{array}{c} \\ e_1 \\ e_2 \\ e_5 \\ e_6 \end{array} \begin{array}{c} \begin{array}{ccccccc} e_1 & e_2 & e_5 & e_6 & e_3 & e_4 & e_7 \end{array} \\ \begin{bmatrix} 1 & 0 & 0 & 0 & -1 & -1 & -1 \\ 0 & 1 & 0 & 0 & -1 & -1 & -1 \\ 0 & 0 & 1 & 0 & 0 & -1 & -1 \\ 0 & 0 & 0 & 1 & 1 & 1 & 0 \end{bmatrix} \end{array}$$

It is clear from Equation 7.6 that the rank of Q_f is $n-1$. Hence,

$$\text{rank}(Q_c) \geq n - 1 \tag{7.7}$$

7.4.3 Circuit Matrix

Consider a circuit C in a connected directed graph G with n vertices and m edges. This circuit can be traversed in one of two directions, clockwise or counterclockwise. The direction we choose for traversing C is called the orientation of C. If an edge $e = (v_i, v_j)$ directed from v_i to v_j is in C, and if v_i appears before v_j as we traverse C in the direction specified by its orientation, then we say that the orientation of e agrees with the orientation of C.

The circuit matrix $B_c = [b_{ij}]$ of G has m columns, one for each edge, and has one row for each circuit in G. The element b_{ij} is defined as follows:

$$b_{ij} = \begin{cases} 1, & \text{if the } j\text{th edge is in the i th circuit and its orientation agrees with the circuit orientation} \\ \pm 1, & \text{if the } j\text{th edge is in the } i\text{th circuit and its orientation does not agree with the orientation} \\ 0, & \text{if the } j\text{th edge is not in the } i\text{th circuit} \end{cases}$$

Each row of B_c is called a circuit vector.

The submatrix of B_c corresponding to the fundamental circuits defined by the chords of a spanning tree T is called the fundamental circuit matrix B_f of G with respect to the spanning tree T.

Let $c_1, c_2, \ldots, c_{m-n+1}$ denote the chords of T. Suppose we arrange the columns and the rows of B_f so that the ith row corresponds to the fundamental circuit defined by the chord c_i, and the ith column corresponds to the chord c_i.

If, in addition, we choose the orientation of a fundamental circuit to agree with the orientation of the defining chord, we can write B_f as

$$B_f = [U|B_{ft}] \tag{7.8}$$

where U is the unit matrix of order $m-n+1$, and its columns correspond to the chords of T.

As an example, the fundamental circuit matrix of the graph shown in Figure 7.9 with respect to the tree $T=(e_1, e_2, e_5, e_6)$ is given below:

$$B_f = \begin{array}{c} \\ e_3 \\ e_4 \\ e_7 \end{array} \begin{array}{c} \begin{array}{ccccccc} e_3 & e_4 & e_7 & e_1 & e_2 & e_5 & e_6 \end{array} \\ \begin{bmatrix} 1 & 0 & 0 & 1 & 1 & 0 & -1 \\ 0 & 1 & 0 & 1 & 1 & 1 & -1 \\ 0 & 0 & 1 & 1 & 1 & 1 & 0 \end{bmatrix} \end{array}$$

It is clear from Equation 7.8 that the rank of B_f is $m-n+1$. Hence,

$$\text{rank}(B_c) \geq m-n+1 \tag{7.9}$$

7.5 Orthogonality Relation and Ranks of Circuit and Cut Matrices

THEOREM 7.11

If a cut and a circuit in a directed graph have 2k edges in common, then k of these edges have the same relative orientation in the cut and in the circuit, and the remaining k edges have one orientation in the cut and the opposite orientation in the circuit.

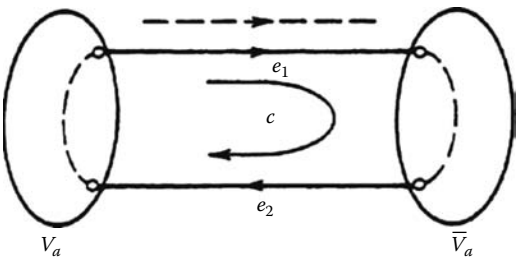

FIGURE 7.10 Relative orientations of an edge in a cut and a circuit.

Proof: Consider a cut $\langle V_a, \overline{V}_a \rangle$ and a circuit C in a directed graph. Suppose we traverse C starting from a vertex in V_a. Then, for every edge e_1 that leads from V_a to $\overline{V}_a$, an edge e_2 leads from $\overline{V}_a$ to V_a. Suppose the orientation of e_1 agrees with the orientation of the cut and that of the circuit. Then we can easily verify that e_2 has one orientation in the cut and the opposite orientation in the circuit (Figure 7.10). On the other hand, we can also verify that if e_1 has one orientation in the cut and the opposite orientation in the circuit, then e_2 will have the same relative orientation in the circuit and in the cut. This proves the theorem.

Next we prove the orthogonality relation.

THEOREM 7.12

If the columns of the circuit matrix B_c and the columns of the cut matrix Q_c are arranged in the same edge order, then

$$B_c Q_c^t = 0 \tag{7.10}$$

Proof: Each entry of the matrix $B_c Q_c^t$ is the inner product of a circuit vector and a cut vector. Suppose a circuit and a cut have $2k$ edges in common. The inner product of the corresponding vectors is zero, because by Theorem 7.11, this product is the sum of k 1's and $k-1$'s.

The orthogonality relation is a profound result with interesting applications in electrical network theory. Consider a connected graph G with m edges and n vertices. Let Q_f be the fundamental cutset matrix and B_f be the fundamental circuit matrix of G with respect to a spanning tree T. If we write Q_f and B_f as in Equations 7.6 and 7.8, then using the orthogonality relation we get

$$B_f Q_f^t = 0$$

that is,

$$[B_{ft} U] \begin{bmatrix} U \\ Q_{fc}^t \end{bmatrix} = 0$$

that is,

$$B_{ft} = -Q_{fc}^t \tag{7.11}$$

Using Equation 7.11, each circuit vector can now be expressed as a linear combination of the fundamental circuit vectors. Consider a circuit vector $\beta = \beta_1, \beta_2, \ldots, \beta_\rho \,|\beta_{\rho+1}, \ldots, \beta_m$ of G where $\rho = n-1$, is the rank of G. Then, again by the orthogonality relation we have

$$\beta Q_f^t = [\beta_1, \beta_2, \ldots, \beta_\rho | \beta_{\rho+1} \cdots \beta_m] \begin{bmatrix} U \\ Q_{fc}^t \end{bmatrix} = 0 \tag{7.12}$$

Therefore,

$$\begin{aligned} [\beta_1, \beta_2, \ldots, \beta_\rho] &= -[\beta_{\rho+1}, \beta_{\rho+2}, \ldots, \beta_m] Q_{fc}^t \\ &= [\beta_{\rho+1}, \beta_{\rho+2}, \ldots, \beta_m] B_{ft} \end{aligned}$$

So,

$$\begin{aligned} [\beta_1, \beta_2, \ldots, \beta_m] &= [\beta_{\rho+1}, \beta_{\rho+2} \cdots \beta_m] \, [\, B_{ft} \quad U \,] \\ &= [\beta_{\rho+1}, \beta_{\rho+2} \cdots \beta_m] B_f \end{aligned} \tag{7.13}$$

Thus, any circuit vector can be expressed as a linear combination of the fundamental circuit vectors. So

$$\text{rank}(B_c) \leq \text{rank}(B_f) = m - n + 1$$

Combining the above with Equation 7.9 we obtain

$$\text{rank}(B_c) = m - n + 1 \tag{7.14}$$

Starting from a cut vector and using the orthogonality relation, we can prove in an exactly similar manner that

$$\text{rank}(Q_c) \leq \text{rank}(Q_f) = n - 1$$

Combining the above with Equation 7.7, we get

$$\text{rank}(Q_c) = n - 1$$

Summarizing, we have the following theorem.

THEOREM 7.13

For a connected graph G with m edges and n vertices

$$\text{rank}(B_c) = m - n + 1$$
$$\text{rank}(Q_c) = n - 1$$

We wish to note from Equation 7.13 that the vector corresponding to a circuit C can be expressed as an appropriate linear combination of the fundamental circuit vectors corresponding to the chords present in C. Similarly, the vector corresponding to a cut can be expressed as an appropriate linear combination of the fundamental cut vectors corresponding to the branches present in the cut. Because modulo 2 addition of two vectors corresponds to the ring sum of the corresponding subgraphs, we have the following results for undirected graphs.

THEOREM 7.14

Let G be a connected undirected graph.

1. *Every circuit can be expressed as a ring sum of the fundamental circuits with respect to a spanning tree.*
2. *Every cut can be expressed as a ring sum of the fundamental cutsets with respect to a spanning tree.*

We can easily verify the following consequences of the orthogonality relation:

1. A linear relationship exists among the columns of the cut matrix (also of the incidence matrix), which correspond to the edges of a circuit.
2. A linear relationship exists among the columns of the circuit matrix, which correspond to the edges of a cut.

The following theorem characterizes the submatrices of A_c, Q_c, and B_c which correspond to spanning trees and cospanning trees. Proof follows from the above results and may be found in Ref. [2].

THEOREM 7.15

Let G be a connected graph G with n vertices, and m edges.

1. *A square submatrix of order $n-1$ of Q_c (also of A_c) is nonsingular iff the edges corresponding to the columns of this submatrix form a spanning tree of G.*
2. *A square submatrix of order $m-n+1$ of B_c is nonsingular iff the edges corresponding to the columns of this submatrix form a cospanning tree of G.*

7.6 Spanning Tree Enumeration

Here, we first establish a formula for counting the number of spanning trees of an undirected graph. We then state a generalization of this result for the case of a directed graph. These formulas have played key roles in the development of topological formulas for electrical network functions. A detailed development of topological formulas for network functions may be found in Swamy and Thulasiraman [1].

The formula for counting the number of spanning trees of a graph is based on Theorem 7.9 and a result in matrix theory, known as the Binet–Cauchy theorem.

A major of a matrix is a determinant of a maximum order. Consider a matrix P of order $p \times q$ and a matrix Q of order $q \times p$, with $p \leq q$. The majors of P and Q are of order p. If a major of P consists of columns $i_1, i_2, \ldots, i_p$, the corresponding major of Q is formed by rows $i_1, i_2, \ldots, i_p$ of Q. For example, if

$$P = \begin{bmatrix} 1 & -2 & -2 & 4 \\ 2 & 3 & -1 & 2 \end{bmatrix} \quad \text{and} \quad Q = \begin{bmatrix} -5 & 0 \\ 2 & 1 \\ -2 & 2 \\ 3 & 1 \end{bmatrix}$$

then for the major

$$\begin{vmatrix} -2 & 4 \\ 3 & 2 \end{vmatrix}$$

of P

$$\begin{vmatrix} 2 & 1 \\ 3 & 1 \end{vmatrix}$$

is the corresponding major of Q.

The Binet–Cauchy theorem is stated next. Proof of this theorem may be found in Hohn [3].

THEOREM 7.16

If P is a $p \times q$ matrix and Q is a $q \times p$ matrix, with $p \leq q$, then

$$\det(PQ) = \Sigma \text{ (product of the corresponding majors of } P \text{ and } Q).$$

THEOREM 7.17

Let G be a connected undirected graph and A an incidence matrix of a directed graph obtained by assigning orientations to the edges of G. Then

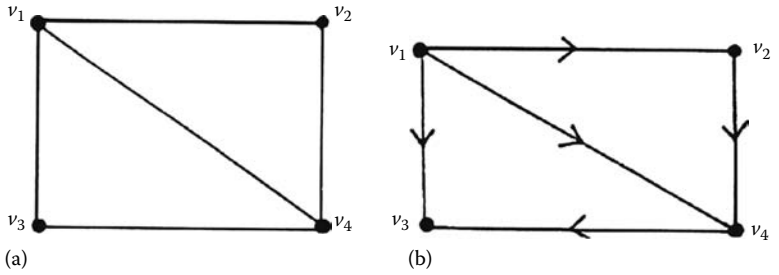

FIGURE 7.11 (a) An undirected graph G; (b) directed graph obtained after assigning arbitrary orientations to the edges of G.

$$\tau(G) = \det(AA^t) \tag{7.15}$$

where $\tau(G)$ is the number of spanning trees of G.

Proof: By the Binet–Cauchy theorem, we have

$$\det(AA^t) = \Sigma \text{ (product of the corresponding majors of } A \text{ and } A^t) \tag{7.16}$$

Recall from Theorem 7.15 that a major of A is nonzero iff the edges corresponding to the columns of the major form a spanning tree of G. Also, the corresponding majors of A and A^t have the same value equal to 0, 1, or -1 (Theorem 7.9). Thus, each nonzero term in the sum on the right-hand side of Equation 7.16 has the value 1, and it corresponds to a spanning tree and vice versa—hence the theorem.

For example, consider the undirected graph G shown in Figure 7.11a. Assigning arbitrary orientations to the edges of G, we obtain the directed graph in Figure 7.11b. If A is the incidence matrix of this directed graph with vertex v_4 as reference vertex then it can be verified that

$$AA^t = \begin{bmatrix} 3 & -1 & -1 \\ -1 & 2 & 0 \\ -1 & 0 & 2 \end{bmatrix}$$

and $\det(AA^t) = 8$. Thus, G has eight spanning trees.

An interesting and useful interpretation of the matrix AA^t now follows. Let $v_1, v_2, \ldots, v_n$ be the vertices of an undirected graph G. The degree matrix $K = [k_{ij}]$ of G is an $n \times n$ matrix defined as follows.

$$k_{ij} = \begin{cases} -p, & \text{if } i \neq j \text{ and } p \text{ parallel edges connect } v_i \text{ and } v_j \\ d(v_i), & \text{if } i = j \end{cases}$$

We may easily verify that $K = A_c \cdot A_c^t$, and that it is independent of the choice of orientations for the edges of G. Also, if v_i is the reference vertex, AA^t is obtained by removing row i and column i of K. In other words, $\det(AA^t)$ is the (i, i) cofactor of K. It then follows from Theorem 7.17 that all of the cofactors of K are equal to the number of spanning trees of G. Thus, Theorem 7.17 may be stated in the following form originally presented by Kirchhoff [4].

THEOREM 7.18

All the cofactors of the degree matrix of an undirected graph G have the same value equal to the number of spanning trees of G.

Consider a connected undirected graph G. Let A be the incidence matrix of G with reference vertex v_n. Let $\tau_{i,n}$ denote the number of spanning 2-trees of G such that the vertices v_i and v_n are in different components of these spanning 2-trees. Also, let $\tau_{ij,n}$ denote the number of spanning 2-trees such that vertices v_i and v_j are in the same component, and vertex v_n is in a different component of these spanning 2-trees. If Δ_{ij} denotes the (i, j) cofactor of (AA^t), then we have the following result, proof of which may be found in Ref. [2].

THEOREM 7.19

For a connected graph G,

$$\tau_{i,n} = \Delta_{ii} \tag{7.17}$$

$$\tau_{ij,n} = \Delta_{ij} \tag{7.18}$$

Consider next a directed graph $G = (V, E)$ without self-loops and with $V = (v_1, v_2, \ldots, v_n)$. The in-degree matrix $K = [k_{ij}]$ of G is an $(n \times n)$ matrix defined as follows:

$$k_{ij} = \begin{cases} -p & \text{if } i \neq j \text{ and } p \text{ parallel edges are directed from } v_i \text{ to } v_j \\ d_{\text{in}}(v_i), & \text{if } i = j \end{cases}$$

The following result is due to Tutte [5]. Proof of this result may also be found in Ref. [2].

THEOREM 7.20

Let K be the in-degree matrix of a directed graph G without self-loops. Let the ith row of K correspond to vertex v_i. Then, the number τ_d of directed spanning trees of G having v_r as root is given by

$$\tau_d = \Delta_{rr} \tag{7.19}$$

where Δ_{rr} is the (r, r) cofactor of K.

Note the similarity between Theorem 7.18 and Theorem 7.20.

To illustrate Theorem 7.20, consider the directed graph G shown in Figure 7.12. The in-degree matrix K and G is

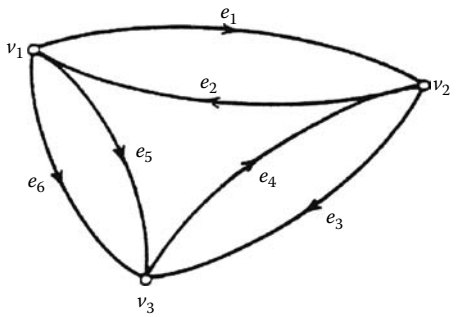

FIGURE 7.12 A directed graph G.

$$K = \begin{bmatrix} 1 & -1 & -2 \\ -1 & 2 & -1 \\ 0 & -1 & 3 \end{bmatrix}$$

Then

$$\Delta_{11} = \begin{bmatrix} 2 & -1 \\ -1 & 3 \end{bmatrix} = 5$$

The five directed spanning trees of G with vertex v_1 as root are (e_1, e_5), (e_1, e_6), (e_1, e_3), (e_4, e_5), and (e_4, e_6).

7.7 Graphs and Electrical Networks

An electrical network is an interconnection of electrical network elements such as resistances, capacitances, inductances, voltage and current sources, etc. Each network element is associated with two variables, the voltage variable $v(t)$ and the current variable $i(t)$. We also assign reference directions to the network elements (Figure 7.13) so that $i(t)$ is positive whenever the current is in the direction of the arrow, and $v(t)$ is positive whenever the voltage drop in the network element is in the direction of the arrow. Replacing each element and its associated reference direction by a directed edge results in the directed graph representing the network. For example, a simple electrical network and the corresponding directed graph are shown in Figure 7.14.

The physical relationship between the current and voltage variables of a network element is specified by Ohm's law. For voltage and current sources, the voltage and current variables are required to have specified values. The linear dependence among the voltage variables in the network and the linear dependence among the current variables are governed by Kirchhoff's voltage and current laws.

Kirchhoff's Voltage Law (KVL): The algebraic sum of the voltages around any circuit is equal to zero.

Kirchhoff's Current Law (KCL): The algebraic sum of the currents flowing out of a node is equal to zero.

As an example, the KVL equation for the circuit 1, 3, 5 and the KCL equation for the vertex b in the graph of Figure 7.14 are

$$\text{Circuit: } 1, 3, 5 \quad v_1 + v_3 + v_5 = 0$$

$$\text{Vertex } b\text{: } -i_1 + i_2 + i_3 = 0$$

It can easily be seen that KVL and KCL equations for an electrical network N can be conveniently written as

$$A_c I_e = 0 \tag{7.20}$$

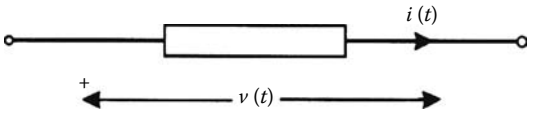

FIGURE 7.13 A network element with reference convention.

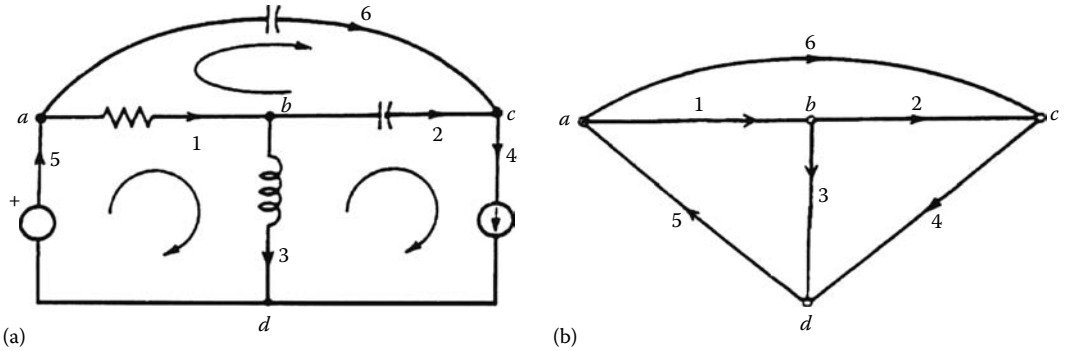

FIGURE 7.14 (a) An electrical network N; (b) directed graph representation of N.

and

$$B_c V_e = 0 \tag{7.21}$$

where

A_c and B_c are, respectively, the incidence and circuit matrices of the directed graph representing N
I_e and V_e are, respectively, the column vectors of element currents and voltages in N

Because each row in the cut matrix Q_c can be expressed as a linear combination of the rows of the matrix, in Equation 7.20 we can replace A_c by Q_c. Thus, we have

$$\text{KCL:} \quad Q_c I_e = 0 \tag{7.22}$$

$$\text{KVL:} \quad B_e V_e = 0 \tag{7.23}$$

From Equation 7.22, we can see that KCL can also be stated as: The algebraic sum of the currents in any cut of N is equal to zero.

If a network N has n vertices, m elements, and its graph is connected then there are only $(n-1)$ linearly independent cuts and only $(m-n+1)$ linearly independent circuits (Theorem 7.13). Thus, in writing KVL and KCL equations we need to use only, B_f, a fundamental circuit matrix and Q_f, a fundamental cutset matrix, respectively. Thus, we have

$$\text{KCL:} \quad Q_f I_e = 0 \tag{7.24}$$

$$\text{KVL:} \quad B_f V_e = 0 \tag{7.25}$$

We note that the KCL and the KVL equations depend only on the way the network elements are interconnected and not on the nature of the network elements. Thus, several results in electrical network theory are essentially graph theoretic in nature. Some of these results and their usefulness in electrical network analysis are presented in the remainder of this chapter. In the following a network N and its directed graph are both denoted by N.

THEOREM 7.21

Consider an electrical network N. Let T be a spanning tree of N, and let B_f and Q_f denote the fundamental circuit and the fundamental cutset matrices of N with respect to T. If I_e and V_e are the column vectors of element currents and voltages and I_c and V_t are, respectively, the column vector of currents associated with the chords of T and the column vector of voltages associated with the branches of T, then

$$\text{Loop transformation:} \quad I_e = B_f^t I_c \tag{7.26}$$

$$\text{Cutset transformation:} \quad V_e = Q_f^t V_t \tag{7.27}$$

Proof: From Kirchhoff's laws, we have

$$Q_f I_e = 0 \tag{7.28}$$

and

$$B_f V_e = 0 \tag{7.29}$$

Let us partition I_e and V_e as

$$I_e = \begin{bmatrix} I_c \\ I_t \end{bmatrix}$$

and

$$V_e = \begin{bmatrix} V_c \\ V_t \end{bmatrix}$$

where the vectors that correspond to the chords and branches of T are distinguished by the subscripts c and t, respectively. Then Equations 7.28 and 7.29 can be written as

$$[\, Q_{fc} \quad U \,] \begin{bmatrix} I_c \\ I_t \end{bmatrix} = 0 \tag{7.30}$$

and

$$[\, U \quad B_{ft} \,] \begin{bmatrix} V_c \\ V_t \end{bmatrix} = 0 \tag{7.31}$$

Recall Equation 7.11 that

$$B_{ft} = -Q_{fc}^t$$

Then, we get from Equation 7.30

$$\begin{aligned} I_t &= -Q_{fc} I_c \\ &= B_{ft}^t I_c \end{aligned}$$

Thus,

$$I_e = \begin{bmatrix} U \\ B_{ft}^t \end{bmatrix} I_c = B_f^t I_c$$

This establishes the loop transformation.

Starting from Equation 7.31, we can show in a similar manner that

$$V_e = Q_f^t V_t$$

thereby establishing the cutset transformation.

In the special case in which the incidence matrix A is used in place of the fundamental cutset matrix, the cutset transformation (Equation 7.27) is called the node transformation. The loop, cutset, and node transformations have been extensively employed to develop different methods of network analysis. The loop method of analysis develops a system of network equations which involve only the chord currents as

variables. The cutset (node) method of analysis develops a system of equations involving only the branch (node) voltages as variables. Thus, the loop and cutset (node) methods result in systems of equations involving $m - n + 1$ and $n - 1$ variables, respectively. In the mixed-variable method of analysis, which is essentially a combination of both the loop and cutset methods, some of the independent variables are currents and the others are voltages. The minimum number of variables required in the mixed-variable method of analysis is determined by what is known as the principal partition of a graph introduced by Kishi and Kajitani in a classic paper [6]. Ohtsuki et al. [7] discuss several issues relating to the mixed-variable method of analysis. A detailed discussion of the principal partition of a graph and the different methods of network analysis including the state-variable method may be found in Ref. [1].

7.8 Tellegen's Theorem and Network Sensitivity Computation

Here, we first present a simple and elegant theorem due to Tellegen [8]. The proof of this theorem is essentially graph theoretic in nature and is based on the loop and the cutset transformations, Equations 7.26 and 7.27, and the orthogonality relation (Theorem 7.12). Using this theorem, we develop the concept of the adjoint of a network and its application in network sensitivity computations.

THEOREM 7.22

Consider two electrical networks, N and $\hat{N}$, such that the graphs associated with them are identical. Let V_e and ψ_e denote the element voltage vectors of N and $\hat{N}$, respectively, and let I_e and Λ_e be the corresponding element current vectors. Then,

$$V_e^t \Lambda_e = 0$$
$$I_e^t \psi_e = 0$$

Proof: If B_f and Q_f are the fundamental circuit and cutset matrices of N (and hence also of $\hat{N}$), then from the loop and cutset transformations, we obtain

$$V_e = Q_f^t V_t$$

and

$$\Lambda_e = B_f^t \Lambda_c$$

So

$$\begin{aligned} V_e^t \Lambda_e &= V_t^t (Q_f B_f^t) \Lambda_c \\ &= 0, \text{ by Theorem 7.12} \end{aligned}$$

Proof of the second part follows in a similar manner.

The adjoint network was introduced by Director and Rohrer [9], and our discussion is based on their work. A more detailed discussion may be found in Ref. [1].

Consider a lumped, linear time-invariant network N. We assume, without loss of generality, that N is a 2-port network. Let $\hat{N}$ be a 2-port network that is topologically equivalent to N. In other words, the graph of $\hat{N}$ is identical to that of N. The corresponding elements of N and $\hat{N}$ are denoted by the same symbol.

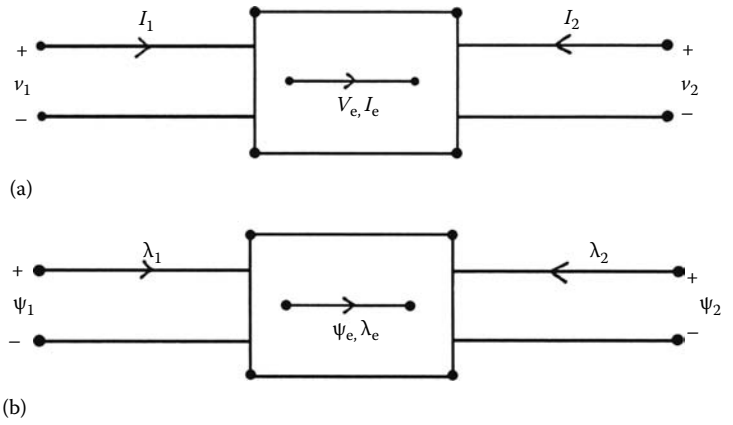

FIGURE 7.15 (a) A 2-port network N; (b) adjoint network $\hat{N}$ of N.

Our goal now is to define the elements of $\hat{N}$ so that $\hat{N}$ in conjunction with N can be used in computing the sensitivities of network functions of N.

Let V_e and I_e denote, respectively, the voltage and the current associated with the element e in N, and ψ_e and λ_e denote, respectively, the voltage and the current associated with the corresponding element e in $\hat{N}$. Also, V_i and I_i, $i = 1, 2$, denote the voltage and current variables associated with the ports of N, and ψ_i and λ_i, $i = 1, 2$, denote the corresponding variables for the ports of $\hat{N}$ (Figure 7.15).

Applying Tellegen's theorem to N and $\hat{N}$, we get

$$V_1\lambda_1 + V_2\lambda_2 = \sum_e V_e\lambda_e \tag{7.32}$$

and

$$I_1\psi_1 + I_2\psi_2 = \sum_e I_e\psi \tag{7.33}$$

Suppose we now perturb the values of elements of N and apply Tellegen's theorem to $\hat{N}$ and the perturbed network N:

$$(V_1 + \Delta V_1)\lambda_1 + (V_2 + \Delta V_2)\lambda_2 = \sum_e (V_e + \Delta V_e)\lambda_e \tag{7.34}$$

and

$$(I_1 + \Delta I_1)\psi_1 + (I_2 + \Delta I_2)\psi_2 = \sum_e (I_e + \Delta I_e)\psi_e \tag{7.35}$$

where ΔV and ΔI represent the changes in the voltage and current which results as a consequence of the perturbation of the element values in N. Subtracting Equation 7.32 from Equation 7.34 and subtracting Equation 7.33 from Equation 7.35,

$$\Delta V_1\lambda_1 + \Delta V_2\lambda_2 = \sum_e \Delta V_e\lambda_e \tag{7.36}$$

and

$$\Delta I_1\psi_1 + \Delta I_2\psi_2 = \sum_{\mathrm{e}} \Delta I_{\mathrm{e}}\psi_{\mathrm{e}} \tag{7.37}$$

Subtracting Equation 7.37 from Equation 7.36 yields

$$(\Delta V_1\lambda_1 - \Delta I_1\psi_1) + (\Delta V_2\lambda_2 - \Delta I_2\psi_2) = \sum_{\mathrm{e}} (\Delta V_{\mathrm{e}}\lambda_{\mathrm{e}} - \Delta I_{\mathrm{e}}\psi_{\mathrm{e}}) \tag{7.38}$$

We wish to define the corresponding element of $\hat{N}$ for every element in N so that each term in the summation on the right-hand side of Equation 7.38 reduces to a function of the voltage and current variables and the change in value of the corresponding network element. We illustrate this for resistance elements. Consider a resistance element R in N. For this element, we have

$$V_{\mathrm{R}} = RI_{\mathrm{R}} \tag{7.39}$$

Suppose we change R to ΔR, then

$$(V_{\mathrm{R}} + \Delta V_{\mathrm{R}}) = (R + \Delta R)(I_{\mathrm{R}} + \Delta I_{\mathrm{R}}) \tag{7.40}$$

Neglecting second-order terms, Equation 7.40 simplifies to

$$V_{\mathrm{R}} + \Delta V_{\mathrm{R}} = RI_{\mathrm{R}} + R\Delta I_{\mathrm{R}} + I_{\mathrm{R}}\Delta R \tag{7.41}$$

Subtracting Equation 7.39 from Equation 7.41,

$$\Delta V_{\mathrm{R}} = R\Delta I_{\mathrm{R}} + I_{\mathrm{R}}\Delta R \tag{7.42}$$

Now using Equation 7.42 the terms in Equation 7.38 corresponding to the resistance elements of N can be written as

$$\sum_{\mathrm{R}} [R\lambda_{\mathrm{R}} - \psi_{\mathrm{R}}]\Delta I_{\mathrm{R}} + I_{\mathrm{R}}\lambda_{\mathrm{R}}\Delta R \tag{7.43}$$

If we now choose

$$\psi_{\mathrm{R}} = R\lambda_{\mathrm{R}} \tag{7.44}$$

then Equation 7.43 reduces to

$$\sum_{R} I_{\mathrm{R}}\lambda_{\mathrm{R}}\Delta R \tag{7.45}$$

which involves only the network variables in N (before perturbation) and $\hat{N}$ and the changes in resistance values. Equation 7.44 is the relation for a resistance. Therefore, the element in $\hat{N}$ corresponding to a resistance element of value R in N is also a resistance of value R.

Proceeding in a similar manner we can determine the element of $\hat{N}$ corresponding to other types of network elements (inductance, capacitance, controlled sources, etc.) The network $\hat{N}$ so obtained is called the adjoint of N. A table defining adjoint elements corresponding to different types of network elements may be found in Ref. [1].

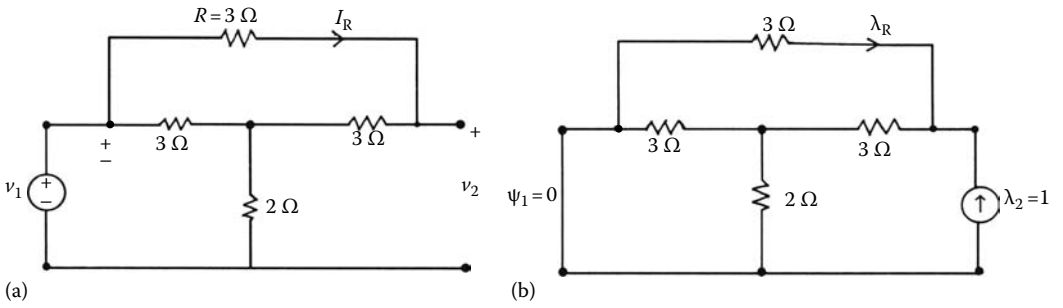

FIGURE 7.16 (a) A 2-port network N; (b) adjoint network $\hat{N}$.

We now illustrate the application of the adjoint network in the computation of the sensitivity of a network function. Note that the sensitivity of a network function F with respect to a parameter x is a measure of the effect on F of an incremental change in x. Computing this sensitivity essentially involves determining $\partial F/\partial x$.

For the sake of simplicity, consider the resistance network shown in Figure 7.16a. Let us assume that resistance R is perturbed from its nominal value of 3 Ω. Assume that no changes occur in the values of the other resistance elements. We wish to compute $\partial F/\partial R$ where F is the open-circuit voltage ratio, that is,

$$F = \left.\frac{V_2}{V_1}\right|_{I_{2=0}}$$

In other words, to compute F, we connect a voltage source of value $V_1 = 1$ across port 1 of N and open-circuit port 2 of N (so that $I_2 = 0$). So, $\Delta V_1 = 0$ and $\Delta I_2 = 0$ and Equation 7.38 reduces to

$$-\Delta I_1 \psi_1 + \Delta V_2 \lambda_2 = I_R \lambda_R \Delta R \tag{7.46}$$

Now we need to determine ΔV_2 as a function of ΔR. This could be achieved if we set $\psi_1 = 0$ and $\lambda_2 = 1$ for the adjoint network $\hat{N}$. Connect a current source of value $\lambda_2 = 1$ across port 2 and short circuit port 1 of $\hat{N}$. The resulting adjoint network is shown in Figure 7.16b. With port variables of $\hat{N}$ defined as above, Equation 7.46 reduces to

$$\Delta V_2 = I_R \lambda_R \Delta_R$$

Thus,

$$\partial F/\partial R = \partial V_2/\partial R = I_R \lambda_R$$

where I_R and λ_R are the currents in the networks N and $\hat{N}$ shown in Figure 7.16. Thus, in general, computing the sensitivity of a network function essentially reduces to the analysis of N and $\hat{N}$ under appropriate excitations at their ports. Note that we do not need to express the network function explicitly in terms of network elements, nor do we need to calculate partial derivatives.

For the example under consideration, we calculate $I_R = 1/12$ A and $\lambda_R = -7/12$ A with the result that $\partial F/\partial R = -7/144$. A further discussion of the adjoint network and related results may be found in Section 7.3.

7.9 Arc Coloring Theorem and the No-Gain Property

We now derive a profound result in graph theory, the arc coloring theorem for directed graphs, and discuss its application in establishing the no-gain property of resistance networks. In the special case of undirected graphs the arc coloring theorem reduces to the "painting" theorem. Both of these theorems [10] are based on the notion of painting a graph.

Given an undirected graph with edge set E, a painting of the graph is a partitioning of E into three subsets, R, G, and B, such that $|G| = 1$. We may consider the edges in the set R as being "painted red," edge in G as being "painted green," and the edges in B as being "painted blue."

THEOREM 7.23

For any painting of a graph, there exists a circuit C consisting of the green edge and no blue edges, or a cutset C^* consisting of the green edge and no red edges.

Proof: Consider a painting of the edge set E of a graph G. Assuming that there does not exist a required circuit, we shall establish the existence of a required cutset.

Let $E' = R \cup G$ and T' denote a spanning forest of the subgraph induced by E' containing the green edge. (Note that the subgraph induced by E' may not be connected). Then, construct a spanning tree T of G such that $T' \subseteq T$.

Now consider any red edge y that is not in T', and hence not in T. Because the fundamental circuit of y with respect to T is the same as the fundamental circuit of y with respect to T', this circuit consists of no blue edges. Furthermore, this circuit will not contain the green edge, for otherwise a circuit consisting of the green edge and no blue edges would exist contrary to our assumption. Thus, the fundamental circuit of a red edge with respect to T does not contain the green edge. Then, it follows from Theorem 7.8 that the fundamental cutset of the green edge with respect to T contains no red edges. Thus, this cutset satisfies the requirements of the theorem.

A painting of a directed graph with edge set E is a partitioning of E into three sets R, G, and B, and the distinguishing of one element of the set G. Again, we may regard the edges of the graph as being colored red, green, or blue with exactly one edge of G being colored dark green. Note that the dark green edge is also to be treated as a green edge.

Next, we state and prove Minty's arc coloring theorem.

THEOREM 7.24

For any painting of a directed graph exactly one of the following is true.

1. *A circuit exists containing the dark green edge, but no blue edges, in which all the green edges are similarly oriented.*
2. *A cutset exists containing the dark green edge, but no red edges, in which all the green edges are similarly oriented.*

Proof: Proof is by induction on the number of green edges. If only one green edge exists, then the result will follow from Theorem 7.23. Assume then that the result is true when the number of green edges is

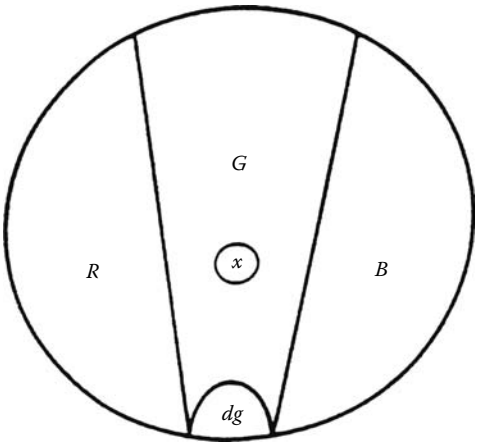

FIGURE 7.17 Painting of a directed graph.

$m \geq 1$. Consider a painting in which $m+1$ edges are colored green. Pick a green edge x other than the dark green edge (Figure 7.17). Color the edge x red. In the resulting painting we find m green edges. If a cutset of type 2 is now found, then the theorem is proved. On the other hand if we color the edge x blue and in the resulting painting a circuit of type 1 exists, then the theorem is proved.

Suppose neither occurs. Then, using the induction hypothesis we have following:

1. Cutset of type 2 exists when x is colored blue.
2. Circuit of type 1 exists when x is colored red.

Now let the corresponding rows of the circuit and cutset matrices be

	dg	R		B	G	x
Cutset	$+1$	$00\cdots0$	0	$1-1\cdots01$	$111\cdots0$	?
Circuit	$+1$	$-11\cdots0-1$	0	$0\cdots00$	$011\cdots0$	?

Here, we have assumed, without loss of generality, that $+1$ appears in the dark green position of both rows.

By the orthogonality relation (Theorem 7.12) the inner product of these two row vectors is zero. No contribution is made to this inner product from the red edges or from the blue edges. The contribution from the green edges is a non-negative integer p. The dark green edge contributes 1 and the edge x contributes an unknown integer q which is 0, 1, or -1. Thus, we have $1+p+q=0$. This equation is satisfied only for $p=0$ and $q=-1$. Therefore, in one of the rows, the question mark is $+1$ and in the other it is -1. The row in which the question mark is 1 corresponds to the required circuit or cutset. Thus, either statement 1 or 2 of the theorem occurs. Both cannot occur simultaneously because the inner product of the corresponding circuit and cutset vectors will then be nonzero.

THEOREM 7.25

Each edge of a directed graph belongs to either a directed circuit or to a directed cutset, but no edge belongs to both. (Note: A cutset is a directed cutset if all its edges are similarly oriented.)

Proof: Proof will follow if we apply the arc coloring theorem to a painting in which all the edges are colored green and the given edge is colored dark green.

We next present an application of the arc coloring theorem in the study of electrical networks. We prove what is known as the no-gain property of resistance networks. Our proof is the result of the work of Wolaver [11] and is purely graph theoretic in nature.

THEOREM 7.26

In a network of sources and (linear/nonlinear) positive resistances, the magnitude of the current through any resistance with nonzero voltage is not greater than the sum of the magnitudes of the currents through the sources.

Proof: Let us eliminate all the elements with zero voltage by considering them to be short-circuits and then assign element reference directions so that all element voltages are positive.

Consider a resistance with nonzero voltage. Thus, no directed circuit can contain this resistance, for if such a directed circuit were present, the sum of all the voltages in the circuit would be nonzero, contrary to Kirchhoff's voltage law. It then follows from Theorem 7.25 that a directed cutset contains the resistance under consideration.

Pick a directed cutset that contains the considered resistance. Let the current through this resistance be i_0. Let R be the set of all other resistances in this cutset and let S be the set of all sources. Then, applying Kirchhoff's current law to the cutset, we obtain

$$i_0 + \sum_{k \in R} i_k + \sum_{s \in S} \pm i_s = 0 \tag{7.47}$$

Because all the resistances and voltages are positive, every resistance current is positive. Therefore, we can write the above equation as

$$|i_0| + \sum_{k \in R} |i_k| + \sum_{s \in S} \pm i_s = 0 \tag{7.48}$$

and so

$$|i_0| \leq \sum_{s \in S} \mp i_s \leq \sum_{s \in S} |i_s| \tag{7.49}$$

Thus follows the theorem.

The following result is the dual of the above theorem. Proof of this theorem follows in an exactly dual manner, if we replace current with voltage, voltage with current, and circuit with cutset in the proof of the above theorem.

THEOREM 7.27

In a network of sources and (linear/nonlinear) positive resistances, the magnitude of the voltage across any resistance is not greater than the sum of the voltages across all the sources.

Chua and Green [12] used the arc coloring theorem to establish several properties of nonlinear networks and nonlinear multiport resistive networks.

8.1 Introduction

Signal flow graph theory is concerned with the development of a graph theoretic approach to solving a system of linear algebraic equations. Two closely related methods proposed by Coates [1] and Mason [2,3] have appeared in the literature and have served as elegant aids in gaining insight into the structure and nature of solutions of systems of equations. In this chapter, we develop these two methods. Our development follows these methods closely [4].

An extensive discussion of signal flow theory may be found in Ref. [5]. Applications of signal flow theory in the analysis and synthesis electrical networks may be found in Sections 8.3 and 8.4. Coates' and Mason's methods may be viewed as generalizations of a basic theorem in graph theory due to Harary [6], which provides a formula for finding the determinant of the adjacency matrix of a directed graph. Thus, our discussion begins with the development of this theorem. For graph theoretic terminology, the reader may refer to Chapter 7.

8.2 Adjacency Matrix of a Directed Graph

Consider a directed graph $G = (V, E)$ with no parallel edges. Let $V = \{v_1, \ldots, v_n\}$. The adjacency matrix $M = [m_{ij}]$ of G is an $n \times n$ matrix defined as follows:

$$m_{ij} = \begin{cases} 1, & \text{if } (v_i, v_j) \in E \\ 0, & \text{otherwise} \end{cases}$$

The graph in Figure 8.1 has the following adjacency matrix:

$$M = \begin{array}{c} \\ v_1 \\ v_2 \\ v_3 \\ v_4 \end{array} \begin{array}{c} \begin{array}{cccc} v_1 & v_2 & v_3 & v_4 \end{array} \\ \begin{bmatrix} 1 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 \end{bmatrix} \end{array}$$

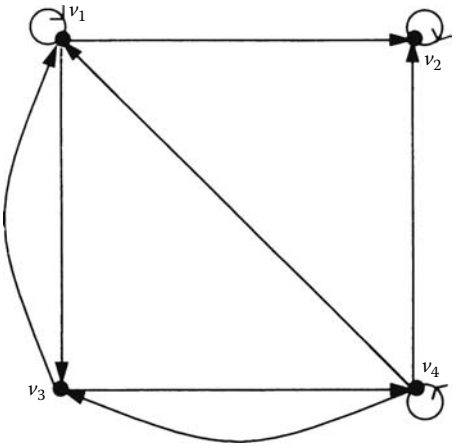

FIGURE 8.1 Graph *G*.

In the following, we shall develop a topological formula for det *M*. Toward this end, we introduce some basic terminology. A 1-factor of a directed graph *G* is a spanning subgraph of *G* in which the in-degree and the out-degree of every vertex are both equal to 1. It is easy to see that a 1-factor is a collection of vertex-disjoint directed circuits. Because a self-loop at a vertex contributes 1 to the in-degree and 1 to the out-degree of the vertex, a 1-factor may have some self-loops. As an example, the three 1-factors of the graph of Figure 8.1 are illustrated in Figure 8.2.

A permutation $(j_1, j_2, \ldots, j_n)$ of integers $1, 2, \ldots, n$ is even (odd) if an even (odd) number of interchanges are required to rearrange it as $(1, 2, \ldots, n)$. The notation

$$\begin{pmatrix} 1, 2, \ldots, n \\ j_1, j_2, \ldots, j_n \end{pmatrix}$$

is also used to represent the permutation $(j_1, j_2, \ldots, j_n)$. As an example, the permutation (4, 3, 1, 2) is odd because it can be rearranged as (1, 2, 3, 4) using the following sequence of interchanges:

1. Interchange 2 and 4
2. Interchange 1 and 2
3. Interchange 2 and 3

For a permutation $(j) = (j_1, j_2, \ldots, j_n)$, $\varepsilon_{j_1, j2, \ldots, jn}$, is defined as equal to 1, if (j) is an even permutation; otherwise, $\varepsilon_{j_1, j2, \ldots, jn}$, is equal to -1.

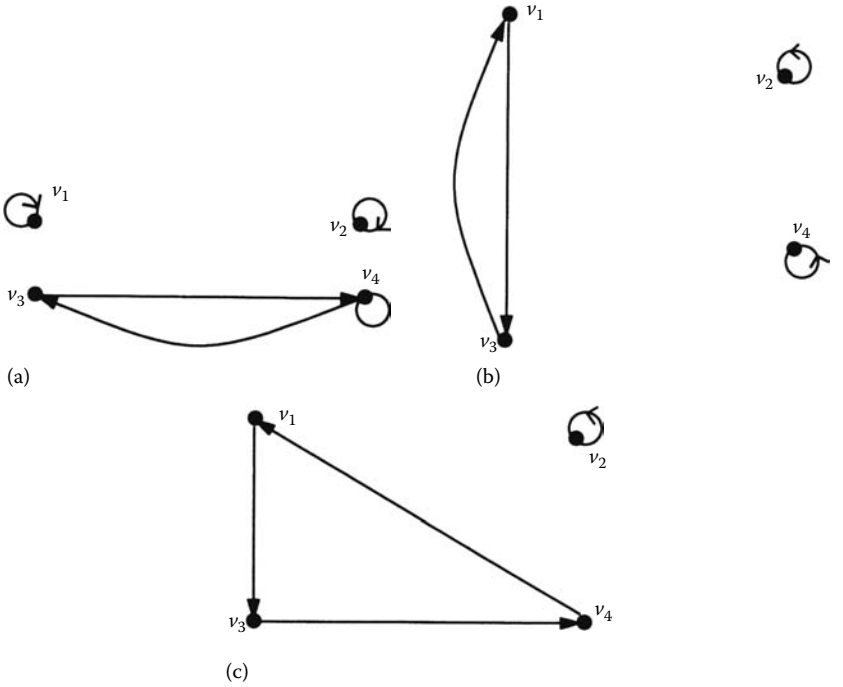

FIGURE 8.2 Three 1-factors of the graph of Figure 8.1.

Given an $n \times n$ square matrix $X = [x_{ij}]$, we note that det X is given by

$$\det X = \sum_{(j)} \varkappa_{j_1, j_2, j_3, \ldots, j_n} \, x_{1j_1}, x_{2j_2}, \ldots, x_{n_{jn}}$$

where the summation $\Sigma_{(j)}$ is over all permutations of 1, 2, …, n [7].

The following theorem is due to Harary [6].

THEOREM 8.1

Let H_i, $i = 1, 2, \ldots, p$ be the 1-factors of an n-vertex directed graph G. Let L_i denote the number of directed circuits in H_i, and let M denote the adjacency matrix of G. Then,

$$\det M = (-1)^n \sum_{i=1}^{p} (-1)^{L_i}$$

Proof. From the definition of a determinant, we have

$$\det M = \sum_{(j)} \varepsilon_{j_1, j_2, \ldots, j_n} m_{1j_1} \cdot m_{2j_2} \cdots m_{nj_n} \tag{8.1}$$

Proof will follow if we establish the following:

1. Each nonzero term $m_{1j_1} \cdot m_{2j_2} \cdots m_{nj_n}$ corresponds to a 1-factor of G, and conversely, each 1-factor of G corresponds to a nonzero term $m_{1j_1} \cdot m_{2j_2} \cdots m_{nj_n}$.
2. $\varepsilon_{j1,\, j2, \ldots,\, jn} = (-1)^{n+L}$ if the 1-factor corresponding to a nonzero $m_{1j_1} \cdot m_{2j_2} \cdots m_{nj_n}$ has L directed circuits.

A nonzero term $m_{1j_1} \cdot m_{1j_2} \cdots m_{nj_n}$ corresponds to the set of edges (v_1, v_{j1}), $(v_2, v_{j2}), \ldots, (v_n, v_{jn})$. Each vertex appears exactly twice in this set, once as an initial vertex and once as a terminal vertex of a pair of edges. Therefore, in the subgraph induced by these edges, for each vertex its in-degree and its out-degree are both equal to 1, and this subgraph is a 1-factor of G. In other words, each nonzero term in the sum in Equation 8.1 corresponds to a 1-factor of G. The fact that each 1-factor of G corresponds to a nonzero term $m_{1j_1} \cdot m_{2j_2} \cdots m_{nj_n}$ is obvious.

Regarding $\varepsilon_{j_1,\, j2, \ldots,\, jn}$, consider a directed circuit C in the 1-factor corresponding to $m_{1j_1} \cdot m_{2j_2} \cdots m_{nj_n}$. Without loss of generality, assume that C consists of the w edges

$$(v_1, v_2), (v_2, v_3), \ldots, (v_w, v_1)$$

It is easy to see that the corresponding permutation (2, 3, …, w, 1) can be rearranged as (1, 2, …, w) using $w - 1$ interchanges. If the 1-factor has L directed circuits with lengths $w_1, \ldots, w_L$, the permutation $(j_1, \ldots, j_n)$ can be rearranged as (1, 2, …, n) using

$$(w_1 - 1) + (w_2 - 1) + \cdots + (w_L - 1) = n - L$$

interchanges. So,

$$\varepsilon_{j_1, j_2, j_n} = (-1)^{n+L}$$

As an example, for the 1-factors (Figure 8.2) of the graph of Figure 8.1, the corresponding L_i are $L_1 = 3$, $L_2 = 3$, and $L_3 = 2$. So, the determinant of the adjacency matrix of the graph of Figure 8.1 is

$$(-1)^4\left[(-1)^3 + (-1)^3 + (-1)^2\right] = -1$$

Consider next a weighted directed graph G in which each edge (v_i, v_j) as associated with a weight w_{ij}. Then we may define the adjacency matrix $M = [m_{ij}]$ of G as follows:

$$m_{ij} = \begin{cases} w_{ij} & \text{if } (v_i, v_j) \in E \\ 0, & \text{otherwise} \end{cases}$$

Given a subgraph H of G, let us define weight $w(H)$ of H as the product of the weights of all edges in H. If H has no edges, then we define $w(H) = 1$. The following result is an easy generalization of Theorem 8.1.

THEOREM 8.2

The determinant of the adjacency matrix of an n-vertex directed graph G is given by

$$\det M = (-1)^n \sum_H (-1)^{L_H} w(H),$$

where H is a 1-factor, w(H) is the weight of H, and L_H is the number of directed circuits in H.

8.3 Coates' Gain Formula

Consider a linear system described by the equation

$$AX = Bx_{n+1} \tag{8.2}$$

where

A is a nonsingular $n \times n$ matrix
X is a column vector of unknown variables $x_1, x_2, \ldots, x_n$
B is a column vector of elements $b_1, b_2, \ldots, b_n$
x_{n+1} is the input variable

It is well known that

$$\frac{x_k}{x_{n+1}} = \frac{\sum_{i=1}^{n} b_i \Delta_{ik}}{\det A} \tag{8.3}$$

where Δ_{ik} is the (i, k) cofactor of A.

To develop Coates' topological formulas for the numerator and the denominator of Equation 8.3, let us first augment the matrix A by adding $-B$ to the right of A and adding a row of zeroes at the bottom of the resulting matrix. Let this matrix be denoted by A'. The Coates flow graph* $G_c(A')$, or simply the Coates graph, associated with matrix A' is a weighted directed graph whose adjacency matrix is the transpose of the matrix A'. Thus, $G_c(A')$ has $n+1$ vertices $x_1, x_2, \ldots, x_{n+1}$, and if $a_{ji} \ldots \neq 0$, $G_c(A')$ has an edge directed from x_i to x_j with weight a_{ji}. Clearly, the Coates graph $G_c(A)$ associated with matrix A can be obtained from $G_c(A')$ by removing the vertex x_{n+1}.

* In network and systems theory literature, the Coates graph is referred to as a flow graph.

As an example, for the following system of equations

$$\begin{bmatrix} 3 & -2 & 1 \\ -1 & 2 & 0 \\ 3 & -2 & 2 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 3 \\ 1 \\ -2 \end{bmatrix} x_4 \tag{8.4}$$

the matrix A' is

$$A' = \begin{bmatrix} 3 & -2 & 1 & -3 \\ -1 & 2 & 0 & -1 \\ 3 & -2 & 2 & 2 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

The Coates' graphs $G_c(A')$ and $G_c(A)$ are depicted in Figure 8.3.

Because a matrix and its transpose have the same determinant value, and because A is the transpose of the adjacency matrix of $G_c(A)$, we obtain the following result from Theorem 8.2.

THEOREM 8.3

If a matrix A is nonsingular, then

$$\det A = (-1)^n \sum_H (-1)^{L_H} w(H) \tag{8.5}$$

where H is a 1-factor of $G_c(A)$, w(H) is the weight of H, and L_H is the number of directed circuits in H.

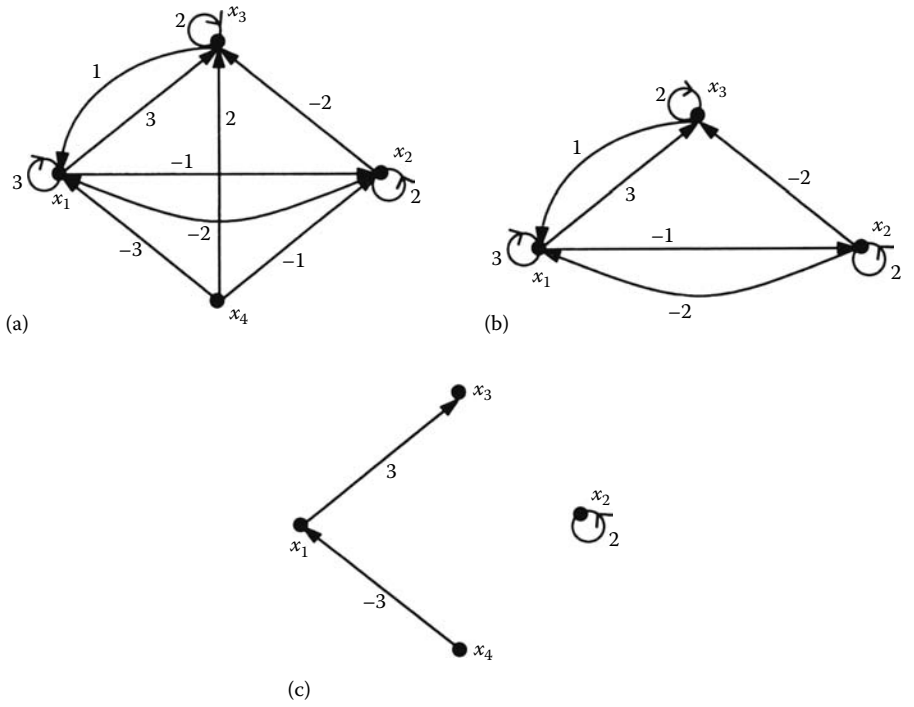

FIGURE 8.3 (a) The Coates graph $G_c(A')$; (b) the graph $G_c(A)$; (c) a 1-factorial connection $H_{4,3}$ of the graph $G_c(A')$.

To derive a similar expression for the sum in the numerator of Equation 8.3, we first define the concept of a 1-factorial connection. A 1-factorial connection H_{ij} from x_i to x_j in $G_c(A)$ is a spanning subgraph of G that contains a directed path P from x_i to x_j and a set of vertex-disjoint directed circuits, which include all the vertices of $G_c(A)$ other than those that lie on P. Similarly, a 1-factorial connection of $G_c(A')$ can be defined. As an example, a 1-factorial connection from x_4 to x_3 of the graph $G_c(A')$ of Figure 8.3a is also in Figure 8.3c.

THEOREM 8.4

Let $G_c(A')$ be the Coates graph associated with an $n \times n$ matrix A. Then,

1. $\Delta_{ii} = (-1)^{n-1} \sum_{H} (-1)^{L_H} w(H)$
2. $\Delta_{ij} = (-1)^{n-1} \sum_{H_{ij}} (-1)^{L'_H} w(H_{ij}) \quad i \neq j$

where H is a 1-factor in the graph obtained by removing vertex x_i from $G_c(A)$, H_{ij} is a 1-factorial connection in $G_c(A)$ from vertex x_i to vertex x_j, and L_H and L'_H are the numbers of directed circuits in H and H_{ij}, respectively.

Proof

1. Note that Δ_{ii} is the determinant of the matrix obtained from A by removing its row i and column i. Also, the Coates graph of the resulting matrix can be obtained from $G_c(A)$ by removing vertex x_i. Proof follows from these observations and Theorem 8.3.
2. Let A_α denote the matrix obtained from A by replacing its jth column by a column of zeroes, except for the element in row i, which is 1. Then it is easy to see that

$$\Delta_{ij} = \det A_\alpha$$

Now, the Coates graph $G_c(A_\alpha)$ can be obtained from $G_c(A)$ by removing all edges incident out of vertex x_j and adding an edge directed from x_j to x_i with weight 1. Then from Theorem 8.3, we get

$$\begin{aligned} \Delta_{ij} &= \det A_\alpha \\ &= (-1)^n \sum_{H_\alpha} (-1)^{L_\alpha} w(H_\alpha) \end{aligned} \tag{8.6}$$

where
H_α is a 1-factor of $G_c(A_\alpha)$
L_α is the number of directed circuits in H_α

Consider now a 1-factor H_α in $G_c(A_\alpha)$. Let C be the directed circuit of H_α containing x_i. Because in $G_c(A_\alpha)$, (x_j, x_i) is the only edge incident out of x_j, it follows that x_j also lies in C. If we remove the edge (x_j, x_i) from H_α we get a 1-factorial connection, H_{ij}. Furthermore, $L'_H = L_\alpha - 1$ and $w(H_{ij}) = w(H_\alpha)$ because (x_j, x_i) has weight equal to 1. Thus, each H_α corresponds to a 1-factorial connection H_{ij} of $G_c(A_\alpha)$ with $w(H_\alpha) = w(H_{ij})$ and $L'_H = L_\alpha - 1$. The converse of this is also easy to see. Thus, in Equation 8.6 we can replace H_α by H_{ij} and L_α by $(L'_H + 1)$. Then we obtain

$$\Delta_{ij} = (-1)^{n-1} \sum_{H_{ij}} (-1)^{L'_H} w(H_{ij})$$

Having shown that each Δ_{ij} can be expressed in terms of the weights of the 1-factorial connections H_{ij} in $G_c(A)$, we now show that $\Sigma b_i\Delta_{ik}$ can be expressed in terms of the weights of the 1-factorial connections $H_{n+1,k}$ in $G_c(A')$.

First, note that adding the edge (x_{n+1}, x_i) to H_{ik} results in a 1-factorial connection $H_{n+1,k}$, with $w(H_{n+1,k}) = -b_i\, w(H_{ik})$. Also, $H_{n+1,k}$ has the same number of directed circuits as H_{ik}. Conversely, from each $H_{n+1,k}$ that contains the edge (x_{n+1}, x_i) we can construct a 1-factorial connection H_{ik} satisfying $w(H_{n+1,k}) = -b_i\, w(H_{ik})$. Also, $H_{n+1,k}$ and the corresponding H_{ik} will have the same number of directed circuits. Thus, a one-to-one correspondence exists between the set of all 1-factorial connections $H_{n+1,k}$ in $G_c(A')$ and the set of all 1-factorial connections in $G_c(A)$ of the form H_{ik} such that each $H_{n+1,k}$ and the corresponding H_{ik} have the same number of directed circuits and satisfy the relation $w(H_{n+1,k}) = -b_i\, w(H_{ik})$. Combining this result with Theorem 8.4, we get

$$\sum_{i=1}^{n} b_i\Delta_{ik} = (-1)^n \sum_{H_{n+1,k}} (-1)^{L'_H}\, w(H_{n+1,k}) \tag{8.7}$$

where the summation is over all 1-factorial connections, $H_{n+1,k}$ in $G_c(A')$, and L'_H is the number of directed circuits in $H_{n+1,k}$. From Equations 8.5 and 8.7 we get the following theorem.

THEOREM 8.5

If the coefficient matrix A is nonsingular, then the solution of Equation 8.2 is given by

$$\frac{x_k}{x_{n+1}} = \frac{\sum_{H_{n+l,k}} (-1)^{L'_H}\, w(H_{n+1,k})}{\sum_H (-1)^{L_H}\, w(H)} \tag{8.8}$$

for $k = 1, 2, \ldots, n$, where $H_{n+1,k}$ is a 1-factorial connection of $G_c(A')$ from vertex x_{n+1} to vertex x_k, H is a 1-factor of $G_c(A)$, and L'_H and L_H are the numbers of directed circuits in $H_{n+1,k}$ and H, respectively.

Equation 8.8 is the called Coates' gain formula. We now illustrate Coates' method by solving the system, Equation 8.4, for x_2/x_4. First, we determine the 1-factors of the Coates' graph $G_c(A)$ shown in Figure 8.3b. These 1-factors, along with their weights, are listed below. The vertices enclosed within parentheses represent a directed circuit.

1-Factor, H	Weight, $w(H)$	L_H
$(x_1)\ (x_2)\ (x_3)$	12	3
$(x_2)\ (x_1, x_3)$	6	2
$(x_3)\ (x_1, x_2)$	4	2
(x_1, x_2, x_3)	2	1

From the above we get the denominator in Equation 8.8 as

$$\sum_H (-1)^{L_H}\, w(H) = (-1)^3 \cdot 12 + (-1)^2 \cdot 6 + (-1)^2 \cdot 4 + (-1)^1 \cdot 2 = -4$$

To compute the numerator in Equation 8.8 we need to determine the 1-factorial connections $H_{4,2}$ in the Coates graph $G_c(A')$, shown in Figure 8.3a. They are listed below along with their weights. The vertices in a directed path from x_4 to x_2 are given within parentheses.

1-Factorial Connection, $H_{4,2}$	$w(H_{4,2})$	L'_H
$(x_4, x_1, x_2)\ (x_3)$	6	1
$(x_4, x_2)\ (x_1)\ (x_3)$	−6	2
$(x_4, x_2)\ (x_1, x_3)$	−3	1
(x_4, x_3, x_1, x_2)	−2	0

From the above we get the numerator in Equation 8.8 as

$$\sum_{H_{4,2}} (-1)^{L'_H} w(H_{4,2}) = (-1)^1 \cdot 6 + (-1)^2(-6) + (-1)^1(-3) + (-1)^0(-2) = -11$$

Thus, we get

$$\frac{x_2}{x_4} = \frac{11}{4}$$

8.4 Mason's Gain Formula

Consider again the system of equations

$$AX = Bx_{n+1}$$

We can rewrite the above as

$$x_j = (a_{jj} + 1)x_j + \sum_{\substack{k=1 \\ k \neq j}}^{n} a_{jk}x_k - b_j x_{n+1}, \quad j = 1, 2, \ldots, n, \quad x_{n+1} = x_{n+1} \tag{8.9}$$

Letting X' denote the column vector of the variables $x_1, x_2, \ldots, x_{n+1}$, and U_{n+1} denote the unit matrix of order n, we can write Equation 8.9 in matrix form as follows:

$$(A' + U_{n+1})X' = X' \tag{8.10}$$

where A' is the matrix defined earlier in Section 8.3.

The Coates graph $G_c(A' + U_{n+1})$ is called the Mason's signal flow graph or simply the Mason graph* associated with A' and it is denoted by $G_m(A')$. The Mason graph $G_m(A)$ is defined in a similar manner. The Mason graphs $G_m(A')$ and $G_m(A)$ associated with the system (Equation 8.4) are illustrated in Figure 8.4. Mason's graph elegantly represents the flow of variables in a system. If we associate each vertex with a variable and if an edge is directed from x_i to x_j, then we may consider the variable x_i as contributing $(a_{ji}x_i)$ to the variable x_j. Thus, x_j is equal to the sum of the products of the weights of the edges incident into vertex x_j and the variables corresponding to the vertices from which these edges emanate.

Note that, to obtain the Coates graph $G_c(A)$ from the Mason graph $G_m(A)$, we simply subtract one from the weight of each self-loop. Equivalently, we may add at each vertex of the Mason graph a self-loop of weight –1. Let S denote the set of all such loops of weight –1 added to construct the Coates graph G_c from the Mason graph $G_m(A)$.

* In network and systems theory literature, Mason graphs are usually referred to as signal flow graphs.

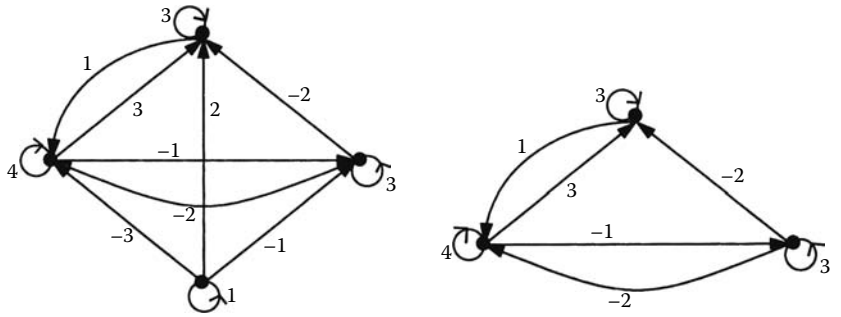

FIGURE 8.4 (a) The Mason graph $G_m(A')$; (b) the Mason graph $G_m(A)$.

Consider now the Coates graph G_c constructed as above and a 1-factor H in G_c having j self-loops from the set S. If H has a total of $L_Q + j$ directed circuits, then removing the j self-loops from H will result in a subgraph Q of $G_m(A)$, which is a collection of L_Q vertex disjoint directed circuits. Also,

$$w(H) = (-1)^j w(Q)$$

Then, from Theorem 8.3 we get

$$\begin{aligned} \det A &= (-1)^n \sum_H (-1)^{L_Q + j} w(H) \\ &= (-1)^n \sum_Q (-1)^{L_Q} w(Q) \\ &= (-1)^n \left[1 + \sum_Q (-1)^{L_Q} w(Q) \right] \end{aligned} \tag{8.11}$$

We can rewrite the above as

$$\det A = (-1)^n \left[1 - \sum_j Q_{j1} + \sum_j Q_{j2} - \sum_j Q_{j3} \cdots \right] \tag{8.12}$$

where each term in $\Sigma_j Q_{ji}$ is the weight of a collection of i vertex-disjoint directed circuits in $G_m(A)$.

Suppose we refer to $(-1)^n \det A$ as the determinant of the graph $G_m(A)$. Then, starting from $H_{n+1,k}$ and reasoning exactly as above we can express the numerator of Equation 8.3 as

$$\sum_{i=1}^{n} b_i \Delta_{ik} = (-1)^n \sum_j w\left(P^j_{n+1,k}\right) \Delta_j \tag{8.13}$$

where

$P^j_{n+1,k}$ is a directed path from x_{n+1} to x_k of $G_m(A')$

Δ_j is the determinant of the subgraph of $G_m(A')$, which is vertex disjoint from the path $P^j_{n+1,k}$

From Equations 8.12 and 8.13, we get the following theorem.

THEOREM 8.6

If the coefficient matrix A in Equation 8.2 *is nonsingular, then*

$$\frac{x_k}{x_{n+1}} = \frac{\sum_j w\left(P^j_{n+l,k}\right)\Delta_j}{\Delta}, \quad k = 1, 2, \ldots, n \tag{8.14}$$

where $P^j_{n+1,k}$ *is the jth directed path from* x_{n+1} to x_k *of* $G_m(A')$, Δ_j *is the determinant of the subgraph of* $G_m(A')$, *which is vertex disjoint from the jth directed path* $P^j_{n+1,k}$, *and* Δ *is the determinant of the graph of* $G_m(A)$.

Equation 8.14 is known as Mason's gain formula. In network and systems theory, $P^j_{n+1,k}$ is referred to as a forward path from vertex x_{n+1} to vertex x_k. The directed circuits of $G_m(A')$ are called the feedback loops.

We now illustrate Mason's method by solving the system (Equation 8.4) for x_2/x_4. To compute the denominator in Equation 8.14, we determine the different collections of vertex-disjoint directed circuits of the Mason graph $G_m(A)$ shown in Figure 8.4b. They are listed below along with their weights.

Collection of Vertex-Disjoint Directed Circuits of $G_m(A)$	Weight	No. of Directed Circuits
(x_1)	4	1
(x_2)	3	1
(x_3)	3	1
(x_1, x_2)	2	1
(x_1, x_3)	3	1
(x_1, x_2, x_3)	2	1
$(x_1)\ (x_2)$	12	2
$(x_1)\ (x_3)$	12	2
$(x_2)\ (x_3)$	9	2
$(x_2)\ (x_1, x_3)$	9	2
$(x_3)\ (x_1, x_2)$	6	2
$(x_1)\ (x_2)\ (x_3)$	36	3

From the above, we obtain the denominator in Equation 8.14

$$\begin{aligned}\Delta = 1 &+ (-1)^1[4 + 3 + 3 + 2 + 3 + 2] \\ &+ (-1)^2[12 + 12 + 9 + 9 + 6] + (-1)^3\ 36 = -4\end{aligned}$$

To compute the numerator in Equation 8.14 we need the forward paths in $G_m(A')$ from x_4 to x_2. They are listed below with their weights.

j	$P^j_{4,2}$	Weight
1	(x_4, x_2)	–1
2	(x_4, x_1, x_2)	3
3	(x_4, x_3, x_1, x_2)	–2

The directed circuits which are vertex disjoint from $P^1_{4,2}$ are (x_1), (x_3), (x_1, x_3). Thus

$$\Delta_1 = 1 - (4 + 3 + 3) + 12 = 1 - 10 + 12 = 3$$

(x_3) is the only directed circuit which is vertex disjoint from $P^2_{4,2}$. So,

$$\Delta_2 = 1 - 3 = -2$$

No directed circuit is vertex disjoint from $P^3_{4,2}$ so $\Delta_3 = 1$. Thus, the numerator in Equation 8.14 is

$$P^1_{4,2}\Delta_1 + P^1_{4,2}\Delta_2 + P^1_{4,3}\Delta_3 = -3 - 6 - 2 = -11$$

and

$$\frac{x_2}{x_4} = \frac{11}{4}$$

9.1 Introduction

The advances in two-dimensional (2-D) signal and image processing activities have stimulated active research in 2-D circuits and systems area. Two-variable (2-V) or 2-D Hurwitz polynomial study finds application in areas such as generation and testing of (2-V) reactance functions, bounded/positive real functions, and matrices; testing the stability of 2-D digital filters; and the generation of stable 2-D digital transfer functions. Stability analysis is an important aspect of the design of dynamic systems. This analysis is often carried out by examining for the absence of zeroes of the denominator polynomial of a system transfer function in some specified regions of the complex plane. 1-D systems are studied through the characterization whether or not the denominator polynomial is Hurwitz. By expanding this idea, we can define and study 2-D (also called bivariate, 2-V) Hurwitz polynomials. In view of the diverse needs of

several different applications a number of 2-D Hurwitz polynomials have been defined and their test procedures established. In this chapter, a detailed presentation of various 2-D Hurwitz polynomials and their relationships to one another is given. We also study their relevant applications.

To highlight the relationships among the various Hurwitz polynomials, the definitions of all the Hurwitz polynomials are presented. This is done in terms of the absence of or the nature of their zerosets in specified regions such as the open or closed right half of the (S_1, S_2)-biplane. The goal is to make a tutorial exposition on 2-D Hurwitz polynomials.

Section 9.2 gives some preliminaries and notations. We next present the definitions of a number of (S_1, S_2)-domain Hurwitz polynomials. Based on the continuity property of the zeroes of 2-V polynomials, testsets for the various Hurwitz polynomials are given in Section 9.5. Following that, a 2-D, very strict Hurwitz polynomial is discussed in detail because this is the counterpart of strict Hurwitz in the 1-D case. Some of the applications of the various Hurwitz polynomials are described in Section 9.7.

9.2 Preliminaries and Notations

9.2.1 Infinite Distant Points

The following discussion is crucial to the understanding of certain classes of stable 2-D polynomials. The points at infinite distances in the (S_1, S_2)-biplane play an important role in the definition of certain 2-D Hurwitz polynomials. Some of the confusion that resulted in the application of these Hurwitz polynomials can be attributed to the neglect or omission of these infinite distant points. This chapter considers the extended (S_1, S_2)-biplane, which includes the infinite distance points. For the sake of clarity, we also explicitly indicate whether the infinite distant points are included in or excluded from the regions considered. The behavior of 2-V polynomials at infinite distant points is well described in the literature [2,3]. Seemingly many infinite distant points in the 1-D plane, such as the S_1-plane or the S_2-plane, may be assumed to merge to a single point. Thus, infinity is treated as a single point, and any shift from this infinite distant point, however small, leads to a finite distant point.

9.2.2 Analog Biplane

$\mathrm{Re}(s) =$ Real part of the variable s

For $i = 1, 2$

$S_{i\,+} = \{s_i | \mathrm{Re}(s_i) > 0,\ |s_i| < \infty\}$, open right half of the S_i-plane

$S_{io} = \{s_i | \mathrm{Re}(s_i) = 0,\ |s_i| \leq \infty\}$, imaginary axis of the S_i-plane

$S_{i\oplus} = \{s_i | \mathrm{Re}(s_i) \geq 0,\ |s_i| \leq \infty\}$, closed right half of the S_i-plane

$S^2_{+0} = \{(s_1, s_2) \mid \mathrm{Re}(s_1) > 0,\ \mathrm{Re}(s_2) = 0,\ |s_1| < \infty,\ |s_2| \leq \infty\}$, open right half of the S_1-plane and the imaginary axis of the S_2-plane

$S^2_{0+} = \{(s_1, s_2) \mid \mathrm{Re}(s_1) = 0,\ \mathrm{Re}(s_2) > 0,\ |s_1| \leq \infty,\ |s_2| < \infty\}$, open right half of the S_2-plane and the imaginary axis of the S_1-plane

$S^2_{++} = \{(s_1, s_2) \mid \mathrm{Re}(s_1) > 0, \mathrm{Re}(s_2) > 0,\ |s_1| < \infty,\ |s_2| < \infty\}$, open right half of the (S_1, S_2)-biplane

$S^2_{00} = \{(s_1, s_2) \mid \mathrm{Re}(s_1) = 0,\ \mathrm{Re}(s_2) = 0,\ |s_1| \leq \infty,\ |s_2| \leq \infty\}$, distinguished boundary of the (S_1, S_2)-biplane

$S^2_{\oplus\oplus} = \{(s_1, s_2) \mid \mathrm{Re}(s_1) \geq 0, \mathrm{Re}(s_2) \geq 0,\ |s_1| \leq \infty,\ |s_2| \leq \infty\}$, closed right half of the (S_1, S_2)-biplane

PRF: Positive real function
RF: Reactance function
TPRF: 2-Variable positive real function
TRF: 2-Variable reactance function
TBRF: 2-Variable bounded real function

TLBRF: 2-Variable lossless bounded real function
$B_*(s_1, s_2) =$ Paraconjugate of $B(s_1, s_2) = [B(-s_1{}^*, -s_2{}^*)]^*$, where s^* represents complex conjugate of s
$B_e(s_1, s_2) =$ Para-even part of $B(s_1, s_2) = [B(s_1, s_2) + B_*(s_1, s_2)]/2$
$B_0(s_1, s_2) =$ Para-odd part of $B(s_1, s_2) = [B(s_1, s_2) - B_*(s_1, s_2)]/2$

Definition A: A rational function $F(s)$ with real coefficients such that $\mathrm{Re}[F(s)] > 0$ for $\mathrm{Re}(s) > 0$ is called a positive real function (PRF).

Definition B: A PRF $F(s)$ is said to be a strict PRF if $\mathrm{Re}[F(s)] > 0$ for $\mathrm{Re}(s) \geq 0$.

Definition C: A PRF $F(s)$ is said to be a minimum reactive and susceptive if it has neither poles nor zeroes on the imaginary axis of the S-plane.

Definition D: A PRF $F(s)$ is called a reactance function (RF) if $\mathrm{Re}[F(s)] = 0$ for $\mathrm{Re}(s) = 0$.

Definition E: A 2-V rational function $F(s_1, s_2)$ with real coefficients such that $\mathrm{Re}[F(s_1, s_2)] > 0$ for S^2_{++} is called a TPRF. A TPRF $F(s_1, s_2) = -F(-s_1, -s_2)$ is called a TRF.

Definition F: A 2-V rational function $H(s_1, s_2)$ with real coefficients such that $|H(s_1, s_2)| < 1$ for S^2_{++} is called a TBRF. A TBRF $H(s_1, s_2)$ satisfying the condition $|H(s_1, s_2)| = 1$ or $0/0$ for S^2_{00} is called TLBRF.

9.2.3 Isolated and Continuum of Zeroes

Some types of Hurwitz polynomials are distinguished on the basis of whether they have isolated zeroes or a continuum of zeroes on S^2_{00}. As a point on S^2_{00} is characterized by $s_1 = jw_1$ and $s_2 = jw_2$, where w_1 and w_2 are real quantities, the region S^2_{00} can be graphically represented by the (W_1, W_2)-plane. The isolated zeroes on S^2_{00} are, thus, points on this plane and the continuum of zeroes is represented by continuous curves. Isolated and continuum of zeroes for the 2-D case are illustrated on the (W_1, W_2)-plane in Figure 9.1, where zeroes of some simple polynomials are shown.

9.3 Value of a Two-Variable Polynomial at Infinity

Because later in the chapter it is necessary to determine the value of a 2-V polynomial at infinite distance points, the following explanation is in order. In 1-D complex plane S the infinite distant points can be represented by a single point, and the value of any function at this point is found by applying some transformation which transforms the point at infinity to some finite point s', and the value of the transformed function at s' is determined. Often $s = 1/u$ is the transformation used and infinity is mapped onto the origin. Using this transformation, the value of $B(s)$ at infinity can be defined as $B(\infty) = B_T(0)$, where $B_T(u) = B(1/u)$.

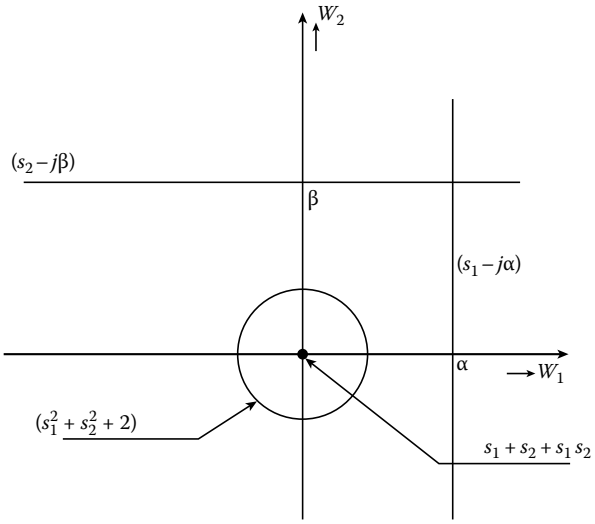

FIGURE 9.1 Zero distribution of some simple polynomials in (W_1, W_2) plane (S_{00}^2). (Polynomial $(s_1 + s_2 + s_1 s_2)$ has an isolated zero, whereas polynomials $(s_1 - j\alpha)$, $(s_2 - j\beta)$, and $(S_1^2 + S_2^2 + 2)$ have a continuum of zeroes.)

In the 2-D biplane (S_1, S_2) consisting of two complex planes, S_1 and S_2, an infinite distant point can have infinite coordinates in either one or both of these planes, and thus an infinite number of infinite distant points exists. They can be classified into three categories [3]:

$$1.\ s_1 = \infty \text{ and } s_2 = \text{finite} \tag{9.1a}$$

$$2.\ s_1 = \text{finite and } s_2 = \infty \tag{9.1b}$$

$$3.\ s_1 = \infty \text{ and } s_2 = \infty \tag{9.1c}$$

Applying the transformation method to each variable, the value of the function at each of the above points is defined as

$$B(\infty, s_2') = B_1(0, s_2') \quad \text{where } B_1(u, s_2) = B(1/u, s_2), \left|s_2'\right| < \infty \tag{9.2a}$$

$$B(s_1', \infty) = B_2(s_1', 0) \quad \text{where } B_2(s_1, v) = B(s_1, 1/v), \left|s_1'\right| < \infty \tag{9.2b}$$

$$B(\infty, \infty) = B_3(0, 0) \quad \text{where } B_3(u, v) = B(1/u, 1/v) \tag{9.2c}$$

9.3.1 Nonessential Singularities of the Second Kind

It is well known [3] that 2-V polynomials may have nonessential singularities of the second kind (NSSK) at some infinite distant points where the value of the polynomial is indeterminate. For the sake of notational convenience and to indicate the type of indeterminacy involved we write $B(s_{10}, s_{20}) = 0/0$ to say that $B(s_1, s_2)$ has an NSSK at (s_{10}, s_{20}). Of course, for a polynomial $B(s_1, s_2)$, this can occur only if s_{10}, s_{20}, or both, have infinite value.

9.4 Various Analog Hurwitz Polynomials

Following up the definition of 1-V Hurwitz polynomials, 2-D Hurwitz polynomials have been traditionally defined on the basis of the regions in the S_2-biplane where the 2-V polynomials have no zeroes or have only some constrained types of zeroes. At least eight types of Hurwitz polynomials have been

defined. Below we present their definitions so as to bring out their zero-free regions and the constraints (if any) on their zeroes in some regions.

9.4.1 Self-Paraconjugate Polynomial

A 2-V polynomial $B(s_1, s_2)$ is said to be an (analog) self-paraconjugate polynomial if $B_*(s_1, s_2) = cB(s_1, s_2)$, where c is a unimodular complex constant, i.e., $|c| = 1$. When $c = +1$, $B(s_1, s_2)$ is said to be a para-even polynomial, and when $c = -1$, a para-odd polynomial. It is easy to verify that the para-even and para-odd parts of a polynomial are self-paraconjugate, i.e., $B_{e^*}(s_1, s_2) = B_e(s_1, s_2)$ and $B_{0^*}(s_1, s_2) = -B_0(s_1, s_2)$. In the case of real polynomials para-even and para-odd polynomials are simply called even and odd polynomials.

9.4.2 Broad-Sense Hurwitz Polynomial

This represents the weakest class of Hurwitz polynomials in the sense that their zero-free region in the S_2-biplane is the smallest of all the 2-D Hurwitz polynomials. $B(s_1, s_2)$ is a broad-sense Hurwitz polynomial (BHP) if $B(s_1, s_2) \neq 0$ in S^2_{++}. For example,

$$B_1(s_1, s_2) = (s_2^2 + 4)^i (s_1 + s_2)^j (s_1 s_2 + s_1 + s_2)^k (s_1 + s_2 + 1)^l (s_1 s_2 + s_1 + s_2 + 1)^m$$

where i, j, k, l, m are nonnegative integers. In the literature this Hurwitz polynomial has been known by different names: Hurwitz polynomial in the extended sense, widest sense Hurwitz, or simply Hurwitz [4–7,10].

9.4.3 Narrow-Sense Hurwitz Polynomial

A subclass of BHP is narrow-sense Hurwitz polynomial (NHP), which was introduced by Ansell [1] in the study of two-variable reactance functions (TRFs). They may be characterized by the following equivalent definitions:

1. $B(s_1, s_2)$ is an NHP if $B(s_1, s_2) \neq 0$ in $S^2_{\oplus\oplus} - S^2_{00} = S^2_{++} + S^2_{+0} + S^2_{0+}$ where the minus sign is used to denote set theoretic subtraction and the plus sign, set theoretic union.
2. $B(s_1, s_2)$ is an NHP if $B(s_1, s_2)$ is a BHP [i.e., $B(s_1, s_2) \neq 0$ in S^2_{++}] and $B(s_1, s_2)$ has no 1-V factor having zeroes on the imaginary axis of the S_1- or S_2-plane. For example,

$$B_1(s_1, s_2) = (s_1 + s_2)^i (s_1 s_2 + s_1 + s_2)^j (s_1 + s_2 + 1)^m (s_1 s_2 + s_1 + s_2 + 1)^n$$

   where i, j, m, n are nonnegative constants, is an NHP, whereas $(S_1^2 + 1)(s_1 + s_2 + 1)$ is not an NHP because of the factor $(S_1^2 + 1)$.

We see that an NHP may have zeroes on S^2_{00}. The irreducible 2-V factors that give rise to zeroes on S^2_{00} with no zeroes on S^2_{++} can be shown to belong to one of two types: (1) those that become zero only at isolated points on S^2_{00}; (2) those that become zero on a continuum of points on S^2_{00}. The fact that no irreducible factor can have isolated zeroes as well as continuum of zeroes without having zeroes in S^2_{++} can be established based on the continuity property of the zeroes of 2-V polynomials. For example, the factor $(s_1 s_2 + s_1 + s_2)$ with a zero at (0,0) on S^2_{00} corresponds to the first type, and the factor $s_1 + s_2$ with a continuum of zeroes given by $s_1 = -s_2$ on S^2_{00} corresponds to the second type.

9.4.4 Scattering Hurwitz Polynomial

Based on the above observation, the next class is identified as a subclass of NHP which can have only discrete (isolated) zeroes on S^2_{00}. Scattering Hurwitz polynomial (SHP) or principal Hurwitz polynomial corresponds to this class [7,13,18]. The following equivalent definitions characterize an SHP:

1. A 2-V polynomial $B(s_1, s_2)$ is an SHP if $B(s_1, s_2)$ is an NHP and if $B(s_1, s_2)$ has no (1-D) continuum of zeroes on S^2_{00}.
2. A 2-V polynomial $B(s_1, s_2)$ is an SHP if $B(s_1, s_2)$ is a BHP and if $B(s_1, s_2)$ has no (1-D) continuum of zeroes on S^2_{00}.
3. A 2-V polynomial $B(s_1, s_2)$ is an SHP if $B(s_1, s_2)$ is a BHP and if $B(s_1, s_2)$ has no 1- or 2-V self-paraconjugate factors.
4. A 2-V polynomial $B(s_1, s_2)$ is an SHP if $B(s_1, s_2)$ is a BHP, i.e., $B(s_1, s_2) \neq 0$ in S^2_{++}, and if $B(s_1, s_2)$ and $B_*(s_1, s_2)$ are relatively prime. For example,

$$B(s_1, s_2) = (s_1 s_2 + s_1 + s_2)^i (s_1 + s_2 + 4)^j (3s_1 s_2 + s_1 + s_2 + 1)^k$$

   where *i, j, k* are nonnegative integers.

Fettweis [14] identified and popularized this class and suggested the names "principal Hurwitz polynomials" and "scattering Hurwitz polynomials." He studied the properties of SHP in depth, and his pioneering efforts established SHP as a very important class of Hurwitz polynomials in stability and passivity studies.

9.4.5 Hurwitz Polynomial in the Strict Sense

Increasing the zero-free regions of a Hurwitz polynomial further by the addition of the whole finite imaginary axes of the S_1- and S_2-planes, we get the definition of a Hurwitz polynomial in the strict sense: $B(s_1, s_2)$ is a Hurwitz polynomial in the strict sense (HPSS) if $B(s_1, s_2) \neq 0$ in $\{S^2_{\oplus\oplus}$–infinite distant points$\}$. For example,

$$B(s_1, s_2) = (s_1 + s_2 + 7)^m (4s_1 s_2 + s_1 + s_2 + 1)^n$$

where integers m and n are nonnegative.

This class appears to have been first defined and used by Saito [4] and Youla [5,17]. This strict Hurwitz polynomial definition has been used by a number of authors such as Huang [8], in the derivation of stability tests for 2-D digital filters, Strintzis [15], in the extension of digital filter stability tests to continuous domain functions, and Goodman [16,23], in the study of double bilinear transformation. In order to get a 2-D Hurwitz polynomial that is a counterpart of 1-D strict Hurwitz we need to include the infinite distant points in the 2-D plane. (Note that, in certain cases, 2-D scattering Hurwitz appears to be the counterpart of the 1-D strict Hurwitz polynomial.)

9.4.6 Very Strict Hurwitz Polynomial

By including the infinite distant points we get the most strict Hurwitz polynomial, the very strict Hurwitz polynomial (VSHP), named by Reddy et al. [2,24]. Similar conclusions were reached by Delsarte et al. [9]. The following equivalent definitions characterize this type of Hurwitz polynomial:

1. $B(s_1, s_2)$ is a VSHP if $B(s_1, s_2) \neq 0$ or if $B(s_1, s_2) \neq 0/0$ in $S^2_{\oplus\oplus}$
2. $B(s_1, s_2)$ is a VSHP if $1/B(s_1, s_2)$ has no (first or second kind) singularities in $S^2_{\oplus\oplus}$. For example,

$$B(s_1, s_2) = (5s_1 s_2 + s_1 + s_2 + 8)$$

   We discuss 2-D VSHP in detail in a later section of this chapter.

9.4.7 Self-Paraconjugate Hurwitz Polynomial

$B(s_1, s_2)$ is said to be a self-paraconjugate Hurwitz polynomial (SPHP) if $B(s_1, s_2)$ is a self-paraconjugate polynomial and if $B(s_1, s_2) \neq 0$ in S^2_{++}. In other words, $B(s_1, s_2)$ is a BHP. For example,

$$B(s_1, s_2) = (s_1^2 + 1)^j (s_1 s_2 + 1)^k$$

where j, k are nonnegative integers.

9.4.8 Reactance Hurwitz Polynomial

A reactance Hurwitz polynomial (RHP) is defined as the para-even or para-odd part of a SHP. $B(s_1, s_2)$ is said to be a RHP if $B(s_1, s_2)$ is an SPHP and if each zero locus of $B(s_1, s_2)$ on S^2_{00} is of multiplicity unity; i.e., $B(s_1, s_2)$ has no repeated factors. For example,

$$B(s_1, s_2) = (s_1^2 + 1)(s_1 s_2 + 1)^k$$

is an RHP whereas

$$B(s_1, s_2) = (s_1^2 + 1)^2 (3 s_1 s_2 + 1)^2$$

is not an RHP.

9.4.9 Immittance Hurwitz Polynomial

An immittance Hurwitz polynomial (IHP) is defined as the product of an RHP and an SHP [10]. An alternate definition is given in terms of the zero-free regions.

$B(s_1, s_2)$ is said to be an IHP if $B(s_1, s_2)$ is a BHP and if each continuum zero locus of $B(s_1, s_2)$ on S^2_{00} is of multiplicity unity; i.e., $B(s_1, s_2)$ has no repeated self-paraconjugate factors. For example, $B(s_1, s_2) = (s_1^2 + 1)(s_1 s_2 + 1)(2 s_1 s_2 + 7 s_1 + s_2)(s_1 + s_2 + 1)$.

9.4.10 Summary

The definitions of BHP, NHP, SHP, HPSS, and VSHP are such that in the above sequence each Hurwitz polynomial satisfies the conditions required for each of the preceding polynomials, and hence form a subset of each. In other words,

$$\{\text{VSHP}\} \subset \{\text{HPSS}\} \subset \{\text{SHP}\} \subset \{\text{NHP}\} \subset \{\text{BHP}\}$$
$$\{\text{IHP}\} \subset \{\text{BHP}\}$$
$$\{\text{SPHP}\} \subset \{\text{BHP}\}$$
$$\{\text{RHP}\} = \{\text{IHP}\} \cap \{\text{SPHP}\}$$

9.5 Testsets for Analog Hurwitz Polynomials

9.5.1 Continuity Property of the Zeroes of 2-V Polynomials

Let $B(s_1, s_2)$ be a 2-V polynomial of degree m in s_1 and n in s_2. Let x_1 be a point in the S_1-plane. Then, $B(x_1, s_2)$ is a 1-V polynomial in s_2 and has n zeroes (possible some at infinity) in the S_2-plane. When x_1 is such that the coefficients of r consecutive terms s_2^n, $s_2^{n-1}, \ldots, s_2^{n-r+1}$ become zero, $B(x_1, s_2)$ becomes a

polynomial of degree $n-r$ in s_2 and has only $(n-r)$ zeroes in the finite part of the S_2-plane. If this polynomial is considered an $n-r$ degree polynomial in s_2, then it has n poles at $s_2=\infty$. Further, we also know that for a polynomial (in general, for a rational function), the number of poles and zeroes are equal when those that are at infinity are also counted. Hence, in the present use, where r leading coefficients become zero, the r missing zeroes are accounted to be at infinity.

As discussed earlier, the infinite distant points of the S_2-plane are assumed to converge to a single point at infinity. We further note that at an NSSK the function possesses zeroes as well as poles. Consider a zero s_2' of $B(x_1, s_2)$. When x_1 is moved on a continuous line in the S_1-plane, S_2' either moves continuously or remains stationary. Further, when $K(K \leq n)$, zeroes are present at a point, among which K' zeroes are stationary, $(K-K')$ incoming and $(K-K')$ outgoing loci exist at that point. We may associate an incoming locus with an outgoing locus arbitrarily on a one-to-one basis. With these remarks in mind, the continuity property of the zeroes of 2-V polynomials can be stated in the form of a theorem.

THEOREM 9.1

Let $B(x_1, s_2)$ be not identically zero. [*If $B(x_1, s_2) \equiv 0, (s_1 - x_1)^k$, $K \leq M$, is a factor of $B(s_1, s_2)$. Divide this factor out and consider the resulting polynomial*]. *Then, the locus of a zero $\hat{s}_2$ of $B(x_1, s_2)$ generated by the movement of x_1 on a continuous line in the S_1-plane is a continuous line or a fixed point in the S_2 plane. In the latter case, $(s_2 - \hat{s}_2)$ is a factor of $B(s_1, s_2)$.*

Proof: The proof of Theorem 9.1 can be given based on the properties of algebraic functions discussed by Bliss [27]. Also note that the locus may pass through the point at infinity; this is treated just like any other point in the S_2-plane. A similar property also holds for the zeroes s_1 of $B(s_1, x_2)$.

As a first step to identifying smaller testsets, we show that, because of the continuity property of the zeroes of 2-V polynomials, tests at some isolated points can be omitted. We do this for the tests in the region s_{0+}^2 in the following lemma [24].

LEMMA 9.1

A 2-V polynomial $B(s_1, s_2) \neq 0$ or $0/0$ in the region S_{0+}^2 if $B(s_1, s_2) \neq 0$ or $0/0$ in $\{S_{10}$–some isolated points$\} \times S_{2+}$ (i.e., the Cartesian product of the whole imaginary axis of the S_1-plane, except some isolated points, and the open right half of the S_2-plane), and if $B(\hat{s}_1, s_2) \neq 0$, where $\hat{s}_1$ is any such isolated point in S_{10} [*i.e., no 1-V factor of the form $(s_1 - \hat{s}_1)$ is present in $B(s_1, s_2)$*].

COROLLARY 9.1

A 2-V polynomial $B(s_1, s_2) \neq 0$ or $0/0$ in the region S_{0+}^2 if $B(jw_1, s_2) \neq 0$ for $-\infty < w_1 < \infty$ and $Re(s_2) > 0$, $|s_2| < \infty$.

Note that to test for the absence of the zeroes of $B(s_1, s_2)$ in $s_{0\oplus}^2$, we must test all the boundary points and we cannot leave any isolated point untested, as in the case of s_{0+}^2.

Next, we discuss test procedure for the various Hurwitz polynomials.

THEOREM 9.2

A 2-V polynomial $B(s_1, s_2)$ is a BHP iff $B(jw_1, s_2) \neq 0$ in S_{2+} for all real finite w_1, except possibly some isolated w_1 and if the polynomial $B(s_1, b)$ has no zeroes in S_{1+} for some $b \in S_{2+}$.

THEOREM 9.3

A 2-V polynomial $B(s_1, s_2)$ is an NHP iff for all real finite w_1, $B(jw_1, s_2) \neq 0$ in S_{2+}; the polynomial in s_1, $B(s_1, b) \neq 0$ in S_{1+} for some $b \in S_{2+}$, and $B(s_1, s_2)$ has no factor of the type $(s_2 - j\alpha)$, where α is a real constant.

THEOREM 9.4

A 2-V polynomial $B(s_1, s_2)$ is an SHP iff for all real finite w_1, $B(jw_1, s_2)$ has no zeroes in S_{2+}; the polynomial $B(s_1, b)$ has no zeroes in S_{1+} for some $b \in S_{2+}$, and $B(s_1, s_2)$ and $B_*(s_1, s_2)$ are relatively prime.

THEOREM 9.5

A 2-V polynomial $B(s_1, s_2)$ is a HPSS iff for all finite w_1, $B(jw_1, s_2)$ has no zeroes in $\{s_2: Re(s_2) \geq 0, |s_2| < \infty\}$ and the polynomial, $B(s_1, b)$ has no zeroes in Re $s_1 \geq 0$, for some $b \in S_{2+}$. It is easy to verify that only infinite distant points on S_{00}^2 are omitted from S_{00}^2 in testing for the zero locations of $B(s_1, s_2)$. Hence, $B(s_1, s_2)$ is a HPSS.

THEOREM 9.6

The necessary and sufficient conditions for a 2-V polynomial $B(s_1, s_2)$ to be a VSHP are [19]

1. *$B(s_1, s_2)$ is a HPSS*

2*a*. *$B(\infty, s_2) \neq 0/0$ for $Re(s_2) = 0$ and $|s_2| < \infty$*

2*b*. *$B(s_1, \infty) \neq 0/0$ for $Re(s_1) = 0$ and $|s_1| < \infty$*

2*c*. *$B(\infty, \infty) \neq 0/0$*

The infinite point testing method shown in Equations 9.2a *through* c *could be followed for the testing of the three conditions under number* 2 *above.* Let

$$B(s_1, s_2) = \sum_{i=0}^{M} \sum_{j=0}^{N} b_{ij} s_1^i s_2^j$$

Then, conditions 2a to 2c are equivalent to:

$$A_M(s_2) = \sum_{j=0}^{N} b_{Mj} s_2^j \neq 0 \quad \text{for Re}(s_2) = 0$$

$$B_N(s_1) = \sum_{i=0}^{M} b_{iN} s_1^i \neq 0 \quad \text{for Re}(s_1) = 0$$

$$b_{MN} \neq 0$$

THEOREM 9.7

Let

$$\begin{aligned} B(s_1, s_2) &= \sum_{j=0}^{N} a_j(s_1) s_2^j \\ &= \sum_{i=0}^{M} b_i(s_2) s_1^i \\ &= \sum_{i=0}^{M} \sum_{j=0}^{N} c_{ij}\ s_1^i s_2^j \end{aligned}$$

Then, $B(s_1, s_2)$ is a VSHP iff $B(jw_1, jw_2) \neq 0, -\infty < w_i < \infty\ i = 1, 2$, and $a_N(s_1) \neq 0$ in $S_{1\oplus}$, and $b_M(s_2) \neq 0$ in $S_{2\oplus}$, and $c_{MN} \neq 0$.

Testsets for SPHP, RHP, and IHP can be formulated easily based on their definitions and the testset of a BHP.

9.6 Two-Variable Very Strict Hurwitz Polynomials

A brief, additional discussion of VSHPs is given in this section because this class of 2-V Hurwitz polynomials is a counterpart to the 1-V SHP, at least from the domain description of a closed right-half plane. We now state some of the properties of 2-V VSHPs. Let a two-variable transfer function $T(s_1, s_2)$ be expressed as

$$T(s_1, s_2) = P(s_1, s_2)/Q(s_1, s_2) \tag{9.3}$$

where

$$P(s_1, s_2) = \sum_i \sum_j p_{ij} s_1^i s_2^j \quad (i = 0, 1, \ldots, k; j = 0, 1, \ldots, l)$$

$$Q(s_1, s_2) = \sum_i \sum_j q_{ij} s_1^i s_2^j \quad (i = 0, 1, \ldots, m; j = 0, 1, \ldots, n)$$

By applying the transformation method of Equations 9.2a through c it can be shown that unless $m \geq k$ and $n \geq l$, polar singularities exist at a set of infinite distant points in the closed right half of the $\{S_1, S_2\}$-biplane. Therefore, assume the $m \geq k$ and $n \geq 1$. Then, the following theorem regarding the singularity in the closed right-half biplane can be stated.

THEOREM 9.8

$T(s_1, s_2)$ does not possess any singularity on the closed right half of $\{S_1, S_2\}$-biplane defined by $S^2_{\oplus\oplus}$ iff $Q(s_1, s_2)$ is a VSHP.

Proof: The proof of the theorem is straightforward if the infinite distant points are also taken into account.

Some other useful properties of VSHPs are [2]

- $B(s_1, s_2) = [B_1(s_1, s_2).\ B_2(s_1, s_2)]$ is a VSHP iff $B_1(s_1, s_2)$ and $B_2(s_1, s_2)$ are VSHPs.
- If $B(s_1, s_2)$ is a VSHP, then $\partial/\partial s_i\ [B(s_1, s_2)]$, $i = 1, 2$ are also VSHPs. This property is not true for other 2-D Hurwitz polynomials. Let

$$B(s_1, s_2) = A_M(s_2)s_1^M + A_{M-1}(s_2)s_1^{M-1} + \cdots + A_1(s_2)s_1 + A_0(s_2) \tag{9.4}$$

$$= C_N(s_1)s_2^N + C_{N-1}(s_1)s_2^{N-1} + \cdots + C_1(s_1)s_2 + C_0(s_1) \tag{9.5}$$

- Let $B(s_1, s_2)$ be expressed as in Equations 9.4 and 9.5. Then, $A_i(s_2)$, $i = 0, 1, \ldots, M$ and $C_j(s_1)$, $j = 0, 1, \ldots, N$ are 1-V strict Hurwitz polynomials. This property readily follows from the preceding partial derivative property.
- Let $B(s_1, s_2) = \Sigma_i\ \Sigma_j\ b_{ij}\ s_1^i s_2^j$ be a real 2-D VSHP. Then $b_{MN}\ b_{ij} > 0$ for all i and j ($i = 0, 1, \ldots, M$; $j = 0, 1, \ldots, N$).
- Let $B(s_1, s_2)$ be expressed as in Equations 9.4 and 9.5. Then, $A_i(s_2)/A_{i-1}\ (s_2)$ for $i = 1, \ldots, M$ and $C_j(s_1)/C_{j-1}(s_1)$ for $j = 1, \ldots, N$ are minimum reactive, susceptive, strict PRFs.

The preceding property gives the following the necessary and sufficient condition for $B(s_1, s_2)$, which has a first degree in s_1 and any degree in s_2.

The necessary and sufficient condition that allows a 2-V polynomial $B(s_1, s_2) = B_1(s_2)s_1 + B_0(s_2)$ to be a VSHP is that the 1-V function $F(s_2) = B_1(s_2)/B_0(s_2)$ be a minimum reactive, susceptive, strict PRF.

Finally, we give a transformation theorem that transforms a 1-D strict Hurwitz polynomial into a 2-D VSHP. This is called a reactance transformation.

THEOREM 9.9

Let $D(s)$ be any strict Hurwitz polynomial of order n. Generate a 2-D polynomial in the following way:

$$B(s_1, s_2) = [N(s_1, s_2)\,]^n \cdot \{D(s)\}|s = M(s_1, s_2)/N(s_1, s_2)$$

where M and N are, respectively, the even and odd 2-D polynomials. The necessary and sufficient condition for $B(s_1, s_2)$ to be a VSHP is that $M(s_1, s_2) + N(s_1, s_2)$ be a VSHP [2].

The odd TPRF $Z(s_1, s_2) = M(s_1, s_2)/N(s_1, s_2)$ does not possess NSSK on the distinguished boundary S_{00}^2 and is called a proper or strict 2-D reactance function [2].

9.7 Application of Two-Dimensional Hurwitz Polynomials for Two-Variable Passive Networks and Stability

This section enumerates some properties of 2-V passive network functions, with particular reference to the Hurwitz nature of the polynomials [24]. (The following assumes Re $F(1, 1) > 0$.)

Let $F(s_1, s_2) = N(s_1, s_2)/D(s_1, s_2)$ be the driving-point immittance of a passive network. Then, $N(s_1, s_2)$ and $D(s_1, s_2)$ are BHPs. Let the common factors of $N(s_1, s_2)$ and $D(s_1, s_2)$ be canceled out and the resulting polynomials be called $N_1(s_1, s_2)$ and $D_1(s_1, s_2)$. Then, $N_1(s_1, s_2)$ and $D_1(s_1, s_2)$ are immittance Hurwitz polynomials.

Let $F(s_1, s_2) = A(s_1, s_2)/B(s_1, s_2)$ be a relatively prime 2-V odd rational function. Then, $F(s_1, s_2)$ is a 2-V reactance function if $A(s_1, s_2) + B(s_1, s_2)$ is a VSHP. $F(s_1, s_2)$ is A 2-V reactance function iff $A(s_1, s_2) + B(s_1, s_2)$ is a scattering Hurwitz polynomial. The self-paraconjugate polynomials $A(s_1, s_2)$ and $B(s_1, s_2)$ satisfy the reactance Hurwitz properties.

A relatively prime 2-V odd function $F(s_1, s_2) = A(s_1, s_2)/B(s_1, s_2)$ having no second-kind singularities is a reactance function iff $A(s_1, s_2) + B(s_1, s_2)$ is a VSHP. Such functions are called proper or strict reactance functions [2], and are useful as transformation functions to generate a (structurally stable) 2-D network from a stable 1-D network. This is one of the main applications of VSHP.

Let us now consider a relatively prime function $F(s_1, s_2) = N(s_1, s_2)/D(s_1, s_2)$. $F(s_1, s_2)$ is a TPRF iff $N(s_1, s_2) + D(s_1, s_2)$ is a scattering Hurwitz polynomial. Further, if no second-kind singularities exist for $F(s_1, s_2)$ on S^2_{00}, $N(s_1, s_2) + D(s_1, s_2)$ will be a VSHP. From the previous discussion, we can conclude that the Hurwitz nature determines important necessary conditions (and in some cases necessary and sufficient conditions) of 2V positive lossless functions. Hurwitz polynomials can be used to generate 2-V positive and lossless functions as in 1-V case through partial derivative operations [6].

The following property relates to sum separability and Hurwitz nature [20]. Let $F(s_1, s_2) = N(s_1, s_2)/D(s_1, s_2)$ be a 2-V positive function. Assume $D(s_1, s_2)$ is an immittance Hurwitz polynomial having self-paraconjugate factors. In other words, $D(s_1, s_2)$ is written as $D(s_1, s_2) = D_1(s_1, s_2)D_2(s_1, s_2)$, where $D_1(s_1, s_2)$ is a reactance Hurwitz and $D_1(s_1, s_2)$ is a scattering Hurwitz. Then, $F(s_1, s_2)$ is sum separable as

$$F(s_1, s_2) = \frac{N_1(s_1, s_2)}{D_1(s_1, s_2)} + \frac{N_2(s_1, s_2)}{D_2(s_1, s_2)}$$

where N_1/D_1 is a reactance function and N_2/D_2 is a positive function.

Now, we turn our attention to some applications concerning transfer functions. Let $T(s_1, s_2) = A(s_1, s_2)/B(s_1, s_2)$ be the transfer function of a singly terminated or doubly terminated 2-V lossless network. Then, $B(s_1, s_2)$ is a scattering Hurwitz polynomial. References [21,22] provide a detailed discussion of networks with transfer functions having scattering and VSHP denominators. It is not necessary that the denominator of all RLC 2-V network transfer functions be scattering Hurwitz. In the most general case it could be a broad-sense Hurwitz.

Another interesting observation is that in the 1-V case the voltage transfer function cannot have a pole at origin and infinity. Extending this to the 2-V situation, we find that the 2-V voltage transfer function, $T(s_1, s_2)$ cannot have first-kind (polar) singularities at $s_i = 0$ or ∞ $(i = 1, 2)$, but $T(s_1, s_2)$ can be 0/0 at $s_i = 0$ or ∞ $(i = 1, 2)$.

Let $H(s_1, s_2) = P(s_1, s_2)/Q(s_1, s_2)$ be a 2-V bounded real or lossless bounded real function. Then, $Q(s_1, s_2)$ is a scattering Hurwitz polynomial. If $H(s_1, s_2)$ has no NSSK on S^2_{00} then $Q(s_1, s_2)$ must be a VSHP.

9.7.1 Application to Two-Dimensional Analog System Stability

We consider the following important theorem [12].

THEOREM 9.10

The 2-D analog transfer function $T(s_1, s_2) = A(s_1, s_2)/B(s_1, s_2)$ is bounded-input–bounded-output (BIBO) stable only if $B(s_1, s_2)$ is a scattering Hurwitz polynomial. The sufficient *condition for stability is that $B(s_1, s_2)$ be a VSHP (assume that $T(s_1, s_2)$ has no polar singularities at infinite distant points).*

We conclude this section with the following unresolved problem of BIBO stability of 2-D continuous time systems [12]:

Conjecture: *The 2-D analog transfer function $T(s_1, s_2)$ described in Theorem* 9.10 *is BIBO stable with no NSSK on S^2_{00} iff $B(s_1, s_2)$ is a VSHP.*

The sufficiency part of this statement is proved. The necessity has yet to be established.

9.8 Conclusion

This chapter provides a comprehensive, yet compact treatment of the theory of 2-D (analog) Hurwitz polynomials. With the help of double bilinear transformation $s_1 = (1 - z_i)/(1 + z_i)$, $i = 1, 2$, most of the theory could easily be translated to the 2-D discrete case, and thus to the stability theory and design of 2-D digital filters [2,24]. As in the 1-D case the 2-D Hurwitz polynomials play a critical role in the study of 2-D circuits, systems, and filters. In this chapter, a detailed classification and testing (see theorems) of various 2-D Hurwitz polynomials is presented. Discussion of the properties of 2-D very strict Hurwitz polynomials is also given. The various testing procedures (algorithms) are not discussed. The test procedures can be found in Refs. [11,12,25,26]. The chapter concludes by discussing how various Hurwitz polynomials arise in passive 2-V circuit theory and 2-D analog stability.

Acknowledgments

As always, Dr. P. K. Rajan of the Tennessee Technological University and Dr. E. I. Jury of the University of California at Berkeley and the University of Miami provided constant encouragement. Dr. Rajan made significant contributions to the theory of stable 2-D polynomials discussed in this chapter. The material in this chapter is based mainly on Refs. [2,24] (including Figure 9.1).

10.1 Introduction

Two-dimensional (2-D) digital filters find applications in many fields such as image processing and seismic signal processing. Design of 2-D digital filters is more complicated than that of 1-D digital filters because of the increase in the number of coefficients with the increase in the dimension and also the difficulty of testing their stability. Fortunately, 2-D frequency responses possess many types of symmetries and the presence of these symmetries can be used to reduce the complexity of the design as well as the implementation of these filters. Symmetry in the frequency response of a filter induces certain constraints on the coefficients of the filter, which in turn reduces the filter design complexity [1–28]. Therefore, a study of the symmetries of the filter frequency responses and the resulting constraints on the filter coefficients is undertaken in this chapter. As there is a close relationship between digital and analog filter functions, symmetry properties are discussed in this chapter for both analog and digital domain functions. In addition to filter design, symmetry can also be applied in the computation of Fourier transform of 2-D signals. To facilitate this, the symmetry properties in the Fourier transform pairs will be presented. It will also be shown that the presence of symmetry will reduce the complexity in the implementation of the fast Fourier transform (FFT) of 2-D signals [29].

The following is the layout of the sections. First, the symmetries are defined. Then, the Fourier transform pairs with symmetry and the use of symmetry in the implementation of FFT are presented. Next, symmetry in the magnitude functions of filters is discussed. This is followed by the symmetry constraints on polynomials and a procedure to design 2-D filters employing the constraints. Finally, several examples are given to illustrate the application of the symmetry-based filter design procedure.

10.2 Basic Symmetry Definitions

Let us consider a real rational function $f(x_1, x_2)$ in two independent variables x_1 and x_2, where the function f assumes a unique value for each pair of x_1 and x_2. The existence of symmetry in $f(x_1, x_2)$ implies the value of the function at (x_1, x_2) is related to the value at (x_{1T}, x_{2T}), where (x_{1T}, x_{2T}) is obtained by some operation on (x_1, x_2) [30–32]. Expanding on this concept, a function f is said to possess a symmetry if a pair of operations, T and ψ, performed simultaneously on the vector of variables, (x_1, x_2), and the function value leaves the shape of the function f undisturbed. The $T - \psi$ symmetry of a function is defined as follows:

Definition 10.1: A function $f(\underline{x})$ is said to possess a $T - \psi$ symmetry over a domain D if

$$\psi[f(T[\underline{x}])] = f(\underline{x}) \quad \text{for all } x \in D \tag{10.1}$$

where

ψ is an operation on the value of $f(\underline{x})$

T is an operation on $\underline{x}$ that maps D onto itself on a one-to-one basis

Depending on the $T-\psi$ operations, different symmetries are obtained such as $x_1 = x_2$ diagonal reflection antisymmetry, fourfold rotational conjugate symmetry, and so on. The nature of T and ψ operations is discussed next.

10.2.1 Nature of *T*-Operations

In the study of symmetry, the basic T-operation can be represented by the transformation:

$$T[\underline{x}] = \underline{A} \cdot \underline{x} + \underline{b} \tag{10.2}$$

where

$\underline{A}$ is a nonsingular (2×2) real square matrix
$\underline{b}$ is a (2×1) real vector

Some of the common T-transformations are displacement transformation, rotational transformation, and reflection transformation. In Table 10.1, we list only the basic reflection and rotational transformations where $\underline{b} = \underline{0}$ and the $\underline{A}$ matrices are formed using 1 or -1 as elements on the diagonal or off the diagonal. Of the seven operations listed, only the first five are needed as the product of them will give the remaining two. Thus we will only focus on operations (i)–(v) listed in the table.

It is to be noted that the T-operations can be compounded. For example, T_1T_2 refers to the compound operation consisting of operation T_2 followed by T_1. The compounding of transformations always obey the associative law, i.e., $T_1(T_2T_3) = (T_1T_2)T_3$.

The T-operations can also be classified by the number of cycles. A T-operation is said to be k-cyclic if k repeated T-operations on $\underline{x}$ yield the same original $\underline{x}$. That is: $T^k[\underline{x}] = \underline{x}$ or stated in another way $T^k = \underline{I}$ (where $\underline{I}$ is the identity matrix). For example, $T_1^2 = \underline{I}$ and $T_5^4 = \underline{I}$. So, operations (i)–(iv) listed in Table 10.1 are 2-cyclic, while (v) is 4-cyclic.

TABLE 10.1 Basic T-Operations

	$\underline{A}$	$\underline{b}$	Name of Operation	Symbol
(i)	$\begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$	$\underline{0}$	Reflection about x_1-axis	T_1
(ii)	$\begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}$	$\underline{0}$	Reflection about x_2-axis	T_2
(iii)	$\begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$	$\underline{0}$	Reflection about $x_1 = x_2$ diagonal	T_3
(iv)	$\begin{bmatrix} 0 & -1 \\ -1 & 0 \end{bmatrix}$	$\underline{0}$	Reflection about $x_1 = -x_2$ diagonal	T_4
(v)	$\begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}$	$\underline{0}$	90° clockwise rotation about origin	T_5
(vi)	$\begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}$	$\underline{0}$	90° anticlockwise rotation about origin	T_6
(vii)	$\begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}$	$\underline{0}$	180° rotation about origin	T_7

10.2.2 Nature of ψ-Operations

The basic ψ-operation can be represented by

$$\psi[f(\underline{x})] = |f(\underline{x})|e^{j(\delta \angle f(\underline{x}) + \underline{\beta}^t \underline{x} + \phi)} \tag{10.3}$$

where

$\delta = \pm 1$
$\angle f(\underline{x})$ denotes the argument of $f(\underline{x})$
$\underline{\beta}$ is a (2×1) real constant vector
ϕ is a real constant

In Equation 10.3, it can be seen that ψ does not alter the magnitude of $f(\underline{x})$ as the parameters δ, $\underline{\beta}$, and φ affect only the argument of $f(\underline{x})$. Most commonly occurring symmetries have $\underline{\beta} = 0$. The term $\underline{\beta}'$ has been included in the ψ operation to account for delay type symmetries that may be present in some functions. In Table 10.2, we list four common ψ-operations that are used in various symmetry descriptions.

10.2.3 Various *T*–ψ Symmetries

The T and ψ operations in Equations 10.2 and 10.3 can be combined to form a composite symmetry operation that is described by the symmetry parameters ($\underline{A}$, $\underline{b}$, δ, $\underline{\beta}$, φ). This composite operation can be used to generate various symmetries. For example, using the T-operations (i)–(v) in Table 10.1 and assuming the identity ψ_I, we have the following standard symmetries. (Note that the corresponding antisymmetry, conjugate-symmetry, and conjugate-antisymmetry can be obtained by applying the ψ_A, ψ_C, and ψ_{CA} operations, respectively, shown in Table 10.2.)

1. Reflection about x_1-axis symmetry: $f(\underline{x}) = f(T_1[\underline{x}])$.
2. Reflection about x_2-axis symmetry: $f(\underline{x}) = f(T_2[\underline{x}])$.
3. Reflection about $x_1 = x_2$ diagonal symmetry: $f(\underline{x}) = f(T_3[\underline{x}])$.
4. Reflection about $x_1 = -x_2$ diagonal symmetry: $f(\underline{x}) = f(T_4[\underline{x}])$.
5. 90° clockwise rotational symmetry: $f(\underline{x}) = f(T_5[\underline{x}])$. This also implies $f(T_5[\underline{x}]) = f(T_5^2[\underline{x}])$ and $f(T_5^2[\underline{x}]) = f(T_5^3[\underline{x}])$, through repeated substitution of $\underline{x} = T_5[\underline{x}]$.
6. Centrosymmetry (180° rotation): $f(\underline{x}) = f(-\underline{x})$. This can also be expressed as $f(\underline{x}) = f(T_5^2[\underline{x}])$ or $f(\underline{x}) = f(T_1T_2[\underline{x}])$ or $f(\underline{x}) = f(T_3T_4[\underline{x}])$.

These symmetries are shown in Figure 10.1a through f. It is to be noted that the values of the function at corresponding points in the shaded regions are the same since we assume $\psi = \psi_I$.

The various symmetries can also be classified according to their cycles. Reflection symmetries about x_1-axis, x_2-axis, $x_1 = x_2$ diagonal, $x_1 = -x_2$ diagonal, and centrosymmetry are all 2-cyclic symmetries. On the other hand, 90° clockwise rotational symmetry is 4-cyclic, and we usually call it fourfold (90°) rotational symmetry.

TABLE 10.2 Basic ψ-Operations

δ	$\underline{\beta}$	φ	ψ-Operations	Symmetry Name	Symbol
1	$\underline{0}$	0	$\psi[f(\underline{x})] = f(\underline{x})$	Identity symmetry	ψ_I
1	$\underline{0}$	π	$\psi[f(\underline{x})] = -f(\underline{x})$	Antisymmetry	ψ_A
−1	$\underline{0}$	0	$\psi[f(\underline{x})] = [f(\underline{x})]^*$	Conjugate symmetry	ψ_C
−1	$\underline{0}$	π	$\psi[f(\underline{x})] = -[f(\underline{x})]^*$	Conjugate antisymmetry	ψ_{CA}

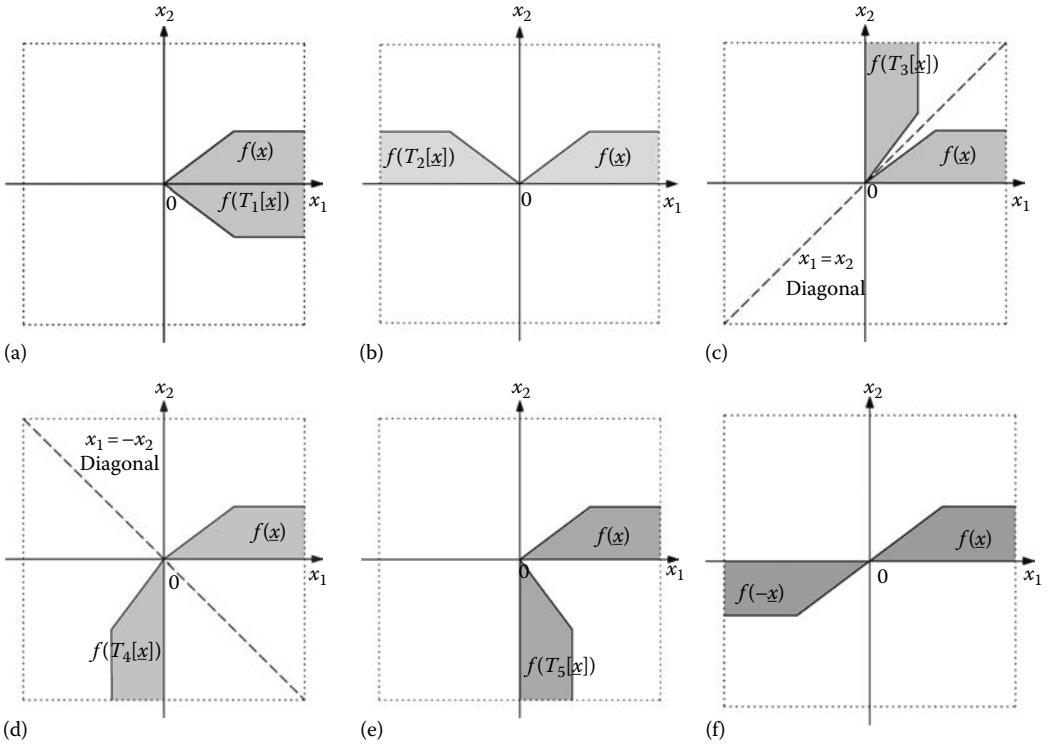

FIGURE 10.1 (a) x_1-Axis reflection symmetry, (b) x_2-axis reflection symmetry, (c) $x_1 = x_2$ diagonal reflection symmetry, (d) $x_1 = -x_2$ diagonal reflection symmetry, (e) 90° clockwise rotation symmetry, and (f) centrosymmetry (180° rotation).

In addition to these basic symmetries, more complex symmetries can be generated using a combination of different T-operations. For example, using a combination of T_1 and T_2 operations, we can obtain quadrantal symmetry. These compound symmetries are listed in Table 10.3. (Once again, for illustration, we show only the symmetries resulting from the ψ_I operation.)

We can make some important observations on the compound symmetries in Table 10.3:

1. Quadrantal symmetry is a combination of x_1-axis reflection, x_2-axis reflection, and centrosymmetries. The presence of any two of the symmetries implies the existence of the third, i.e., $T_1 \cdot T_2 \Rightarrow -\underline{I}$, $-\underline{I} \cdot T_1 \Rightarrow T_2$, and $-\underline{I} \cdot T_2 \Rightarrow T_1$. So only two of the three symmetries are needed to ensure quadrantal symmetry. In terms of cycles, quadrantal symmetry is a double 2-cyclic symmetry as $(T_1 \cdot T_2) \cdot (T_1 \cdot T_2) = \underline{I}$.

TABLE 10.3 Definitions of Compound T–ψ_I Symmetries

Type of Symmetry	Conditions
Quadrantal symmetry	$f(\underline{x}) = f(T_1[\underline{x}]) = f(T_1T_2[\underline{x}]) = f(T_2[\underline{x}])$
Diagonal symmetry	$f(\underline{x}) = f(T_3[\underline{x}]) = f(T_3T_4[\underline{x}]) = f(T_4[\underline{x}])$
Fourfold (90°) rotational symmetry	$f(\underline{x}) = f(T_5[\underline{x}]) = f(T_5^2[\underline{x}]) = f(T_5^3[\underline{x}])$
Octagonal symmetry	$f(\underline{x}) = f(T_1[\underline{x}]) = f(T_2[\underline{x}])$ $= f(T_3[\underline{x}]) = f(T_4[\underline{x}])$ $= f(T_5[\underline{x}]) = f(T_5^2[\underline{x}]) = f(T_5^3[\underline{x}])$

2. Diagonal symmetry is a combination of $x_1 = x_2$ diagonal, $x_1 = -x_2$ diagonal, and centrosymmetries. The presence of any two of the three symmetries implies the existence of the third and is enough to ensure diagonal symmetry. Diagonal symmetry is a double 2-cyclic symmetry.
3. Fourfold (90°) rotational symmetry is a 4-cyclic symmetry. It is formed by four repeated applications of T_5.
4. Octagonal symmetry is a combination of quadrantal, diagonal, and fourfold rotational symmetries. The presence of any two of the three symmetries implies the existence of the third, and is sufficient to guarantee octagonal symmetry. Octagonal symmetry can be classified as a triple 2-cyclic symmetry, or a combination of 4-cyclic and 2-cyclic symmetries.

To aid in understanding, Figure 10.2a through d shows the graphical interpretation of the quadrantal, diagonal, rotational, and octagonal symmetries. Once again, the values of the function in the shaded regions are related to one another in the manner specified by the ψ operation (i.e., identity, negative, conjugate, or negative conjugate). From the figures, one can also see that there are four regions of

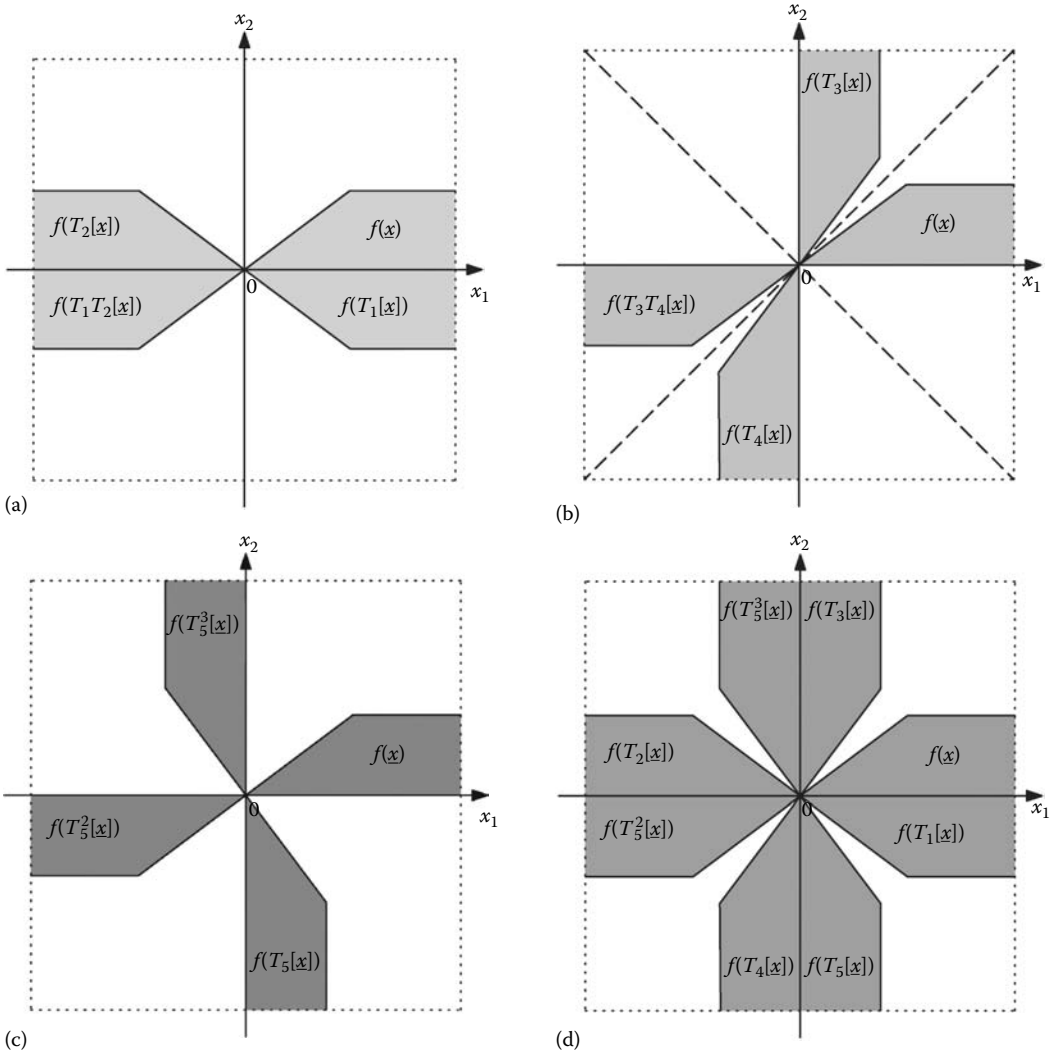

FIGURE 10.2 (a) Quadrantal symmetry, (b) diagonal symmetry, (c) fourfold rotational symmetry, and (d) octagonal symmetry.

symmetry in the X-plane for quadrantal, diagonal, and fourfold rotational symmetries, and eight regions for octagonal symmetry.

10.3 Two-Dimensional Fourier Transform Pairs with Symmetry

Two-dimensional Fourier transform is a very important tool in the analysis and design of 2-D linear systems. Since the transform uniquely relates the impulse or unit sample response of a linear system with its frequency response, symmetry present in one response may be expected to induce some form of symmetry in the other response. The existence of such symmetries can then be utilized to simplify the analysis and design of these systems. In this section, we present, for both continuous and discrete-time signals, the type of symmetry induced in one function (Fourier transform or inverse Fourier transform) as a result of a particular symmetry in the other function.

10.3.1 Continuous-Time Continuous-Frequency Case

Let $h(\underline{l}) = h(l_1, l_2)$ be a 2-D signal, and $H(\underline{\omega}) = H(\omega_1, \omega_2)$ be the 2-D Fourier transform of $h(\underline{l})$. If $h(\underline{l})$ is the impulse response of a stable continuous-time system, then its Fourier transform $H(\underline{\omega})$ always exists and the Fourier transform pair are given as follows:

$$H(\underline{\omega}) = \int_{\underline{l} \in L} h(\underline{l}) \cdot e^{-j\underline{\omega}^t \underline{l}} \cdot d\underline{l} \tag{10.4}$$

and

$$h(\underline{l}) = \frac{1}{(2\pi)^2} \int_{\underline{\omega} \in W} H(\underline{\omega}) \cdot e^{j\underline{l}^t \underline{\omega}} \cdot d\underline{\omega} \tag{10.5}$$

where

$d\underline{l} \triangleq dl_1 \cdot dl_2$

$d\underline{\omega} \triangleq d\omega_1 \cdot d\omega_2$

The following theorem describes the nature of the symmetry that will be present in $h(\underline{l})$, given a symmetry in $H(\underline{\omega})$, and vice versa [29].

THEOREM 10.1

Let $h(\underline{l})$ and $H(\underline{\omega})$ form a 2-D Fourier transform pair. Then $H(\underline{\omega})$ possesses a $T - \psi$ symmetry with parameters $(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)$, $|\underline{A}| = \pm 1$, if and only if $h(\underline{l})$ possesses a $T - \psi$ symmetry with parameters $(\delta \cdot (\underline{A}^{-1})^t, \delta\underline{\beta}, \delta, -\delta\underline{b}, \underline{b}^t\,\underline{\beta} + \phi)$ where $\underline{A}$, $\underline{b}$, δ, $\underline{\beta}$, ϕ are as defined in Section 10.2.

Observations

We can make the following observations based on Theorem 10.1:

1. If $(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)_\omega$ and $(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)_l$ are respectively the $\underline{\omega}$-domain and the $\underline{l}$-domain symmetry parameters, the corresponding $\underline{l}$ and $\underline{\omega}$ domain parameters are obtained by the following relations:

$$(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)_{\underline{\omega}} \Rightarrow (\delta \cdot (\underline{A}^{-1})^t, \delta\underline{\beta}, \delta, -\delta\underline{b}, \underline{b}^t\underline{\beta} + \phi)_{\underline{l}} \tag{10.6}$$

and

$$(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)_{\underline{l}} \Rightarrow (\delta \cdot (\underline{A}^{-1})^t, \ -\delta\underline{\beta}, \ \delta, \delta\underline{b}, \ \underline{b}^t\underline{\beta} + \phi)_{\underline{\omega}} \tag{10.7}$$

This illustrates the duality present in $\underline{\omega}$ and $\underline{l}$ domain symmetries.

2. Nature of symmetry transformation, such as rotation, reflection, etc., as identified by the $\underline{A}$-matrix remains the same in both the $\underline{\omega}$ and $\underline{l}$ domains.
3. Identical symmetries resu1t in both $\underline{\omega}$ and $\underline{l}$ domains if $\delta = 1$, $\underline{b} = 0$, and $\underline{\beta} = 0$.

10.3.2 Continuous-Time Discrete-Frequency Case (Fourier Series)

Let $h(\underline{l}) = h(l_1, l_2)$ be a 2-D continuous-time periodic signal with periods L_1 and L_2, respectively in l_1 and l_2 directions. Let $H[\underline{k}] = H[k_1, k_2]$ be the 2-D Fourier series coefficients of $h(l_1, l_2)$. The relations between $h(\underline{l})$ and $H[\underline{k}]$ are given by

$$H[\underline{k}] = \frac{1}{L_1 \cdot L_2} \cdot \int_{l_1=0}^{L_1} \int_{l_2=0}^{L_2} h(\underline{l}) \cdot e^{-j \cdot \underline{k}^t \cdot \underline{V} \cdot \underline{l}} \cdot d\underline{l} \tag{10.8}$$

and

$$h(\underline{l}) = \sum_{\underline{k}} H[\underline{k}] \cdot e^{j \cdot \underline{k}^t \cdot \underline{V} \cdot \underline{l}} \tag{10.9}$$

where

$$\underline{V} = \begin{bmatrix} V_1 & 0 \\ 0 & V_2 \end{bmatrix} = \begin{bmatrix} \frac{2 \cdot \pi}{L_1} & 0 \\ 0 & \frac{2 \cdot \pi}{L_2} \end{bmatrix}$$

It may be verified that $h(\underline{l})$ is a doubly periodic function indicating the existence of displacement symmetries. In the following, we will consider the general $T - \psi$ symmetry relations.

THEOREM 10.2

Let $H[\underline{k}]$ be the Fourier series representation of a periodic function $h(\underline{l})$. Then $h(\underline{l})$ possesses a $T - \psi$ symmetry with parameters $(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)$, $|\underline{A}| = \pm 1$, if and only if $H[\underline{k}]$ possesses a $T - \psi$ symmetry with parameters $(\delta \cdot (\underline{A}^{-1})^t, -\delta \cdot \underline{V}^{-1} \cdot \underline{\beta}, \delta, \delta \cdot \underline{V} \cdot \underline{b}, \underline{b}^t \underline{\beta} + \phi)$ where $\underline{A}$, $\underline{b}$, δ, $\underline{\beta}$, ϕ are as defined in Section 10.2. It should be noted that $\underline{b}$ and $-\delta \cdot \underline{V}^{-1} \cdot \underline{\beta}$ are integer vectors.

Since the observations made on the continuous domain case are also applicable here, the relations between $\underline{k}$ and $\underline{l}$ domain parameters are given by

$$(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)_{\underline{l}} \Rightarrow (\delta \cdot (\underline{A}^{-1})^t, -\delta \cdot \underline{V}^{-1} \cdot \underline{\beta}, \delta, \delta \cdot \underline{V} \cdot \underline{b}, \underline{b}^t \underline{\beta} + \phi)_{\underline{k}} \tag{10.10}$$

and

$$(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)_{\underline{k}} \Rightarrow (\delta \cdot (\underline{A}^{-1})^t, \delta \cdot \underline{V}^{-1} \cdot \underline{\beta}, \delta, -\delta \cdot \underline{V} \cdot \underline{b}, \underline{b}^t \underline{\beta} + \phi)_{\underline{l}} \tag{10.11}$$

10.3.3 Discrete-Time Continuous-Frequency Case

Let $h(\underline{n}) = h(n_1, n_2)$, where n_1, n_2 are integers, be a 2-D discrete-domain signal and $H(\underline{\theta}) = H(e^{-j\theta_1}, e^{-j\theta_2})$ be the 2-D Fourier transform of $h(\underline{n})$. The Fourier transform pair connecting $h(\underline{n})$ and $H(\underline{\theta})$ are given by

$$H(\underline{\theta}) = \sum_{\underline{n} \in N^2} h(\underline{n}) \cdot e^{-j\underline{\theta}^t \underline{n}} \tag{10.12}$$

and

$$h(\underline{n}) = \frac{1}{(2\pi)^2} \int_{\underline{\theta} \in \theta_p} H(\underline{\theta}) \cdot e^{j\underline{n}^t \underline{\theta}} \cdot d\underline{\theta} \tag{10.13}$$

where

$\theta_p = \{\underline{\theta} | -\pi \le \theta_1 \le \pi, \ -\pi \le \theta_2 \le \pi\}$

$d\underline{\theta} = d\theta_1 \cdot d\theta_2$

It may easily be verified from Equation 10.12 that $H(\underline{\theta})$ is a periodic function of $\underline{\theta}$ with a period of 2π in the θ_1 and θ_2 directions. Because of the periodic nature of $H(\underline{\theta})$, displacement symmetries in θ_1 and θ_2 directions are always present. This is due to the discrete nature of $h(\underline{n})$. We will consider the effects of the remaining symmetries that will be present in $h(\underline{n})$, given a symmetry in $H(\underline{\theta})$ and vice versa, in the following theorem.

THEOREM 10.3

Let $h(\underline{n})$ and $H(\underline{\theta})$ be a 2-D Fourier transform pair. Then $H(\underline{\theta})$ possesses a $T - \psi$ symmetry with parameters $(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)$, $|\underline{A}| = \pm 1$, if and only if $h(\underline{n})$ possesses a $T - \psi$ symmetry with parameters $(\delta \cdot (\underline{A}^{-1})^t, \delta\underline{\beta}, \delta, -\delta\underline{b}, \underline{b}^t \underline{\beta} + \phi)$ where $\underline{A}$, $\underline{b}$, δ, $\underline{\beta}$, ϕ are as defined in Section 10.2.

Because of the similarity between Theorem 10.3 and Theorem 10.1, the observations made in the continuous domain case are also applicable here. Consequently, the relations between $\underline{\theta}$ and $\underline{n}$ symmetry parameters are given by

$$(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)_{\underline{\theta}} \Rightarrow (\delta \cdot (\underline{A}^{-1})^t, \delta\underline{\beta}, \delta, -\delta\underline{b}, \underline{b}^t\underline{\beta} + \phi)_{\underline{n}} \tag{10.14}$$

and

$$(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)_{\underline{n}} \Rightarrow (\delta \cdot (\underline{A}^{-1})^t, -\delta\underline{\beta}, \delta, \delta\underline{b}, \underline{b}^t\underline{\beta} + \phi)_{\underline{\theta}} \tag{10.15}$$

In the application of this theorem, it should be noted that $h(\underline{n})$ is a function of discrete-domain variable $\underline{n}$ and $h(\underline{n}) = \underline{0}$ if $\underline{n}$ is not an integer vector.

10.3.4 Discrete-Time Discrete-Frequency Case (Discrete Fourier Transform)

Let $h[\underline{n}] = h[n_1, n_2]$ be a 2-D discrete-domain signal defined over $0 \le n_1 \le (N_1 - 1)$ and $0 \le n_2 \le (N_2 - 1)$. Then its (N_1, N_2) length 2-D discrete Fourier transform (DFT) is given by

$$H[\underline{k}] = H[k_1, k_2] = \sum_{n_1=0}^{N_1-1} \sum_{n_2=0}^{N_2-1} h[\underline{n}] \cdot e^{-j \cdot \underline{k}^t \cdot \underline{V} \cdot \underline{n}}, \quad 0 \le k_1 \le (N_1 - 1), \quad 0 \le k_2 \le (N_2 - 1) \tag{10.16}$$

where

$$\underline{V} = \begin{bmatrix} \frac{2\cdot\pi}{N_1} & 0 \\ 0 & \frac{2\cdot\pi}{N_2} \end{bmatrix}$$

The inverse DFT is given by

$$h[\underline{n}] = h[n_1, n_2] = \frac{1}{N_1 \cdot N_2} \cdot \sum_{k_1=0}^{N_1-1} \sum_{k_2=0}^{N_2-1} H[\underline{k}] \cdot e^{j\cdot \underline{k}^t \cdot \underline{V} \cdot \underline{n}} \tag{10.17}$$

It may be noted that even though $h[n_1, n_2]$ and $H[k_1, k_2]$ are defined in the rectangle $[0, N_1 - 1] \times [0, N_2 - 1]$, they satisfy the doubly periodic relations:

$$h[n_1 + r_1 \cdot N_1, n_2 + r_2 \cdot N_2] = h[n_1, n_2] \quad \text{for any integer } r_1 \text{ and } r_2$$

and similarly

$$H[k_1 + r_1 \cdot N_1, k_2 + r_2 \cdot N_2] = H[k_1, k_2] \quad \text{for any integer } r_1 \text{ and } r_2$$

The symmetry relations between h and H are given in terms of $T - \psi$ parameters in the following theorem.

THEOREM 10.4

Let $H[\underline{k}]$ be the DFT of $h[\underline{n}]$. Then $h[\underline{n}]$ possesses a $T - \psi$ symmetry with parameters $(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)$ if and only if $H[\underline{k}]$ possesses a $T - \psi$ symmetry with parameters $(\delta \cdot (\underline{A}^{-1})^t, -\delta \cdot \underline{V}^{-1} \cdot \underline{\beta}, \delta, \delta \cdot \underline{V} \cdot \underline{b}, \underline{b}^t\ \underline{\beta} + \phi)$ where $\underline{A}$, $\underline{b}$, δ, $\underline{\beta}$, ϕ are as defined in Section 10.2.

As in the previous cases, the symmetry parameters of $\underline{n}$ and $\underline{k}$ domains can be written as

$$(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)_{\underline{n}} \Rightarrow (\delta \cdot (\underline{A}^{-1})^t, -\delta \cdot \underline{V}^{-1} \cdot \underline{\beta}, \delta, \delta \cdot \underline{V} \cdot \underline{b}, \underline{b}^t \underline{\beta} + \phi)_{\underline{k}} \tag{10.18}$$

and

$$(\underline{A}, \underline{b}, \delta, \underline{\beta}, \phi)_{\underline{k}} \Rightarrow (\delta \cdot (\underline{A}^{-1})^t, \delta \cdot \underline{V}^{-1} \cdot \underline{\beta}, \delta, -\delta \cdot \underline{V} \cdot \underline{b}, \underline{b}^t \underline{\beta} + \phi)_{\underline{n}} \tag{10.19}$$

In the application of this theorem it should be noted that $\underline{n}$ and $\underline{k}$ are integer vectors and $h[\underline{n}]$ and $H[\underline{k}]$ are periodic with periods N_1 and N_2 in the two dimensions.

10.4 Symmetry and 2-D Fast Fourier Transform

FFT is a frequently used operation on 2-D signals. For large size signals, it is also a very time-consuming operation. So, any technique that reduces this complexity is desirable. As noted earlier, presence of symmetry in a signal yields some constraints on the spectrum. Therefore, use of symmetry constraints can be expected to reduce the complexity of evaluation of 2-D Fourier transforms. In this section, we will see how symmetry constraints can be used to speed up the computation of the FFT. First we will consider 1-D signals and then we will discuss symmetry application to 2-D FFTs.

10.4.1 Symmetry-Based 1-D FFT

Let $x[n]$, $n = 0, 1, \ldots, (N-1)$ be an N-length 1-D complex signal and $X[k]$, $k = 0, 1, \ldots, (N-1)$, be the N-length DFT of $x[n]$. $X[k]$ is given by

$$X[k] = \sum_{n=0}^{N-1} x[n] \cdot W_N^{k \cdot n}, \quad k = 0, 1, \ldots, (N-1) \tag{10.20}$$

where $W_N = e^{-j\frac{2\pi}{N}}$.

The DFT requires approximately N^2 complex multiplication and N^2 complex additions. When N is a power of 2, this can be reduced to $\frac{N}{2} \log_2 N$ complex multiplications and N^2 additions using what is called the Cooley–Tukey FFT.

1-D signals may possess reflection symmetries, translation symmetries, and identity symmetries. Reflection symmetries themselves can be with respect to the point at $N/2$ or $(N-1)/2$. To illustrate the application of symmetries and the resultant reduction in the complexity, we use reflection symmetry about the point $(N-1)/2$. Application of other symmetries yields similar reductions in complexity.

If $x[n]$ possesses reflection symmetry about $n = (N-1)/2$, then $x[N-1-n] = x[n]$ for $n = 0, 1, \ldots, (N-1)$. In terms of $T - \psi$ parameters, this corresponds to $A = [-1]$, $b = [N-1]$, $\delta = 1$, $\beta = 0$, and $\phi = 0$. The corresponding symmetry parameters in DFT domain is given by

$$A_k = [-1], \quad b_k = [0], \quad \delta_k = 1, \quad \beta_k = N-1, \quad \text{and} \quad \phi_k = 0,$$

which yields the symmetry relation after employing the periodic property of $X[k]$,

$$X[k] = W_N^{-k} \cdot X[N-k], \quad k = 0, 1, \ldots, (N-1) \tag{10.21}$$

Therefore, only half of $X[k]$ and $x[n]$ are independent and once they are known, the other half can be determined using the symmetry relation (Equation 10.21).

Assuming N to be even, we next show how $X[k]$ can be determined with less number of operations than the FFT. Using even and odd sample decomposition we can write $X[k]$ as

$$\begin{aligned} X[k] &= \sum_{\substack{n=0 \\ n \text{ even}}}^{N-1} x[n] \cdot W_N^{k \cdot n} + \sum_{\substack{n=0 \\ n \text{ odd}}}^{N-1} x[n] \cdot W_N^{k \cdot n} \\ &= \sum_{r=0}^{\frac{N}{2}-1} x[2r] \cdot W_N^{k \cdot 2r} + \sum_{r=0}^{\frac{N}{2}-1} x[2r+1] \cdot W_N^{k \cdot (2r+1)} \\ &= S_0[k] + W_N^k \cdot S_1[k] \end{aligned} \tag{10.22}$$

where S_0 and S_1 are $N/2$ point DFTs. Now using the symmetry properties $x[N-1-n] = x[n]$, we can write $S_1[k]$ in terms of $S_0[k]$ as

$$S_1[k] = W_N^{-2k} \cdot S_0\left[\frac{N}{2} - k\right] \tag{10.23}$$

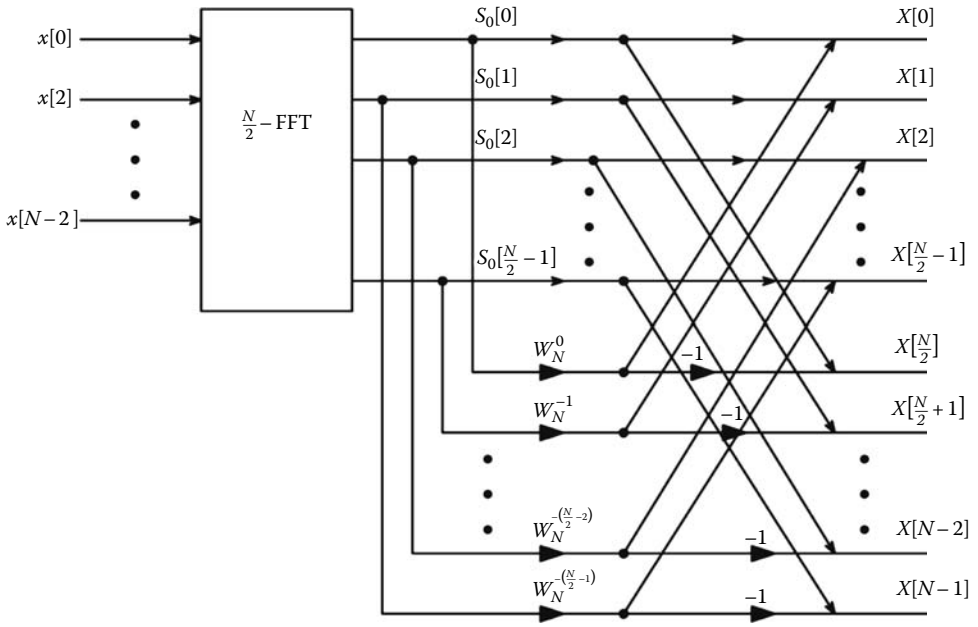

FIGURE 10.3 Symmetry-based FFT diagram.

So, for $k = 0, 1, 2, \ldots, \frac{N}{2} - 1$,

$$\begin{aligned} X[k] &= S_0[k] + W_N^k \cdot W_N^{-2k} \cdot S_0\left[\frac{N}{2} - k\right] \\ &= S_0[k] + W_N^{-k} \cdot S_0\left[\frac{N}{2} - k\right] \\ X\left[\frac{N}{2} + k\right] &= S_0[k] - W_N^{-k} \cdot S_0\left[\frac{N}{2} - k\right] \end{aligned} \tag{10.24}$$

Thus, $X[k]$ for $k = 0, 1, 2, \ldots, (N-1)$ can be determined using $N/2$ even indexed samples. This is illustrated in the flow diagram shown in Figure 10.3.

It is noted that we need only one $\frac{N}{2}$-point FFT instead of the normal two. As a result, the total number of complex multiplications needed is reduced to $\frac{N}{4}\log_2\left(\frac{N}{2}\right) + \frac{N}{2}$ instead of $\frac{N}{2}\log_2 N$ in the nonsymmetrical case. Thus use of symmetry results in approximately 50% reduction in the computational complexity.

10.4.2 2-D Symmetries

As in the 1-D case, symmetry can be utilized to reduce the computational complexity of 2-D DFTs. In the following, we illustrate the symmetry application for centrosymmetry and quadrantal symmetry cases.

As in the 1-D case, the reflection and rotation symmetries can be defined with respect to $\left(\frac{N}{2}, \frac{N}{2}\right)$ point or $\left(\frac{N-1}{2}, \frac{N-1}{2}\right)$ point. Because of periodicity of h, the symmetries with respect to $\left(\frac{N}{2}, \frac{N}{2}\right)$ will also correspond to symmetries with respect to the origin (0,0) for the periodically extended signal. On the other hand, with the choice of $\left(\frac{N-1}{2}, \frac{N-1}{2}\right)$ point for reflection or rotation, the various symmetries will occur for $h[\underline{n}]$ with respect to the center of the given data. In the following, $\left(\frac{N-1}{2}, \frac{N-1}{2}\right)$ is chosen in the definition of various symmetries for $h[\underline{n}]$.

10.4.2.1 Centrosymmetry about $\left(\frac{N-1}{2}, \frac{N-1}{2}\right)$

An $N \times N$ array 2-D signal $x[m, n]$ is said to possess centrosymmetry about $\left(\frac{N-1}{2}, \frac{N-1}{2}\right)$ if

$$x[N-1-m, N-1-n] = x[m, n] \quad \text{for } 0 \leq m, n \leq N-1$$

The corresponding symmetry relation for its 2-D DFT $X[k, l]$ is given by

$$X[N-k, N-l] = W_N^{k+l} \cdot X[k, l] \tag{10.25}$$

Now employing the even- and odd-indexed samples decomposition, $X[k, l]$ can be written as

$$X[k, l] = S_{00}[k, l] + W_N^k \cdot S_{10}[k, l] + W_N^l \cdot S_{01}[k, l] + W_N^{k+l} \cdot S_{11}[k, l] \tag{10.26}$$

where

$$S_{00}[k, l] = \sum_{\substack{p=0 \\ p \text{ even}}}^{\frac{N}{2}-1} \sum_{\substack{q=0 \\ q \text{ even}}}^{\frac{N}{2}-1} x[2p, 2q] \cdot W_{\frac{N}{2}}^{k \cdot p + l \cdot q}$$

$$S_{10}[k, l] = \sum_{p=0}^{\frac{N}{2}-1} \sum_{q=0}^{\frac{N}{2}-1} x[2p+1, 2q] \cdot W_{\frac{N}{2}}^{k \cdot p + l \cdot q}$$

$$S_{01}[k, l] = \sum_{p=0}^{\frac{N}{2}-1} \sum_{q=0}^{\frac{N}{2}-1} x[2p, 2q+1] \cdot W_{\frac{N}{2}}^{k \cdot p + l \cdot q}$$

$$S_{11}[k, l] = \sum_{p=0}^{\frac{N}{2}-1} \sum_{q=0}^{\frac{N}{2}-1} x[2p+1, 2q+1] \cdot W_{\frac{N}{2}}^{k \cdot p + l \cdot q}$$

Now applying the symmetry relation we can write

$$S_{01}[k, l] = W_N^{-2(k+l)} \cdot S_{10}\left[\frac{N}{2} - k, \frac{N}{2} - l\right]$$

$$\text{and} \quad S_{11}[k, l] = W_N^{-2(k+l)} \cdot S_{00}\left[\frac{N}{2} - k, \frac{N}{2} - l\right]$$

Then,

$$X[k, l] = S_{00}[k, l] + W_N^k \cdot S_{10}[k, l] + W_N^{-2k-l} \cdot S_{10}\left[\frac{N}{2} - k, \frac{N}{2} - l\right] + W_N^{-(k+l)} \cdot S_{00}\left[\frac{N}{2} - k, \frac{N}{2} - l\right] \tag{10.27}$$

From the above expression it is seen that when the centrosymmetry relation is employed, we need to compute only two $\left(\frac{N}{2} \times \frac{N}{2}\right)$ size 2-D FFTs instead of four $\left(\frac{N}{2} \times \frac{N}{2}\right)$ size 2-D FFTs. Thus there is a 50% reduction in the computational complexity.

10.4.2.2 Quadrantal Symmetry

A 2-D array $x[m, n]$ is said to possess quadrantal symmetry if the following condition is satisfied:

$$x[m,n] = x[N-1-m,n] = x[m,N-1-n] = x[N-1-m,N-1-n] \tag{10.28}$$

It may be noted that quadrantal symmetry is defined here with respect to the center of the array, $\left(\frac{N-1}{2},\frac{N-1}{2}\right)$. In the expression for $X[k, l]$ in Equation 10.26, $S_{10}[k, l]$, $S_{01}[k, l]$, and $S_{11}[k, l]$ can be expressed in terms of $S_{00}[k, l]$ as

$$\begin{aligned} S_{10}[k,l] &= \sum_{p=0}^{\frac{N}{2}-1}\sum_{q=0}^{\frac{N}{2}-1} x[2p+1,2q]\cdot W_{\frac{N}{2}}^{p\cdot k+q\cdot l} \\ &= W_N^{-2k}\cdot S_{00}\left[\frac{N}{2}-k,l\right] \\ S_{01}[k,l] &= W_N^{-2l}\cdot S_{00}\left[k,\frac{N}{2}-l\right] \\ \text{and}\quad S_{11}[k,l] &= W_N^{-2(k+l)}\cdot S_{00}\left[\frac{N}{2}-k,\frac{N}{2}-l\right]. \end{aligned}$$

Then $X[k, l]$ can be written in terms of S_{00} solely as

$$X[k,l] = S_{00}[k,l] + W_N^{-k}\cdot S_{00}\left[\frac{N}{2}-k,l\right] + W_N^{-l}\cdot S_{00}\left[k,\frac{N}{2}-l\right] + W_N^{-(k+l)}\cdot S_{00}\left[\frac{N}{2}-k,\frac{N}{2}-l\right] \tag{10.29}$$

It is then noted that evaluation of $X[k, l]$ requires the evaluation of four $\frac{N}{2}\times\frac{N}{2}$ size 2-D FFTs when $x[m, n]$ does not possess any symmetry whereas only one $\frac{N}{2}\times\frac{N}{2}$ size 2-D FFT is required when quadrantal symmetry is present in $x[m, n]$. In other words, utilization of the quadrantal symmetry in $x[m, n]$ reduces the computational complexity by approximately 75%. It may also be noted that quadrantal symmetry in $x[m,n]$ as defined in Equation 10.28 results in a form of quadrantal symmetry in $X[k, l]$ as

$$X[k,l] = W_N^{-k}\cdot X[N-k,l] = W_N^{-l}\cdot X[k,N-l] = W_N^{-(k+l)}\cdot X[N-k,N-l] \tag{10.30}$$

10.4.3 Symmetrical Decomposition for Data without Symmetry

In many situations, signals do not possess any symmetries. In those cases, symmetry results cannot be applied if we process the signals as they are. One way of dealing with this situation is to decompose the signal into signals possessing symmetries and antisymmetries [20,33]. For example, $x[m, n]$ can be decomposed as

$$x[m,n] = x_{00}[m,n] + x_{10}[m,n] + x_{01}[m,n] + x_{11}[m,n] \tag{10.31}$$

where

x_{00} possesses quadrantal symmetry
x_{10} possesses quadrantal antisymmetry of type 1 (antisymmetry w.r.t. m and symmetry w.r.t. n)
x_{01} possesses quadrantal antisymmetry of type 2 (symmetry w.r.t. m and antisymmetry w.r.t. n)
x_{11} possesses quadrantal antisymmetry of type 3 (antisymmetry w.r.t. both m and n)

Then each component can be processed using appropriate symmetry properties. While this method may not reduce the overall complexity, it will facilitate parallel processing of major computations.

10.5 Symmetry in 2-D Magnitude Response

In the design of 2-D filters, the design specifications are usually given in terms of the magnitude spectrum which possesses certain symmetries, while the phase characteristic is either not known or is not important. In such cases, it is desirable to know the types of transfer functions that can support the specified symmetry in the magnitude response. Recall that the ψ operation only affects the phase of the frequency response and not the magnitude. Hence, when dealing with magnitude symmetry, we assume $\psi = \psi_I$ and call our $T-\psi$ symmetry as simply T-symmetry. Now, in order for the magnitude response of a transfer function to possess a particularly symmetry, both the numerator and denominator polynomials have to possess the symmetry individually. In other words, when studying the symmetry constraints on the transfer function, one need only focus on the polynomial symmetry constraints on the numerator and denominator. In this section, we discuss the frequency response of the continuous-time and discrete-time 2-D polynomials and present the symmetry that might be present in the magnitude responses.

10.5.1 Continuous-Time Frequency Response

Let $P(s_1, s_2)$ be a 2-D s-domain polynomial with complex coefficients. Its frequency response is given by $P(j\omega_1, j\omega_2)$ where ω_1 and ω_2 are the radian frequencies. This is equivalent to evaluating the polynomial on the imaginary axes of the (s_1, s_2) biplane as shown in Figure 10.4. The magnitude-squared function of the frequency response is then given by

$$\begin{aligned} F(\omega_1, \omega_2) &= P(j\omega_1, j\omega_2) \cdot P^{\star}(-j\omega_1, -j\omega_2) \\ &= P(s_1, s_2) \cdot P^{\star}(-s_1, -s_2)\big|_{s_i = j\omega_i}, \quad i = 1, 2 \end{aligned} \tag{10.32}$$

where $P^{\star}$ is obtained by complex conjugating the coefficients of P.

10.5.2 Discrete-Time Frequency Response

For a 2-D z-domain polynomial $Q(z_1, z_2)$ with complex coefficients, its frequency response is given by $Q(e^{j\theta_1}, e^{j\theta_2})$. This is the same as evaluating the polynomial on the boundary of the unit circle in the (z_1, z_2) biplane as shown in Figure 10.5. Note that $\theta_i = \omega_i T$, where ω_1 and ω_2 are the same analog radian frequencies as above, and T is the sampling period. The magnitude-squared function of the frequency response is given by

$$\begin{aligned} F(\theta_1, \theta_2) &= Q\left(e^{j\theta_1}, e^{j\theta_2}\right) \cdot Q^{\star}\left(e^{-j\theta_1}, e^{-j\theta_2}\right) \\ &= Q(z_1, z_2) \cdot Q^{\star}\left(z_1^{-1}, z_2^{-1}\right)\Big|_{z_i = e^{j\theta_i}}, \quad i = 1, 2 \end{aligned} \tag{10.33}$$

where $Q^{\star}$ is obtained by complex conjugating the coefficients of Q.

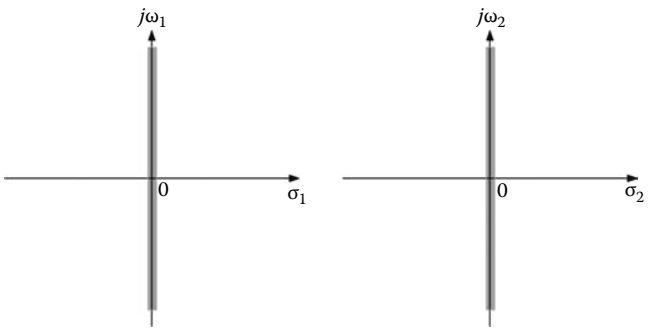

FIGURE 10.4 (s_1, s_2) biplane. (The frequency response is evaluated on the imaginary axes, $s_i = j\omega_i$.)

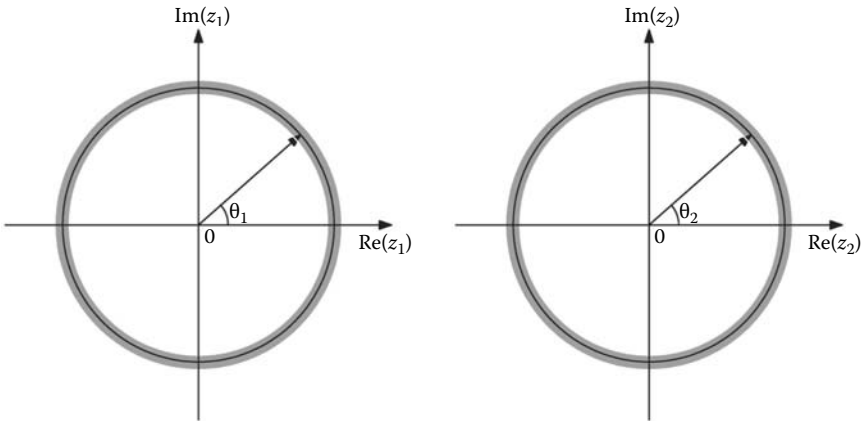

FIGURE 10.5 (z_1, z_2) biplane. (The frequency response is evaluated on the unit circles, $z_i = e^{j\theta_i}$.)

10.5.3 Symmetry in Magnitude Response

It can be seen in Equations 10.32 and 10.33 that if P and Q are real coefficient polynomials, $F(\omega_1, \omega_2) = F(-\omega_1, -\omega_2)$ and $F(\theta_1, \theta_2) = F(-\theta_1, -\theta_2)$. Therefore, a real polynomial, analog or digital, always possesses centrosymmetry. Because of this, only the compound symmetries in Table 10.3 need to be considered. We summarize in Table 10.4 these symmetry conditions for the magnitude-squared functions in both continuous and discrete domains. These symmetries are the same as those shown in Figure 10.2a–d, with the appropriate change in function and variable names.

TABLE 10.4 Symmetries Conditions for Continuous and Discrete Domain Magnitude-Squared Functions

Type of Symmetry	Condition on $F(\omega_1, \omega_2)$, $\forall$ (ω_1, ω_2)	Condition on $F(\theta_1, \theta_2)$, $\forall$ (θ_1, θ_2)
Quadrantal	$F(\omega_1, \omega_2) = F(-\omega_1, \omega_2)$ $= F(\omega_1, -\omega_2)$ $= F(-\omega_1, -\omega_2)$	$F(\theta_1, \theta_2) = F(-\theta_1, \theta_2)$ $= F(\theta_1, -\theta_2)$ $= F(-\theta_1, -\theta_2)$
Diagonal	$F(\omega_1, \omega_2) = F(\omega_2, \omega_1)$ $= F(-\omega_1, -\omega_2)$ $= F(-\omega_2, -\omega_1)$	$F(\theta_1, \theta_2) = F(\theta_2, \theta_1)$ $= F(-\theta_1, -\theta_2)$ $= F(-\theta_2, -\theta_1)$
Fourfold (90°) Rotational	$F(\omega_1, \omega_2) = F(-\omega_2, \omega_1)$ $= F(-\omega_1, -\omega_2)$ $= F(\omega_2, -\omega_1)$	$F(\theta_1, \theta_2) = F(-\theta_2, \theta_1)$ $= F(-\theta_1, -\theta_2)$ $= F(\theta_2, -\theta_1)$
Octagonal	$F(\omega_1, \omega_2) = F(\omega_2, \omega_1)$ $= F(-\omega_2, \omega_1)$ $= F(-\omega_1, \omega_2)$ $= F(-\omega_1, -\omega_2)$ $= F(-\omega_2, -\omega_1)$ $= F(\omega_2, -\omega_1)$ $= F(\omega_1, -\omega_2)$	$F(\theta_1, \theta_2) = F(\theta_2, \theta_1)$ $= F(-\theta_2, \theta_1)$ $= F(-\theta_1, \theta_2)$ $= F(-\theta_1, -\theta_2)$ $= F(-\theta_2, -\theta_1)$ $= F(\theta_2, -\theta_1)$ $= F(\theta_1, -\theta_2)$

10.6 Polynomial Operations and Definitions

In this section, we present the polynomial operations and definitions that will be used later for deriving the polynomial factors with symmetry.

Definition 10.2: Paraconjugate operation

The paraconjugate of an analog polynomial $P(s_1, s_2)$ is defined as

$$P_*(s_1, s_2) = P^*(-s_1, -s_2) \tag{10.34}$$

The subscript "*" indicates the paraconjugate of a polynomial, whereas the superscript "*" indicates the complex conjugation of coefficients alone.

Then in terms of the paraconjugate of a polynomial, the magnitude-squared function of $P(s_1, s_2)$ can be expressed as

$$F(\omega_1, \omega_2) = P(s_1, s_2) \cdot P_*(s_1, s_2)\big|_{s_i = j\omega_i}, \quad i = 1, 2 \tag{10.35}$$

The paraconjugate operation can also be performed w.r.t. a single variable, s_1 or s_2:

$$P_{*_{s_1}}(s_1, s_2) = P^*(-s_1, s_2) \tag{10.36}$$

$$P_{*_{s_2}}(s_1, s_2) = P^*(s_1, -s_2) \tag{10.37}$$

The paraconjugate of a discrete-time polynomial $Q(z_1, z_2)$ is called the inverse polynomial, and is defined as

$$Q_*(z_1, z_2) = Q^*(z_1^{-1}, z_2^{-1}) \tag{10.38}$$

It may be noted that $Q(z_1, z_2)$ is considered to be a pseudo polynomial which may have negative powers also.

The inverse operation for discrete-time polynomials can also be performed w.r.t. a single variable, z_1 or z_2.

$$Q_{*_{z_1}}(z_1, z_2) = Q^*(z_1^{-1}, z_2) \tag{10.39}$$

$$Q_{*_{z_2}}(z_1, z_2) = Q^*(z_1, z_2^{-1}) \tag{10.40}$$

Definition 10.3: Self-paraconjugate polynomial

$P(s_1, s_2)$ is said to be self-paraconjugate or para-even if

$$P_*(s_1, s_2) = P(s_1, s_2) \tag{10.41}$$

Henceforth, $P_e(s_1, s_2)$ will denote a para-even polynomial.

A polynomial can also be para-even w.r.t. a single variable s_i:

$$P_{*_{s_i}}(s_1, s_2) = P(s_1, s_2), \quad i = 1, 2 \tag{10.42}$$

An example of a polynomial that is para-even w.r.t. s_1 is $P_{e,s_1}(s_1, s_2) = s_1^2 + s_2 + 1$.

Definition 10.4: Anti-self-paraconjugate polynomial

$P(s_1, s_2)$ is said to be anti-self-paraconjugate or para-odd if

$$P*(s_1, s_2) = -P(s_1, s_2) \tag{10.43}$$

Henceforth, $P_o(s_1, s_2)$ will denote a para-odd polynomial.

A polynomial can also be para-odd w.r.t. a single variable s_i:

$$P_{*_{s_i}}(s_1, s_2) = -P(s_1, s_2), \quad i = 1, 2 \tag{10.44}$$

Para-even and para-odd in (s_1, s_2) correspond to self-inverse and anti-self-inverse in (z_1, z_2) respectively.

A discrete-time polynomial $Q(z_1, z_2)$ is self-inverse if

$$Q*(z_1, z_2) = Q(z_1, z_2) \tag{10.45}$$

$Q(z_1, z_2)$ is anti-self-inverse if

$$Q*(z_1, z_2) = -Q(z_1, z_2) \tag{10.46}$$

The discrete-time polynomial can also be self-inverse or anti-self-inverse w.r.t. a single variable, z_1 or z_2.

Property 1: Unique decomposition of polynomials

Any analog polynomial can be expressed as the sum of a para-even and a para-odd polynomial. That is,

$$P(s_1, s_2) = P_e(s_1, s_2) + P_o(s_1, s_2) \tag{10.47}$$

From the above, $P_e(s_1, s_2)$ and $P_o(s_1, s_2)$ are given by

$$P_e(s_1, s_2) = \frac{P(s_1, s_2) + P*(s_1, s_2)}{2} \tag{10.48}$$

$$P_o(s_1, s_2) = \frac{P(s_1, s_2) - P*(s_1, s_2)}{2} \tag{10.49}$$

The same holds when we deal with the operation w.r.t. a single variable s_i:

$$P(s_1,s_2) = P_{e,s_i}(s_1,s_2) + P_{o,s_i}(s_1, s_2) \tag{10.50}$$

where

$$P_{e,s_i}(s_1,s_2)=\frac{P(s_1,s_2)+P_{\star_{s_i}}(s_1,s_2)}{2} \tag{10.51}$$

$$P_{o,s_i}(s_1,s_2)=\frac{P(s_1,s_2)-P_{\star_{s_i}}(s_1,s_2)}{2} \tag{10.52}$$

In Equations 10.51 and 10.52 above, if $i=1$, then we have a polynomial restricted in s_1 and general in s_2. In such a case, we can further decompose into para-even and para-odd w.r.t. s_2 variable. In other words, $P(s_1, s_2)$ can be expressed as

$$P(s_1,s_2)=P_{e,s_1;e,s_2}(s_1,s_2)+P_{o,s_1;o,s_2}(s_1,s_2)+P_{o,s_1;e,s_2}(s_1,s_2)+P_{e,s_1;o,s_2}(s_1,s_2) \tag{10.53}$$

More specifically,

$$P(s_1,s_2)=P_1\left(s_1^2,s_2^2\right)+s_1s_2P_2\left(s_1^2,s_2^2\right)+s_1P_3\left(s_1^2,s_2^2\right)+s_2P_4\left(s_1^2,s_2^2\right) \tag{10.54}$$

The above (s_1, s_2) decomposition is the most general w.r.t. paraconjugate operation. It compares as follows to the standard decomposition in discrete-time (z_1, z_2):

$$Q(z_1,z_2)=Q_1(x_1,x_2)+y_1y_2Q_2(x_1,x_2)+y_1Q_3(x_1,x_2)+y_2Q_4(x_1,x_2) \tag{10.55}$$

where

$$\begin{aligned}x_i&=z_i+z_i^{-1}\\ y_i&=z_i-z_i^{-1},\quad i=1,2\end{aligned}$$

10.7 Spectral Forms for Magnitude-Squared Function

In this section, we present the spectral forms of the magnitude-squared function for the various symmetries.

Recall that the magnitude-squared function, $F(\omega_1, \omega_2)$, of a polynomial $P(s_1, s_2)$ is defined as

$$F(\omega_1,\omega_2)=P(s_1,s_2)\cdot P^*(-s_1,-s_2)|_{s_i=j\omega_i},\quad i=1,\,2 \tag{10.56}$$

Analogous to Equation 10.54, we can express the general magnitude-squared function as

$$F(\omega_1,\omega_2)=F_1\left(\omega_1^2,\omega_2^2\right)+\omega_1\omega_2F_2\left(\omega_1^2,\omega_2^2\right)+\omega_1F_3\left(\omega_1^2,\omega_2^2\right)+\omega_2F_4\left(\omega_1^2,\omega_2^2\right) \tag{10.57}$$

A polynomial with real coefficients always possesses centrosymmetry in its magnitude response. So,

$$F(\omega_1,\omega_2)=F(-\omega_1,-\omega_2)$$

Using Equation 10.57, this can be written as

$$\begin{aligned}&F_1\left(\omega_1^2,\omega_2^2\right)+\omega_1\omega_2F_2\left(\omega_1^2,\omega_2^2\right)+\omega_1F_3\left(\omega_1^2,\omega_2^2\right)+\omega_2F_4\left(\omega_1^2,\omega_2^2\right)\\ &\quad=F_1\left(\omega_1^2,\omega_2^2\right)+\omega_1\omega_2F_2\left(\omega_1^2,\omega_2^2\right)-\omega_1F_3\left(\omega_1^2,\omega_2^2\right)-\omega_2F_4\left(\omega_1^2,\omega_2^2\right)\\ \Leftrightarrow\quad&\omega_1F_3\left(\omega_1^2,\omega_2^2\right)+\omega_2F_4\left(\omega_1^2,\omega_2^2\right)=-\omega_1F_3\left(\omega_1^2,\omega_2^2\right)-\omega_2F_4\left(\omega_1^2,\omega_2^2\right)\end{aligned} \tag{10.58}$$

The above is only possible if $F_3(\omega_1^2, \omega_2^2)=0$ and $F_4(\omega_1^2, \omega_2^2)=0$.

Thus,

$$F(\omega_1,\omega_2) = F_1\left(\omega_1^2,\omega_2^2\right) + \omega_1\omega_2 F_2\left(\omega_1^2,\omega_2^2\right) \tag{10.59}$$

Using analytic continuation and Equation 10.56, this can be written as

$$\begin{aligned} P(s_1,s_2)\cdot P(-s_1,-s_2) &= F_1\left(s_1^2,s_2^2\right) + s_1 s_2 F_2\left(s_1^2,s_2^2\right) \\ &= \sum_{i=0}^{m_1}\sum_{j=0}^{n_1} a_{ij}s_1^{2i}s_2^{2j} + s_1 s_2 \sum_{i=0}^{m_2}\sum_{j=0}^{n_2} b_{ij}s_1^{2i}s_2^{2j} \end{aligned} \tag{10.60}$$

The above is the spectral form of the magnitude-squared function possessing centrosymmetry.

Now, for a real-coefficient $P(s_1, s_2)$ to possess quadrantal symmetry in its magnitude-squared response, we need

$$F(\omega_1,\omega_2) = F(\omega_1,-\omega_2)$$

Using Equation 10.59, this can be written as

$$F_1\left(\omega_1^2,\omega_2^2\right) + \omega_1\omega_2 F_2\left(\omega_1^2,\omega_2^2\right) = F_1\left(\omega_1^2,\omega_2^2\right) - \omega_1\omega_2 F_2\left(\omega_1^2,\omega_2^2\right) \tag{10.61}$$

The above is only possible if $F_2(\omega_1^2, \omega_2^2) = 0$. Thus,

$$F(\omega_1,\omega_2) = F_1\left(\omega_1^2,\omega_2^2\right), \tag{10.62}$$

TABLE 10.5 Spectral Forms of Magnitude-Squared Function for Various Symmetries

Diagonal symmetry	
$P(s_1,s_2)\cdot P(-s_1,-s_2) = \sum_{i=0}^{m_1}\sum_{j=0}^{n_1} a_{ij}s_1^{2i}s_2^{2j} + s_1 s_2 \sum_{i=0}^{m_2}\sum_{j=0}^{n_2} b_{ij}s_1^{2i}s_2^{2j}$	$Q(z_1,z_2)\cdot Q(z_1^{-1},z_2^{-1}) = \sum_{i=0}^{m_1}\sum_{j=0}^{n_1} c_{ij}x_1^i x_2^j + y_1 y_2 \sum_{i=0}^{m_2}\sum_{j=0}^{n_2} d_{ij}x_1^i x_2^j$
where $a_{ij} = a_{ji}$ and $b_{ij} = b_{ji}$	where $c_{ij} = c_{ji}$ and $d_{ij} = d_{ji}$
Fourfold (90°) rotational symmetry	
$P(s_1,s_2)\cdot P(-s_1,-s_2) = \sum_{i=0}^{m_1}\sum_{j=0}^{n_1} a_{ij}s_1^{2i}s_2^{2j} + s_1 s_2 \sum_{i=0}^{m_2}\sum_{j=0}^{n_2} b_{ij}s_1^{2i}s_2^{2j}$	$Q(z_1,z_2)\cdot Q(z_1^{-1},z_2^{-1}) = \sum_{i=0}^{m_1}\sum_{j=0}^{n_1} c_{ij}x_1^i x_2^j + y_1 y_2 \sum_{i=0}^{m_2}\sum_{j=0}^{n_2} d_{ij}x_1^i x_2^j$
where $a_{ij} = a_{ji}$ and $b_{ij} = -b_{ji}$	where $c_{ij} = c_{ji}$ and $d_{ij} = -d_{ji}$
Octagonal symmetry	
$P(s_1,s_2)\cdot P(-s_1,-s_2) = \sum_{i=0}^{m_1}\sum_{j=0}^{n_1} a_{ij}s_1^{2i}s_2^{2j}$	$Q(z_1,z_2)\cdot Q(z_1^{-1},z_2^{-1}) = \sum_{i=0}^{m_1}\sum_{j=0}^{n_1} c_{ij}x_1^i x_2^j$
where $a_{ij} = a_{ji}$	where $c_{ij} = c_{ji}$

[a] Note that $x_i = z_i + z_i^{-1}$ and $y_i = z_i - z_i^{-1}$, $i = 1, 2$.

and so the spectral form for the magnitude-squared function that possesses quadrantal symmetry is

$$\begin{aligned} P(s_1, s_2) \cdot P(-s_1, -s_2) &= F_1\left(s_1^2, s_2^2\right) \\ &= \sum_{i=0}^{m_1} \sum_{j=0}^{n_1} a_{ij} s_1^{2i} s_2^{2j} \end{aligned} \tag{10.63}$$

We can obtain the spectral forms for the other symmetries in a similar manner. They are listed in Table 10.5, together with the spectral forms for the z-domain functions.

10.8 Determination of 2-D Polynomials Possessing Various Symmetries

In this section, we present the polynomial factors that possess symmetry in their magnitude responses. We begin by showing the conditions that the s-domain polynomials must satisfy in order to possess the required symmetry. Then, the s-domain polynomial factors that satisfy those conditions are given. (The proof is provided for quadrantal symmetry). Finally, at the end of the section, the z-domain polynomial factors possessing symmetry are listed, alongside the analog polynomial factors.

10.8.1 Quadrantal Symmetry for Analog Polynomials

THEOREM 10.5

A polynomial $P(s_1, s_2)$ possesses quadrantal symmetry in its magnitude response if its factors either alone or jointly satisfy one of the following conditions:

$$1.\ P(s_1, s_2) = P(s_1, -s_2) \tag{10.64}$$

$$2.\ P(s_1, s_2) = -P(s_1, -s_2) \tag{10.65}$$

$$3.\ P(s_1, s_2) = P(-s_1, s_2) \tag{10.66}$$

$$4.\ P(s_1, s_2) = -P(-s_1, s_2) \tag{10.67}$$

$$5.\ P(s_1, s_2) = P_1(s_1, s_2) \cdot P_1(s_1, -s_2) \tag{10.68}$$

$$6.\ P(s_1, s_2) = P_1(s_1, s_2) \cdot P_1(-s_1, s_2) \tag{10.69}$$

Proof of Theorem 10.5: From Table 10.4, a magnitude-squared response possesses quadrantal symmetry if

$$F(\omega_1, \omega_2) = F(\omega_1, -\omega_2) \tag{10.70}$$

Applying Equation 10.32, this can be written as

$$P(j\omega_1, j\omega_2) \cdot P(-j\omega_1, -j\omega_2) = P(j\omega_1, -j\omega_2) \cdot P(-j\omega_1, j\omega_2)$$

Using analytic continuation, this becomes

$$P(s_1, s_2) \cdot P(-s_1, -s_2) = P(s_1, -s_2) \cdot P(-s_1, s_2) \tag{10.71}$$

If we assume $P(s_1, s_2)$ to be irreducible, the unique factorization property of 2-variable polynomials [34] states that $P(s_1, s_2)$ should satisfy one of the following two conditions:

$$\text{(i) } P(s_1, s_2) = k_1 \cdot P(s_1, -s_2) \text{ where } k_1 \text{ is a real constant} \tag{10.72}$$

$$\text{(ii) } P(s_1, s_2) = k_2 \cdot P(-s_1, s_2) \text{ where } k_2 \text{ is a real constant} \tag{10.73}$$

We first consider case (i) above. Substituting $s_2 = -s_2$ into Equation 10.72, we obtain

$$P(s_1, -s_2) = k_1 \cdot P(s_1, s_2)$$

Substituting this back into Equation 10.72, we get

$$P(s_1, s_2) = k_1^2 \cdot P(s_1, s_2) \tag{10.74}$$

So, $k_1^2 = 1$, i.e., $k_1 = +1$ or -1. Thus, Equation 10.72 becomes

$$P(s_1, s_2) = \pm 1 \cdot P(s_1, -s_2) \tag{10.75}$$

With that, we have the first two conditions of Theorem 10.5, Equations 10.64 and 10.65.

We now work on case (ii). Substituting $s_1 = -s_1$ into Equation 10.73, we have

$$P(-s_1, s_2) = k_2 \cdot P(s_1, s_2) \tag{10.76}$$

Substituting Equation 10.76 back into Equation 10.73, we get $k_2^2 = 1$, i.e., $k_2 = +1$ or -1. This gives us the next two conditions for Theorem 10.5, Equations 10.66 and 10.67.

So far, we have assumed $P(s_1, s_2)$ to be irreducible. If $P(s_1, s_2)$ is reducible, then it can be expressed as a product of irreducible factors:

$$P(s_1, s_2) = k \cdot \prod_{i=1}^{N} P_i(s_1, s_2) \tag{10.77}$$

Let $P_i(s_1, s_2)$ be one such irreducible factor in $P(s_1, s_2)$. Invoking the unique factorization property on Equation 10.71, we can see that $P_i(s_1, s_2)$ must be present in either $P(s_1, -s_2)$ or $P(-s_1, s_2)$ and thus must satisfy one of the following four conditions:

(a) $P_i(s_1, s_2) = k_1 \cdot P_i(s_1, -s_2)$
(b) $P_i(s_1, s_2) = k_2 \cdot P_j(s_1, -s_2)$ where $i \neq j$
(c) $P_i(s_1, s_2) = k_3 \cdot P_i(-s_1, s_2)$
(d) $P_i(s_1, s_2) = k_4 \cdot P_j(-s_1, s_2)$ where $i \neq j$

Cases (a) and (c) are identical to the ones for irreducible polynomials, so the previous results apply. We need only investigate cases (b) and (d) here.

For case (b),

$$P_i(s_1, s_2) = k_2 \cdot P_j(s_1, -s_2) \tag{10.78}$$

We solve for $P_j(s_1, s_2)$ by multiplying both sides by $1/k_2$ and substituting $s_2 = -s_2$:

$$P_j(s_1, s_2) = \frac{1}{k_2} \cdot P_i(s_1, -s_2) \tag{10.79}$$

$P_i(s_1, s_2) \cdot P_j(s_1, s_2)$ is a factor in $P(s_1, s_2)$. Using Equation 10.79, this can be expressed as

$$P_i(s_1, s_2) \cdot P_j(s_1, s_2) = P_i(s_1, s_2) \cdot \frac{1}{k_2} \cdot P_i(s_1, -s_2) \tag{10.80}$$

So, $P_i(s_1, s_2) \cdot P_i(s_1, -s_2)$ is a possible factor in $P(s_1, s_2)$. This proves Equation 10.68 in Theorem 10.5.

Now, we work on case (d),

$$P_i(s_1, s_2) = k_4 \cdot P_j(-s_1, s_2) \tag{10.81}$$

Solving for $P_j(s_1, s_2)$:

$$P_j(s_1, s_2) = \frac{1}{k_4} \cdot P_i(-s_1, s_2) \tag{10.82}$$

Now using Equation 10.82, the product of $P_i(s_1, s_2) \cdot P_j(s_1, s_2)$ can be expressed as

$$P_i(s_1, s_2) \cdot P_j(s_1, s_2) = P_i(s_1, s_2) \cdot \frac{1}{k_4} \cdot P_i(-s_1, s_2) \tag{10.83}$$

Therefore $P_i(s_1, s_2) \cdot P_i(-s_1, s_2)$ is a factor in $P(s_1, s_2)$ and this corresponds to Equation 10.69 in Theorem 10.5. This concludes the proof for Theorem 10.5.

Theorem 10.5 specifies the conditions each factor of a polynomial should satisfy to ensure quadrantal symmetry in the magnitude response of the overall polynomial. However, these conditions (except 5 and 6) do not show the way of generating the polynomial factor that possesses the symmetry. In the following, we will derive the forms of the polynomial factors that satisfy conditions 1 to 4 of Theorem 10.5.

Corollary of Condition 1

Using Equation 10.54, we can write Equation 10.64 as the following:

$$\begin{aligned} &P_1\left(s_1^2, s_2^2\right) + s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) \\ &\quad = P_1\left(s_1^2, s_2^2\right) - s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) - s_2 P_4\left(s_1^2, s_2^2\right) \end{aligned}$$

$$\Leftrightarrow \quad s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) = -s_1 s_2 P_2\left(s_1^2, s_2^2\right) - s_2 P_4\left(s_1^2, s_2^2\right)$$

The above is only possible if $P_2(s_1^2, s_2^2) = 0$ and $P_4(s_1^2, s_2^2) = 0$.

Therefore,

$$P(s_1, s_2) = P_1\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right)$$

This can be expressed as

$$P_5(s_1, s_2^2) \tag{10.84}$$

Corollary of Condition 2
Using Equation 10.54, we can write Equation 10.65 as the following:

$$\begin{aligned} &P_1\left(s_1^2, s_2^2\right) + s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) \\ &\quad = -P_1\left(s_1^2, s_2^2\right) + s_1 s_2 P_2\left(s_1^2, s_2^2\right) - s_1 P_3\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) \end{aligned}$$

$$\Leftrightarrow \quad P_1\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) = -P_1\left(s_1^2, s_2^2\right) - s_1 P_3\left(s_1^2, s_2^2\right)$$

The above is only possible if $P_1(s_1^2, s_2^2) = 0$ and $P_3(s_1^2, s_2^2) = 0$. So,

$$P(s_1, s_2) = s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right)$$

This can be expressed as

$$s_2 \cdot P_5(s_1, s_2^2) \tag{10.85}$$

Corollary of Condition 3
Using Equation 10.54, we can write Equation 10.66 as the following:

$$\begin{aligned} &P_1\left(s_1^2, s_2^2\right) + s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) \\ &\quad = P_1\left(s_1^2, s_2^2\right) - s_1 s_2 P_2\left(s_1^2, s_2^2\right) - s_1 P_3\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) \end{aligned}$$

$$\Leftrightarrow \quad s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) = -s_1 s_2 P_2\left(s_1^2, s_2^2\right) - s_1 P_3\left(s_1^2, s_2^2\right)$$

The above is only possible if $P_2(s_1^2, s_2^2) = 0$ and $P_3(s_1^2, s_2^2) = 0$.
Therefore,

$$P(s_1, s_2) = P_1\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right)$$

This can be expressed as

$$P_6(s_1^2, s_2) \tag{10.86}$$

Corollary of Condition 4
Using Equation 10.54, we can write Equation 10.67 as the following:

$$\begin{aligned} &P_1\left(s_1^2, s_2^2\right) + s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) \\ &\quad = -P_1\left(s_1^2, s_2^2\right) + s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) - s_2 P_4\left(s_1^2, s_2^2\right) \end{aligned}$$

$$\Leftrightarrow \quad P_1\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) = -P_1\left(s_1^2, s_2^2\right) - s_2 P_4\left(s_1^2, s_2^2\right)$$

The above is only possible if $P_1(s_1^2, s_2^2) = 0$ and $P_4(s_1^2, s_2^2) = 0$. So,

$$P(s_1, s_2) = s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right)$$

This can be expressed as

$$s_1 \cdot P_6(s_1^2, s_2) \tag{10.87}$$

Reviewing all the above, we can see that the general polynomial form, $P_5\ (s_1,\ s_2^2) \cdot P_6\ (s_1^2,\ s_2)$, satisfies Equations 10.84 through 10.87.

Now, we can state the polynomials factors that satisfy conditions 1 through 6 of Theorem 10.5 in the following corollary.

Corollary of Theorem 10.5
The following polynomial factors possess quadrantal symmetry in their magnitude responses:

$$1.\ P(s_1, s_2^2) \tag{10.88}$$

$$2.\ P(s_1^2, s_2) \tag{10.89}$$

$$3.\ P(s_1, s_2) \cdot P(s_1, -s_2) \tag{10.90}$$

$$4.\ P(s_1, s_2) \cdot P(-s_1, s_2) \tag{10.91}$$

It is obvious that the product of any of the above polynomial factors satisfy the symmetry as well.

Examples

We now provide examples of (2,2) degree polynomials satisfying Equations 10.88 and 10.90.

1. $P(s_1, s_2^2) = a_0 + a_1 s_1 + a_2 s_1^2 + a_3 s_2^2 + a_4 s_1 s_2^2 + a_5 s_1^2 s_2^2.$
2. $P(s_1, s_2) \cdot P(s_1, -s_2)$

Let $P(s_1,\ s_2) = b_0 + b_1\ s_1 + b_2\ s_2 + b_3\ s_1\ s_2$
Then,

$$\begin{aligned} P(s_1, s_2) \cdot P(s_1, -s_2) &= (b_0 + b_1 s_1 + b_2 s_2 + b_3 s_1 s_2) \cdot (b_0 + b_1 s_1 - b_2 s_2 - b_3 s_1 s_2) \\ &= b_0^2 + 2b_0 b_1 s_1 + b_1^2 s_1^2 - b_2^2 s_2^2 - 2b_2 b_3 s_1 s_2^2 - b_3^2 s_1^2 s_2^2 \end{aligned}$$

Using the same derivation procedure outlined above for quadrantal symmetry, we can obtain the conditions and polynomial factors for the other symmetries.

10.8.2 Diagonal Symmetry for Analog Polynomials

THEOREM 10.6

A polynomial $P(s_1,\ s_2)$ possesses diagonal symmetry in its magnitude response if its factors either alone or jointly satisfy one of the following conditions:

$$1.\ P(s_1, s_2) = P(s_2, s_1) \tag{10.92}$$

$$2.\ P(s_1, s_2) = -P(s_2, s_1) \tag{10.93}$$

$$3.\ P(s_1, s_2) = P(-s_2, -s_1) \tag{10.94}$$

$$4.\ P(s_1, s_2) = -P(-s_2, -s_1) \tag{10.95}$$

$$5.\ P(s_1, s_2) = P_1(s_1, s_2) \cdot P_1(s_2, s_1) \tag{10.96}$$

$$6.\ P(s_1, s_2) = P_1(s_1, s_2) \cdot P_1(-s_2, -s_1) \tag{10.97}$$

Corollary of Theorem 10.6
The following polynomial factors possess diagonal symmetry in their magnitude responses:

$$1.\ P_1(s_1, s_2) \tag{10.98}$$

$$2.\ P_2\left(s_1^2, s_2^2\right) + s_1 s_2 P_3\left(s_1^2, s_2^2\right) + s_1 P_4\left(s_1^2, s_2^2\right) - s_2 P_4(s_2^2, s_1^2) \tag{10.99}$$

$$3.\ P(s_1, s_2) \cdot P(s_2, s_1) \tag{10.100}$$

$$4.\ P(s_1, s_2) \cdot P(-s_2, -s_1) \tag{10.101}$$

where

$$P_1(s_1, s_2) = P_1(s_2, s_1)$$

$$P_k\left(s_1^2, s_2^2\right) = P_k(s_2^2, s_1^2) \quad \text{for } k = 2, 3$$

10.8.3 Fourfold (90°) Rotational Symmetry for Analog Polynomials

---

THEOREM 10.7

A polynomial $P(s_1, s_2)$ possesses fourfold rotational symmetry in its magnitude response if its factors either alone or jointly satisfy one of the following conditions:

$$1.\ P(s_1, s_2) = P(-s_2, s_1) \tag{10.102}$$

$$2.\ P(s_1, s_2) = -P(-s_2, s_1) \tag{10.103}$$

$$3.\ P(s_1, s_2) = P(s_2, -s_1) \tag{10.104}$$

$$4.\ P(s_1, s_2) = -P(s_2, -s_1) \tag{10.105}$$

$$5.\ P(s_1, s_2) = P_1(s_1, s_2) \cdot P_1(-s_2, s_1) \tag{10.106}$$

$$6.\ P(s_1, s_2) = P_1(s_1, s_2) \cdot P_1(s_2, -s_1) \tag{10.107}$$

$$7.\ P(s_1, s_2) = P_1(s_1, s_2) \cdot P_1(-s_2, s_1) \cdot P_1(-s_1, -s_2) \cdot P_1(s_2, -s_1) \tag{10.108}$$

Corollary of Theorem 10.7
The following polynomial factors possess fourfold rotational symmetry in their magnitude responses:

$$1.\ P_1\left(s_1^2, s_2^2\right) + s_1 s_2 \cdot (s_1^2 - s_2^2) \cdot P_2\left(s_1^2, s_2^2\right) \tag{10.109}$$

$$2.\ (s_1^2 - s_2^2) P_1\left(s_1^2, s_2^2\right) + s_1 s_2 P_2\left(s_1^2, s_2^2\right) \tag{10.110}$$

$$3.\ P(s_1, s_2) \cdot P(-s_2, s_1) \tag{10.111}$$

$$4.\ P(s_1, s_2) \cdot P(s_2, -s_1) \tag{10.112}$$

$$5.\ P(s_1, s_2) \cdot P(-s_2, s_1) \cdot P(-s_1, -s_2) \cdot P(s_2, -s_1) \tag{10.113}$$

where $P_k(s_1^2, s_2^2) = P_k(s_2^2, s_1^2)$ for $k = 1, 2$.

10.8.4 Octagonal Symmetry for Analog Polynomials

THEOREM 10.8

The following polynomial factors possess octagonal symmetry in their magnitude responses:

$$1.\ (s_1^2 - s_2^2)^{\alpha} \cdot P_1\left(s_1^2, s_2^2\right), \quad \text{where } \alpha = 0 \text{ or } 1 \tag{10.114}$$

$$2.\ P(s_1^2, s_2) \cdot P(s_2^2, s_1) \tag{10.115}$$

$$3.\ P(s_1^2, s_2) \cdot P(s_2^2, -s_1) \tag{10.116}$$

$$4.\ P(s_1, s_2^2) \cdot P(-s_2, s_1^2) \tag{10.117}$$

$$5.\ P_2(s_1, s_2) \cdot P_2(-s_1, s_2) \tag{10.118}$$

$$6.\ P_2(s_1, s_2) \cdot P_2(s_1, -s_2) \tag{10.119}$$

where

$$P_1\left(s_1^2, s_2^2\right) = P_1(s_2^2, s_1^2)$$

$$P_2(s_1, s_2) = P_2(s_2, s_1)$$

10.8.5 Summary of Analog and Digital Polynomial Factors Possessing Symmetry

In Table 10.6, we state the digital polynomial factors that possess the various symmetries, alongside the analog polynomial factors presented earlier. The digital polynomial factors can be derived by assuming the general z-domain polynomial form in Equation 10.55 and following the same derivation steps as the analog case.

10.9 Symmetry and Stability

A sufficient condition for the stability of 2-D analog filters [35–37] is that their transfer functions do not have any poles in the region of the (s_1, s_2) biplane defined by $\mathrm{Re}(s_1) \geq 0$ and $\mathrm{Re}(s_2) \geq 0$, including infinite distant points. Similarly, a sufficient condition for the stability of 2-D digital filters is that their transfer functions do not have any poles in the region of the (z_1, z_2) biplane defined by $|z_1| \geq 1$ and $|z_2| \geq 1$. We will next consider the analog domain and the digital domain stability conditions under the presence of symmetry.

10.9.1 Stability of Analog Filters with Symmetric Magnitude Response

The transfer function of an analog 2-D filter can be represented as a rational function in s_1 and s_2 as

$$T(s_1, s_2) = \frac{P(s_1, s_2)}{Q(s_1, s_2)} \tag{10.120}$$

It can be shown that $T(j\omega_1, j\omega_2)$ possesses various magnitude symmetries if $P(j\omega_1, j\omega_2)$ and $Q(j\omega_1, j\omega_2)$ possess the same symmetries individually. Then for $T(s_1, s_2)$ to possess a symmetry and be stable, $Q(s_1, s_2)$ should satisfy the conditions for the symmetry as well as the conditions for stability. The type of $Q(s_1, s_2)$ that satisfies these two conditions for quadrantal symmetry is presented in the following theorem.

TABLE 10.6 Analog and Digital Polynomial Factors Possessing Symmetry

Analog s-Domain	Digital z-Domain[a]
Quadrantal symmetry	
1. $P(s_1, s_2^2)$	1. $Q(z_1, x_2)$
2. $P(s_1^2, s_2)$	2. $Q(x_1, z_2)$
3. $P(s_1, s_2)\cdot P(s_1, -s_2)$	3. $Q(z_1, z_2)\cdot Q(z_1, z_2^{-1})$
4. $P(s_1, s_2)\cdot P(-s_1, s_2)$	4. $Q(z_1, z_2)\cdot Q(z_1^{-1}, z_2)$
Diagonal symmetry	
1. $P_1(s_1, s_2)$	1. $Q_1(z_1, z_2)$
2. $P_2(s_1^2, s_2^2) + s_1 s_2 P_3(s_1^2, s_2^2) + s_1 P_4(s_1^2, s_2^2) - s_2 P_4(s_2^2, s_1^2)$	2. $Q_2(x_1, x_2) + y_1 y_2 Q_3(x_1, x_2) + y_1 Q_4(x_1, x_2) - y_2 Q_4(x_2, x_1)$
3. $P(s_1, s_2)\cdot P(s_2, s_1)$	3. $Q(z_1, z_2)\cdot Q(z_2, z_1)$
4. $P(s_1, s_2)\cdot P(-s_2, -s_1)$	4. $Q(z_1, z_2)\cdot Q(z_2^{-1}, z_1^{-1})$
where $P_1(s_1, s_2) = P_1(s_2, s_1)$ and $P_k(s_1^2, s_2^2) = P_k(s_2^2, s_1^2)$ for $k = 2, 3$.	where $Q_1(z_1, z_2) = Q_1(z_2, z_1)$ and $Q_k(x_1, x_2) = Q_k(x_2, x_1)$ for $k = 2, 3$.
Fourfold (90°) rotational symmetry	
1. $P_1(s_1^2, s_2^2) + s_1 s_2\cdot(s_1^2 - s_2^2)\cdot P_2(s_1^2, s_2^2)$	1. $Q_1(x_1, x_2) + y_1 y_2\cdot(x_1 - x_2)\cdot Q_2(x_1, x_2)$
2. $(s_1^2 - s_2^2) P_1(s_1^2, s_2^2) + s_1 s_2 P_2(s_1^2, s_2^2)$	2. $(x_1 - x_2) Q_1(x_1, x_2) + y_1 y_2 Q_2(x_1, x_2)$
3. $P(s_1, s_2)\cdot P(-s_2, s_1)$	3. $Q(z_1, z_2)\cdot Q(z_2^{-1}, z_1)$
4. $P(s_1, s_2)\cdot P(s_2, -s_1)$	4. $Q(z_1, z_2)\cdot Q(z_2, z_1^{-1})$
5. $P(s_1, s_2)\cdot P(-s_2, s_1)\cdot P(-s_1, -s_2)\cdot P(s_2, -s_1)$	5. $Q(z_1, z_2)\cdot Q(z_2^{-1}, z_1)\cdot Q(z_1^{-1}, z_2^{-1})\cdot Q(z_2, z_1^{-1})$
where $P_k(s_1^2, s_2^2) = P_k(s_2^2, s_1^2)$ for $k = 1, 2$	where $Q_k(x_1, x_2) = Q_k(x_2, x_1)$ for $k = 1, 2$
Octagonal symmetry	
1. $(s_1^2 - s_2^2)^{\alpha}\cdot P_1(s_1^2, s_2^2)$, where $\alpha = 0$ or 1	1. $(x_1 - x_2)^{\alpha}\cdot Q_1(x_1, x_2)$, where $\alpha = 0$ or 1
2. $P(s_1^2, s_2)\cdot P(s_2^2, s_1)$	2. $Q(x_1, z_2)\cdot Q(x_2, z_1)$
3. $P(s_1^2, s_2)\cdot P(s_2^2, -s_1)$	3. $Q(x_1, z_2)\cdot Q(x_2, z_1^{-1})$
4. $P(s_1, s_2^2)\cdot P(-s_2, s_1^2)$	4. $Q(z_1, x_2)\cdot Q(z_2^{-1}, x_1)$
5. $P_2(s_1, s_2)\cdot P_2(-s_1, s_2)$	5. $Q_2(z_1, z_2)\cdot Q_2(z_1^{-1}, z_2)$
6. $P_2(s_1, s_2)\cdot P_2(s_1, -s_2)$	6. $Q_2(z_1, z_2)\cdot Q_2(z_1, z_2^{-1})$
where $P_1(s_1^2, s_2^2) = P_1(s_2^2, s_1^2)$ and $P_2(s_1, s_2) = P_2(s_2, s_1)$	where $Q_1(x_1, x_2) = Q_1(x_2, x_1)$ and $Q_2(z_1, z_2) = Q_2(z_2, z_1)$

[a] Note that $x_i = z_i + z_i^{-1}$ and $y_i = z_i - z_i^{-1}$ for $i = 1, 2$.

10.9.1.1 Quadrantal Symmetry

THEOREM 10.9

For $T(s_1, s_2)$ to be stable and to possess quadrantal magnitude symmetry, $P(s_1, s_2)$ should satisfy the quadrantal symmetry conditions listed in Table 10.6 and the denominator polynomial should be product separable as $Q(s_1, s_2) = Q_1(s_1)\cdot Q_2(s_2)$ where Q_1 and Q_2 are stable 1-D polynomials.

Proof of Theorem 10.9: As mentioned above for $T(s_1, s_2)$ to possess quadrantal magnitude symmetry in its frequency response, $Q(s_1, s_2)$ should be expressible as

$$Q(s_1, s_2) = Q_A(s_1, s_2^2)\cdot Q_B(s_1^2, s_2) \tag{10.121}$$

Now it can be easily seen that for any s_1, $Q_A(s_1, s_2^2)$ will have zeros in the right half of s_2 plane unless Q_A is a polynomial of s_1 alone. Similarly it can be argued that Q_B should be a polynomial of s_2 alone. In other words, for $Q(s_1, s_2)$ to possess stability and quadrantal magnitude symmetry, it should be expressible as a product of two 1-D polynomials as

$$Q(s_1, s_2) = Q_1(s_1) \cdot Q_2(s_2) \tag{10.122}$$

such that Q_1 and Q_2 are stable analog polynomials.Q.E.D.

10.9.1.2 Octagonal Symmetry

As quadrantal symmetry is an integral part of octagonal symmetry, for $T(s_1, s_2)$ to possess octagonal symmetry it should first satisfy the conditions for quadrantal symmetry, i.e., the denominator polynomial should be separable. Then it can be shown that as octagonal symmetry also implies diagonal symmetry, $Q(s_1, s_2)$ should be expressible as

$$Q(s_1, s_2) = Q_1(s_1) \cdot Q_1(s_2) \tag{10.123}$$

10.9.1.3 Rotational Symmetry

In a similar manner examining the various factors that can be present in the polynomials possessing rotational symmetry, it can be shown that the denominator polynomial of a stable 2-D analog filter possessing rotational magnitude symmetry should be expressible as

$$Q(s_1, s_2) = Q_1(s_1) \cdot Q_1(s_2) \tag{10.124}$$

10.9.1.4 Diagonal Symmetry

It can be shown that the denominator of a stable 2-D analog filter possessing diagonal magnitude symmetry should satisfy the stability conditions and satisfy the symmetry condition:

$$Q(s_1, s_2) = Q(s_2, s_1) \tag{10.125}$$

10.9.2 Stability of Digital Filters with Symmetric Magnitude Response

Now applying the stability conditions on the polynomial factors that possess the various magnitude symmetries, the following conditions on the denominator polynomials of 2-D digital filters are obtained.

10.9.2.1 Quadrantal Symmetry

The denominator polynomial of a stable 2-D digital filter possessing quadrantal symmetry in its magnitude response can be expressed as

$$Q(z_1, z_2) = Q_1(z_1) \cdot Q_2(z_2) \tag{10.126}$$

where Q_1 and Q_2 are 1-D stable polynomials.

10.9.2.2 Octagonal Symmetry

The denominator polynomial of a stable 2-D digital filter possessing octagonal symmetry in its magnitude response can be expressed as

$$Q(z_1, z_2) = Q_1(z_1) \cdot Q_1(z_2) \tag{10.127}$$

10.9.2.3 Rotational Symmetry

The denominator polynomial of a stable 2-D digital filter possessing rotational symmetry in its magnitude response can be expressed as

$$Q(z_1, z_2) = Q_1(z_1) \cdot Q_1(z_2) \tag{10.128}$$

10.9.2.4 Diagonal Symmetry

The denominator polynomial of a stable 2-D digital filter possessing diagonal symmetry in its magnitude response should satisfy the stability condition and satisfy the symmetry condition:

$$Q(z_1, z_2) = Q(z_2, z_1) \tag{10.129}$$

10.10 Filter Design Procedure

We now present the design steps for 2-D z-domain separable denominator IIR filters with symmetry in the magnitude response. Computer optimization is used in this procedure to obtain the filter coefficients such that the filter specifications are satisfied.

Steps:

1. Identify the type of symmetry in the magnitude response specifications for the filter.
2. Assume a transfer function of the form

$$H(z_1, z_2) = \frac{N(z_1, z_2)}{D(z_1) \cdot D(z_2)} \tag{10.130}$$

   Select the numerator from the list of polynomials in Table 10.6, such that it satisfies the required symmetry identified in Step 1. The denominator is chosen to be separable so that its stability can be easily assured. This denominator possesses all four types of symmetries.
3. Select a suitable order for the filter such that the specifications can be met.
4. Choose a region in the (θ_1, θ_2) frequency plane to specify the desired magnitude response. (Note that $\theta_i = \omega_i \cdot T$). For quadrantal, diagonal, and rotational symmetries, the region need only be a 90° sector in the frequency plane. For octagonal symmetry, it need only be a 45° sector. Specify the frequency sample points in this region using concentric circles or rectangular grids.
5. Form an objective function to be minimized. This will be based on the difference between the magnitude response of the transfer function and the desired magnitude response, at the selected frequency points. One such objective function is

$$J = \sum_k \sum_l w_{kl}[F(\theta_{1k}, \theta_{2l}) - F_d(\theta_{1k}, \theta_{2l})]^2 \tag{10.131}$$

where

F is the magnitude-squared response

θ_{1k}, θ_{2l} are the sample frequency points where the desired response is specified

w_{kl} are the weights on errors

In this function, the variables to be optimized are the coefficients of the transfer function. The weights w_{kl} are chosen so as to provide the emphasis on the accuracy needed at different frequency points.

6. Use any minimization algorithm, such as those provided in MATLAB, to minimize the objective function J and obtain the optimal values for the filter coefficients. Verify that the filter specifications can be met with this set of filter coefficients. If not, make adjustment to the minimization algorithm and repeat the process.
7. Check the stability of the filter by finding the poles. Any unstable pole can be stabilized by replacing it with its inverse pole.

10.11 Filter Design Examples

10.11.1 Bandpass Filter

Using the procedure discussed in Section 10.10, we now design a bandpass filter with the ideal filter specification shown in Figure 10.6.

It can be seen that the filter possesses diagonal symmetry. So we select the numerator to be $N(z_1, z_2) = N(z_2, z_1)$, which is case (1) in the list of polynomials for diagonal symmetry in Table 10.6. We choose the order of the filter to be (4,4) and w_{kl} equal to 1 for all k and l. Because of the diagonal symmetry constraints, the number of variables to optimize is reduced from 33 to 19. The following are the forms for the numerator and denominator:

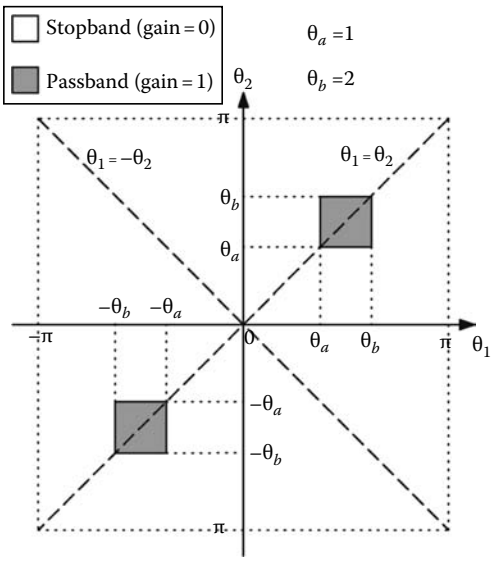

FIGURE 10.6 Specification for a bandpass filter with diagonal symmetry.

$$N(z_1, z_2) = \begin{array}{c} \\ z_2^0 \\ z_2^1 \\ z_2^2 \\ z_2^3 \\ z_2^4 \end{array} \begin{array}{c} \begin{array}{ccccc} z_1^0 & z_1^1 & z_1^2 & z_1^3 & z_1^4 \end{array} \\ \begin{bmatrix} a_{00} & a_{10} & a_{20} & a_{30} & a_{40} \\ \boxed{a_{10}} & a_{11} & a_{21} & a_{31} & a_{41} \\ \boxed{a_{20}} & \boxed{a_{21}} & a_{22} & a_{32} & a_{42} \\ \boxed{a_{30}} & \boxed{a_{31}} & \boxed{a_{32}} & a_{33} & a_{43} \\ \boxed{a_{40}} & \boxed{a_{41}} & \boxed{a_{42}} & \boxed{a_{43}} & a_{44} \end{bmatrix} \end{array} \tag{10.132}$$

and $D(z_i) = b_0 + b_1 z_i + b_2 z_i^2 + b_3 z_i^3 + z_i^4$, $i = 1, 2$

Also, because of symmetry, we need only specify the desired response in a reduced region (90° sector) in the frequency plane. In this case, we use the sector from 45° to 135°, and specify the sample points using rectangular grids.

We use the ''lsqnonlin'' routine in MATLAB Optimization Toolbox to minimize the objective function. The MATLAB M-files used to optimize the filter are listed in the Appendix at the end of the chapter. Optimize.m is the main program. Z2diir1.m calculates the objective and gradient functions. Diasym.m, Diasym1.m, and Diasym2.m are supporting M-files that impose the diagonal symmetry constraints on the objective and gradient functions. The coefficients to be optimized are arranged in vector form: xzo = [a_{00} a_{10} a_{20} a_{30} a_{40} a_{11} a_{21} a_{31} a_{41} a_{22} a_{32} a_{42} a_{33} a_{43} a_{44} b_0 b_1 b_2 b_3].

The transfer function coefficients of the optimized filter are listed below, together with the contour and 3-D magnitude plots (Figure 10.7). We verified that the filter is stable and meets the specification.

$a_{00} = 0.05691572886174$ $\quad a_{10} = -0.02461862190217$
$a_{20} = 0.00986568924226$ $\quad a_{30} = -0.01034804473379$
$a_{40} = 0.05820287661798$ $\quad a_{11} = -0.02118017629239$
$a_{21} = -0.00404160157329$ $\quad a_{31} = 0.03303916563349$
$a_{41} = -0.01033357674522$ $\quad a_{22} = 0.00255022502754$

$a_{33} = -0.02118784417373$ $\quad a_{43} = -0.02462035270181$
$a_{44} = 0.05691802180139$
$b_0 = 0.45583704915947$ $\quad b_1 = -0.09763672454601$
$b_2 = 0.87533799314168$ $\quad b_3 = -0.03923759607499$

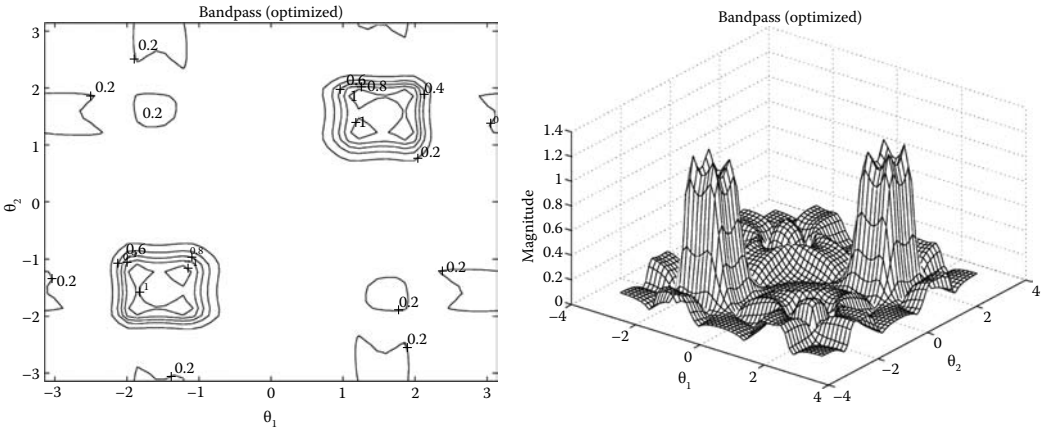

FIGURE 10.7 Contour and 3-D magnitude plots of the optimized bandpass filter.

Other types of filters can be designed using the same procedure. In the following, we provide examples of low-pass, high-pass, and bandstop filters with diagonal symmetry. We assume the same forms for the numerator and denominator as in Equation 10.132, and the same (4,4) filter order. Only minor modifications to optimize.m are needed to accommodate the different filter specifications. For each example, the initial filter specification, together with the final optimized filter coefficients and magnitude plots are shown (Figures 10.8 through 10.13).

10.11.2 Low-Pass Filter

Optimized low-pass filter coefficients:

$$
\begin{aligned}
a_{00} &= 0.00529914307068 & a_{10} &= -0.01633617926751\\
a_{20} &= -0.02625235827634 & a_{30} &= 0.01872969469730\\
a_{40} &= 0.01576064607841 & a_{11} &= 0.04957401022387\\

11.1 Resistor

11.1.1 Linear Resistor

11.1.1.1 Introduction

An ideal resistor is an electronic component, the fundamental feature of which is resistance R according to Ohm's law expressed by the equation

$$V = RI \tag{11.1}$$

where
V represents voltage in volts
I is the current in amperes
R is the resistance in ohms

The main parameters of a resistor are nominal resistance value, nominal power dissipation, and limited voltage value. According to their construction and technology, we can divide resistors into five groups: wirewound resistors, foil resistors, thin film resistors, thick film resistors, and bulk resistors. Each group has some advantages and disadvantages; until now it has been impossible to manufacture all of the needed resistors within one technology. It is more interesting to divide resistors with respect to their application into two groups as follows:

1. Fixed resistors, including low-power resistors of 0.05–2 W, high-power resistors of 2–100 W, high-voltage resistors, high-ohmic resistors, chip resistors, resistive networks
2. Variable resistors (potentiometers), including rotary control potentiometers, slide control potentiometers, preset potentiometers, and special potentiometers

11.1.1.2 Fixed Resistor

An ideal fixed resistor is an electronic component, the resistance value of which is constant with time and different environmental conditions. In practice, we can observe some changes of resistance in time and under high temperature, high humidity, frequency, and electrical load conditions, and so on. Those changes of a resistance, called the instability of resistor, are the basis for classification of resistors according to the requirements of the International Electrical Commission (IEC) and the International Organization for Standardization (ISO 9000–9004) in order to build in a reliability system.

Figure 11.1 presents different kinds of fixed resistors. Each resistor is marked mainly by resistance value *R* and production tolerance $\delta_{p(\pm)}$. Nominal resistance is rated according to the E6, E12, E24, E48, and E96 series. It is very important for the user to know not only the production deviation δ_p but also dynamic tolerance Δ.

Dynamic tolerance Δ and resistor class: The author's proposal for calculation of the dynamic tolerance Δ is given by Equations 11.2 and 11.3:

$$\Delta_+ = \delta_{p(+)} + \overline{\delta} + c * s \tag{11.2}$$

$$\Delta_- = \delta_{p(-)} - \overline{\delta} - c * s \tag{11.3}$$

where

$$\overline{\delta} = \frac{1}{n}\sum_{i=1}^{n}\delta_i \tag{11.4}$$

$$\delta_i = \frac{R_i(t) - R_i(0)}{R_i(0)} \times 100\% \tag{11.5}$$

where
n is the quantity of samples in test
t is the test time
R_i is the resistance of *i*, the resistor

$$s = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(\delta_i - \overline{\delta})^2} \tag{11.6}$$

$c = 1.28$ for probability level 90% cases inside the range $\overline{\delta} \pm 1.28^* s$, $c = 1.64$ for probability level 95% cases inside the range $\overline{\delta} \pm 1.64^* s$.

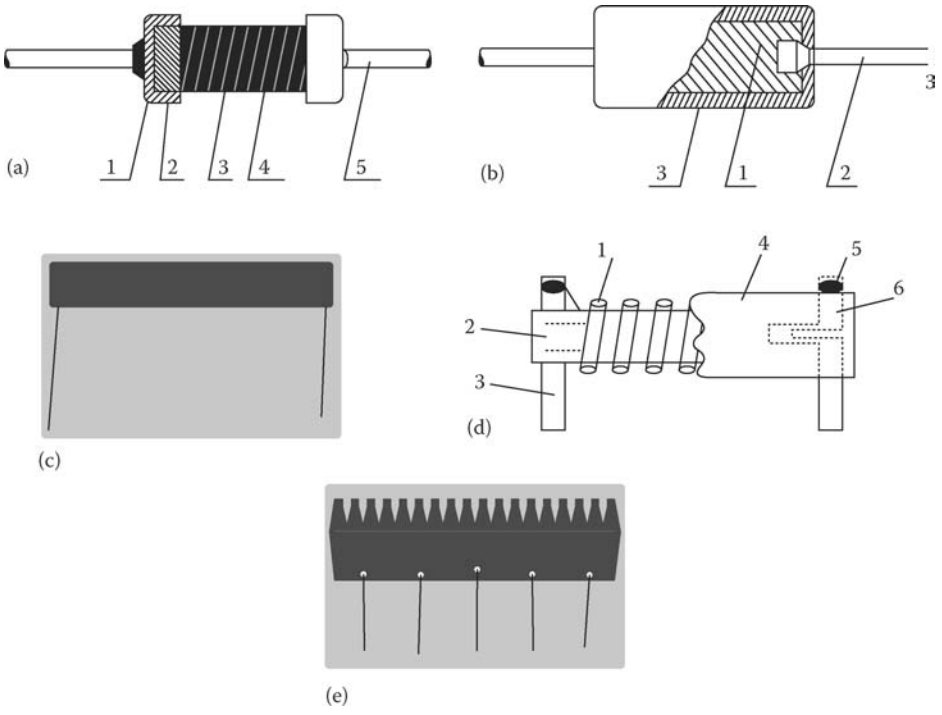

FIGURE 11.1 Typical fixed resistors: (a) film resistor: 1—metal cap, 2—electrode, 3—resistive layer, 4—groove, cut along screw line, 5—termination; (b) bulk composition resistor: 1—resistive composition, 2—termination, 3—pressed encapsulation; (c) high-voltage 100 MΩ thick film resistor; (d) wirewound power resistor, 1—resistive wire, 2—ceramic tube (substrate), 3—termination, 4—cement overcoating, 5—welded point, 6—cut for mechanical fixing of termination; and (e) thick film resistor with radiator.

Figure 11.2 illustrates dynamic tolerance Δ as an example of a thick film resistor endurance test prolonged up to 10,000 h. Resistors of 20 kΩ were manufactured by the Telpod factory (Poland) from Birox 1441 Du Pont paste. In Equations 11.2 and 11.3, for the long-life stability test, the coefficient c is chosen for normal distribution of changes δ_i for $t_j = 1000$ h because many experiments performed by author improved it with a high level of confidence. The hot humidity test causes distribution of changes asymmetrical, however.

The results of tests obtained for 400 resistors are shown in Figure 11.3a and b. For asymmetrical distribution, the following values for c parameters are suggested: $c_1 = -1$ for $\delta_i < \overline{\delta}$ and $c_2 = +3$ for $\delta_i > \overline{\delta}$. Dynamic tolerance Δ is recommended by IEC Publ. 115, 1982 because quality classes are connected directly, with instability δ_{max}, which is presented in Table 11.1. In practice, $\delta_{max} = \delta + cs$ according to Equation 11.2.

In accordance with IEC Publ. 115-5, 1982, the following classes of resistors are ranked according to precision group (see Table 11.2).

Temperature coefficient or resistance: The influence of temperature on resistance might be observed:

1. When the resistor is exposed to high temperature for a long time; this results in irreversible changes in resistance.
2. When the resistor is exposed to thermal condition of short duration (0.5 h); this results in reversible changes in resistance that are measured as temperature coefficient of resistance (TCR).

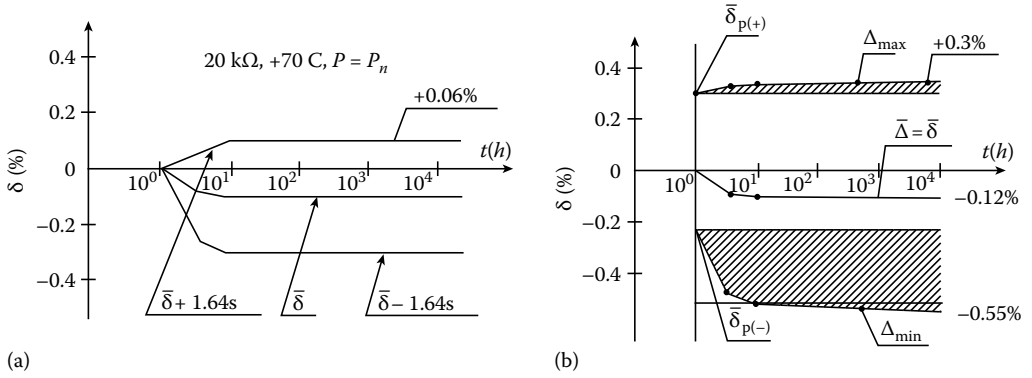

FIGURE 11.2 Resistor tolerance in exploitation. (a) The changes of resistance δ in time t $\overline{t\delta} = \varphi_1(t)$, $\overline{\delta} + 1.64^{*}s = \varphi_2(t)\overline{\delta} - 1.64^{*}s = \varphi_3(t)$ and (b) dynamic tolerance Δ as a function of time. Test time 10,000 h, $\delta_p = \pm 0.25\%$.

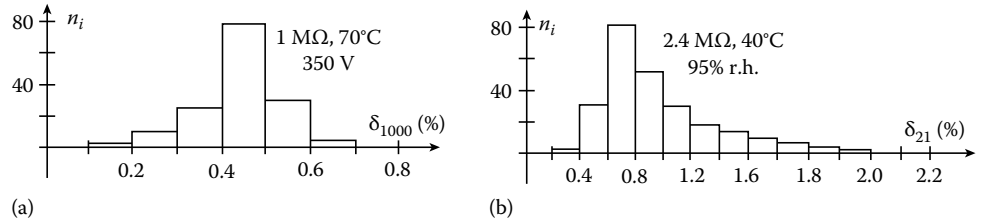

FIGURE 11.3 Distribution of δ (histogram). (a) Results after 1000 h endurance test: $\chi^2 = 5.01$, $\chi^2_{0.05,5} = 11.7$, $n = 150$ pcs, $-\overline{\delta} = 0.45\%$, $s = 0.24\%$; (b) result after 21-day hot humidity test: $\chi^2 = 100$, $\chi^2_{0.05,8} = 15.5$, $n = 246$ pcs, $\overline{\delta} = 0.79\%$, $s = 0.47\%$, χ^2—chi square distribution.

TABLE 11.1 Instability after Tests for Different Quality Resistor Classes

Classes	δ_{max} after Tests: Endurance Test Hot Humidity Test Climate Cycles Test	Recommended δ_p	Remarks
15	±(15% + 0.5 Ω)	±20%, ±10%, ±5%	
10	±(10% + 0.5 Ω)	±2%, ±1%	Common use resistor
5	±(5% + 0.1 Ω)		
3	±(3% + 0.1 Ω)		
2	±(2% + 0.1 Ω)	±5%, ±2%, ±1%	
1	±(1% + 0.05 Ω)	±0.5%, ±0.25%	Stable resistor
0.5	±(0.5% + 0.05 Ω)	±0.1%	
0.25	±(0.25% + 0.05 Ω)		

TABLE 11.2 Different Resistor Classes Ranked according to Precision Group

Classes	δ_{max} after Tests	Recommended δ_p
0.5	±(0.5% + 0.05 Ω)	±1%, ±0.5%, ±0.25%
0.25	±(0.25% + 0.05 Ω)	±0.1%, ±0.05%
0.1	±(0.1% + 0.01 Ω)	±0.025%
0.05	±(0.05% + 0.01 Ω)	±0.01%

TCR may be calculated from Equation 11.7 and in practice from Equation 11.8

$$\text{TCR} = \frac{1}{R}\frac{\partial R}{\partial T} \tag{11.7}$$

$$\text{TCR} = \frac{1}{R_0}\frac{R_T - R_0}{T - T_0} \tag{11.8}$$

where

R_0 is the resistance measured at room temperature T_0
R_T is the resistance measured at temperature T
T_0 is the room temperature

In Figure 11.4, some curves $R(T)$ are presented versus temperature for four types of resistors. It can be seen that in the tested range of temperature, TCR is positive and constant for curves 1 and 2 but negative and constant for curve 4. A different result is obtained for curve 3; at temperatures lower than T_m, TCR is negative, at higher temperatures than T_m, TCR is positive, and at T_m, TCR = 0. When $T_m = 40°C$, that type of resistor is the most interesting for users, because in the operating temperature range of 20°C–60°C, TCR is very small, almost zero.

As recommended by IEC Publ. 115, 1982, TCR limit values for different quality classes of resistors are shown in Table 11.3. Data in positions 1–5 refer to common use resistors, in positions 6–10, data refer to stable resistors, and in positions 11–15 to precision resistors.

Resistive network: In electronic circuits, resistors are often used as elements of dividers. In that case, it is more convenient to apply resistive networks (see Figure 11.5).

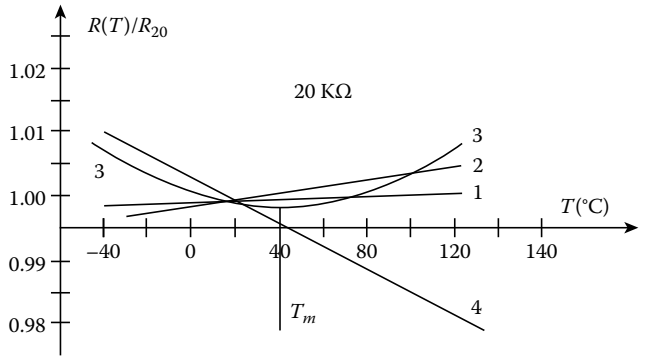

FIGURE 11.4 Dependence of resistance on ambient temperature. 1—wirewound resistor, 2—thin film resistor, 3—thick film ruthenium based resistor, 4—pyrolitic carbon resistor.

TABLE 11.3 TCR Limit Values for Different Quality Classes of Resistors

Number	TCR (ppm/K)	Number	TCR (ppm/K)	Number	TCR (ppm/K)
1	±2500	6	±250	11	±25
2	−800 to +2500	7	±100	12	±20
3	±1000	8	±50	13	±15
4	−400 to −1000	9	±25	14	±10
5	±500	10			

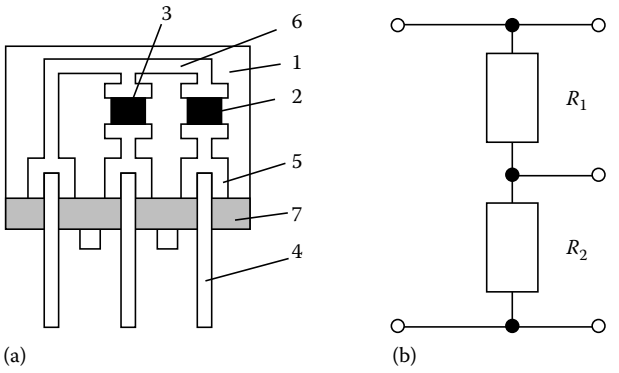

FIGURE 11.5 Thick film resistive network. (a) Topography of divider: 1—substrate, 2—resistor R_1, 3—resistor R_2, 4—wire termination, 5—soldering point, 6—conductive path, 7—insulating saddle and (b) electrical circuit.

Because the resistive network is deposited on a substrate in one technological cycle, both the TCR and time instability δ are almost the same for different resistors in the network. It appears to be more important for a user of a circuit to know differences Δ TCR and Δδ instead of absolute values of TCR or δ. It is estimated that Δ TCR can exhibit values of 1–3 ppm/K for TCR $\leq$ 50 ppm/K and Δδ can get value of 0.02% for $\delta = 0.5\%$.

Chip resistor: The development of electronic circuit mounting technology is going toward reliability and flexibility improvement and this results in a new assembly technique, known as surface mounting technology (SMT). Because SMT components have no terminations, their dimensions can be reduced. The smallest chip resistor is 2.5 mm long. Figure 11.6 depicts a 0.25 W chip resistor. Requirement

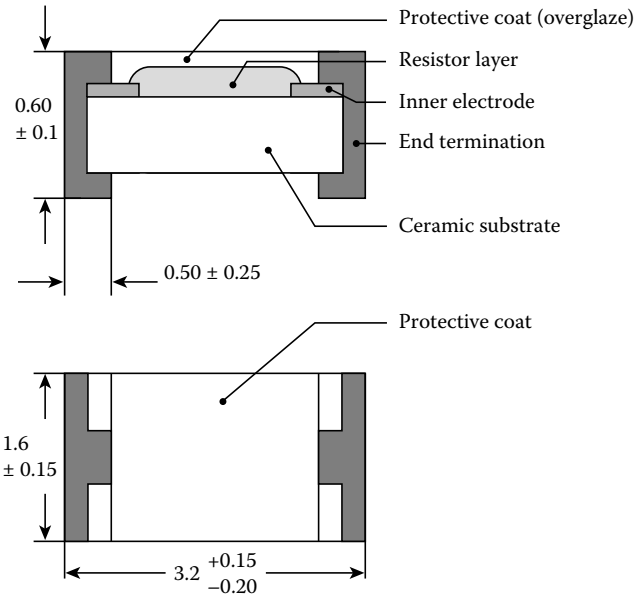

FIGURE 11.6 Chip resistor, nominal power 0.25 W (Philips Components Catalogue, 1989). Dimensions are in millimeters.

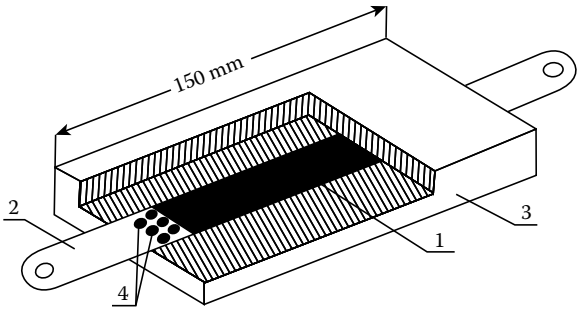

FIGURE 11.7 High-frequency resistor, nominal power 60 W. 1—resistive band, 2—band termination, 3—hot pressed overcoat, 4—holes for decreasing contact resistance.

parameters for chip resistors are the same as for fixed resistors with terminations. Thick film technology is often used in manufacturing chip resistors.

High-ohmic, high-voltage resistor: Usually resistors have resistances below 10 MΩ but sometimes resistors up to 10 GΩ are needed (e.g., in pH measurements, radiation particle detection, and so on). Only thick film technology enables production resistors of such high resistance values. Because the range of sheet resistance of the thick film layer changes from 1 Ω/square to 100 MΩ/square, we can easily get a resistance range from 1 to 10 GΩ. Laser trimming and shaping of the layer allows easily to get from 100 to 1000 squares of resistive layer.

A very high value of sheet resistance decreases the thermal and long-life stability of resistors, so it is advisable to design stable resistance with inks of 1 MΩ/square and to obtain the required resistance value by multiplying the number of squares.

High-ohmic resistors can be used as high-voltage resistors if their resistive paths are long enough.

The required voltage strength is a maximum of 2 kV/cm of resistive path. These types of resistors are used up to 10 kV in TV focusing systems.

High-power resistor: Very often, in electrical systems as well as in some electronic circuits (e.g., power suppliers, power amplifiers, R-TV transmitters, and radar equipment), resistors with dissipation power above 5 W are necessary. For dc and low-frequency applications up to 100 W, power resistors are realized by a cement layer but high parasitic inductance makes them useless for higher frequency performances. Film and band resistors have very good high-frequency characteristics and they are suggested for high-frequency applications. Resistive bands are made of boron–carbon or other compositions. Nominal resistance ranges are as follows: 50, 75, 300, and 600 Ω. In Figure 11.7, a band resistor of low inductance is shown.

11.1.1.3 Variable Resistor

The variable resistor, very often called a potentiometer, is an electronic component in which by movement of mechanical wiper the resistance is regulated. A variable resistor can regulate voltage when it is joined to the circuit as a fourth-pole element (Figure 11.8a). It can regulate current when it is joined to the circuit as a twin-pole element in series with load R_L (Figure 11.8b). Requirements for variable resistors are similar as for fixed resistors but several additional problems must be considered: mechanical endurance, rotational noise, contact resistance variation (CRV), the type of regulation curve (taper), and parallel curves in tandem potentiometers (stereo potentiometers).

Variable potentiometers can be divided into three groups: rotary control potentiometers, slide control potentiometers, and preset potentiometers.

In Figure 11.9, photos of different types of potentiometers are shown. With respect to their application we can divide potentiometers into several categories: standard type (common use) potentiometers with a

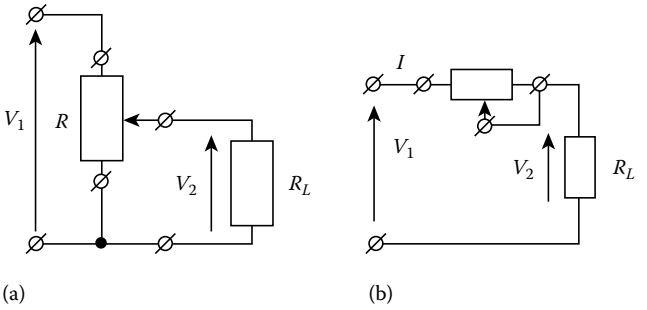

FIGURE 11.8 Potentiometer in an electric circuit: (a) as four-pole, voltage divider and (b) as twin-pole, rheostat.

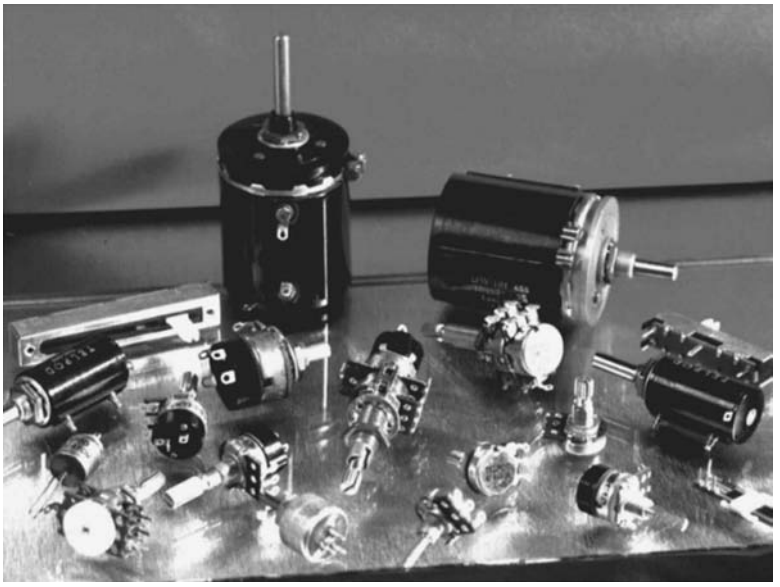

FIGURE 11.9 Photos of different potentiometers.

carbon polymer resistive layer, high-stability potentiometers with a cermet layer, precision potentiometers formed as wirewound, or thin film ones.

To increase sensitivity of regulation, a lead screw actuated potentiometer is used, in which the screw moves the nut connected with the wiper. Slow displacement of the wiper causes fluent resistance regulation.

Specially built potentiometers (helipots) are used for precise regulation (see Figure 11.10). In that case, the wiper is moving along a screw line. This means that for 10 rotations of shaft, the total angle is 3600° and the way of wiper is 10 times longer than in a simple rotary potentiometer. In helipots, precision of adjustment depends on the diameter of potentiometer. This type

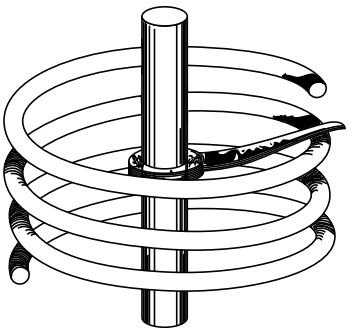

FIGURE 11.10 Helipot—a principle of work. (From Bourns, Inc., *The Potentiometer Handbook*, McGraw-Hill, New York, 1975. With permission.)

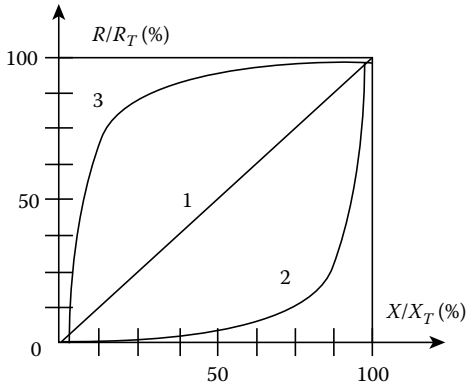

FIGURE 11.11 The main tapers of potentiometers. 1—linear, 2—exponential, 3—antiexponential. X_T—total wiper direction, R_T—total resistance. At the beginning and at the end of wiper movements there are very low resistive paths.

of a potentiometer is manufactured by Beckman, Bourns, and others.

Mechanical endurance: During the test of mechanical endurance, the wiper has to perform many total cycles. For present potentiometers, the number of cycles is 100–500; for control potentiometers it is 10^5–10^6 cycles.

***Regulation curves* (*taper*)**: The most popular regulation curve is a straight line; but as it is well known, our ear has a logarithmic characteristic. Therefore, for volume regulation in radios, audio amplifiers, and television sets, potentiometers with an exponential curve must be used. Figure 11.11 shows typical curves (tapers) of potentiometers.

In practice, a nonlinear curve is exactly realized by a few linear segments of resistive layer. Because each segment has another resistivity, it is necessary to use several segments to obtain a better exponential or antiexponential approximation. The minimum number of segments to perform an exponential curve is two, but then some steps in regulation are unavoidable. In production, we can achieve potentiometers performing sinus, cosinus, and other curves.

Curve parallelism of stereo tandem potentiometers: A stereo potentiometer with an exponential curve has to fulfill the additional requirement for parallel curves; both potentiometers are controlled by one roller (e.g., at attenuation of 40 dB the difference between both curves must be smaller than 2 dB).

11.1.2 Nonlinear

11.1.2.1 Varistor

A voltage-dependent resistor (VDR), called a varistor, is a resistor whose characteristic V versus I is not a straight line and a small change of voltage causes a significant change of current according to the equation

$$V = CI^{\beta} \tag{11.9}$$

where

β is the nonlinearity coefficient = 0.03–0.4 (it depends on the material and manufacturing technology)

C is the varistor-dependent coefficient

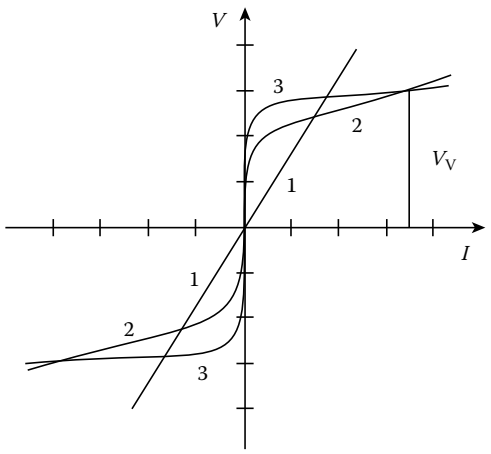

FIGURE 11.12 Voltage versus current characteristics. 1—linear resistor, 2—SiC varistor, 3—ZnO varistor, V_v—varistor voltage.

The main parameters of varistor are nonlinearity coefficient β and varistor voltage V_v measured at constant current, for example, 1 mA. Comparisons of the characteristics of a linear resistor and two types of varistors are shown in Figure 11.12.

A varistor can be used for dc voltage stabilization and especially for electronic circuit protection against

overvoltage pulses caused by industrial distortions and atmospheric discharges. Coefficient β is calculated from Equation 11.10:

$$\beta = \frac{\lg(V_2)/(V_1)}{\lg(I_2)/(I_1)} \tag{11.10}$$

when $I_2/I_1 = 10$, the denominator is equal to 1 and

$$\beta = \lg V_2 - \lg V_1 \tag{11.11}$$

To explain the above relation, Figure 11.13 is helpful, where both V and I are in logarithmic scale. The slope of the straight line segment of this curve equals β. For SiC varistors (curve 2 in Figure 11.12), $\beta = 0.12–0.4$; for ZnO varistors however $\beta = 0.03–0.1$.

Varistor voltage is in the range of 4 V up to 2 kV; it depends on varistor thickness (length). To get a higher operating voltage, disk varistors should be connected in pile. Maximum pulse current is in the range of 0.2 A up to 2 kA; it depends on the diameter of the varistor body. For pulse work, the following additional parameters are important: the capacity of the varistor (it is in the range of 100 pF up to 1 μF) and absorption energy (it is in the range 1–2200 J) [10].

11.1.2.2 Thermistor

A temperature-dependent resistor, called a thermistor, is a resistor with significant TCR, which can be positive (PTC) or negative (NTC). Some groups of thermistors are characterized by a very rapid change of resistance in temperature. Those thermistors are called critical temperature resistors (CTR). They can be positive CTR_P or negative CTR_N. Figure 11.14 presents typical characteristics R versus T for different types of thermistors.

NTC and PTC thermistors are used for stabilization of the working point in temperature for different electric circuits and as well as for temperature measurement. CTR thermistors are applied as protective elements against overheating in electronic circuits. CTR_Ps are used in degaussing circuits in color TV tubes. In some catalogs, CTR_Ps are called PTCs [7]. The electrical, climatic, and mechanical requirements of thermistors are almost the same as for fixed resistors but some additional parameters were introduced as well, such as thermal time constant (in seconds), heat capacity (in J/K), dissipation factor (in mW/K), switch temperature or critical temperature (in °C) (for CTRs only). The first three

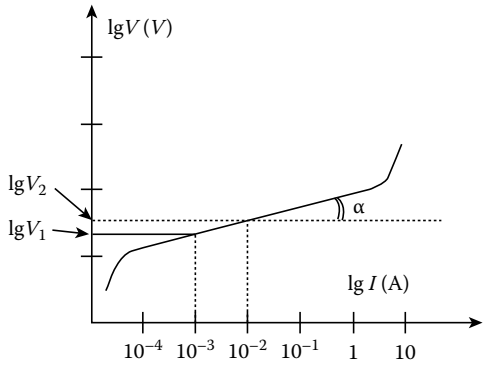

FIGURE 11.13 log(*V*)/log(*I*) characteristic of a varistor for nonlinearity coefficient β description. $\beta = \text{tg}\alpha = \log V_2 - \log V_1$; $I_2/I = 10$.

NTC—negative temperature coefficient thermistor; PTC—positive temperature coefficient thermistor; CTR—thermistor with critical temperature of resistance; index *N* curve falling with temperature; index *P*-curve rising with temperature.

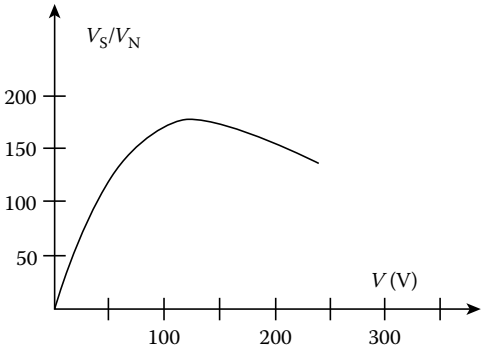

FIGURE 11.15 Signal-to-noise ratio versus polarization voltage V_{DC} of PbS photoresistor, Mullard type, 615 V. V_S—signal voltage, V_N–noise voltage, photo source temperature 473 K, $f = 800$ Hz, $\Delta f = 50$ Hz. (From Nowak, S., Wenta, A., and Kuzma, E., *Handbuch der Elektronik*, Vol. 2 and Ambroziak, A. et al., Vol. 7, Franzis-Verlag, Munich, 1979. With permission.)

are related to the thermistor dimensions, the remaining to the row material and technological process.

11.1.2.3 Photoresistor

A photoresistor is a film resistor whose resistance is sensitive to the light, that is, it depends on light intensity and light wavelength λ. The latter, in turn, depends on the kind of material used as follows.

For Cd S: $\lambda = 0.4$–0.7 μm, (visible light), for Pb S: $\lambda = 0.9$–3.5 μm (infrared), for Ge Si-doped Zn: $\lambda = 4$–15 μm, for Ge doped Sb: $\lambda = 30$–100 μm. This means that for a different photoresistor there exists an optimal wavelength at which maximum sensitivity (maximum change of resistance between lightness and darkness) occurs. During the design of a circuit with a photoresistor it is necessary to know at which polarization voltage the smallest noise exists. Figure 11.15 presents V_S/V_N versus polarization voltage for a PbS photoresistor made by Mullard.

11.1.2.4 Magnetoresistor

Some thin film multilayer ferromagnetic structures cause changes in magnetic field H. This phenomenon is called the magnetoresistive effect. An electronic component in which the magnetoresistive effect occurs is called a magnetoresistor and is usually used as a sensor. Special preparation of a ferromagnetic multilayer allows achievement of magnetosensitivity up to 100 MHz. The change of resistance is 1%–5% at the change of magnetic field H of about 10 Oe. Very often, two magnetoresistors are joined in a Wheatstone bridge and then sensitivity of the sensor is doubled.

11.1.3 Dependence on Material Properties

Materials selected for resistors have played a fundamental role in resistor production. Resistive elements are composed for a metal alloy, carbon, metal oxide, and mixtures of insulating and conducting particles such as polymer and black carbon, glass, and bismuth ruthenate, as well as glass and metal oxide. Semiconductors are also good materials for resistors, especially for nonlinear resistors such as varistors, thermistors, and photoresistors.

11.1.3.1 Influence of Resistive Material on TCR

Nonmagnetic metals: According to Grüneisenn's principle [2,3] temperature influences resistivity as follows:

$$\rho_T = \rho_\Theta \frac{T - 0.15\Theta}{0.85\Theta} \quad \text{for } T \geq 0.15\Theta \tag{11.12}$$

and

$$\mathrm{TCR}_{20} = \frac{1}{293 - 0.15\Theta} \tag{11.13}$$

$$\Theta = \frac{h\nu_{\max}}{k} \tag{11.14}$$

TABLE 11.4 Debye Temperature and Resistivity of Nonmagnetic Metals

Metal	ρ_{20} at $T = 293$ K (10^{-8} Ω m)	Θ (K)	0.15Θ (K)	ρ at Θ (10^{-8} Ω m)
Ag	1.62	214	32	1.16
Cu	1.68	320	48	1.94
Au	2.22	160	24	1.17

Source: Neudeck, G.W., *The PN Junction Diode*, Vol. II, Modular Series on Solid-State Devices, Reading, MA: Addison-Wesley, 1983. With permission.

where

$h = 6.625$ Js = Planck's constant
$k = 1.38$ J/K = Boltzmann's constant
Θ = the Debye temperature (for several nonmagnetic metals is given in Table 10.4)
ν_{max} = the maximal elastic frequency of the atom in a lattice of metal
ρ_Θ = the resistivity of the metal at the Debye temperature

From Table 11.4, 0.15Θ is in the range 10–60 K, which means that

$$\text{TCR}_{20} = \frac{1}{283} \text{ to } \frac{1}{233} \tag{11.15}$$

that is, TCR = +3500 up to +4300 ppm/K.

For nonmagnetic metal, TCR_{20} is constant, and temperate dependency of resistivity can be written as follows:

$$\rho_T = A\rho_\Theta T \tag{11.16}$$

where A = constant.

It appears that for nonmagnetic metal in the range of temperature $T \geq 0.15\Theta$, resistivity is proportional to the ambient temperature. On this basis, the resistive platinum thermometer is built.

Magnetic metal: For magnetic metal, for example, Fe, Ni, Co, the relation $\rho_T = f(T)$ is nonlinear and given by following equation:

$$\rho_T = CT^{1.7} \quad \text{for } T \leq T_c \tag{11.17}$$

where T_c is the Curie temperature (see Table 11.5).

TCRs measured for iron and nickel are about +4500 ppm/K. Pure metal, both magnetic and nonmagnetic, is not useful for resistor design due to its large TCR and low resistivity.

TABLE 11.5 Curie Temperature for Different Metals

Metal	T_c [K]
Fe	1043
Ni	635
Co	1400

Metal alloy: Increasing of resistivity with temperature can be explained by atomic vibrations in the crystalline lattice. Those atoms cause obstructions to free electrons and the higher temperature causes an increase of resistance (obstruction).

Such a resistivity is the first component ρ_s of an alloy resistivity ρ. According to Mathiessen's rule [2], we can add the second component of resistivity ρ_i that presents obstruction of free electrons by atoms of impurities in the metal lattice.

$$\begin{aligned} \rho &= \rho_s + \rho_i \\ \rho_i &= \text{const}, \quad \rho_i \neq \varphi(T) \end{aligned} \tag{11.18}$$

where ρ_s is given by Equations 11.16 and 11.17.

When $\rho_i \gg \rho_s$, TCR is very small. In this case $\rho \gg \rho_s$ as well. This means that a resistor made of a specially prepared metal alloy can have very small TCR and large resistivity ρ. That result is very remarkable for a metal alloy resistor design.

Example:

Constantin 60% Cu + 40% Ni: $TCR_{20} = 1$–5 ppm/K, $\rho_{20} = 0.49 \times 10^{-6}$ Ωm in contrast with pure copper: TCR = 4000 ppm/K and $\rho_{20} = 0.0168 \times 10^{-6}$ Ωm; Canthal 70% Fe + 23% Cr + 4.5% Al + 1% Co + 1.5% other metals: $TCR_{20} = 50$ ppm/K, $\rho_{20} = 1.4 \times 10^{-6}$ Ωm.

This example demonstrates that, for alloys, TCR is from 100 up to 1000 times smaller and ρ_{20} is from 20 up to 100 times greater in comparison to pure metals (see also Table 11.4). This information is useful for wirewound and foil resistor design.

11.1.3.2 Thin Film Resistor

Over 90% of thin film resistors are made of metal alloy. A thin layer of metal alloy is deposited on ceramic or glass substrate. Sheet resistance $R(\Omega/\text{square})$ of a metal alloy thin film resistor varies from 10 Ω/square up to 200 Ω/square; the nominal resistance range is from 10 Ω to 10 MΩ; TCR ≈ 15–150 ppm/K; classes 5, 3, 2, 1; precision resistors are available.

For a high nominal resistance value, the resistance layer is specially shaped by laser trimming to get enough squares. Some features of thin film layer are a bit different from bulk metal alloy.

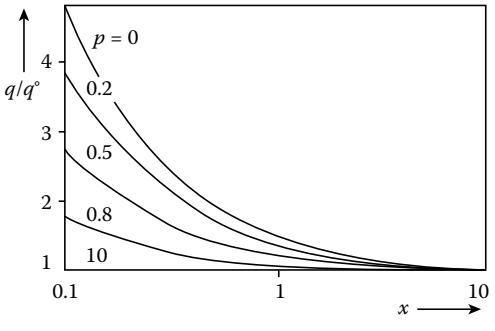

FIGURE 11.16 Influence of layer thickness on resistivity of metal thin film. ρ_0—resistivity of bulk metal; p—quantity of reflected electrons; $1 - p$—quantity of absorbed electrons. (From Maissel, L.I. and Glang, R. eds., *Handbook of Thin Film Technology*, McGraw-Hill, New York, 1970. With permission.)

***Fuchs's and Sondheimer's effect* [2]**: When the thickness of the resistive layer is smaller than a free path of the free electron, the resistivity increases.

Figure 11.16 shows the influence of normalized thickness κ on resistivity ρ:

$$\kappa = \frac{t}{\lambda} \tag{11.19}$$

where

t is the thickness of a layer

λ is the free path of the electron, which equals 20–30 nm [2]

κ is expressed by Equation 11.19

Grain effect: Because free electrons are reflected and absorbed by edges of grains, the resistivity increases when the quantity of grains becomes greater. Annealing processes of the layer limit that effect.

Figure 11.17 illustrates the result of the annealing process [2]. Small grains of the resistive layer are also the reason for the large absorption of humidity and gases that causes instability of the resistor.
