Preface

The purpose of this book is to provide in a single volume a comprehensive reference work covering the broad spectrum of feedback amplifier design; analysis, synthesis, and design of nonlinear circuits; their representation, approximation, identification, and simulation; cellular neural networks; multiconductor transmission lines; and analysis and synthesis of distributed circuits. It also includes the design of multiple-loop feedback amplifiers. This book is written and developed for the practicing electrical engineers and computer scientists in industry, government, and academia. The goal is to provide the most up-to-date information in the field.

Over the years, the fundamentals of the field have evolved to include a wide range of topics and a broad range of practice. To encompass such a wide range of knowledge, this book focuses on the key concepts, models, and equations that enable the design engineer to analyze, design, and predict the behavior of feedback amplifiers, nonlinear and distributed systems. While design formulas and tables are listed, emphasis is placed on the key concepts and theories underlying the processes.

This book stresses fundamental theories behind professional applications and uses several examples to reinforce this point. Extensive development of theory and details of proofs have been omitted. The reader is assumed to have a certain degree of sophistication and experience. However, brief reviews of theories, principles, and mathematics of some subject areas are given. These reviews have been done concisely with perception.

The compilation of this book would not have been possible without the dedication and efforts of Professors Leon O. Chua and Thomas Koryu Ishii, and most of all the contributing authors. I wish to thank them all.

Wai-Kai Chen

Editor-in-Chief

Wai-Kai Chen is a professor and head emeritus of the Department of Electrical Engineering and Computer Science at the University of Illinois at Chicago. He received his BS and MS in electrical engineering at Ohio University, where he was later recognized as a distinguished professor. He earned his PhD in electrical engineering at the University of Illinois at Urbana–Champaign.

Professor Chen has extensive experience in education and industry and is very active professionally in the fields of circuits and systems. He has served as a visiting professor at Purdue University, the University of Hawaii at Manoa, and Chuo University in Tokyo, Japan. He was the editor-in-chief of the *IEEE Transactions on Circuits and Systems*, *Series I and II*, the president of the IEEE Circuits and Systems Society, and is the founding editor and the editor-in-chief of the *Journal of Circuits, Systems and Computers*. He received the Lester R. Ford Award from the Mathematical Association of America; the Alexander von Humboldt Award from Germany; the JSPS Fellowship Award from the Japan Society for the Promotion of Science; the National Taipei University of Science and Technology Distinguished Alumnus Award; the Ohio University Alumni Medal of Merit for Distinguished Achievement in Engineering Education; the Senior University Scholar Award and the 2000 Faculty Research Award from the University of Illinois at Chicago; and the Distinguished Alumnus Award from the University of Illinois at Urbana–Champaign. He is the recipient of the Golden Jubilee Medal, the Education Award, and the Meritorious Service Award from the IEEE Circuits and Systems Society, and the Third Millennium Medal from the IEEE. He has also received more than a dozen honorary professorship awards from major institutions in Taiwan and China.

A fellow of the Institute of Electrical and Electronics Engineers (IEEE) and the American Association for the Advancement of Science (AAAS), Professor Chen is widely known in the profession for the following works: *Applied Graph Theory* (North-Holland), *Theory and Design of Broadband Matching Networks* (Pergamon Press), *Active Network and Feedback Amplifier Theory* (McGraw-Hill), *Linear Networks and Systems* (Brooks/Cole), *Passive and Active Filters: Theory and Implements* (John Wiley), *Theory of Nets: Flows in Networks* (Wiley-Interscience), *The Electrical Engineering Handbook* (Academic Press), and *The VLSI Handbook* (CRC Press).

1.1 Introduction

Feedback, whether intentional or parasitic, is pervasive of all electronic circuits and systems. In general, feedback is comprised of a subcircuit that allows a fraction of the output signal of an overall network to modify the effective input signal in such a way as to produce a circuit response that can differ substantially from the response produced in the absence of such feedback. If the magnitude and relative phase angle of the fed back signal decreases the magnitude of the signal applied to the input port of an amplifier, the feedback is said to be *negative* or degenerative. On the other hand, *positive* (or regenerative) feedback, which gives rise to oscillatory circuit responses, is the upshot of a feedback signal that increases the magnitude of the effective input signal. Because negative feedback produces stable circuit responses, the majority of all intentional feedback architectures is degenerative [1,2]. However, parasitic feedback incurred by the energy storage elements associated with circuit layout, circuit packaging, and second-order high-frequency device phenomena often degrades an otherwise degenerative feedback circuit into either a potentially regenerative or severely underdamped network.

Intentional degenerative feedback applied around an analog network produces four circuit performance benefits. First, negative feedback desensitizes the gain of an open-loop amplifier (an amplifier implemented without feedback) with respect to variations in circuit element and active device model parameters. This desensitization property is crucial in view of parametric uncertainties caused by aging phenomena, temperature variations, biasing perturbations, and nonzero fabrication and manufacturing tolerances. Second, and principally because of the foregoing desensitization property, degenerative feedback reduces the dependence of circuit responses on the parameters of inherently nonlinear active devices, thereby reducing the total harmonic distortion evidenced in open loops. Third, negative feedback

broadbands the dominant pole of an open-loop amplifier, thereby affording at least the possibility of a closed-loop network with improved high-frequency performance. Finally, by modifying the driving-point input and output impedances of the open-loop circuit, negative feedback provides a convenient vehicle for implementing voltage buffers, current buffers, and matched interstage impedances.

The disadvantages of negative feedback include gain attenuation, a closed-loop configuration that is disposed to potential instability, and, in the absence of suitable frequency compensation, a reduction in the open-loop gain-bandwidth product (GBP). In uncompensated feedback networks, open-loop amplifier gains are reduced in almost direct proportion to the amount by which closed-loop amplifier gains are desensitized with respect to open-loop gains. Although the 3 dB bandwidth of the open-loop circuit is increased by a factor comparable to that by which the open-loop gain is decreased, the closed-loop GBP resulting from uncompensated degenerative feedback is never greater than that of the open-loop configuration [3]. Finally, if feedback is incorporated around an open-loop amplifier that does not have a dominant pole [4], complex conjugate closed-loop poles yielding nonmonotonic frequency responses are likely. Even positive feedback is possible if substantive negative feedback is applied around an open-loop amplifier for which more than two poles significantly influence its frequency response.

Although the foregoing detail is common knowledge deriving from Bode's pathfinding disclosures [5], most circuit designers remain uncomfortable with analytical procedures for estimating the frequency responses, I/O impedances, and other performance indices of practical feedback circuits. The purposes of this section are to formulate systematic feedback circuit analysis procedures and ultimately, to demonstrate their applicability to six specific types of commonly used feedback architectures. Four of these feedback types, the series–shunt, shunt–series, shunt–shunt, and series–series configurations, are single-loop architectures, while the remaining two types are the series–series/shunt–shunt and series–shunt/shunt–series dual-loop configurations.

1.2 Methods of Analysis

Several standard techniques are used for analyzing linear feedback circuits [6]. The most straightforward of these entails writing the Kirchhoff equilibrium equations for the small-signal model of the entire feedback system. This analytical tack presumably leads to the idealized feedback circuit block diagram abstracted in Figure 1.1. In this model, the circuit voltage or current response, X_R, is related to the source current or voltage excitation, X_S, by

$$G_{cl} \triangleq \frac{X_R}{X_S} = \frac{G_o}{1 + fG_o} \equiv \frac{G_o}{1 + T} \tag{1.1}$$

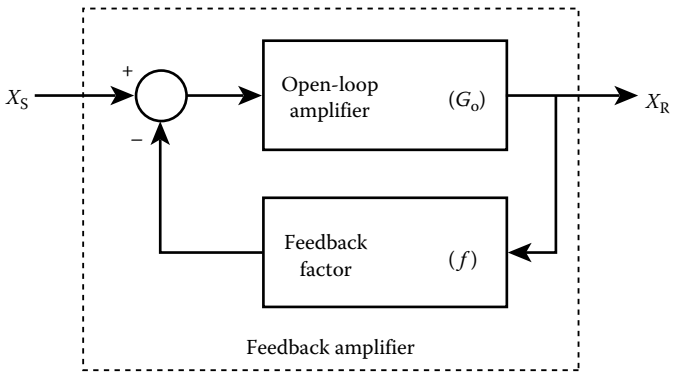

FIGURE 1.1 Block diagram model of a feedback network.

where

G_{cl} is the closed-loop gain of the feedback circuit

f, the feedback factor, is the proportion of circuit response fed back for antiphase superposition with the source signal

G_o represents the open-loop gain

The product fG_o is termed the loop gain T.

Equation 1.1 demonstrates that, for loop gains with magnitudes that are much larger than one, the closed-loop gain collapses to $1/f$, which is independent of the open-loop gain. To the extent that the open-loop amplifier, and not the feedback subcircuit, contains circuit elements and other parameters that are susceptible to modeling uncertainties, variations in the fabrication of active and passive elements, and nonzero manufacturing tolerances, large loop gain achieves a desirable parametric desensitization. Unfortunately, the determination of G_o and f directly from the Kirchhoff relationships is a nontrivial task, especially because G_o is rarely independent of f in practical electronics. Moreover, Equation 1.1 does not illuminate the manner in which the loop gain modifies the driving-point input and output impedances of the open-loop amplifier.

A second approach to feedback network analysis involves modeling the open loop, feedback, and overall closed-loop networks by a homogeneous set of two-port parameters [7]. When the two-port parameter model is selected judiciously, the two-port parameters for the closed-loop network derive from a superposition of the respective two-port parameters of the open loop and feedback subcircuits. Given the resultant parameters of the closed-loop circuit, standard formulas can then be exploited to evaluate closed-loop values of the circuit gain and the driving-point input and output impedances.

Unfortunately, several limitations plague the utility of feedback network analysis predicated on two-port parameters. First, the computation of closed-loop two-port parameters is tedious if the open-loop configuration is a multistage amplifier, or if multiloop feedback is utilized. Second, the two-loop method of feedback circuit analysis is straightforwardly applicable to only those circuits that implement global feedback (feedback applied from output port to input port). Many single-ended feedback amplifiers exploit only local feedback, wherein a fraction of the signal developed at the output port is fed back to a terminal pair other than that associated with the input port. Finally, the appropriate two-port parameters of the open-loop amplifier can be superimposed with the corresponding parameter set of the feedback subcircuit if and only if the Brune condition is satisfied [8]. This requirement mandates equality between the pre- and postconnection values of the two-port parameters of open loop and feedback cells, respectively. The subject condition is often not satisfied when the open-loop amplifier is not a simple three-terminal two-port configuration.

The third method of feedback circuit analysis exploits Mason's signal flow theory [9–11]. The circuit level application of this theory suffers few of the shortcomings indigenous to block diagram and two-port methods of feedback circuit analysis [12]. Signal flow analyses applied to feedback networks efficiently express I/O transfer functions, driving-point input impedances, and driving-point output impedances in terms of an arbitrarily selected critical or reference circuit parameters, say P.

An implicit drawback of signal flow methods is the fact that unless P is selected to be the feedback factor f, which is not always transparent in feedback architectures, expressions for the loop gain and the open-loop gain of feedback amplifiers are obscure. However, by applying signal flow theory to a feedback circuit model engineered from insights that derive from the results of two-port network analyses, the feedback factor can be isolated. The payoff of this hybrid analytical approach includes a conventional block diagram model of the I/O transfer function, as well as convenient mathematical models for evaluating the closed-loop driving-point input and output impedances. Yet, another attribute of hybrid methods of feedback circuit analysis is its ability to delineate the cause, nature, and magnitude of the feedforward transmittance produced by interconnecting a certain feedback subcircuit to a given open-loop amplifier. This information is crucial in feedback network design because feedforward invariably decreases gain and often causes undesirable phase shifts that can lead to significantly underdamped or unstable closed-loop responses.

1.3 Signal Flow Analysis

Guidelines for feedback circuit analysis by hybrid signal flow methods can be established with the aid of Figure 1.2 [13]. Figure 1.2a depicts a linear network whose output port is terminated in a resistance, R_L. The output signal variable is the voltage V_O, which is generated in response to an input port signal whose Thévenin voltage and resistance are respectively, V_S and R_S. Implicit to the linear network is a current-controlled voltage source (CCVS) Pi_b, with a value that is directly proportional to the indicated network branch current i_b. The problem at hand is the deduction of the voltage gain $G_v(R_S, R_L) = V_O/V_S$, the driving-point input resistance (or impedance) R_{in}, and the driving-point output resistance (or impedance) R_{out}, as explicit functions of the critical transimpedance parameter P. Although the following systematic procedure is developed in conjunction with the diagram in Figure 1.2, with obvious changes in notation, it is applicable to determine any type of transfer relationship for any linear network in terms of any type of reference parameter [14].

1. Set $P = 0$, as depicted in Figure 1.2b, and compute the resultant voltage gain $G_{vo}(R_S, R_L)$, where the indicated notation suggests an anticipated dependence of gain on source and load resistances. Also, compute the corresponding driving-point input and output resistances R_{in}, and R_{out}, respectively. In this case, the "critical" parameter P is associated with a controlled voltage source. Accordingly, $P = 0$ requires that the branch containing the controlled source be supplanted by a

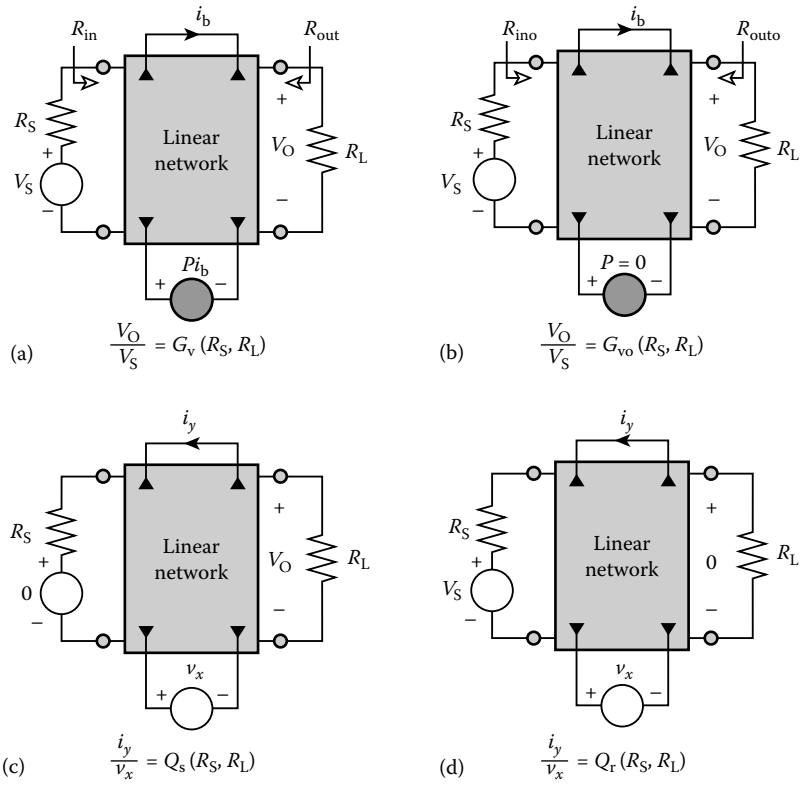

FIGURE 1.2 (a) Linear network with an identified critical parameter P. (b) Model for calculating the $P = 0$ value of voltage gain. (c) The return ratio with respect to P is $PQ_s(R_S, R_L)$. (d) The null return ratio with respect to P is $PQ_r(R_S, R_L)$.

short circuit. If, for example, P is associated with a controlled current source, $P = 0$ mandates the replacement of the controlled source by an open circuit.

2. Set the Thévenin source voltage V_S to zero, and replace the original controlled voltage source Pi_b by an independent voltage source of symbolic value, v_x. Then, calculate the ratio, i_y/v_x, where, as illustrated in Figure 1.2c, i_y flows in the branch that originally conducts the controlling current i_b. Note, however, that the reference polarity of i_y is opposite to that of i_b. The computed transfer function i_y/v_x is denoted by $Q_s(R_S, R_L)$. This transfer relationship, which is a function of the source and load resistances, is used to determine the *return ratio* $T_s(P, R_S, R_L)$ with respect to parameter P of the original network. In particular,

$$T_s(P, R_S, R_L) = PQ_s(R_S, R_L) \tag{1.2}$$

3. If P is associated with a controlled current source, the controlled generator Pi_b is replaced by a current source of value i_x. If the controlling variable is a voltage, instead of a current, the ratio v_y/v_x, is computed, where v_y is the voltage developed across the controlling branch and the polarity is opposite to that of the original controlling voltage.
4. The preceding computational step is repeated, but instead of setting V_S to zero, the output variable, which is the voltage V_O in the present case, is nulled, as indicated in Figure 1.2d. Let the computed ratio i_y/v_x, be symbolized as $Q_r(R_S, R_L)$. In turn, the *null return ratio* $T_r(P, R_S, R_L)$, with respect to parameter P is

$$T_r(P, R_S, R_L) = PQ_r(R_S, R_L) \tag{1.3}$$

5. Desired voltage gain $G_v(R_S, R_L)$, of the linear network undergoing study can be shown to be [5,12]

$$G_v(R_S, R_L) = \frac{V_O}{V_S} = G_{vo}(R_S, R_L)\left[\frac{1 + PQ_r(R_S, R_L)}{1 + PQ_s(R_S, R_L)}\right] \tag{1.4}$$

6. Given the function $Q_s(R_S, R_L)$, the driving-point input and output resistances follow straightforwardly from [12]

$$R_{in} = R_{ino}\left[\frac{1 + PQ_s(0, R_L)}{1 + PQ_s(\infty, R_L)}\right] \tag{1.5}$$

$$R_{out} = R_{outo}\left[\frac{1 + PQ_s(R_S, 0)}{1 + PQ_s(R_S, \infty)}\right] \tag{1.6}$$

An important special case entails a controlling electrical variable i_b associated with the selected parameter P that is coincidentally the voltage or current output of the circuit under investigation. In this situation, a factor P of the circuit response is fed back to the port (not necessarily the input port) defined by the terminal pair across which the controlled source is incident. When the controlling variable i_b is the output voltage or current of the subject circuit $Q_r(R_S, R_L)$, which is evaluated under the condition of a nulled network response, is necessarily zero. With $Q_r(R_S, R_L) = 0$, the algebraic form of Equation 1.4 is identical to that of Equation 1.1, where the loop gain T is the return ratio with respect to parameter P; that is,

$$PQ_s(R_S, R_L)|_{Q_r(R_S, R_L) = 0} = T \tag{1.7}$$

Moreover, a comparison of Equation 1.4 to Equation 1.1 suggests that $G_v(R_S, R_L)$ symbolizes the closed-loop gain of the circuit, $G_{vo}(R_S, R_L)$ represents the corresponding open-loop gain, and the circuit feedback factor f is

$$f = \frac{PQ_s(R_S, R_L)}{G_{vo}(R_S, R_L)} \tag{1.8}$$

1.4 Global Single-Loop Feedback

Consider the global feedback scenario illustrated in Figure 1.3a, in which a fraction P of the output voltage V_O is fed back to the voltage-driven input port. Figure 1.3b depicts the model used to calculate the return ratio $Q_s(R_S, R_L)$, where, in terms of the branch variables in the schematic diagram, $Q_s(R_S, R_L) = v_y/v_x$. An inspection of this diagram confirms that the transfer function v_y/v_x, is identical to the $P = 0$ value of the gain V_O/V_S, which derives from an analysis of the structure in Figure 1.3a. Thus, for global voltage feedback in which a fraction of the output voltage is fed back to a voltage-driven input port, $Q_s(R_S, R_L)$ is the open-loop voltage gain; that is, $Q_s(R_S, R_L) + G_{vo}(R_S, R_L)$. It follows from Equation 1.8 that the feedback factor f is identical to the selected critical parameter P. Similarly, for the global current feedback architecture of Figure 1.4a, a fraction P of the output current, I_O, is fed back to the current-driven input port $f = P$. As implied by the model of Figure 1.4b, $Q_s(R_S, R_L) \equiv G_{io}(R_S, R_L)$, the open-loop current gain.

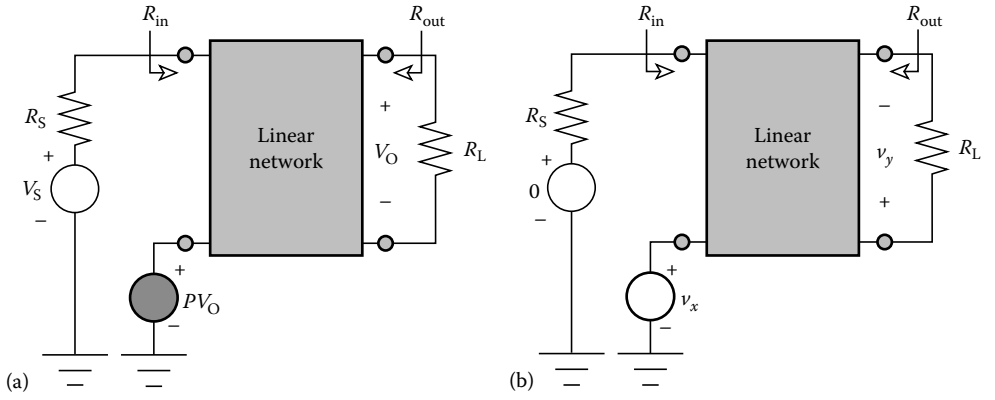

FIGURE 1.3 (a) Voltage-driven linear network with global voltage feedback. (b) Model for the calculation of loop gain.

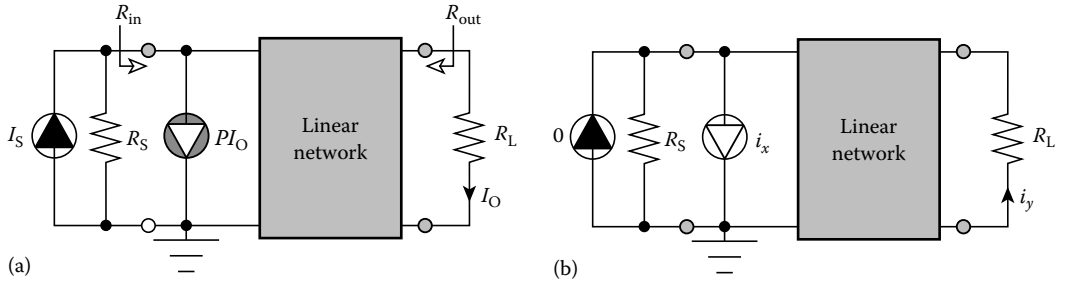

FIGURE 1.4 (a) Current-driven linear network with global current feedback. (b) Model for the calculation of loop gain.

1.4.1 Driving-Point I/O Resistances

Each of the two foregoing circuit architectures has a closed-loop gain where the algebraic form mirrors (Equation 1.1). It follows that for sufficiently large loop gain (equal to either $PG_{vo}(R_S, R_L)$ or $PG_{io}(R_S, R_L)$), the closed-loop gain approaches $(1/P)$ and is therefore desensitized with respect to open-loop gain parameters. However, such a desensitization with respect to the driving-point input and output resistances (or impedances) cannot be achieved. For the voltage feedback circuit in Figure 1.3a, $Q_s(\infty, R_L)$, is the $R_S = \infty$ value, $G_{vo}(R_S, R_L)$, of the open-loop voltage gain. This particular open-loop gain is zero, because $R_S = \infty$ decouples the source voltage from the input port of the amplifier. On the other hand, $Q_s(0, R_L)$ is the $R_S = 0$ value, $G_{vo}(0, R_L)$, of the open-loop voltage gain. This gain is at least as large as $G_{vo}(R_S, R_L)$, since a short-circuited Thévenin source resistance implies lossless coupling of the Thévenin signal to the amplifier input port. Recalling Equation 1.5, the resultant driving-point input resistance of the voltage feedback amplifier is

$$R_{in} = R_{ino}[1 + PG_{vo}(0, R_L)] \geq R_{ino}[1 + PG_{vo}(R_S, R_L)] \tag{1.9}$$

which shows that the closed-loop driving-point input resistance is larger than its open-loop counterpart and is dependent on open-loop voltage gain parameters.

Conversely, the corresponding driving-point output resistance in Figure 1.3a is smaller than the open-loop output resistance and approximately inversely proportional to the open-loop voltage gain. These assertions derive from the facts that $Q_s(R_S, 0)$ is the $R_L = 0$ value of the open-loop voltage gain $G_{vo}(R_S, R_L)$. Because $R_L = 0$ corresponds to the short-circuited load resistance, $G_{vo}(R_S, 0) = 0$. In contrast, $Q_s(R_S, \infty)$, is the $R_L = \infty$ value, $G_{vo}(R_S, \infty)$, of the open-loop gain, which is a least as large as $G_{vo}(R_S, R_L)$. By Equation 1.6,

$$R_{out} = \frac{R_{outo}}{1 + PG_{vo}(R_S, \infty)} \leq \frac{R_{outo}}{1 + PG_{vo}(R_S, R_L)} \tag{1.10}$$

Similarly, the driving-point input and output resistances of the global current feedback configuration of Figure 1.4a are sensitive to open-loop gain parameters. In contrast to the voltage amplifier of Figure 1.3a, the closed loop, driving-point input resistance of current amplifier is smaller than its open-loop value, while the driving-point output resistance is larger than its open-loop counterpart. Noting that the open-loop current gain $G_{io}(R_S, R_L)$ is zero for both $R_S = 0$ (which short circuits the input port), and $R_L = \infty$ (which open circuits the load port), Equations 1.5 and 1.6 give

$$R_{in} = \frac{R_{ino}}{1 + PG_{io}(\infty, R_L)} \tag{1.11}$$

$$R_{out} = R_{outo}[1 + PG_{io}(R_S, 0)] \tag{1.12}$$

1.4.2 Diminished Closed-Loop Damping Factor

In addition to illuminating the driving-point and forward transfer characteristics of single-loop feedback architectures, the special case of global single-loop feedback illustrates the potential instability problems pervasive of almost all feedback circuits. An examination of these problems begins by returning to Equation 1.1 and letting the open-loop gain, G_o, be replaced by the two-pole frequency-domain function,

$$G_o(s) = \frac{G_o(0)}{\left(1 + \frac{s}{p_1}\right)\left(1 + \frac{s}{p_2}\right)} \tag{1.13}$$

where $G_o(0)$ symbolizes the zero-frequency open-loop gain. The pole frequencies p_1 and p_2 in Equation 1.13 are either real numbers or complex conjugate pairs. Alternatively, Equation 1.13 is expressible as

$$G_s(s) = \frac{G_o(0)}{1 + \frac{2\zeta_{ol}}{\omega_{nol}}s + \frac{s^2}{\omega_{nol}^2}} \tag{1.14}$$

where

$$\omega_{nol} = \sqrt{p_1 p_2} \tag{1.15}$$

represents the *undamped natural frequency* of oscillation of the open-loop configuration, and

$$\zeta_{ol} = \frac{1}{2}\left[\sqrt{\frac{p_2}{p_1}} + \sqrt{\frac{p_1}{p_2}}\right] \tag{1.16}$$

is the *damping factor* of the open-loop circuit.

In Equation 1.1, let the feedback factor f be the single left-half-plane zero function,

$$f(s) = f_o\left(1 + \frac{s}{z}\right) \tag{1.17}$$

where

z is the frequency of the real zero introduced by feedback
f_o is the zero-frequency value of the feedback factor

The resultant loop gain is

$$T(s) = f_o\left(1 + \frac{s}{z}\right)G_o(s) \tag{1.18}$$

the zero-frequency value of the loop gain is

$$T(0) = f_o G_o(0) \tag{1.19}$$

and the zero-frequency closed-loop gain $G_{cl}(0)$, is

$$G_{cl}(0) = \frac{G_o(0)}{1 + f_o G_o(0)} = \frac{G_o(0)}{1 + T(0)} \tag{1.20}$$

Upon inserting Equations 1.14 and 1.17 into Equation 1.1, the closed-loop transfer function is determined to be

$$G_{cl}(s) = \frac{G_{cl}(0)}{1 + \frac{2\zeta_{cl}}{\omega_{ncl}}s + \frac{s^2}{\omega_{ncl}^2}} \tag{1.21}$$

where the closed-loop undamped natural frequency of oscillation ω_{ncl} relates to its open-loop counterpart ω_{nol}, in accordance with

$$\omega_{ncl} = \omega_{nol}\sqrt{1 + T(0)} \tag{1.22}$$

Moreover, the closed-loop damping factor ζ_{cl} is

$$\zeta_{cl} = \frac{\zeta_{ol}}{\sqrt{1+T(0)}} + \left[\frac{T(0)}{1+T(0)}\right]\frac{\omega_{ncl}}{2z} = \frac{\zeta_{ol}}{\sqrt{1+T(0)}} + \left[\frac{T(0)}{\sqrt{1+T(0)}}\right]\frac{\omega_{nol}}{2z} \tag{1.23}$$

A frequency invariant feedback factor $f(s)$ applied to the open-loop configuration whose transfer function is given by Equation 1.13 implies an infinitely large frequency, z, of the feedback zero. For this case, Equation 1.23 confirms a closed-loop damping factor that is always less than the open-loop damping factor. Indeed, for a smaller than unity open-loop damping factor (which corresponds to complex conjugate open-loop poles) and reasonable values of the zero-frequency loop gain $T(0)$, $\zeta_{cl} \ll 1$. Thus, constant feedback applied around an underdamped two-pole open-loop amplifier yields a severely underdamped closed-loop configuration. It follows that the closed-loop circuit has a transient step response plagued by overshoot and a frequency response that displays response peaking within the closed-loop passband. Observe that underdamping is likely to occur even in critically damped (identical real open-loop poles) or overdamped (distinct real poles) open-loop amplifiers, which correspond to $\zeta_{ol} = 1$ and $\zeta_{ol} > 1$, respectively, when a large zero-frequency loop gain is exploited.

Underdamped closed-loop amplifiers are not unstable systems, but they are nonetheless unacceptable. From a practical design perspective, closed-loop underdamping predicted by relatively simple mathematical models of the loop gain portend undesirable amplifier responses or even closed-loop instability. The problem is that simple transfer function models invoked in a manual circuit analysis are oblivious to presumably second-order parasitic circuit layout and device model energy storage elements with effects that include a deterioration of phase and gain margins.

1.4.3 Frequency Invariant Feedback Factor

Let the open-loop amplifier be overdamped, such that its real satisfy the relationship

$$p_2 = \kappa^2 p_1 \tag{1.24}$$

If the open-loop amplifier pole p_1 is dominant, κ^2 is a real number that is greater than the magnitude, $|G_o(0)|$, of the open-loop zero-frequency gain, which is presumed to be much larger than one. As a result, the open-loop damping factor in Equation 1.16 reduces to $\zeta_{o1} \approx \kappa/2$. With $\kappa^2 > |G_o(0)| \gg 1$, which formally reflects the *dominant pole approximation*, the 3 dB bandwidth B_{ol} of the open-loop amplifier is given approximately by [15]

$$B_{ol} \approx \frac{\omega_{nol}}{2\zeta_{ol}} = \frac{1}{\frac{1}{p_1}+\frac{1}{p_2}} = \left(\frac{\kappa^2}{\kappa^2+1}\right)p_1 \tag{1.25}$$

As expected, Equation 1.25 predicts an open-loop 3 dB bandwidth that is only slightly smaller than the frequency of the open-loop dominant pole.

The frequency, z, in Equation 1.23 is infinitely large if frequency invariant degenerative feedback is applied around an open-loop amplifier. For a critically damped or overdamped closed-loop amplifier, $\zeta_{cl} > 1$. Assuming open-loop pole dominance, this constraint imposes the open-loop pole requirement,

$$\frac{p_2}{p_1} \geq 4[1+T(0)] \tag{1.26}$$

Thus, for large zero-frequency loop gain, $T(0)$, an underdamped closed-loop response is avoided if and only if the frequency of the nondominant open-loop pole is substantially larger than that of the dominant open-loop pole. Unless frequency compensation measures are exploited in the open loop, Equation 1.26

is difficult to satisfy, especially if feedback is implemented expressly to realize a substantive desensitization of response with respect to open-loop parameters. On the chance that Equation 1.26 can be satisfied, and if the closed-loop amplifier emulates a dominant pole response, the closed-loop bandwidth is, using Equations 1.22, 1.23, and 1.25,

$$B_{\mathrm{cl}} \approx \frac{\omega_{\mathrm{ncl}}}{2\zeta_{\mathrm{cl}}} \approx [1 + T(0)]B_{\mathrm{ol}} \approx [1 + T(0)]p_1 \tag{1.27}$$

Observe from Equations 1.26 and 1.27 that the maximum possible closed-loop 3 dB bandwidth is 2 octaves below the minimum acceptable frequency of the nondominant open-loop pole.

Although Equation 1.27 theoretically confirms the broadbanding property of negative feedback amplifiers, the attainment of very large closed-loop 3 dB bandwidths is nevertheless a challenging undertaking. The problem is that Equation 1.26 is rarely satisfied. As a result, the open-loop configuration must be suitably compensated, usually by pole splitting methodology [16–18], to force the validity of Equation 1.26. However, the open-loop poles are not mutually independent, so any compensation that increases p_2 is accompanied by decreases in p_1. The pragmatic upshot of the matter is that the closed-loop 3 dB bandwidth is not directly proportional to the uncompensated value of p_1 but instead, it is proportional to the smaller, compensated value of p_1.

1.4.4 Frequency Variant Feedback Factor (Compensation)

Consider now the case where the frequency, z, of the compensating feedback zero is finite and positive. Equation 1.23 underscores the stabilizing property of a left-half-plane feedback zero in that a sufficiently small positive z renders a closed-loop damping factor ζ_{cl} that can be made acceptably large, regardless of the value of the open-loop damping factor ζ_{ol}. To this end, $\zeta_{\mathrm{cl}} > 1/\sqrt{2}$ is a desirable design objective in that it ensures a monotonically decreasing closed-loop frequency response. If, as is usually a design goal, the open-loop amplifier subscribes to pole dominance, Equation 1.23 translates the objective, $\zeta_{\mathrm{cl}} > 1/\sqrt{2}$, into the design constraint

$$z \leq \frac{\left[\frac{T(0)}{1+T(0)}\right]\omega_{\mathrm{ncl}}}{\sqrt{2} - \frac{\omega_{\mathrm{ncl}}}{[1+T(0)]B_{\mathrm{ol}}}} \tag{1.28}$$

where use is made of Equation 1.25 to cast ζ in terms of the open-loop bandwidth B_{ol}. When the closed-loop damping factor is precisely equal to $1/\sqrt{2}$ a maximally flat magnitude closed-loop response results for which the 3 dB bandwidth is ω_{ncl}. Equation 1.28 can then be cast into the more useful form

$$zG_{\mathrm{cl}}(0) = \frac{\mathrm{GBP_{ol}}}{\sqrt{2}\left(\frac{\mathrm{GBP_{ol}}}{\mathrm{GBP_{cl}}}\right) - 1} \tag{1.29}$$

where Equation 1.20 is exploited, $\mathrm{GBP_{ol}}$ is the gain-bandwidth product of the open-loop circuit, and $\mathrm{GBP_{cl}}$ is the gain-bandwidth product of the resultant closed-loop network.

For a given open-loop gain-bandwidth product $\mathrm{GBP_{ol}}$, a desired low-frequency closed-loop gain, $G_{\mathrm{cl}}(0)$, and a desired closed-loop gain-bandwidth product, $\mathrm{GBP_{cl}}$, Equation 1.29 provides a first-order estimate of the requisite feedback compensation zero. Additionally, note that Equation 1.29 imposes an upper limit on the achievable high-frequency performance of the closed-loop configuration. In particular, because z must be positive to ensure acceptable closed-loop damping, Equation 1.29 implies

$$\mathrm{GBP_{ol}} > \frac{\mathrm{GBP_{cl}}}{\sqrt{2}} \tag{1.30}$$

In effect, Equation 1.30 imposes a lower limit on the required open-loop GBP commensurate with feedback compensation implemented to achieve a maximally flat, closed-loop frequency response.

1.5 Pole Splitting Open-Loop Compensation

Equation 1.26 underscores the desirability of achieving an open-loop dominant pole frequency response in the design of a feedback network. In particular, Equation 1.26 shows that if the ultimate design goal is a closed-loop dominant pole frequency response, the frequency, p_2, of the nondominant open-loop amplifier pole must be substantially larger than its dominant pole counterpart, p_1. Even if closed-loop pole dominance is sacrificed as a trade-off for other performance merits, open-loop pole dominance is nonetheless a laudable design objective. This contention follows from Equations 1.16 and 1.23, which combine to suggest that the larger p_2 is in comparison to p_1, the larger is the open-loop damping factor. In turn, the unacceptably underdamped closed-loop responses that are indicative of small, closed-loop damping factors are thereby eliminated. Moreover, Equation 1.23 indicates that larger, open-loop damping factors impose progressively less demanding restrictions on the feedback compensation zero that may be required to achieve acceptable closed-loop damping. This observation is important because in an actual circuit design setting, small z in Equation 1.23 generally translates into a requirement of a correspondingly large RC time constant, where implementation may prove difficult in monolithic circuit applications.

Unfortunately, many amplifiers, and particularly broadbanded amplifiers, earmarked for use as open-loop cells in degenerative feedback networks, are not characterized by dominant pole frequency responses. The frequency response of these amplifiers is therefore optimized in accordance with a standard design practice known as pole splitting compensation. Such compensation entails the connection of a small capacitor between two high impedance, phase-inverting nodes of the open-loop topology [17,19–21]. Pole splitting techniques increase the frequency p_2 of the uncompensated nondominant open-loop pole to a compensated value, say p_{2c}. The frequency, p_1, of the uncompensated dominant open-loop pole is simultaneously reduced to a smaller frequency, say p_{1c}. Although these pole frequency translations complement the design requirement implicit to Equations 1.23 and 1.26, they do serve to limit the resultant closed-loop bandwidth, as discussed earlier. As highlighted next, they also impose other performance limitations on the open loop.

1.5.1 Open-Loop Amplifier

The engineering methods, associated mathematics, and engineering trade-offs underlying pole splitting compensation are best revealed in terms of the generalized, phase-inverting linear network abstracted in Figure 1.5. Although this amplifier may comprise the entire open-loop configuration, in the most general case, it is an interstage of the open loop. Accordingly, R_{st} in this diagram is viewed as the Thévenin equivalent resistance of either an input signal source or a preceding amplification stage. The response to the Thévenin driver, V_{st}, is the indicated output voltage, V_l, which is developed across the Thévenin load resistance, R_{lt}, seen by the stage under investigation. Note that the input current conducted by the amplifier is I_s, while the current flowing into the output port of the unit is denoted as I_l. The dashed branch containing the capacitor C_c, which is addressed later, is the pole splitting compensation element.

Because the amplifier under consideration is linear, any convenient set of two-port parameters can be used to model its terminal volt–ampere characteristics. Assuming the existence of the short-circuit admittance, or y parameters,

$$\begin{bmatrix} I_s \\ I_l \end{bmatrix} = \begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_2 \end{bmatrix} \begin{bmatrix} V_i \\ V_l \end{bmatrix} \tag{1.31}$$

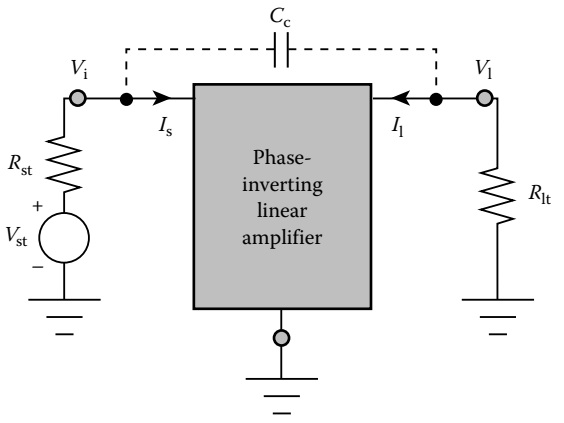

FIGURE 1.5 Linear amplifier for which a pole splitting compensation capacitance C_c is incorporated.

Defining

$$\begin{aligned} y_o &\triangleq y_{11} + y_{12} \\ y_o &\triangleq y_{22} + y_{12} \\ y_f &\triangleq y_{21} + y_{12} \\ y_r &\triangleq -y_{12} \end{aligned} \tag{1.32}$$

Equation 1.31 implies

$$I_s = y_i V_i + y_r(V_i - V_l) \tag{1.33}$$

$$I_l = y_f V_i + y_o V_1 + y_r(V_l - V_i) \tag{1.34}$$

The last two expressions produce the y-parameter model depicted in Figure 1.6a, in which y_i represents an effective shunt input admittance, y_o is a shunt output admittance, y_f is a forward transadmittance, and y_r reflects voltage feedback intrinsic to the amplifier.

Amplifiers amenable to pole splitting compensation have capacitive input and output admittances; that is, y_i and y_o are of the form

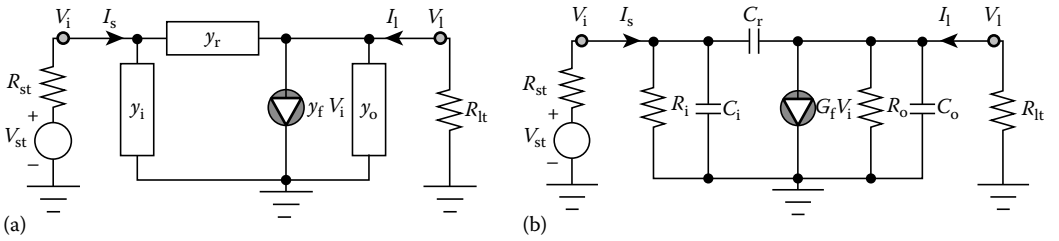

FIGURE 1.6 y-Parameter equivalent circuit of the phase-inverting linear amplifier in Figure 1.5. (b) Approximate form of the model in (a).

$$y_i = \frac{1}{R_i} + sC_i$$
$$y_o = \frac{1}{R_o} + sC_o \tag{1.35}$$

Similarly,

$$y_f = G_f - sC_f$$
$$y_r = \frac{1}{R_r} + sC_r \tag{1.36}$$

In Equation 1.36, the conductance component G_f of the forward transadmittance y_f positive in a phase-inverting amplifier. Moreover, the reactive component $-sC_f$ of y_f produces an *excess phase angle*, and hence, a *group delay*, in the forward gain function. This component, which deteriorates phase margin, can be ignored to first order if the signal frequencies of interest are not excessive in comparison to the upper-frequency limit of performance of the amplifier. Finally, the feedback internal to many practical amplifiers is predominantly capacitive so that the feedback resistance R_r can be ignored. These approximations allow the model in Figure 1.6a to be drawn in the form offered in Figure 1.6b.

It is worthwhile interjecting that the six parameters indigenous to the model in Figure 1.6b need not be deduced analytically from the small-signal models of the active elements embedded in the subject interstage. Instead, SPICE can be exploited to evaluate the y parameters in Equation 1.31 at the pertinent biasing level. Because these y parameters display dependencies on signal frequency, care should be exercised to evaluate their real and imaginary components in the neighborhood of the open loop, 3 dB bandwidth to ensure acceptable computational accuracy at high frequencies. Once the y parameters in Equation 1.31 are deduced by computer-aided analysis, the alternate admittance parameters in Equation 1.23, as well as numerical estimates for the parameters, R_i, C_i, R_o, C_o, C_r, and G_f, in Equations 1.35 and 1.36 follow straightforwardly.

1.5.2 Pole Splitting Analysis

An analysis of the circuit in Figure 1.6b produces a voltage transfer function $A_v(s)$ of the form

$$A_v(s) = \frac{V_l(s)}{V_{st}(s)} = A_v(0)\left[\frac{1 - \frac{s}{z_r}}{\left(1 + \frac{s}{p_1}\right)\left(1 + \frac{s}{p_2}\right)}\right] \tag{1.37}$$

Letting

$$R_{ll} = R_{lt} \| R_o \tag{1.38}$$

an inspection of the circuit in Figure 1.6b confirms that

$$A_v(0) = -G_f R_{ll}\left(\frac{R_i}{R_i + R_{st}}\right) \tag{1.39}$$

is the zero-frequency voltage gain. Moreover, the frequency, z_r, of the right-half-plane zero is

$$z_r = \frac{G_f}{C_r} \tag{1.40}$$

The lower pole frequency, p_1, and the higher pole frequency, p_2, derive implicitly from

$$\frac{1}{p_1}+\frac{1}{p_2}=R_{ll}(C_o+C_r)+R_{ss}[C_i+(1+G_fR_{ll})C_r] \tag{1.41}$$

and

$$\frac{1}{p_1p_2}=R_{ss}R_{ll}C_o\left[C_i+\left(\frac{C_o+C_i}{C_o}\right)C_r\right] \tag{1.42}$$

where

$$R_{ss}=R_{st}\stackrel{\Delta}{=}R_i \tag{1.43}$$

Most practical amplifiers, and particularly amplifiers realized in bipolar junction transistor technology, have very large forward transconductance, G_f, and small internal feedback capacitance, C_r. The combination of large G_f and small C_r renders the frequency in Equation 1.40 so large as to be inconsequential to the passband of interest. When utilized in a high-gain application, such as the open-loop signal path of a feedback amplifier, these amplifiers also operate with a large effective load resistance, R_{ll}. Accordingly, Equation 1.41 can be used to approximate the pole frequency p_1 as

$$p_1\approx\frac{1}{R_{ss}[C_i+(1+G_fR_{ll})C_r]} \tag{1.44}$$

Substituting this result into Equation 1.42, the approximate frequency p_2 of the high-frequency pole is

$$p_2\approx\frac{C_i+(1+G_fR_{ll})C_r}{R_{ll}C_o\left[C_i+\left(\frac{C_o+C_i}{C_o}\right)C_r\right]} \tag{1.45}$$

Figure 1.7 illustrates asymptotic frequency responses corresponding to pole dominance and to a two-pole response. Figure 1.7a depicts the frequency response of a dominant pole amplifier, which does not

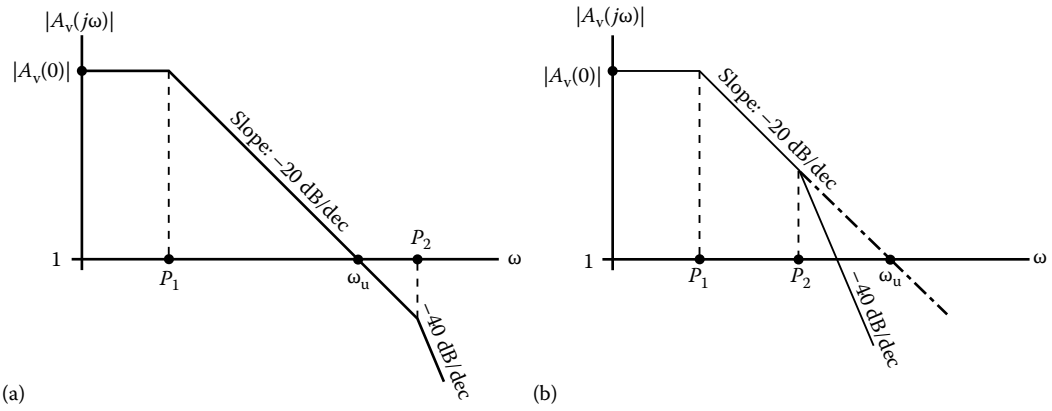

FIGURE 1.7 (a) Asymptotic frequency response for a dominant pole amplifier. Such an amplifier does not require pole splitting compensation because the two lowest frequency amplifier poles, p_1 and p_2, are already widely separated. (b) Frequency response of an amplifier with high-frequency response that is strongly influenced by both of its lowest frequency poles. The basic objective of pole splitting compensation is to transform the indicated frequency response to a form that emulates that depicted in (a).

require pole splitting compensation. Observe that its high-frequency response is determined by a single pole (p_1 in this case) through the signal frequency at which the gain ultimately degrades to unity. In this interpretation of a dominant pole amplifier, p_2 is not only much larger than p_1, but is in fact larger than the unity gain frequency, which is indicated as ω_u in the figure. This unity gain frequency, which can be viewed as an upper limit to the useful passband of the amplifier, is approximately, $|A_v(0)|p_1$. To the extent that p_1 is essentially the 3 dB bandwidth when $p_2 \gg p_1$, the unity gain frequency is also the GBP of the subject amplifier. In short, with $|A_v(j\omega_u)| \triangleq 1$, $p_2 \gg p_1$ in Equation 1.37 implies

$$\omega_u \approx |A_v(0)|p_1 \approx \text{GBP} \tag{1.46}$$

The contrasting situation of a response indigenous to the presence of two significant open-loop poles is illustrated in Figure 1.7b. In this case, the higher pole frequency p_2 is smaller than ω_u and hence, the amplifier does not emulate a single-pole response throughout its theoretically useful frequency range. The two critical frequencies, p_1 and p_2, remain real numbers, and as long as $p_2 \neq p_1$, the corresponding damping factor, is greater than 1. However, the damping factor of the two-pole amplifier (its response is plotted in Figure 1.7b) is nonetheless smaller than that of the dominant pole amplifier. It follows that, for reasonable loop gains, unacceptable underdamping is more likely when feedback is invoked around the two-pole amplifier, as opposed to the same amount of feedback applied around a dominant pole amplifier. Pole splitting attempts to circumvent this problem by transforming the pole conglomeration of the two-pole amplifier into one that emulates the dominant pole situation inferred by Figure 1.7a.

To the foregoing end, append the compensation capacitance C_c between the input and the output ports of the phase-inverting linear amplifier, as suggested in Figure 1.5. With reference to the equivalent circuit in Figure 1.6b, the electrical impact of this additional element is the effective replacement of the internal feedback capacitance C_r by the capacitance sum $(C_r + C_c)$. Letting

$$C_p \triangleq C_r + C_c \tag{1.47}$$

it is apparent that Equations 1.40 through 1.42 remain applicable, provided that C_r in these relationships is supplanted by C_p. Because C_p is conceivably significantly larger than C_c, however, the approximate expressions for the resultant pole locations differ from those of Equations 1.44 and 1.45. In particular, a reasonable approximation for the compensated value, say P_{1c}, of the lower pole frequency is now

$$p_{1c} \approx \frac{1}{[R_{ll} + (1 + G_f R_{ll})R_{ss}]C_p} \tag{1.48}$$

while the higher pole frequency, p_{2c}, becomes

$$p_{2c} \approx \frac{1}{\left(R_{ss} \| R_{ll} \| \frac{1}{G_f}\right)(C_o + C_i)} \tag{1.49}$$

Clearly, $p_{1c} < p_1$ and $p_{2c} > p_2$. Moreover, for large G_f, p_{2c} is potentially much larger than p_{1c}. It should also be noted that the compensated value, say, z_{rc}, of the right-half-plane zero is smaller than its uncompensated value, z_r, because Equation 1.40 demonstrates that

$$z_{rc} = \frac{G_f}{C_p} = z_r\left(\frac{C_r}{C_r + C_c}\right) \tag{1.50}$$

Although z_{rc} can conceivably exert a significant influence on the high-frequency response of the compensated amplifier, the following discussion presumes tacitly that $z_{rc} > p_{2c}$ [2].

Assuming a dominant pole frequency response, the compensated unity gain frequency, ω_{uc}, is, using Equations 1.39, 1.46, and 1.48,

$$\omega_{uc} \approx |A_v(0)|p_{1c} \approx \left(\frac{1}{R_{st}C_p}\right)\left[G_f\left(R_{ss}\|R_{ll}\|\frac{1}{G_f}\right)\right] \tag{1.51}$$

It is interesting to note that

$$\omega_{uc} < \left(\frac{1}{R_{st}C_p}\right) \tag{1.52}$$

that is, the unity gain frequency is limited by the inverse of the RC time constant formed by the Thévenin source resistance R_{st} and the net capacitance C_p appearing between the input port and the phase inverted output port. The subject inequality comprises a significant performance limitation, for if p_{2c} is indeed much larger than p_{ic}, ω_{uc} is approximately the GBP of the compensated cell. Accordingly, for a given source resistance, a required open-loop gain, and a desired open-loop bandwidth, Equation 1.52 imposes an upper limit on the compensation capacitance that can be exploited for pole splitting purposes.

In order for the compensated amplifier to behave as a dominant pole configuration, p_{2c} must exceed ω_{uc}, as defined by Equation 1.51. Recalling Equation 1.49, the requisite constraint is found to be

$$R_{st}C_p > G_f\left(R_{ss}\|R_{ll}\|\frac{1}{G_f}\right)^2(C_o + C_i) \tag{1.53}$$

Assuming $G_f\,(R_{ss}/R_{ll}) \ll 1$, Equation 1.53 reduces to the useful simple form

$$C_fR_{st} > \frac{C_o + C_i}{C_p} \tag{1.54}$$

which confirms the need for large forward transconductance G_f if pole splitting is to be an effective compensation technique.

1.6 Summary

The use of negative feedback is fundamental to the design of reliable and reproducible analog electronic networks. Accordingly, this chapter documents the salient features of the theory that underlies the efficient analysis and design of commonly used feedback networks. Four especially significant points are postulated in this section.

1. By judiciously exploiting signal flow theory, the classical expression, Equation 1.1, for the I/O transfer relationship of a linear feedback system is rendered applicable to a broad range of electronic feedback circuits. This expression is convenient for design-oriented analysis because it clearly identifies the open-loop gain, G_o, and the loop gain, T. The successful application of signal flow theory is predicated on the requirement that the feedback factor, to which T is proportional and that appears in the signal flow literature as a ''critical'' or ''reference'' parameter, can be identified in a given feedback circuit.
2. Signal flow theory, as applied to electronic feedback architectures, proves to be an especially expedient analytical tool because once the loop gain T is identified, the driving-point input and output impedances follow with minimal additional calculations. Moreover, the functional dependence of T on the Thévenin source and terminating load impedances unambiguously brackets the

magnitudes of the driving point I/O impedances attainable in particular types of feedback arrangements.

3. Damping factor concept is advanced herewith as a simple way of assessing the relative stability of both the open and closed loops of a feedback circuit. The open-loop damping factor derives directly from the critical frequencies of the open-loop gain, while these frequencies and any zeros appearing in the loop gain unambiguously define the corresponding closed-loop damping factor. Signal flow theory is once again used to confirm the propensity of closed loops toward instability unless the open-loop subcircuit functions as a dominant pole network. Also confirmed is the propriety of the common practice of implementing a feedback zero as a means of stabilizing an otherwise potentially unstable closed loop.
4. Pole splitting as a means to achieve dominant pole open-loop responses is definitively discussed. Generalized design criteria are formulated for this compensation scheme, and limits of performance are established. Of particular interest is the fact that pole splitting limits the GBP of the compensated amplifier to a value that is determined by a source resistance–compensation capacitance time constant.

2.1 Introduction

Four basic types of single-loop feedback amplifiers are available: the series–shunt, shunt–series, shunt–shunt, and series–series architectures [1]. Each of these cells is capable of a significant reduction of the dependence of forward transfer characteristics on the ill-defined or ill-controlled parameters implicit to the open-loop gain; but none of these architectures can simultaneously offer controlled driving-point input and output impedances. Such additional control is afforded only by dual global loops comprised of series and/or shunt feedback signal paths appended to an open-loop amplifier [2,3]. Only two types of global dual-loop feedback architectures are used: the series–series/shunt–shunt feedback amplifier and the series–shunt/shunt–series feedback amplifier.

Although only bipolar technology is exploited in the analysis of the aforementioned four single-loop and two dual-loop feedback cells, all disclosures are generally applicable to metal-oxide-silicon (MOS), heterostructure bipolar transistor (HBT), and III–V compound metal-semiconductor field-effect transistor (MESFET) technologies. All analytical results derive from an application of a hybrid, signal flow/two-port parameter analytical tack. Because the thought processes underlying this technical approach apply to all feedback circuits, the subject analytical procedure is developed in detail for only the series–shunt feedback amplifier.

2.2 Series–Shunt Feedback Amplifier

2.2.1 Circuit Modeling and Analysis

Figure 2.1a depicts the ac schematic diagram (a circuit diagram divorced of biasing details) of a series–shunt feedback amplifier. In this circuit, the output voltage V_O, which is established in response to a single source represented by the Thévenin voltage V_{ST}, and the Thévenin resistance, R_{ST}, is sampled by the feedback network composed of the resistances, R_{EE} and R_F. The sampled voltage is fed back in such a way that the closed-loop input voltage, V_I, is the sum of the voltage, V_{1A}, across the input port of the amplifier and the voltage V_{1F}, developed across R_{EE} in the feedback subcircuit. Because $V_I = V_{1A} + V_{1F}$, the output port of the feedback configuration can be viewed as connected in series with the amplifier input port. On the other hand, output voltage sampling constrains the net load current, I_O, to be the algebraic sum of the amplifier output port current, I_{2A}, and the feedback network input current, I_{2F}. Accordingly, the output topology is indicative of a shunt connection between the feedback subcircuit and the amplifier output port. The fact that voltage is fed back to a voltage-driven input port renders the driving-point input resistance, R_{in}, of the closed-loop amplifier large, whereas the driving-point output resistance, R_{out}, seen by the terminating load resistance, R_{LT}, is small. The resultant closed-loop amplifier

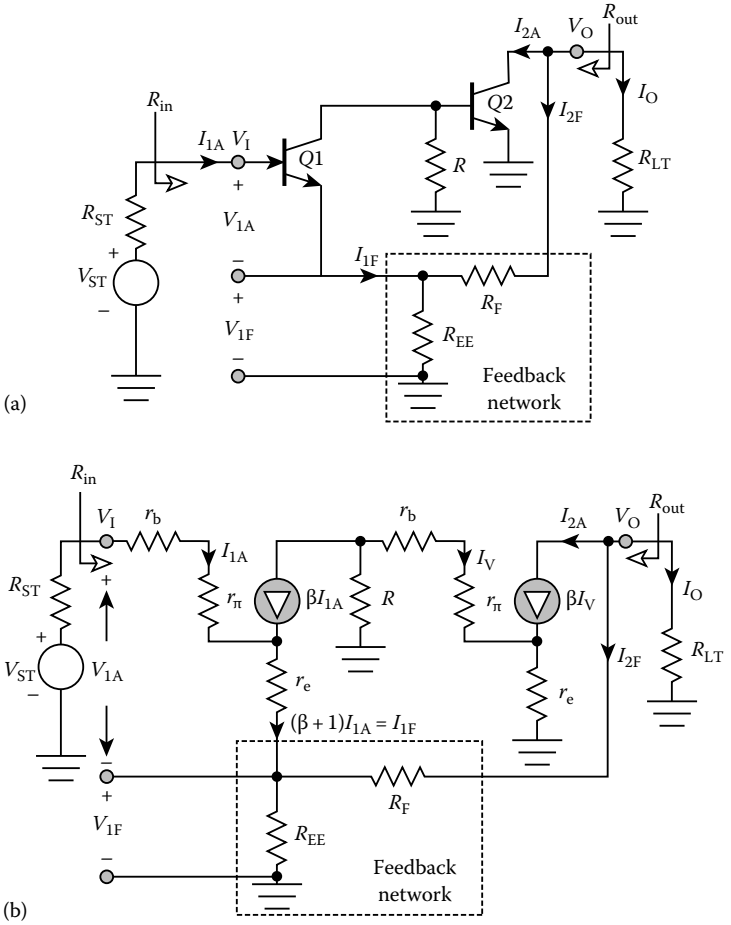

FIGURE 2.1 (a) AC schematic diagram of a bipolar series–shunt feedback amplifier. (b) Low-frequency small-signal equivalent circuit of the feedback amplifier.

is therefore best suited for voltage amplification, in the sense that the closed-loop voltage gain, V_O/V_{ST}, can be made approximately independent of source and load resistances. For large loop gain, this voltage transfer function is also nominally independent of transistor parameters.

Assuming that transistors $Q1$ and $Q2$ are identical devices that are biased identically, Figure 2.1b is the applicable low-frequency equivalent circuit. This equivalent circuit exploits the hybrid-π model [4] of a bipolar junction transistor, subject to the proviso that the forward Early resistance [5] used to emulate base conductivity modulation is sufficiently large to warrant its neglect. Because an infinitely large forward Early resistance places the internal collector resistance (not shown in the figure) of a bipolar junction transistor in series with the current-controlled current source, this collector resistance can be ignored as well.

The equivalent circuit of Figure 2.1b can be reduced to a manageable topology by noting that the ratio of the signal current, I_V, flowing into the base of transistor $Q2$ to the signal current, I_{1A}, flowing into the base of transistor $Q1$ is

$$\frac{I_V}{I_{1A}} \triangleq -K_\beta = -\frac{\beta R}{R + r_b + r_\pi + (\beta + 1)r_e} = -\frac{\alpha R}{r_{ib} + (1 - \alpha)R} \tag{2.1}$$

where

$$\alpha = \frac{\beta}{\beta + 1} \tag{2.2}$$

is the small-signal, short-circuit common base current gain, and

$$r_{ib} = r_e + \frac{r_\pi + r_b}{\beta + 1} \tag{2.3}$$

symbolizes the short-circuit input resistance of a common base amplifier. It follows that the current source βI_v in Figure 2.1b can be replaced by the equivalent current $(-\beta K_\beta I_{1A})$.

A second reduction of the equivalent circuit in Figure 2.1b results when the feedback subcircuit is replaced by a model that reflects the h-parameter relationships

$$\begin{bmatrix} V_{1F} \\ I_{2F} \end{bmatrix} = \begin{bmatrix} h_{if} & h_{rf} \\ h_{ff} & h_{of} \end{bmatrix} \begin{bmatrix} I_{1F} \\ V_O \end{bmatrix} \tag{2.4}$$

where

$V_{1F}(V_O)$ represents the signal voltage developed across the output (input) port of the feedback subcircuit

$I_{1F}(I_{2F})$ symbolizes the corresponding current flowing into the feedback output (input) port

Although any homogeneous set of two-port parameters can be used to model the feedback subcircuit, h-parameters are the most convenient selection herewith. In particular, the feedback amplifier undergoing study is a series–shunt configuration. The h-parameter equivalent circuit represents its input port as a Thévenin circuit and its input port as a Norton configuration, therefore, the h-parameter equivalent circuit is likewise a series–shunt structure.

For the feedback network at hand, which is redrawn for convenience in Figure 2.2a, the h-parameter equivalent circuit is as depicted in Figure 2.2b. The latter diagram exploits the facts that the short-circuit input resistance h_{if} is a parallel combination of the resistance R_{EE} and R_F, and the open-circuit output conductance h_{of} is $1/(R_{EE} + R_F)$. The open-circuit reverse voltage gain h_{rf} is

$$h_{rf} = \frac{R_{EE}}{R_{EE} + R_F} \tag{2.5}$$

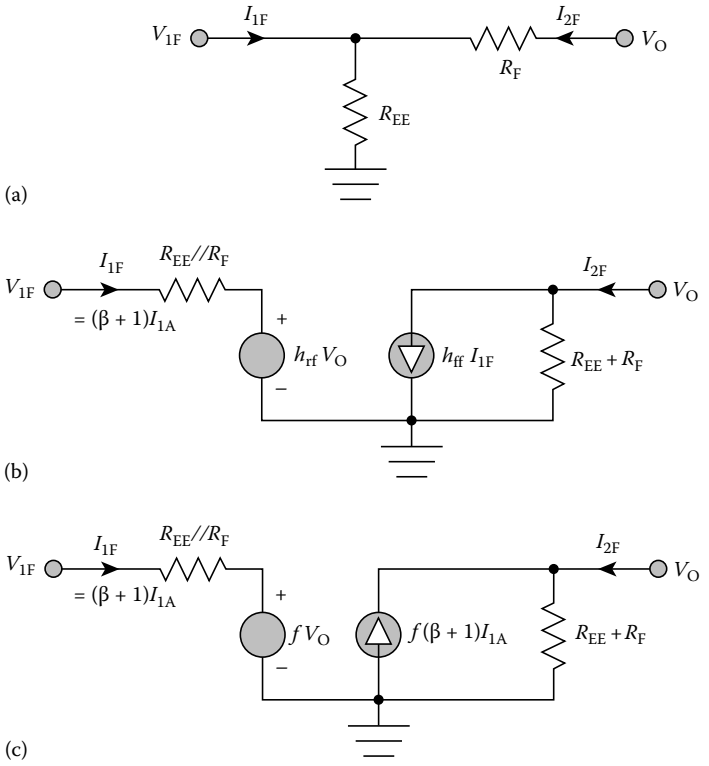

FIGURE 2.2 (a) Feedback subcircuit in the series–shunt feedback amplifier of Figure 2.1a. (b) *h*-Parameter equivalent circuit of the feedback subcircuit. (c) Alternative form of the *h*-parameter equivalent circuit.

while the short-circuit forward current gain h_{ff} is

$$h_{ff} = \frac{R_{EE}}{R_{EE} + R_F} = -h_{rf} \tag{2.6}$$

Figure 2.2c modifies the equivalent circuit in Figure 2.2b in accordance with the following two arguments. First, h_{rf} in Equation 2.5 is recognized as the fraction of the feedback subcircuit input signal that is fed back as a component of the feedback subcircuit output voltage, V_{1F}. But this subcircuit input voltage is identical to the closed-loop amplifier output signal V_O. Moreover, V_{1F} superimposes with the Thévenin input signal applied to the feedback amplifier to establish the amplifier input port voltage, V_{1A}. It follows that h_{rf} is logically referenced as a feedback factor, say *f*, of the amplifier under consideration; that is,

$$h_{rf} = \frac{R_{EE}}{R_{EE} + R_F} \triangleq f \tag{2.7}$$

and by Equation 2.6,

$$h_{ff} = -\frac{R_{EE}}{R_{EE} + R_F} = -f \tag{2.8}$$

Second, the feedback subcircuit output current, I_{1F}, is, as indicated in Figure 2.1b, the signal current, $(\beta + 1)I_{1A}$. Thus, in the model of Figure 2.2b,

$$h_{ff}I_{1F} = -f(\beta + 1)I_{1A} \tag{2.9}$$

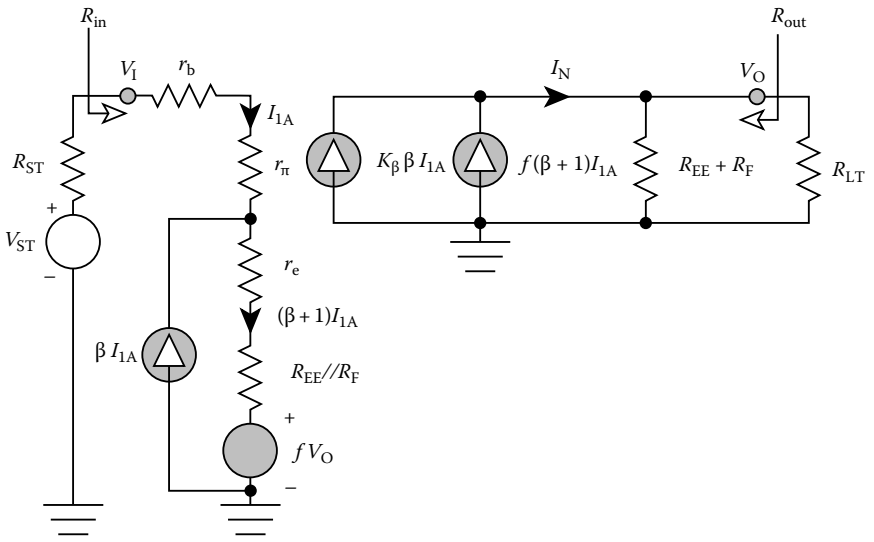

FIGURE 2.3 Modified small-signal model of the series–shunt feedback amplifier.

If the model in Figure 2.2c is used to replace the feedback network in Figure 2.1b the equivalent circuit of the series–shunt feedback amplifier becomes the alternative structure offered in Figure 2.3. In arriving at this model, care has been exercised to ensure that the current flowing through the emitter of transistor $Q1$ is $(\beta + 1)I_{1A}$. It is important to note that the modified equivalent circuit delivers transfer and driving-point impedance characteristics that are identical to those implicit to the equivalent circuit of Figure 2.1b. In particular, the traditional analytical approach to analyzing a series–shunt feedback amplifier tacitly presumes the satisfaction of the Brune condition [6] to formulate a composite structure where the h-parameter matrix is the sum of the respective h-parameter matrices for the open loop and feedback circuits. In contrast, the model of Figure 2.3 derives from Figure 2.1b without invoking the Brune requirement, which is often not satisfied. It merely exploits the substitution theorem; that is, the feedback network in Figure 2.1b is substituted by its h-parameter representation.

In addition to modeling accuracy, the equivalent circuit in Figure 2.3 boasts at least three other advantages. The first is an illumination of the vehicle by which feedback is implemented in the series–shunt configuration. This vehicle is the voltage-controlled voltage source, fV_O, which feeds back a fraction of the output signal to produce a branch voltage that algebraically superimposes with, and thus modifies, the applied source voltage effectively seen by the input port of the open-loop amplifier. Thus, with $f = 0$, no feedback is evidenced, and the model at hand emulates an open-loop configuration. But even with $f = 0$, the transfer and driving-point impedance characteristics of the resultant open-loop circuit are functionally dependent on the feedback elements, R_{EE} and R_F, because appending the feedback network to the open-loop amplifier incurs additional impedance loads at both the input and the output ports of the amplifier.

The second advantage of the subject model is its revelation of the magnitude and nature of feed-forward through the closed loop. In particular, note that the signal current, I_N, driven into the effective load resistance comprised of the parallel combination of $(R_{EE} + R_F)$ and R_{LT}, is the sum of two current components. One of these currents, $\beta K_\beta I_{1A}$, materializes from the transfer properties of the two transistors utilized in the amplifier. The other current, $f(\beta + 1)I_{1A}$, is the feed-forward current resulting from the bilateral nature of the passive feedback network. In general, negligible feed-forward through the feedback subcircuit is advantageous, particularly in high-frequency signal-processing applications. To this end, the model in Figure 2.3 suggests the design requirement,

$$f \ll \alpha K_\beta \tag{2.10}$$

When the resistance, R, in Figure 2.1a is the resistance associated with the output port of a PNP current source used to supply biasing current to the collector of transistor $Q1$ and the base of transistor $Q2$, K_β approaches β, and Equation 2.10 is easily satisfied; however, PNP current sources are undesirable in broadband low-noise amplifiers. In these applications, the requisite biasing current must be supplied by a passive resistance, R, connected between the positive supply voltage and the junction of the $Q1$ collector and the $Q2$ base. Unfortunately, the corresponding value of K_β can be considerably smaller than β, with the result that Equation 2.10 may be difficult to satisfy. Circumvention schemes for this situation are addressed later.

A third attribute of the model in Figure 2.3 is its disposition to an application of signal flow theory. For example, with the feedback factor f selected as the reference parameter for signal flow analysis, the open-loop voltage gain $G_{vo}(R_{ST}, R_{LT})$, of the series–shunt feedback amplifier is computed by setting f to zero. Assuming that Equation 2.10 is satisfied, circuit analysis reveals this gain as

$$G_{vo}(R_{ST}, R_{LT}) = \alpha K_\beta \left[\frac{(R_{EE} + R_F) \| R_{LT}}{r_{ib} + (1 - \alpha) R_{ST} + (R_{EE} \| R_F)} \right] \tag{2.11}$$

The corresponding input and output driving-point resistances, R_{ino} and R_{outo}, respectively, are

$$R_{ino} = r_B + r_\pi + (\beta + 1)(r_E + R_{EE} \| R_F) \tag{2.12}$$

and

$$R_{outo} = R_{EE} + R_F \tag{2.13}$$

It follows that the closed-loop gain $G_v(R_{ST}, R_{LT})$ of the series–shunt feedback amplifier is

$$G_v(R_{ST}, R_{LT}) = \frac{G_{vo}(R_{ST}, R_{LT})}{1 + T} \tag{2.14}$$

where the loop gain T is

$$\begin{aligned} T = fG_{vo}(R_{ST}, R_{LT}) &= \left(\frac{R_{EE}}{R_{EE} + R_F} \right) G_{vo}(R_{ST}, R_{LT}) \\ &= \alpha K_\beta \left(\frac{R_{EE}}{R_{EE} + R_F + R_{LT}} \right) \left[\frac{R_{LT}}{r_{ib} + (1 - \alpha) R_{ST} + (R_{EE} \| R_F)} \right] \end{aligned} \tag{2.15}$$

For $T \gg 1$, which mandates a sufficiently large K_β in Equation 2.11, the closed-loop gain collapses to

$$G_v(R_{ST}, R_{LT}) \approx \frac{1}{f} = 1 + \frac{R_F}{R_{EE}} \tag{2.16}$$

which is independent of active element parameters. Moreover, to the extent that $T \gg 1$ the series–shunt feedback amplifier behaves as an ideal voltage-controlled voltage source in the sense that its closed-loop voltage gain is independent of source and load terminations. The fact that the series–shunt feedback network behaves approximately as an ideal voltage amplifier implies that its closed-loop driving-point input resistance is very large and its closed-loop driving-point output resistance is very small. These facts are confirmed analytically by noting that

$$\begin{aligned} R_{in} = R_{ino}[1 + fG_{vo}(0, R_L)] &\approx fR_{ino}G_{vo}(0, R_L) \\ &= \beta K_\beta \left(\frac{R_{EE}}{R_{EE} + R_F + R_{LT}} \right) R_{LT} \end{aligned} \tag{2.17}$$

and

$$R_{\text{out}} = \frac{R_{\text{outo}}}{1 + fG_{\text{vo}}(R_{\text{S}}, \infty)} \approx \frac{R_{\text{outo}}}{fG_{\text{vo}}(R_{\text{S}}, \infty)} = \left(1 + \frac{R_{\text{F}}}{R_{\text{EE}}}\right)\left[\frac{r_{\text{ib}} + (1-\alpha)R_{\text{ST}} + R_{\text{EE}} \| R_{\text{F}}}{\alpha K_{\beta}}\right] \tag{2.18}$$

To the extent that the interstage biasing resistance, R, is sufficiently large to allow K_{β} to approach β, observe that R_{in} in Equation 2.17 is nominally proportional to β^2, while R_{out} in Equation 2.18 is inversely proportional to β.

2.2.2 Feed-Forward Compensation

When practical design restrictions render the satisfaction of Equation 2.10 difficult, feed-forward problems can be circumvented by inserting an emitter follower between the output port of transistor $Q2$ in the circuit diagram of Figure 2.1a and the node to which the load termination and the input terminal of the feedback subcircuit are incident [2]. The resultant circuit diagram, inclusive now of simple biasing subcircuits, is shown in Figure 2.4. The buffer transistor $Q3$ increases the original short-circuit forward current gain, $K_{\beta}\beta$, of the open-loop amplifier by a factor approaching $(\beta + 1)$, while not altering the feed-forward factor implied by the feedback network in Figure 2.1a. In effect, K_{β} is increased by a factor of almost $(\beta + 1)$, thereby making Equation 2.10 easy to satisfy. Because of the inherently low output resistance of an emitter follower, the buffer also reduces the driving-point output resistance achievable by the original configuration.

The foregoing contentions can be confirmed through an analysis of the small-signal model for the modified amplifier in Figure 2.4. Such an analysis is expedited by noting that the circuit to the left of the current-controlled current source, $K_{\beta}\beta I_{1\text{A}}$, in Figure 2.3 remains applicable. For zero feedback, it follows that the small-signal current $I_{1\text{A}}$ flowing into the base of transistor $Q1$ derives from

$$\left.\frac{I_{1\text{A}}}{V_{\text{ST}}}\right|_{f=0} = \frac{1-\alpha}{r_{\text{ib}} + (1-\alpha)R_{\text{ST}} + (R_{\text{EE}} \| R_{\text{F}})} \tag{2.19}$$

The pertinent small-signal model for the buffered series–shunt feedback amplifier is resultantly the configuration offered in Figure 2.5.

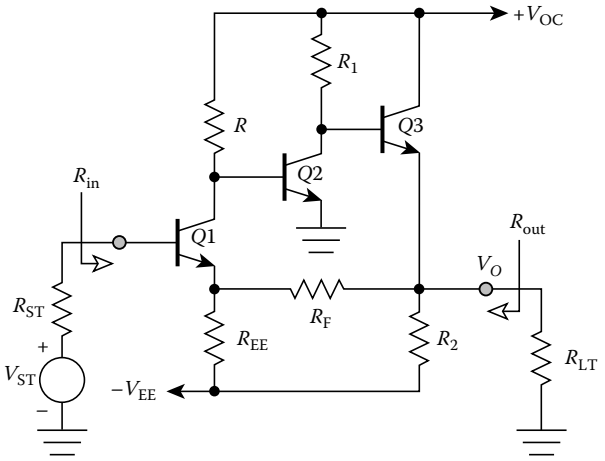

FIGURE 2.4 Series–shunt feedback amplifier that incorporates an emitter follower output stage to reduce the effects of feed-forward through the feedback network.

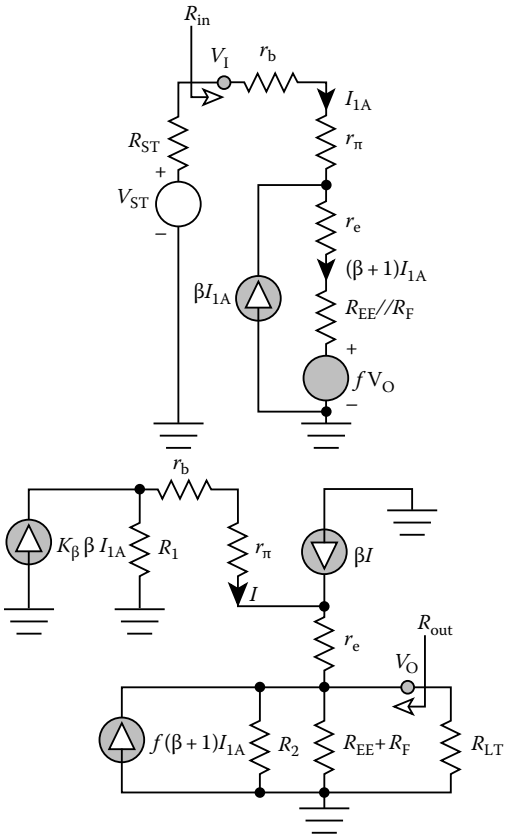

FIGURE 2.5 Small-signal model of the buffered series–shunt feedback amplifier.

Letting

$$R' = R_2 \| (R_{EE} + R_F) \| R_{LT} \tag{2.20}$$

an analysis of the structure in Figure 2.5 reveals

$$\frac{V_O}{I_{1A}} = (\beta + 1)\left[\frac{R'}{R' + r_{ib} + (1-\alpha)R_1}\right]\left\{\alpha K_\beta R_1 + f[r_{ib} + (1-\alpha)R_1]\right\} \tag{2.21}$$

which suggests negligible feed-forward for

$$f \ll \frac{\alpha K_\beta R_1}{r_{ib} + (1-\alpha)R_1} \tag{2.22}$$

Note that for large R_1, Equation 2.22 implies the requirement $f \ll \beta K_\beta$, which is easier to satisfy than is Equation 2.10. Assuming the validity of Equations 2.19, 2.21, and 2.22 deliver an open-loop voltage gain, $G_{vo}(R_{ST}, R_{LT})$, of

$$G_{vo}(R_{ST}, R_{LT}) = \alpha K_\beta \left[\frac{R'}{r_{ib} + (1-\alpha)R_{ST} + R_{EE} \| R_F}\right]\left[\frac{R_1}{R' + r_{ib} + (1-\alpha)R_1}\right] \tag{2.23}$$

Recalling Equation 2.1, which demonstrates that K_β approaches β for large R, Equation 2.23 suggests an open-loop gain that is nominally proportional to β^2 if R_1 is also large.

Using the concepts evoked by Equations 2.17 and 2.18, the driving-point input and output impedances can now be determined. In a typical realization of the buffered series–shunt feedback amplifier, the resistance, R_2, in Figure 2.4 is very large because it is manifested as the output resistance of a common base current sink that is employed to stabilize the operating point of transistor $Q3$. For this situation, and assuming the resistance R_1 is large, the resultant driving-point input resistance is larger than its predecessor input resistance by a factor of approximately $(\beta + 1)$. Similarly, it is easy to show that for large R_1 and large R_2, the driving-point output resistance is smaller than that predicted by Equation 2.18 by a factor approaching $(\beta + 1)$.

Although the emitter follower output stage in Figure 2.4 all but eliminates feed-forward signal transmission through the feedback network and increases both the driving-point input resistance and output conductance, a potential bandwidth penalty is paid by its incorporation into the basic series–shunt feedback cell. The fundamental problem is that if R_1 is too large, potentially significant Miller multiplication of the base–collector transition capacitance of transistor $Q2$ materializes. The resultant capacitive loading at the collector of transistor $Q1$ is exacerbated by large R, which may produce a dominant pole at a frequency that is too low to satisfy closed-loop bandwidth requirements. The bandwidth problem may be mitigated by coupling resistance R_1 to the collector of $Q2$ through a common base cascode. This stage appears as transistor $Q4$ in Figure 2.6.

Unfortunately, the use of the common base cascode indicated in Figure 2.6 may produce an open-loop amplifier with transfer characteristics that do not emulate a dominant pole response. In other words, the frequency of the compensated pole established by capacitive loading at the collector of transistor $Q1$ may be comparable to the frequencies of poles established elsewhere in the circuit, and particularly at the base node of transistor $Q1$. In this event, frequency compensation aimed toward achieving acceptable closed-loop damping can be implemented by replacing the feedback resistor R_F with the parallel combination of R_F and a feedback capacitance, say C_F, as indicated by the dashed branch in Figure 2.6. The resultant frequency-domain feedback factor $f(s)$ is

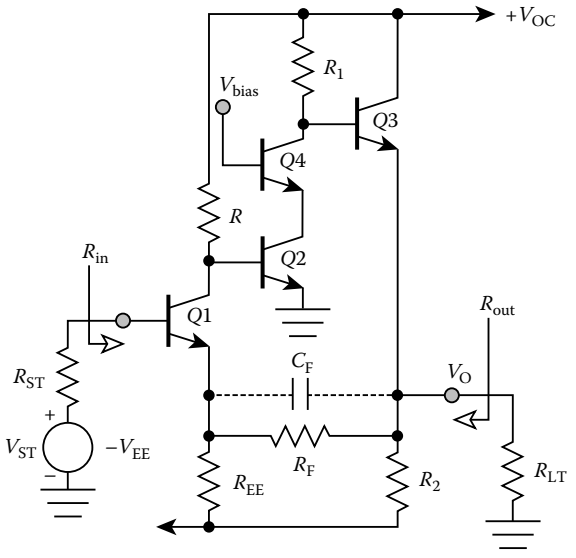

FIGURE 2.6 Buffered series–shunt feedback amplifier with common base cascode compensation of the common emitter amplifier formed by transistor $Q2$. A feedback zero is introduced by the capacitance C_F to achieve acceptable closed-loop damping.

$$f(s) = f\left[\frac{1+\frac{s}{z}}{1+\frac{fs}{z}}\right] \tag{2.24}$$

where

f is the feedback factor given by Equation 2.7

z is the frequency of the introduced compensating zero

$$z = \frac{1}{R_F C_F} \tag{2.25}$$

The pole in Equation 2.24 is inconsequential if the closed-loop amplifier bandwidth B_{cl} satisfies the restriction, $fB_{cl}R_FC_F = B_{cl}(R_{EE}||R_F)C_F \ll 1$.

2.3 Shunt–Series Feedback Amplifier

Although the series–shunt circuit functions as a voltage amplifier, the shunt–series configuration (see the ac schematic diagram depicted in Figure 2.7a) is best suited as a current amplifier. In the subject circuit,

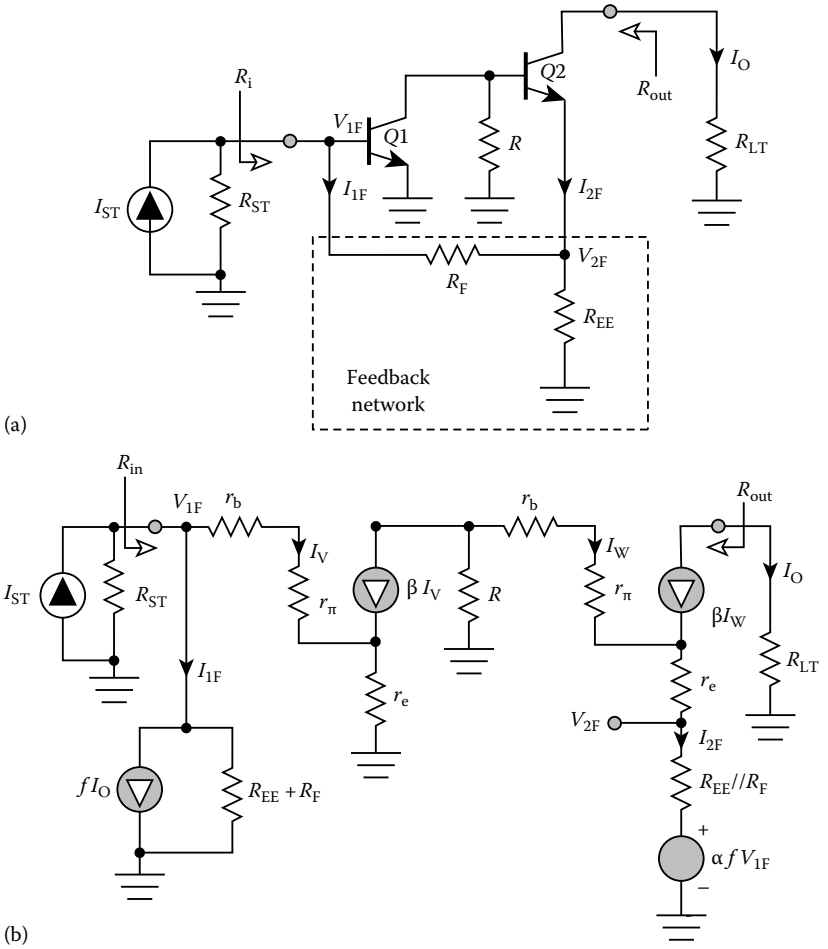

FIGURE 2.7 (a) AC schematic diagram of a bipolar shunt–series feedback amplifier. (b) Low-frequency small-signal equivalent circuit of the feedback amplifier.

the $Q2$ emitter current, which is a factor of $(1/\alpha)$ of the output signal current, I_O, is sampled by the feedback network formed of the resistances, R_{EE} and R_F. The sampled current is fed back as a current in shunt with the amplifier input port. Because output current is fed back as a current to a current-driven input port, the resultant driving-point output resistance is large, and the driving-point input resistance is small. These characteristics allow for a closed-loop current gain, $G_1(R_{ST}, R_{LT}) = I_O/I_{ST}$, that is relatively independent of source and load resistances and insensitive to transistor parameters.

In the series–shunt amplifier, h-parameters were selected to model the feedback network because the topology of an h-parameter equivalent circuit is, similar to the amplifier in which the feedback network is embedded, a series shunt, or Thévenin–Norton, topology. In analogous train of thought compels the use of g-parameters to represent the feedback network in Figure 2.7a. With reference to the branch variables defined in the schematic diagram,

$$\begin{bmatrix} I_{1F} \\ V_{2F} \end{bmatrix} = \begin{bmatrix} \frac{1}{R_{EE}+R_F} & -\frac{R_{EE}}{R_{EE}+R_F} \\ \frac{R_{EE}}{R_{EE}+R_F} & R_{EF} \| R_F \end{bmatrix} \begin{bmatrix} V_{1F} \\ I_{2F} \end{bmatrix} \tag{2.26}$$

Noting that the feedback network current, I_{2F}, relates to the amplifier output current, I_O, in accordance with

$$I_{2F} = -\frac{I_O}{\alpha} \tag{2.27}$$

and letting the feedback factor, f, be

$$f = \frac{1}{\alpha}\left(\frac{R_{EE}}{R_{EE}+R_F}\right) \tag{2.28}$$

the small-signal equivalent circuit of shunt–series feedback amplifier becomes the network diagrammed in Figure 2.7b. Note that the voltage-controlled voltage source, $\alpha f V_{1F}$, models the feed-forward transfer mechanism of the feedback network, where the controlling voltage, V_{1F}, is

$$V_{1F} = [r_b + r_\pi + (\beta+1)r_c]I_V = (\beta+1)r_{ib}I_V \tag{2.29}$$

An analysis of the model in Figure 2.7b confirms that the second-stage, signal-base current I_W relates to the first-stage, signal-base current I_v as

$$\frac{I_W}{I_V} = -\frac{\alpha(R + f r_{ib})}{r_{ib} + R_{EE} \| R_F + (1-\alpha)R} \tag{2.30}$$

For

$$f \ll \frac{R}{r_{ib}} \tag{2.31}$$

which offsets feed-forward effects,

$$\frac{I_W}{I_V} \approx -\frac{\alpha R}{r_{ib} + R_{EE} \| R_F + (1-\alpha)R} \triangleq -K_r \tag{2.32}$$

Observe that the constant K_r tends toward β for large R, as can be verified by an inspection of Figure 2.7b.

Using Equation 2.32, the open-loop current gain, found by setting f to zero, is

$$G_{IO}(R_{ST}, R_{LT}) = \frac{I_O}{I_{ST}}\bigg\|_{f=0} = \alpha K_r \left\{ \frac{R_{ST} \| (R_{EE} + R_F)}{r_{ib} + (1-\alpha)[R_{ST} \| (R_{EE} + R_F)]} \right\} \tag{2.33}$$

and recalling Equation 2.28, the loop gain T is

$$\begin{aligned} T = fG_{IO}(R_{ST}, R_{LT}) &= \frac{1}{\alpha}\left(\frac{R_{EE}}{R_{EE} + R_F}\right) G_{IO}(R_{ST}, R_{LT}) \\ &= K_r \left(\frac{R_{EE}}{R_{EE} + R_F + R_{ST}}\right) \left\{ \frac{R_{ST}}{r_{ib} + (1-\alpha)[R_{ST} \| (R_{EE} + R_F)]} \right\} \end{aligned} \tag{2.34}$$

By inspection of the model in Figure 2.7b, the open-loop input resistance, R_{ino}, is

$$R_{ino} = (R_{EE} + R_F) \| [(\beta + 1) r_{ib}] \tag{2.35}$$

and, within the context of an infinitely large Early resistance, the open-loop output resistance, R_{outo}, is infinitely large.

The closed-loop current gain of the shunt–series feedback amplifier is now found to be

$$G_1(R_{ST}, R_{LT}) = \frac{G_{IO}(R_{ST}, R_{LT})}{1 + T} \approx \alpha \left(1 + \frac{R_F}{R_{EE}}\right) \tag{2.36}$$

where the indicated approximation exploits the presumption that the loop gain T is much larger than one. As a result of the large loop-gain assumption, note that the closed-loop gain is independent of the source and load resistances and is invulnerable to uncertainties and perturbations in transistor parameters. The closed-loop output resistance, which exceeds its open-loop counterpart, remains infinitely large. Finally, the closed-loop driving-point input resistance of the shunt–series amplifier is

$$R_{in} = \frac{R_{ino}}{1 + fG_{IO}(\infty, R_{LT})} \approx \left(1 + \frac{R_F}{R_{EE}}\right) \frac{r_{ib}}{K_r} \tag{2.37}$$

2.4 Shunt–Shunt Feedback Amplifier

2.4.1 Circuit Modeling and Analysis

The ac schematic diagram of the third type of single-loop feedback amplifier, the shunt–shunt triple, is drawn in Figure 2.8a. A cascade interconnection of three transistors $Q1$, $Q2$, and $Q3$, forms the open loop, while the feedback subcircuit is the single resistance, R_F. This resistance samples the output voltage, V_O, as a current fed back to the input port. Output voltage is fed back as a current to a current-driven input port, so both the driving-point input and output resistances are very small. Accordingly, the circuit operates best as a transresistance amplifier in that its closed-loop transresistance, $R_M(R_{ST}, R_{LT}) = V_O/I_{ST}$, is nominally invariant with source resistance, load resistance, and transistor parameters.

The shunt–shunt nature of the subject amplifier suggests the propriety of y-parameter modeling of the feedback network. For the electrical variables indicated in Figure 2.8a,

$$\begin{bmatrix} I_{1F} \\ I_{2F} \end{bmatrix} = \begin{bmatrix} \frac{1}{R_F} & -\frac{1}{R_F} \\ -\frac{1}{R_F} & \frac{1}{R_F} \end{bmatrix} \begin{bmatrix} V_{1F} \\ V_O \end{bmatrix} \tag{2.38}$$

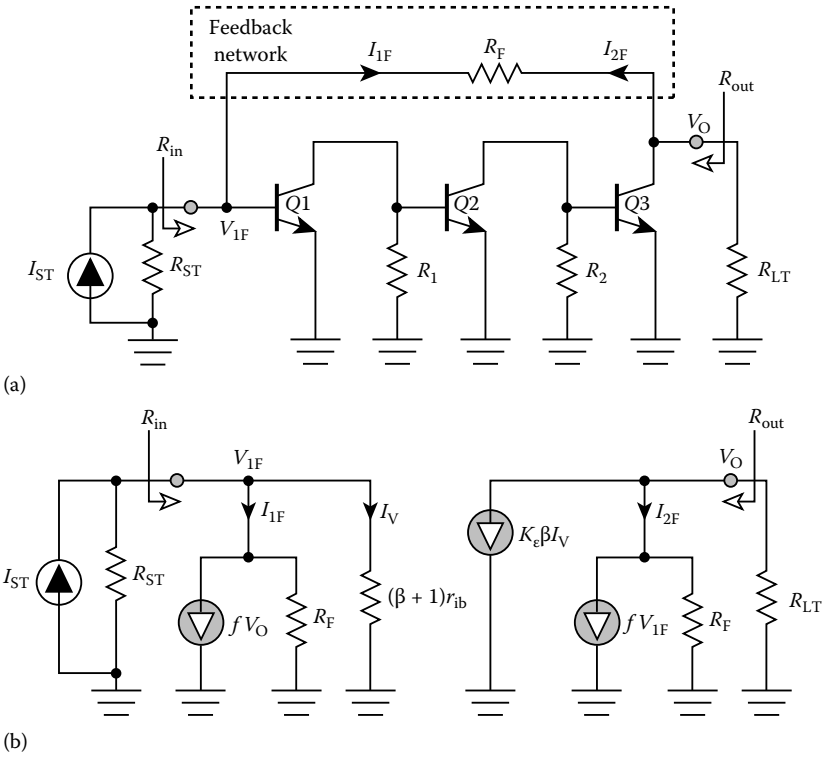

FIGURE 2.8 (a) AC schematic diagram of a bipolar shunt–shunt feedback amplifier. (b) Low-frequency small-signal equivalent circuit of the feedback amplifier.

which implies that a resistance, R_F, loads both the input and the output ports of the open-loop three-stage cascade. The short-circuit admittance relationship in Equation 2.38 also suggests a feedback factor, f, given by

$$f = \frac{1}{R_F} \tag{2.39}$$

The foregoing observations and the small-signal modeling experience gained with the preceding two feedback amplifiers lead to the equivalent circuit submitted in Figure 2.8b. For analytical simplicity, the model reflects the assumption that all three transistors in the open loop have identical small-signal parameters. Moreover, the constant, K_ε, which symbolizes the ratio of the signal-base current flowing into transistor $Q3$ to the signal-base current conducted by transistor $Q1$, is given by

$$K_\varepsilon = \left[\frac{\alpha R_1}{r_{ib} + (1-\alpha)R_1}\right]\left[\frac{\alpha R_2}{r_{ib} + (1-\alpha)R_2}\right] \tag{2.40}$$

Finally, the voltage-controlled current source, fV_{1F}, accounts for feed-forward signal transmission through the feedback network. If such feed-forward is to be negligible, the magnitude of this controlled current must be significantly smaller than $K_\varepsilon\beta I_v$, a current that emulates feed-forward through the open-loop amplifier. Noting that the input port voltage, V_{1F}, in the present case remains the same as that specified by Equation 2.29, negligible feed-forward through the feedback network mandates

$$R_F \gg \frac{r_{ib}}{\alpha K_\varepsilon} \tag{2.41}$$

Because the constant K_ε in Equation 2.40 tends toward β^2 if R_1 and R_2 are large resistances, Equation 2.41 is relatively easy to satisfy.

With feed-forward through the feedback network ignored, an analysis of the model in Figure 2.8b provides an open-loop transresistance, $R_{MO}(R_{ST}, R_{LT})$, of

$$R_{MO}(R_{ST}, R_{LT}) = -\alpha K_\varepsilon \left[\frac{R_F \| R_{ST}}{r_{ib}(1-\alpha)(R_F \| R_{ST})}\right](R_F \| R_{LT}) \tag{2.42}$$

while the loop gain is

$$\begin{aligned} T = fR_{MO}(R_{ST}, R_{LT}) &= -\frac{R_{MO}(R_{ST}, R_{LT})}{R_F} \\ &= \alpha K_\varepsilon \left[\frac{R_{ST}}{R_{ST}+R_F}\right]\left[\frac{R_F \| R_{ST}}{r_{ib}(1-\alpha)(R_F \| R_{ST})}\right] \end{aligned} \tag{2.43}$$

For $T \gg 1$, the corresponding closed-loop transresistance $R_M(R_{ST}, R_{LT})$ is

$$R_M(R_{ST}, R_{LT}) = \frac{R_{MO}(R_{ST}, R_{LT})}{1+T} \approx -R_F \tag{2.44}$$

Finally, the approximate driving-point input and output resistances are, respectively,

$$R_{in} \approx \left(\frac{r_{ib}}{\alpha K_\varepsilon}\right)\left(1 + \frac{R_F}{R_{LT}}\right) \tag{2.45}$$

$$R_{out} \approx \left[\frac{r_{ib} + (1-\alpha)(R_F \| R_{ST})}{\alpha K_\varepsilon}\right]\left(1 + \frac{R_F}{R_{ST}}\right) \tag{2.46}$$

2.4.2 Design Considerations

Because the shunt–shunt triple uses three gain stages in the open-loop amplifier, its loop gain is significantly larger than the loop gains provided by either of the previously considered feedback cells. Accordingly, the feedback triple affords superior desensitization of the closed-loop gain with respect to transistor parameters and source and load resistances; but the presence of a cascade of three common emitter gain stages in the open loop of the amplifier complicates frequency compensation and limits the 3 dB bandwidth. The problem is that, although each common emitter stage approximates a dominant pole amplifier, none of the critical frequencies in the cluster of poles established by the cascade interconnection of these units is likely to be dominant. The uncompensated closed loop is therefore predisposed to unacceptable underdamping, thereby making compensation via an introduced feedback zero difficult.

At least three compensation techniques can be exploited to optimize the performance of the shunt–shunt feedback amplifier [3,7–9]. The first of these techniques entail pole splitting of the open-loop interstage through the introduction of a capacitance, C_c, between the base and the collector terminals of transistor $Q2$, as depicted in the ac schematic diagram of Figure 2.9. In principle, pole splitting can be invoked on any one of the three stages of the open loop; but pole splitting of the interstage is most desirable because such compensation of the first stage proves effective only for large source resistance. Moreover, the resultant dominant pole becomes dependent on the source termination. On the other hand, pole splitting of the third stage produces a dominant pole that is sensitive to load termination. In conjunction with pole splitting, a feedback zero can be introduced, if necessary, to increase closed-loop damping by replacing the feedback resistance, R_F, by the parallel combination of R_F and a feedback

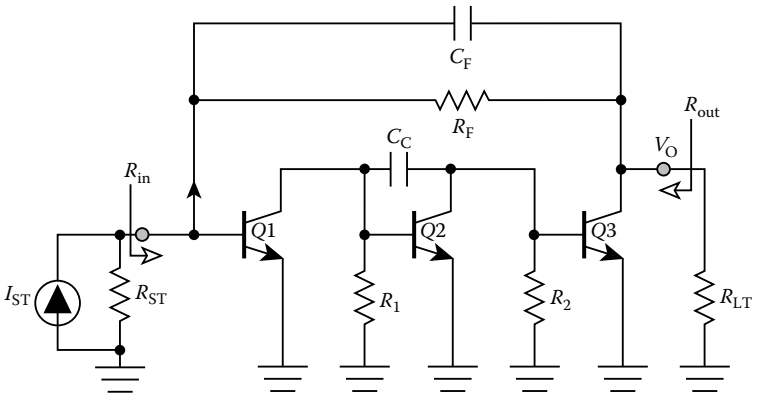

FIGURE 2.9 AC schematic diagram of a frequency-compensated shunt–shunt triple. The capacitance, C_c, achieves open-loop pole splitting, while the capacitance, C_F, implements a compensating feedback network zero.

capacitance, C_F, as illustrated in Figure 2.9. This compensation produces left-half-plane zero in the feedback factor at $s = -(1/R_F)$.

A second compensation method broadbands the interstage of the open-loop amplifier through local current feedback introduced by the resistance, R_X, in Figure 2.10. Simultaneously, the third stage is broadbanded by way of a common base cascode transistor $Q4$. Because emitter degeneration of the interstage reduces the open-loop gain, an emitter follower (transistor $Q5$) is embedded between the feedback network and the output port of the open-loop third stage. As in the case of the series–shunt feedback amplifier, the first-order effect of this emitter follower is to increase feed-forward signal transmission through the open-loop amplifier by a factor that approaches $(\beta + 1)$.

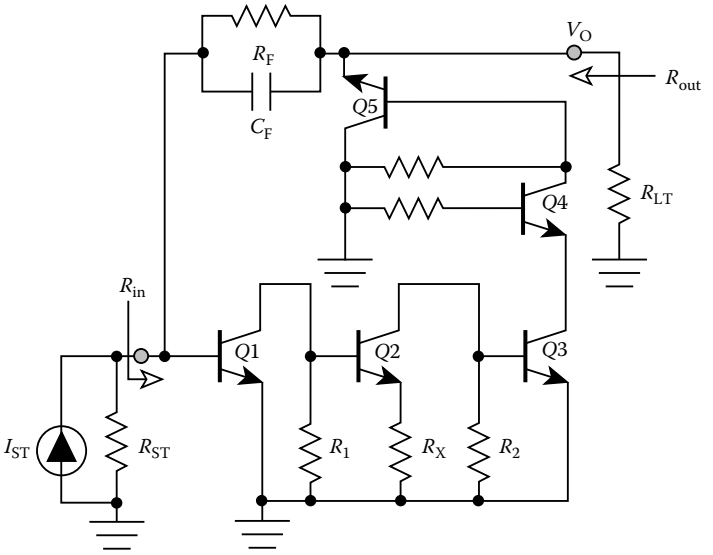

FIGURE 2.10 AC schematic diagram of an alternative compensation scheme for the shunt–shunt triple. Transistor $Q2$ is broadbanded by the emitter degeneration resistance R_X and transistor $Q3$ is broadbanded by the common base cascode transistor $Q4$. The emitter follower transistor, $Q5$, minimizes feed-forward signal transmission through the feedback network.

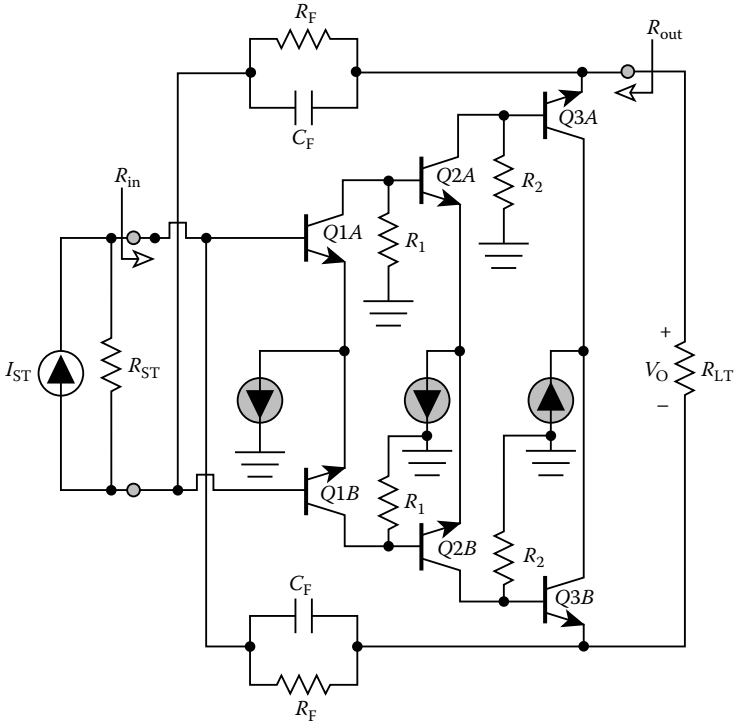

FIGURE 2.11 AC schematic diagram of a differential realization of the compensated shunt–shunt feedback amplifier. The balanced stage boasts improved bandwidth over its single-ended counterpart because of its use of only two high-gain stages in the open loop. The emitter follower pair *Q*3*A* and *Q*3*B* diminishes feed-forward transmission through the feedback network composed of the shunt interconnection of resistor R_F with capacitor C_F.

A final compensation method is available if shunt–shunt feedback is implemented as the balanced differential architecture (see the ac schematic diagram offered in Figure 2.11). By exploiting the antiphase nature of opposite collectors in a balanced common emitter topology, a shunt–shunt feedback amplifier can be realized with only two gain stages in the open loop. The resultant closed-loop 3 dB bandwidth is invariably larger than that of its three-stage single-ended counterpart, because the open loop is now characterized by only two, as opposed to three, fundamental critical frequencies. Because the forward gain implicit to two amplifier stages is smaller than the gain afforded by three stages of amplification, a balanced emitter follower (transistors *Q*3*A* and *Q*3*B*) is incorporated to circumvent the deleterious relative effects of feed-forward signal transmission through the feedback network.

2.5 Series–Series Feedback Amplifier

Figure 2.12a is the ac schematic diagram of the series–series feedback amplifier. Three transistors, *Q*1, *Q*2, and *Q*3, are embedded in the open-loop amplifier, while the feedback subcircuit is the wye configuration formed of the resistances R_X, R_Y, and R_Z. Although it is possible to realize series–series feedback via emitter degeneration of a single-stage amplifier, the series–series triple offers substantially more loop gain and thus better desensitization of the forward gain with respect to both transistor parameters and source and load terminations.

In Figure 2.12a, the feedback wye senses the *Q*3 emitter current, which is a factor of $(1/\alpha)$ of the output signal current I_O. This sampled current is fed back as a voltage in series with the emitter of *Q*1. Because output current is fed back as a voltage to a voltage-driven input port, both the driving-point input and

output resistances are large. The circuit is therefore best suited as a transconductance amplifier in the sense that for large loop gain, its closed-loop transconductance, $G_M(R_{ST}, R_{LT}) = I_O/V_{ST}$, is almost independent of the source and load resistances.

The series–series topology of the subject amplifier conduces *z*-parameter modeling of the feedback network. Noting the electrical variables delineated in the diagram of Figure 2.12a,

$$\begin{bmatrix} V_{1F} \\ V_{2F} \end{bmatrix} = \begin{bmatrix} R_X + R_Z & R_Z \\ R_Z & R_Y + R_Z \end{bmatrix} \begin{bmatrix} I_{1F} \\ I_{2F} \end{bmatrix} \tag{2.47}$$

Equation 2.47 suggests that the open-circuit feedback network resistances loading the emitters of transistors $Q1$ and $Q3$ are $(R_X + R_Z)$ and $(R_Y + R_Z)$, respectively, and the voltage fed back to the emitter of transistor $Q1$ is $R_Z I_{2F}$. Because the indicated feedback network current I_{2F} is $(-I_O/\alpha)$, this fed back voltage is equivalent to $(-R_Z I_O/\alpha)$, which suggests a feedback factor, f, of

$$f = \frac{R_Z}{\alpha} \tag{2.48}$$

Finally, the feed-forward through the feedback network if $R_Z I_{1F}$. Because I_{1F} relates to the signal-base current I_V flowing into transistor $Q1$ by $I_{1F} = (\beta + 1)I_V$, this feed-forward voltage is also expressible

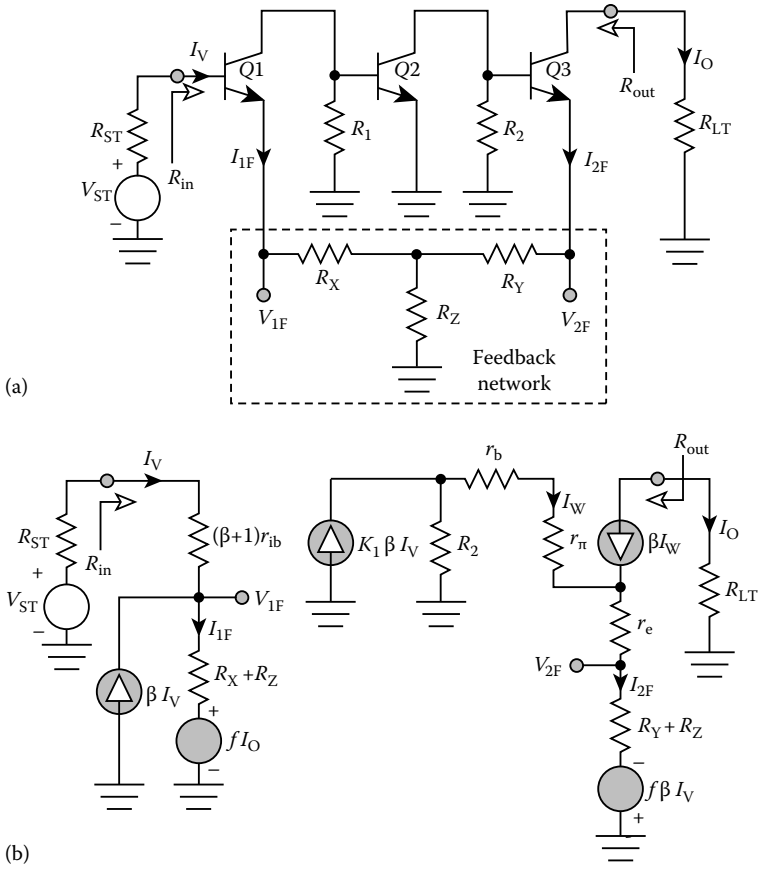

FIGURE 2.12 (a) AC schematic diagram of a bipolar series–series feedback amplifier. (b) Low-frequency, small-signal equivalent circuit of the feedback amplifier.

as $(-f\beta I_V)$. The foregoing observations and the hybrid-π method of a bipolar junction transistor produce the small-signal model depicted in Figure 2.12b. In this model, all transistors are presumed to have identical corresponding small-signal parameters, and the constant, K_1, is

$$K_1 = \frac{\alpha R_1}{r_{ib} + (1-\alpha)R_1} \tag{2.49}$$

An analysis of the model of Figure 2.12b confirms that the ratio of the signal current, I_W, flowing into the base of transistor $Q3$ to the signal-base current, I_V, of transistor $Q1$ is

$$\frac{I_W}{I_V} = \frac{\alpha K_1 R_2 \left(1 + \frac{f}{K_1 R_2}\right)}{r_{ib} + R_Y + R_Z + (1-\alpha)R_2} \tag{2.50}$$

This result suggests that feed-forward effects through the feedback network are negligible if $|f| \ll K_1 R_2$, which requires

$$R_Z \ll \alpha K_1 R_2 \tag{2.51}$$

In view of the fact that the constant, K_1, approaches β for large values of the resistance, R_1, Equation 2.51 is not a troublesome inequality. Introducing a second constant, K_2, such that

$$K_2 \triangleq \frac{\alpha R_2}{r_{ib} + R_Y + R_Z + (1-\alpha)R_2} \tag{2.52}$$

the ratio I_W/I_V in Equation 2.50 becomes

$$\frac{I_W}{I_V} \approx K_1 K_2 \tag{2.53}$$

assuming Equation 2.51 is satisfied.

Given the propriety of Equation 2.50 and using Equation 2.53 the open-loop transconductance, $G_{MO}(R_{ST}, R_{LT})$ is found to be

$$G_{MO}(R_{ST}, R_{LT}) = -\left\{\frac{\alpha K_1 K_2}{r_{ib} + R_X + R_Z + (1-\alpha)R_{ST}}\right\} \tag{2.54}$$

and recalling Equation 2.48, the loop gain T is

$$T = -\left(\frac{R_Z}{\alpha}\right) G_{MO}(R_{ST}, R_{LT}) = \frac{K_1 K_2 R_Z}{r_{ib} + R_X + R_Z + (1-\alpha)R_{ST}} \tag{2.55}$$

It follows that for $T \gg 1$, the closed-loop transconductance is

$$G_M(R_{ST}, R_{LT}) = \frac{G_{MO}(R_{ST}, R_{LT})}{1+T} \approx -\frac{\alpha}{R_Z} \tag{2.56}$$

The Early resistance is large enough to justify its neglect, so the open loop, and thus the closed-loop, driving-point output resistances are infinitely large. On the other hand, the closed-loop driving-point input resistance R_{in} can be shown to be

$$R_{in} = R_{ino}[1 + fG_{MO}(0, R_{LT})] \approx (\beta + 1)K_1 K_2 R_Z \tag{2.57}$$

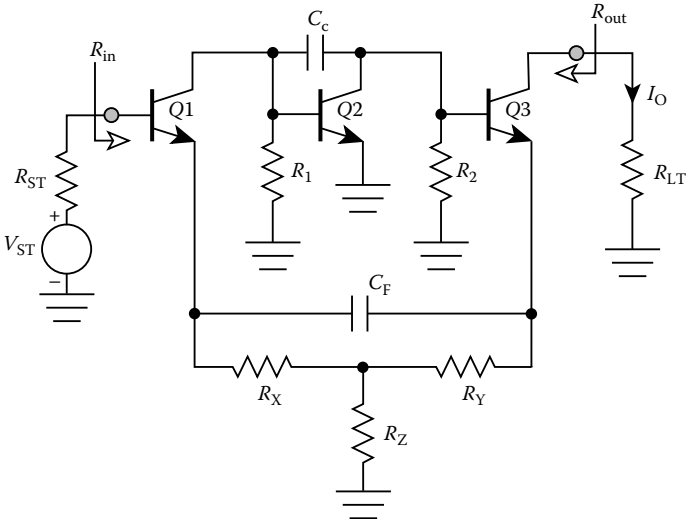

FIGURE 2.13 AC schematic diagram of a frequency-compensated series–series feedback triple. The capacitance, C_c, achieves pole splitting in the open-loop configuration, while the capacitance, C_F, introduces a zero in the feedback factor of the closed-loop amplifier.

Similar to its shunt–shunt counterpart, the series–series feedback amplifier uses three open-loop gain stages to produce large loop gain. However, also similar to the shunt–shunt triple, frequency compensation via an introduced feedback zero is difficult unless design care is exercised to realize a dominant pole open-loop response. To this end, the most commonly used compensation is pole splitting in the open loop, combined, if required, with the introduction of a zero in the feedback factor. The relevant ac schematic diagram appears in Figure 2.13 where the indicated capacitance, C_c, inserted across the base–collector terminals of transistor $Q3$ achieves the aforementioned pole splitting compensation. The capacitance, C_F, in Figure 2.13 delivers a frequency-dependent feedback factor, $f(s)$ of

$$f(s) = f\left[\frac{1+\frac{s}{z}}{1+\frac{s}{z}\left(\frac{R_Z}{R_Z+R_X\|R_Y}\right)}\right] \tag{2.58}$$

where the frequency z of the introduced zero derives from

$$\frac{1}{z} = (R_X + R_Y)\left(1+\frac{R_X\|R_Y}{R_Z}\right)C_F \tag{2.59}$$

The corresponding pole in Equation 2.58 is insignificant if the closed-loop amplifier is designed for a bandwidth, B_{cl} that satisfies the inequality, $B_{c1}(R_X + R_Y)C_F \ll 1$.

As is the case with shunt–shunt feedback, an alternative frequency compensation scheme is available if series–series feedback is implemented as a balanced differential architecture. The pertinent ac schematic diagram, inclusive of feedback compensation, appears in Figure 2.14. This diagram exploits the fact that the feedback wye consisting of the resistances, R_X, R_Y, and R_Z as utilized in the single-ended configurations of Figures 2.12a and 2.13 can be transformed into the feedback delta of Figure 2.15. The terminal volt–ampere characteristics of the two networks in Figure 2.15 are identical, provided that the delta subcircuit elements, R_F, R_U, and R_V, are chosen in accordance with

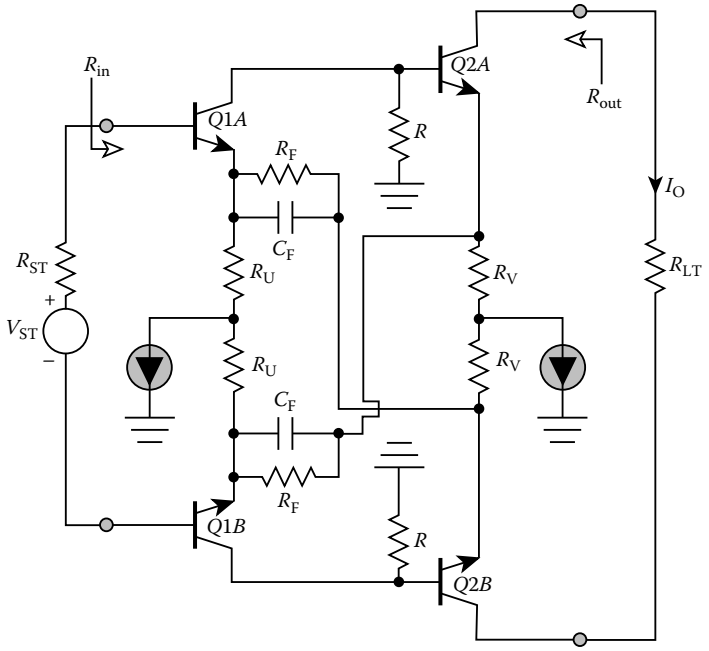

FIGURE 2.14 AC schematic diagram of a balanced differential version of the series–series feedback amplifier. The circuit utilizes only two, as opposed to three, gain stages in the open loop.

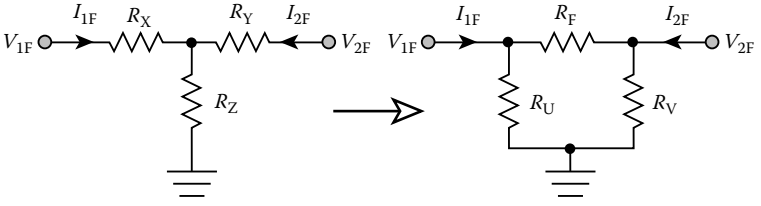

FIGURE 2.15 Transformation of the wye feedback subcircuit used in the amplifier of Figure 2.13 to the delta subcircuit exploited in Figure 2.14. The resistance transformation equations are given by Equations 2.60 through 2.62.

$$R_F = (R_X + R_Y)\left(1 + \frac{R_X \| R_Y}{R_Z}\right) \tag{2.60}$$

$$\frac{R_U}{R_F} = \frac{R_Z}{R_Y} \tag{2.61}$$

$$\frac{R_V}{R_F} = \frac{R_Z}{R_X} \tag{2.62}$$

2.6 Dual-Loop Feedback

As mentioned previously, a simultaneous control of the driving-point I/O resistances, as well as the closed-loop gain, mandates the use of dual global loops comprised of series and shunt feedback signal paths. The two global dual-loop feedback architectures are the series–series/shunt–shunt feedback amplifier and the series–shunt/shunt–series feedback amplifier. In Sections 2.6.1 and 2.6.2, both of

these units are studied by judiciously applying the relevant analytical results established earlier for pertinent single-loop feedback architectures. The ac schematic diagrams of these respective circuit realizations are provided, and engineering design considerations are offered.

2.6.1 Series–Series/Shunt–Shunt Feedback Amplifier

Figure 2.16 is a behavioral abstraction of the series–series/shunt–shunt feedback amplifier. Two port z parameters are used to model the series–series feedback subcircuit, for which feed-forward is tacitly ignored and the feedback factor associated with its current-controlled voltage source is f_{ss}. On the other hand, y parameters model the shunt–shunt feedback network, where the feedback factor relative to its voltage-controlled current source is f_{pp}. As in the series–series network, feed-forward in the shunt–shunt subcircuit is presumed negligible. The four-terminal amplifier around which the two feedback units are connected has an open loop (meaning $f_{ss} = 0$ and $f_{pp} = 0$, but with the loading effects of both feedback circuits considered) transconductance of $G_{MO}(R_{ST}, R_{LT})$.

With f_{pp} set to zero to deactivate shunt–shunt feedback, the resultant series–series feedback network is a transconductance amplifier with a closed-loop transconductance, $G_{MS}(R_{ST}, R_{LT})$, is

$$G_{MS}(R_{ST}, R_{LT}) = \frac{I_O}{V_{ST}} = \frac{G_{MO}(R_{ST}, R_{LT})}{1 + f_{ss}G_{MO}(R_{ST}, R_{LT})} \approx \frac{1}{f_{ss}} \tag{2.63}$$

where the loop gain, $f_{ss}G_{MO}(R_{ST}, R_{LT})$, is presumed much larger than one, and the loading effects of both the series–series feedback subcircuit and the deactivated shunt–shunt feedback network are incorporated into $G_{MO}(R_{ST}, R_{LT})$. The transresistance, $R_{MS}(R_{ST}, R_{LT})$, implied by Equation 2.63, which expedites the study of the shunt–shunt component of the feedback configuration, is

$$R_{MS}(R_{ST}, R_{LT}) = \frac{V_O}{I_{ST}} = R_{ST}R_{LT}\frac{I_O}{V_{ST}} \approx \frac{R_{ST}R_{LT}}{f_{ss}} \tag{2.64}$$

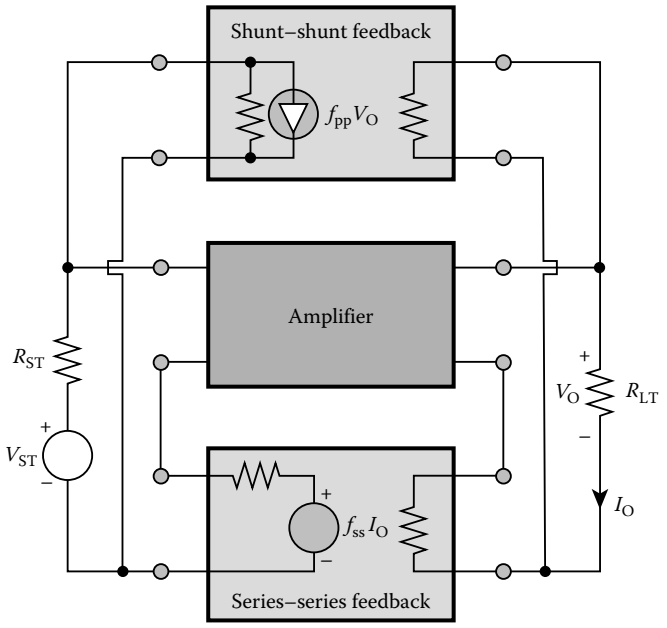

FIGURE 2.16 System-level diagram of a series–series/shunt–shunt dual-loop feedback amplifier. Note that feed-forward signal transmission through either feedback network is ignored.

The series–series feedback input and output resistances R_{ins} and R_{outs}, respectively, are large and given by

$$R_{ins} = R_{ino}[1 + f_{ss}G_{MO}(0, R_{LT})] \tag{2.65}$$

and

$$R_{outs} = R_{outo}[1 + f_{ss}G_{MO}(R_{ST}, 0)] \tag{2.66}$$

where the zero feedback ($f_{ss} = 0$ and $f_{pp} = 0$) values, R_{ino} and R_{outo}, of these driving-point quantities are computed with due consideration given to the loading effects imposed on the amplifier by both feedback subcircuits.

When shunt–shunt feedback is applied around the series–series feedback cell, the configuration becomes a transresistance amplifier. The effective open-loop transresistance is $R_{MS}(R_{ST}, R_{LT})$, as defined by Equation 2.64. Noting a feedback of f_{pp}, the corresponding closed-loop transresistance is

$$R_M(R_{ST}, R_{LT}) \approx \frac{\frac{R_{ST}R_{LT}}{f_{ss}}}{1 + f_{pp}\left(\frac{R_{ST}R_{LT}}{f_{ss}}\right)} \tag{2.67}$$

which is independent of amplifier model parameters, despite the unlikely condition of an effective loop gain $f_{pp}R_{ST}R_{LT}/f_{ss}$ that is much larger than 1. It should be interjected, however, that Equation 2.67 presumes negligible feed-forward through the shunt–shunt feedback network. This presumption may be inappropriate owing to the relatively low closed-loop gain afforded by the series–series feedback subcircuit. Ignoring this potential problem temporarily, Equation 2.67 suggests a closed-loop voltage gain $A_V(R_{ST}, R_{LT})$ of

$$A_V(R_{ST}, R_{LT}) = \frac{V_O}{V_S} = \frac{R_M(R_{ST}, R_{LT})}{R_{ST}} \approx \frac{R_{LT}}{f_{ss} + f_{pp}R_{ST}R_{LT}} \tag{2.68}$$

The closed-loop, driving-point output resistance R_{out}, can be straightforwardly calculated by noting that the open circuit ($R_{LT} \to \infty$) voltage gain, A_{VO}, predicted by Equation 2.68 is $A_{VO} = 1/f_{pp}\ R_{ST}$. Accordingly, Equation 2.68 is alternatively expressible as

$$A_V(R_{ST}, R_{LT}) \approx A_{VO}\left(\frac{R_{LT}}{R_{LT} + \frac{f_{ss}}{f_{pp}R_{ST}}}\right) \tag{2.69}$$

Because Equation 2.69 is a voltage divider relationship stemming from a Thévenin model of the output port of the dual-loop feedback amplifier, as delineated in Figure 2.17, it follows that the driving-point output resistance is

$$R_{out} \approx \frac{f_{ss}}{f_{pp}R_{ST}} \tag{2.70}$$

Observe that, similar to the forward gain characteristics, the driving-point output resistance is nominally insensitive to changes and other uncertainties in open-loop amplifier parameters. Moreover, this output resistance is directly proportional to the ratio f_{ss}/f_{pp} of feedback factors. As illustrated in preceding sections, the individual feedback factors, and thus the ratio of feedback factors, is likely to be proportional to a ratio of resistances. In view of the fact that resistance ratios can be tightly controlled in a monolithic fabrication process, R_{out} in Equation 2.70 is accurately prescribed for a given source termination.

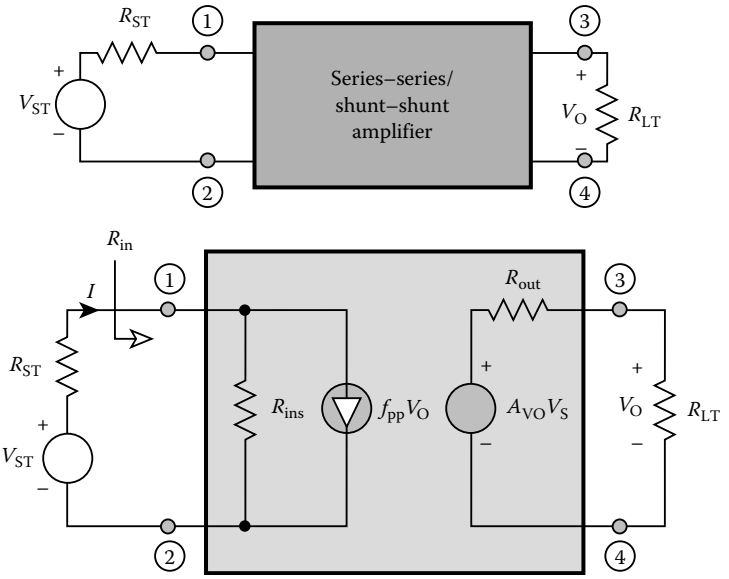

FIGURE 2.17 Norton equivalent input and Thévenin equivalent output circuits for the series–series/shunt–shunt dual-loop feedback amplifier.

The driving-point input resistance R_{in} can be determined from a consideration of the input port component of the system-level equivalent circuit depicted in Figure 2.17. This resistance is the ratio of V_{ST} to I, under the condition of $R_S = 0$. With $R_S = 0$, Equation 2.68 yields $V_O = R_{LT}V_{ST}/f_{ss}$ and thus, Kirchhoff's voltage law (KVL) applied around the input port of the model at hand yields

$$R_{in} = \frac{R_{ins}}{1 + \frac{f_{pp}R_{LT}R_{ins}}{f_{ss}}} \approx \frac{f_{ss}}{f_{pp}R_{LT}} \tag{2.71}$$

where the "open-loop" input resistance R_{ins}, defined by Equation 2.65, is presumed large. Similar to the driving-point output resistance of the series–series/shunt–shunt feedback amplifier, the driving-point input resistance is nominally independent of open-loop amplifier parameters.

It is interesting to observe that the input resistance in Equation 2.71 is inversely proportional to the load resistance by the same factor (f_{ss}/f_{pp}) that the driving-point output resistance in Equation 2.70 is inversely proportional to the source resistance. As a result,

$$\frac{f_{ss}}{f_{pp}} \approx R_{in}R_{LT} \equiv R_{out}R_{ST} \tag{2.72}$$

Thus, in addition to being stable performance indices for well-defined source and load terminations, the driving-point input and output resistances track one another, despite manufacturing uncertainties and changes in operating temperature that might perturb the individual values of the two feedback factors f_{ss} and f_{pp}.

The circuit property stipulated by Equation 2.72 has immediate utility in the design of wideband communication transceivers and other high-speed signal-processing systems [10–14]. In these and related applications, a cascade of several stages is generally required to satisfy frequency response, distortion, and noise specifications. A convenient way of implementing a cascade interconnection is to force each member of the cascade to operate under the match terminated case of

$R_{ST} = R_{in} = R_{LT} = R_{out} \triangleq R$. From Equation 2.72 match terminated operation demands feedback factors selected so that

$$R = \sqrt{\frac{f_{ss}}{f_{pp}}} \tag{2.73}$$

which forces a match terminated closed-loop voltage gain A_V^* of

$$A_V^* \approx \frac{1}{2f_{pp}R} = \frac{1}{2\sqrt{f_{pp}f_{ss}}} \tag{2.74}$$

The ac schematic diagram of a practical, single-ended series–series/shunt–shunt amplifier is submitted in Figure 2.18. An inspection of this diagram reveals a topology that coalesces the series–series and shunt–shunt triples studied earlier. In particular, the wye network formed of the three resistances, R_{Xx}, R_Y, and R_Z, comprises the series–series component of the dual-loop feedback amplifier. The capacitor, C_c, narrowbands the open-loop amplifier to facilitate frequency compensation of the series–series loop through the capacitance, C_{F1}. Compensated shunt feedback of the network is achieved by the parallel combination of the resistance, R_F and the capacitance, C_{F2}. If C_{F1} and C_c combine to deliver a dominant pole series–series feedback amplifier, C_{F2} is not necessary. Conversely, C_{F1} is superfluous if C_{F2} and C_c interact to provide a dominant pole shunt–shunt feedback amplifier. As in the single-ended series–series configuration, transistor $Q3$ can be broadbanded via a common base cascode. Moreover, if feedback through the feedback networks poses a problem, an emitter follower can be inserted at the port to which the shunt feedback path and the load termination are incident.

A low-frequency analysis of the circuit in Figure 2.18 is expedited by assuming high-β transistors having identical corresponding small-signal model parameters. This analysis, which in contrast to the

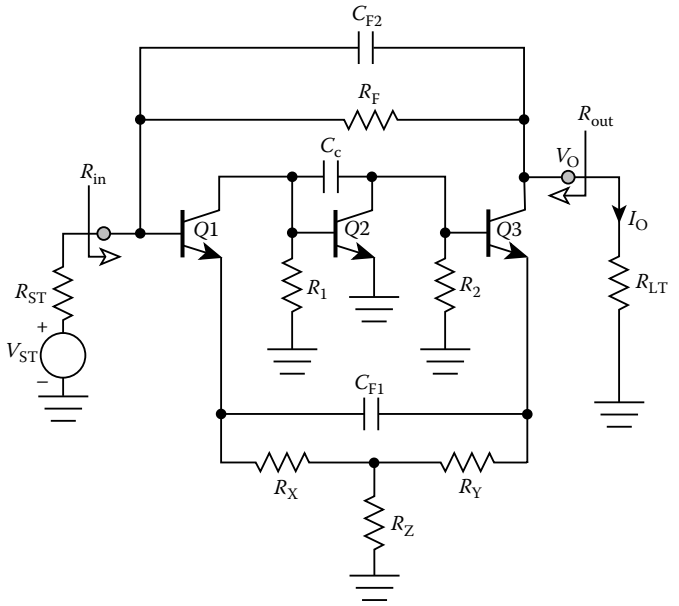

FIGURE 2.18 AC schematic diagram of a frequency-compensated, series–series/shunt–shunt, dual-loop feedback amplifier. The compensation is affected by the capacitances C_{F1} and C_{F2}, while C_c achieves pole splitting in the open-loop amplifier.

simplified behavioral analysis, does not ignore the electrical effects of the aforementioned feed-forward through the shunt–shunt feedback network, yields a voltage gain $A_V(R_{ST}, R_{LT})$, of

$$A_V(R_{ST}, R_{LT}) \approx -\left(\frac{R_{in}}{R_{in} + R_{ST}}\right)\left(\frac{R_{LT}}{R_{LT} + R_F}\right)\left(\frac{\alpha R_F}{R_Z} - 1\right) \tag{2.75}$$

where the driving-point input resistance of the amplifier R_{in} is

$$R_{in} \approx \frac{R_F + R_{LT}}{1 + \frac{\alpha R_{LT}}{R_Z}} \tag{2.76}$$

The driving-point output resistance R_{out} is

$$R_{out} \approx \frac{R_F + R_{ST}}{1 + \frac{\alpha R_{ST}}{R_z}} \tag{2.77}$$

As predicted by the behavioral analysis R_{in}, R_{out}, and $A_V(R_{ST}, R_{LT})$, are nominally independent of transistor parameters. Observe that the functional dependence of R_{in} on the load resistance, R_{LT}, is identical to the manner in which R_{out} is related to the source resistance R_{ST}. In particular, $R_{in} \equiv R_{out}$ if $R_{ST} \equiv R_{LT}$. For the match terminated case in which $R_{ST} = R_{in} = R_{LT} = R_{out} \triangleq R$,

$$R \approx \sqrt{\frac{R_F R_Z}{\alpha}} \tag{2.78}$$

The corresponding match terminated voltage gain in Equation 2.75 collapses to

$$A_V^* \approx -\left(\frac{R_F - R}{2R}\right) \tag{2.79}$$

Similar to the series–series and shunt–shunt triples, many of the frequency compensation problems implicit to the presence of three open-loop stages can be circumvented by realizing the series–series/shunt–shunt amplifier as a two-stage differential configuration. Figure 2.19 is the ac schematic diagram of a compensated differential series–series/shunt–shunt feedback dual.

2.6.2 Series–Shunt/Shunt–Series Feedback Amplifier

The only other type of global dual-loop architecture is the series–shunt/shunt–series feedback amplifier; the behavioral diagram appears in Figure 2.20. The series–shunt component of this system, which is modeled by *h*-parameters, has a negligibly small feed-forward factor and a feedback factor of f_{sp}. Hybrid *g*-parameters model the shunt–series feedback structure, which has a feedback factor of f_{ps} and a presumably negligible feed-forward factor. The four-terminal amplifier around which the two feedback units are connected has an open loop (meaning $f_{sp} = 0$ and $f_{ps} = 0$, but with the loading effects of both feedback circuits considered) voltage gain of $A_{VO}(R_{ST}, R_{LT})$.

For $f_{ps} = 0$, the series–shunt feedback circuit voltage gain $A_{VS}(R_{ST}, R_{LT})$, is

$$A_{VS}(R_{ST}, R_{LT}) = \frac{V_O}{V_{ST}} = \frac{A_{VO}(R_{ST}, R_{LT})}{1 + f_{sp}A_{VO}(R_{ST}, R_{LT})} \approx \frac{1}{f_{sp}} \tag{2.80}$$

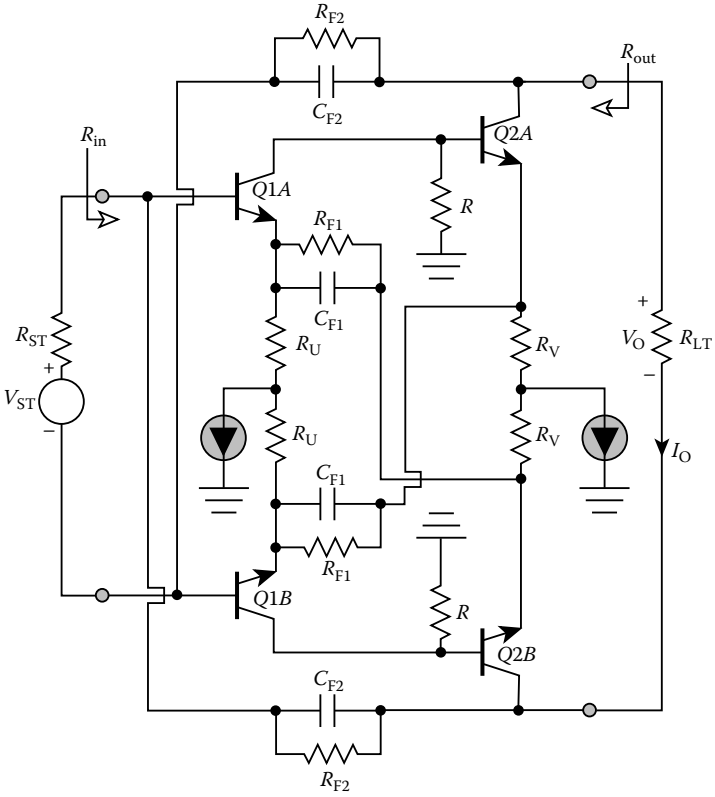

FIGURE 2.19 AC schematic diagram of the differential realization of a compensated series–series/shunt–shunt feedback amplifier.

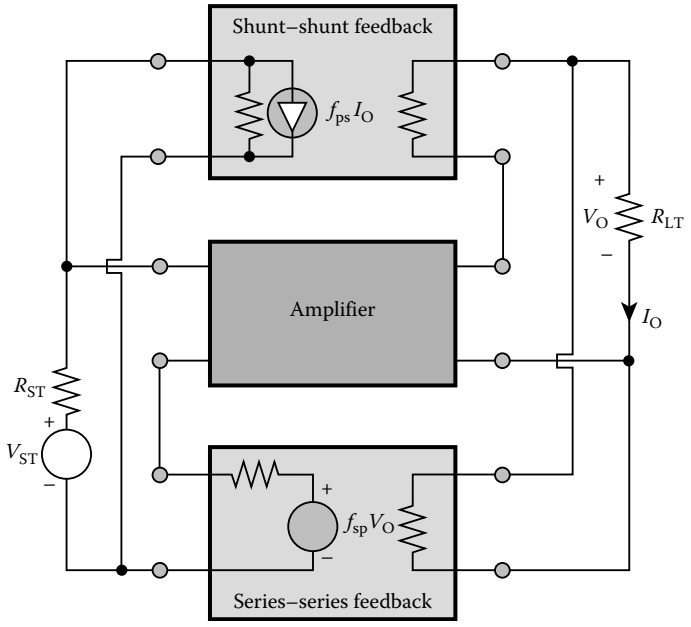

FIGURE 2.20 System-level diagram of a series–shunt/shunt–series, dual-loop feedback amplifier. Note that feedforward signal transmission through either feedback network is ignored.

where the approximation reflects an assumption of a large loop gain. When the shunt–series component of the feedback amplifier is activated, the dual-loop configuration functions as a current amplifier. Its effective open-loop transfer function is the current gain, $A_{IS}(R_{ST}, R_{LT})$, established by the series–shunt amplifier; namely,

$$A_{IS}(R_{ST}, R_{LT}) = \frac{I_O}{I_{ST}} = \left(\frac{R_{ST}}{R_{LT}}\right)\frac{V_O}{V_{ST}} \approx \frac{R_{ST}}{f_{sp}R_{LT}} \tag{2.81}$$

It follows that the current gain, $A_I(R_{ST}, R_{LT})$, of the closed loop is

$$A_I(R_{ST}, R_{LT}) \approx \frac{\frac{R_{ST}}{f_{sp}R_{LT}}}{1 + f_{ps}\left(\frac{R_{ST}}{f_{sp}R_{LT}}\right)} = \frac{R_{ST}}{f_{sp}R_{LT} + f_{ps}R_{ST}} \tag{2.82}$$

while the corresponding voltage gain, $A_V(R_{ST}, R_{LT})$, assuming negligible feed-forward through the shunt–series feedback network, is

$$A_V(R_{ST}, R_{LT}) = \frac{R_{LT}}{R_{ST}}A_I(R_{ST}, R_{LT}) \approx \frac{R_{LT}}{f_{sp}R_{LT} + f_{ps}R_{ST}} \tag{2.83}$$

Repeating the analytical strategy employed to determine the input and output resistances of the series–series/shunt–shunt configuration, Equation 2.83 delivers a driving-point input resistance of

$$R_{in} \approx \frac{f_{sp}R_{LT}}{f_{ps}} \tag{2.84}$$

and a driving-point output resistance of

$$R_{out} \approx \frac{f_{ps}R_{ST}}{f_{sp}} \tag{2.85}$$

Similar to the forward voltage gain, the driving-point input and output resistances of the series–shunt/shunt–series feedback amplifier are nominally independent of active element parameters. Note, however, that the input resistance is directly proportional to the load resistance by a factor (f_{sp}/f_{ps}), which is the inverse of the proportionality constant that links the output resistance to the source resistance. Specifically,

$$\frac{f_{sp}}{f_{ps}} = \frac{R_{in}}{R_{LT}} = \frac{R_{ST}}{R_{out}} \tag{2.86}$$

Thus, although R_{in} and R_{out} are reliably determined for well-defined load and source terminations, they do not track one another as well as they do in the series–series/shunt–shunt amplifier. Using Equation 2.86, the voltage gain in Equation 2.83 is expressible as

$$A_V(R_{ST}, R_{LT}) \approx \frac{1}{f_{sp}\left(1 + \sqrt{\frac{R_{out}R_{ST}}{R_{in}R_{LT}}}\right)} \tag{2.87}$$

The simplified ac schematic diagram of a practical series–shunt/shunt–series feedback amplifier appears in Figure 2.21. In this circuit, series–shunt feedback derives from the resistances, R_{EE1} and R_{F1}, and

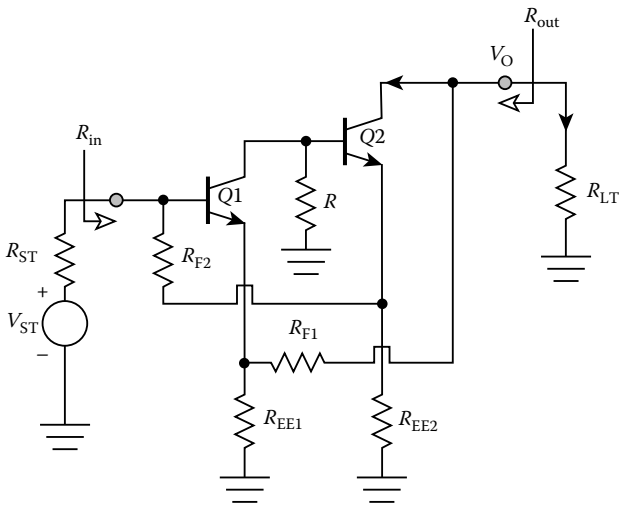

FIGURE 2.21 AC schematic diagram of a series–shunt/shunt–series, dual-loop feedback amplifier.

shunt–series feedback is determined by the resistances, R_{EE2} and R_{F2}. Because this circuit topology merges the series–shunt and shunt–series pairs, requisite frequency compensation, which is not shown in the subject figure, mirrors the relevant compensation schemes studied earlier. Note, however, that a cascade of only two open-loop gain stages renders compensation easier to implement and larger 3 dB bandwidths easier to achieve in the series–series/shunt–shunt circuit, which requires three open-loop gain stages for a single-ended application.

For high-β transistors having identical corresponding small-signal model parameters, a low-frequency analysis of the circuit in Figure 2.21 gives a voltage gain of

$$A_V(R_{ST}, R_{LT}) \approx \left(\frac{\alpha R_{in}}{R_{in} + \alpha R_S}\right)\left(1 + \frac{R_{F1}}{R_{EE1}}\right) \tag{2.88}$$

where the driving-point input resistance, R_{in}, of the subject amplifier is

$$R_{in} \approx \alpha R_{LT}\left(\frac{1 + \frac{R_{F2}}{R_{EE2}}}{1 + \frac{R_{F1}}{R_{EE1}} + \frac{R_{LT}}{R_{EE1} \| R_{EE2}}}\right) \tag{2.89}$$

The driving-point output resistance, R_{out}, is

$$R_{out} \approx R_{ST}\left(\frac{1 + \frac{R_{F1}}{R_{EE1}}}{1 + \frac{R_{F2}}{R_{EE2}} + \frac{R_{ST}}{R_{EE1} \| R_{EE2}}}\right) \tag{2.90}$$

2.7 Summary

This section documents small-signal performance equations, general operating characteristics, and engineering design guidelines for the six most commonly used global feedback circuits. These observations derive from analyses based on the judicious application of signal flow theory to the small-signal model that results when the subject feedback network is supplanted by an appropriate two-port parameter equivalent circuit.

Four of the six fundamental feedback circuits are single-loop architectures.

1. Series–shunt feedback amplifier functions best as a voltage amplifier in that its input resistance is large, and its output resistance is small. Because only two gain stages are required in the open loop, the amplifier is relatively easy to compensate for acceptable closed-loop damping and features potentially large 3 dB bandwidth. A computationally efficient analysis aimed toward determining loop gain, closed-loop gain, I/O resistances, and the condition that renders feed-forward through the feedback network inconsequential is predicated on replacing the feedback subcircuit with its *h*-parameter model.
2. Shunt–series feedback amplifier is a current amplifier in that its input resistance is small, and its output resistance is large. Similar to its series–shunt dual, only two gain stages are required in the open loop. Computationally efficient analyses are conducted by replacing the feedback subcircuit with its *g*-parameter model.
3. Shunt–shunt feedback amplifier is a transresistance signal processor in that both its input and output resistances are small. Although this amplifier can be realized theoretically with only a single open-loop stage, a sufficiently large loop gain generally requires a cascade of three open-loop stages. As a result, pole splitting is invariably required to ensure an open-loop dominant pole response, thereby limiting the achievable closed-loop bandwidth. In addition compensation of the feedback loop may be required for acceptable closed-loop damping. The bandwidth and stability problems implicit to the use of three open-loop gain stages can be circumvented by a balanced differential realization, which requires a cascade of only two open-loop gain stages. Computationally efficient analyses are conducted by replacing the feedback subcircuit with its *y*-parameter model.
4. Series–series feedback amplifier is a transconductance signal processor in that both its input and output resistances are large. Similar to its shunt–shunt counterpart, its implementation generally requires a cascade of three open-loop gain stages. Computationally efficient analyses are conducted by replacing the feedback subcircuit with its *z*-parameter model.

The two remaining feedback circuits are dual-loop topologies that can stabilize the driving-point input and output resistances, as well as the forward gain characteristics, with respect to shifts in active element parameters. One of these latter architectures, the series–series/shunt–shunt feedback amplifier, is particularly well suited to electronic applications that require a multistage cascade.

1. Series–series/shunt–shunt feedback amplifier coalesces the series–series architecture with its shunt–shunt dual. It is particularly well suited to applications, such as wideband communication networks, which require match terminated source and load resistances. Requisite frequency compensation and broadbanding criteria mirror those incorporated in the series–series and shunt–shunt single-loop feedback topologies.
2. Series–shunt/shunt–series feedback amplifier coalesces the series–shunt architecture with its shunt–series dual. Although its input resistance can be designed to match the source resistance seen by the input port of the amplifier, and its output resistance can be matched to the load resistance driven by the amplifier, match terminated operating ($R_{in} = R_{ST} = R_{LT} = R_{out}$) is not feasible. Requisite frequency compensation and broadbanding criteria mirror those incorporated in the series–shunt and shunt–series single-loop feedback topologies.

3.1 Introduction

In Section 1.2, we used the ideal feedback model to study the properties of feedback amplifiers. The model is useful only if we can separate a feedback amplifier into the basic amplifier $\mu(s)$ and the feedback network $\beta(s)$. The procedure is difficult and sometimes virtually impossible, because the forward path may not be strictly unilateral, the feedback path is usually bilateral, and the input and output coupling networks are often complicated. Thus, the ideal feedback model is not an adequate representation of a practical amplifier. In the remainder of this section, we shall develop Bode's feedback theory, which is applicable to the general network configuration and avoids the necessity of identifying the transfer functions $\mu(s)$ and $\beta(s)$.

Bode's feedback theory [1] is based on the concept of return difference, which is defined in terms of network determinants. We show that the return difference is a generalization of the concept of the feedback factor of the ideal feedback model, and can be measured physically from the amplifier itself. We then introduce the notion of null return difference and discuss its physical significance. Because the feedback theory will be formulated in terms of the first- and second-order cofactors of the elements of the indefinite-admittance matrix of a feedback circuit, we first review briefly the formulation of the indefinite-admittance matrix.

3.2 Indefinite-Admittance Matrix

Figure 3.1 is an n-terminal network N composed of an arbitrary number of active and passive network elements connected in any way whatsoever. Let $V_1, V_2, \ldots, V_n$ be the Laplace-transformed potentials measured between terminals $1, 2, \ldots, n$ and some arbitrary but unspecified reference point, and let $I_1, I_2, \ldots, I_n$ be the Laplace-transformed currents entering the terminals $1, 2, \ldots, n$ from outside the network. The network N together with its load is linear, so the terminal current and voltages are related by the equation

$$\begin{bmatrix} I_1 \\ I_2 \\ \vdots \\ I_n \end{bmatrix} = \begin{bmatrix} y_{11} & y_{12} & \cdots & y_{1n} \\ y_{21} & y_{22} & \cdots & y_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ y_{n1} & y_{n2} & \cdots & y_{nn} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ \vdots \\ V_n \end{bmatrix} + \begin{bmatrix} J_1 \\ J_2 \\ \vdots \\ J_n \end{bmatrix} \tag{3.1}$$

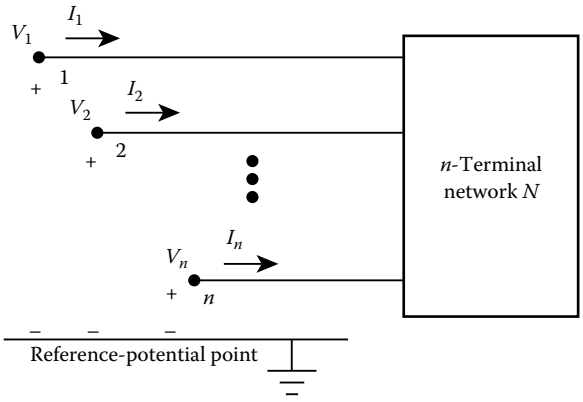

FIGURE 3.1 General symbolic representation of an n-terminal network.

or more succinctly as

$$\mathbf{I}(s) = \mathbf{Y}(s)\mathbf{V}(s) + \mathbf{J}(s) \tag{3.2}$$

where J_k ($k = 1, 2, \ldots, n$) denotes the current flowing into the kth terminal when all terminals of N are grounded to the reference point. The coefficient matrix $\mathbf{Y}(s)$ is called the indefinite-admittance matrix because the reference point for the potentials is some arbitrary but unspecified point outside the network. Notice that the symbol $\mathbf{Y}(s)$ is used to denote either the admittance matrix or the indefinite-admittance matrix. This should not create any confusion because the context will tell. In the remainder of this section, we shall deal exclusively with the indefinite-admittance matrix.

We remark that the short-circuit currents J_k result from the independent sources and/or initial conditions in the interior of N. For our purposes, we shall consider all independent sources outside the network and set all initial conditions to zero. Hence, $\mathbf{J}(s)$ is considered to be zero, and Equation 3.2 becomes

$$\mathbf{I}(s) = \mathbf{Y}(s)\mathbf{V}(s) \tag{3.3}$$

where the elements y_{ij} of $\mathbf{Y}(s)$ can be obtained as

$$y_{ij} = \left.\frac{I_i}{V_j}\right|_{v_x=0, x\neq j} \tag{3.4}$$

As an illustration, consider a small-signal equivalent model of a transistor in Figure 3.2. Its indefinite-admittance matrix is found to be

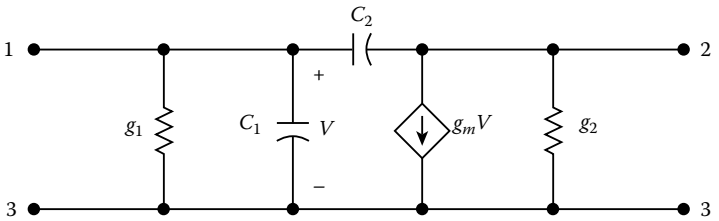

FIGURE 3.2 Small-signal equivalent network of a transistor.

$$\mathbf{Y}(s) = \begin{bmatrix} g_1 + sC_1 + sC_2 & -sC_2 & -g_1 - sC_1 \\ g_m - sC_2 & g_2 + sC_2 & -g_2 - g_m \\ -g_1 - sC_1 - g_m & -g_2 & g_1 + g_2 + g_m + sC_1 \end{bmatrix} \tag{3.5}$$

Observe that the sum of elements of each row or column is equal to zero. The fact that these properties are valid in general for the indefinite-admittance matrix will now be demonstrated.

To see that the sum of the elements in each column of $\mathbf{Y}(s)$ equals zero, we add all n equations of Equation 3.1 to yield

$$\sum_{i=1}^{n} \sum_{j=1}^{n} y_{ji} V_i = \sum_{m=1}^{n} I_m - \sum_{m=1}^{n} J_m = 0 \tag{3.6}$$

The last equation is obtained by appealing to Kirchhoff's current law for the node corresponding to the reference point. Setting all the terminal voltages to zero except the kth one, which is nonzero, gives

$$V_k \sum_{j=1}^{n} y_{jk} = 0 \tag{3.7}$$

Because $V_k \neq 0$, it follows that the sum of the elements of each column of $\mathbf{Y}(s)$ equals zero. Thus, the indefinite-admittance matrix is always singular.

To demonstrate that each row sum of $\mathbf{Y}(s)$ is also zero, we recognize that because the point of zero potential may be chosen arbitrarily, the currents J_k and I_k remain invariant when all the terminal voltages V_k are changed by the same but arbitrary constant amount. Thus, if V_0 is an n-vector, each element of which is $v_0 \neq 0$, then

$$\mathbf{I}(s) - \mathbf{J}(s) = \mathbf{Y}(s)[\mathbf{V}(s) + \mathbf{V}_0] = \mathbf{Y}(s)\mathbf{V}(s) + \mathbf{Y}(s)\mathbf{V}_0 \tag{3.8}$$

which after invoking Equation 3.2 yields that

$$\mathbf{Y}(s)\mathbf{V}_0 = 0 \tag{3.9}$$

or

$$\sum_{j=1}^{n} y_{ij} = 0, \quad i = 1, 2, \ldots, n \tag{3.10}$$

showing that each row sum of $\mathbf{Y}(s)$ equals zero.

Thus, if $\mathbf{Y}_{uv}$ denotes the submatrix obtained from an indefinite-admittance matrix $\mathbf{Y}(s)$ by deleting the uth row and vth column, then the (first order) cofactor, denoted by the symbol Y_{uv}, of the element y_{uv} of $\mathbf{Y}(s)$, is defined by

$$Y_{uv} = (-1)^{u+v} \det \mathbf{Y}_{uv} \tag{3.11}$$

As a consequence of the zero-row-sum and zero-column-sum properties, all the cofactors of the elements of the indefinite-admittance matrix are equal. Such a matrix is also referred to as the equicofactor matrix. If Y_{uv} and Y_{ij} are any two cofactors of the elements of $\mathbf{Y}(s)$, then

$$Y_{uv} = Y_{ij} \tag{3.12}$$

for all u, v, i, and j. For the indefinite-admittance matrix $\mathbf{Y}(s)$ of Equation 3.5 it is straightforward to verify that all of its nine cofactors are equal to

$$Y_{uv} = s^2C_1C_2 + s(C_1g_2 + C_2g_1 + C_2g_2 + g_mC_2) + g_1g_2 \tag{3.13}$$

for $u, v = 1, 2, 3$.

Denote by $\mathbf{Y}_{rp,sq}$ the submatrix obtained from $\mathbf{Y}(s)$ by striking out rows r and s and columns p and q. Then the second-order cofactor, denoted by the symbol $Y_{rp,sq}$ of the elements y_{rp}, and y_{sq} of $\mathbf{Y}$(s) is a scalar quantity defined by the relation

$$Y_{rp,sq} = \text{sgn}(r-s)\text{sgn}(p-q)(-1)^{r+p+s+q}\ \det\mathbf{Y}_{rp,sq} \tag{3.14}$$

where $r \neq s$ and $p \neq q$, and

$$\text{sgn}\ u = +1 \quad \text{if}\ u > 0 \tag{3.15a}$$

$$\text{sgn}\ u = -1 \quad \text{if}\ u < 0 \tag{3.15b}$$

The symbols $\mathbf{Y}_{uv}$ and Y_{uv} or $\mathbf{Y}_{rp,sq}$ and $Y_{rp,sq}$ should not create any confusion because one is in boldface whereas the other is italic. Also, for our purposes, it is convenient to define

$$Y_{rp,sq} = 0, \quad r = s \text{ or } p = q \tag{3.16a}$$

or

$$\text{sgn}\ 0 = 0 \tag{3.16b}$$

This convention will be followed throughout the remainder of this section.

As an example, consider the hybrid-pi equivalent network of a transistor in Figure 3.3. Assume that each node is an accessible terminal of a four-terminal network. Its indefinite-admittance matrix is

$$\mathbf{Y}(s) = \begin{bmatrix} 0.02 & 0 & -0.02 & 0 \\ 0 & 5\times10^{-12}s & 0.2 - 5\times10^{-12}s & -0.2 \\ -0.02 & -5\times10^{-12}s & 0.024 + 105\times10^{-12}s & -0.004 - 10^{-10}s \\ 0 & 0 & -0.204 - 10^{-10}s & 0.204 + 10^{-10}s \end{bmatrix} \tag{3.17}$$

The second-order cofactor $Y_{31,42}$ and $Y_{11,34}$ of the elements of $\mathbf{Y}(s)$ of Equation 3.17 are computed as follows:

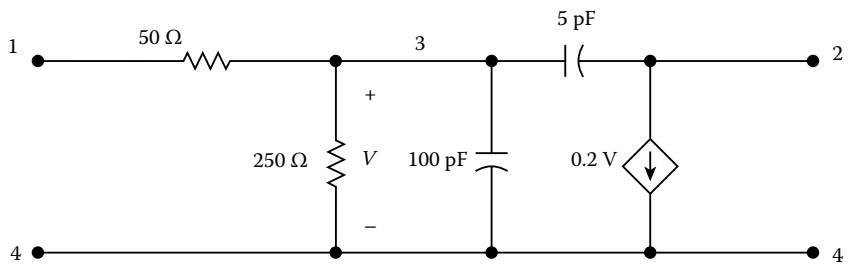

FIGURE 3.3 Hybrid-pi equivalent network of a transistor.

$$Y_{31,42} = \text{sgn}(3-4)\text{sgn}(1-2)(-1)^{3+1+4+2}\ \det\begin{bmatrix} -0.02 & 0 \\ 0.2 - 5\times 10^{-12}s & -0.2 \end{bmatrix}$$
$$= 0.004 \tag{3.18a}$$

$$Y_{11,34} = \text{sgn}(1-3)\text{sgn}(1-4)(-1)^{1+1+3+4}\ \det\begin{bmatrix} 5\times 10^{-12}s & 0.2 - 5\times 10^{-12}s \\ 0 & -0.204 - 10^{-10}s \end{bmatrix}$$
$$= 5\times 10^{-12}s\left(0.204 + 10^{-10}s\right) \tag{3.18b}$$

The usefulness of the indefinite-admittance matrix lies in the fact that it facilitates the computation of the driving-point or transfer functions between any pair of nodes or from any pair of nodes to any other pair. In the following, we present elegant, compact, and explicit formulas that express the network functions in terms of the ratios of the first- and/or second-order cofactors of the elements of the indefinite-admittance matrix.

Assume that a current source is connected between any two nodes r and s so that a current I_{sr} is injected into the rth node and at the same time is extracted from the sth node. Suppose that an ideal voltmeter is connected from node p to node q so that it indicates the potential rise from q to p, as depicted symbolically in Figure 3.4. Then the transfer impedance, denoted by the symbol $z_{rp,sq}$, between the node pairs rs and pq of the network of Figure 3.4 is defined by the relation

$$z_{rp,sq} = \frac{V_{pq}}{I_{sr}} \tag{3.19}$$

with all initial conditions and independent sources inside N set to zero. The representation is, of course, quite general. When $r = p$ and $s = q$, the transfer impedance $z_{rp,sq}$, becomes the *driving-point impedance* $z_{rr,ss}$ between the terminal pair rs.

In Figure 3.4, set all initial conditions and independent sources in N to zero and choose terminal q to be the reference-potential point for all other terminals. In terms of Equation 3.1, these operations are equivalent to setting $\mathbf{J} = 0$, $V_q = 0$, $I_x = 0$ for $x \neq r, s$ and $I_r = -I_s = I_{sr}$. Because $\mathbf{Y}(s)$ is an equicofactor matrix, the equations of Equation 3.1 are not linearly independent and one of them is superfluous. Let us suppress the sth equation from Equation 3.1, which then reduces to

$$\mathbf{I}_{-s} = \mathbf{Y}_{sq}\mathbf{V}_{-q} \tag{3.20}$$

where $\mathbf{I}_{-s}$ and $\mathbf{V}_{-q}$ denote the subvectors obtained from $\mathbf{I}$ and $\mathbf{V}$ of Equation 3.3 by deleting the sth row and qth row, respectively. Applying Cramer's rule to solve for V_p yields

$$V_p = \frac{\det\tilde{\mathbf{Y}}_{sq}}{\det\mathbf{Y}_{sq}} \tag{3.21}$$

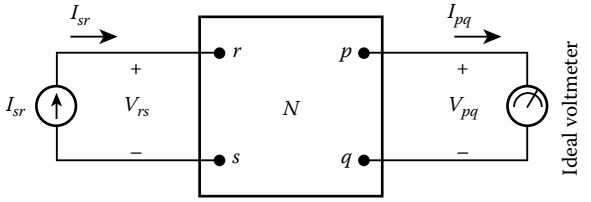

FIGURE 3.4 Symbolic representation for the measurement of the transfer impedance.

where $\tilde{\mathbf{Y}}_{sq}$ is the matrix derived from $\mathbf{Y}_{sq}$ by replacing the column corresponding to V_p by $\mathbf{I}_{-s}$. We recognize that $\mathbf{I}_{-s}$ is in the pth column if $p < q$ but in the $(p-1)$th column if $p > q$. Furthermore, the row in which I_{sr} appears is the rth row if $r < s$, but is the $(r-1)$th row if $r > s$. Thus, we obtain

$$(-1)^{s+q} \det\tilde{\mathbf{Y}}_{sq} = I_{sr} Y_{rp,sq} \tag{3.22}$$

In addition, we have

$$\det\mathbf{Y}_{sq} = (-1)^{s+q} Y_{sq} \tag{3.23}$$

Substituting these in Equation 3.21 in conjunction with Equation 3.19, we obtain

$$z_{rp,sq} = \frac{Y_{rp,sq}}{Y_{uv}} \tag{3.24}$$

$$z_{rr,ss} = \frac{Y_{rr,ss}}{Y_{uv}} \tag{3.25}$$

in which we have invoked the fact that $Y_{sq} = Y_{uv}$.

The *voltage gain*, denoted by $g_{rp,sq}$, between the node pairs rs and pq of the network of Figure 3.4 is defined by

$$g_{rp,sq} = \frac{V_{pq}}{V_{rs}} \tag{3.26}$$

again with all initial conditions and independent sources in N being set to zero. Thus, from Equations 3.24 and 3.25 we obtain

$$g_{rp,sq} = \frac{z_{rp,sq}}{z_{rr,ss}} = \frac{Y_{rp,sq}}{Y_{rr,ss}} \tag{3.27}$$

The symbols have been chosen to help us remember. In the numerators of Equations 3.24, 3.25, and 3.27, the order of the subscripts is as follows: r, the current injecting node; p, the voltage measurement node; s, the current extracting node; and q, the voltage reference node. Nodes r and p designate the input and output transfer measurement, and nodes s and q form a sort of double datum.

As an illustration, we consider the hybrid-pi transistor equivalent network of Figure 3.3. For this transistor, suppose that we connect a 100 Ω load resistor between nodes 2 and 4, and excite the resulting circuit by a voltage source V_{14}, as depicted in Figure 3.5. To simplify our notation, let $p = 10^{-9}s$. The indefinite-admittance matrix of the amplifier is

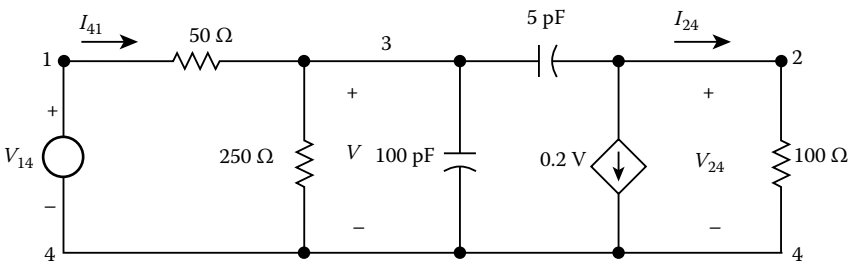

FIGURE 3.5 Transistor amplifier used to illustrate the computation of $g_{rp,sq}$.

$$\mathbf{Y}(s) = \begin{bmatrix} 0.02 & 0 & -0.02 & 0 \\ 0 & 0.01 + 0.005p & 0.2 - 0.005p & -0.21 \\ -0.02 & -0.005p & 0.024 + 0.105p & -0.004 - 0.1p \\ 0 & -0.01 & -0.204 - 0.1p & 0.214 + 0.1p \end{bmatrix} \tag{3.28}$$

To compute the voltage gain $g_{12,44}$, we appeal to Equation 3.27 and obtain

$$g_{12,44} = \frac{V_{24}}{V_{14}} = \frac{Y_{12,44}}{Y_{11,44}} = \frac{p - 40}{5p^2 + 21.7p + 2.4} \tag{3.29}$$

The input impedance facing the voltage source V_{14} is determined by

$$z_{11,44} = \frac{V_{14}}{I_{41}} = \frac{Y_{11,44}}{Y_{uv}} = \frac{Y_{11,44}}{Y_{44}} = \frac{50p^2 + 217p + 24}{p^2 + 4.14p + 0.08} \tag{3.30}$$

To compute the current gain defined as the ratio of the current I_{24} in the 100 Ω resistor to the input current I_{41}, we apply Equation 3.24 and obtain

$$\frac{I_{24}}{I_{41}} = 0.01\frac{V_{24}}{I_{41}} = 0.01 z_{12,44} = 0.01\frac{Y_{12,44}}{Y_{44}} = \frac{0.1p - 4}{p^2 + 4.14p + 0.08} \tag{3.31}$$

Finally, to compute the transfer admittance defined as the ratio of the load current I_{24} to the input voltage V_{14}, we appeal to Equation 3.27 and obtain

$$\frac{I_{24}}{V_{14}} = 0.01\frac{V_{24}}{V_{14}} = 0.01 g_{12,44} = 0.01\frac{Y_{12,44}}{Y_{11,44}} = \frac{p - 40}{500p^2 + 2170p + 240} \tag{3.32}$$

3.3 Return Difference

In the study of feedback amplifier response, we are usually interested in how a particular element of the amplifier affects that response. This element is either crucial in terms of its effect on the entire system or of primary concern to the designer. It may be the transfer function of an active device, the gain of an amplifier, or the immittance of a one-port network. For our purposes, we assume that this element x is the controlling parameter of a voltage-controlled current source defined by the equation

$$I = xV \tag{3.33}$$

To focus our attention on the element x, Figure 3.6 is the general configuration of a feedback amplifier in which the controlled source is brought out as a two-port network connected to a general four-port network, along with the input source combination of I_s and admittance Y_1 and the load admittance Y_2.

We remark that the two-port representation of a controlled source Equation 3.33 is quite general. It includes the special situation where a one-port element is characterized by its immittance. In this case, the controlling voltage V is the terminal voltage of the controlled current source I, and x become the one-port admittance.

The *return difference* $F(x)$ of a feedback amplifier with respect to an element x is defined as the ratio of the two functional values assumed by the first-order cofactor of an element of its indefinite-admittance matrix under the condition that the element x assumes its nominal value and the condition that the element x assumes the value zero. To emphasize the importance of the feedback element x, we express the

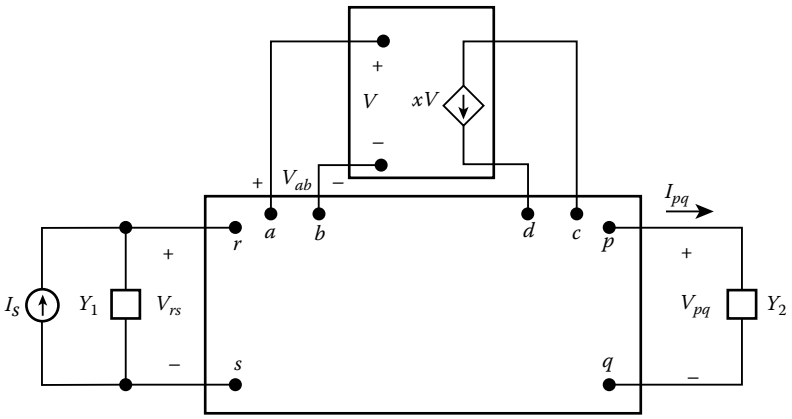

FIGURE 3.6 General configuration of a feedback amplifier.

indefinite-admittance matrix $\mathbf{Y}$ of the amplifier as a function of x, even though it is also a function of the complex-frequency variable s, and write $\mathbf{Y} = \mathbf{Y}(x)$. Then, we have [2]

$$F(x) \equiv \frac{Y_{uv}(x)}{Y_{uv}(0)} \tag{3.34}$$

where

$$Y_{uv}(0) = Y_{uv}(x)|_{x=0} \tag{3.35}$$

The physical significance of the return difference will now be considered. In the network of Figure 3.6, the input, the output, the controlling branch, and the controlled source are labeled as indicated. Then, the element x enters the indefinite-admittance matrix $\mathbf{Y}(x)$ in a rectangular pattern as shown next:

$$\mathbf{Y}(x) = \begin{array}{c} \\ a \\ b \\ c \\ d \end{array} \begin{array}{c} \begin{array}{cccc} a & b & c & d \end{array} \\ \begin{bmatrix} & & & \\ & & & \\ x & -x & & \\ -x & x & & \end{bmatrix} \end{array} \tag{3.36}$$

If in Figure 3.6 we replace the controlled current source xV by an independent current source of xA and set the excitation current source I_s to zero, the indefinite-admittance matrix of the resulting network is simply $\mathbf{Y}(0)$. By appealing to Equation 3.24, the new voltage V'_{ab} appearing at terminals a and b of the controlling branch is

$$V'_{ab} = x\frac{Y_{da,cb}(0)}{Y_{uv}(0)} = -x\frac{Y_{ca,db}(0)}{Y_{uv}(0)} \tag{3.37}$$

Notice that the current injecting point is terminal d, not c.

The preceding operation of replacing the controlled current source by an independent current source and setting the excitation I_s to zero can be represented symbolically as in Figure 3.7. Observe that the controlling branch is broken off as marked and a 1 V voltage source is applied to the right of the breaking mark. This 1 V sinusoidal voltage of a fixed angular frequency produces a current of x A at the controlled

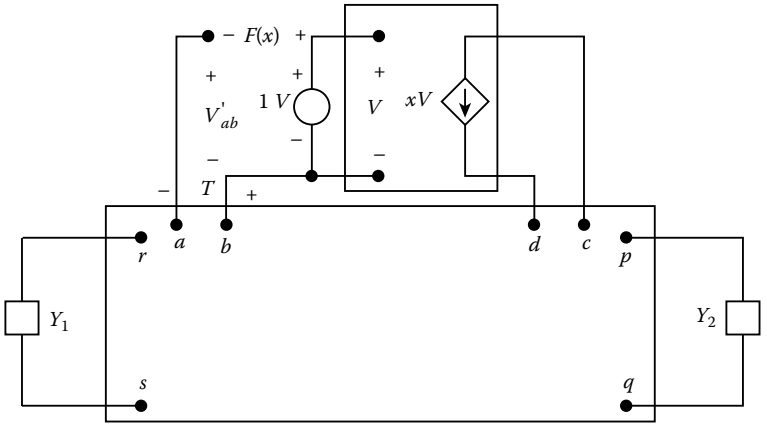

FIGURE 3.7 Physical interpretation of the return difference with respect to the controlling parameter of a voltage-controlled current source.

current source. The voltage appearing at the left of the breaking mark caused by this 1 V excitation is then V'_{ab} as indicated. This returned voltage V'_{ab} has the same physical significance as the loop transmission $\mu\beta$ defined for the ideal feedback model in Chapter 1. To see this, we set the input excitation to the ideal feedback model to zero, break the forward path, and apply a unit input to the right of the break, as depicted in Figure 3.8. The signal appearing at the left of the break is precisely the loop transmission.

For this reason, we introduce the concept of return ratio T, which is defined as the negative of the voltage appearing at the controlling branch when the controlled current source is replaced by an independent current source of x A and the input excitation is set to zero. Thus, the return ratio T is simply the negative of the returned voltage V'_{ab}, or $T = -V'_{ab}$. With this in mind, we next compute the difference between the 1 V excitation and the returned voltage V'_{ab} obtaining

$$\begin{aligned} 1 - V'_{ab} &= 1 + x\frac{Y_{ca,db}}{Y_{uv}(0)} = \frac{Y_{uv}(0) + xY_{ca,db}}{Y_{uv}(0)} = \frac{Y_{db}(0) + xY_{ca,db}}{Y_{db}(0)} \\ &= \frac{Y_{db}(x)}{Y_{db}(0)} = \frac{Y_{uv}(x)}{Y_{uv}(0)} = F(x) \end{aligned} \tag{3.38}$$

in which we have invoked the identities $Y_{uv} = Y_{ij}$ and

$$Y_{db}(x) = Y_{db}(0) + xY_{ca,db} \tag{3.39}$$

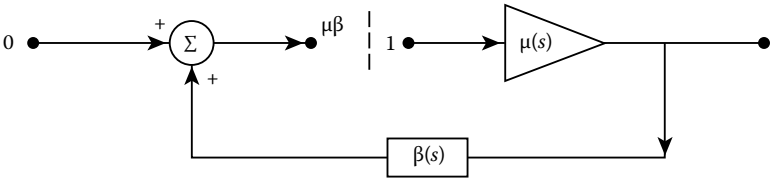

FIGURE 3.8 Physical interpretation of the loop transmission.

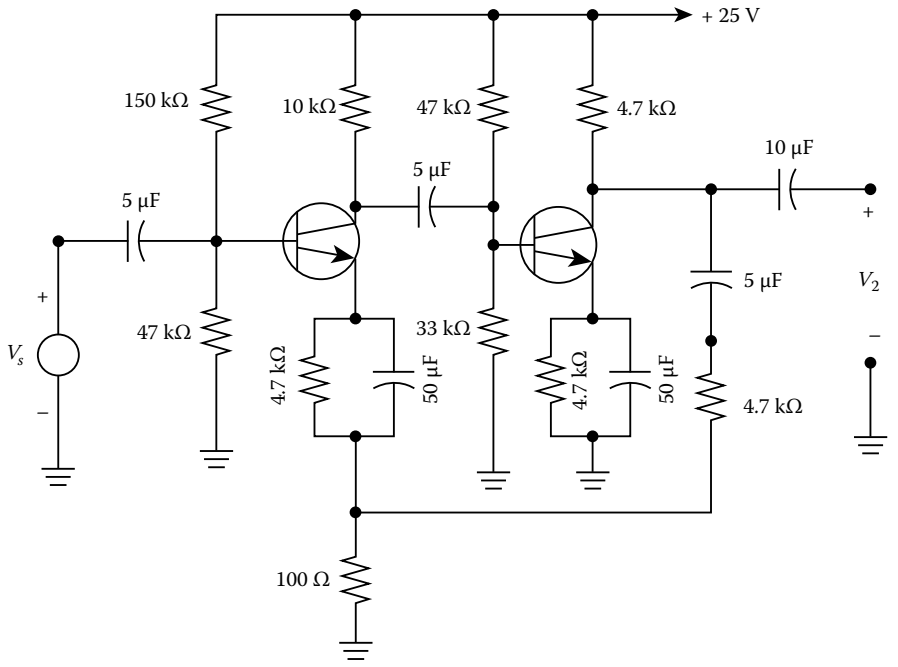

FIGURE 3.9 Voltage-series feedback amplifier together with its biasing and coupling circuitry.

We remark that we write $Y_{ca,db}(x)$ as $Y_{ca,db}$ because it is independent of x. In other words, the return difference $F(x)$ is simply the difference of the 1 V excitation and the returned voltage V'_{ab} as illustrated in Figure 3.7, and hence its name. Because

$$F(x) = 1 + T = 1 - \mu\beta \tag{3.40}$$

we conclude that the return difference has the same physical significance as the feedback factor of the ideal feedback model. The significance of the previous physical interpretations is that it permits us to determine the return ratio T or $-\mu\beta$ by measurement. Once the return ratio is measured, the other quantities such as return difference and loop transmission are known.

To illustrate, consider the voltage-series or the series-parallel feedback amplifier of Figure 3.9. Assume that the two transistors are identical with the following hybrid parameters:

$$h_{ie} = 1.1\ \text{k}\Omega, \quad h_{fe} = 50, \quad h_{re} = h_{oe} = 0 \tag{3.41}$$

After the biasing and coupling circuitry have been removed, the equivalent network is presented in Figure 3.10. The effective load of the first transistor is composed of the parallel combination of the 10, 33, 47, and 1.1 kΩ resistors. The effect of the 150 and 47 kΩ resistors can be ignored; they are included in the equivalent network to show their insignificance in the computation.

To simplify our notation, let

$$\tilde{\alpha}_k = \alpha_k \times 10^{-4} = \frac{h_{fe}}{h_{ie}} = 455 \times 10^{-4}, \quad k = 1, 2 \tag{3.42}$$

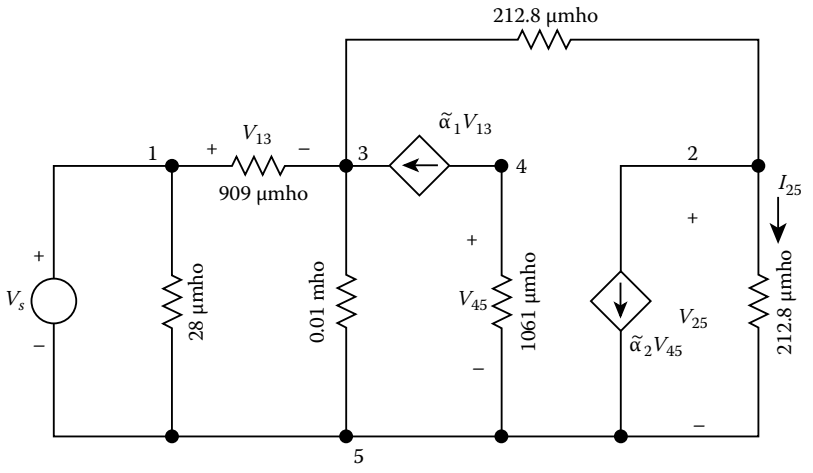

FIGURE 3.10 Equivalent network of the feedback amplifier of Figure 3.9.

The subscript k is used to distinguish the transconductances of the first and the second transistors. The indefinite-admittance matrix of the feedback amplifier of Figure 3.9 is

$$\mathbf{Y} = 10^{-4}\begin{bmatrix} 9.37 & 0 & -9.09 & 0 & -0.28 \\ 0 & 4.256 & -2.128 & \alpha_2 & -2.128-\alpha_2 \\ -9.09-\alpha_1 & -2.128 & 111.218+\alpha_1 & 0 & -100 \\ \alpha_1 & 0 & -\alpha_1 & 10.61 & -10.61 \\ -0.28 & -2.128 & -100 & -10.61-\alpha_1 & 113.018+\alpha_1 \end{bmatrix} \tag{3.43}$$

By applying Equation 3.27, the amplifier voltage gain is computed as

$$g_{12,25} = \frac{V_{25}}{V_s} = \frac{V_{12,25}}{V_{11,25}} = \frac{211.54 \times 10^{-7}}{4.66 \times 10^{-7}} = 45.39 \tag{3.44}$$

To calculate the return differences with respect to the transconductances $\tilde{\alpha}_k$ of the transistors, we short circuit the voltage source V_s. The resulting indefinite-admittance matrix is obtained from Equation 3.43 by adding the first row to the fifth row and the first column to the fifth column and then deleting the first row and column. Its first-order cofactor is simply $Y_{11,55}$. Thus, the return differences with respect to $\tilde{\alpha}_k$ are

$$F(\tilde{\alpha}_1) = \frac{Y_{11,55}(\tilde{\alpha}_1)}{Y_{11,55}(0)} = \frac{466.1 \times 10^{-9}}{4.97 \times 10^{-9}} = 93.70 \tag{3.45a}$$

$$F(\tilde{\alpha}_2) = \frac{Y_{11,55}(\tilde{\alpha}_2)}{Y_{11,55}(0)} = \frac{466.1 \times 10^{-9}}{25.52 \times 10^{-9}} = 18.26 \tag{3.45b}$$

3.4 Null Return Difference

In this section, we introduce the notion of null return difference, which is found to be very useful in measurement situations and in the computation of the sensitivity for the feedback amplifiers.

The null return difference $\hat{F}(x)$ of a feedback amplifier with respect to an element x is defined to be the ratio of the two functional values assumed by the second-order cofactor $Y_{rp,sq}$ of the elements of its

indefinite-admittance matrix **Y** under the condition that the element x assumes its nominal value and the condition that the element x assumes the value zero where r and s are input terminals, and p and q are the output terminals of the amplifier, or

$$\hat{F}(x) = \frac{Y_{rp,sq}(x)}{Y_{rp,sq}(0)} \tag{3.46}$$

Likewise, the null return ratio $\hat{T}$, with respect to a voltage-controlled current source $I = xV$, is the negative of the voltage appearing at the controlling branch when the controlled current source is replaced by an independent current source of xA and when the input excitation is adjusted so that the output of the amplifier is identically zero.

Now, we demonstrate that the null return difference is simply the return difference in the network under the situation that the input excitation I_s has been adjusted so that the output is identically zero. In the network of Figure 3.6, suppose that we replace the controlled current source by an independent current source of xA. Then by applying Equation 3.24 and the superposition principle, the output current I_{pq} at the load is

$$I_{pq} = Y_2\left[I_s\frac{Y_{rp,sq}(0)}{Y_{uv}(0)} + x\frac{Y_{dp,cq}(0)}{Y_{uv}(0)}\right] \tag{3.47}$$

Setting $I_{pq} = 0$ or $V_{pq} = 0$ yields

$$I_s \equiv I_0 = -x\left[\frac{Y_{dp,cq}(0)}{Y_{rp,sq}(0)}\right] \tag{3.48}$$

in which $Y_{dp,cq}$ is independent of x. This adjustment is possible only if a direct transmission occurs from the input to the output when x is set to zero. Thus, in the network of Figure 3.7, if we connect an independent current source of strength I_0 at its input port, the voltage V'_{ab} is the negative of the null return ratio $\hat{T}$. Using Equation 3.24, we obtain [3]

$$\begin{aligned}\hat{T} = -V'_{ab} &= -x\frac{Y_{da,cb}(0)}{Y_{uv}(0)} - I_0\frac{Y_{ra,sb}(0)}{Y_{uv}(0)}\\ &= -\frac{x\left[Y_{da,cb}(0)Y_{rp,sq}(0) - Y_{ra,sb}(0)Y_{dp,cq}(0)\right]}{Y_{uv}(0)Y_{rp,sq}(0)}\\ &= \frac{x\dot{Y}_{rp,sq}}{Y_{rp,sq}(0)} = \frac{Y_{rp,sq}(x)}{Y_{rp,sq}(0)} - 1\end{aligned} \tag{3.49}$$

where

$$\dot{Y}_{rp,sq} \equiv \frac{\mathrm{d}Y_{rp,sq}(x)}{\mathrm{d}x} \tag{3.50}$$

This leads to

$$\hat{F}(x) = 1 + \hat{T} = 1 - V'_{ab} \tag{3.51}$$

which demonstrates that the null return difference $\hat{F}(x)$ is simply the difference of the 1 V excitation applied to the right of the breaking mark of the broken controlling branch of the controlled source and

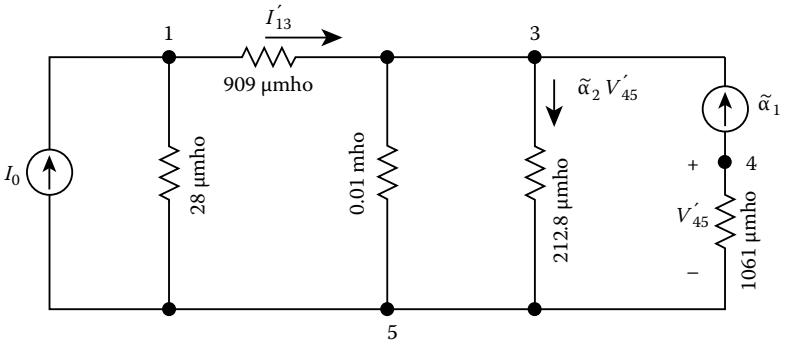

FIGURE 3.11 Network used to compute the null return difference $\hat{F}(\tilde{\alpha}_1)$ by its physical interpretation.

the returned voltage V'_{ab} appearing at the left of the breaking mark under the situation that the input signal I_s is adjusted so that the output is identically zero.

As an illustration, consider the voltage-series feedback amplifier of Figure 3.9, an equivalent network of which is presented in Figure 3.10. Using the indefinite-admittance matrix of Equation 3.43 in conjunction with Equation 3.42, the null return differences with respect to $\tilde{\alpha}_k$ are

$$\hat{F}(\tilde{\alpha}_1) = \frac{Y_{12,55}(\tilde{\alpha}_1)}{Y_{12,55}(0)} = \frac{211.54 \times 10^{-7}}{205.24 \times 10^{-12}} = 103.07 \times 10^3 \tag{3.52a}$$

$$\hat{F}(\tilde{\alpha}_2) = \frac{Y_{12,55}(\tilde{\alpha}_2)}{Y_{12,55}(0)} = \frac{211.54 \times 10^{-7}}{104.79 \times 10^{-10}} = 2018.70 \tag{3.52b}$$

Alternatively, $\hat{F}(\tilde{\alpha}_1)$ can be computed by using its physical interpretation as follows. Replace the controlled source $\tilde{\alpha}_1 V_{13}$ in Figure 3.10 by an independent current source of $\tilde{\alpha}_1$ A. We then adjust the voltage source V_s so that the output current I_{25} is identically zero. Let I_0 be the input current resulting from this source. The corresponding network is presented in Figure 3.11. From this network, we obtain

$$\hat{F}(\tilde{\alpha}_1) = 1 + \hat{T} = 1 - V'_{13} = 1 - \frac{100V'_{35} + \alpha_2 V'_{45} - \alpha_1}{9.09} = 103.07 \times 10^3 \tag{3.53}$$

Likewise, we can use the same procedure to compute the return difference $\hat{F}(\tilde{\alpha}_2)$.

Network Functions and Feedback

Wai-Kai Chen
University of Illinois at Chicago

4.1 Blackman's Formula **4**-1
4.2 Sensitivity Function **4**-6

We now study the effects of feedback on amplifier impedance and gain and obtain some useful relations among the return difference, the null return difference, and impedance functions in general.

Refer to the general feedback configuration of Figure 3.6. Let w be a transfer function. As before, to emphasize the importance of the feedback element x, we write $w = w(x)$. To be definite, let $w(x)$ for the time being be the current gain between the output and input ports. Then, from Equation 3.24 we obtain

$$w(x) = \frac{I_{pq}}{I_s} = \frac{Y_2 V_{pq}}{I_s} = \frac{Y_{rp,sq}(x)}{Y_{uv}(x)} Y_2 \tag{4.1}$$

yielding

$$\frac{w(x)}{w(0)} = \frac{Y_{rp,sq}(x)}{Y_{uv}(x)} \frac{Y_{uv}(0)}{Y_{rp,sq}(0)} = \frac{\hat{F}(x)}{F(x)} \tag{4.2}$$

provided that $w(0) \neq 0$. This gives a very useful formula for computing the current gain:

$$w(x) = w(0) \frac{\hat{F}(x)}{F(x)} \tag{4.3}$$

Equation 4.3 remains valid if $w(x)$ represents the transfer impedance $z_{rp,sq} = V_{pq}/I_s$ instead of the current gain.

4.1 Blackman's Formula

In particular, when $r = p$ and $s = q$, $w(x)$ represents the driving-point impedance $z_{rr,ss}(x)$ looking into the terminals r and s, and we have a somewhat different interpretation. In this case, $F(x)$ is the return difference with respect to the element x under the condition $I_s = 0$. Thus, $F(x)$ is the return difference for the situation when the port where the input impedance is defined is left open without a source and we write $F(x) = F$(input open circuited). Likewise, from Figure 3.6, $\hat{F}(x)$ is the return difference with respect to x for the input excitation I_s and output response V_{rs} under the condition I_s is adjusted so that V_{rs} is identically zero. Thus, $\hat{F}(x)$ is the return difference for the situation when the port where the input

impedance is defined is short circuited, and we write $\hat{F}(x) = F$ (input short circuited). Consequently, the input impedance $Z(x)$ looking into a terminal pair can be conveniently expressed as

$$Z(x) = Z(0)\frac{F(\text{input short circuited})}{F(\text{input open circuited})} \tag{4.4}$$

This is the well-known Blackman's formula for computing an active impedance. The formula is extremely useful because the right-hand side can usually be determined rather easily. If x represents the controlling parameter of a controlled source in a single-loop feedback amplifier, then setting $x = 0$ opens the feedback loop and $Z(0)$ is simply a passive impedance. The return difference for x when the input port is short circuited or open circuited is relatively simple to compute because shorting out or opening a terminal pair frequently breaks the feedback loop. In addition, Blackman's formula can be used to determine the return difference by measurements. Because it involves two return differences, only one of them can be identified and the other must be known in advance. In the case of a single-loop feedback amplifier, it is usually possible to choose a terminal pair so that either the numerator or the denominator on the right-hand side of Equation 4.4 is unity. If F(input short circuited) = 1, F(input open circuited) becomes the return difference under normal operating condition and we have

$$F(x) = \frac{Z(0)}{Z(x)} \tag{4.5}$$

On the other hand, if F(input open circuited) = 1, F(input short circuited) becomes the return difference under normal operating condition and we obtain

$$F(x) = \frac{Z(x)}{Z(0)} \tag{4.6}$$

Example 4.1

The network of Figure 4.1 is a general active RC one-port realization of a rational impedance. We use Blackman's formula to verify that its input admittance is given by

$$Y = 1 + \frac{Z_3 - Z_4}{Z_1 - Z_2} \tag{4.7}$$

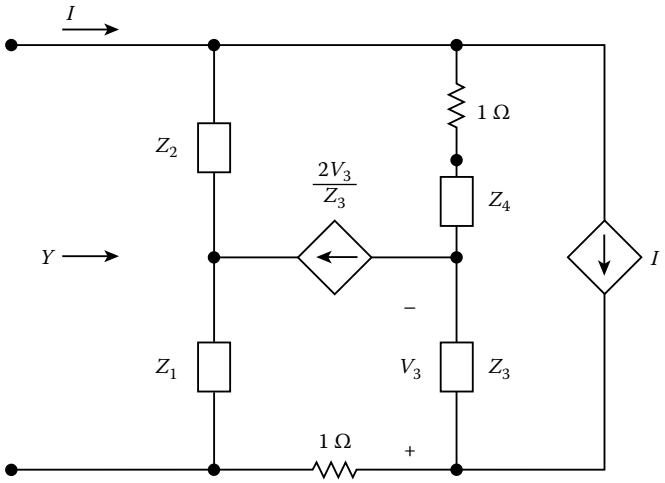

FIGURE 4.1 General active RC one-port realization of a rational function.

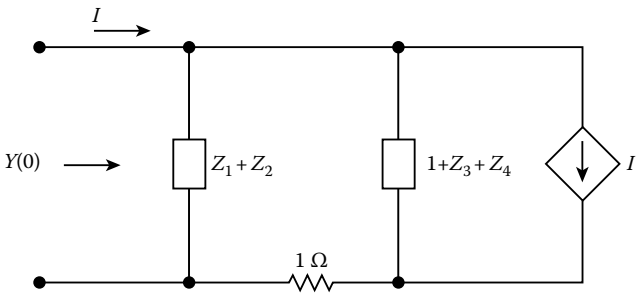

FIGURE 4.2 Network used to compute $Y(0)$.

Appealing to Equation 4.4, the input admittance written as $Y = Y(x)$ can be written as

$$Y(x) = Y(0)\frac{F(\text{input open circuited})}{F(\text{input short circuited})} \tag{4.8}$$

where $x = 2/Z_3$. By setting x to zero, the network used to compute $Y(0)$ is shown in Figure 4.2. Its input admittance is

$$Y(0) = \frac{Z_1 + Z_2 + Z_3 + Z_4 + 2}{Z_1 + Z_2} \tag{4.9}$$

When the input port is open circuited, the network of Figure 4.1 degenerates to that depicted in Figure 4.3. The return difference with respect to x is

$$F(\text{input open circuited}) = 1 - V_3' = \frac{Z_1 + Z_3 - Z_2 - Z_4}{2 + Z_1 + Z_2 + Z_3 + Z_4} \tag{4.10}$$

where the returned voltage V_3' at the controlling branch is given by

$$V_3' = \frac{2(1 + Z_2 + Z_4)}{2 + Z_1 + Z_2 + Z_3 + Z_4} \tag{4.11}$$

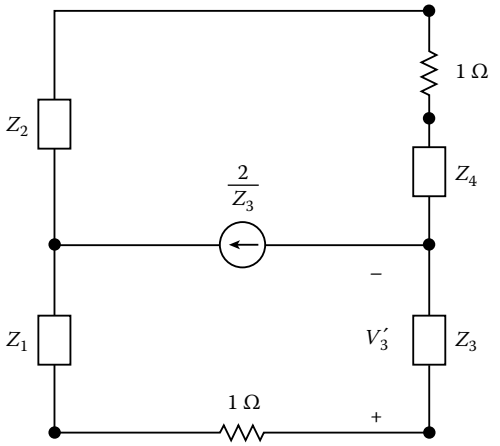

FIGURE 4.3 Network used to compute F(input open circuited).

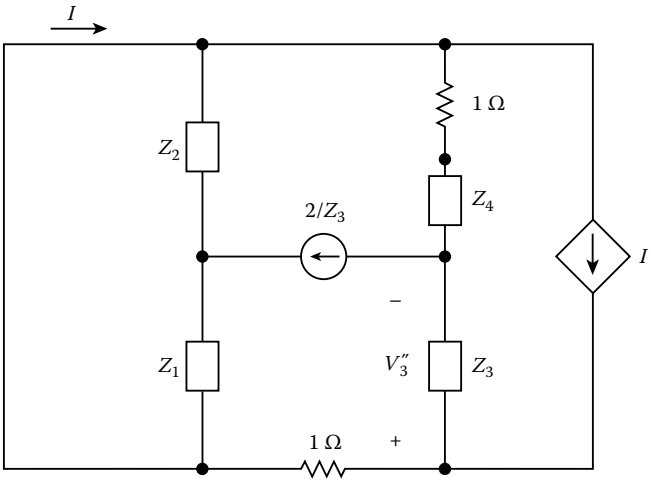

FIGURE 4.4 Network used to compute F(input short circuited).

To compute the return difference when the input port is short circuited, we use the network of Figure 4.4 and obtain

$$F(\text{input short circuited}) = 1 - V_3'' = \frac{Z_1 - Z_2}{Z_1 + Z_2} \tag{4.12}$$

where the return voltage V_3'' at the controlling branch is found to be

$$V_3'' = \frac{2Z_2}{Z_1 + Z_2} \tag{4.13}$$

Substituting Equations 4.9, 4.10, and 4.12 in Equation 4.8 yields the desired result.

$$Y = 1 + \frac{Z_3 - Z_4}{Z_1 - Z_2} \tag{4.14}$$

To determine the effect of feedback on the input and output impedances, we choose the series-parallel feedback configuration of Figure 4.5. By shorting the terminals of Y_2, we interrupt the feedback loop,

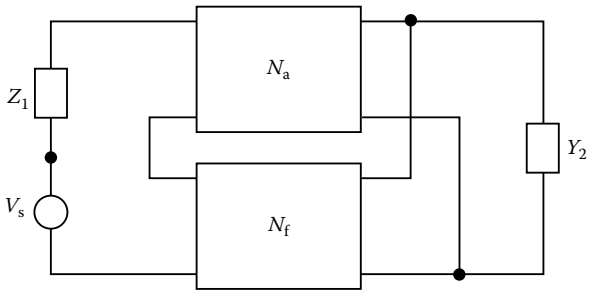

FIGURE 4.5 Series-parallel feedback configuration.

therefore, formula (Equation 4.5) applies and the output impedance across the load admittance Y_2 becomes

$$Z_{\text{out}}(x) = \frac{Z_{\text{out}}(0)}{F(x)} \tag{4.15}$$

demonstrating that the impedance measured across the path of the feedback is reduced by the factor that is the normal value of the return difference with respect to the element x, where x is an arbitrary element of interest. For the input impedance of the amplifier looking into the voltage source V_s of Figure 4.5, by open circuiting or removing the voltage source V_s, we break the feedback loop. Thus, formula (Equation 4.6) applies and the input impedance becomes

$$Z_{\text{in}}(x) = F(x)Z_{\text{in}}(0) \tag{4.16}$$

meaning that the impedance measured in series lines is increased by the same factor $F(x)$. Similar conclusions can be reached for other types of configurations discussed in Chapter 2 by applying Blackman's formula.

Again, refer to the general feedback configuration of Figure 3.6. If $w(x)$ represents the voltage gain V_{pq}/V_{rs} or the transfer admittance I_{pq}/V_{rs}. Then, from Equation 4.27 we can write

$$\frac{w(x)}{w(0)} = \frac{Y_{rp,sq}(x)}{Y_{rp,sq}(0)} \frac{Y_{rr,ss}(0)}{Y_{rr,ss}(x)} \tag{4.17}$$

The first term in the product on the right-hand side is the null return difference $\hat{F}(x)$ with respect to x for the input terminals r and s and output terminals p and q. The second term is the reciprocal of the null return difference with respect to x for the same input and output port at terminals r and s. This reciprocal can then be interpreted as the return difference with respect to x when the input port of the amplifier is short circuited. Thus, the voltage gain or the transfer admittance can be expressed as

$$w(x) = w(0)\frac{\hat{F}(x)}{F(\text{input short circuited})} \tag{4.18}$$

Finally, if $w(x)$ denotes the short circuit current gain I_{pq}/I_s as Y_2 approaches infinity, we obtain

$$\frac{w(x)}{w(0)} = \frac{Y_{rp,sq}(x)}{Y_{rp,sq}(0)} \frac{Y_{pp,qq}(0)}{Y_{pp,qq}(x)} \tag{4.19}$$

The second term in the product on the right-hand side is the reciprocal of the return difference with respect to x when the output port of the amplifier is short circuited, giving a formula for the short circuit current gain as

$$w(x) = w(0)\frac{\hat{F}(x)}{F(\text{output short circuited})} \tag{4.20}$$

Again, consider the voltage-series or series-parallel feedback amplifier of Figure 3.9 an equivalent network of which is given in Figure 3.10. The return differences $F(\tilde{\alpha}_k)$, the null return differences $\hat{F}(\tilde{\alpha}_k)$ and the voltage gain w were computed earlier in Equations 3.45, 3.52, and 3.44, and are repeated next:

$$F(\tilde{\alpha}_1) = 93.70, \quad F(\tilde{\alpha}_2) = 18.26 \tag{4.21a}$$

$$\hat{F}(\tilde{\alpha}_1) = 103.07 \times 10^3, \quad \hat{F}(\tilde{\alpha}_2) = 2018.70 \tag{4.21b}$$

$$w = \frac{V_{25}}{V_s} = w(\tilde{\alpha}_1) = w(\tilde{\alpha}_2) = 45.39 \tag{4.21c}$$

We apply Equation 4.18 to calculate the voltage gain w, as follows:

$$w(\tilde{\alpha}_1) = w(0)\frac{\hat{F}(\tilde{\alpha}_1)}{F(\text{input short circuited})} = 0.04126\frac{103.07 \times 10^3}{93.699} = 45.39 \tag{4.22}$$

where

$$w(0) = \left.\frac{Y_{12,55}(\tilde{\alpha}_1)}{Y_{11,55}(\tilde{\alpha}_1)}\right|_{\tilde{\alpha}_1=0} = \frac{205.24 \times 10^{-12}}{497.41 \times 10^{-11}} = 0.04126 \tag{4.23a}$$

$$F(\text{input short circuited}) = \frac{Y_{11,55}(\tilde{\alpha}_1)}{Y_{11,55}(0)} = \frac{466.07 \times 10^{-9}}{4.9741 \times 10^{-9}} = 93.699 \tag{4.23b}$$

and

$$w(\tilde{\alpha}_2) = w(0)\frac{\hat{F}(\tilde{\alpha}_2)}{F(\text{input short circuited})} = 0.41058\frac{2018.70}{18.26} = 45.39 \tag{4.24}$$

where

$$w(0) = \frac{Y_{12,55}(\tilde{\alpha}_2)}{Y_{11,55}(\tilde{\alpha}_2)}|_{\tilde{\alpha}_2=0} = \frac{104.79 \times 10^{-10}}{255.22 \times 10^{-10}} = 0.41058 \tag{4.25a}$$

$$F(\text{input short circuited}) = \frac{Y_{11,55}(\tilde{\alpha}_2)}{Y_{11,55}(0)} = \frac{466.07 \times 10^{-9}}{25.52 \times 10^{-9}} = 18.26 \tag{4.25b}$$

4.2 Sensitivity Function

One of the most important effects of negative feedback is its ability to make an amplifier less sensitive to the variations of its parameters because of aging, temperature variations, or other environment changes. A useful quantitative measure for the degree of dependence of an amplifier on a particular parameter is known as the sensitivity. The sensitivity function, written as $\mathcal{S}(x)$, for a given transfer function with respect to an element x is defined as the ratio of the fractional change in a transfer function to the fractional change in x for the situation when all changes concerned are differentially small. Thus, if $w(x)$ is the transfer function, the sensitivity function can be written as

$$\mathcal{S}(x) = \lim_{\Delta x \to 0} \frac{\Delta w/w}{\Delta x/x} = \frac{x}{w}\frac{\partial w}{\partial x} = x\frac{\partial \ln w}{\partial x} \tag{4.26}$$

Refer to the general feedback configuration of Figure 3.6, and let $w(x)$ represent either the current gain I_{pq}/I_s or the transfer impedance V_{pq}/I_s for the time being. Then, we obtain from Equation 3.24

$$w(x) = Y_2\frac{Y_{rp,sq}(x)}{Y_{uv}(x)} \text{ or } \frac{Y_{rp,sq}(x)}{Y_{uv}(x)} \tag{4.27}$$

As before, we write

$$\dot{Y}_{uv}(x) = \frac{\partial Y_{uv}(x)}{\partial x} \tag{4.28a}$$

$$\dot{Y}_{rp,sq}(x) = \frac{\partial Y_{rp,sq}(x)}{\partial x} \tag{4.28b}$$

obtaining

$$Y_{uv}(x) = Y_{uv}(0) + x\dot{Y}_{uv}(x) \tag{4.29a}$$

$$Y_{rp,sq}(x) = Y_{rp,sq}(0) + x\dot{Y}_{rp,sq}(x) \tag{4.29b}$$

Substituting Equation 4.27 in Equation 4.26, in conjunction with Equation 4.29, yields

$$\begin{aligned}\mathcal{S}(x) &= x\frac{\dot{Y}_{rp,sq}(x)}{Y_{rp,sq}(x)} - x\frac{\dot{Y}_{uv}(x)}{Y_{uv}(x)} = \frac{Y_{rp,sq}(x) - Y_{rp,sq}(0)}{Y_{rp,sq}(x)} - \frac{Y_{uv}(x) - Y_{uv}(0)}{Y_{uv}(x)} \\ &= \frac{Y_{uv}(0)}{Y_{uv}(x)} - \frac{Y_{rp,sq}(0)}{Y_{rp,sq}(x)} = \frac{1}{F(x)} - \frac{1}{\hat{F}(x)}\end{aligned} \tag{4.30}$$

Combining this with Equation 4.3, we obtain

$$\mathcal{S}(x) = \frac{1}{F(x)}\left[1 - \frac{w(0)}{w(x)}\right] \tag{4.31}$$

Observe that if $w(0) = 0$, Equation 4.31 becomes

$$\mathcal{S}(x) = \frac{1}{F(x)} \tag{4.32}$$

meaning that sensitivity is equal to the reciprocal of the return difference. For the ideal feedback model, the feedback path is unilateral. Hence, $w(0) = 0$ and

$$\mathcal{S} = \frac{1}{F} = \frac{1}{1+T} = \frac{1}{1-\mu\beta} \tag{4.33}$$

For a practical amplifier, $w(0)$ is usually very much smaller than $w(x)$ in the passband, and $F \approx 1/\mathcal{S}$ may be used as a good estimate of the reciprocal of the sensitivity in the same frequency band. A single-loop feedback amplifier composed of a cascade of common-emitter stages with a passive network providing the desired feedback fulfills this requirements. If in such a structure any one of the transistors fails, the forward transmission is nearly zero and $w(0)$ is practically zero. Our conclusion is that if the failure of any element will interrupt the transmission through the amplifier as a whole to nearly zero, the sensitivity is approximately equal to the reciprocal of the return difference with respect to that element. In the case of driving-point impedance, $w(0)$ is not usually smaller than $w(x)$, and the reciprocity relation is not generally valid.

Now assume that $w(x)$ represents the voltage gain. Substituting Equation 4.27 in Equation 4.26 results in

$$\begin{aligned}\mathcal{S}(x) &= x\frac{\dot{Y}_{rp,sq}(x)}{Y_{rp,sq}(x)} - x\frac{\dot{Y}_{rr,ss}(x)}{Y_{rr,ss}(x)} = \frac{Y_{rp,sq}(x) - Y_{rp,sq}(0)}{Y_{rp,sq}(x)} - \frac{Y_{rr,ss}(x) - Y_{rr,ss}(0)}{Y_{rr,ss}(x)} \\ &= \frac{Y_{rr,ss}(0)}{Y_{rr,ss}(x)} - \frac{Y_{rp,sq}(0)}{Y_{rp,sq}(x)} = \frac{1}{F(\text{input short circuited})} - \frac{1}{\hat{F}(x)}\end{aligned} \tag{4.34}$$

Combining this with Equation 4.18 gives

$$\mathcal{S}(x) = \frac{1}{F(\text{input short circuited})}\left[1 - \frac{w(0)}{w(x)}\right] \tag{4.35}$$

Finally, if $w(x)$ denotes the short circuit current gain I_{pq}/I_s as Y_2 approaches infinity, the sensitivity function can be written as

$$\mathcal{S}(x) = \frac{Y_{pp,qq}(0)}{Y_{pp,qq}(x)} - \frac{Y_{rp,sq}(0)}{Y_{rp,sq}(x)} = \frac{1}{F(\text{output short circuited})} - \frac{1}{\hat{F}(x)} \tag{4.36}$$

which when combined with Equation 4.20 yields

$$\mathcal{S}(x) = \frac{1}{F(\text{output short circuited})}\left[1 - \frac{w(0)}{w(x)}\right] \tag{4.37}$$

We remark that Equations 4.31, 4.35, and 4.39 are quite similar. If the return difference $F(x)$ is interpreted properly, they can all be represented by the single relation Equation 4.31. As before, if $w(0) = 0$, the sensitivity for the voltage gain function is equal to the reciprocal of the return difference under the situation that the input port of the amplifier is short circuited, whereas the sensitivity for the short circuit current gain is the reciprocal of the return difference when the output port is short circuited.

Example 4.2

The network of Figure 4.6 is a common-emitter transistor amplifier. After removing the biasing circuit and using the common-emitter hybrid model for the transistor at low frequencies, an equivalent network of the amplifier is presented in Figure 4.7 with

$$I_s' = \frac{V_s}{R_1 + r_x} \tag{4.38a}$$

$$G_1' = \frac{1}{R_1'} = \frac{1}{R_1 + r_x} + \frac{1}{r_\pi} \tag{4.38b}$$

$$G_2' = \frac{1}{R_2'} = \frac{1}{R_2} + \frac{1}{R_c} \tag{4.38c}$$

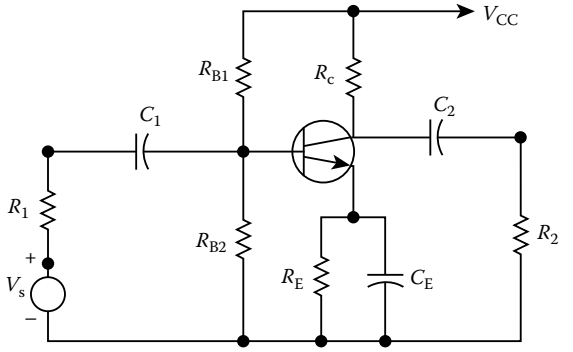

FIGURE 4.6 Common-emitter transistor feedback amplifier.

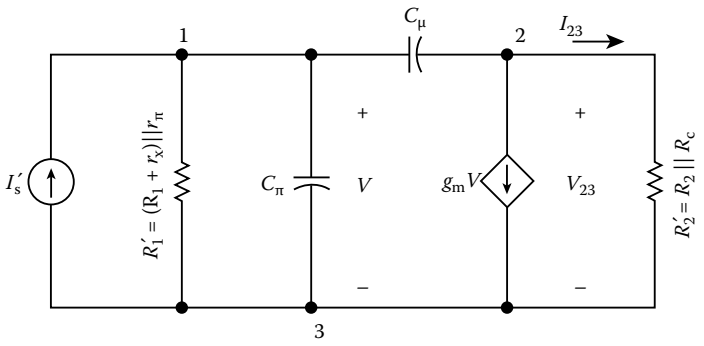

FIGURE 4.7 Equivalent network of the feedback amplifier of Figure 4.6.

The indefinite admittance matrix of the amplifier is

$$\mathbf{Y} = \begin{bmatrix} G'_1 + sC_\pi + sC_\mu & -sC_\mu & -G'_1 - sC_\pi \\ g_m - sC_\mu & G'_2 + sC_\mu & -G'_2 - g_m \\ -G'_1 - sC_\pi - g_m & -G'_2 & G'_1 + G'_2 + sC_\pi + g_m \end{bmatrix} \tag{4.39}$$

Assume that the controlling parameter g_m is the element of interest. The return difference and the null return difference with respect to g_m in Figure 4.7 with I'_s as the input port and R'_2, as the output port, are

$$F(g_m) = \frac{Y_{33}(g_m)}{Y_{33}(0)} = \frac{(G'_1 + sC_\pi)(G'_2 + sC_\mu) + sC_\mu(G'_2 + g_m)}{(G'_1 + sC_\pi)(G'_2 + sC_\mu) + sC_\mu G'_2} \tag{4.40}$$

$$\hat{F}(g_m) = \frac{Y_{12,33}(g_m)}{Y_{12,33}(0)} = \frac{sC_\mu - g_m}{sC_\mu} = 1 - \frac{g_m}{sC_\mu} \tag{4.41}$$

The current gain I_{23}/I'_s as defined in Figure 4.7, is computed as

$$w(g_m) = \frac{Y_{12,33}(g_m)}{R'_2 Y_{33}(g_m)} = \frac{sC_\mu - g_m}{R'_2[(G'_1 + sC_\pi)(G'_2 + sC_\mu) + sC_\mu(G'_2 + g_m)]} \tag{4.42}$$

Substituting these in Equations 4.30 or 4.31 gives

$$\mathcal{S}(g_m) = -\frac{g_m(G'_1 + sC_\pi + sC_\mu)(G'_2 + sC_\mu)}{(sC_\mu - g_m)[(G'_1 + sC_\pi)(G'_2 + sC_\mu) + sC_\mu(G'_2 + g_m)]} \tag{4.43}$$

Finally, we compute the sensitivity for the driving-point impedance facing the current source I'_s. From Equation 4.31, we obtain

$$\mathcal{S}(g_m) = \frac{1}{F(g_m)}\left[1 - \frac{Z(0)}{Z(g_m)}\right] = -\frac{sC_\mu g_m}{(G'_1 + sC_\pi)(G'_2 + sC_\mu) + sC_\mu(G'_2 + g_m)} \tag{4.44}$$

where

$$Z(g_m) = \frac{Y_{11,33}(g_m)}{Y_{33}(g_m)} = \frac{G'_2 + sC_\mu}{(G'_1 + sC_\pi)(G'_2 + sC_\mu) + sC_\mu(G'_2 + g_m)} \tag{4.45}$$

Measurement of Return Difference

5.1 Blecher's Procedure **5**-2
5.2 Impedance Measurements **5**-4
References **5**-7

Wai-Kai Chen
University of Illinois at Chicago

The zeros of the network determinant are called the natural frequencies. Their locations in the complex-frequency plane are extremely important in that they determine the stability of the network. A network is said to be stable if all of its natural frequencies are restricted to the open left-half side of the complex-frequency plane. If a network determinant is known, its roots can readily be computed explicitly with the aid of a computer if necessary, and the stability problem can then be settled directly. However, for a physical network there remains the difficulty of getting an accurate formulation of the network determinant itself, because every equivalent network is, to a greater or lesser extent, an idealization of the physical reality. As frequency is increased, parasitic effects of the physical elements must be taken into account. What is really needed is some kind of experimental verification that the network is stable and will remain so under certain prescribed conditions. The measurement of the return difference provides an elegant solution to this problem.

The return difference with respect to an element x in a feedback amplifier is defined by

$$F(x) = \frac{Y_{uv}(x)}{Y_{uv}(0)} \tag{5.1}$$

Because $Y_{uv}(x)$ denotes the nodal determinant, the zeros of the return difference are exactly the same as the zeros of the nodal determinant provided that there is no cancellation of common factors between $Y_{uv}(x)$ and $Y_{uv}(0)$. Therefore, if $Y_{uv}(0)$ is known to have no zeros in the closed right-half side of the complex-frequency plane, which is usually the case in a single-loop feedback amplifier when x is set to zero, $F(x)$ gives precisely the same information about the stability of a feedback amplifier as does the nodal determinant itself. The difficulty inherent in the measurement of the return difference with respect to the controlling parameter of a controlled source is that, in a physical system, the controlling branch and the controlled source both form part of a single device such as a transistor, and cannot be physically separated. In the following, we present a scheme that does not require the physical decomposition of a device.

Let a device of interest be brought out as a two-port network connected to a general four-port network as shown in Figure 5.1. For our purposes, assume that this device is characterized by its y parameters, and represented by its y-parameter equivalent two-port network as indicated in Figure 5.2, in which the parameter y_{21} controls signal transmission in the forward direction through the device, whereas y_{12} gives

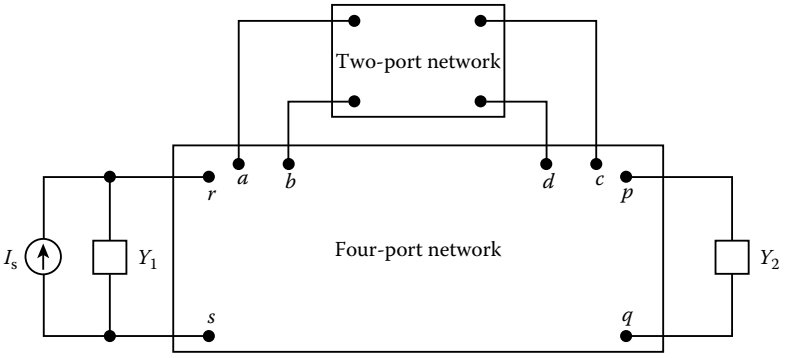

FIGURE 5.1 The general configuration of a feedback amplifier with a two-port device.

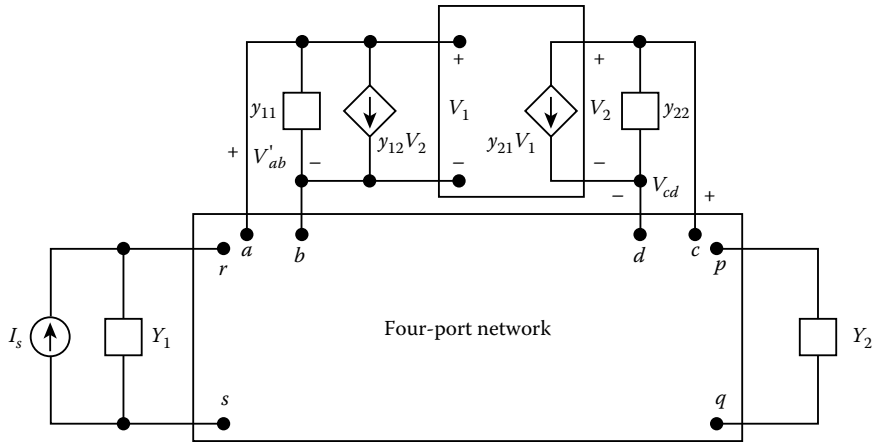

FIGURE 5.2 The representation of a two-port device in Figure 5.1 by its *y* parameters.

the reverse transmission, accounting for the internal feedback within the device. Our objective is to measure the return difference with respect to the forward short circuit transfer admittance y_{21}.

5.1 Blecher's Procedure [1]

Let the two-port device be a transistor operated in the common-emitter configuration with terminals a, $b = d$, and c representing, respectively, the base, emitter, and collector terminals. To simplify our notation, let $a = 1$, $b = d = 3$, and $c = 2$, as exhibited explicitly in Figure 5.3.

To measure $F(y_{21})$, we break the base terminal of the transistor and apply a 1 V excitation at its input as exhibited in Figure 5.3. To ensure that the controlled current source $y_{21}V_{13}$ drives a replica of what it sees during normal operation, we connect an active one-port network composed of a parallel combination of the admittance y_{11} and a controlled current source $y_{12}V_{23}$ at terminals 1 and 3. The returned voltage V_{13} is precisely the negative of the return ratio with respect to the element y_{21}. If, in the frequency band of interest, the externally applied feedback is large compared with the internal feedback of the transistor, the controlled source $y_{12}V_{23}$ can be ignored. If, however, we find that this internal feedback cannot be ignored, we can simulate it by using an additional transistor, connected as shown in Figure 5.4. This additional transistor must be matched as closely as possible to the one in question. The one-port

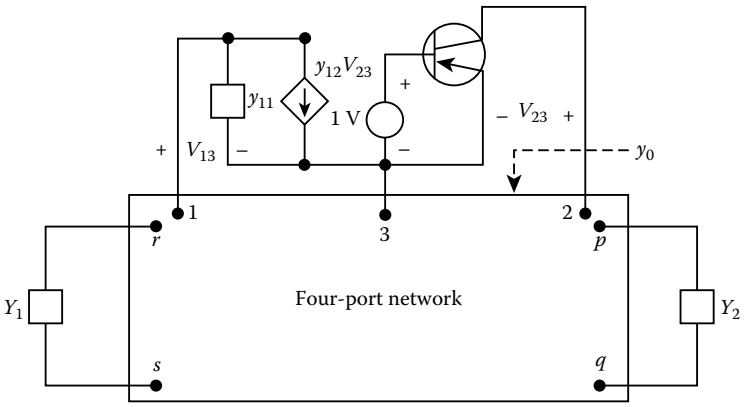

FIGURE 5.3 A physical interpretation of the return difference $F(y_{21})$ for a transistor operated in the common-emitter configuration and represented by its y parameters y_{ij}.

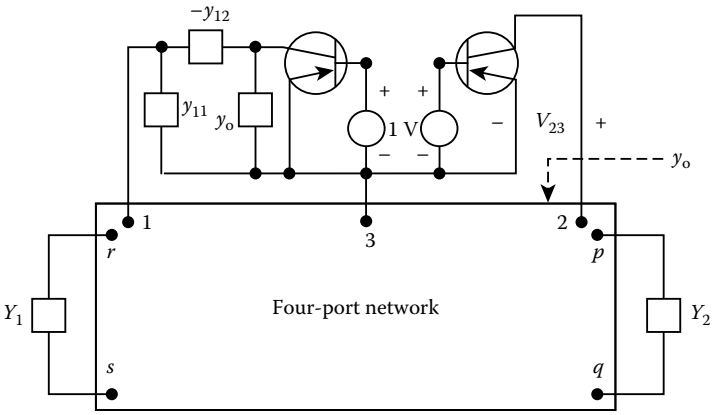

FIGURE 5.4 The measurement of return difference $F(y_{21})$ for a transistor operated in the common-emitter configuration and represented by its y parameters y_{ij}.

admittance y_o denotes the admittance presented to the output port of the transistor under consideration as indicated in Figures 5.3 and 5.4. For a common-emitter state, it is perfectly reasonable to assume that $|y_0| \gg |y_{12}|$ and $|y_{11}| \gg |y_{12}|$. Under these assumptions, it is straightforward to show that the Norton equivalent network looking into the two-port network at terminals 1 and 3 of Figure 5.4 can be approximated by the parallel combination of y_{11} and $y_{12}V_{23}$, as indicated in Figure 5.3. In Figure 5.4, if the voltage sources have very low internal impedances, we can join together the two base terminals of the transistors and feed them both from a single voltage source of very low internal impedance. In this way, we avoid the need of using two separate sources. For the procedure to be feasible, we must demonstrate the admittances y_{11} and $-y_{12}$ can be realized as the input admittances of one-port RC networks.

Consider the hybrid-pi equivalent network of a common-emitter transistor of Figure 5.5, the short circuit admittance matrix of which is found to be

$$\mathbf{Y}_{sc} = \frac{1}{g_x + g_\pi + sC_\pi + sC_\mu} \begin{bmatrix} g_x(g_\pi + sC_\pi + sC_\mu) & -g_x sC_\mu \\ g_x(g_m - sC_\mu) & sC_\mu(g_x + g_\pi + sC_\pi + g_m) \end{bmatrix} \tag{5.2}$$

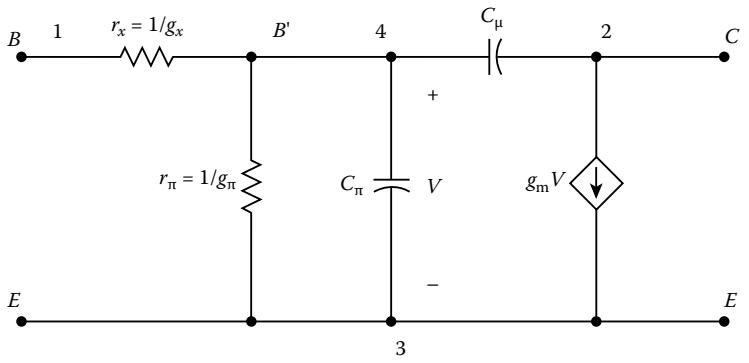

FIGURE 5.5 The hybrid-pi equivalent network of a common-emitter transistor.

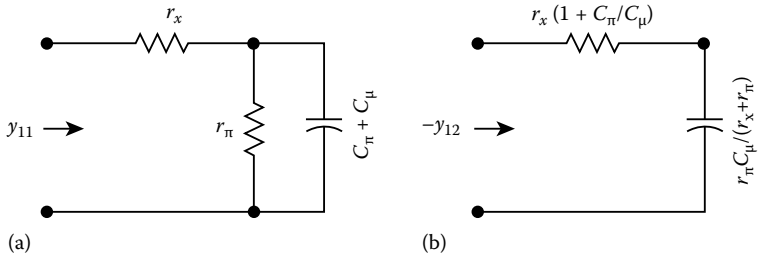

FIGURE 5.6 (a) The realization of y_{11} and (b) the realization of $-y_{12}$.

It is easy to confirm that the admittance y_{11} and $-y_{12}$ can be realized by the one-port networks of Figure 5.6.

5.2 Impedance Measurements

In this section, we show that the return difference can be evaluated by measuring two driving-point impedances at a convenient port in the feedback amplifier [2].

Refer again to the general feedback configuration of Figure 5.2. Suppose that we wish to evaluate the return difference with respect to the forward short circuit transfer admittance y_{21}. The controlling parameters y_{12} and y_{21} enter the indefinite-admittance matrix $\mathbf{Y}$ in the rectangular patterns as shown next:

$$\mathbf{Y}(x) = \begin{array}{c} \\ a \\ b \\ c \\ d \end{array} \begin{array}{c} \begin{array}{cccc} a & b & c & d \end{array} \\ \begin{bmatrix} & & y_{12} & -y_{12} \\ & & -y_{12} & y_{12} \\ y_{21} & -y_{21} & & \\ -y_{21} & y_{21} & & \end{bmatrix} \end{array} \tag{5.3}$$

To emphasize the importance of y_{12} and y_{21}, we again write $Y_{uv}(x)$ as $Y_{uv}(y_{12}, y_{21})$ and $z_{aa,bb}(x)$ as $z_{aa,bb}(y_{12}, y_{21})$. By appealing to Equation 3.25, the impedance looking into terminals a and b of Figure 5.2 is

$$z_{aa,bb}(y_{12}, y_{21}) = \frac{Y_{aa,bb}(y_{12}, y_{21})}{Y_{dd}(y_{12}, y_{21})} \tag{5.4}$$

The return difference with respect to y_{21} is given by

$$F(y_{21}) = \frac{Y_{dd}(y_{12}, y_{21})}{Y_{dd}(y_{12}, 0)} \tag{5.5}$$

Combining these yields

$$\begin{aligned} F(y_{21})z_{aa,bb}(y_{12}, y_{21}) &= \frac{Y_{aa,bb}(y_{12}, y_{21})}{Y_{dd}(y_{12}, 0)} = \frac{Y_{aa,bb}(0, 0)}{Y_{dd}(y_{12}, 0)} \\ &= \frac{Y_{aa,bb}(0, 0)}{Y_{dd}(0, 0)} \frac{Y_{dd}(0, 0)}{Y_{dd}(y_{12}, 0)} = \frac{z_{aa,bb}(0, 0)}{F(y_{12})|_{y_{21}=0}} \end{aligned} \tag{5.6}$$

obtaining a relation

$$F(y_{12})|_{y_{21}=0} F(y_{21}) = \frac{z_{aa,bb}(0, 0)}{z_{aa,bb}(y_{12}, y_{21})} \tag{5.7}$$

among the return differences and the driving-point impedances. $F(y_{12})|_{y21\,=\,0}$ is the return difference with respect to y_{12} when y_{21} is set to zero. This quantity can be measured by the arrangement of Figure 5.7. $z_{aa,bb}(y_{12}, y_{21})$ is the driving-point impedance looking into terminals a and b of the network of Figure 5.2. Finally, $z_{aa,bb}(0, 0)$ is the impedance to which $z_{aa,bb}(y_{12}, y_{21})$ reduces when the controlling parameters y_{12} and y_{21} are both set to zero. This impedance can be measured by the arrangement of Figure 5.8. Note that, in all three measurements, the independent current source I_s is removed.

Suppose that we wish to measure the return difference $F(y_{21})$ with respect to the forward transfer admittance y_{21} of a common-emitter transistor shown in Figure 5.2. Then, the return difference $F(y_{12})$ when y_{21} is set to zero, for all practical purposes, is indistinguishable from unity. Therefore, Equation 5.7 reduces to the following simpler form:

$$F(y_{21}) \approx \frac{z_{11,\,33}(0, 0)}{z_{11,\,33}(y_{12}, y_{21})} \tag{5.8}$$

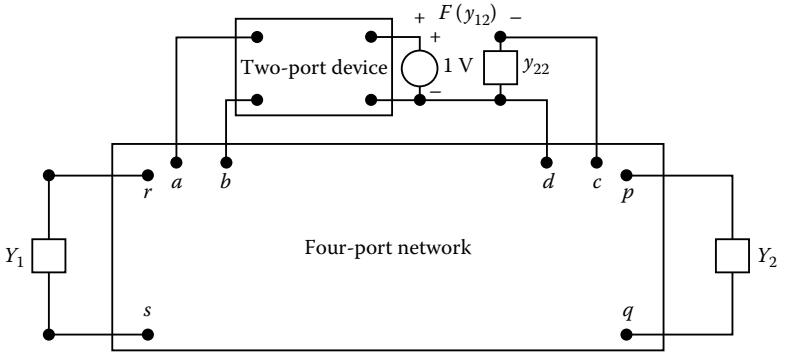

FIGURE 5.7 The measurement of the return difference $F(y_{12})$ with y_{21} set to zero.

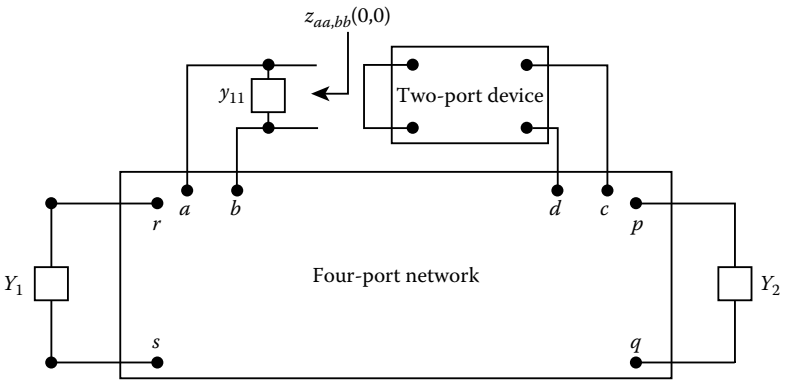

FIGURE 5.8 The measurement of the driving-point impedance $z_{aa,bb}(0, 0)$.

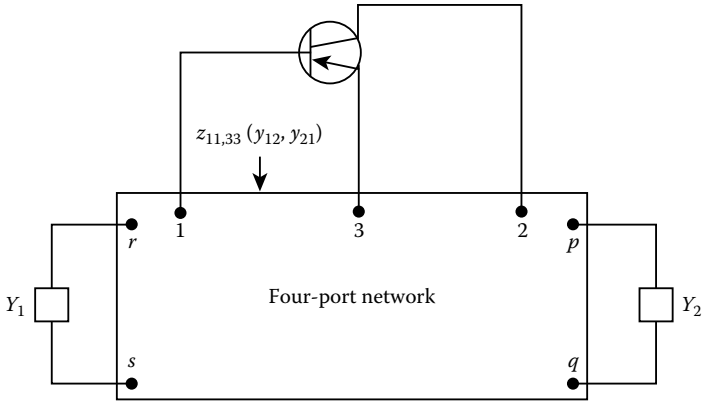

FIGURE 5.9 The measurement of the driving-point impedance $z_{11,33}(y_{12}, y_{21})$.

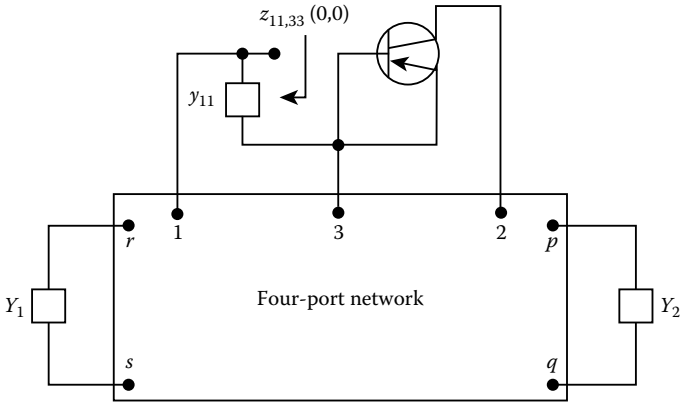

FIGURE 5.10 The measurement of the driving-point impedance $z_{11,33}(0, 0)$.

showing that the return difference $F(y_{21})$ effectively equals the ratio of two functional values assumed by the driving-point impedance looking into terminals 1 and 3 of Figure 5.2 under the condition that the controlling parameters y_{12} and y_{21} are both set to zero and the condition that they assume their nominal values. These two impedances can be measured by the network arrangements of Figures 5.9 and 5.10.

Wai-Kai Chen
University of Illinois at Chicago

So far, we have studied the single-loop feedback amplifiers. The concept of feedback was introduced in terms of return difference. We found that return difference is the difference between the unit applied signal and the returned signal. The returned signal has the same physical meaning as the loop transmission in the ideal feedback mode. It plays an important role in the study of amplifier stability, its sensitivity to the variations of the parameters, and the determination of its transfer and driving point impedances. The fact that return difference can be measured experimentally for many practical amplifiers indicates that we can include all the parasitic effects in the stability study, and that stability problem can be reduced to a Nyquist plot.

In this section, we study amplifiers that contain a multiplicity of inputs, outputs, and feedback loops. They are referred to as the multiple-loop feedback amplifiers. As might be expected, the notion of return difference with respect to an element is no longer applicable, because we are dealing with a group of elements. For this, we generalize the concept of return difference for a controlled source to the notion of return difference matrix for a multiplicity of controlled sources. For measurement situations, we introduce the null return difference matrix and discuss its physical significance. We demonstrate that the determinant of the overall transfer function matrix can be expressed explicitly in terms of the determinants of the return difference and the null return difference matrices, thereby allowing us to generalize Blackman's formula for the input impedance.

6.1 Multiple-Loop Feedback Amplifier Theory

The general configuration of a multiple-input, multiple-output, and multiple-loop feedback amplifier is presented in Figure 6.1, in which the input, output, and feedback variables may be either currents or voltages. For the specific arrangement of Figure 6.1, the input and output variables are represented by an n-dimensional vector $\mathbf{u}$ and an m-dimensional vector $\mathbf{y}$ as

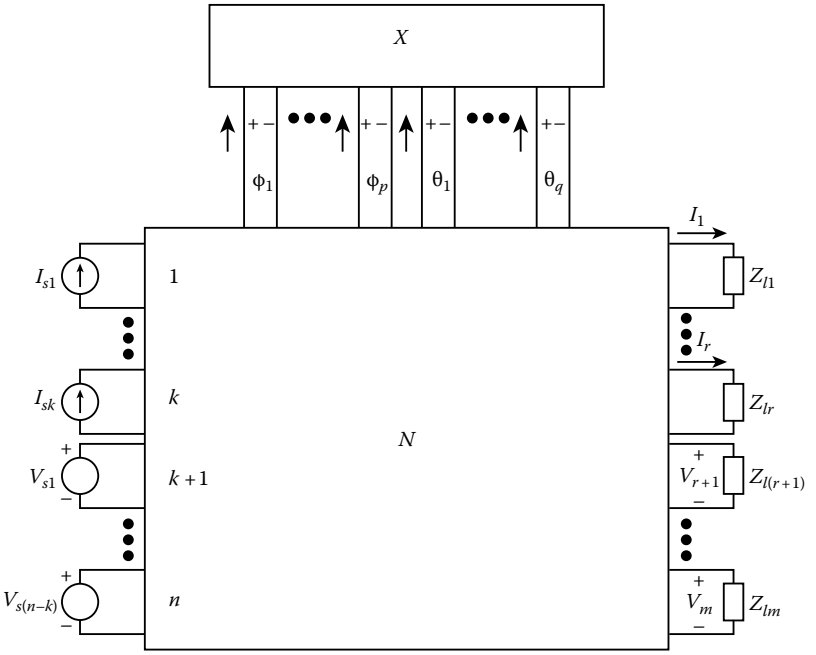

FIGURE 6.1 The general configuration of a multiple-input, multiple-output, and multiple-loop feedback amplifier.

$$\mathbf{u}(s) = \begin{bmatrix} u_1 \\ u_2 \\ \vdots \\ u_k \\ u_{k+1} \\ u_{k+2} \\ \vdots \\ u_n \end{bmatrix} = \begin{bmatrix} I_{s1} \\ I_{s2} \\ \vdots \\ I_{sk} \\ V_{s1} \\ V_{s2} \\ \vdots \\ V_{s(n-k)} \end{bmatrix}, \quad \mathbf{y}(s) = \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_r \\ y_{r+1} \\ y_{r+2} \\ \vdots \\ y_m \end{bmatrix} = \begin{bmatrix} I_1 \\ I_2 \\ \vdots \\ I_r \\ V_{r+1} \\ V_{r+2} \\ \vdots \\ V_m \end{bmatrix} \tag{6.1}$$

respectively. The elements of interest can be represented by a rectangular matrix $\mathbf{X}$ of order $q \times p$ relating the controlled and controlling variables by the matrix equation

$$\mathbf{\Theta} = \begin{bmatrix} \theta_1 \\ \theta_2 \\ \vdots \\ \theta_q \end{bmatrix} = \begin{bmatrix} x_{11} & x_{12} & \cdots & x_{1p} \\ x_{21} & x_{22} & \cdots & x_{2p} \\ \vdots & \vdots & \vdots & \vdots \\ x_{q1} & x_{q2} & \cdots & x_{qp} \end{bmatrix} \begin{bmatrix} \phi_1 \\ \phi_2 \\ \vdots \\ \phi_p \end{bmatrix} = \mathbf{X}\mathbf{\Phi} \tag{6.2}$$

where the p-dimensional vector $\mathbf{\Phi}$ is called the controlling vector, and the q-dimensional vector $\mathbf{\Theta}$ is the controlled vector. The controlled variables θ_k and the controlling variables Φ_k can either be currents or voltages. The matrix $\mathbf{X}$ can represent either a transfer-function matrix or a driving-point function matrix. If $\mathbf{X}$ represents a driving-point function matrix, the vectors $\mathbf{\Theta}$ and $\mathbf{\Phi}$ are of the same dimension ($q = p$) and their components are the currents and voltages of a p-port network.

The general configuration of Figure 6.1 can be represented equivalently by the block diagram of Figure 6.2 in which N is a $(p + q + m + n)$-port network and the elements of interest are exhibited

explicitly by the block **X**. For the $(p+q+m+n)$-port network N, the vectors **u** and are **Θ** are its inputs, and the vectors **Φ** and **y** its outputs. Since N is linear, the input and output vectors are related by the matrix equations

$$\mathbf{\Phi} = \mathbf{A\Theta} + \mathbf{Bu} \tag{6.3a}$$

$$\mathbf{y} = \mathbf{C\Theta} + \mathbf{Du} \tag{6.3b}$$

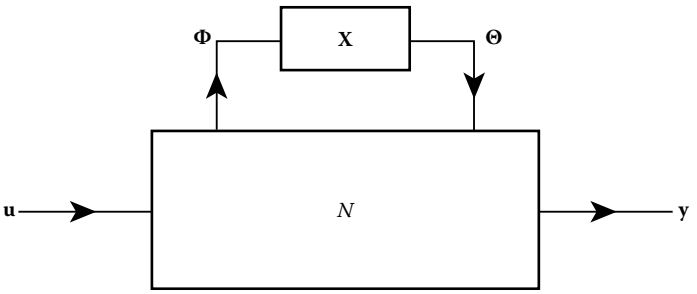

FIGURE 6.2 The block diagram of the general feedback configuration of Figure 6.1.

where **A**, **B**, **C**, and **D** are transfer-function matrices of orders $p \times q$, $p \times n$, $m \times q$, and $m \times n$, respectively. The vectors **Θ** and **Φ** are not independent and are related by

$$\mathbf{\Theta} = \mathbf{X\Phi} \tag{6.3c}$$

The relationships among the above three linear matrix equations can also be represented by a matrix signal-flow graph as shown in Figure 6.3 known as the fundamental matrix feedback-flow graph. The overall closed-loop transfer-function matrix of the multiple-loop feedback amplifier is defined by the equation

$$\mathbf{y} = \mathbf{W}(\mathbf{X})\mathbf{u} \tag{6.4}$$

where $\mathbf{W}(\mathbf{X})$ is of order $m \times n$. As before, to emphasize the importance of **X**, the matrix **W** is written as $\mathbf{W}(\mathbf{X})$ for the present discussion, even though it is also a function of the complex-frequency variable s. Combining the previous matrix equations, the transfer-function matrix is

$$\mathbf{W}(\mathbf{X}) = \mathbf{D} + \mathbf{CX}(\mathbf{1}_p - \mathbf{AX})^{-1}\mathbf{B} \tag{6.5a}$$

or

$$\mathbf{W}(\mathbf{X}) = \mathbf{D} + \mathbf{C}(\mathbf{1}_q - \mathbf{XA})^{-1}\mathbf{XB} \tag{6.5b}$$

where $\mathbf{1}_p$ denotes the identity matrix of order p. Clearly, we have

$$\mathbf{W}(\mathbf{0}) = \mathbf{D} \tag{6.6}$$

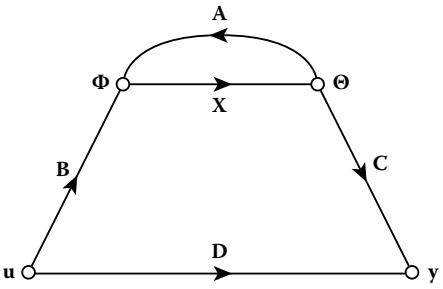

FIGURE 6.3 The fundamental matrix feedback-flow graph.

In particular, when **X** is square and nonsingular, Equation 6.5 can be written as

$$\mathbf{W}(\mathbf{X}) = \mathbf{D} + \mathbf{C}(\mathbf{X}^{-1} - \mathbf{A})^{-1}\mathbf{B} \tag{6.7}$$

Example 6.1

Consider the voltage-series feedback amplifier of Figure 3.9. An equivalent network is shown in Figure 6.4 in which we have assumed that the two transistors

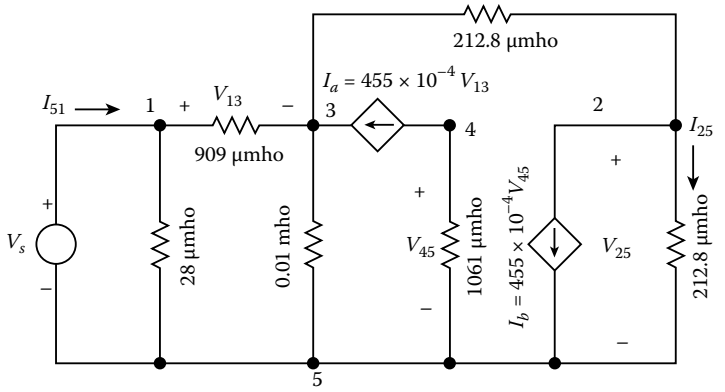

FIGURE 6.4 An equivalent network of the voltage-series feedback amplifier of Figure 3.9.

are identical with $h_{ie} = 1.1$ kΩ, $h_{fe} = 50$, $h_{re} = h_{oe} = 0$. Let the controlling parameters of the two controlled sources be the elements of interest. Then we have

$$\mathbf{\Theta} = \begin{bmatrix} I_a \\ I_b \end{bmatrix} = 10^{-4} \begin{bmatrix} 455 & 0 \\ 0 & 455 \end{bmatrix} \begin{bmatrix} V_{13} \\ V_{45} \end{bmatrix} = \mathbf{X\Phi} \tag{6.8}$$

Assume that the output voltage V_{25} and input current I_{51} are the output variables. Then the seven-port network N defined by the variables V_{13}, V_{45}, V_{25}, I_{51}, I_a, I_b, and V_s can be characterized by the matrix equations

$$\begin{aligned} \mathbf{\Phi} = \begin{bmatrix} V_{13} \\ V_{45} \end{bmatrix} &= \begin{bmatrix} -90.782 & 45.391 \\ -942.507 & 0 \end{bmatrix} \begin{bmatrix} I_a \\ I_b \end{bmatrix} + \begin{bmatrix} 0.91748 \\ 0 \end{bmatrix} [V_s] \\ &= \mathbf{A\Theta} + \mathbf{Bu} \end{aligned} \tag{6.9a}$$

$$\begin{aligned} \mathbf{y} = \begin{bmatrix} V_{25} \\ I_{51} \end{bmatrix} &= \begin{bmatrix} 45.391 & -2372.32 \\ -0.08252 & 0.04126 \end{bmatrix} \begin{bmatrix} I_a \\ I_b \end{bmatrix} + \begin{bmatrix} 0.041260 \\ 0.000862 \end{bmatrix} [V_s] \\ &= \mathbf{C\Theta} + \mathbf{Du} \end{aligned} \tag{6.9b}$$

According to Equation 6.4, the transfer-function matrix of the amplifier is defined by the matrix equation

$$\mathbf{y} = \begin{bmatrix} V_{25} \\ I_{51} \end{bmatrix} = \begin{bmatrix} w_{11} \\ w_{21} \end{bmatrix} [V_s] = \mathbf{W}(\mathbf{X})\mathbf{u} \tag{6.10}$$

Because **X** is square and nonsingular, we can use Equation 6.7 to calculate **W**(**X**):

$$\mathbf{W}(\mathbf{X}) = \mathbf{D} + \mathbf{C}(\mathbf{X}^{-1} - \mathbf{A})^{-1}\,\mathbf{B} = \begin{bmatrix} 45.387 \\ 0.369 \times 10^{-4} \end{bmatrix} = \begin{bmatrix} w_{11} \\ w_{21} \end{bmatrix} \tag{6.11}$$

where

$$(\mathbf{X}^{-1} - \mathbf{A})^{-1} = 10^{-4} \begin{bmatrix} 4.856 & 10.029 \\ -208.245 & 24.914 \end{bmatrix} \tag{6.12}$$

obtaining the closed-loop voltage gain w_{11} and input impedance Z_{in} facing the voltage source V_s as

$$w_{11} = \frac{V_{25}}{V_s} = 45.387, \quad Z_{in} = \frac{V_s}{I_{51}} = \frac{1}{w_{21}} = 27.1\ \text{k}\Omega \tag{6.13}$$

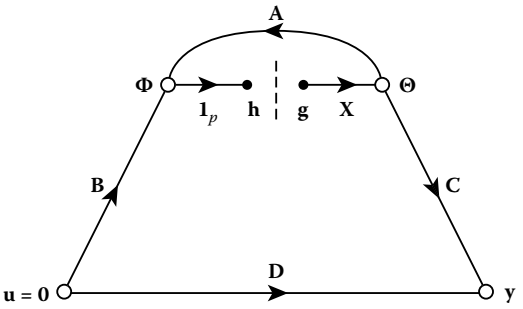

FIGURE 6.5 The physical interpretation of the loop-transmission matrix.

6.2 Return Different Matrix

In this section, we extend the concept of return difference with respect to an element to the notion of return difference matrix with respect to a group of elements.

In the fundamental matrix feedback-flow graph of Figure 6.3, suppose that we break the input of the branch with transmittance **X**, set the input excitation vector **u** to zero, and apply a signal p-vector **g** to the right of the breaking mark, as depicted in Figure 6.5. Then the returned signal p-vector **h** to the left of the breaking mark is found to be

$$\mathbf{h} = \mathbf{AXg} \tag{6.14}$$

The square matrix **AX** is called the loop-transmission matrix and its negative is referred to as the return ratio matrix denoted by

$$\mathbf{T(X)} = -\mathbf{AX} \tag{6.15}$$

The difference between the applied signal vector **g** and the returned signal vector **h** is given by

$$\mathbf{g} - \mathbf{h} = (\mathbf{1}_p - \mathbf{AX})\mathbf{g} \tag{6.16}$$

The square matrix $\mathbf{1}_p - \mathbf{AX}$ relating the applied signal vector **g** to the difference of the applied signal vector **g** and the returned signal vector **h** is called the return difference matrix with respect to **X** and is denoted by

$$\mathbf{F(X)} = \mathbf{1}_p - \mathbf{AX} \tag{6.17}$$

Combining this with Equation 6.15 gives

$$\mathbf{F(X)} = \mathbf{1}_p + \mathbf{T(X)} \tag{6.18}$$

For the voltage-series feedback amplifier of Figure 6.4, let the controlling parameters of the two controlled current sources be the elements of interest. Then the return ratio matrix is found from Equations 6.8 and 6.9a

$$\begin{aligned}\mathbf{T(X)} = -\mathbf{AX} &= -\begin{bmatrix} -90.782 & 45.391 \\ -942.507 & 0 \end{bmatrix}\begin{bmatrix} 455 \times 10^{-4} & 0 \\ 0 & 455 \times 10^{-4} \end{bmatrix} \\ &= \begin{bmatrix} 4.131 & -2.065 \\ 42.884 & 0 \end{bmatrix}\end{aligned} \tag{6.19}$$

obtaining the return difference matrix as

$$\mathbf{F}(\mathbf{X}) = \mathbf{1}_2 + \mathbf{T}(\mathbf{X}) = \begin{bmatrix} 5.131 & -2.065 \\ 42.884 & 1 \end{bmatrix} \tag{6.20}$$

6.3 Null Return Difference Matrix

A direct extension of the null return difference for the single-loop feedback amplifier is the null return difference matrix for the multiple-loop feedback networks.

Refer again to the fundamental matrix feedback-flow graph of Figure 6.3. As before, we break the branch with transmittance **X** and apply a signal p-vector **g** to the right of the breaking mark, as illustrated in Figure 6.6. We then adjust the input excitation n-vector **u** so that the total output m-vector **y** resulting from the inputs **g** and **u** is zero. From Figure 6.6, the desired input excitation **u** is found:

$$\mathbf{Du} + \mathbf{CXg} = \mathbf{0} \tag{6.21}$$

or

$$\mathbf{u} = -\mathbf{D}^{-1}\mathbf{CXg} \tag{6.22}$$

provided that the matrix **D** is square and nonsingular. This requires that the output **y** be of the same dimension as the input **u** or $m = n$. Physically, this requirement is reasonable because the effects at the output caused by **g** can be neutralized by a unique input excitation **u** only when **u** and **y** are of the same dimension. With these inputs **u** and **g**, the returned signal **h** to the left of the breaking mark in Figure 6.6 is computed as

$$\mathbf{h} = \mathbf{Bu} + \mathbf{AXg} = (-\mathbf{BD}^{-1}\mathbf{CX} + \mathbf{AX})\mathbf{g} \tag{6.23}$$

obtaining

$$\mathbf{g} - \mathbf{h} = (\mathbf{1}_p - \mathbf{AX} + \mathbf{BD}^{-1}\mathbf{CX})\mathbf{g} \tag{6.24}$$

The square matrix

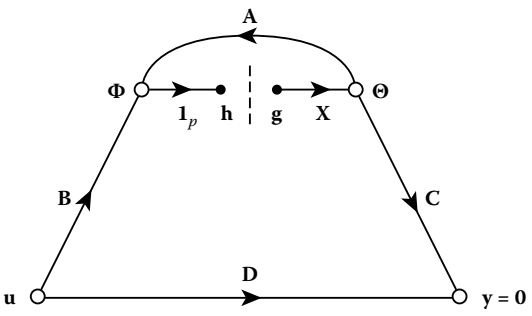

FIGURE 6.6 The physical interpretation of the null return difference matrix.

$$\begin{aligned} \hat{\mathbf{F}}(\mathbf{X}) &= \mathbf{1}_p + \hat{\mathbf{T}}(\mathbf{X}) \\ &= \mathbf{1}_p - \mathbf{AX} + \mathbf{BD}^{-1}\mathbf{CX} = \mathbf{1}_p - \hat{\mathbf{A}}\mathbf{X} \end{aligned} \tag{6.25}$$

relating the input signal vector **g** to the difference of the input signal vector **g**, and the returned signal vector **h** is called the null return difference matrix with respect to **X**, where

$$\hat{\mathbf{T}}(\mathbf{X}) = -\mathbf{AX} + \mathbf{BD}^{-1}\mathbf{CX} = -\hat{\mathbf{A}}\mathbf{X} \tag{6.26a}$$

$$\hat{\mathbf{A}} = \mathbf{A} - \mathbf{BD}^{-1}\mathbf{C} \tag{6.26b}$$

The square matrix $\hat{\mathbf{T}}(\mathbf{X})$ is known as the *null return ratio matrix.*

Example 6.2

Consider again the voltage-series feedback amplifier of Figure 3.9, an equivalent network of which is illustrated in Figure 6.4. Assume that the voltage V_{25} is the output variable. Then from Equation 6.9

$$\begin{aligned}\mathbf{\Phi} = \begin{bmatrix} V_{13} \\ V_{45} \end{bmatrix} &= \begin{bmatrix} -90.782 & 45.391 \\ -942.507 & 0 \end{bmatrix} \begin{bmatrix} I_a \\ I_b \end{bmatrix} + \begin{bmatrix} 0.91748 \\ 0 \end{bmatrix} [V_s] \\ &= \mathbf{A\Theta} + \mathbf{B}u \end{aligned} \tag{6.27a}$$

$$\begin{aligned} y = [V_{25}] &= [45.391 \quad -2372.32] \begin{bmatrix} I_a \\ I_b \end{bmatrix} + [0.04126]\,[V_s] \\ &= \mathbf{C\Theta} + \mathbf{D}u \end{aligned} \tag{6.27b}$$

Substituting the coefficient matrices in Equation 6.26b, we obtain

$$\hat{\mathbf{A}} = \mathbf{A} - \mathbf{BD}^{-1}\mathbf{C} = \begin{bmatrix} -1,\ 100.12 & 52,\ 797.6 \\ -942.507 & 0 \end{bmatrix} \tag{6.28}$$

giving the null return difference matrix with respect to $\mathbf{X}$ as

$$\hat{\mathbf{F}}(\mathbf{X}) = \mathbf{1}_2 - \hat{\mathbf{A}}\mathbf{X} = \begin{bmatrix} 51.055 & -2402.29 \\ 42.884 & 1 \end{bmatrix} \tag{6.29}$$

Suppose that the input current I_{51} is chosen as the output variable. Then, from Equation 6.9b we have

$$y = [I_{51}] = [-0.08252\ \ 0.04126] \begin{bmatrix} I_a \\ I_b \end{bmatrix} + [0.000862]\,[V_s] = \mathbf{C\Theta} + Du \tag{6.30}$$

The corresponding null return difference matrix becomes

$$\hat{\mathbf{F}}(\mathbf{X}) = \mathbf{1}_2 - \hat{\mathbf{A}}\mathbf{X} = \begin{bmatrix} 1.13426 & -0.06713 \\ 42.8841 & 1 \end{bmatrix} \tag{6.31}$$

where

$$\hat{\mathbf{A}} = \begin{bmatrix} -2.95085 & 1.47543 \\ -942.507 & 0 \end{bmatrix} \tag{6.32}$$

6.4 Transfer-Function Matrix and Feedback

In this section, we show the effect of feedback on the transfer-function matrix $\mathbf{W}(\mathbf{X})$. Specifically, we express det $\mathbf{W}(\mathbf{X})$ in terms of the det $\mathbf{X}(\mathbf{0})$ and the determinants of the return difference and null return difference matrices, thereby generalizing Blackman's impedance formula for a single input to a multiplicity of inputs.

Before we proceed to develop the desired relation, we state the following determinant identity for two arbitrary matrices $\mathbf{M}$ and $\mathbf{N}$ of order $m \times n$ and $n \times m$:

$$\det(\mathbf{1}_m + \mathbf{MN}) = \det(\mathbf{1}_n + \mathbf{NM}) \tag{6.33}$$

a proof of which may be found in [1,2]. Using this, we next establish the following generalization of Blackman's formula for input impedance.

THEOREM 6.1

In a multiple-loop feedback amplifier, if $\mathbf{W}(\mathbf{0}) = \mathbf{D}$ *is nonsingular, then the determinant of the transfer-function matrix* $\mathbf{W}(\mathbf{X})$ *is related to the determinants of the return difference matrix* $\mathbf{F}(\mathbf{X})$ *and the null return difference matrix* $\hat{\mathbf{F}}(\mathbf{X})$ *by*

$$\det \mathbf{W}(\mathbf{X}) = \det \mathbf{W}(\mathbf{0}) \frac{\det \hat{\mathbf{F}}(\mathbf{X})}{\det \mathbf{F}(\mathbf{X})} \tag{6.34}$$

PROOF: From Equation 6.5a, we obtain

$$\mathbf{W}(\mathbf{X}) = \mathbf{D}\left[\mathbf{1}_n + \mathbf{D}^{-1}\mathbf{C}\mathbf{X}(\mathbf{1}_p - \mathbf{A}\mathbf{X})^{-1}\mathbf{B}\right] \tag{6.35}$$

yielding

$$\begin{aligned} \det \mathbf{W}(\mathbf{X}) &= [\det \mathbf{W}(\mathbf{0})]\det\left[\mathbf{1}_n + \mathbf{D}^{-1}\mathbf{C}\mathbf{X}(\mathbf{1}_p - \mathbf{A}\mathbf{X})^{-1}\mathbf{B}\right] \\ &= [\det \mathbf{W}(\mathbf{0})]\det\left[\mathbf{1}_p + \mathbf{B}\mathbf{D}^{-1}\mathbf{C}\mathbf{X}(\mathbf{1}_p - \mathbf{A}\mathbf{X})^{-1}\right] \\ &= [\det \mathbf{W}(\mathbf{0})]\det\left[\mathbf{1}_p - \mathbf{A}\mathbf{X} + \mathbf{B}\mathbf{D}^{-1}\mathbf{C}\mathbf{X}\right](\mathbf{1}_p - \mathbf{A}\mathbf{X})^{-1} \\ &= \frac{\det \mathbf{W}(\mathbf{0})\det \hat{\mathbf{F}}(\mathbf{X})}{\det \mathbf{F}(\mathbf{X})} \end{aligned} \tag{6.36}$$

The second line follows directly from Equation 6.33. This completes the proof of the theorem.

As indicated in Equation 4.4, the input impedance $Z(x)$ looking into a terminal pair can be conveniently expressed as

$$Z(x) = Z(0)\frac{F(\text{input short ciruited})}{F(\text{input open circuited})} \tag{6.37}$$

A similar expression can be derived from Equation 6.34 if $\mathbf{W}(\mathbf{X})$ denotes the impedance matrix of an n-port network of Figure 6.1. In this case, $\mathbf{F}(\mathbf{X})$ is the return difference matrix with respect to $\mathbf{X}$ for the situation when the n ports where the impedance matrix are defined are left open without any sources, and we write $\mathbf{F}(\mathbf{X}) = \mathbf{F}(\text{input open-circuited})$. Likewise, $\hat{\mathbf{F}}(\mathbf{X})$ is the return difference matrix with respect to $\mathbf{X}$ for the input port-current vector $\mathbf{I}_s$ and the output port-voltage vector $\mathbf{V}$ under the condition that $\mathbf{I}_s$ is adjusted so that the port-voltage vector $\mathbf{V}$ is identically zero. In other words, $\hat{\mathbf{F}}(\mathbf{X})$ is the return difference matrix for the situation when the n ports, where the impedance matrix is defined, are short-circuited, and we write $\hat{\mathbf{F}}(\mathbf{X}) = \mathbf{F}$ (input short-circuited). Consequently, the determinant of the impedance matrix $\mathbf{Z}(\mathbf{X})$ of an n-port network can be expressed from Equation 6.34 as

$$\det \mathbf{Z}(\mathbf{X}) = \det \mathbf{Z}(\mathbf{0})\frac{\det \mathbf{F}\,(\text{input short circuited})}{\det \mathbf{F}\,(\text{input open circuited})} \tag{6.38}$$ ■

Example 6.3

Refer again to the voltage-series feedback amplifier of Figure 3.9, an equivalent network of which is illustrated in Figure 6.4. As computed in Equation 6.20, the return difference matrix with respect to the two controlling parameters is given by

$$\mathbf{F}(\mathbf{X}) = \mathbf{1}_2 + \mathbf{T}(\mathbf{X}) = \begin{bmatrix} 5.131 & -2.065 \\ 42.884 & 1 \end{bmatrix} \tag{6.39}$$

the determinant of which is

$$\det \mathbf{F}(\mathbf{X}) = 93.68646 \tag{6.40}$$

If V_{25} of Figure 6.4 is chosen as the output and V_s as the input, the null return difference matrix is, from Equation 6.29,

$$\hat{\mathbf{F}}(\mathbf{X}) = \mathbf{1}_2 - \hat{\mathbf{A}}\mathbf{X} = \begin{bmatrix} 51.055 & -2402.29 \\ 42.884 & 1 \end{bmatrix} \tag{6.41}$$

the determinant of which is

$$\det \hat{\mathbf{F}}(\mathbf{X}) = 103,\ 071 \tag{6.42}$$

By appealing to Equation 6.34, the feedback amplifier voltage gain V_{25}/V_s can be written as

$$w(\mathbf{X}) = \frac{V_{25}}{V_s} = w(\mathbf{0})\frac{\det \hat{\mathbf{F}}(\mathbf{X})}{\det \mathbf{F}(\mathbf{X})} = 0.04126\ \frac{103,\ 071}{93.68646} = 45.39 \tag{6.43}$$

confirming Equation 3.44, where $w(\mathbf{0}) = 0.04126$, as given in Equation 6.27b.

Suppose, instead, that the input current I_{51} is chosen as the output and V_s as the input. Then, from Equation 6.31, the null return difference matrix becomes

$$\hat{\mathbf{F}}(\mathbf{X}) = \mathbf{1}_2 - \hat{\mathbf{A}}(\mathbf{X}) = \begin{bmatrix} 1.13426 & -0.06713 \\ 42.8841 & 1 \end{bmatrix} \tag{6.44}$$

the determinant of which is

$$\det \hat{\mathbf{F}}(\mathbf{X}) = 4.01307 \tag{6.45}$$

By applying Equation 6.34, the amplifier input admittance is obtained as

$$\begin{aligned} w(\mathbf{X}) = \frac{I_{51}}{V_s} &= w(\mathbf{0})\frac{\det \hat{\mathbf{F}}(\mathbf{X})}{\det \mathbf{F}(\mathbf{X})} \\ &= 8.62 \times 10^{-4}\ \frac{4.01307}{93.68646} = 36.92\ \mu\text{mho} \end{aligned} \tag{6.46}$$

or 27.1 kΩ, confirming Equation 6.13, where $w(\mathbf{0}) = 862\ \mu$mho is found from Equation 6.30.

Another useful application of the generalized Blackman's formula (Equation 6.38) is that it provides the basis of a procedure for the indirect measurement of return difference. Refer to the general feedback network of Figure 6.2. Suppose that we wish to measure the return difference $F(y_{21})$ with respect to the forward short circuit transfer admittance y_{21} of a two-port device characterized by its y parameters y_{ij}.

Choose the two controlling parameters y_{21} and y_{12} to be the elements of interest. Then, from Figure 5.2 we obtain

$$\mathbf{\Theta} = \begin{bmatrix} I_a \\ I_b \end{bmatrix} = \begin{bmatrix} y_{21} & 0 \\ 0 & y_{12} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \mathbf{X\Phi} \tag{6.47}$$

where I_a and I_b are the currents of the voltage-controlled current sources. By appealing to Equation 6.38, the impedance looking into terminals a and b of Figure 5.2 can be written as

$$z_{aa,bb}(y_{12}, y_{21}) = z_{aa,bb}(0, 0)\frac{\det \mathbf{F} \text{ (input short circuited)}}{\det \mathbf{F} \text{ (input open circuited)}} \tag{6.48}$$

When the input terminals a and b are open-circuited, the resulting return difference matrix is exactly the same as that found under normal operating conditions, and we have

$$\mathbf{F} \text{ (input open circuited)} = \mathbf{F}(\mathbf{X}) = \begin{bmatrix} F_{11} & F_{12} \\ F_{21} & F_{22} \end{bmatrix} \tag{6.49}$$

Because

$$\mathbf{F}(\mathbf{X}) = \mathbf{1}_2 - \mathbf{AX} \tag{6.50}$$

the elements F_{11} and F_{21} are calculated with $y_{12} = 0$, whereas F_{12} and F_{22} are evaluated with $y_{21} = 0$. When the input terminals a and b are short circuited, the feedback loop is interrupted and only the second row and first column element of the matrix $\mathbf{A}$ is nonzero, and we obtain

$$\det \mathbf{F} \text{ (input short circuited)} = 1 \tag{6.51}$$

Because $\mathbf{X}$ is diagonal, the return difference function $F(y_{21})$ can be expressed in terms of $\det \mathbf{F}(\mathbf{X})$ and the cofactor of the first row and first column element of $\mathbf{F}(\mathbf{X})$:

$$F(y_{21}) = \frac{\det \mathbf{F}(\mathbf{X})}{F_{22}} \tag{6.52}$$

Substituting these in Equation 6.48 yields

$$F(y_{12})|_{y_{21}=0}\ F(y_{21}) = \frac{z_{aa,bb}(0, 0)}{z_{aa,bb}(y_{12}, y_{21})} \tag{6.53}$$

where

$$F_{22} = 1 - a_{22}y_{12}|_{y_{21}=0} = F(y_{12})|_{y_{21}=0} \tag{6.54}$$

and a_{22} is the second row and second column element of $\mathbf{A}$. Formula (Equation 6.53) was derived earlier in Equation 5.7 using the network arrangements of Figures 5.7 and 5.8 to measure the elements $F(y_{12})|_{y_{21}=0}$ and $z_{aa,bb}(0,0)$, respectively.

6.5 Sensitivity Matrix

We have studied the sensitivity of a transfer function with respect to the change of a particular element in the network. In a multiple-loop feedback network, we are usually interested in the sensitivity of a transfer function with respect to the variation of a set of elements in the network. This set may include either

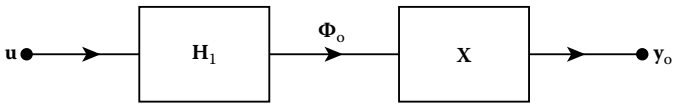

FIGURE 6.7 The block diagram of a multivariable open-loop control system.

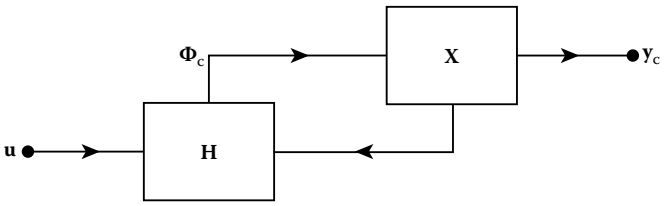

FIGURE 6.8 The general feedback structure.

elements that are inherently sensitive to variation or elements where the effect on the overall amplifier performance is of paramount importance to the designers. For this, we introduce a sensitivity matrix and develop formulas for computing multiparameter sensitivity function for a multiple-loop feedback amplifier [3].

Figure 6.7 is the block diagram of a multivariable open-loop control system with n inputs and m outputs, whereas Figure 6.8 is the general feedback structure. If all feedback signals are obtainable from the output and if the controllers are linear, no loss of generality occurs by assuming the controller to be of the form given in Figure 6.9.

Denote the set of Laplace-transformed input signals by the n-vector $\mathbf{u}$, the set of inputs to the network $\mathbf{X}$ in the open-loop configuration of Figure 6.7 by the p-vector $\mathbf{\Phi}_o$, and the set of outputs of the network $\mathbf{X}$ of Figure 6.7 by the m-vector $\mathbf{y}_o$. Let the corresponding signals for the closed-loop configuration of Figure 6.9 be denoted by the n-vector $\mathbf{u}$, the p-vector $\mathbf{\Phi}_c$, and the m-vector $\mathbf{y}_c$, respectively. Then, from Figures 6.7 and 6.9, we obtain the following relations:

$$\mathbf{y}_o = \mathbf{X}\mathbf{\Phi}_o \tag{6.55a}$$

$$\mathbf{\Phi}_o = \mathbf{H}_1\mathbf{u} \tag{6.55b}$$

$$\mathbf{y}_c = \mathbf{X}\mathbf{\Phi}_c \tag{6.55c}$$

$$\mathbf{\Phi}_c = \mathbf{H}_2(\mathbf{u} + \mathbf{H}_3\mathbf{y}_c) \tag{6.55d}$$

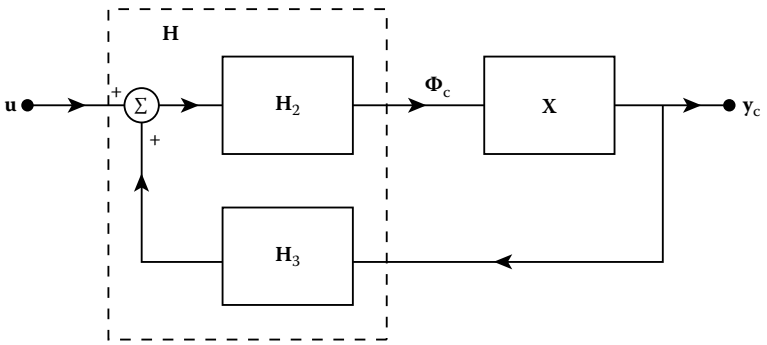

FIGURE 6.9 The general feedback configuration.

where the transfer-function matrices $\mathbf{X}$, $\mathbf{H}_1$, $\mathbf{H}_2$, and $\mathbf{H}_3$ are of order $m \times p$, $p \times n$, $p \times n$, and $n \times m$, respectively. Combining Equation 6.55c and d yields

$$(\mathbf{1}_m - \mathbf{X}\mathbf{H}_2\mathbf{H}_3)\mathbf{y}_c = \mathbf{X}\mathbf{H}_2\mathbf{u} \tag{6.56}$$

or

$$\mathbf{y}_c = (\mathbf{1}_m - \mathbf{X}\mathbf{H}_2\mathbf{H}_3)^{-1}\mathbf{X}\mathbf{H}_2\mathbf{u} \tag{6.57}$$

The closed-loop transfer function matrix $\mathbf{W}(\mathbf{X})$ that relates the input vector $\mathbf{u}$ to the output vector $\mathbf{y}_c$ is defined by the equation

$$\mathbf{y}_c = \mathbf{W}(\mathbf{X})\mathbf{u} \tag{6.58}$$

identifying from Equation 6.57 the $m \times n$ matrix

$$\mathbf{W}(\mathbf{X}) = (\mathbf{1}_m - \mathbf{X}\mathbf{H}_2\mathbf{H}_3)^{-1}\mathbf{X}\mathbf{H}_2 \tag{6.59}$$

Now, suppose that $\mathbf{X}$ is perturbed from $\mathbf{X}$ to $\mathbf{X} + \boldsymbol{\delta}\mathbf{X}$. The outputs of the open-loop and closed-loop systems of Figures 6.7 and 6.9 will no longer be the same as before. Distinguishing the new from the old variables by the superscript $+$, we have

$$\mathbf{y}_o^+ = \mathbf{X}^+\Phi_o \tag{6.60a}$$

$$\mathbf{y}_c^+ = \mathbf{X}^+\boldsymbol{\Phi}_c^+ \tag{6.60b}$$

$$\boldsymbol{\Phi}_c^+ = \mathbf{H}_2\left(\mathbf{u} + \mathbf{H}_3\mathbf{y}_c^+\right) \tag{6.60c}$$

where $\boldsymbol{\Phi}_o$ remains the same.

We next proceed to compare the relative effects of the variations of $\mathbf{X}$ on the performance of the open-loop and the closed-loop systems. For a meaningful comparison, we assume that $\mathbf{H}_1$, $\mathbf{H}_2$, and $\mathbf{H}_3$ are such that when there is no variation of $\mathbf{X}$, $\mathbf{y}_o = \mathbf{y}_c$. Define the error vectors resulting from perturbation of $\mathbf{X}$ as

$$\mathbf{E}_o = \mathbf{y}_o - \mathbf{y}_o^+ \tag{6.61a}$$

$$\mathbf{E}_c = \mathbf{y}_c - \mathbf{y}_c^+ \tag{6.61b}$$

A square matrix relating $\mathbf{E}_o$ to $\mathbf{E}_c$ is called the **sensitivity matrix** $\mathcal{S}(\mathbf{X})$ for the transfer function matrix $\mathbf{W}(\mathbf{X})$ with respect to the variations of $\mathbf{X}$:

$$\mathbf{E}_c = \mathcal{S}(\mathbf{X})\mathbf{E}_o \tag{6.62}$$

In the following, we express the **sensitivity matrix** $\mathcal{S}(\mathbf{X})$ in terms of the system matrices $\mathbf{X}$, $\mathbf{H}_2$, and $\mathbf{H}_3$.

The input and output relation similar to that given in Equation 6.57 for the perturbed system can be written as

$$\mathbf{y}_c^+ = (\mathbf{1}_m - \mathbf{X}^+\mathbf{H}_2\mathbf{H}_3)^{-1}\mathbf{X}^+\mathbf{H}_2\mathbf{u} \tag{6.63}$$

Substituting Equations 6.57 and 6.63 in Equation 6.61b gives

$$\begin{aligned}\mathbf{E}_c &= \mathbf{y}_c - \mathbf{y}_c^+ = \left[(\mathbf{1}_m - \mathbf{X}\mathbf{H}_2\mathbf{H}_3)^{-1}\mathbf{X}\mathbf{H}_2 - (\mathbf{1}_m - \mathbf{X}^+\mathbf{H}_2\mathbf{H}_3)^{-1}\mathbf{X}^+\mathbf{H}_2\right]\mathbf{u} \\ &= (\mathbf{1}_m - \mathbf{X}^+\mathbf{H}_2\mathbf{H}_3)^{-1}\left\{[\mathbf{1}_m - (\mathbf{X} + \boldsymbol{\delta}\mathbf{X})\mathbf{H}_2\mathbf{H}_3](\mathbf{1}_m - \mathbf{X}\mathbf{H}_2\mathbf{H}_3)^{-1}\mathbf{X}\mathbf{H}_2 - (\mathbf{X} + \boldsymbol{\delta}\mathbf{X})\mathbf{H}_2\right\}\mathbf{u} \\ &= (\mathbf{1}_m - \mathbf{X}^+\mathbf{H}_2\mathbf{H}_3)^{-1}\left[\mathbf{X}\mathbf{H}_2 - \boldsymbol{\delta}\mathbf{X}\mathbf{H}_2\mathbf{H}_3(\mathbf{1}_m - \mathbf{X}\mathbf{H}_2\mathbf{H}_3)^{-1}\mathbf{X}\mathbf{H}_2 - \mathbf{X}\mathbf{H}_2 - \boldsymbol{\delta}\mathbf{X}\mathbf{H}_2\right]\mathbf{u} \\ &= -(\mathbf{1}_m - \mathbf{X}^+\mathbf{H}_2\mathbf{H}_3)^{-1}\boldsymbol{\delta}\mathbf{X}\mathbf{H}_2[\mathbf{1}_n + \mathbf{H}_3\mathbf{W}(\mathbf{X})]\mathbf{u}\end{aligned} \tag{6.64}$$

From Equations 6.55d and 6.58, we obtain

$$\boldsymbol{\Phi}_c = \mathbf{H}_2[\mathbf{1}_n + \mathbf{H}_3\mathbf{W}(\mathbf{X})]\mathbf{u} \tag{6.65}$$

Because by assuming that $\mathbf{y}_o = \mathbf{y}_c$, we have

$$\boldsymbol{\Phi}_o = \boldsymbol{\Phi}_c = \mathbf{H}_2[\mathbf{1}_n + \mathbf{H}_3\mathbf{W}(\mathbf{X})]\mathbf{u} \tag{6.66}$$

yielding

$$\mathbf{E}_o = \mathbf{y}_o - \mathbf{y}_o^+ = (\mathbf{X} - \mathbf{X}^+)\boldsymbol{\Phi}_o = -\boldsymbol{\delta}\mathbf{X}\mathbf{H}_2[\mathbf{1}_n + \mathbf{H}_3\mathbf{W}(\mathbf{X})]\mathbf{u} \tag{6.67}$$

Combining Equations 6.64 and 6.67 yields an expression relating the error vectors $\mathbf{E}_c$ and $\mathbf{E}_o$ of the closed-loop and open-loop systems by

$$\mathbf{E}_c = (\mathbf{1}_m - \mathbf{X}^+\mathbf{H}_2\mathbf{H}_3)^{-1}\mathbf{E}_o \tag{6.68}$$

obtaining the sensitivity matrix as

$$\mathcal{S}(\mathbf{X}) = (\mathbf{1}_m - \mathbf{X}^+\mathbf{H}_2\mathbf{H}_3)^{-1} \tag{6.69}$$

For small variations of $\mathbf{X}$, $\mathbf{X}^+$ is approximately equal to $\mathbf{X}$. Thus, in Figure 6.9, if the matrix triple product $\mathbf{X}\mathbf{H}_2\mathbf{H}_3$ is regarded as the *loop-transmission matrix* and $-\mathbf{X}\mathbf{H}_2\mathbf{H}_3$ as the *return ratio matrix,* then the difference between the unit matrix and the loop-transmission matrix,

$$\mathbf{1}_m - \mathbf{X}\mathbf{H}_2\mathbf{H}_3 \tag{6.70}$$

can be defined as the *return difference matrix*. Therefore, Equation 6.69 is a direct extension of the sensitivity function defined for a single-input, single-output system and for a single parameter. Recall that in Equation 4.33 we demonstrated that, using the ideal feedback model, the sensitivity function of the closed-loop transfer function with respect to the forward amplifier gain is equal to the reciprocal of its return difference with respect to the same parameter.

In particular, when $\mathbf{W}(\mathbf{X})$, $\boldsymbol{\delta}\mathbf{X}$, and $\mathbf{X}$ are square and nonsingular, from Equations 6.55a, 6.55b, and 6.58, 6.61 can be rewritten as

$$\mathbf{E}_c = \mathbf{y}_c - \mathbf{y}_c^+ = [\mathbf{W}(\mathbf{X}) - \mathbf{W}^+(\mathbf{X})]\mathbf{u} = -\boldsymbol{\delta}\mathbf{W}(\mathbf{X})\mathbf{u} \tag{6.71a}$$

$$\mathbf{E}_o = \mathbf{y}_o - \mathbf{y}_o^+ = [\mathbf{X}\mathbf{H}_1 - \mathbf{X}^+\mathbf{H}_1]\mathbf{u} = -\boldsymbol{\delta}\mathbf{X}\mathbf{H}_1\mathbf{u} \tag{6.71b}$$

If $\mathbf{H}_1$ is nonsingular, $\mathbf{u}$ in Equation 6.71b can be solved for and substituted in Equation 6.71a to give

$$\mathbf{E}_c = \boldsymbol{\delta}\mathbf{W}(\mathbf{X})\mathbf{H}_1^{-1}(\boldsymbol{\delta}\mathbf{X})^{-1}\mathbf{E}_o \tag{6.72}$$

As before, for meaningful comparison, we require that $\mathbf{y}_o = \mathbf{y}_c$ or

$$\mathbf{X}\mathbf{H}_1 = \mathbf{W}(\mathbf{X}) \tag{6.73}$$

From Equation 6.72, we obtain

$$\mathbf{E}_c = \boldsymbol{\delta}\mathbf{W}(\mathbf{X})\mathbf{W}^{-1}(\mathbf{X})\mathbf{X}(\boldsymbol{\delta}\mathbf{X})^{-1}\mathbf{E}_o \tag{6.74}$$

identifying that

$$\mathcal{S}(\mathbf{X}) = \mathrm{d}\mathbf{W}(\mathbf{X})\mathbf{W}^{-1}(\mathbf{X})\mathbf{X}(\mathrm{d}\mathbf{X})^{-1} \tag{6.75}$$

This result is to be compared with the scalar sensitivity function defined in Equation 4.26, which can be put in the form

$$\mathcal{S}(x) = (\delta w)w^{-1}x(\delta x)^{-1} \tag{6.76}$$

6.6 Multiparameter Sensitivity

In this section, we derive formulas for the effect of change of $\mathbf{X}$ on a scalar transfer function $w(\mathbf{X})$.

Let x_k, $k = 1, 2, \ldots, pq$, be the elements of $\mathbf{X}$. The multivariable Taylor series expansion of $w(\mathbf{X})$ with respect to x_k is given by

$$\delta w = \sum_{k=1}^{pq} \frac{\partial w}{\partial x_k}\delta x_k + \sum_{j=1}^{pq}\sum_{k=1}^{pq} \frac{\partial^2 w}{\partial x_j \partial x_k}\frac{\delta x_j \delta x_k}{2!} + \cdots \tag{6.77}$$

The first-order perturbation can then be written as

$$\delta w \approx \sum_{k=1}^{pq} \frac{\partial w}{\partial x_k}\delta x_k \tag{6.78}$$

Using Equation 4.26, we obtain

$$\frac{\delta w}{w} \approx \sum_{k=1}^{pq} \mathcal{S}(x_k)\frac{\delta x_k}{x_k} \tag{6.79}$$

This expression gives the fractional change of the transfer function w in terms of the scalar sensitivity functions $\mathcal{S}(x_k)$.

Refer to the fundamental matrix feedback-flow graph of Figure 6.3. If the amplifier has a single input and a single output from Equation 6.35, the overall transfer function $w(\mathbf{X})$ of the multiple-loop feedback amplifier becomes

$$w(\mathbf{X}) = D + \mathbf{C}\mathbf{X}(\mathbf{1}_p - \mathbf{A}\mathbf{X})^{-1}\mathbf{B} \tag{6.80}$$

When $\mathbf{X}$ is perturbed to $\mathbf{X}^+ = \mathbf{X} + \boldsymbol{\delta}\mathbf{X}$, the corresponding expression of Equation 6.80 is given by

$$w(\mathbf{X}) + \delta w(\mathbf{X}) = D + \mathbf{C}(\mathbf{X} + \boldsymbol{\delta}\mathbf{X})(\mathbf{1}_p - \mathbf{A}\mathbf{X} - \mathbf{A}\boldsymbol{\delta}\mathbf{X})^{-1}\mathbf{B} \tag{6.81}$$

or

$$\delta w(\mathbf{X}) = \mathbf{C}\big[(\mathbf{X} + \boldsymbol{\delta}\mathbf{X})(\mathbf{1}_p - \mathbf{A}\mathbf{X} - \mathbf{A}\boldsymbol{\delta}\mathbf{X})^{-1} - \mathbf{X}(\mathbf{1}_p - \mathbf{A}\mathbf{X})^{-1}\big]\mathbf{B} \tag{6.82}$$

As $\boldsymbol{\delta}\mathbf{X}$ approaches zero, we obtain

$$\begin{aligned}
\delta w(\mathbf{X}) &= \mathbf{C}\big[(\mathbf{X} + \boldsymbol{\delta}\mathbf{X}) - \mathbf{X}(\mathbf{1}_p - \mathbf{A}\mathbf{X})^{-1}(\mathbf{1}_p - \mathbf{A}\mathbf{X} - \mathbf{A}\boldsymbol{\delta}\mathbf{X})\big](\mathbf{1}_p - \mathbf{A}\mathbf{X} - \mathbf{A}\boldsymbol{\delta}\mathbf{X})^{-1}\mathbf{B} \\
&= \mathbf{C}\big[\boldsymbol{\delta}\mathbf{X} + \mathbf{X}(\mathbf{1}_p - \mathbf{A}\mathbf{X})^{-1}\mathbf{A}\boldsymbol{\delta}\mathbf{X}\big](\mathbf{1}_p - \mathbf{A}\mathbf{X} - \mathbf{A}\boldsymbol{\delta}\mathbf{X})^{-1}\mathbf{B} \\
&= \mathbf{C}(\mathbf{1}_q - \mathbf{X}\mathbf{A})^{-1}(\boldsymbol{\delta}\mathbf{X})(\mathbf{1}_p - \mathbf{A}\mathbf{X} - \mathbf{A}\boldsymbol{\delta}\mathbf{X})^{-1}\mathbf{B} \\
&\approx \mathbf{C}(\mathbf{1}_q - \mathbf{X}\mathbf{A})^{-1}(\boldsymbol{\delta}\mathbf{X})(\mathbf{1}_p - \mathbf{A}\mathbf{X})^{-1}\mathbf{B}
\end{aligned} \tag{6.83}$$

where $\mathbf{C}$ is a row q vector and $\mathbf{B}$ is a column p vector. Write

$$\mathbf{C} = [c_1 \;\; c_2 \cdots c_q] \tag{6.84a}$$

$$\mathbf{B}' = [b_1 \;\; b_2 \cdots b_p] \tag{6.84b}$$

$$\tilde{\mathbf{W}} = \mathbf{X}(\mathbf{1}_p - \mathbf{A}\mathbf{X})^{-1} = (\mathbf{1}_q - \mathbf{X}\mathbf{A})^{-1}\mathbf{X} = [\tilde{w}_{ij}] \tag{6.84c}$$

The increment $\delta w(\mathbf{X})$ can be expressed in terms of the elements of Equation 6.84 and those of $\mathbf{X}$. In the case where $\mathbf{X}$ is diagonal with

$$\mathbf{X} = \text{diag}[x_1 \;\; x_2 \cdots x_p] \tag{6.85}$$

where $p = q$, the expression for $\delta w(\mathbf{X})$ can be succinctly written as

$$\begin{aligned}
\delta w(\mathbf{X}) &= \sum_{i=1}^{p}\sum_{k=1}^{p}\sum_{j=1}^{p} c_i\left(\frac{\tilde{w}_{ik}}{x_k}\right)(\delta x_k)\left(\frac{\tilde{w}_{kj}}{x_k}\right)b_j \\
&= \sum_{i=1}^{p}\sum_{k=1}^{p}\sum_{j=1}^{p} \frac{c_i\tilde{w}_{ik}\tilde{w}_{kj}b_j}{x_k}\,\frac{\delta x_k}{x_k}
\end{aligned} \tag{6.86}$$

Comparing this with Equation 6.79, we obtain an explicit form for the single-parameter sensitivity function as

$$\mathcal{S}(x_k) = \sum_{i=1}^{p}\sum_{j=1}^{p} \frac{c_i\tilde{w}_{ik}\tilde{w}_{kj}b_j}{x_k w(\mathbf{X})} \tag{6.87}$$

Thus, knowing Equations 6.84 and 6.85, we can calculate the multiparameter sensitivity function for the scalar transfer function $w(\mathbf{X})$ immediately.

Example 6.4

Consider again the voltage-series feedback amplifier of Figure 3.9, an equivalent network of which is shown in Figure 6.4. Assume that V_s is the input and V_{25} the output. The transfer function of interest is the amplifier voltage gain V_{25}/V_s. The elements of main concern are the two controlling parameters of the controlled sources. Thus, we let

$$\mathbf{X} = \begin{bmatrix} \tilde{\alpha}_1 & 0 \\ 0 & \tilde{\alpha}_2 \end{bmatrix} = \begin{bmatrix} 0.0455 & 0 \\ 0 & 0.0455 \end{bmatrix} \tag{6.88}$$

From Equation 6.27 we have

$$\mathbf{A} = \begin{bmatrix} -90.782 & 45.391 \\ -942.507 & 0 \end{bmatrix} \tag{6.89a}$$

$$\mathbf{B}' = [0.91748 \;\; 0] \tag{6.89b}$$

$$\mathbf{C} = [45.391 \;\; -2372.32] \tag{6.89c}$$

yielding

$$\tilde{\mathbf{W}} = \mathbf{X}(\mathbf{1}_2 - \mathbf{AX})^{-1} = 10^{-4}\begin{bmatrix} 4.85600 & 10.02904 \\ -208.245 & 24.91407 \end{bmatrix} \tag{6.90}$$

Also, from Equation 6.13 we have

$$w(\mathbf{X}) = \frac{V_{25}}{V_s} = 45.387 \tag{6.91}$$

To compute the sensitivity functions with respect to $\tilde{\alpha}_1$ and $\tilde{\alpha}_2$, we apply Equation 6.87 and obtain

$$\mathcal{S}(\tilde{\alpha}_1) = \sum_{i=1}^{2}\sum_{j=1}^{2}\frac{c_i\tilde{w}_{i1}\tilde{w}_{1j}b_j}{\tilde{\alpha}_1 w(\mathbf{X})} = \frac{c_1\tilde{w}_{11}\tilde{w}_{11}b_1 + c_1\tilde{w}_{11}\tilde{w}_{12}b_2 + c_2\tilde{w}_{21}\tilde{w}_{11}b_1 + c_2\tilde{w}_{21}\tilde{w}_{12}b_2}{\tilde{\alpha}_1 w}$$
$$= 0.01066 \tag{6.92a}$$

$$\mathcal{S}(\tilde{\alpha}_2) = \frac{c_1\tilde{w}_{12}\tilde{w}_{21}b_1 + c_1\tilde{w}_{12}\tilde{w}_{22}b_2 + c_2\tilde{w}_{22}\tilde{w}_{21}b_1 + c_2\tilde{w}_{22}\tilde{w}_{22}b_2}{\tilde{\alpha}_2 w} = 0.05426 \tag{6.92b}$$

As a check, we use Equation 4.30 to compute these sensitivities. From Equations 3.45 and 3.52, we have

$$F(\tilde{\alpha}_1) = 93.70 \tag{6.93a}$$

$$F(\tilde{\alpha}_2) = 18.26 \tag{6.93b}$$

$$\hat{F}(\tilde{\alpha}_1) = 103.07 \times 10^3 \tag{6.93c}$$

$$\hat{F}(\tilde{\alpha}_2) = 2018.70 \tag{6.93d}$$

Substituting these in Equation 4.30 the sensitivity functions are

$$\mathcal{S}(\tilde{\alpha}_1) = \frac{1}{F(\tilde{\alpha}_1)} - \frac{1}{\hat{F}(\tilde{\alpha}_1)} = 0.01066 \tag{6.94a}$$

$$\mathcal{S}(\tilde{\alpha}_2) = \frac{1}{F(\tilde{\alpha}_2)} - \frac{1}{\hat{F}(\tilde{\alpha}_2)} = 0.05427 \tag{6.94b}$$

confirming Equation 6.92.

Suppose that $\tilde{\alpha}_1$ is changed by 4% and $\tilde{\alpha}_2$ by 6%. The fractional change of the voltage gain $w(\mathbf{X})$ is found from Equation 6.79 as

$$\frac{\delta w}{w} \approx \mathcal{S}(\tilde{\alpha}_1)\frac{\delta\tilde{\alpha}_1}{\tilde{\alpha}_1} + \mathcal{S}(\tilde{\alpha}_2)\frac{\delta\tilde{\alpha}_2}{\tilde{\alpha}_2} = 0.003683 \tag{6.95}$$

or 0.37%.

7.1 Introduction

The main goal of circuit analysis is to determine the solution of the circuit, i.e., the voltages and the currents in the circuit, usually as functions of time. The advent of powerful computers and circuit analysis software has greatly simplified this task. Basically, the circuit to be analyzed is fed to the computer through some circuit description language, or it is analyzed graphically, and the software will produce the desired voltage or current waveforms. Progress has rendered the traditional paper-and-pencil methods obsolete, in which the engineer's skill and intuition led the way through series of clever approximations, until the circuits equations can be solved analytically.

A closer comparison of the numerical and the approximate analytical solution reveals, however, that the two are not quite equivalent. Although the former is precise, it only provides the solution of the circuit with given parameters, whereas the latter is an approximation, but the approximate solutions most often is given explicitly as a function of some circuit parameters. Therefore, it allows us to assess the influence of these parameters on the solution.

If we rely entirely on the numerical solution of a circuit, we never get a global picture of its behavior, unless we carry out a huge number of analyses. Thus, the numerical analysis should be complemented by a qualitative analysis, one that concentrates on general properties of the circuit, properties that do not depend on the particular set of circuit parameters.

7.2 Resistive Circuits

The term ''resistive circuits'' is not used, as one would imagine, for circuits that are composed solely of resistors. It admits all circuit elements that are not dynamic, i.e., whose constitutive relations do not involve time derivatives, integrals over time, or time delays, etc. Expressed positively, resistive circuit elements are described by constitutive relations that involve only currents and voltages at the same time instants.

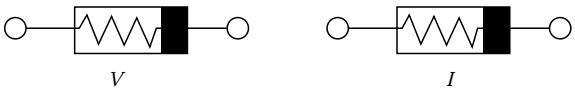

FIGURE 7.1 Symbols of the *V*- and the *I*-resistor.

Physical circuits can never be modeled in a satisfactory way by resistive circuits, but resistive circuits appear in many contexts as auxiliary constructs. The most important problem that leads to a resistive circuit is the determination of the equilibrium points, or, as is current use in electronics, the DC-operating points, of a dynamic circuit. The DC-operating points of a circuit correspond in a one-to-one fashion to the solutions of the resistive circuit obtained by removing the capacitors and by short circuiting the inductors. The resistive circuit associated with the state equations of a dynamic circuit in discussed in Ref. [1].

Among the resistive circuit elements we find, of course, the resistors. For the purposes of this introduction, we distinguish between, linear resistors, *V*-resistors, and *I*-resistors. *V*-resistors are voltage controlled, i.e., defined by constitutive relations of the form

$$i = g(v) \tag{7.1}$$

In addition, we require that g is a continuous, increasing function of v, defined for all real v. Dually, an *I*-resistor is current controlled, i.e., defined by a constitutive relation of the form

$$v = h(i) \tag{7.2}$$

In addition, we require that h is a continuous, increasing function of i, defined for all real i. We use the symbols of Figure 7.1 for *V*- and *I*-resistor. Linear resistors are examples of both *I*- and *V*-resistors. An example of a *V*-resistor that is not an *I*-resistor is the junction diode, modeled by its usual exponential constitutive relation

$$i = I_s(e^{v/nV_T} - 1) \tag{7.3}$$

Although Equation 7.3 could be solved for v and thus the constitutive relation could be written in the form of Equation 7.2, the resulting function h would be defined only for currents between $-I_s$ and $+\infty$, which is not enough to qualify for an *I*-resistor. For the same reason, the static model for a Zener diode would be an *I*-resistor, but not a *V*-resistor. Indeed, the very nature of the Zener diode limits its voltages on the negative side.

A somewhat strange by-product of our definition of *V*- and *I*-resistors is that independent voltage sources are *I*-resistors and independent current sources are *V*-resistors. Indeed, a voltage source of value E has the constitutive relation

$$v = E \tag{7.4}$$

which clearly is of the form (Equation 7.2), with a constant function h, and a current source of value I has the form

$$i = I \tag{7.5}$$

which is of the form (Equation 7.1) with a constant function g. Despite this, we shall treat the independent sources as a different type of element.

Another class of resistive elements is the controlled sources. We consider them to be two-ports, e.g., a voltage-controlled voltage source (VCVS). A VCVS is the two-port of Figure 7.2, where the constitutive relations are

$$v_1 = \alpha v_2 \tag{7.6}$$

$$i_1 = 0 \tag{7.7}$$

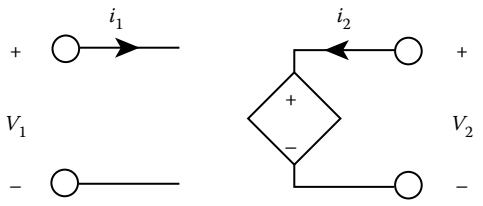

FIGURE 7.2 VCVS as a two-port.

The other controlled sources have similar forms. Another useful resistive circuit element is the ideal operational amplifier. It is a two-port defined by the two constitutive relations

$$v_1 = 0 \tag{7.8}$$

$$i_1 = 0 \tag{7.9}$$

This two-port can be decomposed into the juxtaposition of two singular one-ports, the nullator and the norator, as shown in Figure 7.3. The nullator has two constitutive relations:

$$v = 0, \quad i = 0 \tag{7.10}$$

whereas the norator has no constitutive relation.

For all practical purposes, the resistive circuit elements mentioned thus far are sufficient. By this we mean that all nonlinear resistive circuits encountered in practice possess an equivalent circuit composed of nonlinear resistors, independent and controlled sources, and nullator–norator pairs. Figure 7.4 illustrates this fact. Here, the equivalent circuit of the bipolar transistor is modeled by the Ebers–Moll equations:

$$\begin{pmatrix} i_1 \\ i_2 \end{pmatrix} = \begin{pmatrix} 1 + \frac{1}{\beta_F} & -1 \\ -1 & 1 + \frac{1}{\beta_R} \end{pmatrix} \begin{pmatrix} g(v_1) \\ g(v_2) \end{pmatrix} \tag{7.11}$$

The function g is given by the right-hand side of Equation 7.3.

Actually, the list of basic resistive circuit elements given so far is redundant, and the nullator–norator pairs render the controlled sources superfluous. An example of a substitution of controlled sources by nullator–norator pairs is given in Figure 7.4. Equivalent circuits exist for all four types of controlled sources with nullator–norator pairs. Figure 7.5 gives an equivalent circuit for a voltage-controlled current source (VCCS), where the input port is floating with respect to the output port.

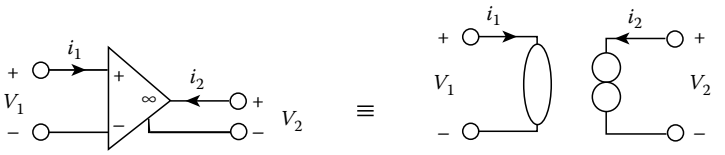

FIGURE 7.3 Operational amplifier as a juxtaposition of a nullator and a norator.

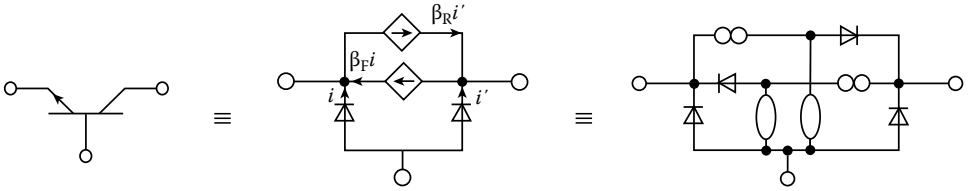

FIGURE 7.4 Equivalent circuit of a bipolar npn transistor.

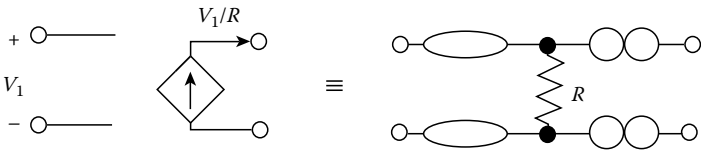

FIGURE 7.5 Equivalent circuit for a floating VCCS.

The system of equations that describes a resistive circuit is the collection of Kirchhoff equations and the constitutive relations of the circuit elements. It has the following form (if we limit ourselves to resistors, independent sources, nullators, and norators):

$$\mathbf{Ai} = \mathbf{0} \text{ (Kirchhoff's voltage law)} \tag{7.12}$$

$$\mathbf{Bv} = \mathbf{0} \text{ (Kirchhoff's voltage law)} \tag{7.13}$$

$$i_k = g(v_k) \text{ } (V\text{-resistor}) \tag{7.14}$$

$$v_k = h(i_k) \text{ } (I\text{-resistor}) \tag{7.15}$$

$$v_k = E_k \text{ (independent voltage source)} \tag{7.16}$$

$$i_k = I_k \text{ (independent current source)} \tag{7.17}$$

$$\begin{matrix} v_k = 0 \\ i_k = 0 \end{matrix} \text{ (nullators)} \tag{7.18}$$

In this system of equations, the unknowns are the branch voltages and the branch currents

$$\mathbf{v} = \begin{pmatrix} v_1 \\ v_2 \\ \vdots \\ v_b \end{pmatrix}, \quad \mathbf{i} = \begin{pmatrix} i_1 \\ i_2 \\ \vdots \\ i_b \end{pmatrix} \tag{7.19}$$

where the b is the number of branches. Because we have b linearly independent Kirchhoff equations [2], the system contains $2b$ equations and $2b$ unknowns. A solution $\xi = \begin{pmatrix} v \\ i \end{pmatrix}$ of the system is called a solution of the circuit. It is a collection of branch voltages and currents that satisfy Equations 7.12 through 7.19.

7.2.1 Number of Solutions of a Resistive Circuit

As we found earlier, the number of equations of a resistive circuit equals the number of unknowns. One may therefore expect a unique solution. This may be the norm, but it is far from being generally true. It is not even true for linear resistive circuits. In fact, the equations for a linear resistive circuit are of the form

$$\mathbf{H}\xi = \mathbf{e} \tag{7.20}$$

where the $2b \times 2b$ matrix $\mathbf{H}$ contains the resistances and elements of value 0, ± 1, whereas the vector $\mathbf{e}$ contains the source values and zeroes. The solution of Equation 7.20 is unique if the determinant of $\mathbf{H}$ differs from zero. If it is zero, then the circuit has either infinitely many solutions or no solution at all. Is such a case realistic? The answer is yes and no. Consider two voltages sources connected as shown in Figure 7.6.

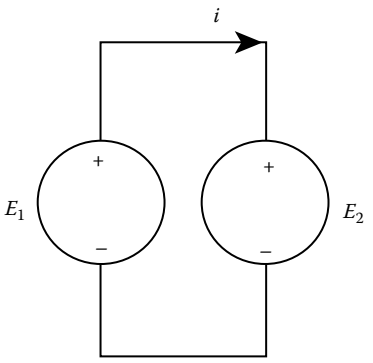

FIGURE 7.6 Circuit with zero or infinite solutions.

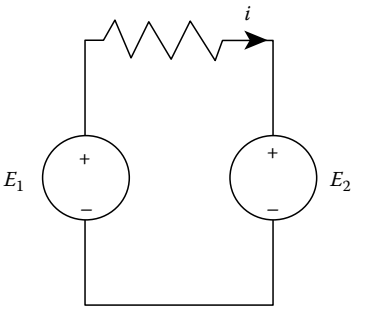

FIGURE 7.7 Circuit with exactly one solution.

If $E_1 \neq E_2$, the constitutive relations of the sources are in contradiction with Kirchhoff's voltage law (KVL), and thus the circuit has no solution, whereas when $E_1 = E_2$, the current i in Figure 7.6 is not determined by the circuit equations, and thus the circuit has infinitely many solutions. One may object that the problem is purely academic, because in practice wires as connections have a small, but positive, resistance, and therefore one should instead consider the circuit of Figure 7.7, which has exactly one solution.

Examples of singular linear resistive circuits exist that are much more complicated. However, the introduction of parasitic elements always permits us to obtain a circuit with a single solution, and thus the special case in which the matrix **H** in Equation 7.9 is singular can be disregarded. Within the framework of linear circuits, this attitude is perfectly justified. When a nonlinear circuit model is chosen, however, the situation changes. An example clarifies this point.

Consider the linear circuit of Figure 7.8. It is not difficult to see that it has exactly one solution, except when

$$R_1 R_3 = R_2 R_4 \tag{7.21}$$

In this case, the matrix **H** in Equation 7.29 is singular and the circuit of Figure 7.8 has zero or infinitely many solutions, depending on whether E differs from zero. From the point of view of linear circuits, we can disregard this singular case because it arises only when Equation 7.21 is exactly satisfied with infinite precision.

Now, replace resistor R_4 by a nonlinear resistor, where the characteristic is represented by the bold line in Figure 7.9. The resulting circuit is equivalent to the connection of a voltage source, a linear resistor, and the nonlinear resistor, as shown in Figure 7.10. Its solutions correspond to the intersections of the nonlinear resistor characteristic and the load line (Figure 7.9). Depending on the value of E, either one, two, or three solutions are available. Although we still need infinite precision to obtain two solutions, this is not the case for one or three solutions. Thus, more than one DC-operating point may be observed in electronic circuits. Indeed, for static memories, and multivibrators in general, multiple DC-operating points are an essential feature.

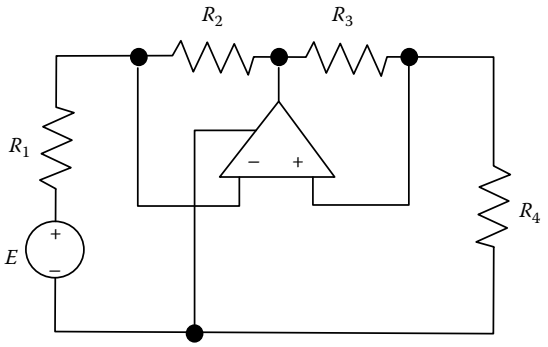

FIGURE 7.8 Circuit with one, zero, or infinite solutions.

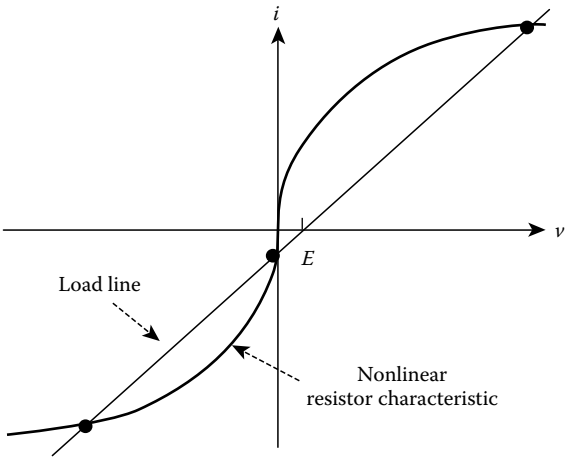

FIGURE 7.9 Characteristic of the nonlinear resistor and solutions of the circuit of Figure 7.10.

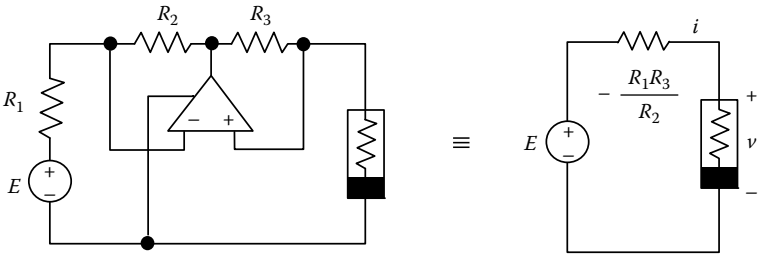

FIGURE 7.10 Circuit with one, two, or three solutions.

The example of Figure 7.10 shows an important aspect of the problem. The number of solutions depends on the parameter values of the circuit. In the example the value of E determines whether one, two, or three solutions are available. This is not always the case. An important class of nonlinear resistive circuits always has exactly one solutions, irrespective of circuit parameters. In fact, for many applications, e.g., amplification, signal shaping, logic operations, etc., it is necessary that a circuit has exactly one DC-operating point. Circuits that are designed for these functionalities should thus have a unique DC-operating point for any choice of element values.

If a resistive circuit contains only two-terminal resistors with increasing characteristics and sources, but no nonreciprocal element such as controlled sources, operational amplifiers, or transistors, the solution is usually unique. The following theorem gives a precise statement.

THEOREM 7.1

A circuit composed of independent voltage and current sources and strictly increasing resistors without loop of voltage sources and without cutset of current sources has at most one solution.

The interconnection condition concerning the sources is necessary. The circuit of Figure 7.6 is an illustration of this statement. Its solution is not unique because of the loop of voltage sources. The loop is

no longer present in the circuit of Figure 7.7, which satisfies the conditions of Theorem 7.1, and which indeed has a unique solution.

If the resistor characteristics are not *strictly* increasing but only increasing (i.e., if the v–i curves have horizontal or vertical portions), the theorem still holds, if we exclude loops of voltage sources and I-resistors, and cutsets of current sources and V-resistors.

Theorem 7.1 guarantees the uniqueness of the solution, but it cannot assure its existence. On the other hand, we do not need increasing resistor characteristics for the existence.

THEOREM 7.2

Let a circuit be composed of independent voltage and current sources and resistors whose characteristics are continuous and satisfy the following passivity condition at infinity:

$$v \to +\infty \Leftrightarrow i \to +\infty \quad \text{and} \quad v \to -\infty \Leftrightarrow i \to -\infty \tag{7.22}$$

If no loop of voltage sources and no cutset of current sources exist, then we have at least one solution of the circuit.

For refinements of this theorem, refer to Refs. [1,3].

If we admit nonreciprocal elements, neither Theorem 7.1 nor Theorem 7.2 remain valid. Indeed, the solution of the circuit of Figure 7.10 may be nonunique, even though the nonlinear resistor has a strictly increasing characteristic. In order to ensure the existence and uniqueness of a nonreciprocal nonlinear resistive circuit, nontrivial constraints on the interconnection of the elements must be observed. The theorems below give different, but basically equivalent, ways to formulate these constraints.

The first result is the culminating point of a series of papers by Sandberg and Wilson [3]. It is based on the following notion.

Definition 7.1:

- The connection of the two bipolar transistors shown in Figure 7.11 is called a feedback structure. The type of the transistors and the location of the collectors and emitters are arbitrary.
- A circuit composed of bipolar transistors, resistors, and independent sources contains a feedback structure, if it can be reduced to the circuit of Figure 7.11 by replacing each voltage source by a short circuit, each current source by an open circuit, each resistor and diode by an open or a short circuit, and each transistor by one of the five short–open circuit combinations represented in Figure 7.12.

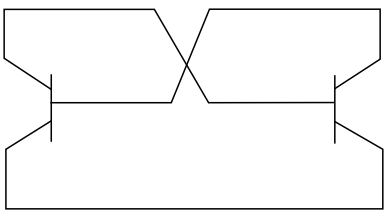

FIGURE 7.11 Feedback structure.

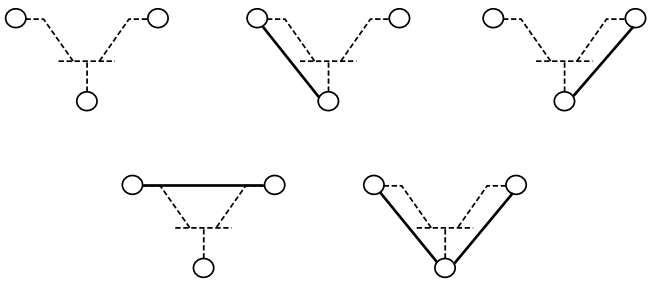

FIGURE 7.12 Short-open-circuit combinations for replacing the transistors.

THEOREM 7.3

Let a circuit be composed of bipolar transistors, described by the Ebers–Moll model, positive linear resistors, and independent sources. Suppose we have no loop of voltage sources and no cutset of current sources. If the circuit contains no feedback structure, it has exactly one solution.

This theorem [4] is extended in Ref. [5] to MOS transistors.

The second approach was developed by Nishi and Chua [6]. Instead of transistors, it admits controlled sources. In order to formulate the theorem, two notions must be introduced.

Definition 7.2: A circuit composed of controlled sources, resistors, and independent sources satisfies the interconnection condition, if the following conditions are satisfied:

- No loop is composed of voltage sources, output ports of (voltage or current) controlled voltage sources, and input ports of current-controlled (voltage or current) sources.
- No cutset is composed of current sources, outputs ports of (voltage or current) controlled current sources, and input ports of voltage-controlled (voltage or current) sources.

Definition 7.3: A circuit composed exclusively of controlled sources has a complementary tree structure if both the input and output ports each form a tree. The fundamental loop matrix of the input port tree has the form

$$B = [B_T|1] \tag{7.23}$$

The circuit is said to have a positive (negative) complementary tree structure, if the determinant of B_T is positive (negative).

THEOREM 7.4

Suppose a circuit composed of controlled sources, strictly increasing resistors satisfying (*Equation 7.22*), *and independent sources satisfies the interconnection condition. If, by replacing each resistor either by a short circuit or an open circuit, all independent and some dependent voltage sources by short circuits, and all independent and some dependent current sources by open circuits, one never obtains a negative complementary tree structure, the circuit has exactly one solution* [6].

A similar theorem for circuits with operational amplifiers instead of controlled sources is proved in Ref. [7].

The third approach is that of Hasler [1,8]. The nonreciprocal elements here are nullator–norator pairs. Instead of reducing the circuit by some operations in order to obtain a certain structure, we must orient the resistors in certain way. Again, we must first introduce a new concept.

Definition 7.4: Let a circuit be composed of nullator–norator pairs, resistors, and independent voltage and current sources. A partial orientation of the resistors is uniform, if the following two conditions are satisfied:

- Every oriented resistor is part of an evenly directed loop composed only of oriented resistors and voltages sources.
- Every oriented resistor is part of an evenly directed cutset composed only of norators, oriented resistors, and voltage sources.

THEOREM 7.5

Let a circuit be composed of nullator–norator pairs, V- *and* I-*resistors, and independent voltage and current sources. If the following conditions are satisfied, the circuit has exactly one solutions*:

- *Norators*, I-*resistors, and voltage sources together form a tree.*
- *Nullators*, I-*resistors, and voltage sources together form a tree.*
- *Resistors have no uniform partial orientation, except for the trivial case, in which no resistor is oriented.*

We illustrate the conditions of this theorem with the example of Figure 7.10. In Figure 7.13 the resistors are specified as *V*- and *I*-resistors and a uniform orientation of the resistors is indicated. Note that the nonlinear resistor is a *V*-resistor, but not an *I*-resistor, because its current saturates. The linear resistors, however, are both *V*- and *I*-resistors. The choice in Figure 7.13 is made in order to satisfy the first two conditions of Theorem 7.5. Correspondingly, in Figures 7.14 and 7.15 the norator–*I*-resistor–voltage source tree and the nullator–*I*-resistor–voltage source tree are represented. Because the third condition is not satisfied, Theorem 7.5 cannot guarantee a unique solution. Indeed, as explained earlier, this circuit may have three solutions.

Theorem 7.5 has been generalized to controlled sources, to resistors that are increasing but neither voltage nor current controlled (e.g., the ideal diode), and to resistors that are decreasing instead of increasing [9].

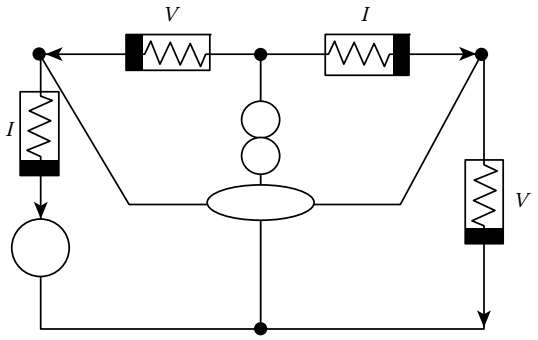

FIGURE 7.13 Circuit of Figure 7.10 with nullator and norator.

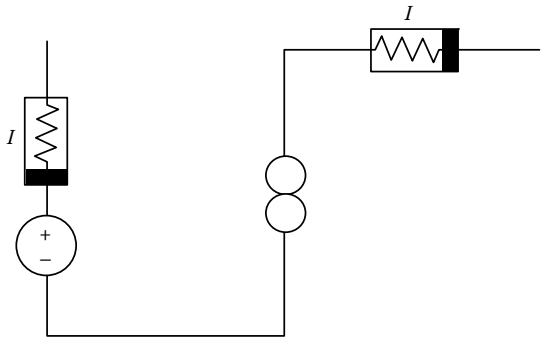

FIGURE 7.14 Norator–*I*-resistor–voltage source tree.

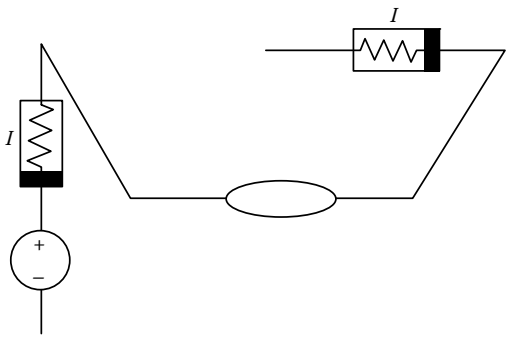

FIGURE 7.15 Nullator–*I*-resistor–voltage source tree.

Theorems 7.3, 7.4, and 7.5 have common features. Their conditions concern the circuit structure—the circuit graph that expresses the interconnection of the elements and the type of elements that occupy the branches of the graph, but not the element values. Therefore, the theorems guarantee the existence and uniqueness of the solution for whole classes of circuits, in which the individual circuits differ by their element values and parameters. In this sense the conditions are not only sufficient, but also necessary. This means, for example, in the case of Theorem 7.5 if all circuits with the same structure have exactly one solution, then the three conditions must be satisfied. However, by logical contraposition, if one of the three conditions is not satisfied for a given circuit structure, a circuit with this structure exists which has either no solution or more than one solutions.

On the other hand, if we consider a specific circuit, the conditions are only sufficient. They permit us to prove that the solution exists and is unique, but some circuits do not satisfy the conditions and still have exactly one solution. However, if the parameters of such a circuit are varied, one eventually falls onto a circuit with no solution or more than one solution.

The main conditions of Theorems 7.3 and 7.4 have an evident intuitive meaning. The orientations to look for in Theorem 7.5 are linked to the sign of the currents and the voltages of the difference of two solutions. Because the resistors are increasing, these signs are the same for the voltage and current differences. If we extend the analysis of the signs of solutions or solution differences to other elements, we must differentiate between voltages and currents. This approach, in which two orientations for all branches are considered, one corresponding to the currents and one corresponding to the voltages, is pursued in Ref. [10].

The conditions of Theorems 7.3 through 7.5 can be verified by inspection for small circuits. For larger circuits, one must resort to combinatorial algorithms. Such algorithms are proposed in Refs. [11,12]. As can be expected from the nature of conditions, the algorithms grow exponentially with the number of resistors. It is not known whether algorithms of polynomial complexity exist.

Some circuits always have either no solution or an infinite number of solutions, irrespective of the element and parameter values. Figure 7.6 gives the simplest example. Such circuits clearly are not very useful in practice. The remaining circuits are those that may have a finite number $n > 1$ of solutions if the circuit parameters are chosen suitably. These are the circuits that are useful for static memories and for multivibrators in general. This class is characterized by the following theorem.

THEOREM 7.6

Let circuit be composed of nullator–norator pairs, V- and I-resistors, and independent voltage and current sources. If the following three conditions are satisfied, the circuit has more than one, but a finite number of solutions for a suitable choice of circuit parameters:

- *Norators, I-resistors, and voltage sources together form a tree.*
- *Nullators, I-resistors, and voltage sources together form a tree.*
- *A nontrivial, uniform partial orientation of the resistors occurs.*

Can we be more precise and formulate conditions on the circuit structure that guarantee four solutions, for example? This is not possible because changing the parameters of the circuit will lead to another number of solutions. Particularly with a circuit structure that satisfies the conditions of Theorem 7.6, there is a linear circuit that always has an infinite number of solutions. If we are more restrictive on the resistor characteristics, e.g., imposing convex or concave characteristics for certain resistors, it is possible to determine the maximum number of solutions. A method to determine an upper bound is given in Ref. [14], whereas the results of Ref. [15] allow us to determine the actual maximum number under certain conditions. Despite these results, however, the maximum number of solutions is still an open problem.

7.2.2 Bounds on Voltages and Currents

It is common sense for electrical engineers that in an electronic circuit all node voltages lie between zero and the power supply voltage, or between the positive and the negative power supply voltages, if both are present. Actually, this is only true for the DC-operating point, but can we prove it in this case? The following theorems give the answer. They are based on the notion of passivity.

Definition 7.5: A resistor is passive if it can only absorb, but never produce power. This means that for any point (v, i) on its characteristic we have

$$v \cdot i \geq 0 \tag{7.24}$$

A resistor is strictly passive, if in addition to Equation 7.24 it satisfies the condition

$$v \cdot i = 0 \rightarrow v = i = 0 \tag{7.25}$$

THEOREM 7.7

Let a circuit be composed of strictly passive resistors and independent voltage and current sources. Then, for every branch k of the circuit the following bounds can be given:

$$|v_k| \leq \sum_{\text{source branches } j} |v_j| \tag{7.26}$$

$$|i_k| \leq \sum_{\text{source branches } j} |i_j| \tag{7.27}$$

If, in addition, the circuit is connected and all sources have a common node, the ground node, then the maximum and the minimum node voltage are at a source terminal.

The theorem implies in particular that in a circuit with a single voltage source, all branch voltages are bounded by the source voltage in magnitude, and all node voltages lie between zero and the source voltage. Similarly, if a circuit has a single current source, all branch currents are bounded by the source current in magnitude. Finally, if several voltage sources are present that are all connected to ground and have positive value, then the node voltages lie between zero and the maximum source voltage. If some sources have positive values and others have negative values, then all node voltages lie between the maximum and the minimum source values.

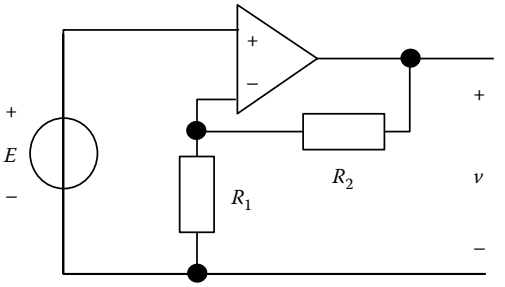

FIGURE 7.16 Voltage amplifier.

This theorem and various generalizations can be found in Ref. [1]. The main drawback is that it does not admit nonreciprocal elements. A simple counterexample is the voltage amplifier of Figure 7.16. The voltage of the output node of the operational amplifier is

$$v = \frac{R_1 + R_2}{R_1} E \tag{7.28}$$

Thus, the output node voltage is higher than the source voltage. Of course, the reason is that the operational amplifier is an active element. It is realized by transistors and needs a positive and a negative voltage source as the power supply. The output voltage of the operational amplifier cannot exceed these supply voltages. This fact is not contained in the model of the ideal operational amplifier, but follows from the extension of Theorem 7.7 to bipolar transistors [1,16].

THEOREM 7.8

Let a circuit be composed of bipolar transistors modeled by the Ebers–Moll equations, of strictly passive resistors, and of independent voltage and current sources. Then, the conclusion of Theorem 7.7 hold.

At first glance, Theorem 7.8 appears to imply that it is impossible to build an amplifier with bipolar transistors. Indeed, it is impossible to build such an amplifier with a single source, the input signal. We need at least one power supply source that sets the limits of dynamic range of the voltages according to Theorem 7.8. The signal source necessarily has a smaller amplitude and the signal can be amplified roughly up to the limit set by the power supply source.

Theorem 7.8 can be extended to MOS transistors. The difficulty is that the nonlinear characteristics of the simplest model is not strictly increasing, and therefore some interconnection condition must be added to avoid parts with undetermined node voltages.

7.2.3 Monotonic Dependence

Instead of looking at single solutions of resistive circuits, as done earlier in the chapter, we consider here a solution as a function of a parameter. The simplest and at the same time the most important case is the dependence of a solution on the value of a voltage or current source. To have a well-defined situation, we suppose that the circuit satisfies the hypotheses of Theorem 7.5. In this case [1,8], the solution is a continuous function of the source values.

As an example, let us consider the circuit of Figure 7.17. We are interested in the dependence of the various currents on the source voltage E. Because the circuit contains only strictly increasing resistors, we

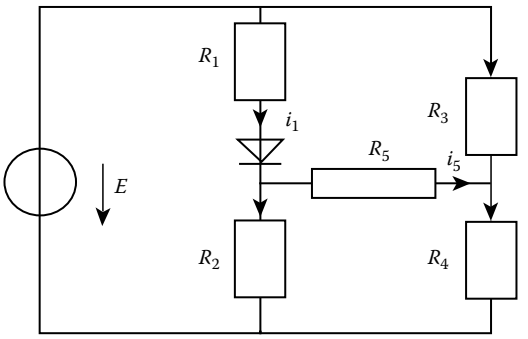

FIGURE 7.17 Circuit example for source dependence.

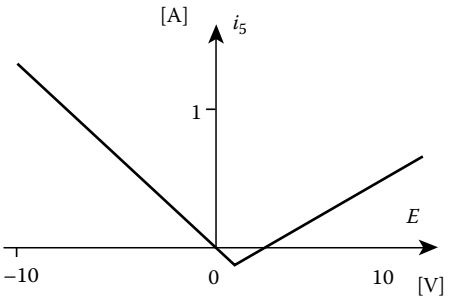

FIGURE 7.18 Nonmonotonic dependence.

expect all currents to be strictly monotonic functions of E. This is not true. In Figure 7.18, the current $i_5(E)$ is represented for $R_1 = R_2 = R_3 = 2R_4 = R_5 = 1\ \Omega$ and for standard diode model parameters. Clearly, it is nonmonotonic.

7.3 Autonomous Dynamic Circuits

7.3.1 Introduction

This section adds to the resistive elements of Section 7.2—the capacitors and the inductors. A nonlinear capacitor is defined by the constitutive relation

$$v = h(q) \tag{7.29}$$

where the auxiliary variable q is the charge of the capacitor, which is linked to the current by

$$i = \frac{\mathrm{d}q}{\mathrm{d}t} \tag{7.30}$$

The dual element, the nonlinear inductor, is defined by

$$i = g(\varphi) \tag{7.31}$$

where the auxiliary variable φ, the flux, is linked to the voltage by

$$v = \frac{\mathrm{d}\varphi}{\mathrm{d}t} \tag{7.32}$$

The symbols of these two elements are represented in Figure 7.19.

The system of equations that describes an autonomous dynamic circuit is composed of Equations 7.12 through 7.17, completed with Equations 7.29 and 7.30 for capacitor branches and Equations 7.31 and 7.32 for inductor branches. Hence, it becomes a mixed differential–nondifferential system of equations. Its solutions are the voltages, currents, charges, and fluxes as functions of time. Because it contains differential equations, we have infinitely many solutions, each one determined by some set of initial conditions.

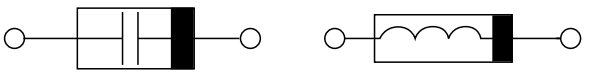

FIGURE 7.19 Symbols of the nonlinear capacitor and the nonlinear inductor.

If all variables except the charges and fluxes are eliminated from the system of equations, one obtains a reduced, purely differential system of equations

$$\frac{d\mathbf{q}}{dt} = \mathbf{f}(\mathbf{q},\varphi) \tag{7.33}$$

$$\frac{d\varphi}{dt} = \mathbf{g}(\mathbf{q},\varphi) \tag{7.34}$$

where $\mathbf{q}$ and φ are the vectors composed of, respectively, the capacitor charges and the inductor fluxes. These are the state equations of the circuit. Under mild assumptions on the characteristics of the nonlinear elements (local Lipschitz continuity and eventual passivity), it can be shown that the solutions are uniquely determined by the initial values of the charges and fluxes at some time t_0, $\mathbf{q}(t_0)$, and $\varphi(t_0)$, and that they exist for all times $t_0 \leq t < \infty$ [1,17].

It cannot be taken for granted, however, that the circuit equations actually can be reduced to that state Equations 7.33 and 7.34. On the one hand, the charges and fluxes may be dependent and thus their initial values cannot be chosen freely. However, the state equations may still exist, in terms of a subset of charges and fluxes. This means that only these charges and fluxes can be chosen independently as initial conditions. On the other hand, the reduction, even to some alternative set of state variables, may be simply impossible. This situation is likely to lead to impasse points, i.e., nonexistence of the solution at a finite time. We refer the reader to the discussion in Ref. [1]. In the sequel we suppose that the solutions exist from the initial time t_0 to $+\infty$ and that they are determined by the charges and fluxes at t_0.

We are interested in the asymptotic behavior, i.e., the behavior of the solutions when the time t goes to infinity. If the dynamic circuit is linear and strictly stable, i.e., if all its natural frequencies are in the open left half of the complex plane, then all solutions converge to one and the same DC-operating (equilibrium) point. This property still holds for many nonlinear circuits, but not for all by far. In particular, the solutions may converge to different DC-operating points, depending on the initial conditions (static memories), they may converge to periodic solutions (free-running oscillators), or they may even show chaotic behavior (e.g., Chua's circuit). Here, we give conditions that guarantee the solutions converge to a unique solution or one among several DC-operating points.

7.3.2 Convergence to DC-Operating Points

The methods to prove convergence to one or more DC-operating points is based on Lyapunov functions. A Lyapunov function is a continuously differentiable function $W(\xi)$, where ξ is the vector composed of the circuit variables (the voltages, currents, charges, and fluxes). In the case of autonomous circuits, a Lyapunov function must have the following properties:

1. W is bounded below, i.e., there exists a constant W_0 such that

$$W(\xi) \geq W_0 \quad \text{for all } \xi \tag{7.35}$$

2. The set of voltages, currents, charges, and fluxes of the circuit such that $W(\xi) \leq E$ is bounded for any real E.
3. For any solution $\xi(t)$ of the circuit

$$\frac{d}{dt} W(\xi(t)) \leq 0 \tag{7.36}$$

4. If

$$\frac{d}{dt} W(\xi(t)) = 0 \tag{7.37}$$

then $\xi(t)$ is a DC-operating point.

If an autonomous circuit has a Lyapunov function and if it has at least one, but a finite number of DC-operating points, then every solution converges to a DC-operating point. The reason is that the Lyapunov function must decrease along each solution, and thus must result in a local minimum, a stable DC-operating point. If more than one DC-operating point exists, it may, as a mathematical exception that cannot occur in practice, end up in a saddle point, i.e., an unstable DC-operating point.

The problem with the Lyapunov function method is that it gives no indication as to how to find such a function. Basically, three methods are available to deal with this problem:

1. Some standard candidates for Lyapunov functions, e.g., the stored energy.
2. Use a certain kind of function and adjust the parameters in order to satisfy points 2 and 3 in the previous list. Often, quadratic functions are used.
3. Use an algorithm to generate Lyapunov functions [18–20].

The following theorems were obtained via approach 1, and we indicate which Lyapunov function was used to prove them. At first glance, this may seem irrelevant from an engineering point of view. However, if we are interested in designing circuits to solve optimization problems, we are likely to be interested in Lyapunov functions. Indeed, as mentioned previously, along any solution of the circuit, the Lyapunov function decreases and approaches a minimum of the function. Thus, the dynamics of the circuit solve a minimization problem. In this case, we look for a circuit with a given Lyapunov function, however, usually we look for a Lyapunov function for a given circuit.

THEOREM 7.9

Let a circuit be composed of capacitors and inductors with a strictly increasing characteristic, resistors with a strictly increasing characteristic, and independent voltage and current sources. Suppose the circuit has a DC-operating point $\bar{\xi}$. *By Theorem 7.1, this DC-operating point is unique. Finally, suppose the circuit has no loop composed of capacitors, inductors, and voltage sources and no cutset composed of capacitors, inductors, and current sources. Then, all solutions of the circuit converge to* $\bar{\xi}$.

The Lyapunov function of this circuit is given by a variant of the stored energy in the capacitors and the resistors, the stored energy with respect to $\bar{\xi}$ [1,17]. If the constitutive relations of the capacitors and the inductors are given by $v_k = h_k(q_k)$ and $i_k = g_k(v_k)$, respectively, then this Lyapunov function becomes

$$W(\xi) = \sum_{\substack{\text{capacitor}\\ \text{branches } k}} \int_{\bar{q}k}^{qk} (h_k(q) - h_k(\bar{q}_k))\mathrm{d}q + \sum_{\substack{\text{inductor}\\ \text{branches } k}} \int_{\bar{\varphi}_k}^{\varphi_k} (g_k(\varphi) - g_k(\bar{\varphi}_k))\mathrm{d}\varphi \tag{7.38}$$

The main condition (Equation 7.36) for a Lyapunov function follows from the fact that the derivative of the stored energy is the absorbed power, here in incremental form:

$$\frac{\mathrm{d}}{\mathrm{d}t} W(\xi) = \sum_{\substack{\text{capacitor}\\ \text{and inductor}\\ \text{branches } k}} \Delta v_k \Delta i_k = -\sum_{\substack{\text{resistor}\\ \text{branches } k}} \Delta v_k \Delta i_k \leq 0 \tag{7.39}$$

Various generalizations of Theorem 7.9 have been given. The condition ''strictly increasing resistor characteristic'' has been relaxed to a condition that depends on $\bar{\xi}$ in Refs. [1,17] and mutual inductances and capacitances have been admitted in Ref. [17].

Theorem 7.10 admits resistors with nonmonotonic characteristics. However, it does not allow for both inductors and capacitors.

THEOREM 7.10

Let a circuit be composed of capacitors with a strictly increasing characteristic, voltage-controlled resistors such that

$$v \to +\infty \Rightarrow i > I_+ > 0 \quad \text{and} \quad v \to -\infty \Rightarrow i < I_- < 0 \tag{7.40}$$

and independent voltage sources. Furthermore, suppose that the circuit has a finite number of DC-operating points. Then every solution of the circuit converges toward a DC-operating point.

This theorem is based on the then following Lyapunov function, called cocontent:

$$W(\xi(t)) = \sum_{\substack{\text{resistor} \\ \text{branches } k}} \int_o^{v_k} g_k(v)\mathrm{d}v \tag{7.41}$$

where $i_k = g_k(v_k)$ is the constitutive relation of the resistor on branch k. The function W is decreasing along a solution of the circuit because

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} W(\xi(t)) &= \sum_{\substack{\text{resistor} \\ \text{branches } k}} \frac{\mathrm{d}v_k}{\mathrm{d}t} i_k = -\sum_{\substack{\text{capacitor} \\ \text{branches } k}} \frac{\mathrm{d}v_k}{\mathrm{d}t} i_k \\ &= -\sum_{\substack{\text{capacitor} \\ \text{branches } k}} \frac{\mathrm{d}h_k}{\mathrm{d}q} i_k^2 \le 0 \end{aligned} \tag{7.42}$$

where $h_k(q_k)$ is the constitutive relation of the capacitor on branch k.

Theorem 7.10 has a dual version. It admits inductors instead of capacitors, current-controlled resistors, and current sources. The corresponding Lyapunov function is the content:

$$W(\xi) = \sum_{\substack{\text{resistor} \\ \text{branches } k}} \int_o^{i_k} h_k(i)\mathrm{d}i \tag{7.43}$$

where $v_k = h_k(i_k)$ is the constitutive relation of the resistor on branch k.

The main drawback of the two preceding theorems is that they do not admit nonreciprocal elements such as controlled sources, operational amplifiers, etc. In other words, no statement about the analog neural network of Figure 7.20 can be made. In this network the nonreciprocal element is the VCVS with the nonlinear characteristics $v_2 = \sigma(v_1)$. However, Theorem 7.10 can be generalized to a reciprocal voltage-controlled N-port resistor closed on capacitors and voltage sources. Such an N-port (Figure 7.21) is described by a constitutive relation of the form

$$i_k = g_k(v_1, \ldots, v_N) \tag{7.44}$$

and it is reciprocal, if for all $\mathbf{v}$, and all k, j we have

$$\frac{\partial g_k}{\partial v_j}(\mathbf{v}) = \frac{\partial g_j}{\partial v_k}(\mathbf{v}) \tag{7.45}$$

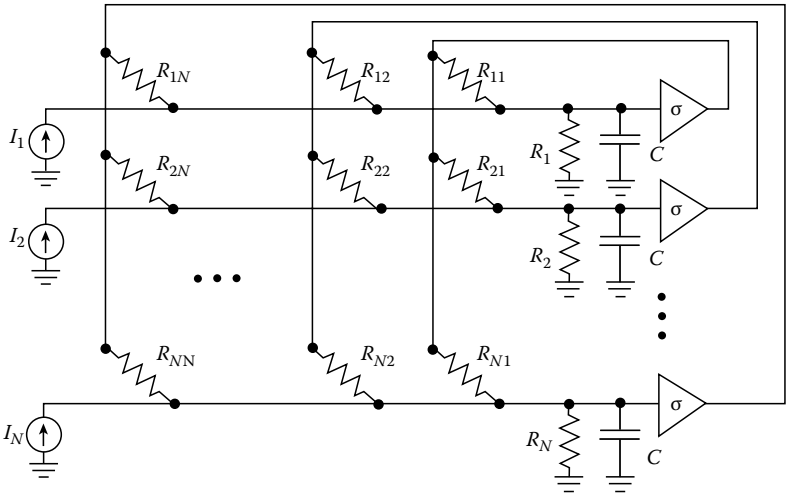

FIGURE 7.20 Analog neural network.

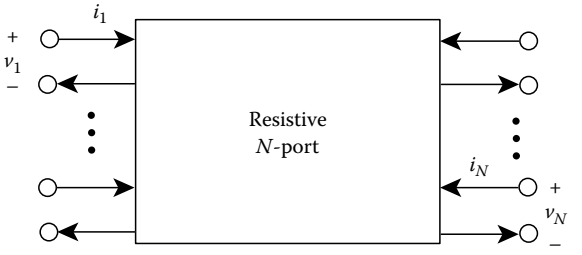

FIGURE 7.21 Resistive N-port.

THEOREM 7.11

Let a circuit be composed of charge-controlled capacitors with a strictly increasing characteristic and independent voltage sources that terminate a reciprocal voltage-controlled N-port with constitutive relation (*Equation 7.42*) *so that we find constants V and* $P > 0$ *such that*

$$\|\mathbf{v}\| \geq V \Rightarrow \mathbf{g} \cdot \mathbf{v} = \sum_{k=1}^{N} g_k(\mathbf{v}) v_k \geq P \tag{7.46}$$

If the number of DC-operating points is finite, then all solutions converge toward a DC-operating point.

The proof of this theorem is based on the Lyapunov function $W(\mathbf{v})$ that satisfies

$$\frac{\partial W}{\partial v_k}(\mathbf{v}) = g_k(\mathbf{v}) \tag{7.47}$$

Thanks to Equation 7.45, function W exists. The first two conditions for a Lyapunov function are a consequence of Equation 7.46. Finally

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}W(\xi(t)) &= \sum_{\substack{\text{resistor}\\ \text{branches}k}} g_k(\mathbf{v})\frac{\mathrm{d}v_k}{\mathrm{d}t}\\ &= \sum_{\substack{\text{resistor}\\ \text{branches } k}} i_k\frac{\mathrm{d}v_k}{\mathrm{d}t}\\ &= -\sum_{\substack{\text{capacitor}\\ \text{branches } k}} \frac{\mathrm{d}h_k}{\mathrm{d}q}i_k^2 \le 0\end{aligned} \tag{7.48}$$

where $h_k(q_k)$ is the constitutive relation of the capacitor on branch k.

To illustrate how Theorem 7.11 can be applied when Theorem 7.10 fails, consider the analog neural network of Figure 7.20. If the capacitor voltages are denoted by u_i and the voltages at the output of the voltage sources by v_i, the state equations for the network of Figure 7.1 become

$$-C_i\frac{\mathrm{d}u_i}{\mathrm{d}t} = \frac{u_i}{R_i} + \sum_{j=1}^{N}\frac{u_i - v_j}{R_{ij}} + I_i \tag{7.49}$$

Suppose that the nonlinear characteristic $\sigma(u)$ is invertible. The state equations can be written in terms of the voltages v_i:

$$-C\frac{\mathrm{d}\sigma^{-1}}{\mathrm{d}v}(v_i)\frac{\mathrm{d}v_i}{\mathrm{d}t} = G_i\sigma^{-1}(v_i) - \sum_{j=1}^{N}\frac{v_j}{R_{ij}} + I_i \tag{7.50}$$

where

$$G_i = \frac{1}{R_i} + \sum_{j=1}^{N}\frac{1}{R_{ij}} \tag{7.51}$$

Equations 7.40 can be reinterpreted as the equations of a resistive N-port with the constitutive relations

$$g_i(\mathbf{v}) = G_i\sigma^{-1}(v_i) - \sum_{j=1}^{N}\frac{v_j}{R_{ij}} + I_i \tag{7.52}$$

closed on nonlinear capacitors with the constitutive relation

$$v = \sigma\left(\frac{q}{C}\right) \tag{7.53}$$

If σ is a sigmoidal function, as is most often supposed in this context (i.e., a strictly increasing function with $s(u) \to \pm 1$ for $u \to \pm\infty$), then the capacitors have a strictly increasing characteristic, as required by Theorem 7.11. Furthermore, the resistive N-port is reciprocal if for $i \neq j$

$$\frac{\partial g_i}{\partial v_j} = -\frac{1}{R_{ij}} = \frac{\partial g_j}{\partial v_i} = -\frac{1}{R_{ji}} \tag{7.54}$$

In other words, if for all i, j

$$R_{ij} = R_{ji} \tag{7.55}$$

On the other hand, inequality Equation 7.46 must be modified because the sigmoids have values only in the interval $[-1, +1]$ and thus Equation 7.50 are defined only on the invariant bounded set $S = \{\mathbf{v} | -1 < v_i < +1\}$. Therefore, inequality Equation 7.50 must be satisfied for vectors $\mathbf{v}$ sufficiently close to the boundary of S. This is indeed the case, because $\sigma^{-1}(v) \to \pm\infty$ as $v \to \pm 1$, whereas the other terms of the right-hand side of Equation 7.52 remain bounded.

It follows that all solutions of the analog neural network of Figure 7.20 converge to a DC-operating point as $t \to \infty$, provided σ is a sigmoid function and the connection matrix R_{ij} (synaptic matrix) is symmetrical. The Lyapunov function can be given explicitly:

$$W(\mathbf{v}) = \sum_{i=1}^{N} G_i \int_0^{v_i} \sigma^{-1}(v)\mathrm{d}v - \frac{1}{2}\sum_{i,j=1}^{N} \frac{v_i v_j}{R_{ij}} + \sum_{i=1}^{N} v_i I_i \tag{7.56}$$

7.4 Nonautonomous Dynamic Circuits

7.4.1 Introduction

This section is a consideration of circuits that contain elements where constitutive relations depend explicitly on time. However, we limit time dependence to the independent sources. For most practical purposes, this is sufficient. A time-dependent voltage source has a constitutive relation

$$v = e(t) \tag{7.57}$$

and a time-dependent current source

$$i = e(t) \tag{7.58}$$

where $e(t)$ is a given function of time which we suppose here to be continuous. In information processing circuits, $e(t)$ represents a signal that is injected into the circuit, whereas in energy transmission circuits $e(t)$ usually is a sinusoidal or nearly sinusoidal function related to a generator.

The time-dependent sources may drive the voltages and the currents to infinity, even if they only inject bounded signals into the circuit. Therefore, the discussion begins with the conditions that guarantee the boundedness of the solutions.

7.4.2 Boundedness of the Solutions

In electronic circuits, even active elements become passive when the voltages and currents grow large. This is the reason that solutions remain bounded.

Definition 7.6: A resistor is eventually passive if, for sufficiently large voltages and/or currents, it can only absorb power. More precisely, eventual passivity means that constants V and I exist such that, for all points (v, i) on the resistor characteristic with $|v| > V$ or $|i| > I$, we have

$$v \cdot i \geq 0 \tag{7.59}$$

Note that sources are not eventually passive, but as soon as an internal resistance of a source is taken into account, the source becomes eventually passive. The notion of eventual passivity can be extended to time-varying resistors.

Definition 7.7: A time-varying resistor is eventually passive if constants V and I are independent of time and are such that all points (v, i), with $|v| > V$ or $|i| > I$ that at some time lie on the characteristic of the resistor, satisfy the passivity condition (Equation 7.59). According to this definition, time-dependent sources with internal resistance are eventually passive if the source signal remains bounded.

Eventual passivity allows us to deduce bounds for the solutions. These bounds are uniform in the sense that they do not depend on the particular solution. To be precise, this is true only asymptotically, as $t \to \infty$.

Definition 7.8: The solutions of a circuit are eventually uniformly bounded if there exist constants V, I, Q, and $\mathbf{\Phi}$ such that, for any solution there exists a time T such that for any $t > T$, the voltages $v_k(t)$ are bounded by V, the currents $i_k(t)$ are bounded by I, the charges $q_k(t)$ are bounded by Q, and the fluxes $\varphi_k(t)$ are bounded by $\mathbf{\Phi}$.

Another manner of expressing the same property is to say that an attracting domain exists in state space [1].

THEOREM 7.12

A circuit composed of eventually passive resistors with $v \cdot i \to +\infty$ as $|v| \to \infty$ or $|i| \to \infty$, capacitors with $v \to \pm\infty$ as $q \to \neq\infty$, and inductors with $i \to \pm\infty$ as $\varphi \to \infty$ has eventually uniformly bounded solutions if no loop or cutset exists without a resistor [1,17].

Again, this theorem is proved by using a Lyapunov function, namely the stored energy

$$W(\xi) = \sum_{\substack{\text{capacitor} \\ \text{branches } k}} \int_0^{q_k} h_k(q)\mathrm{d}q + \sum_{\substack{\text{capacitor} \\ \text{branches } k}} \int_0^{\varphi_k} g_k(\varphi)\mathrm{d}\varphi \tag{7.60}$$

Inequality Equation 7.36 holds only outside of a bounded domain.

7.4.3 Unique Asymptotic Behavior

In the presence of signals with complicated waveforms that are injected into a circuit, we cannot expect simple waveforms for the voltages and the currents, not even asymptotically, as $t \to \infty$. However, we can hope that two solutions, starting from different initial conditions, but subject to the same source, have the same steady-state behavior. The latter term needs a more formal definition.

Definition 7.9: A circuit has unique asymptotic behavior if the following two conditions are satisfied:

1. All solutions are bounded.
2. For any two solutions $\xi_1(t)$ and $\xi_2(t)$

$$\|\xi_1(t) - \xi_2(t)\| \to_{t\to\infty} 0 \tag{7.61}$$

In order to prove unique asymptotic behavior, it is necessary to extend the notion of the Lyapunov function [1]. This does not lead very far, but at least it permits us to prove the following theorem.

THEOREM 7.13

Suppose a circuit is composed of resistors with a strictly increasing characteristic such that $v \cdot i \to \infty$ *as* $|v| \to \infty$ *or* $|i| \to \infty$, *positive linear capacitors*, positive linear inductors, *time-depending voltage* (*current*) *sources with bounded voltage* (*current*) *and a positive resistor in series* (*parallel*). *If no loop or cutset is composed exclusively of capacitors and inductors, the circuit has unique asymptotic behavior* [1,17].

This theorem is unsatisfactory because linear reactances are required and real devices are never exactly linear. It has been shown that slight nonlinearities can be tolerated without losing the unique asymptotic behavior [21]. On the other hand, we cannot expect to get much stronger general results because nonautonomous nonlinear circuits may easily have multiple steady-state regimes and even more complicated dynamics, such as chaos, even if the characteristics of the nonlinear elements are all strictly increasing.

Another variant of Theorem 7.13 considers linear resistors and nonlinear reactances [17].

8.1 Introduction

Nonlinear synthesis and design can be informally defined as a constructive procedure to interconnect components from a catalog of available primitives, and to assign values to their constitutive parameters to meet a specific nonlinear relationship among electrical variables. This relationship is represented as an implicit integrodifferential operator, although we primarily focus on the synthesis of *explicit algebraic* functions,

$$y = f(\mathbf{x}) \tag{8.1}$$

where

y is voltage or current
$f(\cdot)$ is a nonlinear real-valued function
$\mathbf{x}$ is a vector with components that include voltages and currents

This synthesis problem is found in two different circuit-related areas: device modeling [8,76] and analog computation [26]. The former uses ideal circuit elements as primitives to build computer models of real circuits and devices (see Chapter 7). The latter uses real circuit components, available either off the shelf or integrable in a given fabrication technology, to realize hardware for nonlinear signal processing tasks. We focus on this second area, and intend to outline systematic approaches to devise electronic function generators. Synthesis relies upon hierarchical decomposition, conceptually shown in Figure 8.1, which encompasses several subproblems listed from top to bottom:

- Realization of nonlinear operators (multiplication, division, squaring, square rooting, logarithms, exponentials, sign, absolute value, etc.) through the interconnection of primitive components (transistors, diodes, operational amplifiers, etc.)
- Realization of elementary functions (polynomials, truncated polynomials, Gaussian functions, etc.) as the interconnection of the circuit blocks devised to build nonlinear operators
- Approximation of the target as a combination of elementary functions and its realization as the interconnection of the circuit blocks associated with these functions

Figure 8.1 illustrates this hierarchical decomposition of the synthesis problem through an example in which the function is approximated as a linear combination of truncated polynomials [30], where realization involves analog multipliers, built by exploiting the nonlinearities of bipolar junction transistors (BJTs) [63]. Also note that the subproblems cited above are closely interrelated and, depending on the availability of primitives and the nature of the nonlinear function, some of these phases can be bypassed. For instance, a logarithmic function can be realized exactly using BJTs [63], but requires approximation if our catalog includes only field-effect transistors whose nonlinearities are polynomic [44].

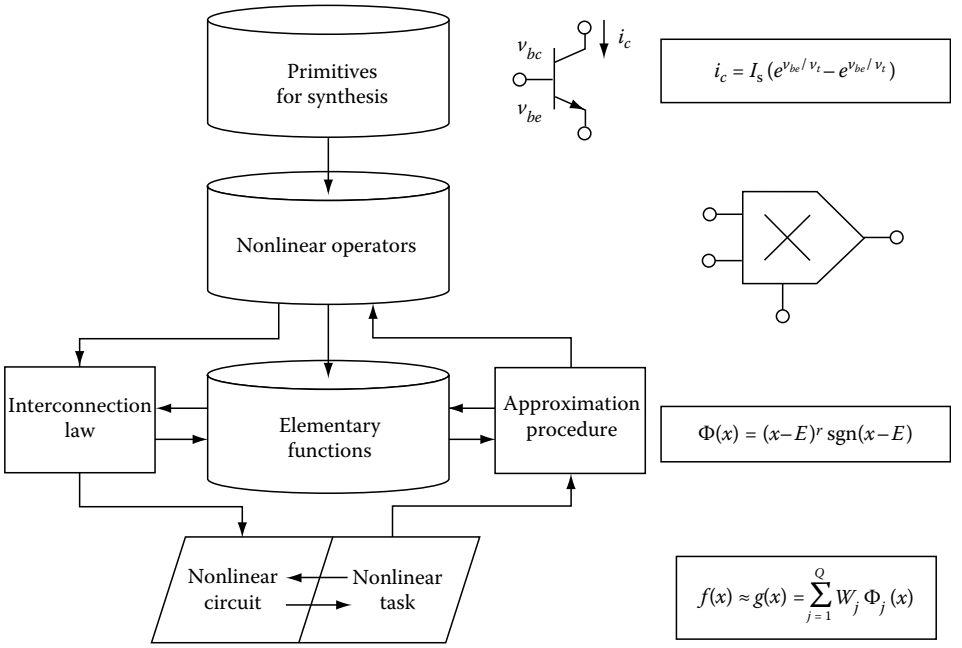

FIGURE 8.1 Hierarchical decomposition of the synthesis problem.

The technical literature contains excellent contributions to the solution of all these problems. These contributions can hardly be summarized or even quoted in just one section. Many authors follow a block-based approach which relies on the pervasive voltage operational amplifier (or op-amp), the rectification properties of junction diodes, and the availability of voltage multipliers, in the tradition of classical analog computation (e.g., Refs. [7,59,80]). Remarkable contributions have been made which focus on qualitative features such as negative resistance or hysteresis, rather than the realization of well-defined approximating functions [9,20,67]. Other contributions focus on the realization of nonlinear operators in the form of IC units. Translinear circuits, BJTs [23,62], and MOSFETs [79] are particularly well suited to realize algebraic functions in IC form. This IC orientation is shared by recent developments in analog VLSI computational and signal processing systems for neural networks [75], fuzzy logic [81], and other nonlinear signal processing paradigms [56,57,71].

This chapter is organized to fit the hierarchical approach in Figure 8.1. We review a wide range of approximation techniques and circuit design styles, for both discrete and monolithic circuits. It is based on the catalog of primitives shown in Appendix A. In addition to the classical op-amp-based continuous-time circuits, we include current-mode circuitry because nonlinear operators are realized simply and accurately by circuits that operate in *current domain* [23,57,62,79]. We also cover discrete-time circuits realized using analog dynamic techniques based on charge transfer, which is very significant for mixed-signal processing and computational microelectronic systems [27,72]. Section 8.2 is devoted to approximation issues and outlines different techniques for uni- and multidimensional functions, emphasizing hardware-oriented approaches. These techniques involve several nonlinear operators and the linear operations of scaling and aggregation (covered in Section 8.3, which also presents circuits to perform transformations among different kinds of characteristics). Sections 8.4 and 8.5 present circuits for piecewise-linear (PWL) and piecewise-polynomial (PWP) functions, Section 8.6 covers neural and fuzzy approximation techniques, and Section 8.7 outlines an extension to dynamic circuits.

8.2 Approximation Issues

8.2.1 Unidimensional Functions

Consider a target function, $f(x)$, given analytically or as a collection of measured data at discrete values of the independent variable. The approximation problem consists of finding a multiparameter function, $g(x, \mathbf{w})$, which yields proper fitting to the target, and implies solving two different subproblems: (1) which approximating functions to use, and (2) how to adjust the parameter vector, $\mathbf{w}$, to render optimum fitting. We only outline some issues related to this first point. Detailed coverage of both problems can be found in mathematics and optimization textbooks [73,78]. Other interesting views are found in circuit-related works [6,11,30], and the literature on neural and fuzzy networks [12,21,33,43,51].

An extended technique to design nonlinear electronic hardware for both discrete [63,80] and monolithic [35,62,79] design styles uses polynomial approximating functions,

$$g(x) = \sum_{j=0}^{Q} \alpha_j x^j \tag{8.2}$$

obtained through expansion by either Taylor series or orthogonal polynomials (Chebyshev, Legendre, or Laguerre) [26]. Other related approaches use rational functions,

$$g(x) = \frac{\sum_{j=0,Q} \alpha_j x^j}{\sum_{j=0,R} \beta_j x^j} \tag{8.3}$$

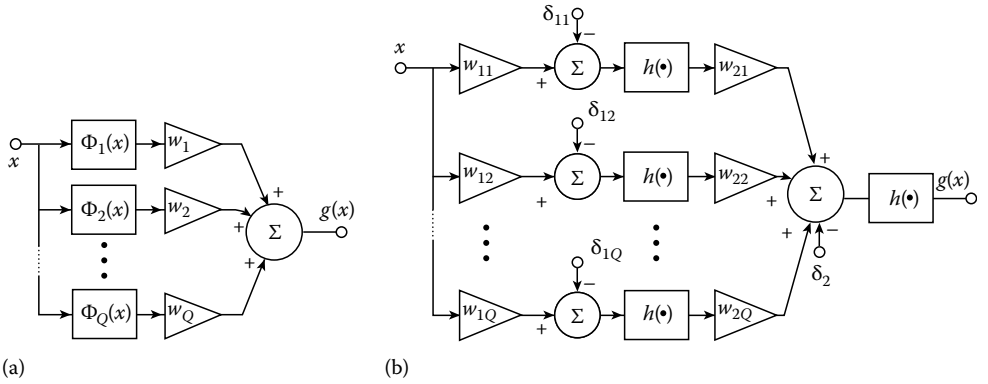

FIGURE 8.2 Block diagram for approximating function hardware. (a) Using linear combination of basis functions; (b) using two layers of nested sigmoids.

to improve accuracy in the approximation of certain classes of functions [14]. These can be realized by polynomial building blocks connected in feedback configuration [63]. In addition, Ref. [39] presents an elegant synthesis technique relying on linearly controlled resistors and conductors to take advantage of linear circuits synthesis methods (further extended in Ref. [28]).

From a more general point of view, hardware-oriented approximating functions can be classified into two major groups:

1. Those involving the linear combination of basis functions

$$g(x) = \sum_{j=1}^{Q} w_j \Phi_j(x) \tag{8.4}$$

   which include polynomial expansions. PWL and PWP interpolation and radial basis functions (RBF). The hardware for these functions consists of two layers, as shown in Figure 8.2a. The first layer contains Q nonlinear processing nodes to evaluate the basis functions; the second layer scales the output of these nodes and aggregates these scaled signals in a summing node.
2. Those involving a multilayer of nested sigmoids [51]; for instance, in the case of two layers [82],

$$g(x) = h\left[\left\{\sum_{j=1,Q} w_{2j} h\left(w_{1j}x - \delta_{1j}\right)\right\} - \delta_2\right] \tag{8.5}$$

   with the sigmoid function given by

$$h(x) = \frac{2}{1 + \exp(-\lambda x)} - 1 \tag{8.6}$$

   where $\lambda > 0$ determines the steepness of the sigmoid. Figure 8.2b shows a hardware concept for this approximating function, also consisting of two layers.

8.2.2 Piecewise-Linear and Piecewise-Polynomial Approximants

A drawback of polynomial and rational approximants is that their behavior in a small region determines their behavior in the whole region of interest [78]. Consequently, they are not appropriate to fit functions

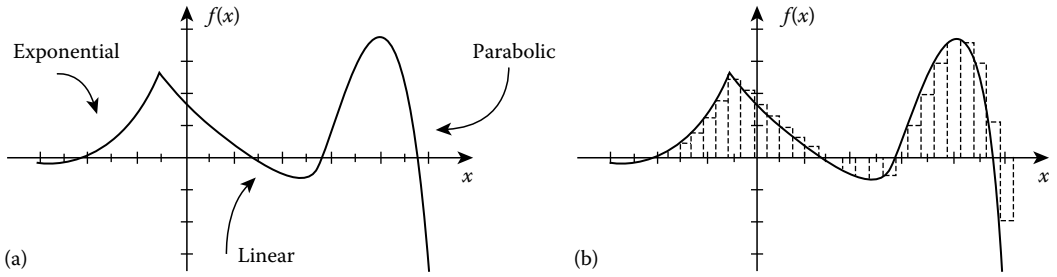

FIGURE 8.3 Example of nonuniform function. (a) A functions that is uniform throughout the whole region. (b) Interpolating the function by its samples associated to infinitely small subintervals.

that are uniform throughout the whole region (see Figure 8.3a). Another drawback is their lack of modularity, a consequence of the complicated dependence of each fitting parameter on multiple target data, which complicates the calculation of optimum parameter values. These drawbacks can be overcome by splitting the target definition interval into Q subintervals, and then expressing approximating function as a linear combination of basis functions, each having compact support over only one subinterval, i.e., zero value outside this subinterval. For the limiting case in which $Q \to \infty$, this corresponds to interpolating the function by its samples associated to infinitely small subintervals (Figure 8.3b). Such action is functionally equivalent to expressing a signal as its convolution with a delta of Dirac [10].

This splitting and subsequent approximation can be performed ad hoc, by using different functional dependences to fit each subregion. However, to support the systematic design of electronic hardware it is more convenient to rely on well-defined classes of approximating functions. In particular, Hermite PWPs provide large modularity by focusing on the interpolation of measured data taken from the target function. Any lack of flexibility as compared to the ad hoc approach may be absorbed in the splitting of the region.

Consider the more general case in which the function, $y = f(x)$, is defined inside a real interval $[\delta_0,\delta_{N+1}]$ and described as a collection of data measured at *knots* of a given interval partition, $\Delta = \{\delta_0, \delta_1, \delta_2, \ldots, \delta_N, \delta_{N+1}\}$. These data may include the function values at these points, as well as their derivatives, up to the $(M-1)$th order,

$$f^{(k)}(\delta_i) = \frac{\mathrm{d}^k}{\mathrm{d}x^k} f(x)\bigg|_{x=\delta_i} \qquad i = 0, 1, 2, \ldots, N, N+1 \tag{8.7}$$

where k denotes the order of the derivative and is zero for the function itself. These data can be interpolated by a linear combination of basis polynomials of degree $2M-1$,

$$g(x) = \sum_{i=0}^{N+1} \sum_{k=0}^{M-1} f^{(k)}(\delta_i)\Phi_{ik}(x) \tag{8.8}$$

where the expressions for these polynomials are derived from the interpolation data and continuity conditions [78]. Note that for a given basis function set and a given partition of the interval, each coefficient in Equation 8.8 corresponds to a single interpolation kust.

The simplest case uses linear basis functions to interpolate only the function values,

$$g(x) = \sum_{i=0}^{N+1} f(\delta_i) l_i(x) \tag{8.9}$$

with no function derivatives interpolated. Figure 8.4 shows the shape of the inner jth linear basis function, which equals 1 at δ_i and decreases to 0 at δ_{i-1} and δ_{i+1}. Figure 8.5a illustrates the representation

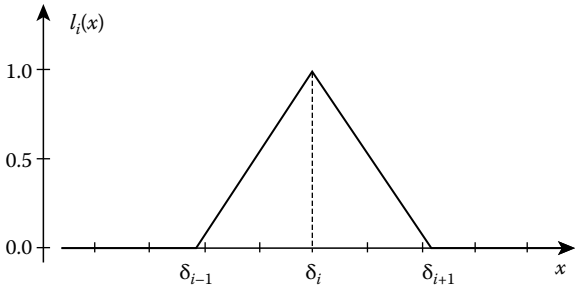

FIGURE 8.4 Hermite linear basis function.

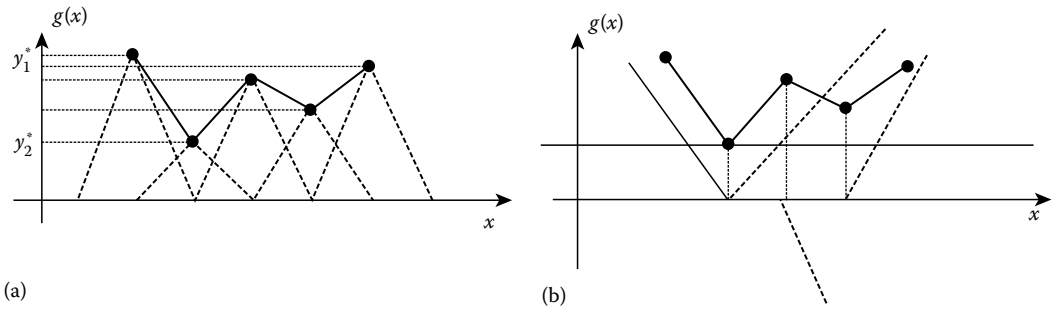

FIGURE 8.5 Decomposition of a PWL function using the extension operator. (a) Illustrating the representation in Equation 8.9. (b) Fitting some pieces from left to right and others from right to left.

in Equation 8.9. By increasing the degree of the polynomials, the function derivatives also can be interpolated. In particular, two sets of third-degree basis functions are needed to retain modularity in the interpolation of the function and its first derivative at the knots

$$g(x) = \sum_{i=0}^{N+1} f(\delta_i) v_i(x) + \sum_{i=0}^{N+1} f^{(1)}(\delta_i) s_i(x) \tag{8.10}$$

where Appendix B shows the shapes and expressions of the value, $v_i(x)$, and slope, $s_i(x)$, basis functions.

The modularity of Hermite polynomials is not free; their implementation is not cheapest in terms of components and, consequently, may not be optimal for application in which the target function is fixed. These applications are more conveniently handled by the so-called canonical representation of PWP functions. A key concept is the extension operator introduced in Ref. [6]; the basic idea behind this concept is to build the approximating function following an iterative procedure. At each iteration, the procedure starts from a function that fits the data on a subinterval, enclosing several pieces of the partition interval, and then adds new terms to also fit the data associated to the next piece. Generally, some pieces are fit from left to right and others from right to left, to yield

$$g(x) = g^0(x) + \sum_{i=1}^{N+} \Delta^+ g_i(x) + \sum_{i=-N_-}^{-1} \Delta^- g_i(x) \tag{8.11}$$

It is illustrated in Figure 8.5b. The functions in Equation 8.11 have the following general expressions

$$\begin{aligned}\Delta^{+}g(x) &= wu_{+}(x-\delta) \equiv w(x-\delta)\text{sgn}(x-\delta)\\ \Delta^{-}g(x) &= wu_{-}(x-\delta) \equiv w(x-\delta)\text{sgn}(\delta-x)\\ g^{0}(x) &= ax+b\end{aligned} \tag{8.12}$$

where sgn(·) denotes the *sign* function, defined as an application of the real axis onto the discrete set {0,1}.

This representation, based on the extension operator, is elaborated in Ref. [6] to obtain the following canonical representation for unidimensional PWL functions:

$$g(x) = ax + b + \sum_{i=1}^{N} w_i|x-\delta_i| \tag{8.13}$$

which has the remarkable feature of involving only one nonlinearity: the absolute value function.

The extension operator concept was applied in Ref. [30] to obtain canonical representations for cubic Hermite polynomials and B-splines. Consequently, it demonstrates that a PWP function admits a global expression consisting of a linear combination of powers of the input variable, plus truncated powers of shifted versions of this variable. For instance, the following expression is found for a cubic B-spline:

$$g(x) = \sum_{r=0}^{3} \alpha_r x^r + \sum_{i=1}^{N} \beta_i (x-\delta_i)^3 \text{sgn}(x-\delta_i) \tag{8.14}$$

with α_r and β_i obtainable through involved operations using the interpolation data. Other canonical PWP representations devised by these authors use

$$(x-\delta_i)^r \text{sgn}(x-\delta_i) = \frac{1}{2}\{|x-\delta_i| + (x-\delta_i)\}(x-\delta_i)^{r-1} \tag{8.15}$$

to involve the absolute value, instead of the sign function, in the expression of the function.

8.2.3 Gaussian and Bell-Shaped Basis Functions

The Gaussian basis function belongs to the general class of RBF [51,52], and has the following expression:

$$\Phi(x) = \exp\left(-\frac{(x-\delta)^2}{2\sigma^2}\right) \tag{8.16}$$

plotted in Figure 8.6. The function value is significant only for a small region of the real axis centered around its center, δ, and its shape is controlled by the *variance* parameter, σ^2. Thus, even though the

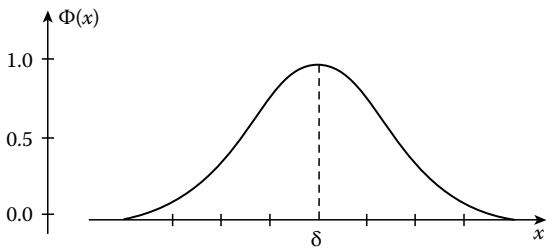

FIGURE 8.6 Guassian basis function.

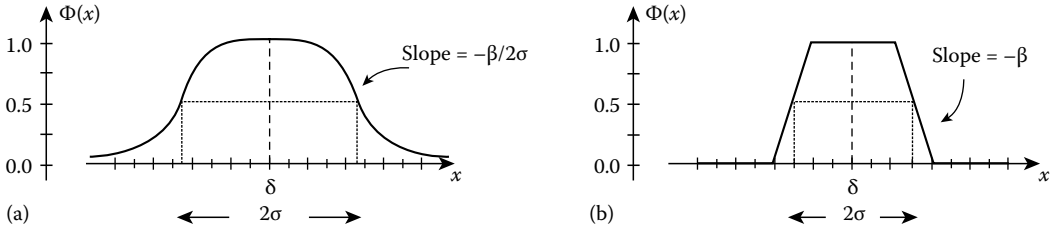

FIGURE 8.7 Fuzzy membership functions: (a) polynomial; (b) PWL.

support of Gaussian functions is not exactly compact, they are negligible except for well-defined local domains of the input values.

By linear combination of a proper number of Gaussians, and a proper choice of their centers and variances, as well as the weighting coefficients, it is possible to approximate nonlinear functions to any degree of accuracy [51]. Also, the local feature of these functions renders this adjustment process simpler than for multilayer networks composed of nested sigmoids, whose components are global [43,50].

A similar interpolation strategy arises in the framework of fuzzy reasoning, which is based on local membership functions whose shape resembles a Gaussian. For instance, in the ANFIS system proposed by Jang [33]

$$\Phi(x) = \frac{1}{1 + \left[\left(\frac{x-\delta}{\sigma}\right)^2\right]^{\beta}} \tag{8.17}$$

as plotted in Figure 8.7a where the shape is controlled by β and σ, and the position is controlled by δ. Other authors, for instance, Yamakawa [81], use the PWL membership function shape of Figure 8.7b, which is similar to the Hermite linear basis function of Figure 8.4. From a more general point of view, cubic B-splines [78] used to build hardware [59] and for device modeling [76] also can be considered to be members of this class of functions.

8.2.4 Multidimensional Functions

Approximation techniques for multidimensional functions are informally classified into five groups:

1. Sectionwise PWP functions [6,30]
2. Canonical PWL representations [11]
3. Neurofuzzy interpolation [33,81]
4. Radial basis functions [51,52]
5. Multilayers of nested sigmoids [82]

8.2.4.1 Sectionwise Piecewise-Polynomial Functions

This technique reduces the multidimensional function to a sum of products of functions of only one variable:

$$g(\mathbf{x}) = \sum_{k_1=1}^{M_1} \sum_{k_2=1}^{M_2} \cdots \sum_{k_P=1}^{M_P} \alpha(k_1, k_2, \ldots, k_P) \prod_{j=1}^{P} \Phi_{k_j}(x_j) \tag{8.18}$$

where $\alpha(k_1, k_2, \ldots, k_P)$ denotes a constant coefficient. These function representations were originally proposed by Chua and Kang for the PWL case [6] where

$$\Phi_1(x_j) = 1 \quad \Phi_2(x_j) = x_j \quad \Phi_3(x_j) = \left|x_j - \delta_{j1}\right| \cdots$$
$$\Phi_{M_P}(x_j) = \left|x_j - \delta_{jM_P-2}\right| \tag{8.19}$$

Similar to the unidimensional case, the only nonlinearity involved in these basis functions is the absolute value. However, multidimensional functions not only require weighted summations, but also multiplications. The extension of Equation 8.18 to PWP functions was covered in Ref. [30], and involves the same kind of nonlinearities as Equations 8.14 and 8.15.

8.2.4.2 Canonical Piecewise Linear Representations

The canonical PWL representation of Equation 8.13 can be extended to the multidimensional case, based on the following representation:

$$g(\mathbf{x}) = \mathbf{a}^{\mathrm{T}}\mathbf{x} + b + \sum_{i=1}^{Q} c_i \left|\mathbf{w}_i^{\mathrm{T}}\mathbf{x} - \delta_i\right| \tag{8.20}$$

where

a and $\mathbf{w}_i$ are P-vectors
b, c_i, and δ_i are scalars

Q represents the number of hyperplanes that divide the whole space R^P into a finite number of polyhedral regions where $g(\cdot)$ can be expressed as an affine representation.

Note that Equation 8.20 avoids the use of multipliers. Thus, $g(\cdot)$ in Equation 8.20 can be realized through the block diagram of Figure 8.8, consisting of Q absolute value nonlinearities and weighted summers.

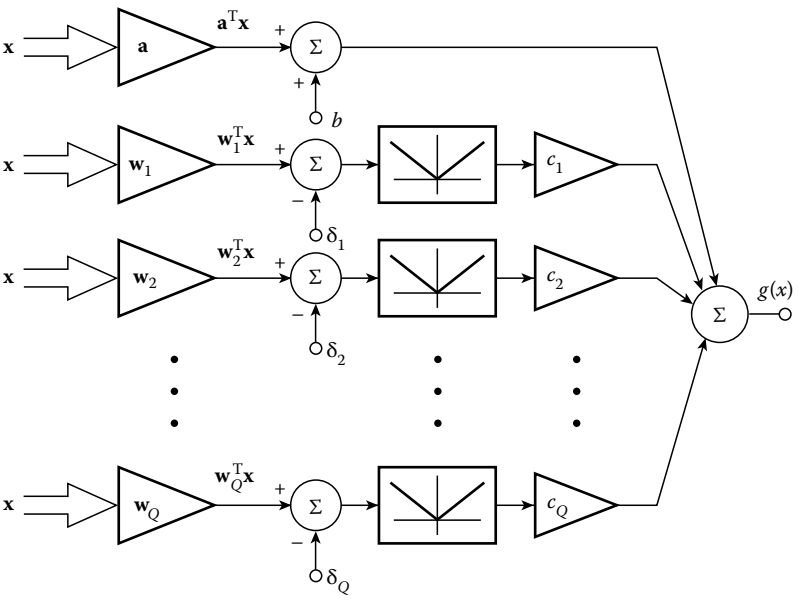

FIGURE 8.8 Canonical block diagram for a canonical PWL function.

8.2.4.3 Radial Basis Functions

The idea behind RBF expansion is to represent the function at each point of the input space as a linear combination of kernel functions whose arguments are the radial distance of the input point to a selected number of centers

$$g(\mathbf{x}) = \sum_{j=1}^{Q} w_j \Phi_j(\|\mathbf{x} - \boldsymbol{\delta}_j\|) \tag{8.21}$$

where $||\cdot||$ denotes a norm imposed on R^P, usually assumed Euclidean. The most common basis function is a Gaussian kernel similar to Equation 8.16,

$$\Phi(\mathbf{x}) = \exp\left(-\frac{\|\mathbf{x} - \boldsymbol{\delta}\|^2}{2\sigma^2}\right) \tag{8.22}$$

although many other alternatives are available [51], for instance,

$$\Phi(r) = (\sigma^2 + r^2)^{-\alpha}, \quad \Phi(r) = r, \quad \alpha \geq -1 \tag{8.23}$$

where r is the radial distance to the center of the basis function, $r \equiv ||\mathbf{x} - \delta||$. Micchelli [42] demonstrated that any function where the first derivative is monotonic qualifies as a RBF. As an example, as Equation 8.23 displays, the identity function $\Phi(r) = r$ falls into this category, which enables connecting the representation by RBF to the canonical PWL representation [40]. Figure 8.9 is a block diagram for the hardware realization of the RBF model.

8.2.4.4 Neurofuzzy Interpolation

This technique exploits the interpolation capabilities of fuzzy inference, and can be viewed as the multidimensional extension of the use of linear combination of bell-shaped basis functions to approximate nonlinear functions of a single variable (see Equations 8.4 and 8.17). Apart from its connection to approximate reasoning and artificial intelligence, this extension exhibits features similar to the sectionwise PWP representation, namely, it relies on a well-defined class of unidimensional functions. However, neurofuzzy interpolation may be advantageous for hardware implementation because it requires easy-to-build collective computation operators instead of multiplications.

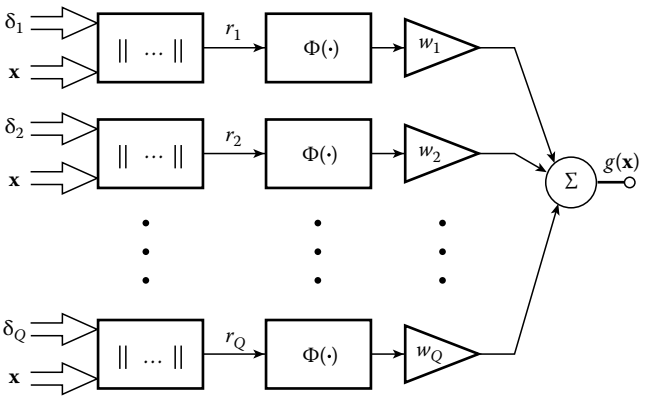

FIGURE 8.9 Concept of RBF hardware.

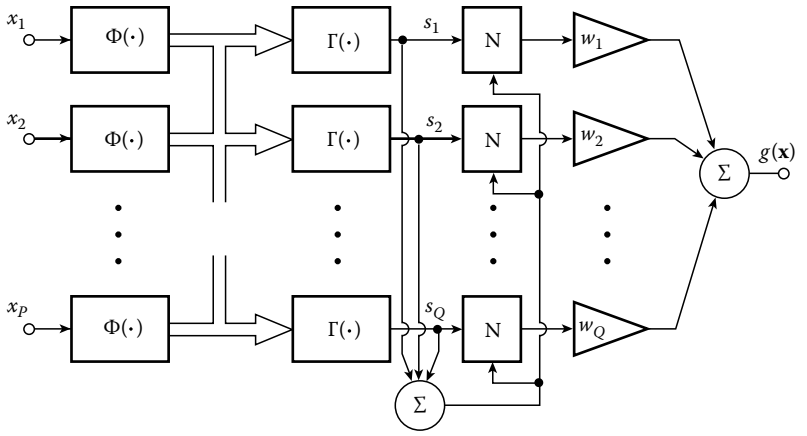

FIGURE 8.10 Conceptual architecture of a neurofuzzy interpolator.

Figure 8.10 depicts the block diagram of a neurofuzzy interpolator for the simplest case in which inference is performed using the singleton algorithm [33] to obtain

$$g(\mathbf{x}) = \sum_{j=1}^{Q} w_j \frac{s_j(\mathbf{x})}{\sum\limits_{i=1,Q} s_i(\mathbf{x})} \tag{8.24}$$

where the functions $s_i(\mathbf{x})$, called activities of the fuzzy rules, are given as

$$s_j(\mathbf{x}) = \Gamma\left\{\Phi_{j1}(x_1), \Phi_{j2}(x_2), \ldots, \Phi_{jP}(x_P)\right\} \tag{8.25}$$

where

$\Gamma(\cdot)$ is any T-norm operator, for instance, the *minimum*
$\Phi(\cdot)$ has a bell-like shape (see Figure 8.7)

8.2.4.5 Multilayer Perceptron

Similar to Equation 8.5, but consists of the more general case of several layers, with the input to each nonlinear block given as a linear combination of the multidimensional input vector [82].

8.3 Aggregation, Scaling, and Transformation Circuits

The mathematical techniques presented in Section 8.2 require several nonlinear operators and the linear operators of scaling and aggregation (covered for completeness in this section). This section also covers transformation circuits. This is because in many practical situations we aim to exploit some nonlinear mechanism which intrinsically involves a particular kind of characteristics. For instance, a MOS transistor has inherent square-law transconductance, while a diode exhibits an exponential driving-point. Similarly, many nonlinear operators are naturally realized in current-mode domain and involve currents at both the input and the output. Thus, transformation circuits are needed to exploit these mechanisms for other types of characteristics.

8.3.1 Transformation Circuits

Two basic problems encountered in the design of transformation circuits are how to convert a voltage node into a current node and vice versa. We know no unique way to realize these functions. Instead, there

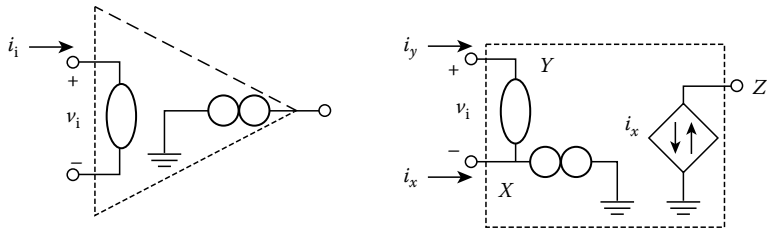

FIGURE 8.11 First-order models for voltage op-amps and CCIIs using nullators and norators.

are many alternatives which depend on which active component from Appendix A is used. The OTA can be represented to a first-order model as a voltage-controlled current source (VCCS) with linear transconductance parameter g_m. Regarding the op-amp and CCII, it is convenient to represent them by the first-order models of Figure 8.11, which contain nullators and norators.* A common appealing feature of both models is the virtual ground created by the input nullator. It enables us to sense the current drawn by nodes with fixed voltage—fully exploitable to design transformation circuits.

8.3.1.1 Voltage-to-Current Transformation

A straightforward technique for voltage-to-current conversion exploits the operation of the OTA as a VCCS (see Figure 8.12a) to obtain $i_0 = g_m v_i$, where g_m is the OTA transconductance parameter [22]. A drawback is that its operation is linear only over a limited range of the input voltage. Also, the scaling factor is inaccurate and strongly dependent on temperature and technology. Consequently,

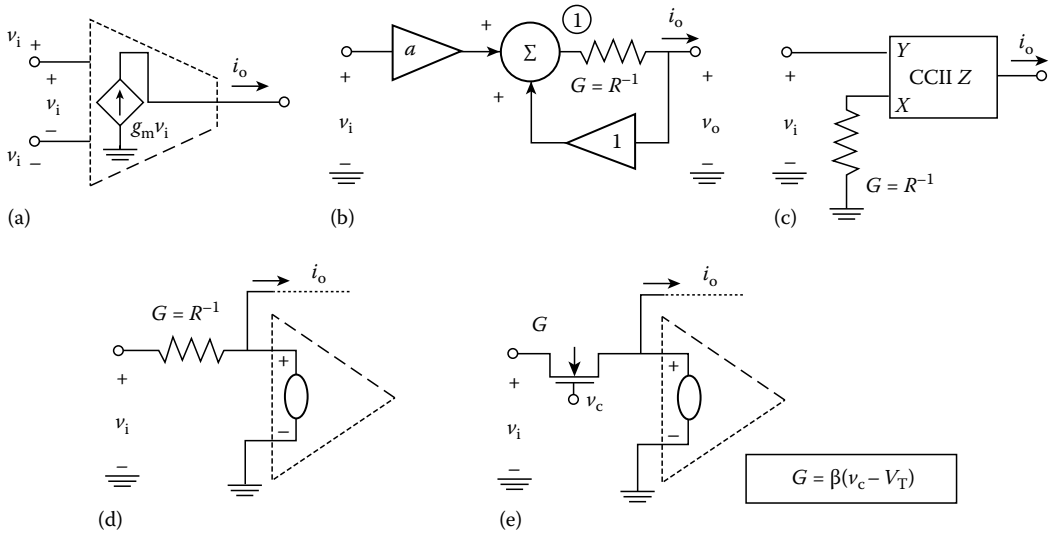

FIGURE 8.12 Voltage-to-current transformation: (a) using an OTA; (b) using voltage feedback; (c) using a current conveyor; (d) using virtual ground of an op-amp; (e) same as Figure 8.12d, but with active resistors.

* A nullator simultaneously yields a short circuit and an open circuit, while the voltage and the current at a norator are determined by the external circuitry. The use of a nullator to model the input port of an op amp is valid only if the component is embedded in a negative feedback configuration. With regard to the CCII, the required feedback is created by the internal circuitry.

voltage-to-current conversion using this approach requires circuit strategies to increase the OTA linear operation range [17,70], and tuning circuits to render the scaling parameter accurate and stable [70]. As counterparts, the value of the scaling factor is continuously adjustable through a bias voltage or current. Also, because the OTA operates in open loop, its operation speed is not restricted by feedback-induced pole displacements.

The use of feedback attenuates the linearity problem of Figure 8.12a by making the conversion rely on the constitutive equation of a passive resistor. Figure 8.12b illustrates a concept commonly found in op-amp-based voltage-mode circuits [29,59]. The idea is to make the voltage at node ① of the resistor change linearly with v_o, $v_1 = v_o + av_i$, and thus render the output current independent of v_o, to obtain $i_o = G(v_o + av_i - v_o) = aGv_i$. The summing node in Figure 8.12b is customarily realized using op-amps and resistors, which is very costly in the more general case in which the summing inputs have high impedance. The circuits of Figure 8.12c and d reduce this cost by direct exploitation of the virtual ground at the input of current conveyors (Figure 8.12c) and op-amps (Figure 8.12d). For both circuits, the virtual ground forces the input voltage v_i across the resistor. The resulting current is then sensed at the virtual ground node and routed to the output node of the conveyor, or made to circulate through the feedback circuitry of the op-amp, to obtain $i_o = Gv_i$.

Those implementations of Figure 8.12b through d that use off-the-shelf passive resistors overcome the accuracy problems of Figure 8.12a. However, the values of monolithic components are poorly controlled. Also, resistors may be problematic for standard VLSI technologies, where high-resistivity layers are not available and consequently, passive resistors occupy a large area. A common IC-oriented alternative uses the ohmic region of the MOS transistor to realize an active resistor [69] (Figure 8.12e). Tuning and linearity problems are similar to those for the OTA. Circuit strategies to overcome the latter are ground in Refs. [13,32,66,69].

8.3.1.2 Current-to-Voltage Transformation

The most straightforward strategy consists of a single resistor to draw the input current. It may be passive (Figure 8.13a) or active (Figure 8.13b). Its drawback is that the node impedance coincides with the resistor value, and thus makes difficult impedance matching to driving and loading stages. These matching problems are overcome by Figure 8.13c, which obtains low impedances at both the input and the output ports. On the other hand, Figure 8.13d obtains low impedance at only the input terminal, but maintains the output impedance equal to the resistor value. All circuits in Figure 8.13 obtain $v_o = Ri_i$, where $R = g_m^{-1}$ for the OTA.

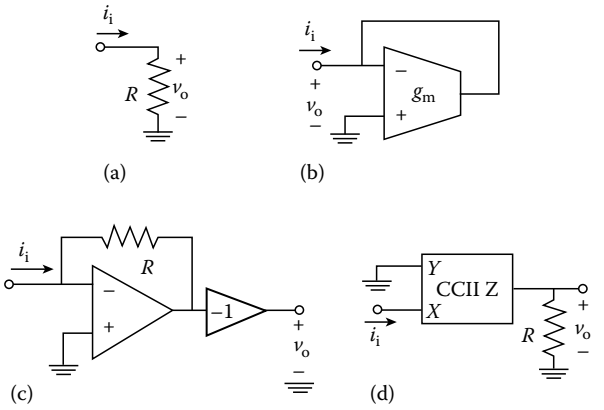

FIGURE 8.13 Current-to-voltage transformation: (a) using a resistor; (b) using a feedback OTA; (c) using op-amps; (d) using current conveyors.

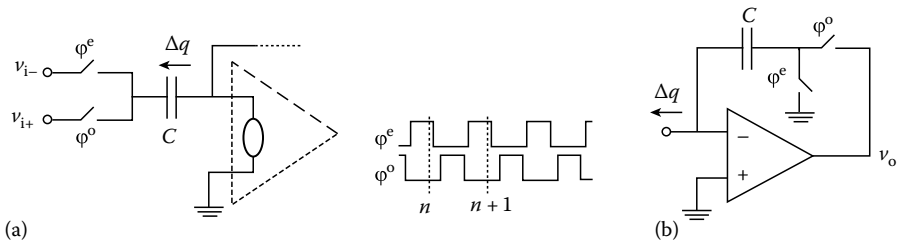

FIGURE 8.14 Transformations for sampled-data circuits: (a) voltage to charge; (b) charge to voltage.

8.3.1.3 Voltage/Charge Domain Transformations for Sampled-Data Circuits

The linearity and tuning problems of previous IC-related transformation approaches are overcome through the use of dynamic circuit design techniques based on switched-capacitors [72]. The price is that the operation is no longer asynchronous: relationships among variables are only valid for a discrete set of time instants. Variables involved are voltage and charge, instead of current, and the circuits use capacitors, switches, and op-amps.

Figure 8.14a is for voltage-to-charge transformation, while Figure 8.14b is for charge-to-voltage transformation. The switches in Figure 8.14a are controlled by nonoverlapping clock signals, so that the structure delivers the following incremental charge to the op-amp virtual ground node:

$$\Delta q^e = C(v_{i^+} - v_{i^-}) = -\Delta q^o \tag{8.26}$$

where the superscript denotes the clock phase during which the charge is delivered. Complementarily, the structure of Figure 8.14b initializes the capacitor during the even clock phase, and senses the incremental charge that circulates through the virtual ground of the op-amp during the odd clock phase. Thus, it obtains

$$v_0^o = C(\Delta q^o) \tag{8.27}$$

References [45,46,68] contain alternative circuits for the realization of the scaling function. Such circuits have superior performance in the presence of parasitics of actual monolithic op-amps and capacitors.

8.3.1.4 Transformation among Transfer Characteristics

Figure 8.15 depicts the general architecture needed to convert one kind of transfer characteristics, e.g., voltage transfer, into another, e.g., current transfer. Variables x' and y' of the original characteristics can be either voltage or current, and the same occurs for x and y of the converted characteristic. The figure depicts the more general case, which also involves a linear transformation of the characteristics themselves:

$$\begin{bmatrix} x \\ y \end{bmatrix} = \mathbf{A}\begin{bmatrix} x' \\ y' \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}\begin{bmatrix} x' \\ y' \end{bmatrix} \tag{8.28}$$

For example, Figure 8.15 encloses the matrices to rotate the characteristics by an angle θ, and to reflect the characteristics with respect to an edge with angle θ. This concept of linear transformation converters and its applications in the synthesis of nonlinear networks was proposed initially by Chua [5] for driving-point characteristics, and further extended by Glover [24] and Huertas [29].

In the simplest case, in which the nondiagonal entries in Equation 8.28 are zero, the transformation performed over the characteristics is scaling, and the circuits of Figures 8.12 and 8.13 can be used directly

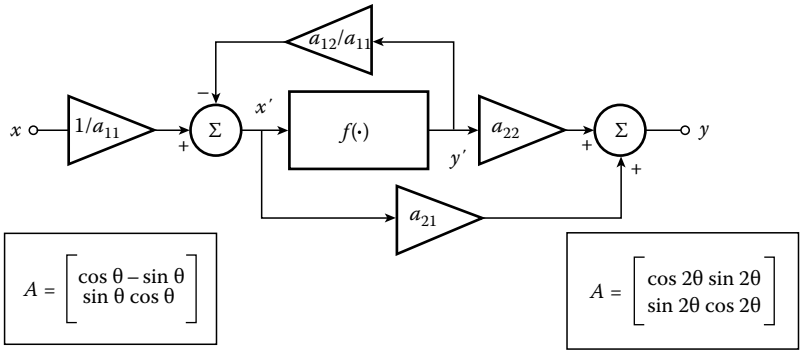

FIGURE 8.15 Concept of linear transformation converter for transfer characteristics: general architecture, and transformation matrices for rotation (left) and reflection (right).

to convert x into x' at the input front-end, and y' at the output front-end. Otherwise, aggregation operation is also required, which can be realized using the circuits described elsewhere.

8.3.1.5 From Driving Point to Transfer and Vice Versa

Figure 8.16 illustrates circuits to transform driving-point characteristics into related transfer characteristics. Figure 8.16a and b uses the same principle as Figure 8.12c and d to transform a voltage-controlled *driving-point* characteristic, $i_i = f(v_i)$, into a *transconductance* characteristics. On the other hand Figure 8.16c operates similarly to Figure 8.13c to transform a current-controlled driving-point characteristic, $v_i = f(i_i)$, into a transimpedance characteristic. If the resistance characteristics of the resistor in Figure 8.16a and b, or the conductance characteristic of the resistor in Figure 8.16c, is invertible, these circuits serve to invert nonlinear functions [63]. For instance, using a common base BJT in Figure 8.16c obtains a logarithmic function from the BJT exponential transconductance. Also, the use of a MOST operating in the ohmic region serves to realize a division operation.

Lastly, let us consider how to obtain driving-point characteristics from related transfer characteristics. Figure 8.17a and b corresponds to the common situation found in op-amp-based circuits, where the transfer is between voltages. Figure 8.17a is for the voltage-controlled case and Figure 8.17b is for the current-controlled case. They use feedback strategies similar to Figure 8.17b to render either the input voltage or the input current independent of the linear contributions of the other port variable. A general theory for this kind of transformation converter can be found in Ref. [29].

Note that these figures rely on a Thévenin representation. Similar concepts based on Norton representations allow us to transform current transfer characteristics into driving-point characteristics. However, careful design is needed to preserve the input current while sensing it.

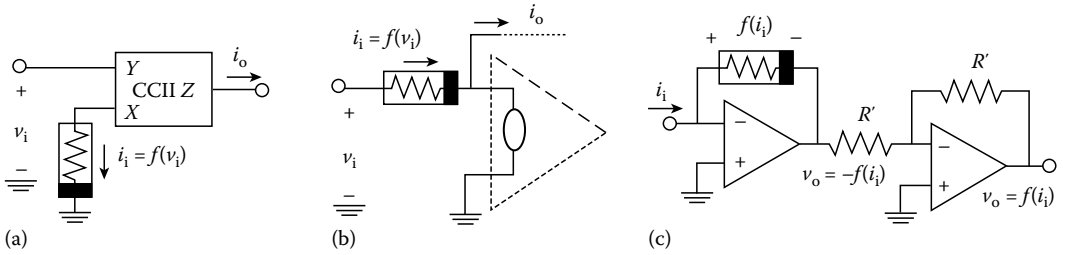

FIGURE 8.16 From driving point to transfer characteristics: (a) and (b) transconductance from voltage-controlled driving-point; (c) transimpedance from current-controlled driving-point.

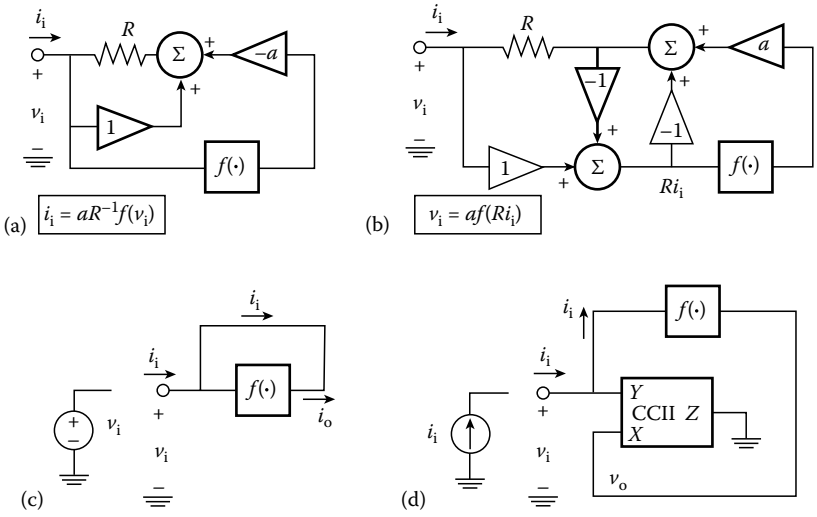

FIGURE 8.17 From transfer to driving-point characteristics. (a) Voltage-controlled case. (b) The current-controlled case. (c) A transconductor. (d) A current-controlled resistor.

Other interesting transformation circuits are depicted in Figure 8.17c and d. The block in Figure 8.17c is a transconductor that obtains $i_o = -f(v_i)$ with very large input impedance. Then, application of feedback around it obtains a voltage-controlled resistor, $i_o = f(v_i)$. Figure 8.17d obtains a current-controlled resistor, $v_i = f(i_i)$, using a current conveyor to sense the input current and feedback the output voltage of a transimpedance device with $v_o = f(i_i)$.

8.3.2 Scaling and Aggregation Circuitry

8.3.2.1 Scaling Operation

Whenever the weights are larger than unity, or are negatives, the operation of scaling requires active devices. Also, because any active device acts basically as a transconductor, the scaling of voltages is performed usually through the transformation of the input voltage into an intermediate current and the subsequent transformation of this current into the output voltage. Figure 8.18 illustrates this for an op-amp-based amplifier and an OTA-based amplifier. The input voltage is first scaled and transformed in i_o, and then this current is scaled again and transformed into the output voltage. Thus, the scaling factor depends on two design parameters. Extra control is achieved by also scaling the intermediate current.

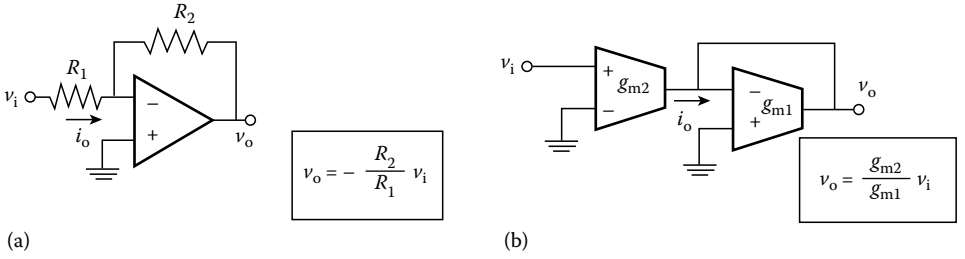

FIGURE 8.18 Mechanisms for voltage scaling. (a) An op-amp-based amplifier. (b) An OTA-based amplifier.

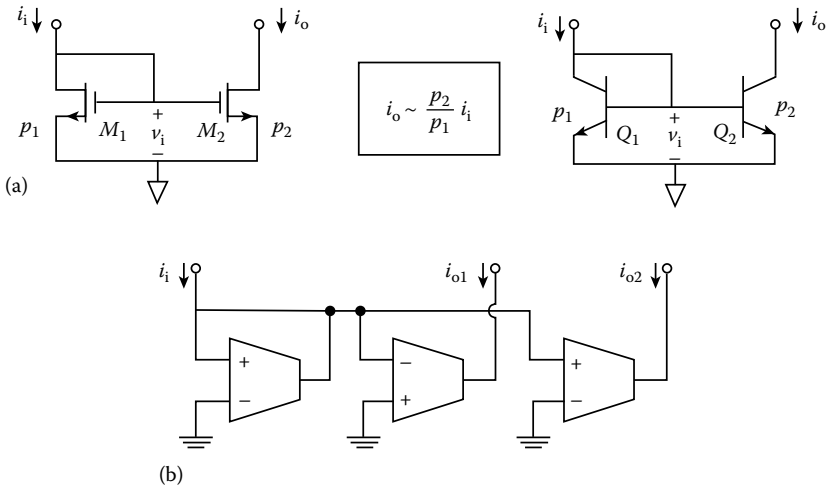

FIGURE 8.19 Current scaling using current mirrors. (a) Two matched transistors. (b) Noninverting amplification.

Let us now consider how to scale currents. The most convenient strategy uses a current mirror, whose simplest structure consists of two matched transistors connected as shown in Figure 8.19a [25]. Its operating principle relies on functional cancellation of the transistor nonlinearities to yield a linear relationship

$$i_o = p_2 f(v_i) = p_2 f\left[f^{-1}\left(\frac{i_i}{p_1}\right)\right] = \frac{p_2}{p_1} i_i \tag{8.29}$$

where p_1 and p_2 are parameters with value that can be designer controlled; for instance, β of the MOST or I_s of the BJT (see Appendix A and Ref. [44]). The input and output currents in Figure 8.19a must be positive. Driving the input and output nodes with bias currents I_B and $(p_2/p_1)I_B$, respectively, one obtains $i_i = i_i' + I_B$ and $i_o = I_o' + (p_2 + p_1)I_B$, and this enables bilateral operation on i_i' and i_o'.

In practical circuits, this simple design concept must be combined with circuit strategies to reduce errors due to nonnegligible input current of BJTs, DC voltage mismatch between input and output terminals, finite input resistance, and finite output resistance. Examples of these strategies can be found in Refs. [25,56,77]. On the other hand, sizing and layout strategies for other problems related to random mismatches between input and output devices are found in Ref. [41,48], which are applicable to most matching problems in MOS IC design.

The current mirror concept is extensible to any pair of matched transconductors, provided their transconductance characteristics are invertible and parameterized by a designer-controlled scale factor p, and that the dependence of the output current with the output voltage is negligible. In particular, the use of differential transconductors enables us to obtain bilateral operation simply, requiring no current-shifted biasing at the input and output nodes. It also simplifies achieving noninverting amplification (that is, positive scale factors), as Figure 8.19b illustrates. This figure also serves to illustrate the extension of the mirror concept to multiple current outputs. Note that except for loading considerations, no other limitations exist on the number of output transconductors that can share the input voltage. Also, because fan-out of a current source is strictly one, this replication capability is needed to enable several nodes to be excited by a common current. On the other hand, the fact that the different current output replicas can be scaled independently provides additional adjusting capability for circuit design.

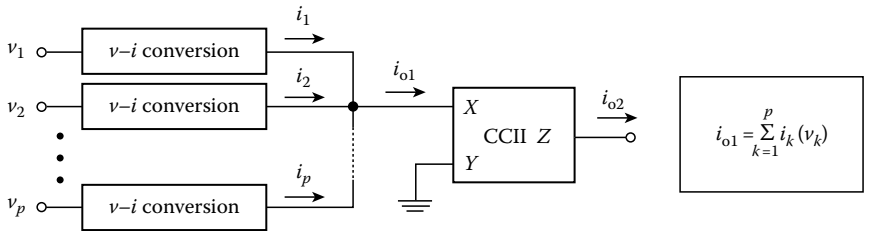

FIGURE 8.20 Aggregation of voltages through intermediate currents and current conveyor.

8.3.2.2 Signal Aggregation

As for the scaling operation, aggregation circuitry operates in current domain, based on Kirchhoff's current law (KCL). Thus, the aggregation of voltages requires that first they be transformed into currents (equivalently, charge packets in the switched-capacitor circuitry) and then added through KCL, while currents and incremental charges are added by routing all the components to a common node. If the number of components is large, the output impedance of the driving nodes is not large enough, and/or the input importance of the load is not small enough, this operation will encompass significant loading errors due to variations of the voltage at the summing node. This is overcome by clamping the voltage of this node using a virtual ground, which in practical circuits is realized by using either the input port of an op-amp, or terminals *X* and *Y* of a current conveyor. Figure 8.20 illustrates the current conveyor case.

8.4 Piecewise-Linear Circuitry

Consider the elementary PWL function that arise in connection with the different methods of representation covered in Section 8.2:

- Two-piece concave and convex characteristics (see Equation 8.12)
- Hermite linear basis function (see Figure 8.4 and Appendix B)
- Absolute value (see Equation 8.13)

where rectification is the only nonlinear operator involved. The circuit primitives in Appendix A exhibit several mechanisms which are exploitable in order to realize rectification:

- Cutoff of diodes and transistors—specifically, current through a diode negligible for negative voltage, output current of BJTs, and MOSTs negligible under proper biasing
- Very large resistance and zero offset voltage of an analog switch for negative biasing of the control terminal
- Digital encoding of the sign of a differential voltage signal using a comparator

Similar to scaling and aggregation operations, rectification is performed in current domain, using the mechanisms listed previously to make the current through a branch negligible under certain conditions. Three techniques are presented, which use current transfer in a transistor-based circuit, current-to-voltage transfer using diodes and op-amp, and charge transfer using switches and comparators, respectively.

8.4.1 Current Transfer Piecewise-Linear Circuitry

Figure 8.21a and b presents the simplest technique to rectify the current transferred from node ① to node ②. They exploit the feature of diodes and diode-connected transistors to support only positive

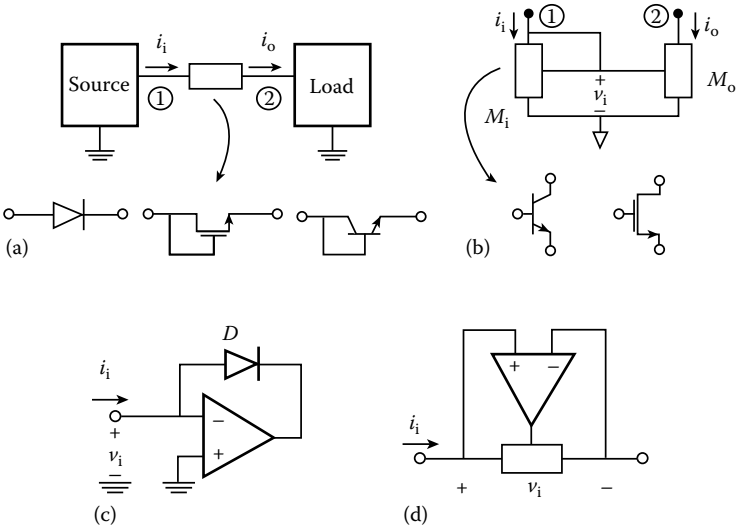

FIGURE 8.21 (a) and (b) Circuit techniques for current rectification; (c) and (d) superdiodes.

currents. Figure 8.21a operates by precluding negative currents to circulate from node ① to node ②, while Figure 8.21b also involves the nonlinear transconductance of the output transistor M_o; negative currents driving the node ① force v_i to become smaller than the cut-in voltage and, consequently, the output current becomes negligible. A drawback to both circuits is that they do not provide a path for negative input currents, which accumulates spurious charge at the input node and forces the driving stage to operate outside its linear operating regime. Solutions to these problems can be found in Refs. [57,61]. Also, Figure 8.21a produces a voltage displacement equal to the cut-in voltage of the rectifying device, which may be problematic for applications in which the voltage at node ① bears information. A common strategy to reduce the voltage displacements uses feedback to create superdiodes (shown in Figure 8.21c for the grounded case and Figure 8.21d for the floating case), and where the reduction of the voltage displacement is proportional to the DC gain of the amplifier.

Figure 8.22a, called a current switch, provides paths for positive and negative currents entering node ①, and obtains both kinds of elementary PWL characteristics exploiting cutoff of either BJTs or MOSTs. It consists of two complementary devices: *npn* (top) and *pnp* BJTs, or *n*-channel (top) and *p*-channel MOSTs. Its operation is very simple: any positive input current increases the input voltage, turning the bottom device ON. Because both devices share the input voltage, the top device becomes OFF. Similarly, the input voltage decreases for negative input currents, so that the top device becomes ON and the bottom OFF. In sum, positive input currents are drawn to the bottom device, while negative currents are drawn to the top device.

An inconvenience of Figure 8.22a is the dead zone exhibited by its input driving-point characteristics, which is very wide for MOSTs. It may produce errors due to nonlinear loading of the circuitry that drives the input node. Figure 8.22b overcomes this by using a circuit strategy similar to that of the superdiodes. The virtual ground at the op-amp input renders the dead zone centered around the voltage level E, and its amplitude is reduced by a factor proportional to the amplifier DC gain. Some considerations related to the realization of this amplifier are found in Ref. [58].

Proper routing and scaling of the currents i_p and i_n in Figure 8.22a gives us the concave and convex basic characteristics with full control of the knot and position and the slope in the conducting region. Figure 8.22c is the associated circuit, in which the input bias current controls the knot position, and the slope in the conducting region is given by the gain of the current mirrors. Note that this circuit also obtains the absolute value characteristics, while Figure 8.22d obtains the Hermite linear basis function.

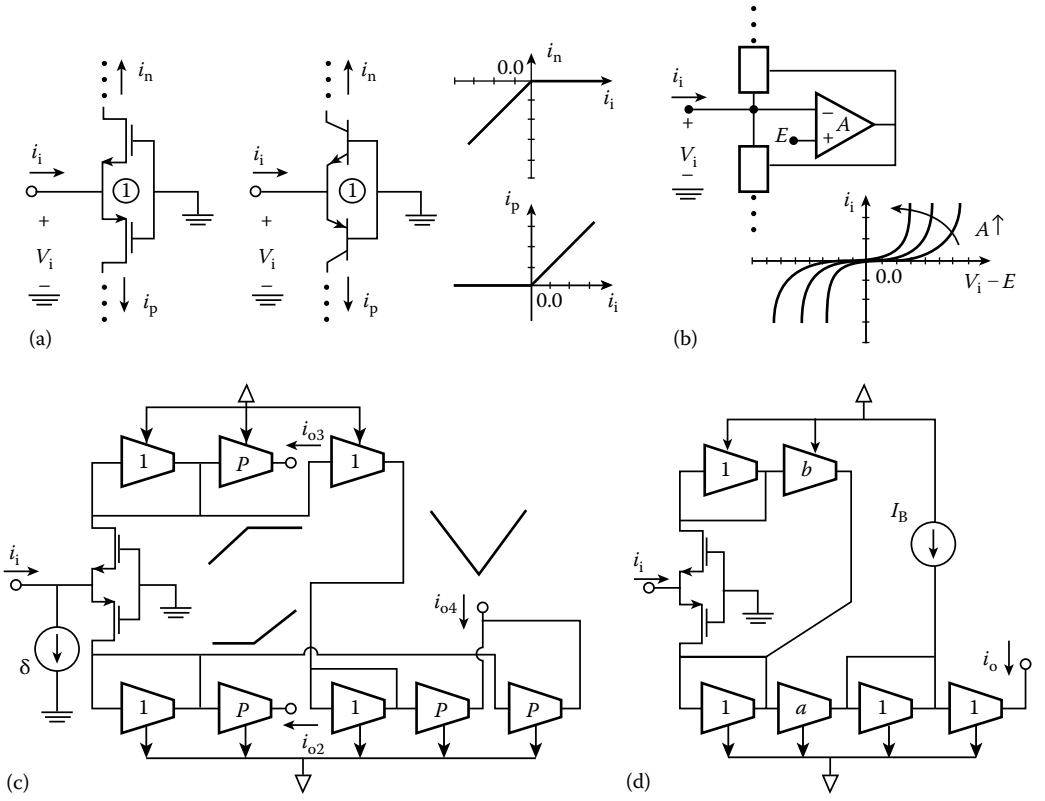

FIGURE 8.22 Current switch and its application for different basic PWL curves. (a) Dead zone exhibited by its input driving-point characteristics. (b) A circuit strategy similar to that of the superdiodes. (c) The associated circuit of (a). (d) A Hermite linear basis function circuit.

The way to obtain the PWL fuzzy membership function from this latter circuit is straightforward, and can be found in Ref. [58].

8.4.2 Transresistance Piecewise-Linear Circuitry

The circuit strategies involved in PWL current transfer can be combined in different ways with the transformation circuits discussed previously to obtain transconductance and voltage-transfer PWL circuits. In many cases design ingenuity enables optimum merging of the components and consequently, simpler circuits. Figure 8.23a depicts what constitutes the most extended strategy to realize the elementary PWL functions using off-the-shelf components [63,80]. The input current is split by the feedback circuitry around the op-amp to make negative currents circulate across D_n and positive currents circulate across D_p. Consequently, this feedback renders the input node of the op-amp a virtual ground and thus reduces errors due to finite diode cut-in voltage in the transresistance characteristics. Similar to Figure 8.22, the position of the knot in these elementary characteristics is directly controlled by an input bias current. Also note that the virtual ground can be exploited to achieve voltage-to-current transformation using the strategy of Figure 8.12d and thus, voltage-transfer operation.

Algebraic combination of the elementary curves provided by Figure 8.23a requires transforming the voltages v_{on} and v_{op} into currents and then aggregating these currents by KCL. For example, Figure 8.23b is the circuit for the absolute value and Figure 8.23c presents a possible implementation of the Hermite basis function.

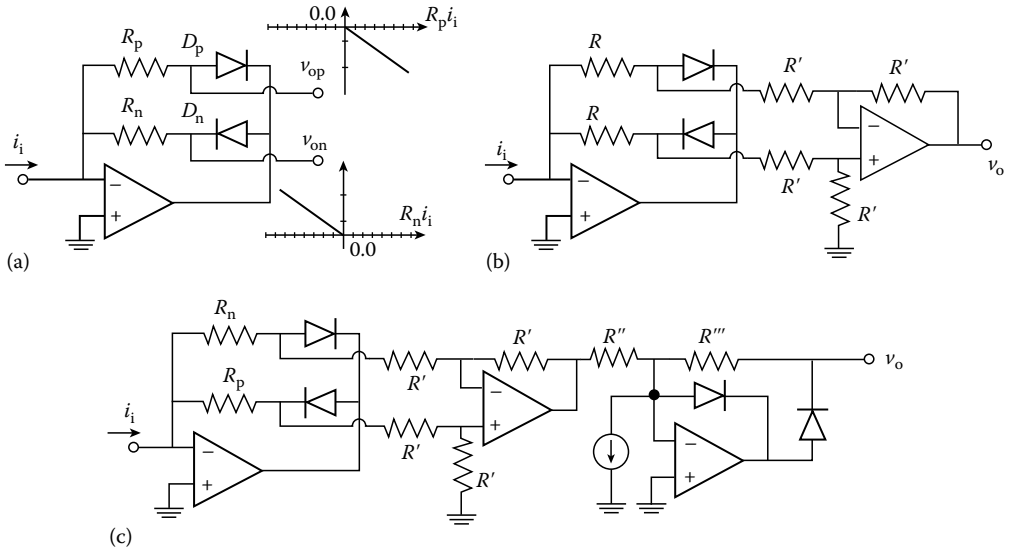

FIGURE 8.23 PWL transimpedance circuits. (a) Circuit for algebraic combination of the elementary curves. (b) Circuit for the absolute value. (c) Circuit for a possible implementation of the Hermite basis function.

Other related contributions found in the literature focus on the systematic realization of PWL driving-point resistors, and can be found in Refs. [7,10].

8.4.3 Piecewise-Linear Shaping of Voltage-to-Charge Transfer Characteristics

The realization of PWL relationships among sampled-data signals is based on nonlinear voltage-to-charge transfer and uses analog switches and comparators. Figure 8.24a is a circuit structure, where one of the capacitor terminals is connected to virtual ground and the other to a switching block. Assume that nodes ① and ② are both grounded. Note that for $(v-\delta)>0$ the switch arrangement set node ④ to δ, while node ⑤ is set to v. For $(v-\delta)<0$, nodes ④ and ⑤ are both grounded. Consequently, voltage at node ③ in this latter situation does not change from one clock phase to the next, and consequently, the incremental charge becomes null for $(v-\delta)<0$. On the other hand, for $(v-\delta)>0$, the voltage at node ③ changes from one clock phase to the next, and generates an incremental charge

$$\Delta q^{e} = C(v-\delta) = -\Delta q^{o} \tag{8.30}$$

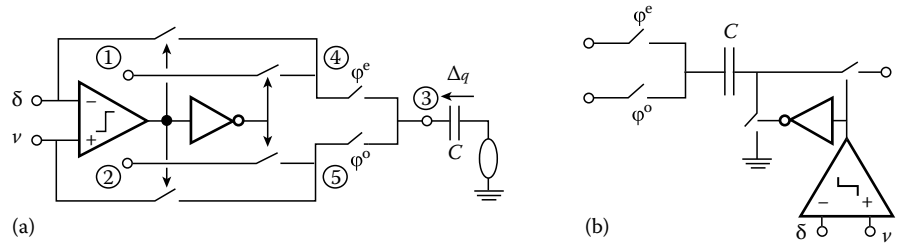

FIGURE 8.24 Circuits for rectification in voltage-to-charge domain. (a) Circuit structure where one of the capacitor terminals is connected to virtual ground and the other to a switching block. (b) Circuitry using series rectification of the circulating charge through a comparator-controlled switch.

which enables us to obtain negative and positive slopes using the same circuit, as shown in Figure 8.24a. To make the characteristics null for $(v - \delta) > 0$, it suffices to interchange the comparator inputs. Also, the technique is easily extended to the absolute value operation by connecting terminal ① to v, and terminal ② to δ. The realization of the Hermite linear basis function is straightforward and can be found in Ref. [55].

Other approaches to the realization of PWL switched-capacitor circuitry use series rectification of the circulating charge through a comparator-controlled switch (Figure 8.24b), and can be found in Refs. [16,31]. The latter also discusses exploitation of these switched-capacitor circuits to realize continuous-time driving-point characteristics, the associated transformation circuits, and the dynamic problematics.

8.5 Polynomials, Rational, and Piecewise-Polynomial Functions

These functions use rectification (required for truncation operation in the PWP case) and analog *multiplication*,

$$z = \frac{xy}{\alpha} \tag{8.31}$$

as basic nonlinear operators.* Joining the two inputs of the multiplier realizes the square function. Analog division is realized by applying feedback around a multiplier, illustrated at the conceptual level in Figure 8.25a; the multiplier obtains $e = (zy)/\alpha$, and for $A \to \infty$, the feedback forces $x = e$. Thus, if $y \neq 0$, the circuit obtains $z = \alpha(x/y)$. Joining y and z terminals, the circuit realizes the square root, $z = (\alpha x)^{1/2}$. This concept of division is applicable regardless of the physical nature of the variables involved. In the special case in which e and x are current and z is a voltage, the division can be accomplished using KCL to yield $x = e$. Figure 8.25b shows a circuit for the case in which the multiplication is in voltage domain, and Figure 8.25c is for the case in which multiplication is performed in transconductance domain. The transconductance gain for input z in the latter case must be negative to guarantee stability.

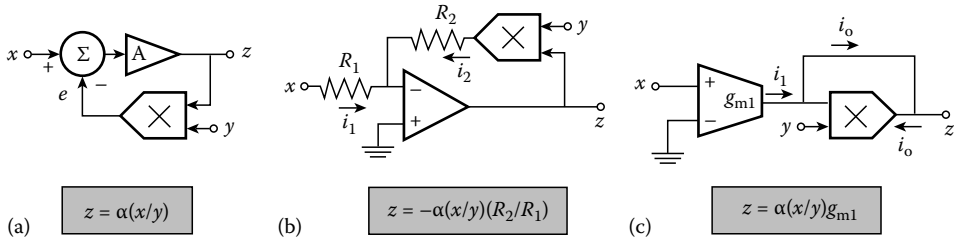

FIGURE 8.25 Division operator using a feedback multiplier: (a) concept; (b) with voltage multiplier and op-amp; (c) with transconductance multiplier and OTA.

* Scale factor α in Equation 1.31 must be chosen to guarantee linear operation in the full variation range of inputs and outputs.

8.5.1 Concepts and Techniques for Polynomic and Rational Functions

Figure 8.26 illustrates conceptual hardware for several polynomials up to the fifth degree. Any larger degree is realized similarly. Figure 8.27 uses polynomials and analog division to realize rational functions

$$g(x) = \frac{\sum\limits_{i=0,Q} \alpha_j x^j}{\sum\limits_{j=0,R} \beta_j x^j} \tag{8.32}$$

For simplicity, we have assumed that the internal scaling factors of the multipliers in Figures 8.26 and 8.27 equal one.

An alternative technique to realize rational functions is based on linearly controlled resistors, described as $v = (Lx)i$, and linearly controlled conductors, $i = (Cx)v$, where L and C are real parameters. This technique exploits the similarity between these characteristics and those which describe inductors and capacitors in the frequency domain, to take advantage of the synthesis techniques for rational transfer function in the s-plane through interconnection of these linear components [28,39] (Figure 8.28). As for the previous cases, realization of linearly controlled resistors and conductors require only multipliers and,

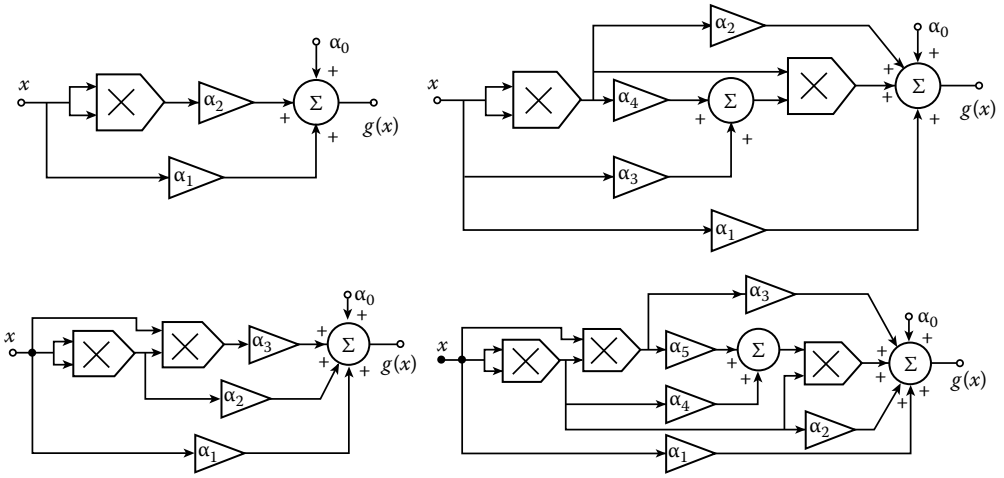

FIGURE 8.26 Conceptual hardware for polynomial functions.

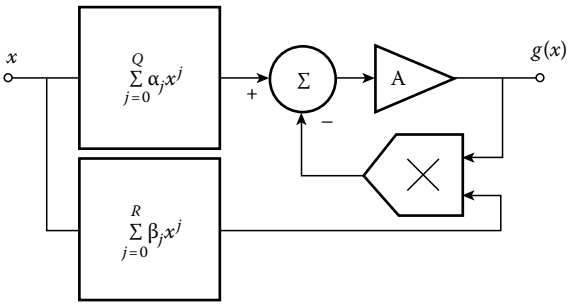

FIGURE 8.27 Rational function generation through feedback division.

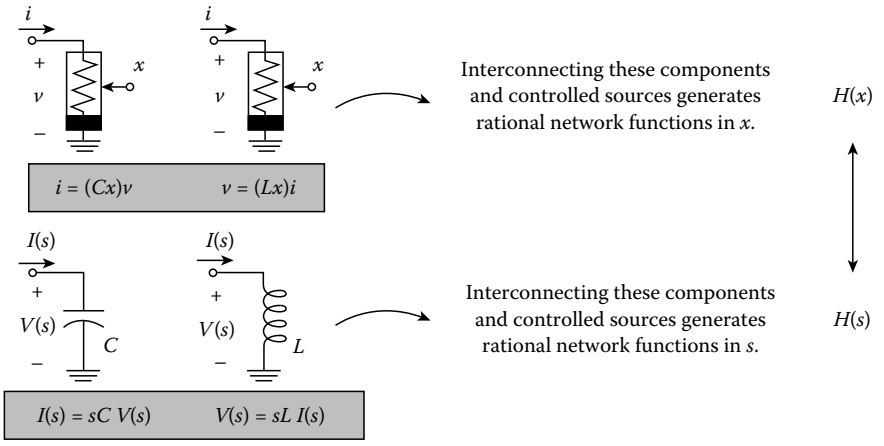

FIGURE 8.28 Usage of linearly controlled resistors to synthesize rational network functions.

depending upon the nature of the variables involved in the multipliers, voltage-to-current and current-to-voltage transformation circuits.

8.5.2 Multiplication Circuitry

Two basic strategies realize multiplication circuitry: using signal processing and exploiting some nonlinear mechanism of the primitive components. Signal processing multipliers rely on the generation of a pulsed signal whose amplitude is determined by one of the multiplicands and its duty cycle by the other, so that the area is proportional to the result of the multiplication operation. Figure 8.29a presents an implementation concept based on averaging. This is performed by a low-pass filter where the input is a pulse train with amplitude proportional to x and duty cycle proportional to y. The latter proportionality is achieved through nonlinear sampling by comparing y with a time reference sawtooth signal. Thus, the

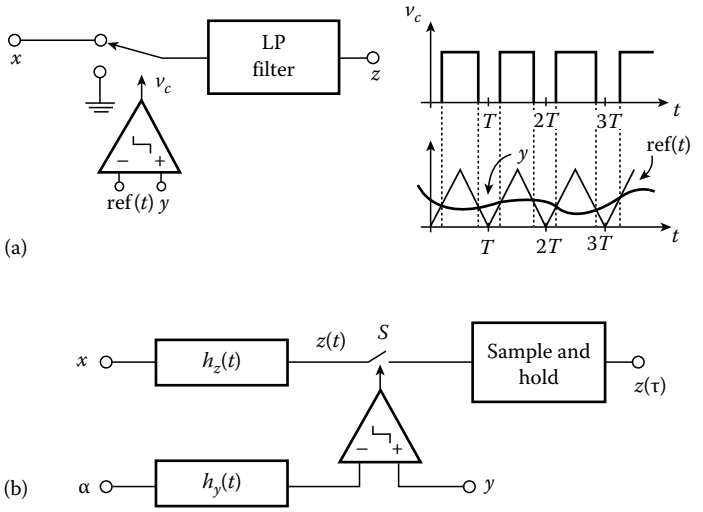

FIGURE 8.29 Signal processing multipliers by (a) averaging; (b) shaping in time domain.

area under each pulse in the train is the product of $x \times y$, extracted by the low-pass filter. This implementation concept is discussed in further detail in classical texts on analog computation [63], and applied more recently to analog VLSI signal processing [72].

Figure 8.29b is an alternative implementation concept based on signal shaping in the time domain. It uses two linear blocks with normalized unit step response given as $h_z(t)$ and $h_y(t)$. The first is driven by level x to obtain

$$z(t) = xh_z(t), \quad 0 \leq t < \tau \tag{8.33}$$

where τ denotes the duration of the time interval during which the switch S remains closed. The other is driven by a references level α, to render τ given by

$$\tau = h_y^{-1}\left(\frac{y}{\alpha}\right) \tag{8.34}$$

Assuming both linear blocks are identical and the time function invertible, one obtains the steady-state value of z, $z(\tau)$, as the product of levels x and y.

The simplest implementation of Figure 8.29 uses integrators, i.e., $h(t) = t$, as linear blocks (see Figure 8.41b). Also note that the principle can be extended to the generation of powers of an input signal by higher-order shaping in time domain. In this case, both linear blocks are driven by reference levels. The block $h_y(t)$ consists of a single integrator, $\tau = y/\alpha$. The other consists of the cascade of P integrators, and obtains $z(t) = \beta t^p$. Thus, $z(t) = \beta(y/\alpha)^p$. Realizations suitable for integrated circuits are found in Refs. [34,55].

8.5.3 Multipliers Based on Nonlinear Devices

The primitives in Appendix A display several mechanisms that are exploitable to realize analog multipliers:

- Exponential functionals associated to the large-signal transconductance of BJTS, and the possibility of obtaining logarithmic dependencies using feedback inversion
- Square-law functionals associated to the large-signal transconductance of the MOS transistor operating in saturation region
- Small-signal transconductance of a BJT in active region as a linear function of collector current
- Small-signal transconductance of a MOST in saturation as a linear function of gate voltage
- Small-signal self-conductance of a MOS transistor in ohmic region as a linear function of gate voltage

These and related mechanisms have been explained in different ways and have resulted in a huge catalog of practical circuits. To quote all the related published material is beyond the scope of this section. The references listed at the end were selected because of their significance, and their cross-references contain a complete view of the state of the art. Also, many of the reported structures can be grouped according to the theory of *translinear circuits*, which provides a unified framework to realize nonlinear algebraic functions through circuits [23,62,79].

8.5.3.1 Log–Antilog Multipliers

Based on the exponential large-signal transconductance of the BJT, and the following relationships,

$$\begin{aligned} z' &= \ln(x) + \ln(y) = \ln(xy) \\ z &= e^{z'} = e^{\ln(xy)} = xy \end{aligned} \tag{8.35}$$

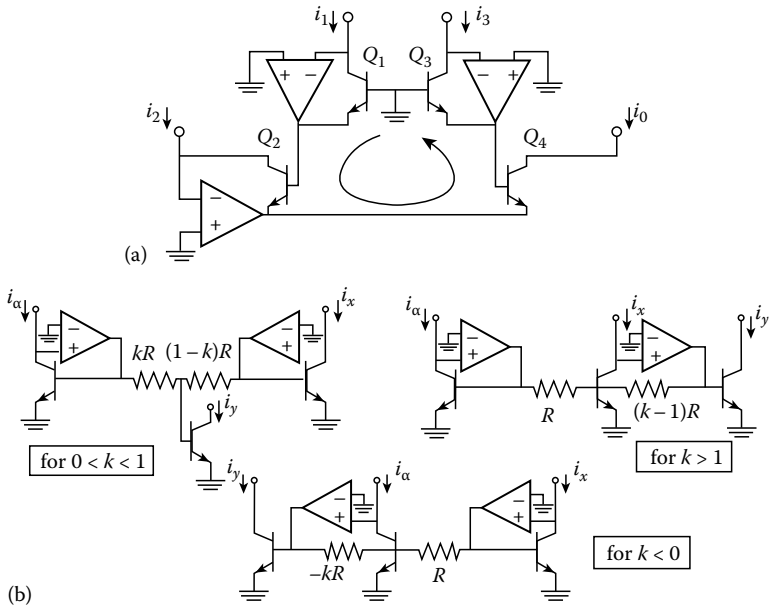

FIGURE 8.30 (a) Core block of a log–antilog multiplier; (b) circuits to elevate to a power.

which can be realized as illustrated in Figure 8.30a [65]. This circuit operates on positive terminal currents to obtain $i_0 = (i_1 i_2)/i_3$, which can be understood from translinear circuit principles by noting that the four base-to-emitter voltages define a translinear loop,

$$\begin{aligned} 0 &= v_{be1} + v_{be2} - v_{be3} - v_{be4} \\ &= \ln\left(\frac{i_1}{I_s}\right) + \ln\left(\frac{i_2}{I_s}\right) - \ln\left(\frac{i_3}{I_s}\right) - \ln\left(\frac{i_o}{I_s}\right) \end{aligned} \tag{8.36}$$

The circuit can be made to operate in four-quadrant mode, though restricted to currents larger than $-I_B$, by driving each terminal with a bias current source of value I_B. Also, because all input terminals are virtual ground the circuit can be made to operate on voltages by using the voltage-to-current transformation concept of Figure 8.12d. Similarly, the output current can be transformed into a voltage by using an extra op-amp and the current-to-voltage transformation concept of Figure 8.13c. Extension of this circuit structure to generate arbitrary powers is discussed in Ref. [23]. Figure 8.30b [1] uses similar techniques, based on introducing scaling factors in the translinear loop, to obtain

$$i_y = i_\alpha^{1-k} i_x^k \tag{8.37}$$

8.5.3.2 Square-Law Multipliers

Square-law multipliers are based on the algebraic properties of the square function, most typically

$$z = \frac{1}{4}\left[(x+y)^2 - (x-y)^2\right] = xy \tag{8.38}$$

shown conceptually in Figure 8.31a, and the possibility of obtaining the square of a signal using circuits, typically consisting of a few MOS transistors operating in saturation region. Figure 8.31b through f depict some squarer circuits reported in the literature.

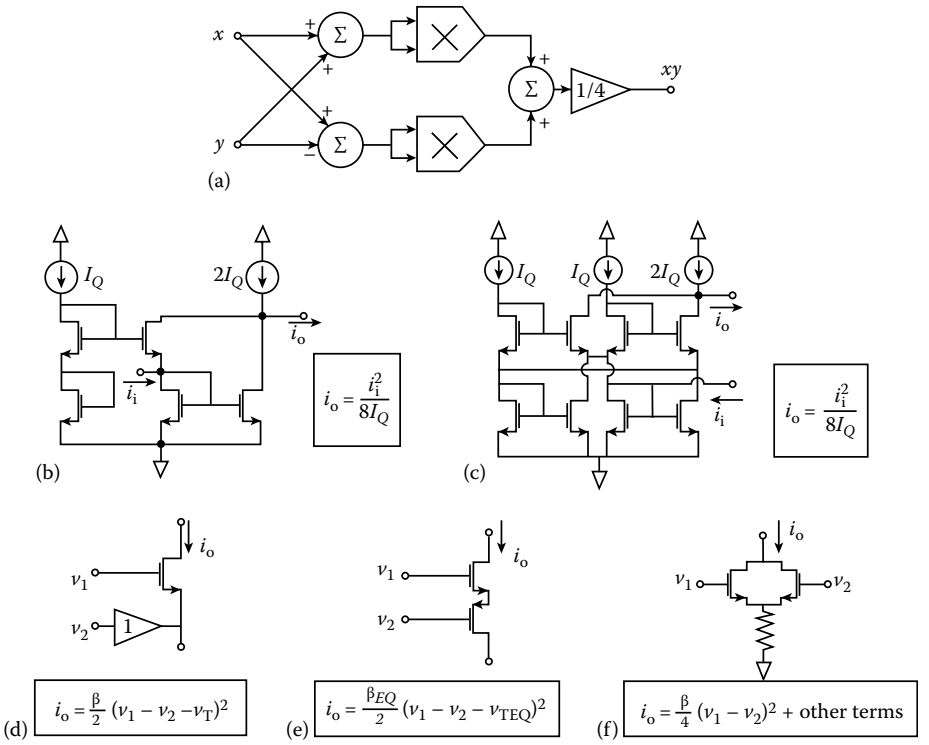

FIGURE 8.31 (a) Block diagram of the quarter-square multiplier; (b) current-mode squarer circuit in Ref. [3]; (c) current-mode squarer circuit in Ref. [79]; (d) voltage-mode squarer circuit in Ref. [36]; (e) voltage-mode squarer circuit in Ref. [60]; (f) voltage-mode squarer circuit in Ref. [49].

The completeness of square-law operators for the realization of nonlinear circuits was demonstrated from a more general point of view in Ref. [47], and their exploitation has evolved into systematic circuit design methodologies to perform both linear and nonlinear functions [3].

8.5.3.3 Transconductance Multipliers

A direct, straightforward technique to realize the multiplication function exploits the possibility of controlling the transconductance of transistors through an electrical variable (current or voltage). Although this feature is exhibited also by unilateral amplifiers, most practical realizations use differential amplifiers to reduce offset problems and enhance linearity [25]. Figure 8.32 presents a generic schematic for a differential amplifier, consisting of two identical three-terminal active devices with common bias current. The expressions on the right display its associated transconductance characteristics for *npn*-BJTs and *n*-channel MOSTs, respectively [25]. These characteristics are approximated to a first-order model as

$$i_{z\mathrm{BJT}} \approx \frac{i_y}{4U_t} v_x, \quad i_{z\mathrm{MOST}} \approx \left(\sqrt{\beta i_y}\right) v_x \tag{8.39}$$

which clearly displays the multiplication operation, although restricted to a rather small linearity range. Practical circuits based on this idea focus mainly on increasing this range of linearity, and follow different design strategies. Figure 8.33 gives an example known as the Gilbert cell or Gilbert multiplier [23]. Corresponding realizations using MOS transistors are discussed in Refs. [2,53]. Sánchez-Sinencio et al. [61] present circuits to realize this multiplication function using OTA blocks. On the other

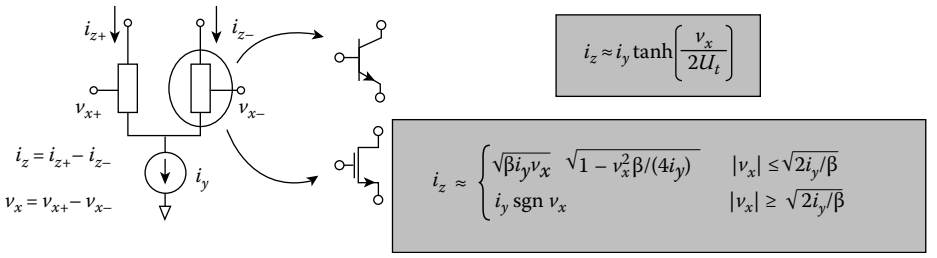

FIGURE 8.32 Differential amplifiers and their associated large-signal transconductances.

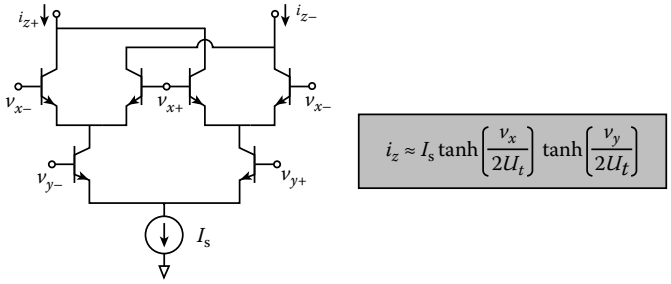

FIGURE 8.33 Bipolar Gilbert cell.

hand, Ref. [17] presents a tutorial discussion of different linearization techniques for MOS differential amplifiers.

8.5.3.4 Multiple Based in the Ohmic Region of MOS Transistors

The ohmic region of JFETs has been used to realize amplifiers with controllable gain for automatic gain control [54]. It is based on controlling the equivalent resistance of the JFET transistor in its ohmic region through a bias voltage. More recently, MOS transistors operating in the ohmic region were used to realize linear [69,70] and nonlinear [35] signal processing tasks in VLSI chips. There exist many ingenious circuits to eliminate second and higher-order nonlinearities in the equivalent resistance characteristics.

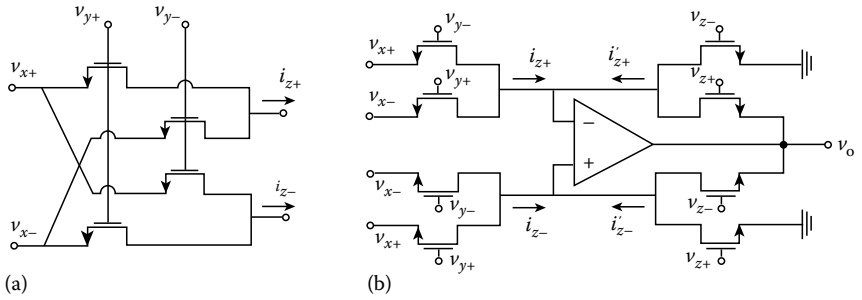

FIGURE 8.34 Four-quadrant multipliers based on MOS transistors in the ohmic region. (a) Circuit achieving very good nonlinear cancellation through cross-coupling and fully differential operation. (b) A more general view showing the conductance as well as the resistance of the MOS ohmic region used to obtain a versatile amplifier-divider building block.

The circuit in Figure 8.34a achieves very good nonlinearity cancellation through cross-coupling and fully differential operation, obtaining

$$i_{z+} - i_{z-} = 2\beta(v_{x+} - v_{x-})(v_{y+} - v_{y-}) \tag{8.40}$$

and its use in multiplication circuits is discussed in Refs. [35,66]. A more general view is presented in Figure 8.34b [35], where the conductance as well as the resistance of the MOS ohmic region are used to obtain a versatile amplifier-divider building block. Enomoto and Yasumoto [18] report another interesting multiplier that combines the ohmic region of the MOS transistor and sampled-data circuits.

8.6 Sigmoids, Bells, and Collective Computation Circuits

8.6.1 Sigmoidal Characteristics

As Equation 8.5 illustrates, approximating a nonlinear function through a multilayer perceptron requires the realization of sigmoidal functions, with arguments given as linear combinations of several variables. The exact shape of the sigmodial is not critical for the approximation itself, although it may play an important role in fitting [82]. Figure 8.35 depicts two shapes used in practice. Figure 8.35a, the hard limiter, has an inner piece of large (ideally infinite) slope, while for Figure 8.35b, the soft limiter, this slope is smaller and can be used as a fitting parameter.

Most amplifiers have large-signal transfer characteristics whose shape is a sigmoid or an inverted sigmoid. We present only those circuits whose inputs are currents because this simplifies the circuitry needed to obtain these inputs as linear combinations of other variables. The op-amp circuit of Figure 8.36a realizes the soft limiter characteristics in transimpedance form. The center is set by the input bias current and the slope through the resistor ($\beta = R$). If the branch composed of the two Zener diodes is eliminated, the saturation levels E_+ and E_- are determined through the internal op-amp circuitry, inappropriate for accurate control. (Otherwise, they are determined through the Zener breakdown voltages.) On the other hand, Figure 8.36b also realizes the hard sigmoid in transimpedance domain [58]. The output saturation levels for this structure are $E_+ = V_{Tn}$ and $E_- = |V_{Tp}|$, where V_{Tn} and V_{Tp} are the threshold voltages of the NMOS transistor and the PMOS transistor, respectively. To obtain the output represented by a current, one can use voltage-to-current transformation circuits. References [15,57,58] discuss simpler alternatives operating directly in current domain. For instance, Figure 8.36c and d depicts circuits for the soft limiter characteristics and the hard limiter characteristics.

With regard to the calculation of the input to the sigmoid as a linear combination of variables, note that the input node of all circuits in Figure 8.36 is virtual ground. Consequently, the input current can be obtained as a linear combination of voltages or currents using the techniques for signal scaling and aggregation presented in Section 8.3.

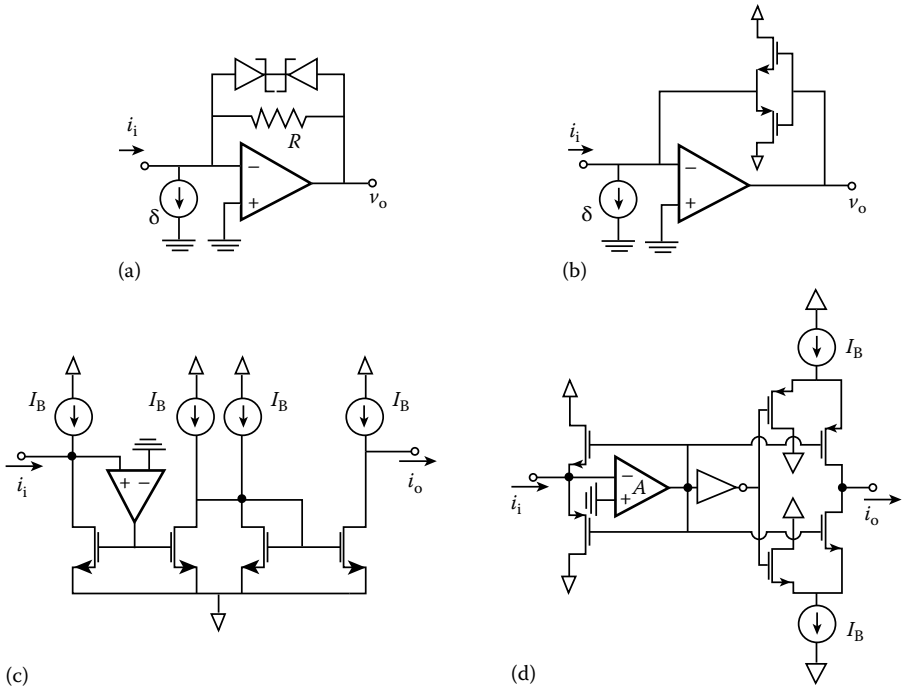

FIGURE 8.36 Realization of sigmoidal characteristics with input current: (a) transimpedance soft limiter; (b) transimpedance hard limiter; (c) and (d) soft and hard limiters in current transfer domain.

8.6.2 Bell-Like Shapes

The exact shapes of Equations 8.16 and 8.17 involve the interconnection of squarers, together with blocks to elevate to power, and exponential blocks—all realizable using techniques previously discussed in this chapter. However, these exact shapes are not required in many applications, and can be approximated using simpler circuits. Thus, let us consider the differential amplifier of Figure 8.32, and define $v_i = v_x$, $I_B = i_y$, and $i_o = i_z$ for convenience. The expressions for the large-signal transconductance displayed along with the figures show that they are sigmoids with saturation levels at I_B and $-I_B$. They are centered at $v_i = 0$, with the slope at this center point given by Equation 8.39. The center can be shifted by making $v_i = v_{x+}$ and $\delta = v_{x-}$.

Similar to the differential amplifier, most OTAs exhibit sigmoid-like characteristics under large-signal operation, exploitable to realize nonlinear functions [19,37,56,61,71]. This may rely on the mathematical techniques behind multilayer perceptrons, or on those behind RBF and fuzzy interpolation.

Figure 8.37a obtains a bell-shaped transconductance through a linear, KCL combination of the two sigmoidal characteristics, one of negative slope and the other of positive slope. The width and center of the bell (see Figure 8.7) are given respectively by

$$2\sigma = \delta_2 - \delta_1, \quad \delta = \frac{\delta_2 + \delta_1}{2} \tag{8.41}$$

controlled by the designer. The slope of the bell at the cross-over points is also controlled through the transconductance of the OTAs.

For simpler circuit realizations, this technique can be used directly with differential amplifiers, as shown in Figure 8.37b. The differential output current provided by the circuit can be transformed into a

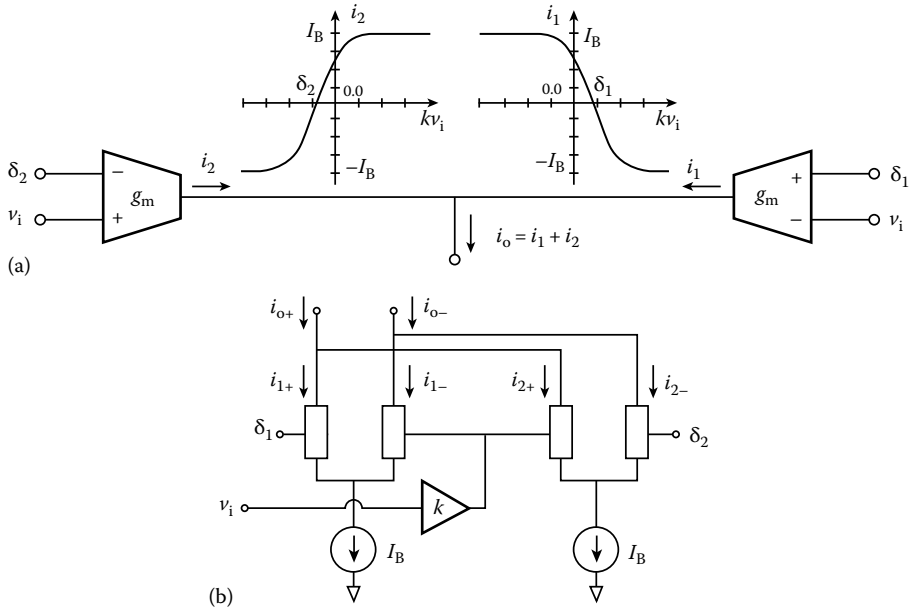

FIGURE 8.37 Transconductance circuits for bell-shaped function: (a) using OTAs; (b) using differential amplifiers.

unilateral one using a *p*-channel current mirror. Equation 8.41 also applies for this circuit, and the slope at the cross-overs is

$$\text{slope}_{\text{MOST}} = k\sqrt{\beta I_B}, \quad \text{slope}_{\text{BJT}} = \frac{kI_B}{4U_t} \tag{8.42}$$

Note that the control of this slope through the bias current changes the height of the bell. It motivates the use of a voltage gain block in Figure 8.37. Thus, the slope can be changed through its gain parameter k. The slope can also be changed through β for the MOSTs. Practical realizations of this concept are found in Refs. [4,71,74]. The voltage amplifier block can be realized using the techniques presented in this chapter. Simpler circuits based on MOS transistors are found in Ref. [53].

8.6.3 Collective Computation Circuitry

RBF and fuzzy inference require multidimensional operators to calculate radial distances in the case of RBF, and to normalize vectors and calculate T-norms in the case of fuzzy inference. These operators can be expressed as the interconnection of the nonlinear blocks discussed previously, or realized in a simpler manner through dedicated collective computation circuitry. Most of these circuits operate intrinsically in current domain and are worth mentioning because of this simplicity and relevance for parallel information processing systems.

8.6.3.1 Euclidean Distance

Figure 8.38 [38] presents a current-mode circuit to compute

$$i_y = \sqrt{\sum_{k=1,P} i_{xk}^2} \tag{8.43}$$

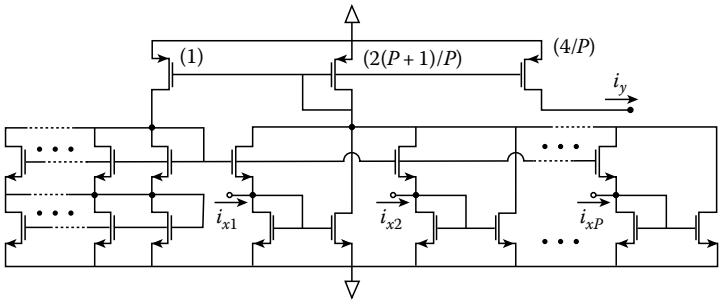

FIGURE 8.38 CMOS self-biased Euclidean distance circuit. (From Landolt, O., Vittoz, E., and Heim, P., *Electr. Lett.*, 28, 352, 1992. With permission.)

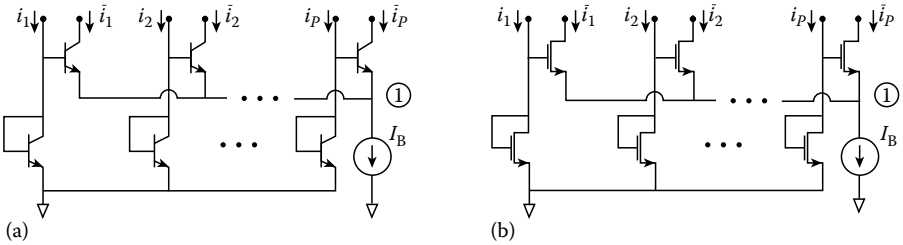

FIGURE 8.39 Current-mode normalization circuits: (a) BJT; (b) CMOS.

based on the square-law of MOS transistors in the saturation region. If the current i_k at each terminal is shifted through a bias current of value δ_k, the circuit serves to compute the Euclidean distance between the vector of input currents and the vector $\boldsymbol{\delta}$.

8.6.3.2 Normalization Operation

Figure 8.39 depicts circuits to normalize an input current vector, for the BJT [23] and the CMOS [74] cases, respectively. Their operation is based on KCL and the current mirror principle. Kirchhoff's circuit law forces the sum of the output currents at node ① to be constant. On the other hand, the current mirror operation forces a functional dependency between each pair of input and output currents. Thus, they obtain

$$\bar{i_k} \approx \frac{i_k}{\sum\limits_{j=1,P} i_j} \tag{8.44}$$

for each current component.

8.6.3.3 T-Norm Operator

The calculation of the minimum of an input vector $\mathbf{x}$ is functionally equivalent to obtaining the complement of the maximum of the complements of its components. Figure 8.40a illustrates a classical approach used in analog computation to calculate the maximum of an input vector $\mathbf{x}$. It is based on the following steady-state equation:

$$-y + \sum_{k=1,P} u_{-1}(A(x_k - y)) = 0 \tag{8.45}$$

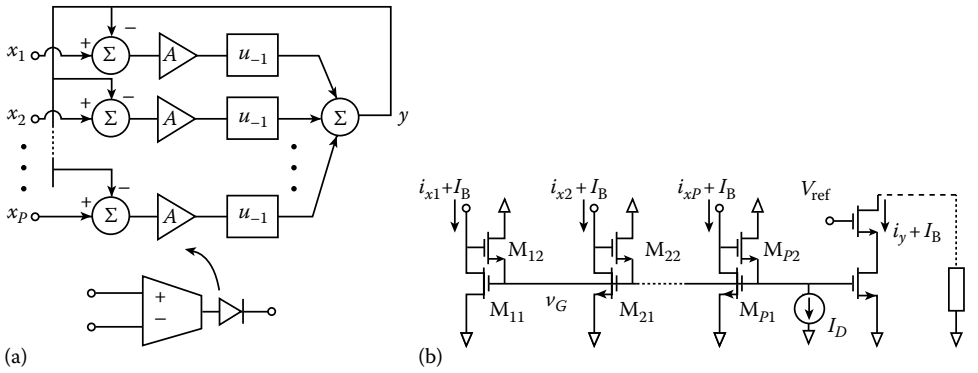

FIGURE 8.40 Concept for maximum operator and current-mode realization. (a) A classical approach used in analog computation to calculate the maximum of an input vector. (b) A CMOS current-mode realization.

where A is large. This concept can be realized in practice using OTAs, op-amps, or diodes. Both of these have voltage input and output. Alternatively, Figure 8.40b shows a CMOS current-mode realization [74]. In this circuit the maximum current determines the value of the common gate voltage, v_G. The only input transistor operating in the saturation region is that which is driven by maximum input current; the rest operate in the ohmic region.

8.7 Extension to Dynamic Systems

A dynamic system with state vector **x** and dynamics represented as

$$T_k \frac{\mathrm{d}x_k}{\mathrm{d}t} = f_k(\mathbf{X}), \quad 1 \le k \le P \tag{8.46}$$

can be mapped on the block diagram of Figure 8.41a, and realized by the interconnection of nonlinear resistive blocks and integrators. This approach is similar to that followed in classical analog computation

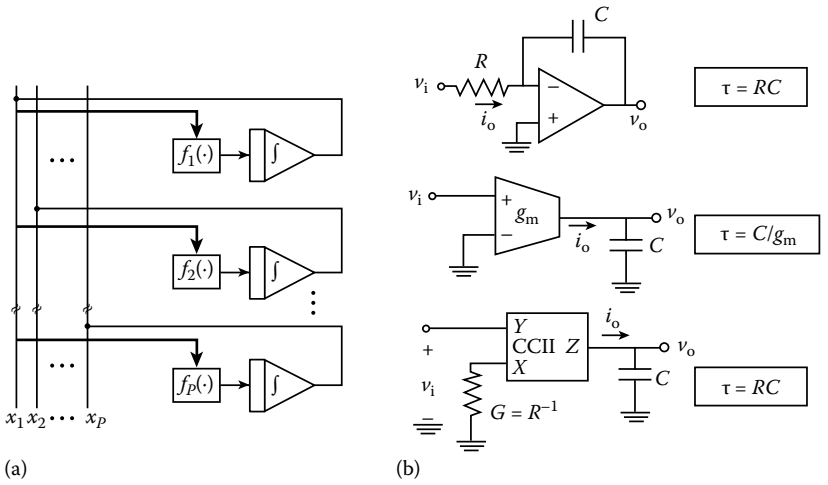

FIGURE 8.41 Conceptual state-variable block diagram of dynamic systems integrator circuits. (a) Block diagram realized by the interconnection of nonlinear resistive blocks and integrators. (b) Several integrated circuits.

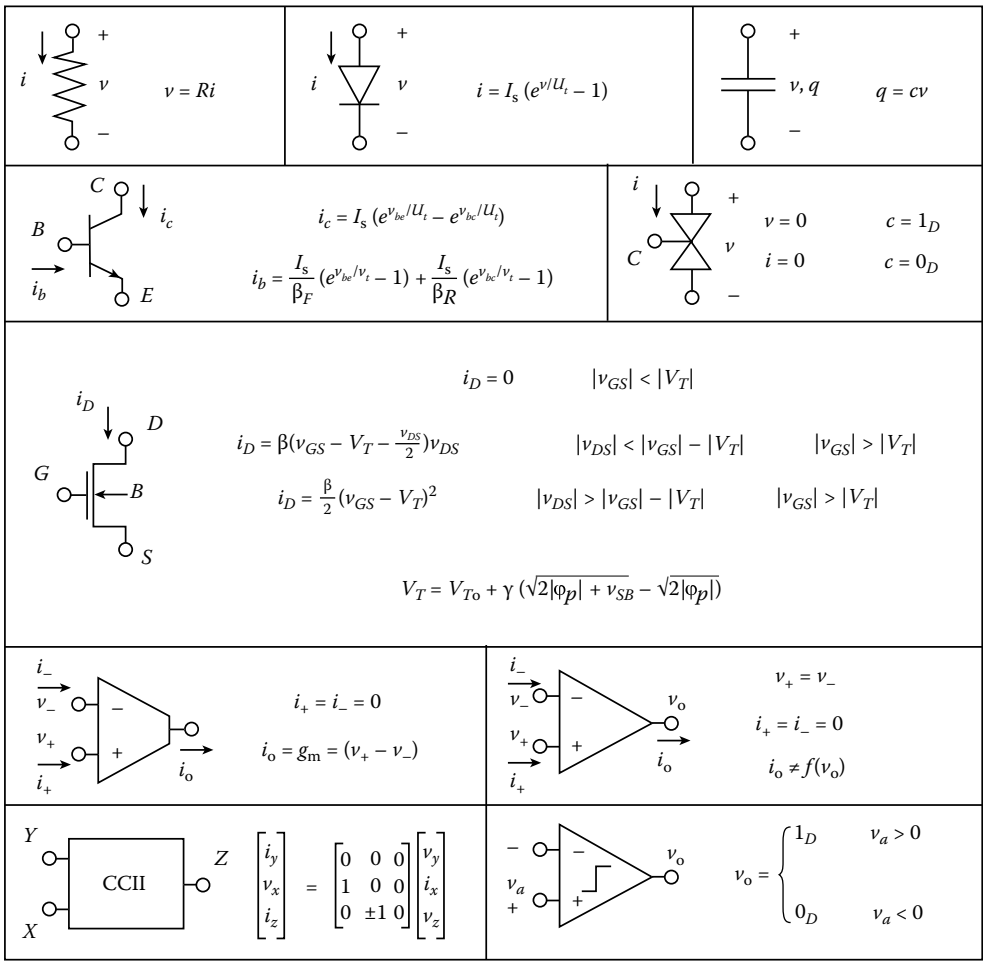
[26] and has integrators as key components. Figure 8.41b illustrates several integrator circuits. Combining these circuits with the circuitry for nonlinear functions provides systematic approaches to synthesize nonlinear dynamic systems based on the approximations presented in this chapter [56]. On the other hand, Rodríguez-Vázquez and Delgado-Restituto [57] discuss related techniques to synthesize nonlinear systems described by finite-difference equations.

Appendix A: Catalog of Primitives

Figure 8.42 outlines our catalog of primitive components, all of which are available off-the-shelf, and, depending on the fabrication technology, can be realized on a common semiconductor substrate [44]. Generally, the catalog differs between individual technologies; for instance, no *npn*-BJTs are available in a CMOS *n*-well technology. The use of linear capacitors may appear surprising because we constrain ourselves to cover only static characteristics. However, we will not exploit their dynamic *i*–*v* relationship, but instead their constitutive equation in the charge–voltage plane, which is algebraic.



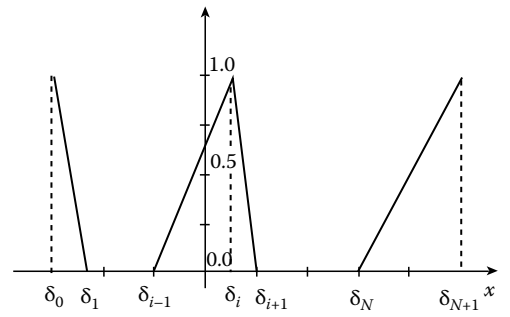


FIGURE 8.42 Section catalog of primitive circuit components.

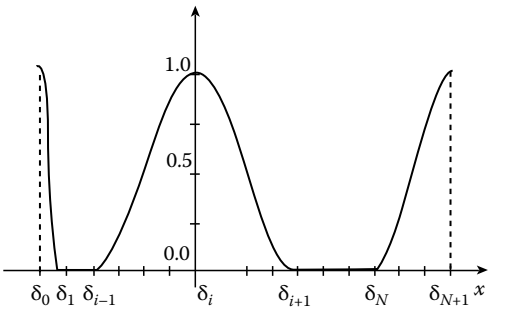
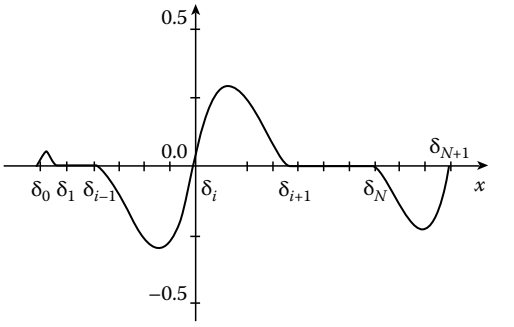
Appendix B: Value and Slope Hermite Basis Functions



(a)

$$I_0(x) = \begin{cases} (\delta_1 - x)/\Delta_0 & \delta_0 \le x \le \delta_1 \\ 0 & \delta_1 \le x \le \delta_{N+1} \end{cases}$$

$$I_i(x) = \begin{cases} 0 & \delta_0 \le x \le \delta_{N+1} \\ (x - \delta_{i-1})/\Delta_{i-1} & \delta_{i-1} \le x \le \delta_i \\ (\delta_{i+1} - x)/\Delta_i & \delta_i \le x \le \delta_{i+1} \\ 0 & \delta_{i+1} \le x \le \delta_{N+1} \end{cases}$$



$$I_{N+1}(x) = \begin{cases} (x - \delta_N)/\Delta_N & \delta_N \le x \le \delta_{N+1} \\ 0 & \delta_0 \le x \le \delta_N \end{cases}$$

$$v_0(x) = \begin{cases} 1 - 2\beta_0^3 + 3\beta_0^2 & \delta_0 \le x \le \delta_1 \\ 0 & \delta_1 \le x \le \delta_{N+1} \end{cases}$$

$$v_i(x) = \begin{cases} 0 & \delta_0 \le x \le \delta_{N+1} \\ 1 - 3\alpha_i^2 - 2\alpha_i^3 & \delta_{i-1} \le x \le \delta_i \\ 1 - 3\beta_i^2 - 2\beta_i^3 & \delta_i \le x \le \delta_{i+1} \\ 0 & \delta_{i+1} \le x \le \delta_{N+1} \end{cases}$$

$$v_{N+1}(x) = \begin{cases} 1 - 3\alpha_{N+1}^2 - 2\alpha_{N+1}^3 & \delta_N \le x \le \delta_{N+1} \\ 0 & \delta_0 \le x \le \delta_N \end{cases}$$

$$s_0(x) = \begin{cases} \Delta_0\beta_0(1 - \beta_0)^2 & \delta_0 \le x \le \delta_1 \\ 0 & \delta_1 \le x \le \delta_{N+1} \end{cases}$$

$$s_i(x) = \begin{cases} 0 & \delta_0 \le x \le \delta_{N+1} \\ \Delta_{i-1}\alpha_i(1 + \alpha_i)^2 & \delta_{i-1} \le x \le \delta_i \\ \Delta_i\beta_i(1 - \beta_i)^2 & \delta_i \le x \le \delta_{i+1} \\ 0 & \delta_{i+1} \le x \le \delta_{N+1} \end{cases}$$

$$s_{N+1}(x) = \begin{cases} \Delta_N\alpha_{N+1}(1 + \alpha_{N+1})^2 & \delta_N \le x \le \delta_{N+1} \\ 0 & \delta_0 \le x \le \delta_N \end{cases}$$

$$\Delta_i = \delta_{i+1} - \delta_i \qquad \alpha_i = (x - \delta_i)/\Delta_{i-1} \qquad \beta_i = (x - \delta_i)/\Delta_i$$

9.1 Introduction

Representation, approximation, and identification of physical systems, linear or nonlinear, deterministic or random, or even chaotic, are three fundamental issues in systems theory and engineering. To describe a physical system, such as a circuit or a microprocessor, we need a mathematical formula or equation that can represent the system both qualitatively and quantitatively. Such a formulation is what we call a mathematical representation of the physical system. If the physical system is so simple that the mathematical formula or equation, or the like, can describe it perfectly without error, then the representation is ideal and ready to use for analysis, computation, and synthesis of the system. An ideal representation of a real system is generally impossible, so that system approximation becomes necessary in practice. Intuitively, approximation is always possible. However, the key issues are what kind of approximation is good, where the sense of ''goodness'' must first be defined, of course, and how to find such a good approximation. On the other hand, when looking for either an ideal or a approximate mathematical representation for a physical system, one must know the system structure (the form of the linearity or nonlinearity) and parameters (their values). If some of these are unknown, then one must identify them, leading to the problem of system identification.

This chapter is devoted to a brief description of mathematical representation, approximation, and identification of, in most cases, nonlinear systems. As usual, a linear system is considered to be a special case of a nonlinear system, but we do not focus on linear systems in this chapter on nonlinear circuits. It is

known that a signal, continuous or discrete, is represented by a function of time. Hence, a signal can be approximated by other functions and also may be identified using its sampled data. These are within the context of ''representation, approximation, and identification,'' but at a lower level—one is dealing with functions. A system, in contrast, transforms input signals to output signals, namely, maps functions to functions, and is therefore at a higher level—it can only be represented by an operator (i.e., a mapping). Hence, while talking about representation, approximation, and identification in this chapter, we essentially refer to operators. However, we notice that two systems are considered to be equivalent over a set of input signals if and only if (iff) they map the same input signal from the set to the same output signal, regardless of the distinct structures of the two systems. From this point of view, one system is a good approximation of the other if the same input produces outputs that are approximately the same under certain measure. For this reason, we also briefly discuss the classical function approximation theory in this chapter.

The issue of system representation is addressed in Section 9.2, while approximation (for both operators and functions) is discussed in Section 9.3, leaving the system identification problem to Section 9.4. Limited by space, we can discuss only deterministic systems. Topics on stochastic systems are hence referred to some standard textbooks [13,17].

It is impossible to cover all the important subjects and to mention many significant results in the field in this short and sketchy chapter. The selections made only touch upon the very elementary theories, commonly used methods, and basic results related to the central topics of the chapter, reflecting the author's personal preference. In order to simplify the presentation, we elected to cite only those closely related references known to us, which may or may not be the original sources. From our citations, the reader should be able to find more references for further reading.

9.2 Representation

The scientific term ''representation'' as used here refers to a mathematical description of a physical system. The fundamental issue in representing a physical system by a mathematical formulation, called a mathematical model, is its correct symbolization, accurate quantization, and strong ability to illustrate and reproduce important properties of the original system.

A circuit consisting of some capacitor(s), inductor(s), and/or resistors(s), and possibly driven by a voltage source or a current source, is a physical system. In order to describe this system mathematically for the purpose of analysis, design, and/or synthesis, a mathematical model is needed. Any mathematical model, which can correctly describe the physical behavior of the circuit, is considered a mathematical representation of the circuit. A lower level mathematical representation of a circuit can, for instance, be a signal flow chart or a circuit diagram like the nonlinear Chua's circuit shown in Figure 9.1, which is discussed next.

A circuit, such as that shown in Figure 9.1, can be used to describe a physical system, including its components and its internal as well as external connections. However, it is not convenient for carrying out theoretical analysis or numerical computations. This is because no qualitative or quantitative description exists about the relations among the circuit elements and their dynamic behavior. Hence, a higher level mathematical model is needed to provide a qualitative and quantitative representation of the real physical circuit.

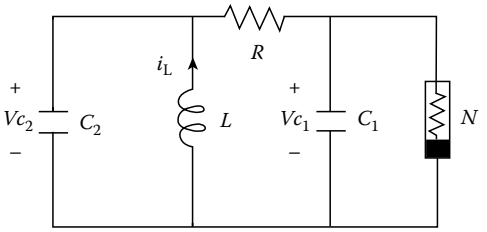

FIGURE 9.1 Chua's circuit.

Among several commonly used mathematical modeling approaches for various physical systems, differential equations, state-space formulations, I–O mappings, and functional series (particularly, the Volterra series) are the most important and useful, which have been very popular in the field of circuits

and systems engineering. In the following, we introduce these mathematical representation methods, along with some brief discussions of other related issues. Limited by space, detailed derivations are omitted.

9.2.1 Differential Equation and State-Space Representations

Mathematical modeling via differential equations and via state-space descriptions are the most basic mathematical representation methods. We illustrate the concept of mathematical modeling and the two representation methods by a simple, yet representative example: the nonlinear circuit in Figure 9.1. This circuit consists of one inductor L, two capacitors C_1 and C_2, one linear resistor R, and one nonlinear resistor, N, which is a nonlinear function of the voltage across its two terminals: $N = N(V_{C_1}(t))$. Let $i_L(t)$ be the current through the inductor L, and $V_{c_1}(t)$ and $V_{c_2}(t)$ be the voltages across C_1 and C_2, respectively. For the time being, let us remove the nonlinear resistor N from Figure 9.1 and consider the remaining linear circuit. This nonlinear resistor N is readded to the circuit with detailed discussions in Equation 9.6.

For this linear circuit without the resistor N, it follows from Kirchhoff's laws that

$$C_1 \frac{\mathrm{d}}{\mathrm{d}t} V_{C_1}(t) = \frac{1}{R}[V_{C_2}(t) - V_{C_1}(t)] \tag{9.1}$$

$$C_2 \frac{\mathrm{d}}{\mathrm{d}t} V_{C_2}(t) = \frac{1}{R}[V_{C_1}(t) - V_{C_2}(t)] + i_L(t) \tag{9.2}$$

$$L \frac{\mathrm{d}}{\mathrm{d}t} i_L(t) = -V_{C_2}(t) \tag{9.3}$$

By simple calculation we can eliminate both $V_{c_2}(t)$ and i_L, leaving a single ordinary differential equation on the unknown voltage $V_{c_1}(t)$ as follows:

$$\frac{\mathrm{d}^3}{\mathrm{d}t^3} V_{C_1}(t) + \frac{1}{R}\left(\frac{1}{C_1} + \frac{1}{C_2}\right) \frac{\mathrm{d}^2}{\mathrm{d}t^2} V_{C_1}(t) + \frac{1}{C_2 L} \frac{\mathrm{d}}{\mathrm{d}t} V_{C_1}(t) + \frac{1}{C_1 C_2 R L} V_{C_1}(t) = 0 \tag{9.4}$$

Once $V_{c_1}(t)$ is obtained from Equation 9.4, based on certain initial conditions, the other two unknowns, $V_{c_2}(t)$ and i_L, can be obtained by using Equations 9.1 and 9.3, successively. Hence, this third-order ordinary differential equation describes both qualitatively and quantitatively the circuit shown in Figure 9.1 (without the nonlinear resistor N). For this reason, Equation 9.4 is considered to be a mathematical representation, called a differential equation representation, of the physical linear circuit.

Very often, a higher-order, single-variable ordinary differential equation similar to Equation 9.4 is not as convenient as a first-order multivariable system of ordinary differential equations as is the original system of Equations 9.1 through 9.3, even when an analytic formulation of the solution is desired. Hence, a more suitable way for modeling a physical system is to introduce the concept of system state variables, which leads to a first-order higher dimensional system of ordinary differential equations.

If we introduce three state variables in Equations 9.1 through 9.3:

$$x_1(t) = V_{C_1}(t), \quad x_2(t) = V_{C_2}(t), \quad x_3(t) = i_L(t)$$

then we can rewrite those equations in the following vector form:

$$\begin{cases} \dot{\mathbf{x}}(t) = A\mathbf{x}(t) + B\mathbf{u}(t), & t \geq 0 \\ \mathbf{x}(0) = \mathbf{x}_0 \end{cases} \tag{9.5}$$

with an initial value $\mathbf{x}_0$ (usually given), where

$$\mathbf{x}(t) = \begin{bmatrix} x_1(t) \\ x_2(t) \\ x_3(t) \end{bmatrix} \quad \text{and} \quad A = \begin{bmatrix} -\dfrac{1}{RC_1} & \dfrac{1}{RC_1} & 0 \\ \dfrac{1}{RC_2} & -\dfrac{1}{RC_2} & \dfrac{1}{C_2} \\ 0 & -\dfrac{1}{L} & 0 \end{bmatrix}$$

in which $\mathbf{x}(t)$ is called the state vector of the system. Here, to be more general and for convenience in the discussions following, we formally added the term $B\mathbf{u}(t)$ to the system, in which B is a constant matrix and $\mathbf{u}(t)$ is called the control input of the system. In the present case, of course, $\mathbf{u} = 0$ and it is not important to specify B. However, note that $\mathbf{u}$ can be a nonzero external input to the circuit [19], which is discussed in more detail below.

This first-order, vector-valued linear ordinary differential equation is equivalent to the third-order differential equation representation (Equation 9.4) of the same physical circuit. A special feature of this state vector formulation is that with different initial state vectors and with zero control inputs, all the possible system state vectors together constitute a linear space of the same dimension [31]. Hence, Equation 9.5 is also called a linear state-space representation (or, a linear state-space description) for the circuit.

A few important remarks are in order. First, if the circuit is nonlinear, its state vectors do not constitute a linear space in general. Hence, its mathematical model in the state vector form should not be called a "state-space" representation. Note, however, that some of the linear system terminology such as state variables and state vectors usually make physical sense for nonlinear systems. Therefore, we use the term nonlinear state-variable representation to describe a first-order, vector-valued nonlinear ordinary differential equation of the form $\cdot\mathbf{x}(t) = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t), t)$, where $\mathbf{f}(\cdot, \cdot, t)$ is generally a vector-valued nonlinear function. This is illustrated in more detail shortly.

Second, a linear state-space representation for a given physical system is not unique because one can choose different state variables. For example, in Equations 9.1 through 9.3 if we instead define $x_1 = V_{c_2}(t)$ and $x_2 = V_{c_1}(t)$, we arrive at a different linear state-space representation of the same circuit. However, we should note that if a linear nonsingular transformation of state vectors can map one state-space representation to another, then these two seemingly different representations are actually equivalent in the sense that the same initial values and control inputs will generate the same outputs (perhaps in different forms) through these two representations. Also worth noting is that not every circuit element can be used as a state variable, particularly for nonlinear systems. A basic requirement is that all the chosen state variables must be "linearly independent" in that the first-order, vector-valued ordinary differential equation has a unique solution (in terms of the control input) for any given initial values of the chosen state variables.

Finally, because A and B in the state-space representation (Equation 9.5) are both constant (independent of time), the representation is called a linear time-invariant system. If A or B is a matrix-valued function of time, then it will be called a linear time-varying system. Clearly, a time-invariant system is a special case of a time-varying system.

Now, let us return to the nonlinear circuit, with the nonlinear resistor N being connected to the circuit, as illustrated in Figure 9.1. Similar to Equations 9.1 through 9.3, we have the following circuit equations:

$$C_1 \frac{\mathrm{d}}{\mathrm{d}t} V_{C_1}(t) = \frac{1}{R}[V_{C_2}(t) - V_{C_1}(t)] - N(V_{C_1}(t)) \tag{9.6}$$

$$C_2 \frac{\mathrm{d}}{\mathrm{d}t} V_{C_2}(t) = \frac{1}{R}[V_{C_1}(t) - V_{C_2}(t)] + i_{\mathrm{L}}(t) \tag{9.7}$$

$$L \frac{\mathrm{d}}{\mathrm{d}t} i_{\mathrm{L}}(t) = -V_{C_2}(t) \tag{9.8}$$

Note that if the nonlinear resistor N is given by

$$\begin{aligned} N(V_{C_1}(t)) &= N(V_{C_1}(t); m_0, m_1) \\ &= m_0 V_{C_1}(t) + \frac{1}{2}(m_1 - m_0)\Big(\big|V_{C_1}(t) + 1\big| - \big|V_{C_1}(t) - 1\big|\Big) \end{aligned} \tag{9.9}$$

with $m_0 < 0$ and $m_1 < 0$ being two appropriately chosen constant parameters, then this nonlinear circuit is the well-known Chua's circuit [24].

It is clear that compared with the linear case, it would be rather difficult to eliminate two unknowns, particularly $V_{c_1}(t)$, in order to obtain a simple third-order, nonlinear differential equation that describes the nonlinear circuit. That is, it would often be inconvenient to use a higher-order, single-variable differential equation representation for a nonlinear physical system in general. By introducing suitable state variables, however, one can easily obtain a nonlinear state-variable representation in a first-order, vector-valued, nonlinear differential equation form. For instance, we may choose the following state variables:

$$x(\tau) = V_{C_1}(t), \quad y(\tau) = V_{C_2}(t), \quad \text{and} \quad z(\tau) = Ri_{\mathrm{L}}(t) \quad \text{with} \quad \tau = t/RC_2$$

where the new variable $z(\tau) = Ri_{\mathrm{L}}(t)$ and the rescaled time variable $\tau = t/RC_2$ are introduced to simplify the resulting representation of this particular circuit. Under this nonsingular linear transform, the previous circuit equations are converted to the following state-variable representation:

$$\begin{cases} \dot{x}(\tau) = p\big[-x(\tau) + y(\tau) - \tilde{N}(x(\tau))\big] \\ \dot{y}(\tau) = x(\tau) - y(\tau) + z(\tau) \\ \dot{z}(\tau) = -qy(\tau) \end{cases} \tag{9.10}$$

where

$p = C_2/C_1$
$q = R^2 C_2/L$

and

$$\begin{aligned} \tilde{N}(x(\tau)) &= N(x(\tau); \tilde{m}_0, \tilde{m}_1) \\ &= \tilde{m}_0 x(\tau) + \frac{1}{2}(\tilde{m}_1 - \tilde{m}_0)\big(\big|x(\tau) + 1\big| - \big|x(\tau) - 1\big|\big) \end{aligned} \tag{9.11}$$

with $\tilde{m}_0 = Rm_0$ and $\tilde{m}_1 = Rm_1$.

It is easy to see that this state-variable representation can be written as a special case in the following form, known as a canonical representation of Chua's circuit family:

$$\dot{\mathbf{x}}(\tau) = \mathbf{a} + A\mathbf{x}(\tau) + \sum_{i=1}^{k} \big|\mathbf{h}_i^{\mathrm{T}}\mathbf{x}(\tau) - \beta_i\big|\mathbf{c}_i + B\mathbf{u}(\tau) \tag{9.12}$$

namely, with $\mathbf{a} = 0$, $k = 2$, $\mathbf{h}_1 = \mathbf{h}_2 = [1\ 0\ 0]^{\mathrm{T}}$, $\beta_1 = -\beta_2 = -1$, $\mathbf{c}_1 = -\mathbf{c}_2 = \mathbf{H}(\tilde{m}_1 - \tilde{m}_0)$, $B\mathbf{u}(\tau)$ being a possible control input to the circuit [19], and

$$A = \begin{bmatrix} -\tilde{m}_0 - p & p & 0 \\ 1 & -1 & 1 \\ 0 & -q & 0 \end{bmatrix}$$

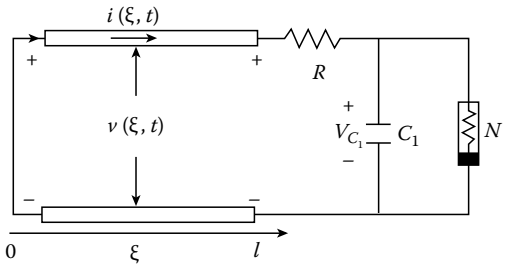

FIGURE 9.2 Time-delayed Chua's circuit.

The canonical (piecewise-linear) representation given by Equation 9.12 describes a large class of circuits that have very rich nonlinear dynamics [25,55].

Now, we return to Equations 9.6 through 9.8 and Figure 9.1. If we replace the $L - C_2$ part of Chua's circuit by a lossless transmission line (with the spatial variable ξ) of length l terminated on its left-hand side (at $\xi = 0$) by a short circuit, as depicted in Figure 9.2, then we obtain a time-delayed Chua's circuit [89]. This circuit has a partial differential equation representation of the form:

$$\begin{cases} \partial v/\partial \xi = -L\partial i(\xi,t)/\partial t \\ \partial i(\xi,t)/\partial \xi = -C_1\partial v(\xi,t)/\partial t \\ v(0,t) = 0 \\ i(l,t) = N(v(l,t) - e - Ri(l,t)) + C_1\partial[v(l,t) - Ri(l,t)]/\partial t \end{cases} \tag{9.13}$$

where $v(\xi, t)$ and $i(\xi, t)$ are the voltage and current, respectively, at the point $\xi \in [0, l]$ at time t, and $V_{c1} = e > 0$ is a constant, with the nonlinear resistor N satisfying

$$N(V_{C_1} - e) = \begin{cases} m_0(V_{C_1} - e) & |V_{C_1} - e| < 1 \\ m_1(V_{C_1} - e) - (m_1 - m_0)\mathrm{sgn}(V_{C_1} - e) & |V_{C_1} - e| \geq 1 \end{cases}$$

In general, systems that are described by (linear or nonlinear) partial differential equations, with initial-boundary value conditions, are studied under a unified framework of (linear or nonlinear) operator semigroup theory, and are considered to have an infinite-dimensional system representation [7].

9.2.2 Input–Output Representation

A state-variable representation of a nonlinear physical system generally can be written as

$$\begin{cases} \dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t), t), \quad t \geq 0 \\ \mathbf{x}(0) = \mathbf{x}_0 \end{cases} \tag{9.14}$$

where

$\mathbf{f}(\cdot, \cdot, t)$ is a nonlinear, vector-valued function
$\mathbf{x}_0$ is a (given) initial value for the state vector $\mathbf{x}$ at $t = 0$
$\mathbf{u}$ is a control input to the system

Because not all state variables in the state vector $\mathbf{x}$ can be measured (observed) in a physical system, let us suppose that what can be measured is only part of $\mathbf{x}$, or a mixture of its components, expressed by a vector-valued function of $\mathbf{x}$ in the form

$$\mathbf{y}(t) = \mathbf{g}(\mathbf{x}(t), t), \quad t \geq 0 \tag{9.15}$$

where

$\mathbf{y}$ is called a (measurement or observation) output of the physical system
$\mathbf{g}$ is in general a lower dimensional vector-valued nonlinear function

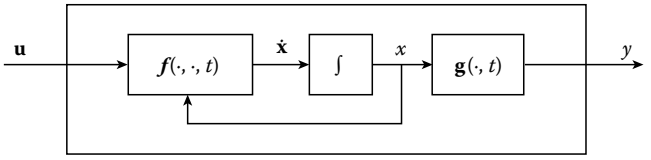

FIGURE 9.3 System I–O relationship.

As a particular case, **g** can be linear or, even more so, be $\mathbf{g}(\mathbf{x}(t), t) = \mathbf{x}(t)$ when all the components of the state vector are directly measurable.

If both $\mathbf{f} = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t))$ and $\mathbf{g} = \mathbf{g}(\mathbf{x}(t))$ are not explicit functions of the independent time variable t, the corresponding state-variable representation (Equations 9.14 and 9.15) is said to be autonomous.

It is clear that with both the system input **u** and output **y**, one can simply represent the overall physical system by its input-output (I–O) relationship, as illustrated in Figure 9.3.

Now, under certain mild conditions on the nonlinear function **f**, for a given control input **u**, and an initial value $\mathbf{x}_0$, the state-variable representation (Equation 9.14) has a unique solution, **x**, which depends on both **u** and $\mathbf{x}_0$. If we denote the solution as

$$\mathbf{x}(t) = \mathcal{F}(t; \mathbf{u}(t), \mathbf{x}_0) \tag{9.16}$$

where $\mathcal{F}$ is called an input-state mapping, then the overall I–O relationship shown in Figure 9.3 can be formulated as

$$\mathbf{y}(t) = \mathbf{g}(\mathcal{F}(t; \mathbf{u}(t), \mathbf{x}_0), t) \tag{9.17}$$

This is an I–O representation of the physical system having the state-variable representation (Equations 9.14 and 9.15).

As a simple example, let us consider the linear state-space representation (Equation 9.5), with a special linear measurement equation of the form $\mathbf{y}(t) = C\mathbf{x}(t)$, where C is a constant matrix. It is well known [31] that

$$\mathbf{y}(t) = C\mathcal{F}(t; \mathbf{u}(t), \mathbf{x}_0) = C\left\{e^{tA}\mathbf{x}_0 + \int_0^t e^{(t-\tau)A}B\mathbf{u}(\tau)\mathrm{d}\tau\right\}, \quad t \geq 0 \tag{9.18}$$

yielding an explicit representation formula for the I–O relationship of the linear circuit (together with the assumed measurement equation).

Note that because the state-variable representation (Equation 9.14) is not unique, as mentioned previously, this I–O representation is not unique in general. However, we note that if two state-variable representations are equivalent, then their corresponding I–O relationships also will be equivalent.

It is also important to note that although the above I–O relationship is formulated for a finite-dimensional open-loop system, it can also be applied to infinite-dimensional [7] and closed-loop systems [39]. In particular, similar to linear systems, many finite-dimensional, closed-loop nonlinear systems possess an elegant coprime factorization representation. The (left or right) coprime factorization representation of a nonlinear feedback system is a general I–O relationship that can be used as a fundamental framework, particularly suitable for studies of stabilization, tracking, and disturbance rejection. The problem is briefly described as follows. Let a nonlinear system (mapping) P be given, not necessarily stable, and assume that it has a right-coprime factorization $P = ND^{-1}$, where both N and D are stable (D^{-1} usually has the same stability as P). One is looking for two stable, nonlinear subsystems (mappings),

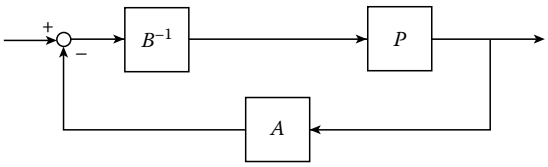

FIGURE 9.4 Right-coprime factorization of a nonlinear feedback system.

A and B^{-1}, representing feedback and feed-forward controllers, respectively, satisfying the Bezout identity

$$AN + BD = I$$

which are connected as shown in Figure 9.4, where B is also stable. If two controllers, A and B, can be found to satisfy such conditions, then even with an unstable P, the resulting closed-loop control system will be I–O, as well as internally, stable. In this sense, A and B together stabilize P.

For the left-coprime factorization, one simply uses formulas $P = D^{-1}N$ and $NA + DB = I$ instead and interchanges the two blocks of A and B^{-1} in Figure 9.4.

Taking into account causality and well-posedness of the overall closed-loop system, it is a technical issue as to how to construct the four subsystems A, B, D, and N, such that the preceding requirements can be satisfied. Some characterization results and construction methods are available in the literature [38,45,51,95].

9.2.3 Volterra Series Representation

Recall from the fundamental theory of ordinary differential equations that an explicit I–O representation of the overall system still can be found, even if the linear state-space representation (Equation 9.5) is time varying, via the state transition matrix $\Phi(t, \tau)$ determined by

$$\begin{cases} \dfrac{\mathrm{d}}{\mathrm{d}t}\Phi(t,\tau) = A(t)\Phi(t,\tau), & t \geq \tau \\ \Phi(\tau,\tau) = I \end{cases} \tag{9.19}$$

where I is the identity matrix. The formula, for the simple case $\mathbf{y}(t) = C(t)\mathbf{x}(t)$, is

$$\mathbf{y}(t) = C(t)\left\{\Phi(t,0)\mathbf{x}_0 + \int_0^t \Phi(t,\tau)B(\tau)\mathbf{u}(\tau)\mathrm{d}\tau\right\}, \quad t \geq 0 \tag{9.20}$$

For linear time-invariant systems, we actually have $\Phi(t, \tau) = e^{(t-\tau)A}$, so that Equation 9.20 reduces to the explicit formula (Equation 9.18).

For a nonlinear system, a simple explicit I–O representation with a single integral of the form (Equation 9.18 or Equation 9.20) is generally impossible. A natural generalization of such an integral formulation is the Volterra series representation. For simplicity, let us consider the one-dimensional case in which $y(t) = g(x(t), t) = x(t)$ below. A Volterra series representation for a nonlinear I–O relationship $\mathcal{F}(\cdot)$, convergent in some measure, is an infinite sum of integrals in the following form:

$$\mathcal{F}(t,u(t)) = \phi_0(t;x_0) + \int_0^t \phi_1(t,\tau_1)u(\tau_1)\mathrm{d}\tau_1 + \cdots + \int_0^t \cdots \int_0^{\tau_2} \phi_n(t,\tau_1,\ldots,\tau_n)u(\tau_1)\cdots u(\tau_n)\mathrm{d}\tau_1 \cdots \mathrm{d}\tau_n + \cdots \tag{9.21}$$

where $\{\phi_n\}_{n=0}^{\infty}$ are called the Volterra kernels of the series. Here, we note that this Volterra series representation can be extended easily to higher-dimensional systems.

For some representations $\mathcal{F}$, the corresponding Volterra series may have only finitely many nonzero terms in the above infinite sum. In this case, it is called a Volterra polynomial, which does not have convergence problem for bounded inputs, provided that all the integrals exist. In particular, when $\mathcal{F}$ is affine (or linear, if initial conditions are zero, so that $\phi_0 = 0$), its Volterra series has at most two nonzero terms, as given by Equations 9.18 and 9.20, and is called a first-order Volterra polynomial. In general, however, the Volterra series (Equation 9.21) is an infinite sum. Hence, the convergence of a Volterra series is a crucial issue in formulating such a representation for a given nonlinear I–O relationship [5,12,59,85].

In order to state a fundamental result about the convergence of a Volterra series, we must first recall that a mapping that takes a function to a (real or complex) value is called a functional and a mapping that takes a function to another function is called an operator. A functional may be considered to be a special operator if one views a value as a constant function in the image of the mapping. Clearly, the I–O relationship (Equation 9.17) and the Volterra series (Equation 9.21), including Volterra polynomials, are nonlinear operators. Recall also that an operator $\mathcal{T}: X \to Y$, where X and Y are normed linear spaces, is said to be continuous at $x \in X$ if $||x_n - x||_x \to 0$ implies $||\mathcal{T}(x_n) - \mathcal{T}(x)||_y \to 0$ as $n \to \infty$. Note that for a linear operator, if it is continuous at a point, then it is also continuous on its entire domain [34], but this is not necessarily true for nonlinear operators.

As usual, we denote by $C[0,T]$ and $L_p[0,T]$, respectively, the space of continuous functions defined on $[0,T]$ and the space of measurable functions f satisfying $\int_0^T |f(t)|^p \mathrm{d}t < \infty$ for $1 \le p < \infty$ or $\sup_{t\in[0,T]}|f(t)| < \infty$ for $p = \infty$. The following result [5] is an extension of the classical Stone–Weierstrass theorem [22,36,40].

THEOREM 9.1

Let X be either $C[0, T]$ or $L_p[0,T]$, with $1 \le p < \infty$, and Ω be a compact subset in X. Then, for any continuous operator $\mathcal{F}: \Omega \to L_q[0,T]$, where $(1/p) + (1/q) = 1$, and for any $\varepsilon > 0$, a Volterra polynomial $P_n(\cdot)$ exists, with n determined by ε, such that

$$\sup_{x\in\Omega} ||\mathcal{F}(x) - P_n(x)|_{L_q} < \varepsilon$$

In other words, $P_n \to \mathcal{F}$ uniformly on the compact subset $\Omega \subset X$ as $n \to \infty$.

In the literature, many variants of this fundamental convergence theorem exist under various conditions in different forms, including the $L_\infty[0,T]$ case [45,59,84,85]. We may also find different methods for constructing the Volterra kernels $\{\phi_n\}_{n=0}^{\infty}$ for $\mathcal{F}$ [83]. In addition, specially structured Volterra series representations abound for nonlinear systems, such as the Volterra series with finite memory [5], approximately finite memory [86], and fading memory [10].

Finally, it should be mentioned that in a more general manner, a few abstract functional series representations exist, including the generating power series representation for certain nonlinear systems [48], from which the Volterra series can be derived. Briefly, an important result is the following theorem [6,54,71,91].

THEOREM 9.2

Consider a nonlinear control system of the form

$$\begin{cases} \dot{x}(t) = g_0(x(t)) + \sum_{k=1}^{m} g_k(x(t))u_k(t), \quad t \in [0, T] \\ y(t) = h(x(t)) \end{cases}$$

where $h(\cdot)$ and $\{g_i(\cdot)\}_{i=0}^{m}$ are sufficiently smooth functionals, with an initial state x_0. If the control inputs satisfy $\max_0 \le \tau \le T\ |u_k(t)| < 1$, *then the corresponding output of this nonlinear system has a convergent functional series of the form*

$$y(t) = h(x_0) + \sum_{i=0}^{\infty} \sum_{k_0,\ldots,k_1=0}^{m} L_{g_{k_0}} \cdots L_{g_{k_i}} h(x_0) \int_0^t d\xi_{k_i} \cdots d\xi_{k_0} \tag{9.22}$$

where $L_g h(x_0) := [\partial h/\partial x] g(x)|_{x=x0}$ and ξ_k are defined by

$$\xi_0(t) = t \quad \xi_k(t) = \int_0^t u_k(\tau) d\tau, \quad k = 1, \ldots, m$$

with the notation

$$\int_0^t d\xi_{k_i} \cdots d\xi_{k_0} := \int_0^t d\xi_{k_i}(\tau) \int_0^t d\xi_{k_{i-1}} \cdots d\xi_{k_0}$$

Note that in order to guarantee the convergence of the functional series (Equation 9.22), in many cases it may be necessary for T to be sufficiently small.

Analogous to the classical Taylor series of smooth functions, a fairly general series representation for some nonlinear systems is still possible using polynomial operators, or the like [90]. As usual, however, the more general the presentation is, the less concrete the results. Moreover, a very general series expansion is likely to be very local, and its convergence is difficult to analyze.

9.3 Approximation

The mathematical term ''approximation'' used here refers to the theory and methodology of function (functional or operator) approximation. Mathematical approximation theory and techniques are important in engineering when one seeks to represent a set of discrete data by a continuous function, to replace a complicated signal by a simpler one, or to approximate an infinite-dimensional system by a finite-dimensional model, etc., under certain optimality criteria.

Approximation is widely used in system modeling, reduction, and identification, as well as in many other areas of control systems and signal processing [32]. A Volterra polynomial as a truncation of the infinite Volterra series (discussed earlier) serves as a good example of system (or operator) approximation, where the question ''In what sense is this approximation good?'' must be addressed further.

9.3.1 Best Approximation of Systems (Operators)

Intuitively, approximation is always possible. However, two key issues are the quality of the approximation and the efficiency of its computation (or implementation). Whenever possible, one would like to

have the best (or optimal) approximation, based on the available conditions and subject to all the requirements.

A commonly used criterion for best (or optimal) approximations is to achieve a minimum norm of the approximation error using a norm that is meaningful to the problem. Best approximations of systems (operators) include the familiar least-squares technique, and various other uniform approximations.

9.3.1.1 Least-Squares Approximation and Projections

Let us start with the most popular "best approximation" technique (the least-squares method), which can also be thought of as a projection, and a special min–max approximation discussed in the Section 9.3.1.2. Discrete data fitting by a continuous function is perhaps the best-known example of least-squares. The special structure of Hilbert space, a complete inner-product space of functions, provides a general and convenient framework for exploring the common feature of various least-squares approximation techniques. Because we are concerned with approximation of nonlinear systems rather than functions, a higher-level framework, the Hilbert space of operators, is needed. We illustrate such least-squares system (or operator) approximations with the following two examples.

First, we consider the linear space, H, of certain nonlinear systems that have a convergent Volterra series representation (Equation 9.21) mapping an input space X to an output space Y. Note that although a nontrivial Volterra series is a nonlinear operator, together they constitute a linear space just like nonlinear functions.

To form a Hilbert space, we first need an inner product between any two Volterra series. One way to introduce an inner product structure into this space is as follows. Suppose that all the Volterra series, $\mathcal{F}$: $X \to Y$, where both X and Y are Hilbert spaces of real-valued functions, have bounded admissible inputs from the set

$$\Omega = \{x \in X \big| \|x\|_X \leq \gamma < \infty\}$$

For any two convergent Volterra series of the form (Equation 9.21), say $\mathcal{F}$ and $\mathcal{G}$, with the corresponding Volterra kernel sequences $\{\phi_n\}$ and $\{\psi_n\}$, respectively, we can define an inner product between them via the convergent series formulation

$$\langle \mathcal{F}, \mathcal{G} \rangle_H := \sum_{n=0}^{\infty} \frac{\rho_n}{n!} |\phi_n \psi_n|$$

with the induced norm $||\mathcal{F}||_H = \langle \mathcal{F}, \mathcal{F} \rangle_H^{1/2}$, where the weights $\{\rho_n\}$ satisfy

$$\sum_{n=0}^{\infty} \frac{1}{\rho_n} \frac{\gamma^{2n}}{n!} < \infty$$

Recall also that a reproducing kernel Hilbert space $\tilde{H}$ is a Hilbert space (of real-valued functions or operators) defined on a set S, with a reproducing kernel $K(x, y)$, which belongs to $\tilde{H}$ for each fixed x or y in S and has the property

$$\langle K(x, y), \mathcal{F}(y) \rangle_{\tilde{H}} = \mathcal{F}(x) \quad \forall \mathcal{F} \in \tilde{H} \text{ and } \forall x, y \in S$$

Using the notation defined above, the following useful result was established [43,45] and is useful for nonlinear systems identification (see Theorem 9.23).

THEOREM 9.3

The family of all the convergent Volterra series of the form (Equation 9.21) *that maps the bounded input set* Ω *to Y constitutes a reproducing kernel Hilbert space with the reproducing kernel*

$$K(x,y) = \sum_{n=0}^{\infty} \frac{1}{n!} \frac{1}{\rho_n} \langle x,y\rangle_X^n, \quad x,y \in \Omega \subset X \tag{9.23}$$

The reproducing kernel Hilbert space H defined above is called a generalized Fock space [46]. For the special case in which $\rho_n \equiv 1$, its reproducing kernel has a nice closed-form formula as an exponential operator $K(x,y) = e^{\langle xy\rangle}$.

Now, suppose that a nonlinear system $\mathcal{F}$ is given, which has a convergent Volterra series representation (Equation 9.21) with infinitely many nonzero terms in the series. For a fixed integer $n \geq 0$, if we want to find an nth-order Volterra polynomial, denoted $V_n^\star$, from the Hilbert space H such that

$$\left\|\mathcal{F} - V_n^\star\right\|_{\mathrm{H}} = \inf_{V_n \in H} \left\|\mathcal{F} - V_n\right\|_{\mathrm{H}} \tag{9.24}$$

then we have a best approximation problem in the least-squares sense. To solve this optimization problem is to find the best Volterra kernels $\{\phi_k(t)\}_{k=0}^n$ over all the possible kernels that define the Volterra polynomial V_n, such that the minimization (Equation 9.24) is achieved.

Note that, if we view the optimal solution $V_n^\star$ as the projection of $\mathcal{F}$ onto the $(n+1)$-dimensional subspace of H, then this least-squares minimization is indeed a projection approximation. It is then clear, even from the Hilbert space geometry (see Figure 9.5), that such an optimal solution, called a best approximant, always exists due to the norm-completeness of Hilbert space and is unique by the convexity of inner product space.

As a second example, let H be a Hilbert space consisting of all the linear and nonlinear systems that have an nth-order Taylor series representation of the form

$$P_n(\,\cdot\,) = \sum_{k=0}^{n} \alpha_k(t) M_k(\cdot) = \alpha_0(t) + \alpha_1(t)(\cdot)(t) + \cdots + \alpha_n(t)(\cdot)^n(t) \tag{9.25}$$

where

$M_k(\cdot) := (\cdot)^k$ is the monomial operator of degree k

$\{\alpha_k\}_{k=0}^n$ are continuous real-valued functions satisfying certain conditions arising from some basic properties of both the domain and the range of the operator

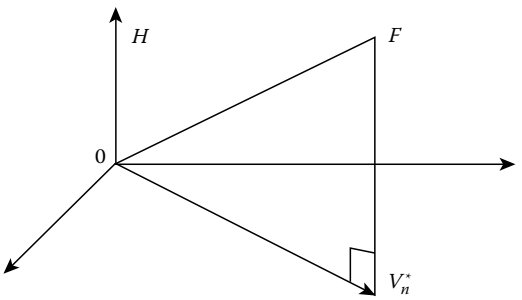

FIGURE 9.5 Projection in a Hilbert space.

Suppose that the monomial operators $\{M_k\}_{k=0}^\infty$ are orthogonal under the inner product of H. Given an lth-order polynomial operator P_l with $\alpha_l(t) \neq 0$ almost everywhere, if for a fixed integer $n < l$ we want to find an nth-order polynomial operator $P_n^\star$ of the form (Equation 9.25) from H, such that

$$\left\|P_l - P_n^\star\right\|_{\mathrm{H}} = \inf_{P_n \in H} \left\|P_l - P_n\right\|_{\mathrm{H}} \tag{9.26}$$

then we have a best approximation problem in the least-squares sense. To solve this optimization problem is to find the best coefficient

functions $\{\alpha_k(t)\}_{k=0}^n$ over all possible functions that define the polynomial operator P_n. Again, because the optimal solution is the projection of P_l onto the $(n+1)$-dimensional subspace H of a Hilbert space to which P_l belongs, it always exists and is unique.

We now state a general result of least-squares approximation for systems, which is a straightforward generalization of the classical result of least-squares approximation for functions [22,36].

THEOREM 9.4

Let H be a Hilbert space of nonlinear operators, and let H_n be its n-dimensional subspace. Then, given an $\mathcal{F} \in H$, the least-squares approximation problem

$$\left\|\mathcal{F}-\mathcal{N}_n^*\right\|_{\mathrm{H}} = \inf_{\mathcal{N}_n \in H_n} \left\|\mathcal{F}-\mathcal{N}_n\right\|_{\mathrm{H}}$$

is always uniquely solvable, with the optimal solution given by

$$\mathcal{N}^*(\cdot) = \sum_{k=1}^{n} \langle \mathcal{F}, h_k \rangle_H h_k(\cdot)$$

where $\{h_k)\}_{k=1}^n$ is an orthonormal basis of H_n.

A more general setting is to replace the Hilber space H by a Banach space (a complete normed linear space, such as L_1 and L_∞, which may not have an inner product structure). This extension includes the Hilbert space setting as a special case, but generally does not have so many special features. Even the existence and uniqueness of best approximants cannot be taken for granted in general—not even for the simpler case of best approximation of real-valued functions—if a Banach (non-Hilbert) space is considered [73]. Nevertheless, the following result is still convenient to use [22].

THEOREM 9.5

Let B be a uniformly convex Banach space and Ω be a closed convex set in B. Then, for any given $\mathcal{F} \in B$, the optimal approximation problem

$$\left\|\mathcal{F}-\omega^*\right\|_B = \inf_{\omega \in \Omega} \left\|\mathcal{F}-\omega\right\|_B$$

has a unique solution.

Here, a space (or subset) B is said to be uniformly convex if, for any $\varepsilon > 0$, there exists a $\|f\|_B = \|g\|_B = 1$ and $\|1/2(f+g)\|_B > 1-\delta$ together imply $\|f-g\|_B < \varepsilon$. Geometrically, a disk is uniformly convex while a triangle is only convex, but not uniformly so. It is then intuitively clear that for a given point outside (or inside) a disk, only a single point exists in the disk that has the shortest distance to the given point. However, this is not always true for a nonuniform case. In fact, a best approximation problem in the general Banach space setting has either a unique solution or has infinitely many solutions (if it is solvable), as can be seen from the next result [32].

THEOREM 9.6

Let Ω be a closed convex set in a Banach space B, and $\omega_1^\star$ and $\omega_2^\star$ be two optimal solutions of the best approximation problem

$$\left\|\mathcal{F} - \omega^\star\right\|_B = \inf_{\omega\in\Omega}\left\|\mathcal{F} - \omega\right\|_B$$

Then, any convex combination of $\omega_1^\star$ and $\omega_2^\star$ in the form

$$\omega^\star = a\omega_1^\star + (1-a)\omega_2^\star, \quad 0 \le a \le 1$$

is also an optimal solution of the problem.

Usually, a best approximant (if it exists) for an optimal approximation problem in a Banach space is also called a (minimal) projection of the given operator from a higher-dimensional subspace onto a lower-dimensional subspace. In this extension, the projection has no simple geometric meaning of ''orthonormality'' due to the lack of an inner product structure. However, a projection operator with a unity norm in the Banach space setting is a natural generalization of the orthonormal projection in the Hilbert space framework.

9.3.1.2 Min–Max (Uniform) Approximation

It is clear from the least-squares approximation formulation that if the given nonlinear representation (operator) $\mathcal{F}$ and the lower-order approximant (used to approximate $\mathcal{F}$) do not have the same structure (the same type of series), then the least-squares approximation cannot be applied directly or efficiently.

To introduce another approach, we first recall that for two given normed linear spaces X and Y and for a given bounded subset Ω of X, with $0 \in \Omega$, the operator norm of a nonlinear operator $\mathcal{N}$: $\Omega \to Y$ satisfying $\mathcal{N}(0) = 0$, can be defined as

$$\left|\left\|\mathcal{N}\right\|\right| = \sup_{\substack{x,y\in\Omega \\ x\neq y}} \frac{\left\|\mathcal{N}(x) - \mathcal{N}(y)\right\|_y}{\left\|x - y\right\|_x} \tag{9.27}$$

Thus, given a norm-bounded nonlinear operator $\mathcal{F}$, representing a given physical system, we may consider the problem of finding another norm-bounded nonlinear operator $\mathcal{N}^\star$ from a certain class 1 of desired nonlinear operators (systems), not necessarily having the same structure as $\mathcal{F}$, to best approximate $\mathcal{F}$ in the sense that

$$\left|\left\|\mathcal{F} - \mathcal{N}^\star\right\|\right| = \inf_{\mathcal{N}\in N}\left|\left\|\mathcal{F} - \mathcal{N}\right\|\right| \tag{9.28}$$

For example, N can be the family of nth-order Volterra polynomilas or nth-order polynomial operators discussed previously. Commonly used function spaces X and Y include the space of all continuous functions, the standard L_p space (or l_p for the discrete case), and the Hardy space H_p (for complex-variable functions [32]), with $1 \le p \le \infty$.

Because the nonlinear operator norm defined by Equation 9.27 is a sup (max) norm and this optimization is an inf (min) operation, the best approximation problem (Equation 9.28) is called a min–max approximation. Note also that because the nonlinear operator norm (Equation 9.27) is defined over all the bounded inputs in the set Ω, this approximation is uniform, and thus independent of each individual input function of the set Ω. For this reason, this approximation is also called a uniform approximation, indicating that the best approximant is the optimal solution over *all* input functions.

It should be noted that both existence and uniqueness of best approximation solutions to the min–max approximation problem (Equation 9.28) must be investigated according to the choice of the operator family N and the I–O spaces X and Y, which generally cannot be taken for granted, as previously discussed.

An important and useful class of nonlinear operators which can be put into a Banach space setting with great potential in systems and control engineering is the family of generalized Lipschitz operators [45]. To introduce this concept, we first need some notation. Let X be a Banach space of real-valued functions defined on $[0, \infty)$ and, for any $f \in X$ and any $T[0, \infty)$, define

$$[f]_{\mathrm{T}}(t) = \begin{cases} f(t), & t < T \\ 0, & t > T \end{cases}$$

Then, form a normed linear space X^{e}, called the extended linear space associated with $\boldsymbol{X}$, by

$$X^{\mathrm{e}} = \left\{ f \in X \middle| \left\| [f]_{\mathrm{T}} \right\|_{\mathrm{X}} < \infty, \forall T < \infty \right\}$$

For a subset $D \subseteq X^{\mathrm{e}}$, any (linear or nonlinear) operator $\mathcal{G}$: $D \to Y^{\mathrm{e}}$ satisfying

$$\left\| [\mathcal{G}(x_1)]_{\mathrm{T}} - [\mathcal{G}(x_2)]_{\mathrm{T}} \right\|_{\mathrm{Y}} \leq L \left\| [x_1]_{\mathrm{T}} - [x_2]_{\mathrm{T}} \right\|_{\mathrm{X}}, \quad \forall x_1, x_2 \in D, \quad \forall T \in [0, \infty)$$

for some constant $L < \infty$, is called a generalized Lipschitz operator defined on D. The least of such constants L is given by the seminorm of the operator $\mathcal{G}$:

$$\left\| \mathcal{G} \right\| : \sup_{T \in [0,\infty)} \sup_{\substack{x_1, x_2 \in D \\ [x_1]_{\mathrm{T}} \neq [x_2]_{\mathrm{T}}}} \frac{\left\| [\mathcal{G}(x_1)]_{\mathrm{T}} - [\mathcal{G}(x_2)]_{\mathrm{T}} \right\|_{Y}}{\left\| [x_1]_{\mathrm{T}} - [x_2]_{\mathrm{T}} \right\|_{X}}$$

and the operator norm of $\mathcal{G}$ is defined via this seminorm by

$$\left\| \mathcal{G} \right\|_{\mathrm{Lip}} = \left\| \mathcal{G}(x_0) \right\|_{Y} + \left\| \mathcal{G} \right\|$$

for an arbitrarily chosen and fixed $x_0 \in D$. The following result has been established [45].

THEOREM 9.7

The family of generalized Lipschitz operators

$$\mathrm{Lip}(D, Y^{\mathrm{e}}) = \{ \mathcal{G}: D \subseteq X^{\mathrm{e}} \to Y^{\mathrm{e}} \Big| \left\| \mathcal{G} \right\|_{\mathrm{Lip}} < \infty \text{ on } D \}$$

is a Banach space.

Based on this theorem, a best approximation problem for generalized Lipschitz operators can be similarly formulated, and many fundamental approximation results can be obtained. In addition, generalized Lipschitz operators provide a self-unified framework for both left and right coprime factorization representations of nonlinear feedback systems. Under this framework, the overall closed-loop system shown in Figure 9.4 can have a causal, stable, and well-posed coprime factorization representation, which can be applied to optimal designs such as tracking and disturbance rejection [45].

We now discuss briefly a different kind of min–max (uniform) approximation: the best Hankel norm approximation, where the norm (Equation 9.27) is replaced by the operator norm of a Hankel operator defined as follows [32,77]. Consider, for instance, the transfer function

$$H(z) = \alpha_0 + \alpha_1 z^{-1} + \alpha_2 z^{-2} + \cdots$$

of a discrete time linear time-invariant system. The Hankel operator associated with this series is defined as the infinite matrix

$$\Gamma_\alpha := \left[\alpha_{|i-j|}\right] = \begin{bmatrix} \alpha_0 & \alpha_1 & \alpha_2 & \cdots \\ \alpha_1 & \alpha_2 & \cdots & \\ \alpha_2 & \cdots & & \\ \vdots & & & \end{bmatrix}$$

which is a linear operator on a normed linear space of sequences. The operator norm of Γ_α over the l_2 space is called the Hankel norm of Γ_α.

One important feature of the Hankel operators is reflected in the following theorem [32,77].

THEOREM 9.8

An infinite Hankel matrix has a finite rank iff its corresponding functional series is rational (*it sums up to a rational function*); *and this is true iff the rational series corresponds to a finite-dimensional bilinear system.*

Another useful property of Hankel operators in system approximation is represented in the following theorem [28].

THEOREM 9.9

The family of compact Hankel operators is an M-ideal in the space of Hankel operators that are defined on a Hilbert space of real-valued functions.

Here, a compact operator is one that maps bounded sets to compact closures and an M-ideal is a closed subspace X of a Banach space Z such that $X^\perp$, the orthogonal complemental subspace of X in Z, is the range of the projection P from the dual space Z^* to $X^\perp$ that has the property

$$\|f\| = \|P(f)\| + \|f - P(f)\| \quad \forall f \in Z^*$$

The importance of the M-ideal is that it is a proximinal subspace with certain useful approximation characteristics, where the proximinal property is defined as follows. Let $L(X)$ and $C(X)$ be the classes of bounded linear operators and compact operators, respectively, both defined on a Banach space X. If every $\mathcal{L} \in L(X)$ has at least one best approximant from $C(X)$, then $C(X)$ is said to be proximinal in $L(X)$. A typical result would be the following: for any $1 < p < \infty$, $C(l_p)$ is proximinal in $L(l_p)$. However, $C(X)$ is not proximinal in $L(X)$ if $X = C[a, b]$, the space of continuous functions defined on $[a, b]$, or $X = L_p[a, b]$ for all $1 < p < \infty$ except $p = 2$.

9.3.2 Best (Uniform) Approximation of Signals (Functions)

Best approximations of signals for circuits and systems are also important. For example, two (different) systems (e.g., circuits) are considered to be equivalent over a set Ω of admissible input signals iff the same input from Ω yields the same outputs through the two systems. Thus, the problem of using a system to best approximate another may be converted, in many cases, to the best approximation problem for their output signals.

A signal is a function of time, usually real valued and one-dimensional. The most general formulation for best approximation of functions can be stated as follows. Let X be a normed linear space of real-valued functions and Ω be a subset of X. For a given f in X but not in Ω, find a $g^\star \in \Omega$ such that

$$\left\|f - g^\star\right\|_X = \inf_{g\in\Omega} \left\|f - g\right\|_X \tag{9.29}$$

In particular, if $X = L_\infty$, l_∞, or H_∞, the optimal solution is the best result for the worst case.

If such a $g^\star$ exists, then it is called a best approximant of f from the subset Ω. In particular, if $\Omega_1 \subset \Omega_2 \subset \cdots$ is a sequence of subspaces in X, such that $\overline{\cup\Omega_n} = X$, an important practical problem is to find a sequence of best approximants $g_n^\star \in \Omega_n$ satisfying the requirement (Equation 9.29) for each $n = 1, 2, \ldots$, such that $||g_n^\star - g^\star||_X \to 0$ as $n \to \infty$. In this way, for each n, one may be able to construct a simple approximant $g_n^\star$ for a complicated (even unknown) function f, which is optimal in the sense of the min–max approximation (Equation 9.29).

Existence of a solution is the first question about this best approximation. The fundamental result is the following [22,36].

THEOREM 9.10

For any $f \in X$, a best approximant $g^\star$ of f in Ω always exists, if Ω is a compact subset of X; or Ω is a finite-dimensional subspace of X.

Uniqueness of a solution is the second question in approximation theory, but it is not as important as the existence issue in engineering applications. Instead, characterization of a best approximant for a specific problem is significant in that it is often useful for constructing a best approximant.

As a special case, the preceding best approximation reduces to the least-squares approximation if X is a Hilbert space. The basic result is the following (compare it with Theorem 9.4, and see Figure 9.5).

THEOREM 9.11

Let H be a Hilbert space of real-valued functions, and let H_n be its n-dimenstional subspace. Then, given an $f \in H$, the least-squares approximation problem

$$\left\|f - h_n^\star\right\|_{\mathrm{H}} = \inf_{h_n\in H_n} \left\|f - h_n\right\|_{\mathrm{H}}$$

is always uniquely solvable, with the optimal solution given by

$$h_n^\star(t) = \sum_{k=1}^{n} \langle f, h_k\rangle_{\mathrm{H}} h_k(t)$$

where $\{h_k\}_{k=1}^n$ is an orthonormal basis of H_n.

Here, the orthonormal basis of H_n is a Chebyshev system, a system of functions which satisfy the Haar condition that the determinant of the matrix $[h_i(t_j)]$ is nonzero at n distinct points $t_1 < \cdots < n_n$ in the domain. Chebyshev systems include many commonly used functions, such as algebraic and trigonometric polynomials, splines, and radial functions. Best approximation by these functions is discussed in more detail below.

We remark that the least-squares solution shown in Theorem 9.11 is very general, which includes the familiar truncations of the Fourier series [36] and the wavelet series [29] as best approximation.

9.3.2.1 Polynomial and Rational Approximations

Let π_n be the space of all algebraic polynomials $p_n(t)$ of degree not greater than n. For any continuous function $f(t)$ defined on $[a, b]$, one is typically looking for a best approximant $g_n^* p_n^* \in \pi_n$ for a fixed n, such that

$$\left\| f - p_n^* \right\|_{L_\infty[a,b]} = \min_{p_n \in \pi_n} \left\| f - p_n \right\|_{L_\infty[a,b]} \tag{9.30}$$

This is a best (min–max and uniform) algebraic polynomial approximation problem. Replacing the algebraic polynomials by the nth-order trigonometrix polynomials of the form $\sum_{k=0}^{n}(a_k \cos(kt) + b_k \sin(kt))$ changes the problem to the best trigonometric polynomial approximation, in the same sense as the best algebraic polynomial approximation, for a given function $f \in C[-\pi, \pi]$. This can be much further extended to any Chebyshev system, such as the radial basis functions and polynomial spline functions, which are discussed later. According to the second part of Theorem 9.10, the best uniform polynomial approximation problem (Equation 9.30) always has a solution that, in this case, is unique. Moreover, this best approximant is characterized by the following important sign-alternation theorem. This theorem is also valid for the best uniform approximation from any other Chebyshev system [22,36].

THEOREM 9.12

The algebraic polynomial p_n^* is a best uniform approximant of $f \in C[a, b]$ from π_n iff there exist $n + 2$ points $a \le t_0 < \cdots < t_{n+1} \le b$ such that

$$f(t_k) = p_n^*(t_{k-} = c(-1)^k \left\| f - p_n^* \right\|_{L_\infty[a,b]}, \quad k = 0, 1, \ldots, n+1$$

where $c = 1$ or -1.

An efficient Remes (exchange) algorithm is available for constructing such a best approximant [79].

Another type of function is related to algebraic polynomials: the algebraic rational functions of the form $r_{n,m}(t) = p_n(t)/q_m(t)$, which has finite values on $[a, b]$ with coprime $p_n \in \pi_n$ and $q_m \in \pi_m$. We denote by $R_{n,m}$ the family of all such rational functions, or a subset of them, with fixed integers $n \ge 0$ and $m \ge 1$. Although $R_{n,m}$ is not a compact set or a linear space, the following result can be established [22].

THEOREM 9.13

For any given function $f \in C[a, b]$, there exists a unique $r_{n,m}^*(t) \in R_{n,m}$ such that

$$\left\| f - r_{n,m}^* \right\|_{L_\infty[a,b]} = \inf_{r_{n,m} \varepsilon R_{n,m}} \left\| f - r_{n,m} \right\|_{L\infty[a,b]} \tag{9.31}$$

The optimal solution $r_{n,m}^*(t)$ of Equation 9.31 is called the best uniform rational approximant of $f(t)$ on $[a, b]$ from $R_{n,m}$.

Note that the unique best rational approximant may have different expressions unless it is coprime, as assumed previously. The following theorem [22] characterizes such a best approximant, in which we use $d(p_n)$ to denote the actual degree of p_n, $0 \le d(p_n) \le n$.

THEOREM 9.14

A rational function $r^\star_{n,m} = p^\star_n / q^\star_m$ is a best uniform approximant of $f \in C[a, b]$ from $R_{n,m}$ iff there exist s points $a \le t_1 < \cdots < t_s \le b$, with $s = 2 + min\{n + d(q_m), m + d(p_n)\}$, such that

$$f(t_k) - r^\star_{n,m}(t_k) = c(-1)^k \left\| f - r^\star_{n,m} \right\| L_{\infty[a,b]}, \quad k = 1, \ldots, s$$

where $c = 1$ or -1.

The Remes (exchange) algorithm [79] also can be used for constructing a best rational approximant.

An important type of function approximation, which utilizes rational functions, is the Padé approximation. Given a formal power series of the form

$$f(t) = c_0 + c_1 t + c_2 t^2 + \cdots, \quad t \in [-1, 1]$$

not necessarily convergent, the question is to find a rational function $p_n(t)/q_m(t)$, where n and m are both fixed, to best approximate $f(t)$ on $[-1, 1]$, in the sense that

$$\left| f(t) - \frac{p_n(t)}{q_m(t)} \right| \le c|t|^l, \quad t \in [-1, 1] \tag{9.32}$$

for a "largest possible" integer l. It turns out that normally the largest possible integer is $l = n + m + 1$. If such a rational function exists, it is called the $[n, m]$th-order Padé approximant of $f(t)$ on $[-1, 1]$. The following result is important [22].

THEOREM 9.15

If $f(t)$ is $(n + m + 1)$ times continuously differentiable in a neighborhood of $t = 0$, then the $[n, m]$th-order Padé approximant of $f(t)$ exists, with $l > n$. If $l \le n + m + 1$, then the coefficients $\{a_k\}_{k=0}^n$ and $\{b_k\}_{k=0}^m$ of $p_n(t)$ and $q_m(t)$ are determined by the following linear system of algebraic equations:

$$\sum_{j=0}^{i} \frac{f^j(0)}{j!} b_{i-j} = a_i, \quad i = 0, 1, \ldots, l - 1$$

with $a_{n+j} = b_{m+j} = 0$ for all $j = 1, 2, \ldots$. Moreover, if p_n/q_m is the $[n, m]$th-order Padé approximant of $f(t) = \sum^\infty \{a_k\}_{k=0}^n f_k t^k$, then the approximation error is given by

$$\left| f(t) - \frac{p_n(t)}{q_m(t)} \right| = \sum_{k=n+1}^{\infty} \left(\sum_{j=0}^{m} f_{k-j} b_j \right) \frac{t^k}{q_m(t)}, \quad t \in [-1, 1]$$

Padé approximation can be extended from algebraic polynomials to any other Chebyshev systems [22].

9.3.2.2 Approximation via Splines and Radial Functions

Roughly speaking, spline functions, or simply splines, are piecewise smooth functions that are structurally connected and satisfy some special properties. The most elementary and useful splines are polynomial splines, which are piecewise algebraic polynomials, usually continuous, with a certain degree of smoothness at the connections. More precisely, let

$$a = t_0 < t_1 < \cdots < t_n < t_{n+1} = b$$

be a partition of interval $[a, b]$. The polynomial spline of degree m with knots $\{t_k\}_{k=1}^{n}$ on $[a, b]$ is defined to be the piecewise polynomial $g_{\mathrm{m}}(t)$ that is a regular algebraic polynomial of degree m on each subinterval $[t_k, t_{k+1}]$, $k = 0, \ldots, n$, and is $(m-1)$ times continuously differentiable at all knots [41,88]. We denote the family of these algebraic polynomial splines by $S_m(t_1, \ldots, t_n)$, which is an $(n+m+1)$-dimensional linear space.

Given a continuous function $f(t)$ on $[a, b]$, the best uniform spline approximation problem is to find a $g_m^{\star} \in S_m(t_1, \ldots, t_n)$ such that

$$\left\| f - g_{\mathrm{m}}^{\star} \right\|_{L_\infty[a,b]} = \inf_{g_{\mathrm{m}} \in S_{\mathrm{m}}} \left\| f - g_{\mathrm{m}} \right\|_{L_\infty[a,b]} \tag{9.33}$$

According to the second part of Theorem 9.10, this best uniform approximation problem always has a solution. A best spline approximant can be characterized by the following sign-alteration theorem [72], which is a generalization of Theorem 9.12, from polynomials to polynomial splines.

THEOREM 9.16

The polynomial spline $g_m^{\star}(t)$ is a best uniform approximant of $f \in C\,[a, b]$ from $S_m(t_1, \ldots, t_n)$ iff there exists a subinterval $[t_r, t_{r+s}] \subset [a, b]$, with integers r and $s \leq 1$, such that the maximal number γ of sign-alteration points on this subinterval $[t_r, t_{r+s}]$, namely,

$$f(t_k) - g_{\mathrm{m}}(t_k) = c(-1)^k \left\| f - g_{\mathrm{m}} \right\|_{L_\infty[a,b]}, \quad t_k \in [t_r, t_{r+s}], \quad k = 1, \ldots, \gamma$$

satisfies $\gamma \geq m + s + 1$, where $c = 1$ or -1.

Polynomial splines can be used for least-squares approximation, just like regular polynomials, if the L_∞-norm is replaced by the L_2-norm in Equation 9.33. For example, B-splines, i.e., basic splines with a compact support, are very efficient in least-squares approximation. The spline quasi-interpolant provides another type of efficient approximation, which has the following structure

$$g_{\mathrm{m}}(t) = \sum_k f(t_k) \phi_k^m(t) \tag{9.34}$$

and can achieve the optimal approximation order, where $\{\phi_k^m\}$ is a certain linear combination of B-splines of order m [18].

Spline functions have many variants and generalizations, including natural splines, perfect splines, various multivariate splines, and some generalized splines defined by linear ordinary or partial differntial operators with initial-boundary conditions [27,41,42,44,88].

Splines are essentially local, in the sense of having compact supports, perhaps with the exception perhaps of the thin-plate splines [94], where the domains do not have a boundary.

Radial functions are global, with the property $\phi(r) \to \infty$ as $r \to \infty$ and, normally, $\phi(0) = 0$. Well-conditioned radial functions include $|r|^{2m+1}$, $r^{2m}\log(r)$, $(r^2 + a^2)^{\pm 1/2}$, $0 < a \ll 1$, etc. [80]. Many radial functions are good candidates for modeling nonlinear circuits and systems [63,64]. For example, for l distinct points $\mathbf{t}_1, \ldots, \mathbf{t}_l$ in R^n, the radial functions $\{\phi(|\mathbf{t} - \mathbf{t}_k|)\}_{k=1}^{l}$ are linearly independent, and thus the minimization

$$\min_{\{c_k\}} \left| f(\mathbf{t}) - \sum_{k=1}^{l} c_k \phi\left(\left|\mathbf{t} - \mathbf{t}_k\right|\right) \right|^2 \tag{9.35}$$

at some scattered points can yield a best least-squares approximant for a given function $f(t)$, with some especially desirable features [81]. In particular, an affine plus radial function in the form

$$\mathbf{a} \cdot \mathbf{t} + b + \sum_{k=1}^{l} c_k \phi(\left|\mathbf{t} - \mathbf{t}_k\right|), \quad \mathbf{t} \in R^n \tag{9.36}$$

where $\mathbf{a}$, b, $\{c_k\}_{k=1}^{l}$ are constants, provides a good modeling framework for the canonical piecewise linear representation (Equation 9.12) of a nonlinear circuit [63].

9.3.2.3 Approximation by Means of Interpolation

Interpolation plays a central role in function approximation theory. The main theme of interpolation is this: suppose that an unknown function exists for which we are given some measurement data such as its function values, and perhaps some values of its derivatives, at some discrete points in the domain. How can we use this information to construct a new function that interpolates these values at the given points as an approximant of the unknown function, preferably in an optimal sense? Constructing such a function, called an interpolant, is usually not a difficult problem, but the technical issue that remains is what kind of functions should be used as the interpolant so that a certain meaningful and optimal objective is attained?

Algebraic polynomial interpolation is the simplest approach for the following Lagrange interpolation problem [22,36].

THEOREM 9.17

For arbitrarily given $n+1$ distinct points $0 \le t_0 < t_1 < \cdots < t_n \le 1$ and $n+1$ real values $v_0, v_1, \ldots, v_n$, there exists a unique polynomial $p_n(t)$ of degree n, which satisfies

$$p_n(t_k) = v_k, \quad k = 0, 1, \ldots, n$$

This polynomial is given by

$$p_n(t) = \sum_{k=0}^{n} v_k L_k(t)$$

with the Lagrange basis polynomials

$$L_k(t) := \frac{(t - t_0)\cdots(t - t_{k-1})(t - t_{k+1})(t - t_n)}{(t_k - t_0)\cdots(t_k - t_{k-1})(t_k - t_{k+1})(t_k - t_n)}, \quad k = 0, \ldots, n$$

Moreover, if $f(t)$ is l ($\leq n+1$) times continuously differentiable on $[a, b]$, then the interpolation error is bounded by

$$\left\|f - p_n\right\|_{L_\infty[0,1]} \leq \frac{1}{n!}\left\|f^{(l)}\right\|_{L_\infty[0,1]}\left\|h\right\|_{L_\infty[0,1]}$$

where $h(t) = \prod_{k=0}^{n-1}(t - t_k)$, and $||h||_{L_\infty[0,[1]]}$ attains its minimum at the Chebyshev points $t_k = \cos(2k+1)\pi/2(n+1))$, $k = 0, 1, \ldots, n$.

Note that the set $\{L_k(t)\}_{k=0}^n$ is a Chebyshev system on the interval $[t_0, t_n]$, which guarantees the existence and uniqueness of the solution. This set of basis functions can be replaced by any other Chebyshev system to obtain a unique interpolant.

If not only functional values, but also derivative values, are available and required to be interpolated by the polynomial,

$$p_n^{(i_k)}(t_k) = v_{k,i_k} \quad i_k = 0, \ldots, m_k, \quad k = 0, 1, \ldots, n$$

then we have a Hermite interpolation problem. An algebraic polynomial of degree $d = n + \sum_{k=0}^n m_k$ always exists as a Hermite interpolant. An explicit closed-form formula for the Hermite interpolant also can be constructed. For example, if only the functional values $\{v_k\}_{k=0}^n$ and the first derivative values $\{w_k\}_{k=0}^n$ are given and required to be interpolated, then the Hermite interpolant is given by

$$p_{2n}(t) = \sum_{k=0}^{n}\{v_k A_k(t) + w_k B_k(t)\}$$

where, with notation $L_k'(t_k) := (\mathrm{d}/\mathrm{d}t)L_k(t)|_{t=t_k}$,

$$A_k(t) = \left[1 - 2(t - t_k)L_k'(t_k)\right]L_k^2(t) \quad \text{and} \quad B_k(t) = (t - t_k)L_k^2(t)$$

in which $L_k(t)$ are Lagrange basis polynomials, $k = 0, 1, \ldots, n$.

However, if those derivative values are not consecutively given, we have a Hermite–Birkhoff interpolation problem, which is not always uniquely solvable [61].

The preceding discussions did not take into consideration any optimality. The unique algebraic polynomial interpolant obtained previously may not be a good result in many cases. A well-known example is provided by Runge, in interpolating the continuous and smooth function $f(t) = 1/(1 + 25t^2)$ at $n+1$ equally spaced points on the interval $-[1, 1]$. The polynomial interpolant $p_n(t)$ shows extremely high oscillations near the two end-points ($|t| > 0.726, \ldots$). Hence, it is important to impose an additional optimality requirement (e.g., a uniform approximation requirement) on the interpolant. In this concern, the following result is useful [36].

THEOREM 9.18

Given a continuous function $f \in C - [1, 1]$, let $\{t_k\}_{k=1}^n$ be the Chebyshev points on $-[1, 1]$; namely, $t_k = \cos((2k-1)\pi/(2n))$, $k = 1, \ldots, n$. Let also $P_{2n-1}(t)$ be the polynomial of degree $2n-1$ that satisfies the following special Hermite interpolation conditions: $P_{2n-1}(t_k) = f(t_k)$ and $P_{2n-1}(t_k) = f(t_k)$ and $P'_{2n-1}(t_k)$ $t(k) = 0$, $k = 1, \ldots, n$. Then, the interpolant $P_{2n}(t)$ has the uniform approximation property

$$\left\|f - P_{2n-1}\right\|_{L_\infty[-1,1]} \to 0 \quad \text{as} \quad n \to \infty$$

Because polynomial splines are piecewise algebraic polynomials, similar uniform approximation results for polynomial spline interpolants may be established [41,72,88].

Finally, a simultaneous interpolation and uniform approximation for a polynomial of a finite (and fixed) degree may be very desirable in engineering applications. The problem is that given and $f \in C[a, b]$ with $n+1$ points $a \leq t_0 < t_1 < \cdots < t_n \leq b$ and a given $\varepsilon > 0$, find a polynomial $p(t)$ of finite degree (usually, larger than n) that satisfies both

$$\|f - p\|_{L_\infty[a,b]} < \varepsilon \quad \text{and} \quad p(t_k) = f(t_k), \quad k = 0, 1, \ldots, n$$

The answer to this question is the Walsh theorem, which states that this is always possible, even for complex polynomials [36]. Note that natural splines can also solve this simultaneous interpolation and uniform-approximation problem.

9.3.3 Best Approximation of Linear Functionals

As already mentioned, a functional is a mapping that maps functions to values. Definite integrals, derivatives evaluated at some points, and interpolation formulas are good examples of linear functionals.

The best approximation problem for a given bounded linear functional, L, by a linear combination of n independent and bounded linear functionals $L_1, \ldots, L_n$, all defined on the same normed linear space X of functions, can be similarly stated as follows: determine n constant coefficients $\{a_k^\star\}_{k=1}^n$ such that

$$\left\| L - \sum_{k=1}^{n} a_k^\star L_k \right\|_{X^\star} = \min_{\{a_k\}} \left\| L - \sum_{k=1}^{n} a_k L_k \right\|_{X^\star} \tag{9.37}$$

where $X^\star$ is the dual space of X, which is also a normed linear space. A basic result is described by the following theorem [36].

THEOREM 9.19

If X is a Hilbert space, then the best approximation problem (Equation 9.37) *is uniquely solvable. Moreover, if r and $\{r_k\}_{k=1}^n$, are the functional representors of L and $\{L_k\}_{k=1}^n$, respectively, then*

$$\left\| r - \sum_{k=1}^{n} a_k r_k \right\|_{X^\star} = \min \Rightarrow \left\| L - \sum_{k=1}^{n} a_k L_k \right\|_{X^\star} = \min$$

It is important to note that for linear functionals, we have an interpolation problem: given bounded linear functionals L and $\{L_k\}_{k=1}^n$, all defined on a normed linear space X, where the last n functionals are linearly independent on X, and given also n points $x_k \in X$, $k = 1, \ldots, n$, determine n constant coefficients $\{a_k\}_{k=1}^n$, such that

$$\sum_{k=1}^{n} a_k L_k(x_i) = L(x_i), \quad i = 1, \ldots, n$$

Obviously, this problem is uniquely solvable. Depending on the specific formulation of the linear functionals, a bulk of the approximation formulas in the field of numerical analysis can be derived from this general interpolation formulation.

Finally, convergence problems also can be formulated and discussed for bounded linear functionals in a manner similar to interpolation and approximation of functions. The following result is significant [36].

THEOREM 9.20

Let L and $\{L_k\}_{k=1}^{\infty}$ be bounded linear functionals defined on a Banach space X. A necessary and sufficient condition for

$$\lim_{k\to\infty} \|L_k - L\|_{X^*} = 0$$

is that $\{L_k\}_{k=1}^{\infty}$ are uniformly bounded:

$$\|L_k\|_{X^*} \le M < \infty \quad \forall k = 1, 2, \ldots$$

and there is a convergent sequence $\{x_i\}_{i=1}^{\infty} \in X$, such that

$$\lim_{k\to\infty} L_k(x_i) = L(x_i) \quad \text{for each } i = 1, 2, \ldots$$

9.3.4 Artificial Neural Network for Approximation

Artificial neural networks offer a useful framework for signal and system approximations, including approximation of continuous and smooth functions of multivariables. Due to its usually mutilayered structure with many weights, an artificial neural network can be ''trained,'' and hence has a certain ''learning'' capability in data processing. For this reason, artificial neural networks can be very efficient in performing various approximations. The main concern with a large-scale artificial neural network is its demand on computational speed and computer memory.

Both parametrized and nonparametrized approaches to approximations use artificial neural networks. In the parametrized approach the activation function, basic function, and network topology are all predetermined; hence, the entire network structure is fixed, leaving only a set of parameters (weights) to be adjusted to best fit the available data. In this way, the network with optimal weights becomes a best approximant, usually in the least-squares sense, to a nonlinear system. Determining the weights from the data is called a training process. Back-propagation multilayered artificial neural networks are a typical example of the parametrized framework. The nonparametrized approach requires that the activation and/or basic functions also be determined, which turns out to be difficult in general.

To illustrate how an artificial neural network can be used as a system or signal approximant, we first describe the structure of a network. The term neuron used here refers to an operator or processing unit, which maps R''–R, with the mathematical expression

$$o_i = f_a(f_b(\mathbf{i}_i, \mathbf{w}_i)) \tag{9.38}$$

where $\mathrm{i}_i = [i_1, \ldots, i_n]^T$ is the input vector, $\mathbf{w}_i = [w_{i1}, \ldots, w_{in}]^T$ is the weight vector associated with the ith neuron, o_i the output of the ith neuron, f_a the activation function (usually sigmoidal or Gaussian), and

f_b the basic function (which can be linear, affine, or radial). For example, if an affine basic function is used, Equation 9.38 takes on the form

$$o_i = f_a(\mathbf{i}_i \cdot \mathbf{w}_i + b_i) \tag{9.39}$$

where b_i is a constant.

A fully connected feed-forward artificial neural network is generally a multi-input/multi-output network, where the output from each neuron of each layer is an input to each neuron of the next layer. Such a network, arranged in one input layer, multiple hidden layers, and one output layer, can be constructed as follows (see Figure 9.6). Suppose we have n-inputs, n_L-outputs and $L-1$ hidden layers, and a linear basic function is used with a sigmoidal activation function $f_a(t) = \sigma(t)$:

$$\sigma(t) \to \begin{cases} 1 & \text{as } t \to +\infty \\ 0 & \text{as } t \to -\infty \end{cases}$$

Also, let $o_{l,i}$ be the output of the ith neuron at the lth layer and $w_{l,i} = [w_{l,i,1} \cdots w_{l,i,s}]^T$ be the weight vector associated with the same neuron connected to the neurons at the $(l-1)$st layer. Then, we have

$$o_{l,i} = \sigma\left(\sum_{j=1}^{n_l} 0_{l-1,j} w_{l,i,j} + w_{l,i,0}\right) \tag{9.40}$$

Inductively, the output of the ith neuron in the last (the Lth) layer is given by

$$o_{L,i} = \sigma\left(\sum_{j=1}^{n_{L-1}} w_{L,i,j}\left(\cdots \sigma\left(\sum_{q=1}^{n_i} w_{1,p,q} i_{n_0} + w_{1,p,o}\right) + w_{2,p,0}\right) + \cdots + w_{L,i,o}\right) \tag{9.41}$$

where $i = 1, \ldots, n_L$.

The following best uniform approximation property of an artificial neural network is a fundamental result in neural-network approximation [35].

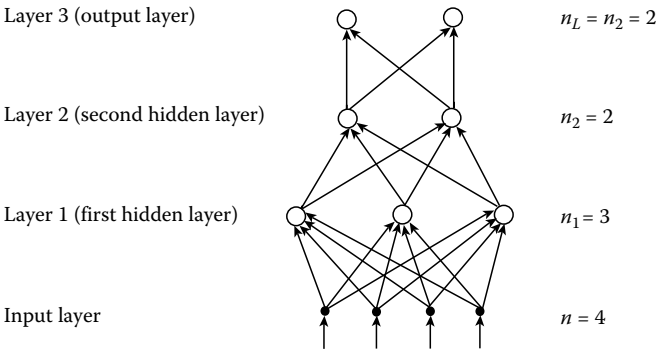

FIGURE 9.6 A two-hidden layer, feed-forward artificial neural network.

THEOREM 9.21

Let $f(t)$ be a continuous function defined on a compact subset $\Omega \subset R^n$. Then, for any $\in > 0$, there exists an integer $m \geq 1$ and real parameters $\{c_k, w_{ki}, b_k\}_{k=1}^{m}$ such that using any nonconstant, bounded, and monotonically increasing continuous function f_a as the activation function, the artificial neural network can uniformly approximate f on Ω, in the sense that

$$\|f - N\|_{L_\infty(\Omega)} < \varepsilon$$

where the network has the form

$$N(\mathbf{t}) = \sum_{k=1}^{m} c_k f_a\left(\sum_{i=1}^{n} w_{k,i} t_i + b_k\right), \quad \mathbf{t} = [t_1 \cdots t_n]^T \in \Omega$$

Neural networks can also provide approximation for a mapping together with its derivatives [52]. On the other hand, neural networks can provide localized approximation, which is advantageous in that if a certain portion of the data is perturbed, only a few weights in the network need to be retrained. It was demonstrated that a single hidden layered network cannot provide localized approximation of continuous functions on any compact set of a Euclidean space with dimension higher than one; however, two hidden layers are sufficient for the purpose [33].

As mentioned previously, the basic function f_b in a network need not be linear. An artificial neural network, using a radial function for f_b, can also give very good approximation results [76]. Also, as a system approximation framework, stability of a network is very important [68]. Finally, a major issue that must be addressed in designing a large-scale network is the computer memory, which requires some special realization techniques [67].

9.4 Identification

System identification is a problem of finding a good mathematical model, preferably optimal in some sense, for an unknown physical system, using some available measurement data. These data usually include system outputs and sometimes also inputs. Very often, the available data are discrete, but the system to be identified is continuous [97].

A general formulation of the system identification problem can be described as follows. Let S be the family of systems under consideration (linear or nonlinear, deterministic or stochastic, or even chaotic), with input u and output γ, and let $R_{(u,y)}$ be the set of I–O data. Define a mapping M: $S \rightarrow R_{(u,y)}$. Then, a system $\mathcal{F} \in S$ is said to be (exactly) identifiable if the mapping M is invertible, and the problem is to find the $\mathcal{F} = M^{-1}(\tilde{u},\tilde{y})$ using the available data $(\tilde{u}, \tilde{y}) \in R_{(u,y)}$. Here, how to define the mapping M, linear or not, is the key to the identification problem. Usually, we also want M^{-1} to be causal for the implementation purpose.

The first question about system identification is of course the identifiability [82]. Not all systems, not even linear deterministic systems, are exactly identifiable [21]. Because many physical systems are not exactly identifiable, system identification in a weaker sense is more realistic.

Suppose that some inputs and their corresponding outputs of an unknown system, $\mathcal{S}_1$, are given. We want to identify this unknown system by an approximate model, $\mathcal{S}_2$, using the available I–O data, such that the corresponding outputs produced by any input through $\mathcal{S}_1$ and $\mathcal{S}_2$, respectively, are "very close" under certain meaningful measure. If the structure of $\mathcal{S}_1$ (hence, $\mathcal{S}_2$) is known *a priori*, then what we need is to identify some system parameters. If the structure of $\mathcal{S}_1$ is not clear, the task becomes much more difficult because we must determine what kind of model to choose in approximating the unknown system [50]. This includes many crucial issues such as the linearity and dimension (or order) of the

model used. In particular, if the system is nonlinear and contains uncertainties, special techniques from set-valued mapping and differential inclusion theories may be needed [58].

Usually, the basic requirement is that $\mathcal{S}_2$ should be a best approximant of $\mathcal{S}_1$ from a desired class of simple and realizable models under a suitably chosen criterion. For example, the least-squares operator approximation discussed previously can be thought of as an identification scheme. For this reason, identification in the weak sense is traditionally considered to be one of the typical best approximation problems in mathematics. If a minimal, worst-case model-matching error bound is required, the approximation is known as the optimal recovery problem, for either functions or functionals [65,66], or for operators [15,45]. In system engineering it usually refers to system identification or reconstruction, with an emphasis on obtaining an identified model or a reconstruction scheme.

Generally speaking, system identification is a difficult problem, often leading to nonunique solutions when it is solvable. This is typically true for nonlinear circuits and systems. In systems and control engineering, an unknown system is identified by a desired model such that they can produce "close enough" outputs from the same input, measured by a norm in the signal space, such as L_p, l_p, or H_p $(1 \le p \le \infty)$. For dynamic systems, however, this norm-measure is generally not a good choice because one is concerned with nonlinear dynamics of the unknown system, such as limit cycles, attractors, bifurcations, and chaos. Hence, it is preferable to have an identified model that preserves the same dynamic behavior. This is a very challenging research topic; its fundamental theories and methodologies are still open for further exploration.

9.4.1 Linear Systems Identification

Compared to nonlinear systems, linear systems, either autoregressive with moving-average (ARMA) or state-space models, can be relatively easily identified, especially when the system dimension (order) is fixed. The mainstream theory of linear system identification has the following characteristics [37]:

1. The model class consists of linear, causal, stable, finite-dimensional systems with constant parameters.
2. Both system inputs and their corresponding outputs are available as discrete or continuous data.
3. Noise, if any, is stationary and ergodic (usually with rational spectral densities), white and uncorrelated with state vectors in the past.
4. Criteria for measuring the closeness in model-matching are of least-squares type (in the deterministic case) or of maximum likelihood type (in the stochastic case).
5. Large-scale linear systems are decomposed into lower-dimensional subsystems, and nonlinear systems are decomposed into linear and simple (e.g., memoryless) nonlinear subsystems.

Because for linear systems, ARMA models and state-space models are equivalent under a nonsingular linear transformation [17,32], we discuss only ARMA models here.

An (n, m, l)th-order ARMAX model (an ARMA model with exogenous noisy inputs) has the general form

$$a\left(z^{-1}\right)\mathbf{y}(t) = b\left(z^{-1}\right)\mathbf{u}(t)c\left(z^{-1}\right)\varepsilon(t), \quad t = \ldots, -1, 0, 1, \ldots \tag{9.42}$$

in which z^{-1} is the time-delay operator defined by $z^{-1}\mathbf{f}(t) = \mathbf{f}(t-l)$, and

$$a\left(z^{-1}\right) = \sum_{i=0}^{n} A_i z^{-i}, \quad b\left(z^{-1}\right) = \sum_{j=0}^{m} B_j z^{-j}, \quad c\left(z^{-1}\right) = \sum_{k=1}^{l} C_k z^{-k}$$

with constant coefficient matrices $\{A_i\}$, $\{B_j\}$, $\{C_k\}$ of appropriate dimensions, where $A_0 = I$ (or, is nonsingular). In the ARMAX model (Equation 9.42) $\mathbf{u}(t)$, $\mathbf{y}(t)$, and $\varepsilon(t)$ are considered to be system

input, output, and noise vectors, respectively, where the input can be either deterministic or random. In particular, if $l = 0$ and $n = 0$ (or $m = 0$), then Equation 9.42 reduces to a simple moving-average (MA) (or autoregressive, AR) model. Kolmogorov [56] proved that every linear system can be represented by an infinite-order AR model. It is also true that every nonlinear system with a Volterra series representation can be represented by a nonlinear AR model of infinite order [53].

The system identification problem for the ARMAX model (Equation 9.42) can now be described as follows. Given the system I–O data $(\mathbf{u}(t), \mathbf{y}(t))$ and the statistics of $\varepsilon(t)$, determine integers (n, m, l) (system-order determination) and constant coefficient matrices $\{A_i\}$, $\{B_j\}$, $\{C_k\}$ (system-parameter identification). While many successful methods exist for system parameter identification [3,23,49,60], system order determination is a difficult problem [47].

As already mentioned, the identifiability of an unknown ARMAX model using the given I–O data is a fundamental issue. We discuss the exact model identification problem here. The ARMAX model (Equation 9.42) is said to be exactly identifiable if $(\tilde{a}(z^{-1}), \tilde{b}(z^{-1}), \tilde{c}(z^{-1}))$ is an ARMAX model with $\tilde{n} \le n$, $\tilde{m} \le m$, and $\tilde{l} \le l$, such that

$$\begin{cases} [\tilde{a}(z^{-1})]^{-1}\tilde{b}(z^{-1}) = [a(z^{-1})]^{-1}b(z^{-1}) \\ [\tilde{a}(z^{-1})]^{-1}\tilde{c}(z^{-1}) = [a(z^{-1})]^{-1}c(z^{-1}) \end{cases}$$

Note that not all ARMAX models are exactly identifiable in this sense. A basic result about this identifiability is the following [21].

THEOREM 9.22

The ARMAX model (Equation 9.42) (*with* $t \ge 0$) *is exactly identifiable iff* $a(z^{-1})$, $b(z^{-1})$, *and* $c(z^{-1})$ *have no common left factor and the rank of the constant matrix* $[A_n, B_m, C_l]$, *consisting of the highest-order coefficient terms in* $a(z^{-1})$, $b(z^{-1})$, $c(z^{-1})$, *respectively, is equal to the dimension of the system output* $\mathbf{y}$.

Even if an unknown system is exactly identifiable and its identification is unique, how to find the identified system is still a very technical issue. For simple AR models, the well-known Levinson–Durbin algorithm is a good scheme for constructing the identified model; for MA models, one can use Trench–Zohar and Berlekamp–Massey algorithms. There exist some generalizations of these algorithms in the literature [23]. For stochastic models with significant exogenous noise inputs, various statistical criteria and estimation techniques, under different conditions, are available [82]. Various recursive least-squares schemes, such as the least-mean-square (LMS) algorithm [96], and various stochastic searching methods, such as the stochastic gradient algorithm [49], are popular. Because of their simplicity and efficiency, the successful (standard and extended) Kalman filtering algorithms [16,30] have also been widely applied in parameters identification for stochastic systems [13,17,62], with many real-world applications [92].

Finally, for linear systems, a new framework, called the behavioral approach, is proposed for mathematical system modeling and some other related topics [2,98].

9.4.2 Nonlinear Systems Identification

Identifying a nonlinear system is much more difficult than identifying a linear system in general, whether it is in the exact or in the weak sense, as is commonly known and can be seen from its information-based complexity analysis [15,45].

For some nonlinear systems with simple Volterra series representations, the least-squares approximation technique can be employed for the purpose of identification in the weak sense [8]. As a simple

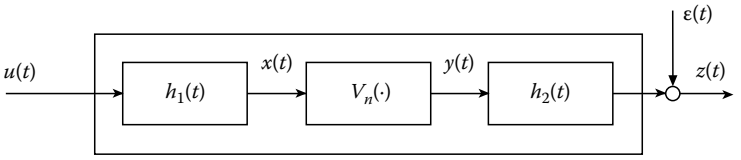

FIGURE 9.7 A cascaded linear–nonlinear system with noise input.

illustrative example, consider the cascaded nonlinear system with noise input shown in Figure 9.7. In this figure $h_1(t)$ and $h_2(t)$ are unit impulse responses of two linear subsystems, respectively, and $V_n(\cdot)$ is a memoryless nonlinear subsystem which is assumed to have an nth-order Volterra polynomial in the special form

$$y(t) = \sum_{k=1}^{n} c_k \int_0^t \cdots \int_0^t \phi_k(\tau_1, \ldots, \tau_k) x(\tau_1) \cdots x(\tau_k) \mathrm{d}\tau_1 \cdots \mathrm{d}\tau_k \tag{9.43}$$

where all the Volterra kernels $\{\phi_k\}_{k=0}^n$ are assumed to be known, but the constant coefficients $\{c_k\}_{k=0}^n$ must be identified.

It is clear from Figure 9.7 that the output of the cascaded system can be expressed via convolution-type integrals as

$$z(t) = c_1 \left(\int h_2 \phi_1 h_1 u \right)(t) + \cdots + c_n \left(\int \cdots \int h_2 \phi_1 h_1 \cdots h_2 u \cdots u \right)(t) + \varepsilon(t) \tag{9.44}$$

Now, because all the integrals can be computed if the input function $u(t)$ is given, the standard least-squares technique can be used to determine the unknown constant coefficients $\{c_k\}_{k=0}^n$, using the measured system output $z(t)$.

A neural network implementation of Volterra series model identification is described in Ref. [1]. Neural network for system identification has been used in many different cases, as can also be seen from Ref. [70].

Finally, we consider one approach to nonlinear systems identification which combines the special structure of the generalized Fock space of Volterra series (Theorem 9.3) and the ''training'' idea from neural networks discussed previously (Theorem 9.21). For simplicity, consider the scalar nonlinear system

$$y(t) + f(y(t-1), y(t-2), \ldots, y(t-n)) = u(t), \quad t = 0, 1, \ldots \tag{9.45}$$

where n is a fixed integer, with the given initial conditions $y(-1) = y_1, \ldots, y(-n) = y_n$. Introducing a simple notation

$$y^{t-1} = (y(t-1), \ldots, y(t-n)) \tag{9.46}$$

we first rewrite this system as

$$\gamma(t) + f\left(\gamma^{t-1}\right) = u(t) \tag{9.47}$$

Then, we denote by E^n as the n-dimensional Euclidean space of continuous functions and let $u^1, \ldots, u^m \in E^n$, called the domain training samples, be given data vectors that are componentwise nonzero and

distinct, namely, $u_i^k \neq u_j^k$ if $i \neq j$ for all $k = 1, \ldots, m$, $1 \leq i, j \leq n$. Here, Equation 9.46 also has been used for these domain training samples. Also, let $r_1, \ldots, r_m$, be given real numbers, called the corresponding range training samples. The identification problem is to find an approximate system, $f^\star(\cdot)$, among all Volterra series representations from the generalized Fock space formulated in Theorem 9.3, such that $f^\star$ maps all the domain training samples to their corresponding range training samples:

$$f^\star(u^k) = r_k, \quad k = 1, \ldots, m \tag{9.48}$$

and $f^\star$ has the minimum operator-norm among all such candidates. The following theorem provides an answer to this problem [45].

THEOREM 9.23

There is a unique element $f^\star$ of minimum norm in the generalized Fock space defined in Theorem 9.3, *with the domain $\Omega = E^n$ therein, that satisfies the constraint* (Equation 9.48). *Moreover, $f^\star$ has the following expression*:

$$f^\star(v) = \sum_{k=1}^{m} a_k K\left(u^k, v\right) \quad \forall v \in E^n$$

where $K(\cdot, \cdot)$ is the reproducing kernel defined in Theorem 9.3, and the system parameters are determined by

$$\begin{bmatrix} a_1 \\ \vdots \\ a_m \end{bmatrix} = \begin{bmatrix} K(u^1, u^1) & \cdots & K(u^1, u^m) \\ \vdots & & \vdots \\ K(u^m, u^1) & \cdots & K(u^m, u^m) \end{bmatrix}^{-1} \begin{bmatrix} r_1 \\ \vdots \\ r_m \end{bmatrix}$$

Here, it should be noted that because K is a reproducing kernel, the set of functions $\{K(u^k, \cdot)\}_{k=1}^m$ are linearly independent, so that the above inverse matrix exists.

Also, note that this system identification method can be applied to higher-dimensional systems and the continuous-time setting [45].

9.4.3 Nonlinear Dynamic Systems Identification from Time Series

Measurement (observation) data obtained from an unknown system are often available in the form of time series. There are some successful techniques for identification of linear and nonlinear systems from time series if the time series is generated from Gaussian white noise. For example, for linear systems we have the Box–Jenkins scheme and for nonlinear systems, a statistical method using a nonlinear filter [75].

Concerned with nonlinear dynamic systems, however, statistical methods and the commonly used norm-measure criterion may not be capable of identifying the system dynamics in general. This is because the main issue in this concern is the nonlinear dynamic behavior of the unknown system, such as limit cycles, attractors, bifurcations, and chaos. Hence, it is preferable that the identified model can preserve the nonlinear dynamics of the unknown system. This turns out to be a very challenging task; many fundamental theories and methodologies for this task remain to be developed.

When an unknown nonlinear dynamic system is measured to produce a set of continuous or discrete data (a time series), a natural approach for studying its dynamics from the available time series is to take an integral transform of the series, so as to convert the problem from the time domain to the frequency domain. Then, some well-developed engineering frequency domain methods can be applied to perform analysis and computation of the nonlinear dynamics [69].

One common approach formulated in the time domain is the (delay-coordinate) embedding method that can be applied to reconstruct (identify) an unknown nonlinear dynamic model from which only a set of discrete measurement data (a time series) is available.

Let us consider the problem of identifying a periodic trajectory of an unknown, nonlinear dynamic system using only an experimental time series measured from the system. Let $\{r_k\}$ be the available data. The embedding theory guarantees this can be done in the space R^m with the embedding dimension $m \geq 2n+1$, where n is the dimension of the dynamic system 93], or $m \geq 2d_A$, where d_A is the dimension of the attractor [87]. A way to achieve this is to use the delay-coordinate technique, which approximates the unknown, nonlinear dynamics in R^m by introducing the embedding vector

$$\mathbf{r}_k = \left[r_k r_{k-\mu} \cdots r_{k-(m-1)\mu}\right]^{\mathrm{T}} \tag{9.49}$$

where μ is the time-delay step. This embedding vector provides enough information to characterize the essence of the system dynamics and can be used to obtain an experimental Poincaré map, which helps in understanding the dynamics. For example, one may let the map be the equation of the first component of the vector being equal to a constant: $r_{ki} = \text{constant}$. This procedure yields the successive points

$$\xi_i := \left[r_{k_i-\mu} \cdots r_{k_i-(m-1)\mu}\right]^{\mathrm{T}} \tag{9.50}$$

at the ith piercing of the map by the trajectory (or the vector r_k), where k_i is the time index at the ith piercing. Then, one can locate the periodic trajectories of the unknown system using the experimental data [4,14]. In this approach, however, determining a reasonably good time-delay step size, i.e., the real number μ in Equation 9.49, remains an open technical problem.

Finally, we note that the embedding method discussed previously has been applied to the control of chaotic circuits and systems [19,20,74].

10.1 Transformation of Nonlinear Dynamical Circuit Equations

One of the basic problems in studying linear and nonlinear dynamical electrical circuits is the analysis of the underlying descriptive equations and their solution manifold. In the case of linear or affine circuits, the constitutive relations of circuit elements are restricted to classes of linear or affine functions and, therefore, possess rather restricted types of solutions. In contrast, the solution manifold of nonlinear networks may consist of many different types. Naturally, it is useful to decompose nonlinear networks into classes that possess certain similarities. One approach, for example, is to consider the solution manifold and to decompose solutions into similar classes. Furthermore, if the descriptive differential equations of dynamic networks are considered to be mathematical sets, their decompositions will be of interest.

The technique of equivalence relations is the preferred method used to decompose a set of mathematical objects into certain classes. A well-known approach to define equivalence relations uses transformation groups. For example, real symmetric $n \times n$ matrices $\mathbb{R}_s^{n\times n}$ can be decomposed into equivalence classes by using the general linear transformation group $GL(n; \mathbb{R})$, and by applying the following similarity transformation:

$$\mathbf{M} \rightarrow \mathbf{U}^{-1}\mathbf{M}\mathbf{U}, \tag{10.1}$$

where $U \in GL(n; \mathbb{R})$. By applying $GL(n; \mathbb{R})$, the set $\mathbb{R}_s^{n\times n}$ is decomposed into similarity classes that are characterized by their eigenvalues. Furthermore, each class of $\mathbb{R}_s^{n\times n}$ contains a diagonal matrix $\mathbf{D}$ with these eigenvalues on the main diagonal [35]. These eigenvalues are invariants of the group and characterize different classes. These and other related results can be applied to classify linear and affine dynamical networks [20]. Thus, properties of the A-matrix of the state-space equations are used for the classification. Note that each linear and affine dynamical network can be described in state-space form.

We discuss the theory of equivalence of linear and affine dynamical networks only as special cases of nonlinear networks. An interesting reformulation of the classical material of the decomposition of real matrices by using similarity transformations in the framework of one-parameter groups in $GL(n; \mathbb{R})$ is given by Ref. [21].

A classification of the vector fields is needed in order to classify differential equations of the type $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$, where $\mathbf{x} \in \mathbb{R}^n$ and $\mathbf{f}$: $\mathbb{R}^n \to \mathbb{R}^n$ is a vector field on $\mathbb{R}^n$. A first concept is established by a k-times differentiable change of coordinates that transforms a differentiable equation $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$ into $\dot{\mathbf{y}} = \mathbf{g}(\mathbf{y})$ by a function $\mathbf{h} \in C^k$. C^k is the set of k-times continuously differentiable functions $\mathbf{h}$: $\mathbb{R}^n \to \mathbb{R}^n$. In other words, two vector fields are called *C^k-conjugate* if there exists a C^k-diffeomorphism $\mathbf{h}$ ($k \geq 1$) such that $\mathbf{h} \circ \mathbf{f} = \mathbf{g} \circ \mathbf{h}$. An equivalent formulation uses the concept of flows associated with differential equations $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$. A flow is a continuously differentiable function φ: $\mathbb{R} \times \mathbb{R}^n \to \mathbb{R}^n$ such that, for each $t \in \mathbb{R}$, the restriction $\varphi(t, \cdot) =: \varphi_t(\cdot)$ satisfies $\varphi_0 = \mathrm{id}_{\mathbb{R}^n}$ and $\varphi_t \circ \varphi_s = \varphi_{t+s}$ for all $t, s \in \mathbb{R}^n$. The relationship to a associated differential equation is given by

$$\mathbf{f}(\mathbf{x}) := \frac{\mathrm{d}\varphi_t}{\mathrm{d}t}(\mathbf{x})\bigg|_{t=0} = \lim_{\varepsilon \to 0} \left\{ \frac{\varphi(\varepsilon, \mathbf{x}) - \varphi(0, \mathbf{x})}{\varepsilon} \right\}. \tag{10.2}$$

For more details see, for example, Ref. [13]. Two flows φ_t and Ψ_t (associated with $\mathbf{f}$ and $\mathbf{g}$, respectively) are called C^k-conjugate, if there exists a C^k-diffeomorphism $\mathbf{h}$ ($k \geq 1$) such that $\mathbf{h} \circ \varphi_t = \Psi_t \circ \mathbf{h}$. In the case that $k = 0$, the term C^k-conjugate needs to be replaced by C^0 or topological conjugate and $\mathbf{h}$ is a homeomorphism. Clearly, differential equations, vector fields, and flows are only alternative ways of presenting the same dynamics.

By the previous definitions, equivalence relations can be generated and the set of differential equations $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$ (as well as vector fields and flows) can be decomposed in certain classes of inequivalent differential equations and so on with different behavior (with respect to the equivalence relation). Although C^k-conjugate seems to be a natural concept for classifying differential equations, vector fields, and flows, this approach leads to a very refined classification (up to a diffeomorphism). In other words, too many systems become inequivalent. We consider two examples for illustrating this statement. Consider the nonlinear dynamical circuit (see Figure 10.1) with the descriptive equations (in a dimensionless form):

$$C\frac{\mathrm{d}v_C}{\mathrm{d}t} = i(v_C, i_L) - i_L, \tag{10.3}$$

$$L\frac{\mathrm{d}i_L}{\mathrm{d}t} = v_C + v(v_C, i_L), \tag{10.4}$$

where the nonlinear functions i: $\mathbb{R}^2 \to \mathbb{R}$ and v: $\mathbb{R}^2 \to \mathbb{R}$ characterize the nonlinear controlled sources. If these controlled sources are given in the following form:

$$i = i(v_C, i_L) := -\frac{1}{2}\left(\sqrt{v_C^2 + i_L^2 - 1}\right) v_C, \tag{10.5}$$

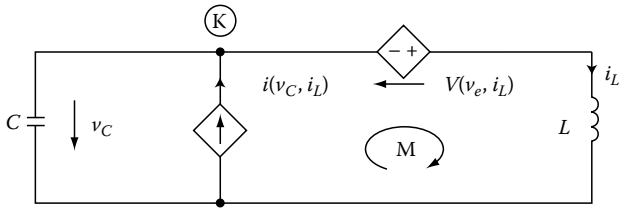

FIGURE 10.1 Circuit with nonlinear controlled sources.

$$v = v(v_C, i_L) = -\frac{1}{2}\left(\sqrt{v_C^2 + i_L^2 - 1}\right) i_L, \tag{10.6}$$

we obtain the following concrete descriptive equations for the circuits

$$C\frac{\mathrm{d}v_C}{\mathrm{d}t} = -\frac{1}{2}\left(\sqrt{v_C^2 + i_L^2 - 1}\right) v_C - i_L, \tag{10.7}$$

$$L\frac{\mathrm{d}i_L}{\mathrm{d}t} = v_C - \frac{1}{2}\left(\sqrt{v_C^2 + i_L^2 - 1}\right) i_L. \tag{10.8}$$

These equations can be transformed into the following form if we use polar coordinates (r, ϕ) by $v_C := r\cos(\phi t)$ and $i_L := r\sin(\phi t)$:

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \frac{1}{2}(1 - r)r, \quad \dot{\phi} = 1, \tag{10.9}$$

where $C = 1$ and $L = 1$. If we consider the same circuit with the parameters $C = 1/2$ and $L = 1/2$ we obtain the slightly different descriptive equations:

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \frac{1}{2}(1 - r)r, \quad \dot{\phi} = 2. \tag{10.10}$$

Note that both differential equations differ only by a time rescaling $t \to 2t$. The question arises whether these two sets of equations are C^1 conjugate.

It can be demonstrated (see Refs. [2,29]) that if a diffeomorphism converts a singular point of a vector field into a singular point of another vector field, then the derivative of the diffeomorphism converts the Jacobian matrix of the first vector field at its singular point into the Jacobian matrix of the second field at its singular point. Consequently, these two Jacobian matrices are in the same similarity class and therefore, have the same eigenvalues. In other words, the eigenvalues of the Jacobian matrices are invariants with respect to a diffeomorphism, and the corresponding decomposition of the set of vector fields (differential equations and flows) is continuous rather than discrete. Obviously, the eigenvalues of Equations 10.9 and 10.10 ($\lambda_1 = 1/2$, $\lambda_2 = 1$ and $\tilde{\lambda}_1 = 1$, $\tilde{\lambda}_2 = 2$, respectively) are different and, in conclusion, the two vector fields are not C^1 conjugate. Moreover, these two vector fields are not topologically or C^0 conjugate. A more "coarse" equivalence relation is needed in order to classify these vector fields, differential equations, and flows. As mentioned above, a time rescaling transforms the differential equations (Equations 10.9 and 10.10) into one another and therefore it should be no essential difference between these two differential equations. This motivates the following definition.

Definition 10.1: *Two flows φ_t and ψ_t are called C^k equivalent ($k \geq 1$) if there exists a C^k diffeomorphism* $\mathbf{h}$ *that takes each orbit of ψ_t into an orbit of ψ_t, preserving their orientation. In the case of $k = 0$, the flows are called C^0 or topologically equivalent.*

Because C^k equivalence preserves the orientation of orbits, the relation $\mathbf{h}(\varphi_t(\mathbf{x})) = \varphi_{\tau_{y(y)}}$ with $\mathbf{y} = \mathbf{h}(\mathbf{x})$ between φ_t and ψ_t is allowed, where τ_y is an increasing function of t for every $\mathbf{y}$.

It can be demonstrated (see Ref. [29]) that the eigenvalues of the Jacobian matrices of the two vector fields must be in the same ratio if a monotonic time rescaling is allowed. Therefore, the two vector fields (Equations 10.9 and 10.10) are C^1 equivalent. However, the two linear vector fields of the equations

$$\begin{pmatrix} \dot{x} \\ \dot{y} \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}, \quad \begin{pmatrix} \dot{x} \\ \dot{y} \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1+\varepsilon \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} \tag{10.11}$$

are not C^1 equivalent for any $\varepsilon \neq 0$, although the solutions of the differential equations are very close for small ε in a finite time interval. In conclusion, topological equivalence is the appropriate setting for classifying differential equations, vector fields, and flows. Note, that the decomposition of the set of linear vector fields into equivalence classes using the topological equivalence does not distinguish between nodes, improper nodes, and foci, but does distinguish between sinks, saddles, and sources. This suggests the following theorem [3]:

THEOREM 10.1

Let $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ ($\mathbf{x} \in \mathbb{R}^n$ *and* $\mathbf{A} \in \mathbb{R}^{n \times n}$) *define a hyperbolic flow on* $\mathbb{R}^n$, *e.g., the eigenvalues of* $\mathbf{A}$ *have only nonzero parts, with* n_s *eigenvalues with a negative real part. Then,* $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x}$ *is topological equivalent to the system* ($n_u := n - n_s$):

$$\dot{\mathbf{x}}_s = -x_s, \quad \mathbf{x}_s \in \mathbb{R}^{n_s}, \tag{10.12}$$

$$\dot{\mathbf{x}}_u = +x_s, \quad \mathbf{x}_u \in \mathbb{R}^{n_u}. \tag{10.13}$$

Therefore, it follows that hyperbolic linear flows can be classified in a finite number of types using topological equivalence.

A local generalization of this theorem to nonlinear differential equations is known as the theorem of Hartmann and Grobman; see, e.g., Ref. [3].

THEOREM 10.2

Let $\mathbf{x}^\star$ *be a hyperbolic fixed point of* $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$ *with the flow* φ_t: $U \subseteq \mathbb{R}^n \rightarrow \mathbb{R}^n$, *i.e., the eigenvalues of the Jacobian matrix* $\mathbf{J}_f(\mathbf{x}^\star)$ *have only nonzero real parts. Then, there is a neighborhood N of* $\mathbf{x}^\star$ *on which* $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$ *is topologically equivalent to* $\dot{\mathbf{x}} = \mathbf{J}_f(\mathbf{x}^\star)\,\mathbf{x}$.

The combination of the two theorems implies that a very large set of differential equations can be classified in an isolated hyperbolic fixed point by a finite number of types (namely, n_s (or n_u)). The reason behind this interesting result is that the theorem of Hartman and Grobman, based on homeomorphisms, leads to a coarse decomposition of the set of vector fields under consideration.

As a consequence of the preceding theorems, the behavior of nonlinear differential equations near hyperbolic fixed points is equivalent up to a homeomorphism to the behavior of a simple system of linear differential equations. In the theory of nonlinear circuits, these mathematical results can be interpreted in the following way: The behavior of nonlinear circuits near an operational point where the Jacobian matrix of the descriptive equations (in statespace form) has only eigenvalues with nonzero real parts is ''similar'' to that of a corresponding linear dynamical circuit. Therefore, the analysis of these nonlinear circuits can be decomposed into two steps: (1) calculation of the operational points and the eigenvalues of

their Jacobian matrix and (2) restricting to the hyperbolic operational points we consider the behavior of the dynamics near these operational points; that is called small-signal behavior.

In the following section, we discuss more general methods for the analysis of vector fields that have at least one nonhyperbolic fixed point.

10.2 Normal Forms of Nonlinear Dynamical Circuit Equations

In Section 10.1, we present theorems useful for classifying the "local" behavior of nonlinear differential equations near hyperbolic fixed points by using "global" results from the theory of linear differential equations. An essential remaining problem is to calculate a homeomorphic transformation **h** in concrete cases. An alternative way to circumvent some of the difficulties is to apply the theory of normal forms that goes back to the beginning of the twentieth century and is based on classical ideas of Poincaré and Dulac. Detailed investigations of this subject are beyond the scope of this section and, therefore, an interested reader should consult the monographs of Refs. [2,3,10] as well as Ref. [29], where also further references of the theory of normal forms can be found. In this section, we present only the main ideas to illustrate its areas of applications.

In contrast to the theory described in Section 10.1, which is dedicated to hyperbolic cases, the theory of normal forms applies diffeomorphisms instead of homeomorphisms. This is necessary in order to distinguish the dynamical behavior of differential equations in more detail. To classify the topological types of fixed points of nonlinear differential equations $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$ one proceeds in two steps:

1. Construction of a "normal form" in which the nonlinear terms of the vector field **f** take their "most simple" form
2. Determination of the topological type of the fixed point (under consideration) from the normal form

We present the main aspects of this "algorithm" without a proof. First, we suppose that the vector field $\mathbf{f}(\mathbf{x})$ of the nonlinear differential equation $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$ satisfies $\mathbf{f}(\mathbf{0}) = \mathbf{0}$ (otherwise, using a suitable transformation) and that it is represented by a formal Taylor expansion:

$$\mathbf{f}(\mathbf{x}) = \mathbf{A}\mathbf{x} + \tilde{\mathbf{f}}(\mathbf{x}), \tag{10.14}$$

where

$\mathbf{A} = \mathbf{J}_f(\mathbf{x})$
$\tilde{\mathbf{f}}(\mathbf{x}) = O(\|\mathbf{x}\|^2)$ is of class C^r

Power (Taylor) series with no assumptions about convergence are called *formal series*. In practice, we begin with the formal series and then we determine the corresponding region of convergence (if available). Otherwise we use the framework of the theory of the so-called asymptotic series where a convergence in a strict sense is not necessary. In perturbation theory of differential equations most of the power series have to be considered as asymptotic series since a convergence in a strict sense is not available. More details about asymptotic series and perturbation theory can be, e.g., found in Refs. [28,45,57].

If a power series representation is derived, we apply a diffeomorphic C^r change of coordinates $\mathbf{h}$: $\mathbb{R}^n \to \mathbb{R}^n$ with $\mathbf{y} \mapsto \mathbf{x} = \mathbf{h}(\mathbf{y})$ ($\mathbf{h}(\mathbf{0}) = \mathbf{0}$) in the form of a near identity transformation:

$$\mathbf{h}(\mathbf{y}) := \mathbf{y} + \mathbf{h}^k(\mathbf{y}), \tag{10.15}$$

where $\mathbf{h}^k(\mathbf{y})$ is a homogeneous polynomial of order k in $\mathbf{y}$ ($k \geq 2$). The result of the transformation is

$$\dot{\mathbf{y}} = \{id + \mathbf{J}_h(\mathbf{y})\}^{-1} A\big(\mathbf{y} + \mathbf{h}^k(\mathbf{y})\big) + \{id + \mathbf{J}_h(\mathbf{y})\}^{-1} \tilde{\mathbf{f}}\big(\mathbf{y} + \mathbf{h}^k(\mathbf{y})\big) \tag{10.16}$$

$$= \mathbf{A}\mathbf{y} + \mathbf{g}(\mathbf{y}) \tag{10.17}$$

where

$\mathbf{J}_h(\mathbf{y})$ is the Jacobian matrix of $\mathbf{h}^k$ with respect to $\mathbf{y}$
$\mathbf{g}(\mathbf{h}) = O(\|\mathbf{y}\|^2)$ is a class C^r

For the following discussion it is useful to define $\mathbf{f}_T^k$ of a sufficient differentiable function $\mathbf{f}$: $\mathbb{R}^n \to \mathbb{R}^n$ as the "truncated" Taylor series in $\mathbf{0}$ expansion that have a degree less or equal k; the ith-order term of the Taylor series of $\mathbf{f}$ is denoted by $\mathbf{f}_i$. In a more abstract setting these "truncated" Taylor series are called *k-jets*; see Ref. [38] for more details. The set of $\mathbf{f}_T^k$'s forms a real vector space of functions and is denoted by H_k^n where the components are homogeneous polynomials in n variables of degree k. Using the k-jet notation and expanding $\mathbf{g}$ into a (formal) Taylor series, Equation 10.17 can be reformulated as

$$\dot{\mathbf{y}} = \mathbf{g}_T^{k-1}(\mathbf{y}) + \mathbf{g}_R^k(\mathbf{y}), \tag{10.18}$$

where $\mathbf{g}_R^k$ contains all terms of degree k or higher.

Expanding $\tilde{\mathbf{f}}$ of Equation 10.14 into a Taylor series

$$\tilde{\mathbf{f}} = \tilde{\mathbf{f}}_2 + \tilde{\mathbf{f}}_3 + \cdots \tag{10.19}$$

and using it to represent $\mathbf{g}_R^k$ of Equation 10.18 we can get

$$\dot{\mathbf{y}} = \mathbf{g}_T^{k-1}(\mathbf{y}) + \left\{\mathbf{f}_k - \left[\mathbf{A}\mathbf{y}, \mathbf{h}^k\right]\right\} + O\left(\|y\|^{k+1}\right), \tag{10.20}$$

where in the sense of Equation 10.17 the so-called Lie bracket $[\mathbf{A}\mathbf{y}, \mathbf{h}^k]$ of the linear vector field $\mathbf{A}\mathbf{y}$ and of $\mathbf{h}^k(\mathbf{y})$ is introduced by

$$\left[\mathbf{A}\mathbf{y}, \mathbf{h}^k\right](\mathbf{y}) := \mathbf{J}_h(\mathbf{y})\mathbf{A}\mathbf{y} - \mathbf{A}\mathbf{h}^k(\mathbf{y}). \tag{10.21}$$

Now we define the linear operator $L_A^k: H_k^n \to H_k^n$ by

$$L_A^k\mathbf{h}^k: \mathbf{y} \to \left[\mathbf{A}\mathbf{y}, \mathbf{h}^k\right](\mathbf{y}) \tag{10.22}$$

with the range $\mathcal{R}_k$, and let C_k ba any complementary subspace to $\mathcal{R}_k$ in H_k^n, i.e., $H_k^n = \mathcal{R}_k \oplus C_k (k \geq 2)$. Then, the following theorem implies a simplification of a nonlinear differential equation $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$, which can be interpreted as an equivalent representation of the associated dynamical circuit equations.

THEOREM 10.3

Let $\mathbf{f}$: $\mathbb{R}^n \to \mathbb{R}^n$ *be a* C^r *vector field with* $\mathbf{f}(\mathbf{0}) = \mathbf{0}$ *and* $\mathbf{A} \in \mathbb{R}^{n \times n}$, *and let the decomposition* $\mathcal{R}_k \oplus C_k$ *of* H_k^n *be given. Then, there exists a series of near identity transformations* $\mathbf{x} = \mathbf{y} + \mathbf{h}^k(\mathbf{y}) \in \Omega$ *for* $k = 2, 3, \ldots, r$, *where* $\Omega \subset R^n$ *is a neighborhood of the origin and* $\mathbf{h}^k \in H_k^n$, *such that the equation* $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$ *is transformed to*

$$\dot{\mathbf{y}} = \mathbf{A}\mathbf{y} + \mathbf{g}_2(\mathbf{y}) + \mathbf{g}_3(\mathbf{y}) + \cdots + \mathbf{g}_k(\mathbf{y}) + O(\|\mathbf{y}\|^{r+1}), \quad \mathbf{y} \in \Omega, \tag{10.23}$$

where $\mathbf{g}_k \in C_k$ *for* $k = 2, 3, \ldots$.

A proof of this theorem and the following definition can be found in, e.g., Ref. [4].

Definition 10.2: *Let $\mathcal{R}_k \oplus C_k$ be decompositions of H_k^n for $k = 2, 3, \ldots, r$. The "truncated" equation of (Equation* 10.23*)*

$$\dot{\mathbf{y}} = \mathbf{A}\mathbf{y} + \mathbf{g}_2(\mathbf{y}) + \mathbf{g}_3(\mathbf{y}) + \cdots + \mathbf{g}_k(\mathbf{y}), \tag{10.24}$$

where $\mathbf{g}_k \in C_k$ $(k = 2, 3, \ldots, r)$ is called normal form of $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \tilde{\mathbf{f}}(\mathbf{x})$ associated with matrix A up to order $r \geq 2$ (with respect to the decomposition where $\mathbf{g}_k \in C_k$ for $k = 2, 3, \ldots, \mathcal{R}_k \oplus C_k$).

Theorem 10.3 suggests an equivalence relation in the set of vector fields $\mathbf{f}$ that decomposes the set into equivalence classes. Each class can be represented by using the definition of normal forms. Because a concrete normal form depends on the choice of complementary subspaces C_k, it is not unique. In practical problems a constructive method of finding these subspaces is needed. An elegant way to find these subspaces is to start with the introduction of a suitable inner product $\langle \cdot \mid \cdot \rangle_n$ in H_k^n that is needed to define the adjoint operator $(L_A^k)^\star$ of L_A^k (in a sense of linear algebra) by

$$\langle \eta | L_A^k(\xi) \rangle_n := \langle (L_A^k)^\star(\eta) | \xi \rangle_n, \quad \text{for all } \eta, \xi \in H_k^n. \tag{10.25}$$

It can be shown that $\left(L_A^k\right)^\star = L_{A^\star}^k$ where $\boldsymbol{A}^\star = \boldsymbol{A}^{\mathrm{T}}$ is the transposed matrix of the matrix $\boldsymbol{A}$. The desired construction is available as an application of the following theorem.

THEOREM 10.4

Vector space ker $\left\{L_{A^\star}^k\right\}$ that is the solution space of the equation $L_{A^\star}^k \xi = 0$ is a complementary subspace of $\mathcal{R}_k$ in H_k^n, i.e.,

$$H_k^n = \mathcal{R}_k \oplus ker\left\{L_{A^\star}^k\right\}. \tag{10.26}$$

The interesting reader is referred to Ref. [4] for a detailed discussion of this subject. As a consequence, finding a normal form in the above sense up to the order r requires solving the partial differential equation $L_{A^\star}^k \xi = 0$ with definition (Equation 10.22). From an algebraic point of view this means that a base of ker $\{L_{A^\star}^k\}$ has to be chosen, but this can be done, again, with some degrees of freedom. For example, the two sets of differential equations are distinct normal form of $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} - \tilde{\mathbf{f}}(\mathbf{x})$ associated with the same matrix $\mathbf{A}$ (see Ref. [4]):

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} + \begin{pmatrix} ax_1^2 \\ bx_2^2 + ax_1x_2 \end{pmatrix}, \tag{10.27}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} + \begin{pmatrix} 0 \\ bx_1^2 + bx_1x_2 \end{pmatrix}. \tag{10.28}$$

To reduce the number of nonlinear monomials in the normal forms, a more useful base of C_k must be determined. If a nonlinear differential equation of the form $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} - \tilde{\mathbf{f}}(\mathbf{x})$ is given with an arbitrary matrix $\mathbf{A}$, several partial differential equations need to be solved. This, in general, is not an easy task. If $\mathbf{A}$ is diagonal or has an upper triangular form, methods for constructing a base are available. For this purpose we introduce the following definition:

Definition 10.3: *Let $\mathbf{A} \in \mathbb{R}^{n \times n}$ possesses the eigenvalues $\lambda_1, \ldots, \lambda_n$ and let $x_1^{\alpha_1} x_1^{\alpha_2} \cdots x_1^{\alpha} x_1^{\alpha_n} \mathbf{e}_j$ be a monomial in n variables. It is called a resonant monomial if the so-called resonant condition*:

$$\alpha \cdot \lambda - \lambda_j = 0 \tag{10.29}$$

is satisfied ($\alpha^T := (\alpha_1, \ldots, \alpha_n)$, $\lambda^T := (\lambda_1, \ldots, \lambda_n)$). *If the resonant condition holds for some* $\sqrt{\alpha^T \alpha} \geq 2$ *and some* $j \in \{1, \ldots, n\}$, *we say that* **A** *has a resonant set of eigenvalues.*

The importance of this definition is that the following statement can be shown: a monomial $x_1^{\alpha_1} x_1^{\alpha_2} \cdots x_1^{\alpha} x_1^{\alpha_n} \mathbf{e}_j$ is an element of ker $\{L_{A^*}^k\}$ if and only if $\alpha^T \cdot \lambda - \lambda_j = 0$ [4]. The next theorem proves that if **A** is diagonal, a minimal normal form exists (in certain sense).

THEOREM 10.5

Let $\boldsymbol{A} = diag(\lambda_1, \ldots, \lambda_n)$. *Then an A-normal form equation up to order r can be chosen to contain all resonant monomials up to order r.*

If some eigenvalues of $\boldsymbol{A}$ are complex, a linear change to complex coordinates is needed to apply this theorem. Furthermore, theorems and definitions need to be modified to such complex cases. In the case of differential equation:

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} 0 & -1 \\ +1 & 0 \end{pmatrix}\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} + O\left(\|\mathbf{x}\|^2\right) \tag{10.30}$$

that can be used to describe oscillator circuits, the coordinates are transformed to

$$\dot{z}_1 := x_1 + jx_2, \tag{10.31}$$

$$\dot{z}_2 = x_1 - jx_2 \tag{10.32}$$

with the resonant set of eigenvalues $\{-j, +j\}$ that can be written in a complex normal form (z represents z_1 and z_2, respectively):

$$\dot{z} = j + a_1|z|^2 z + \cdots + a_k|z|_z^{2k}. \tag{10.33}$$

This normal form equation—Poincaré normal form—is used intensively in the theory of the Poincaré–Andronov–Hopf bifurcation. The monograph of Hale and Koc̀ak [30] is worth reading for the illustration of this phenomenon in nonlinear dynamical systems. A detailed proof of the Poincaré–Andronov–Hopf theorem can be found, e.g., in Ref. [32]. These authors emphasize that further preparation of the system of differential equations is needed before the normal form theorem is applicable. In general, the linearized part of $\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \tilde{\mathbf{f}}(\mathbf{x})$ (in a certain fixed point of the vector field $\mathbf{f}$) has two classes of eigenvalues: (a) *central* eigenvalues $\lambda_i \in j\,\mathbb{R} \subset \mathbb{C}$ and (b) *noncentral* eigenvalues $\lambda_i \in \mathbb{C} \setminus j\,\mathbb{R}$. The dynamic behavior of a system associated with the noncentral eigenvalues is governed by the theorem of Grobman and Hartman (see Section 10.1) and therefore it is oriented in generic sense at the exponential behavior of linear systems. If a system has no central eigenvalues it is called a *hyperbolic system*. In circuit applications network, models with a hyperbolic behavior are related to, e.g., amplifiers and active filters; see, e.g., Ref. [44].

A more complex behavior is only possible if the theorem of Grobman and Hartman cannot be applied, i.e., we have systems with central eigenvalues see Ref. [49]. Therefore in the design of oscillator circuits we have to derive conditions to get central eigenvalues, e.g., Barkhausen criterion. The noncentral eigenvalues in these systems are related with the relaxation behavior and should be eliminated if we are interested in the dominant asymptotic behavior. A systematic procedure to eliminate noncentral eigenvalues from the system is based on the so-called center manifold theorem (see Ref. [11]) that is used also in the paper of Hassard and Wan [32]. A numerical algorithm is presented by Hassard et al. [31]. A more detailed discussion of this essential theorem goes beyond the scope of this section; however, more about the theory of normal forms of vector fields and its applications in circuit analysis can be found

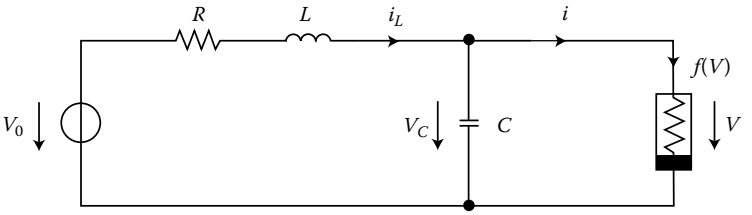

FIGURE 10.2 Nonlinear circuit with tunnel diode.

in Refs. [21,22]. Until now, we have discussed differential equations of the type $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$. Descriptive equations of circuits consist, in general, of linear and nonlinear algebraic equations, as well as differential equations. Therefore, the so-called constrained differential equations need to be considered for applications in circuit theory. A typical example is the well-known circuit shown in Figure 10.2, containing a model of a tunnel diode (see Refs. [9,53]). Circuit equations can be written as

$$C\frac{dv_C}{dt} = i_L - f(v_C), \tag{10.34}$$

$$L\frac{di_L}{dt} = -v_C - Ri_L + V_0, \tag{10.35}$$

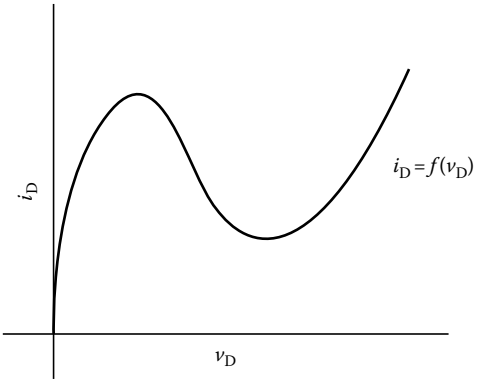

FIGURE 10.3 Characteristic of a tunnel diode.

where $i_D = f(v_D)$ is the characteristic of the tunnel diode (see Figure 10.3).

If the behavior of the circuit is considered with respect to the timescale $\tau := RC$, then the differential equations (Equations 10.34 and 10.35) can be reformulated as

$$\frac{dv}{d\theta} = i - F(v), \tag{10.36}$$

$$\varepsilon\frac{di}{d\theta} = -v - i + 1, \tag{10.37}$$

where

$\theta : t/\tau$
$i := (R/V_0)\, i_L$
$v := v_C/V_0$
$\varepsilon : L/(CR^2)$
$F(v) := (R/V_0)\, f(V_0 \cdot v)$

The behavior of the idealized circuit, where $\varepsilon = 0$ is often of interest. These types of descriptive equations are called constrained equations or differential-algebraic equations (DAEs). The above discussed theory of normal forms for vector fields cannot be applied directly to DAEs; however, a generalized theory is available, as presented (with applications) in Refs. [24,25].

10.3 Dimensionless Forms of Circuit Equations

In Section 10.1, the problem of equivalence is considered in a rather complex manner by adopting the mathematical point of view of dynamical systems. We use this approach in Section 10.6 to classify a

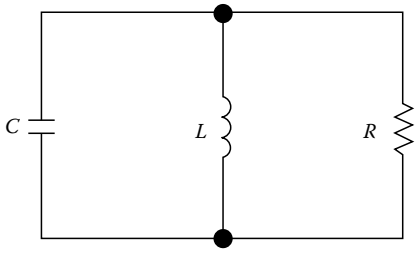

FIGURE 10.4 LCR circuit.

special class of nonlinear dynamical circuits. In contrast to this approach, another kind of equivalence of descriptive equations for linear time-invariant circuits and for certain nonlinear circuits is well known. It is illustrated by means of a simple example. The *RLC* parallel circuit in Figure 10.4, analyzed in the frequency domain, can be described by its impedance

$$Z(j\omega) = \frac{1}{1/R + j(\omega C - \frac{1}{\omega L})}. \tag{10.38}$$

In the case of small damping, this formula can be simplified using the so-called Q-factor that is defined as the ratio of the current flowing through L (or C) to the current flowing through the whole circuit in the case of resonance. The case of small damping is characterized by the condition $R/(2L) \ll \omega_0$, where $\omega_0 := 1 / \sqrt{LC}$ (Thompson's formula for LC circuits with $R = 0$). The Q-factor is given by $Q := 1/(\omega_0 \sqrt{RC})$. Simple calculations lead to a so-called normalized impedance

$$\tilde{Z} := \frac{Z}{R} = \left[1 - jQ^{-1}\left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega}\right)\right]^{-1} \tag{10.39}$$

that contains only two instead of three parameters. By using this method, a whole class of *RLC* circuits may be described by the same normalized impedance and which can be "de-normalized" at a certain frequency if a special filter application is considered. Therefore, an equivalence relation is defined in this manner. Handbooks of filter design written for practical electrical engineers contain diagrams of those and similar frequency curves of normalized impedances as well as admittances. Nor that the formula (Equation 10.39) is exact, although the interpretation of the parameters Q and ω_0 depends on the condition $R/(2L) \ll \omega_0$.

Methods for normalizing descriptive equations of circuits and for reducing the number of parameters are known in linear and nonlinear circuit theory; see, e.g., Ref. [20]. Unfortunately, these methods are stated without a presentation of their mathematisch reasoning. The main ideas for justification of normalization procedures are based on the so-called dimensional analysis. Their first applications in physics and the development of their mathematical foundations can be traced to the end of the nineteenth century. In this section, we discuss only a few aspects of this subject. Interested readers may find more details about the theory and applications of dimensional analysis as well as further references in a paper of Mathis and Chua [50]. In this paper they demonstrated that for a complete mathematical discussion of physical quantities, several algebraic concepts (e.g., Lie groups, etc.) are needed. In this section, a concise introduction into dimensional analysis is preferred and therefore, an intuitive introduction based on multiparameter Lie groups is presented. We use main ideas from the monograph of Ovsiannikov [55].

For describing physical systems, suitable descriptive physical quantities are required that can be measured. To perform a physical measurement of one of these quantities, we need at least one measuring instrument that provides us with corresponding measuring values on its scale. This scale is calibrated with respect to a standard cell. Therefore, an intuitive mathematical model of a physical quantity ϕ consists of two parts: a real number $|\phi|$ that characterizes its value, and a symbol E_ϕ that is due to the standard cell. In general, a measuring instrument is composed of elementary measuring instruments to evaluate, e.g., time or frequency, length, voltage, and charge. Each elementary instrument is calibrated with a corresponding standard cell and, therefore, associated to the instrument. Entirely, an arbitrary physical quantity ϕ is defined by

$$\phi := |\phi| E_1^{\lambda_1} E_2^{\lambda_2} \cdots E_r^{\lambda_r}, \tag{10.40}$$

where

r is the number of elementary instruments for measuring ϕ

λ_k determine how many times an elementary instrument have to be applied and whether the value on the scale needs to multiplied or divided

The dimensionality of a physical quantity ϕ is defined by

$$[\phi] := E_1^{\lambda_1} E_2^{\lambda_2} \cdots E_r^{\lambda_r}, \tag{10.41}$$

where $r \geq n$ such that a physical quantities is fully described by $\phi = |\ \phi\ | [\phi]$.
A physical quantity ϕ is called dimensionless if its dimensionality is null, that is if $\lambda_1 = 0$, $\lambda_2 = 0, \ldots,$ $\lambda_r = 0$. Moreover, a set of n physical quantities $\phi_1, \phi_2, \ldots, \phi_n$ is called dependent (in the sense of their dimensionality) if there exist integers $\chi_1, \chi_2, \ldots, \chi_n$ (not all equal zero) such that the product of these quantities

$$\phi_1^{\chi_1} \phi_2^{\chi_2} \cdots \phi_n^{\chi_n} \tag{10.42}$$

is dimensionless. Otherwise $\phi_1\ \phi_2 \cdots \phi_n$ are called independent.

The main problem of (physical) dimension theory is to determine how many independent physical quantities are included in a set of n describing quantities, to find them, and then express the other quantities in the set in terms of these independent quantities. As an application, a systematic procedure to normalize physical descriptive equations can be given—instead a intuitive manner as considered above.

In order to solve the main problem, the change of measuring instruments and measuring scales needs to be introduced and modeled in a mathematical manner. Obviously, in terms of modeling physical quantities, the same ϕ can be represented in different ways. Using two sets of measuring instruments, denoted by $E_1, E_2, \ldots, E_r$ and $\tilde{E}_1, \tilde{E}_2, \ldots, \tilde{E}_r$, respectively, ϕ is given by

$$|\phi| E_1^{\lambda_1} E_2^{\lambda_2} \cdots E_r^{\lambda_r} = |\tilde{\phi}| \tilde{E}_1^{\tilde{\lambda}_1} \tilde{E}_2^{\tilde{\lambda}_2} \cdots \tilde{E}_r^{\tilde{\lambda}_r}, \tag{10.43}$$

where in general $r \neq p$. This suggests the so-called analogy transformation (see Ref. [50]):

$$E_k = a_1^{\alpha_1} \cdots a_k^{\alpha_k} \tilde{E}_1^{\alpha_1} \cdots \tilde{E}_k^{\alpha_k}, \quad k = 1, \ldots, r. \tag{10.44}$$

Transformations of the scales of measuring instruments—in the following denoted as *scale transformations*—are special analogy transformations:

$$E_k = a_k \tilde{E}_k, \quad k = 1, \ldots, r. \tag{10.45}$$

It can be demonstrated that analogy transformations of dimension theory are special cases of the so-called extension groups. These groups belong to the r-parameter Lie groups and, subsequently, all results of dimension theory can be interpreted by theorems from this mathematical theory. Further details are contained in Ref. [55]. To introduce the main ideas, we consider only scale transformations in this section.

Let $\mathcal{Z} := \mathbb{R}^n \times \mathbb{R}^m$ be the Cartesian product of the set of n-column vectors $\mathbf{x}$ and m-column vectors $\mathbf{y}$, and let $\{\mathbf{e}_1, \ldots, \mathbf{e}_n\}$ and $\{\mathbf{f}_1, \ldots, \mathbf{f}_m\}$, be, respectively, arbitrary (but fixed) bases of these vector spaces. Endowing $\mathcal{Z}$ with the structure of a direct sum $\mathbb{R}^n \oplus \mathbb{R}^m$, each $z \in \mathcal{Z}$ can be represented by (with respect to these bases)

$$z = \sum_{i=1}^{n} x^i \mathbf{e}_i + \sum_{k=1}^{m} y^k \mathbf{f}_k. \tag{10.46}$$

An extension of $\mathcal{Z}$ (with respect to these bases) is defined by the transformation:

$$h: z \to \sum_{i=1}^{n} c^i x^i \mathbf{e}_i + \sum_{k=1}^{m} d^k y^k \mathbf{f}_k \quad (c^i >, \, d^k > 0). \tag{10.47}$$

Obviously, the set of all extensions generates an Abelian group of transformations on $\mathcal{Z}$ that is an $(n+m)$-parameter Lie group. this group is denoted by diag$\{\mathbf{e}_i, \mathbf{f}_k\}$. Any subgroup $H \subset$ diag$\{\mathbf{e}_i, \mathbf{f}_k\}$ is called an extension group of $\mathcal{Z}$. We now consider extension groups H^r, with $0 < r \leq n+m$.

Ovsiannikov [55] demonstrated that extensions of H^r can be represented, choosing a parametric group, in the form:

$$\tilde{x}^i = x^i \prod_{\alpha=1}^{r} (a_\alpha)^{\lambda_\alpha^i}, \quad \tilde{y}^k = y^k \prod_{\alpha=1}^{r} (a_\alpha)^{\mu_\alpha^k}, \tag{10.48}$$

where

$i = 1, \ldots, n$

$k = 1, \ldots, m$

The main property of transformation groups is that they induce equivalence relations decomposing the subjects on which the group acts into equivalence classes. If h_p acts on elements $x \in X$, and let $\mathbf{p} \in \mathbb{R}^p$ the vector of parameters, an *orbit* $U(x)$ *of a point* $x \in X$ is defined by the set $U(x) := \{\xi \in X | \xi = h_p(x, \mathbf{p})$, for all $\mathbf{p} \in \mathbb{R}^p\}$. In this sense, the points of an orbit can be identified by a transformation group. A transformation group acts transitive on X if there exists an orbit $U(x)$ that is an open subset of X, with $\bar{U} = X$.

To study the so-called local Lie groups with actions that are defined near a null neighborhood of the parameter space (including the vector $\mathbf{0}$), we can discuss the Lie algebra that characterizes the local behavior of the associated local Lie group. In finite dimensional parameter spaces, a Lie algebra is generated by certain partial differential operators. Using the representations (Equation 10.48) of H^r, the operators are of the form:

$$\sum_{i=1}^{n} \lambda_\alpha^i x^i \frac{\partial}{\partial x^i} + \sum_{i=1}^{m} \mu_\alpha^k y^k \frac{\partial}{\partial y^k}, \tag{10.49}$$

where

$i = 1, \ldots, n$

$k = 1, \ldots, m$

These operators can be represented in a matrix form:

$$\mathbf{M}(z) := \mathbf{M}_1 \circ \text{diag}\{x^1, \ldots, x^n; y^1, \ldots, y^m\}, \tag{10.50}$$

where

$$\mathbf{M}_1 := \begin{pmatrix} \lambda_1^1 & \cdots & \lambda_1^n, \mu_1^1 & \cdots & \mu_1^m \\ \vdots & \cdots & & \cdots & \vdots \\ \lambda_r^1 & \cdots & \lambda_r^n, \mu_r^1 & \cdots & \mu_r^m \end{pmatrix}. \tag{10.51}$$

Obviously, H^r is not transitive if $r < n+m$.

In order to solve the main problem of dimension theory, we need to introduce invariants of a Lie group. Let $F: X \to Y$ be a function on X and let transformations h_p of a transformation group act on X, then F is an invariant of the group if $F(h_p(x)) = F(x)$ holds for any $x \in X$ and $\mathbf{p} \in \mathbb{R}^p$. The invariant $J: X \to Y$ is called a universal invariant if there exists, for any invariant $F: X \to Y$ of the group, a function Φ such that $F = \Phi \circ J$. The following main theorem can be proved for the extension group [55].

THEOREM 10.6

For the extension group H^r on $\mathcal{Z}$, there exists a universal invariant $J: \mathcal{Z} \to \mathbb{R}^{n+m-r}$ if the condition $r < n + m$ is satisfied. The independent components of J have the monomial form:

$$J^\tau(Z) = \prod_{i=1}^{n} \left(x^i\right)^{\theta_k^\tau} \cdot \prod_{k=1}^{m} \left(y^k\right)^{\sigma_k^\tau}, \tag{10.52}$$

where $\tau = 1, \ldots, n + m - r$.

If dimensional analysis considers only scale transformations (Equation 10.45), this theorem contains the essential result of the so-called *Pi-theorem*. For this purpose we present a connection between the dimensionalities and the extension group H^r (see Ref. [55]). The group H^r of the space $\mathbb{R}^n$, defined only be the dimensions of the physical quantities ϕ_k with respect to the set of symbols $\{E_\alpha\}$, has a one-to-one correspondence with every finite set $\{\phi_k\}$ of n physical quantities, which can be measured in the system of symbols $\{E_\alpha\}$ consisting of r independent measurement units; see Equation 10.43. The transformations belonging to the group H^r give the rule of change in the form

$$|\tilde{\phi}| = |\phi| \prod_{\alpha=1}^{r} (a^\alpha)^{\lambda_\alpha} \tag{10.53}$$

of the numerical values $|\phi_k|$ as a result of the transition from the units $\{E_\alpha\}$ to $\{\tilde{E}_\alpha\}$ by means of Equation 10.45.

As a consequence of this relationship, a quantity ϕ is dimensionless if and only if its numerical value is an invariant of the group H^r. Thus, the problem to determine the independent physical quantities of a given set of quantities is solved by the construction of a universal invariant of H^r stated by the Pi-theorem; see also Ref. [7]. Normalization as well as the popular method of dimension comparison, are consequences of the invariance of physical equations with respect to the group of analogy (scale) transformations. In applications of dimensional theory, a normal form that has certain advantageous properties is desired. For example, it is useful to reduce the number of parameters in physical equations. Normal forms of this type are used very often in practical calculations, but with no clarification of their mathematical foundations.

Circuit equations, similar to other physical equations, contain numberous parameters. In applications, it is often desired to suppress some of these parameters and moreover, they should be replaced by the numerical value 1.

For this purpose, Desloge [26] chooses a new system of units $\{E_\alpha\}$. A theory of Desloge's method, based on analogy transformation (Equation 10.44) instead of scale transformation (Equation 10.45), was presented by Mathis and Chua [50]. The main idea behind this method is that, beside the foundation units time $[T]$, voltage $[E]$, and charge $[Q]$ that are useful in circuit theory, the units of other parameters are considered as foundational units. We denote the units by $[A_\alpha]$ instead of E_α. For example, in the case of the tunnel-diode circuit (see Figure 10.2), $[T]$, $[E]$, and $[Q]$, as well as $[R]$, $[C]$, and $[L]$, need to be

discussed. As a consequence of Desloge's method, three of the four parameters can be suppressed and the other variables will be normalized. The method works in the case of linear as well as nonlinear circuits.

The method is illustrated using the tunnel-diode circuit equations (Equations 10.34 and 10.35). At first, the dimensional matrix is determined by

$$\begin{array}{c} \\ [R] \\ [L] \\ [C] \end{array} \begin{array}{c} \begin{array}{ccc} [T] & [E] & [Q] \end{array} \\ \begin{pmatrix} 1 & 1 & -1 \\ 2 & 1 & -1 \\ 0 & -1 & 1 \end{pmatrix} \end{array} \tag{10.54}$$

that characterizes the relation between the dimensions of *t, v, q, R, C,* and *L*.

Now, Desloge considers another set of power independent dimensional scalars A_1, A_2, and A_3 with

$$[A_i] = [T]^{a_i^1}[E]^{a_i^1 2}[Q]^{a_i^3}, \quad i = 1, 2, 3. \tag{10.55}$$

These relations are interpreted as an analogy transformation (Equation 10.44). Applying the map $L(\cdot)$ that has the same properties as the logarithmic function (see Ref. [50]) to Equation 10.55, the symbols $L([A_1])$, $L([A_2])$, and $L([A_3])$ are represented by linear combinations of $L([T])$, $L([E])$, $L([Q])$. The coefficient matrix in Equation 10.55 is regular and contains the exponents. Solving these linear equations using "antilog," the $[T]$, $[E]$, and $[Q]$ are products of powers of $[A_1]$, $[A_2]$, and $[A_3]$. In this manner, dimensionsless versions of differential equations of the tunnel-diode circuit can be derived.

By using the independent units $A_1 := L$, $A_2 := C$, and $A_3 := V_0$ to replace their values $|V_0|$, $|L|$, and $|C|$ by 1 (with respect to the new units), the following equation is derived by Desloge's approach sketched previously

$$\begin{array}{c} \\ [V_0] \\ [L] \\ [C] \end{array} \begin{array}{c} \begin{array}{ccc} [T] & [E] & [Q] \end{array} \\ \begin{pmatrix} 0 & 1 & 0 \\ 2 & 1 & -1 \\ 0 & -1 & 1 \end{pmatrix} \end{array} \begin{pmatrix} \ln([T]) \\ \ln([E]) \\ \ln([Q]) \end{pmatrix} = \begin{pmatrix} \ln([V_0]) \\ \ln([L]) \\ \ln([C]) \end{pmatrix}. \tag{10.56}$$

Multiplying Equation 10.56 by the inverse of the dimensional matrix

$$\begin{array}{c} \\ [T] \\ [E] \\ [Q] \end{array} \begin{array}{c} \begin{array}{ccc} [V_0] & [L] & [C] \end{array} \\ \begin{pmatrix} 0 & 1/2 & 1/2 \\ 1 & 0 & 0 \\ 1 & 0 & 1 \end{pmatrix} \end{array} \tag{10.57}$$

and applying "antilog" to the result, we obtain

$$[T] = [L]^{1/2}[C]^{-1/2}, \quad [E] = [V_0], \quad [Q] = [V_0]\,[C]. \tag{10.58}$$

From these equations, the relations between the old and new units can be derived; see Ref. [50]. *T, E,* and *Q* are expressed by the new units *L, C,* and V_0 and the parameters and variables in Equations 10.34 and 10.35 can be reformulated if the numerical values of V_0, *L,* and *C* are added

$$T = |L|^{-1/2}|C|^{-1/2}L^{1/2}C^{1/2}, \quad E = |V_0|^{-1}V_0, \quad Q = |V_0|^{-1}|C|^{-1}V_0C. \tag{10.59}$$

These relations represent parameters and variables of the tunnel-diode circuit with respect to the new quantities

$$R = \frac{|R||C|^{1/2}}{|L|^{1/2}} L^{1/2} C^{-1/2}, \quad V_0 = 1 \cdot V_0, \quad L = 1 \cdot L, \quad C = 1 \cdot C, \tag{10.60}$$

$$i_L = \frac{|i_L||L|^{1/2}}{|V_0||C|^{1/2}} V_0 L^{-1/2} C^{1/2}, \quad v_C = \frac{|v_C|}{|V_0|} V_0, \quad t = \frac{|t|}{|L|^{1/2}|C|^{1/2}} L^{1/2} C^{1/2}. \tag{10.61}$$

The dimensional exponents for these quantities can be found by using the inverse dimensional matrix (Equation 10.57):

1. *T, E, Q*: their exponents correspond the associated rows of Equation 10.57
2. V_0, *L, C, R*: premultiply Equation 10.57 with the corresponding row of Equation 10.54

For example, taking $[C] \triangleq (0 - 11)$ results in

$$[C] \begin{array}{c} \begin{array}{ccc} [T] & [E] & [Q] \end{array} \\ \begin{pmatrix} 0 & -1 & 1 \end{pmatrix} \end{array} \begin{array}{c} \begin{array}{c} [T] \\ [E] \\ [Q] \end{array} \\ \begin{pmatrix} 0 & 1/2 & 1/2 \\ 1 & 0 & 0 \\ 1 & 0 & 1 \end{pmatrix} \end{array} \begin{array}{c} \begin{array}{ccc} [V_0] & [L] & [C] \end{array} \\ = [C] \begin{pmatrix} 0 & 0 & 1 \end{pmatrix} \end{array} \tag{10.62}$$

or with the corresponding row $[R] \triangleq (11 - 1)$ of Equation 10.54

$$[R] \begin{array}{c} \begin{array}{ccc} [T] & [E] & [Q] \end{array} \\ \begin{pmatrix} 1 & 1 & -1 \end{pmatrix} \end{array} \begin{array}{c} \begin{array}{c} [T] \\ [E] \\ [Q] \end{array} \\ \begin{pmatrix} 0 & 1/2 & 1/2 \\ 1 & 0 & 0 \\ 1 & 0 & 1 \end{pmatrix} \end{array} \begin{array}{c} \begin{array}{ccc} [V_0] & [L] & [C] \end{array} \\ = [R] \begin{pmatrix} 0 & 1/2 & -1/2 \end{pmatrix}. \end{array} \tag{10.63}$$

With these representations of the dimensional quantities, we can obtain a dimensionless representation of Equations 10.34 and 10.35

$$\frac{\mathrm{d}\bar{v}_C}{\mathrm{d}\bar{t}} = \bar{i}_L - \bar{f}(\bar{v}_C), \tag{10.64}$$

$$\frac{\mathrm{d}\bar{i}_L}{\mathrm{d}\bar{t}} = 1 - \sqrt{\varepsilon}\bar{i}_L - \bar{v}_C, \tag{10.65}$$

where

$$\bar{v}_C := \frac{|v_C|}{|V_0|}, \quad \bar{t} := \frac{|t|}{\sqrt{|L||C|}}, \quad \sqrt{\varepsilon} := \frac{|R||C|^{1/2}}{|L|^{1/2}}, \quad \bar{i}_L := \frac{|i_L||L|^{1/2}}{|V_0||C|^{1/2}}. \tag{10.66}$$

Furthermore, the dimensionless tunnel-diode current $\bar{f}$ is defined by

$$\bar{f}(\bar{v}_C) := V_0^{-1} L^{1/2} C^{-1/2} f(V_0 \bar{v}_C). \tag{10.67}$$

The associated dimensionless form of Equations 10.36 and 10.37 can be derived by another scaling of the current $\hat{i}_L := \sqrt{\varepsilon}\bar{i}_L$. Obviously, the dimensionless normal form is not unique.

The classical dimensional analysis shows that R^2C/L is the only dimensionless constant of the quantities in Equations 10.34 and 10.35. Because the describing equations of the parallel *LCR* circuit

include the same variables constants, the results of the previous dimensional analysis of the tunnel-diode circuit can be used to normalize Equation 10.38.

Further interesting applications of Desloge's approach of suppressing superfluous parameters in the describing equations can be found in the theory of singular perturbation analysis. The reader is referred, e.g., to the monograph of Smith [57] for further details. Miranker [53] demonstrated that the differential equations of the tunnel-diode circuit can be studied on three timescales $\tau_1 := L/R$, $\tau_2 := RC$, and $\tau_3 := \sqrt{LC}$ where different phenomena arise. If these phenomena are known, corresponding timescales can be written down. However, since all dimensionless equations can be derived in a systematic manner using Desloge's approach also the corresponding timescales result. In this way, e.g., all normalized differential equations describing Chua's circuit (see Ref. [42]) can be obtained but other representations of these differential are possible using dimensional analysis.

10.4 Equivalence of Nonlinear Resistive *n*-Ports

In this section, we only consider equivalence of nonlinear resistive n-ports; however, resistive circuits without accessible ports will not be included in the discussion. Although the explanations that follow are restricted to resistive n-ports, this theory can be easily extended to pure capacitive and inductive n-ports; see Ref. [23]. In Section 10.5, we give a definition of those n-ports.

At first, we consider linear resistive 1-ports that contain Ohmic resistors described by $v_k = R_k i_k$ or/and $i_k = G_k u_k$, and independent current and voltage sources $v_k = V_0^k$ and $i_k = I_0^k$. We can use Helmholtz–Thevenin's or Mayer–Norton's theorem [40,51] to compare any two of those 1-ports and reduce a complex 1-port to a more simple ''normal'' form. Therefore, two of those 1-ports are called equivalent if they have the same Helmholtz–Thevenin or Mayer–Norton resistor-source 1-port representation. Clearly, by this approach, an equivalence relation is defined in the set of linear resistive 1-ports and it is decomposed into ''rich'' classes of 1-ports. To calculate these normal forms, Δ-Y and/or Y-Δ transformations are needed; see Refs. [20,51]. It is known that this approach is not applicable to nonlinear resistive networks because, e.g., Δ-Y and/or Y-Δ transformations generally do not exist for nonlinear networks. This was observed by Millar [52] for the first time. Certain circuits where these transformations can be performed were presented by Chua [14]. More recently, Boyd and Chua [5,6] clarified the reasons behind this difficulty from the point of view of Volterra series. As a conclusion, the set of nonlinear resistive 1-ports can be decomposed into equivalence classes, but no reasonable large classes of equivalent 1-ports exist. More general studies of this subject are based on the well-known substitution theorem, which can be used successfully in a certain class of nonlinear circuits. A detailed discussion of the classical substitution theorem can be found in Refs. [27,57] and in an abstract setting in Refs. [33,56]. Some results applicable to 1-ports can be generalized to linear resistive n-ports (extraction of independent sources), but this point of view is not suited for nonlinear resistive n-ports.

Better understanding of nonlinear resistive n-ports and the problem of equivalence cannot be based on the ''operational'' approach mentioned earlier. Instead, a geometrical approach that was developed by Brayton and Moser [9] is more useful. These authors (see also Ref. [8]) characterize a resistive n-port in a generic manner by n independent relations between the $2n$ port variables, n-port currents $i_1, \ldots, i_n$, and n-port voltages $u_1, \ldots, u_n$. Geometrically, this means that in the $2n$-dimensional space of port variables, the external behavior of a resistive n-port can be represented generically by an n-dimensional surface. The classical approach formulates a system of equations by

$$\begin{aligned} y_1 - f_1(x_1, \ldots, x_n) &= 0, \\ &\vdots \\ y_n - f_n(x_1, \ldots, x_n) &= 0, \end{aligned} \tag{10.68}$$

where x's and y's are the port variables. The zero set of equations (Equation 10.69) corresponds to the n-dimensional surface. Therefore, two n-ports are called equivalent if they are different parametrizations of the same n-port surface. As an application of this point of view, Brayton and Moser [9] demonstrated that a 2-port consisting of a Y-circuit and a circuit consisting of a Δ-circuit cannot be equivalent, in general. For example, they proved by means of Legendre transformations that a Y-circuit with two Ohmic resistors and a third resistor can be equivalent to a Δ-circuit if and only if the third resistor is also linear. Therefore, the operational approach is not a very useful equivalence concept for nonlinear n-ports.

The subject of synthesizing a prescribed input–output behavior of nonlinear resistive n-ports is closely related to the problem of of equivalence. Several results were published in this area using ideal diodes, resistors with a concave and convex characteristic, dc voltage and current sources, ideal op-amps, and controlled sources. Therefore, we give a short review of some of these results. On the other hand we do not consider the synthesis of resistive n-ports.

Although the synthesis of nonlinear resistive n-ports was of interest to many circuit designers since the beginning of twentieth century, the first systematic studies of this subject based on previous studies of Millar [52] were published by Chua [13,14]; see, e.g., Itoh [37] for more recent aspects of nonlinear circuit synthesis. Chua's synthesis approach based on the introduction of new linear 2-ports (R-rotators, R-reflectors, and scalors) as well as their electronic realizations. Now, curves in the i–v space of port current i and port voltage v that characterize a (nonlinear) resistive 1-port can be reflected and scaled in a certain manner. Chua suggested that a prescribed behavior of an active or passive nonlinear resistive 1-port can be reduced essentially to the realization of passive i–v curves. Piecewise-linear approximations of characteristics of different types of diodes, as well as the previously mentioned 2-ports, are used to realize a piecewise-linear approximation of any prescribed passive i–v curve. In another article, Chua [15] discussed a unified procedure to synthesize a nonlinear dc circuit mode that represents a prescribed family of input and output curves of any strongly passive 3-terminal device (e.g., a transistor). It was assumed that the desired curves are piecewise-linear. Since then, this research area has grown very rapidly and piecewise-linear synthesis and modeling has become an essential tool in the simulation of nonlinear circuits; see Refs. [19,34,39,41].

10.5 Equivalence of Nonlinear Dynamical *n*-Ports

In this section, we consider more general n-ports that can be used for device modeling; see Ref. [16]. Although many different *lumped* multiterminal and multiport circuits are used, a decomposition into two mutually exclusive classes is possible: algebraic and dynamic multiterminal and multiports. Adopting the definition of Chua [16], an $(n+1)$-terminal of n-port circuit is called an algebraic element if and only if its constitutive relations can be expressed symbolically by algebraic relationships involving at most two dynamically independent variables for each port. In the case of an 1-port, a so-called memristor is described by flux and charge, a resistor by voltage and current, an inductor by flux and current, and a capacitor by voltage and charge. An element is called a dynamic element if and only if it is not an algebraic element.

Despite the fact that the class of all dynamic elements is much larger than that of algebraic ones, the following theorem of Chua [16] suggests that resistive multiports are essential for dynamic elements, too.

THEOREM 10.7

Every lumped $(n+1)$-terminal or n-port element can be synthesized using only a finite number n of linear 2-terminal capacitors (or inductors) and one (generally nonlinear) $(n+m)$-port resistor with n accessible ports and m ports for the capacitors.

This theorem demonstrates that any n-port made of lumped multiterminal and/or multiport elements is equivalent to a multiterminal network where all of its nonlinear elements are *memoryless*. This fact offers a possibility to classify $(n+1)$-terminal and n-port elements in an operational manner.

The proof of this theorem provides the answer of a fundamental question: what constitutes a minimal set of network elements from which all lumped elements can be synthesized?

THEOREM 10.8

The following set $\mathcal{M}$ of network elements constitutes the minimal basic building blocks in the senses that any lumped multiterminal or multiport element described by a continuous constitutive relation on any closed and bounded set can be synthesized using only a finite number of elements of $\mathcal{M}$, and that this statement is false if even one element is deleted from $\mathcal{M}$:

1. *Linear 2-terminal capacitors (or inductors)*
2. *Nonlinear 2-terminal resistors*
3. *Linear 2-port current-controlled voltage sources (CCVS) defined by $v_1 = 0$ and $v_2 = ki_1$*
4. *Linear 2-port current-controlled current sources (CCCS) defined by $i_1 = 0$ and $i_2 = \tilde{k}v_1$*

The proof of Theorem 10.8 (see Ref. [16]) is based on a remarkable theorem of Kolmogoroff, which asserts that a continuous function $\mathbf{f}\colon \mathbb{R}^n \to \mathbb{R}$ can always be decomposed over the unit cube of $\mathbb{R}^n$ into a certain sum of functions of a single variable. Although the proof of Theorem 10.8 is constructive, it is mainly of theoretical interest since the number of controlled sources needed in the realization is often excessive.

10.6 Equivalence of Reciprocal Nonlinear Dynamic Circuits

As already mentioned in Section 10.1, a certain set of circuits can be decomposed into classes of equivalent circuits by some type of equivalence relation. Such equivalence relations are introduced in a direct manner with respect to the descriptive equations, using a transformation group of classifying the behavior of the solution of the descriptive equations. In the last few sections, several useful ideas for defining equivalence relations were discussed that can be suitable for circuit theory. In this section equivalent dynamical circuits are considered in more detail. It should be emphasized again that equivalence has a different meaning depending of the applied equivalence relation.

As the so-called state-space equations in circuit and system theory arose in the early 1960s, a first type of equivalence was defined because various circuits can be described by the same state-space equations. Of course, from this observation an equivalence relation is induced; see Ref. [61] for further references. Although this approach is interesting, in some cases different choices of variables for describing nonlinear circuits exist that need not lead to equivalent state-space equations; see, e.g., Ref [17]. In other words, the transformations of coordinates are not well conditioned. This approach was applied also to nonlinear input–output systems.

If we consider nonlinear reciprocal circuits, the Brayton–Moser approach [9] to formulate the describing equations for this class of circuits is very suitable; see also Ref. [48]. In order to formulate a generalized type of state-space equations, Brayton and Moser used a so-called mixed-potential function P. P depends on the capacitor voltages $\mathbf{v}$ and the inductor currents $\mathbf{i}$ where the vector field of the circuit equations can be derived by partial derivatives. The Brayton–Moser equations can be formulated in the following manner:

$$\mathbf{C}(\mathbf{v})\frac{\mathrm{d}\mathbf{v}}{\mathrm{d}t} = -\frac{\partial P}{\partial \mathbf{v}}(\mathbf{v},\mathbf{i}), \quad -\mathbf{L}(\mathbf{i})\frac{\mathrm{d}\mathbf{i}}{\mathrm{d}t} = -\frac{\partial P}{\partial \mathbf{i}}(\mathbf{v},\mathbf{i}). \tag{10.69}$$

A discussion of the Brayton–Moser equations from a point of view of constrained differential equation in a differential geometric setting can be found in Ref. [46]. A very general concept of constructing mixed-potential functions is presented by Weiss et al. [60]. In the following, we consider the equivalence concept for reciprocal nonlinear dynamical circuits based in Brayton–Moser equations where Varaiya and Verma [58] included external ports (input–output description). For this purpose they use a more compact form of the Brayton–Moser where the generalized state vector $\mathbf{x} := (\mathbf{v}, \mathbf{i})$ and the coefficient matrix $\mathbf{A} := \text{diag}(\mathbf{C}(\mathbf{v}), -\mathbf{L}(\mathbf{i}))$ is introduced. It should be noted that another geometric approach for nonlinear dynamical input–output circuits is available based on Hamiltonian equations with external ports—the so-called port Hamiltonian equations—where a so-called Dirac structure is used for energy preserving interconnections. With respect to this concept, the reader is referred to the literature; see recent publications of Maschke [47] and can der Schaft [12]) and the cited older publications.

The input–output circuit description of Verma [59] is formulated in the following manner: Let $\mathbf{x} \in \mathbb{R}^n$ the state-space vector, $\mathbf{u} \in \mathbb{R}^m$ the input vector, and $\mathbf{e} \in \mathbb{R}^m$ the output vector, then the Brayton–Moser type state-space equations can be generated by a matrix-valued function $\mathbf{A}(\mathbf{x})$: $\mathbb{R}^n \to \mathbb{R}^{n\times n}$ and a real-valued function P: $\mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}$

$$\mathbf{A}(\mathbf{x})\frac{\mathrm{d}\mathbf{x}}{\mathrm{d}t} = -\frac{\partial P}{\partial \mathbf{x}}(\mathbf{x}, \mathbf{u}), \tag{10.70}$$

$$\mathbf{e} = \frac{\partial P}{\partial \mathbf{u}}(\mathbf{x}, \mathbf{u}). \tag{10.71}$$

For two such circuits $N_1 = \{\mathbf{A}_1, P_1\}$ and $N_2 = \{\mathbf{A}_2, P_2\}$, Varaiya and Verma [58] defined the following equivalence concept.

Definition 10.4: *Two Brayton–Moser type circuits N_1 and N_2 with the outputs $\mathbf{e}_1 = \partial P_1/\partial \mathbf{u}$ and $\mathbf{e}_2 = \partial P_2/\partial \mathbf{u}$ are input–output equivalent if there exists a diffeomorphism Θ with $\mathbf{y} = \Theta(\mathbf{x})$, such that for all $\mathbf{x}_0 \in \mathbb{R}^n$, all input functions $\mathbf{u}$, and all $t \geq 0$ the following assumptions are satisfied*

1. $\Theta(x(t, \mathbf{x}_0, \mathbf{u})) = \mathbf{y}(t, \Theta(\mathbf{x}_0), \mathbf{u})$
2. $\mathbf{e}_1(t, \mathbf{x}_0, \mathbf{u}) = \mathbf{e}_2(t, \Theta(\mathbf{x}_0), \mathbf{u})$

The diffeomorphism Θ is called the equivalence map.

Thus, two circuits are equivalent if their external behavior is identical, i.e., if for the same input and corresponding states they yield the same output. It is clear that this definition results an equivalence relation on the set of all dynamical circuits under consideration. In their paper, Varaiya and Verma [58] showed that, under the additional assumption of controllability, the diffeomorphism Θ establishes an isometry between the manifold with the (local) pseudo-Riemannian metric $(\mathrm{d}\mathbf{x}, \mathrm{d}\mathbf{x}) := \langle \mathrm{d}\mathbf{x}, \mathbf{A}_1\, \mathrm{d}\mathbf{x}\rangle$ and the manifold with the (local) pseudo-Riemannian metric $(\mathrm{d}\mathbf{y}, \mathrm{d}\mathbf{y}) := \langle \mathrm{d}\mathbf{y}, \mathbf{A}_2\, \mathrm{d}\mathbf{y}\rangle$ in many interesting cases of nonlinear reciprocal circuits. This statement has an interesting interpretation in the circuit context. It can be proven that Θ must relate the reactive parts of the circuits N_1 and N_2 in such a way that, if N_1 is in the state $\mathbf{x}$ and N_2 is in the state $\mathbf{y} = \Theta(\mathbf{x})$, and if the input $\mathbf{u}$ is applied, then

$$\left\langle \frac{\mathrm{d}\mathbf{i}}{\mathrm{d}t}, \mathbf{L}(\mathbf{i})\frac{\mathrm{d}\mathbf{i}}{\mathrm{d}t}\right\rangle - \left\langle \frac{\mathrm{d}\mathbf{v}}{\mathrm{d}t}, \mathbf{C}(\mathbf{v})\frac{\mathrm{d}\mathbf{v}}{\mathrm{d}t}\right\rangle = \left\langle \frac{\mathrm{d}\tilde{\mathbf{i}}}{\mathrm{d}t}, \tilde{\mathbf{L}}(\tilde{\mathbf{i}})\frac{\mathrm{d}\tilde{\mathbf{i}}}{\mathrm{d}t}\right\rangle - \left\langle \frac{\mathrm{d}\tilde{\mathbf{v}}}{\mathrm{d}t}, \tilde{\mathbf{C}}(\tilde{\mathbf{v}})\frac{\mathrm{d}\tilde{\mathbf{v}}}{\mathrm{d}t}\right\rangle. \tag{10.72}$$

The concept of equivalence defined in a certain subset of nonlinear dynamic circuits with input and output terminals given by Varaiya and Verma [58] is based on diffeomorphic coordinate transformations

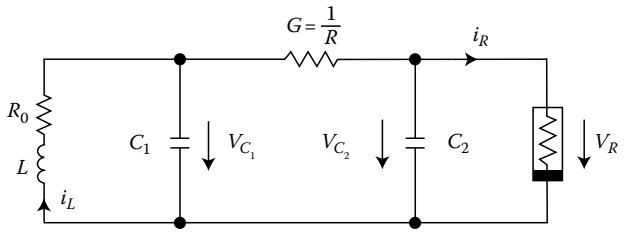

FIGURE 10.5 Modified Chua's circuit.

(the transformation group of diffeomorphisms). Unfortunately, the authors present no ideas about the kind of "coarse graining" produced in this set of circuits by their equivalence relation. However, a comparison to C^k conjugacy or C^k equivalence of vector fields in Section 10.1 implies that input–output equivalence leads to a "fine" decomposition in the set of Brayton–Moser input–output circuits. To classify the main features of the dynamics of circuits, the concept of topological equivalence (the transformation group of homeomorphisms) is useful. On the other hand, in the case of circuits with nonhyperbolic fixed points, the group of diffeomorphisms is needed to distinguish the interesting features. An interesting application of C^1 equivalence of vector fields is given by Chua [18]. To compare nonlinear circuits that generate chaotic signals, Chua applied the concept of equivalence relation and concluded that the class of circuits and systems that are C^1 equivalent to Chua's circuit (see Figure 10.5) is relative small. The nonlinearity in this circuit is described by a piecewise-linear i–v characteristic; see Ref. [42] for further details. The equations describing Chua's circuit are

$$\frac{dv_{C_1}}{dt} = \frac{1}{C_1}[G(v_{C_2} - v_{C_1}) - f(v_{C_1})], \tag{10.73}$$

$$\frac{dv_{C_2}}{dt} = \frac{1}{C_2}[G(v_{C_1} - v_{C_2}) + i_L)], \tag{10.74}$$

$$\frac{di_L}{dt} = \frac{1}{L}[v_{C_2} - R_0 i_L)], \tag{10.75}$$

where $R_0 = 0$ and the piecewise-linear function is defined by (G_a, G_b, E suitable constants)

$$f(v_{C_1}) := G_b v_{C_1} + \frac{1}{2}(G_a - G_b)(|v_{C_1} + E| - |v_{C_1} - E|). \tag{10.76}$$

Chua's extended approach to study the set of the piecewise-linear circuits that includes Chua's circuit introduces the concept of global unfoldings. This concept can be considered as an analogy to the theory of "local unfoldings" of nonhyperbolic systems in a small neighborhood of singularities [3,30]. Heuristically, a minimum number of parameters in a given nonhyperbolic system is obtained. Chua demonstrated that Chua's circuit with arbitrary $R_0 \neq 0$ can be considered as an "unfolding" of the original circuit. Furthermore, he proved that a class of circuits that can be described without any loss of generality by

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{b}, \quad x_1 \leq -1 \tag{10.77}$$

$$= \mathbf{A}\mathbf{x}, \quad -1 \leq x_1 \leq +1 \tag{10.78}$$

$$= \mathbf{A}\mathbf{x} + \mathbf{b}, \quad x_1 \geq +1 \tag{10.79}$$

is equivalent to the unfolded Chua's circuit if certain conditions are satisfied. In the associated parameter space, these conditions defined a set of measure zero. The proof of this theorem as well as some applications are included in Ref. [18].

The ideas of normal forms presented in Section 10.2 can be applied to nonlinear circuits with hyperbolic and nonhyperbolic fixed points. A similar theory of normal forms of maps can be used to study limit cycles, but this subject is beyond our scope; see Ref. [3] for further details. In any case the vector field has to be reduced to lower dimensions and that can be achieved by the application of the so-called center manifold theorem. Altman [1] illustrated this approach by calculating the center manifold of Chua's circuit equations and its normal form in a tutorial style. To perform the analytical computations the piecewise nonlinearity (Equation 10.78) is replaced by a cubic function $f(x) = c_0 x + c_1 x^3$. Based on this normal form, Altman studied bifurcations of Chua's circuits.

In the following, we describe applications of normal form theory from Section 10.2 to decompose nonlinear dynamical circuits at an arbitrary fixed point into nondynamical and dynamical parts; a sketch of this concept is presented by Keidies and Mathis [43]. In this section we restrict ourself to nonlinear dynamical circuits with constant sources where the describing equations are formulated in a state-space form:

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}), \quad \mathbf{f}: \mathbf{R}^n \rightarrow \mathbf{R}^n, \tag{10.80}$$

where all nonlinear reactances are replaced by linear reactances, nonlinear resistors, and linear controlled sources; see, e.g., Ref. [20]. It is assumed that all nonlinearities are polynomial functions and can be interpreted as nonlinear controlled sources. It can be assumed that the circuit is decomposed into a linear part that consists of linear reactances and resistive elements, and the nonlinear controlled sources. In other words, the RHS **f** of Equation 10.82 can be reformulated in the form $\mathbf{f}(\mathbf{x}) = \mathbf{A}\mathbf{x} + \tilde{\mathbf{f}}(\mathbf{x})$; a block diagram is shown in Figure 10.6. Now, the normal form theorem is applied to transform the nonlinear controlled sources to the input. It is known from Section 10.2 that all nonresonant parts of $\tilde{\mathbf{f}}(\mathbf{x})$ can be eliminated until a prescribed order k if the associated homological equation is satisfied. Therefore, after a nearly identity transformation (Equation 10.15) the normal form of the nonresonant part can be described by (see Figure 10.6)

$$\dot{\mathbf{y}} = \mathbf{A}\mathbf{y}, \quad \mathbf{x} = \mathbf{y} + \mathbf{h}(\mathbf{y}). \tag{10.81}$$

For this decomposition we have to define the nonresonant and resonant terms of the vector field where the eigenvalues of the linear part **A** of **f** and the degree of the polynomial nonlinearities must be studied.

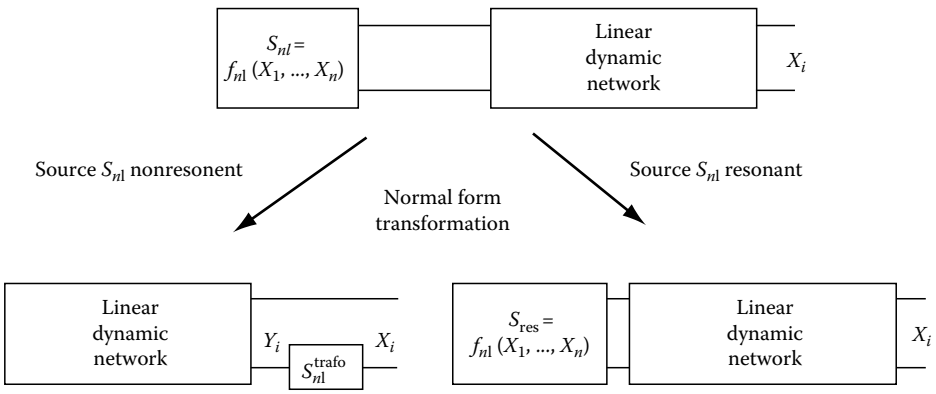

FIGURE 10.6 Decomposition of nonlinear dynamic circuits.

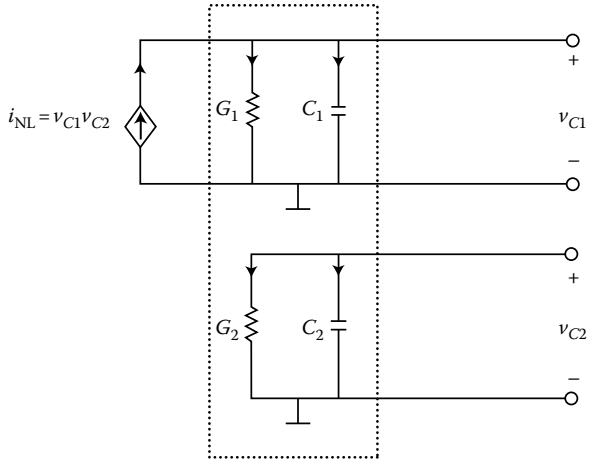

FIGURE 10.7 Decomposition of a simple nonlinear dynamic circuits.

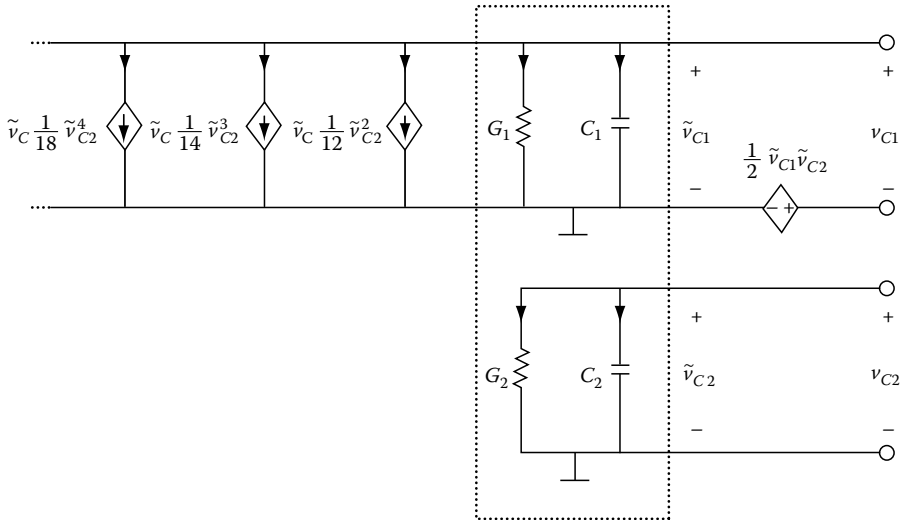

FIGURE 10.8 Decomposition

Under certain conditions, a finite recursive process exists, such that all nonlinear controlled sources can be transformed to the input of the linear part of the circuit under consideration. In these cases, the circuits are described by Equation 10.83 and the corresponding block diagram is shown on the left-hand side in Figure 10.6. If resonant terms occur, a number of additional sources are generated by means of a recursive process. In these cases the controlled cannot transforme to the input what is shown on the right-hand side of Figure 10.6. In order to illustrate these statements, a simple example is presented in Figure 10.7. After a nearly identity transformation, a reduction of the nonresonant terms, and the recursive process with respect to the resonant terms, the decomposed circuit is shown in Figure 10.8. Therefore, this application of normal form theorems in circuit analysis can be interpreted as a kind of extraction of nonlinear controlled sources from a nonlinear dynamic circuit. Finally it should be mentioned that this decomposition based on the normal form theorem is related in a certain sense to the so-called exact linearization that is studied in the theory of nonlinear control systems; see, e.g., Refs. [36,54].

11.1 Introduction and Motivation

In this chapter, we present a comprehensive description of the use of piecewise-linear (PWL) methods in modeling, analysis, and structural properties of nonlinear circuits. The main advantages of piecewise-linear circuits are fourfold. (1) Piecewise-linear circuits are the easiest in the class of nonlinear circuits to analyze exactly, because many methods for linear circuits can still be used. (2) The piecewise-linear approximation is an adequate approximation for most applications. Moreover, certain operational amplifier (op-amp), operational transconductance amplifier (OTA), diode and switch circuits are essentially piecewise linear. (3) Quite a number of methods exist to analyze piecewise-linear circuits. (4) Last, but not least, piecewise-linear circuits exhibit most of the phenomena of nonlinear circuits while still being manageable. Hence, PWL circuits provide unique insight in nonlinear circuits.

This chapter is divided into six sections. First, the piecewise-linear models will be presented and interrelated. A complete hierarchy of models and representations of models is presented. Rather than proving many relations, simple examples are given. Second, the piecewise-linear models for several important electronic components are presented. Third, since many PWL properties are preserved by interconnection, a short discussion on the structural properties of piecewise-linear circuits is given in Section 11.4. Fourth, analysis methods of PWL circuits are presented, ranging from the Katzenelson algorithm to the linear complementarity methods and the homotopy methods. Fifth, we discuss PWL dynamic circuits, such as the famous Chua circuit, which produces chaos. Finally, in Section 11.7, efficient

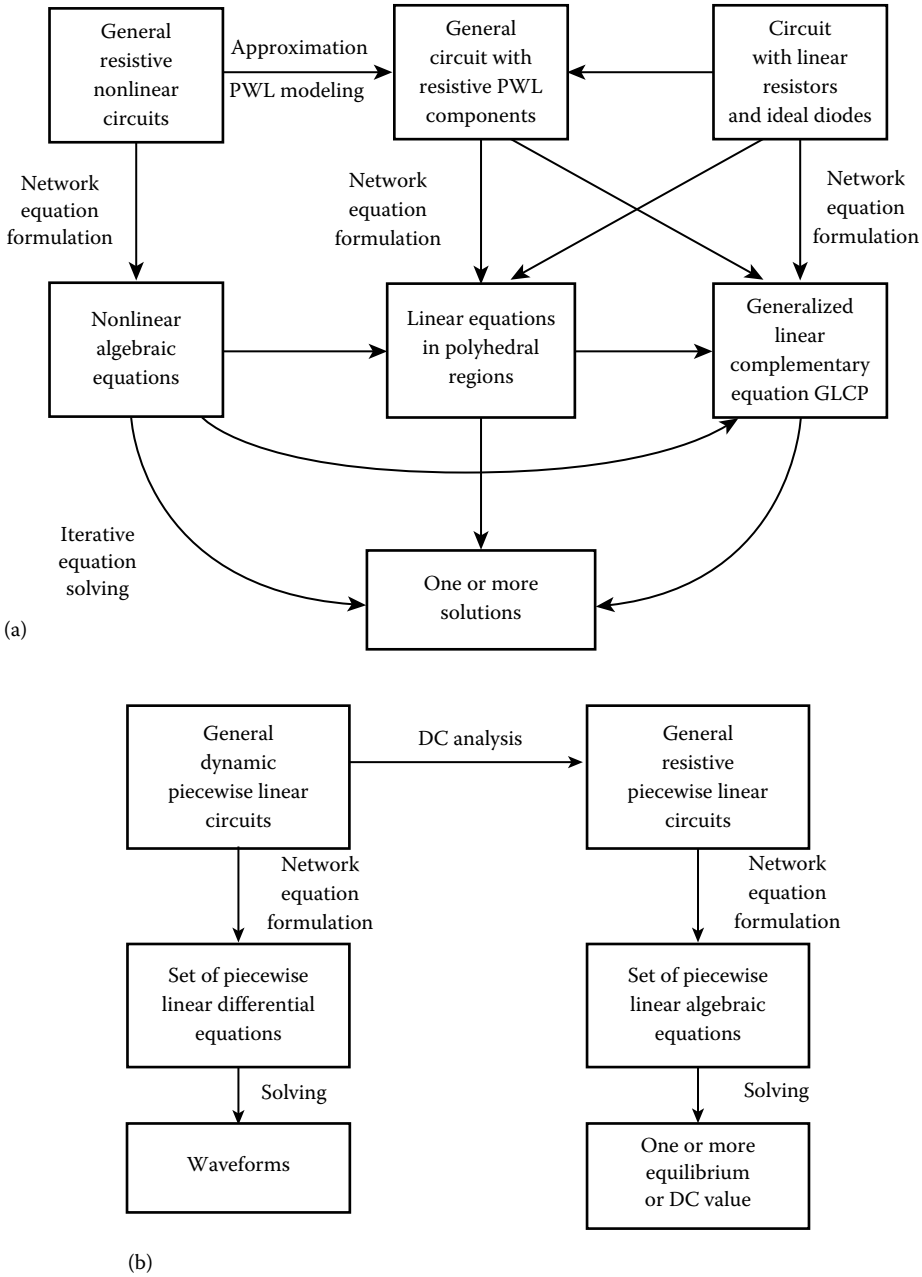

FIGURE 11.1 Interrelation of PWL circuit analysis methods: (a) resistive and (b) dynamic nonlinear circuits.

computer-aided analysis of PWL circuits and the hierarchical mixed-mode PWL analysis are described. A comprehensive reference list is included. For the synthesis of PWL circuits, we refer to Chapter 8.

In order to situate these subjects in the general framework of nonlinear circuits, it is instructive to interrelate the PWL circuit analysis methods (Figure 11.1). In the horizontal direction of the diagrams, one does the PWL approximation of the dc analysis from left to right. In the vertical direction, we show the conversion from a circuit to a set of equations by network equation formulation and the conversion

from equations to solutions (waveforms or dc values) by solution methods. The specific methods and names used in the figure are described in detail in the different parts.

11.2 Hierarchy of Piecewise-Linear Models and Their Representations

In the past 25 years, much progress has been achieved in the representations of piecewise-linear resistive multiports and their relationships (see Refs. [1,2]). From a practical point of view, a clear trade-off exists between the efficiency of a representation in terms of the number of parameters and the ease of evaluation (explicit versus implicit models) on the one hand and the generality or accuracy on the other hand. Here, we go from the easiest and most efficient to the most general representations.

We define here a resistive multiport (Figure 11.2) as an n-port whose port variables (the vector of port currents $i = [i_1, \ldots, i_n]^T$ and the vector of port voltages $v = [v_1, \ldots, v_n]^T$) are related by m algebraic equations called constitutive equations

$$\varphi(i, v) = 0 \tag{11.1}$$

where $i, v \in \mathbb{R}^n$ and $\phi(.,.)$ maps $\mathbb{R}^{2n}$ into $\mathbb{R}^m$.

For example, for a bipolar transistor (Figure 11.3), one obtains the explicit form $i_1 = f_1(v_1, v_2)$ and $i_2 = f_2(v_1, v_2)$, and $i = [i_1, i_2]^T$ and $v = [v_1, v_2]^T$. These relations can be measured with a curve tracer as dc characteristic curves. Clearly, here $\phi(.,.)$ is a map from $\mathbb{R}^4 \rightarrow \mathbb{R}^2$ in the form

$$i_1 - f_1(v_1, v_2) = 0 \tag{11.2}$$

$$i_2 - f_2(v_1, v_2) = 0 \tag{11.3}$$

It is easy to see that a complete table of these relationships would require an excessive amount of computer storage already for a transistor. Hence, it is quite natural to describe a resistive n-port with a piecewise-linear map f over polyhedral regions P_k by

$$v = f(i) = a_k + B_k i, \quad i \in P_k, \quad k \in \{0, 1, \ldots, 2^l - 1\} \tag{11.4}$$

where the Jacobian $B_k \in \mathbb{R}^{n \times n}$ and the offset vector $a_k \in \mathbb{R}^n$ are defined over the polyhedral region P_k, separated by hyperplanes $c_i^T x - d_i = 0$, $i = 1, \ldots, l$ and defined by

$$P_k = \left\{ x \in \mathbb{R}^n | c_j^T x - d_j \geq 0, j \in I_k, c_j^T x - d_j \leq 0, j \notin I_k \right\} \tag{11.5}$$

where

$k = \Sigma_{j \in Ik}\, 2^{j-1}$
$I_k \subseteq \{1, 2, \ldots, l\}$
$c_j \in \mathbb{R}^n$, $d_j \in \mathbb{R}^n$

In other words, the hyperplanes $c_i^T x - d_i = 0$, $i = 1, \ldots, l$ separate the space $\mathbb{R}^n$ into 2^l polyhedral regions P_k (see Figure 11.4) where the constitutive equations are linear.

The computer storage requirements for this representation is still quite large, especially for large multiports. A more fundamental problem with this rather intuitive representation is that it is not necessarily continuous at the boundaries between two polyhedral regions. In fact, the continuity of the nonlinear map is usually desirable for physical reasons and also in order to avoid problems in the analysis.

The canonical PWL representation [6] is a very simple, attractive, and explicit description for a resistive multiport that solves both problems:

$$v = f(i) = a + Bi + \sum_{j=1}^{l} e_j \left| c_j^T i - d_j \right| \qquad (11.6)$$

One can easily understand this equation by looking at the wedge form of the modulus map (see Figure 11.5). It has two linear regions: in the first $x \geq 0$ and $y = x$, while in the second $x \leq 0$ and $y = -x$. At the boundary the function is clearly continuous. Equation 11.6 is hence also continuous and is linear in each of the polyhedral regions P_k described by Equation 11.5. If l modulus terms are in Equation 11.6, there are 2^l polyhedral regions where the map Equation 11.6

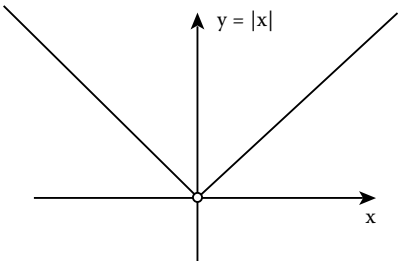

FIGURE 11.5 Absolute value function $y = |x|$.

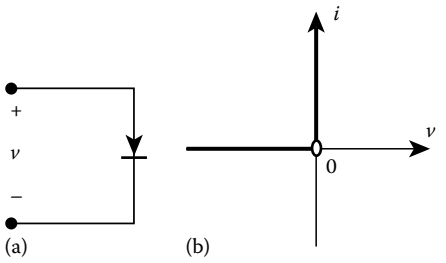

FIGURE 11.6 (a) The ideal diode and (b) the $(i-v)$ relation of an ideal diode.

is linear. Because the map is represented canonically with $n + n^2 + l(n+1)$ real parameters, this is a very compact and explicit representation.

Several examples of canonical PWL models for components are given in Section 11.3.

From Figure 11.5, it should be clear that the right and left derivative of $y = |x|$ at 0 are different, their difference being 2. Hence, the Jacobian J_+ and J_- of Equation 11.6 will be different on the boundary between the two neighboring polyhedral regions where $(c_j i - d_j) \geq 0$ and $(c_j i - d_j) \leq 0$.

$$J_+ - J_- = 2e_j c_j^{\mathrm{T}} \tag{11.7}$$

Observe that this difference is a rank 1 matrix, which is also called a dyadic or outer vector product of e_j and c_j. Moreover, this difference is independent of the location of the independent variable i on the boundary. This important observation is made in Ref. [24], and is called the consistent variation property [10] and essentially says that the variation of the Jacobian of a canonical PWL representation is independent of the place where the hyperplane $c_j i - d_j = 0$ is crossed. Of course, this implies that the canonical PWL representation (Equation 11.6) is not the most general description for a continuous explicit PWL map. In Refs. [26,29] two more general representations, which include nested absolute values, are presented. These are too complicated for our discussion.

Clearly, the canonical PWL representation (Equation 11.6) is valid only for single-valued functions. It can clearly not be used for an important component: the ideal diode (Figure 11.6) characterized by the multivalued (i, v) relation. It can be presented analytically by introducing a real scalar parameter ρ [31].

$$i = \frac{1}{2}(\rho + |\rho|) \tag{11.8}$$

$$v = \frac{1}{2}(\rho - |\rho|) \tag{11.9}$$

This parametric description can easily be seen to correspond to Figure 11.6b because $i = \rho$ and $v = 0$ for $\rho \geq 0$, while $i = 0$ and $v = \rho$ when $\rho \leq 0$. Such a parametric description $i = f(\rho)$ and $v = g(\rho)$ with f and g PWL can be obtained for a whole class of unicursal curves [6].

When we allow implicit representations between v and i for a multiport, we obtain a linear complementarity problem (LCP) model Equations 5.10 through 5.12 with an interesting state space like form [55]:

$$v = Ai + Bu + f \tag{11.10}$$

$$s = Ci + Du + g \tag{11.11}$$

$$u \geq 0, \quad s \geq 0, \quad u^{\mathrm{T}} s = 0 \tag{11.12}$$

where $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times l}$, $f \in \mathbb{R}^{n \times n}$, $c \in \mathbb{R}^{l \times n}$, $D \in \mathbb{R}^{l \times l}$ are the parameters that characterize the relationship between v and i. In the model, u and s are called the state vectors and we say that $u \geq 0$ when all its components are nonnegative. Clearly, Equation 11.12 dictates that all components of u and s should be nonnegative and that, whenever a component u_j satisfies $u_j > 0$, then $s_j = 0$ and, vice versa, when $s_j > 0$, then $u_j = 0$. This is called the linear complementarity property, which we have seen already in the ideal diode equation (Equations 11.8 and 11.9) where $i \geq 0$, $v \geq 0$ and $iv = 0$. Hence, an implicit or LCP model for the ideal diode equation (Equations 11.8 and 11.9) is

$$v = u \tag{11.13}$$

$$s = i \tag{11.14}$$

$$u \geq 0, \quad s \geq 0, \quad us = 0 \tag{11.15}$$

In order to understand that the general equations (Equations 11.10 through 11.12) describe a PWL relation such as Equations 11.4 and 11.5 between i and v over polyhedral regions, one should observe first that $v = Ai + f$ is linear when $u = 0$ and $s = Ci + g \geq 0$. Hence, the relation is linear in the polyhedral region determined by $Ci + g \geq 0$. In general, one can consider 2^l possibilities for u and s according to

$$(u_j \geq 0 \text{ and } s_j = 0) \text{ or } (u_j = 0 \text{ and } s_j = 0) \quad \text{for } j = 1, 2, \ldots, l$$

Denote sets of indexes U and S for certain values of u and s satisfying Equation 11.12

$$U = \{j | u_j \geq 0 \text{ and } s_j = 0\} \tag{11.16}$$

$$S = \{j | u_j = 0 \text{ and } s_j \geq 0\} \tag{11.17}$$

then, clearly, U and S are complementary subsets of $\{1, 2, \ldots, l\}$ when for any j, u_j, and s_j cannot be both zero. Clearly, each of these 2^l possibilities corresponds to a polyhedral region P_U in $\mathbb{R}^n$, which can be determined from

$$u_j \geq 0 \quad (Ci + Du + g)_j = 0 \quad \text{for } j \in U \tag{11.18}$$

$$u_j = 0 \quad (Ci + Du + g)_j \geq 0 \quad \text{for } j \in S \tag{11.19}$$

The PWL map in region P_U is determined by solving the u_j for $j \in U$ from Equation 11.18 and substituting these along with $u_j = 0$ for $j \in S$ into Equation 11.10. This generates, of course, a map that is linear in the region P_U.

When Equation 11.11 is replaced by the implicit equation

$$Es + Ci + Du + g\alpha = 0, \quad \alpha \geq 0$$

in Equations 11.10 through 11.13, we call the problem a generalized linear complementarity problem (GLCP).

A nontrivial example of an implicit PWL relation (LCP model) is the hysteresis one port resistor (see Figure 11.7). Its equations are

$$v = -i + [-\mathbf{1}\ \mathbf{1}] \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} + 1 \tag{11.20}$$

$$\begin{bmatrix} s_1 \\ s_2 \end{bmatrix} = \begin{bmatrix} -1 \\ 1 \end{bmatrix} i + \begin{bmatrix} -1 & 1 \\ 1 & -1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} + \begin{bmatrix} 1 \\ 0 \end{bmatrix} \tag{11.21}$$

$$s_1 \geq 0, \quad s_2 \geq 0, \quad u_1 \geq 0, \quad u_2 \geq 0, \quad u_1 s_1 + u_2 s_2 = 0 \tag{11.22}$$

In the first region P, we have

$$s_1 = -i + 1 \geq 0, \quad s_2 = i \geq 0, \quad \text{and} \quad v = -i + 1 \tag{11.23}$$

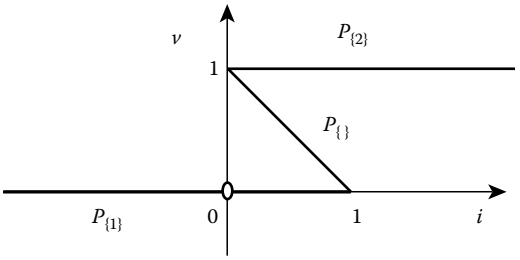

FIGURE 11.7 Hysteresis nonlinear resistor.

The region $P_{\{1,2\}}$, on the other hand, is empty because the following set of equations are contradictory:

$$\begin{gathered} s_1 = s_2 = 0, \quad -i - u_1 + u_2 + 1 = 0, \\ i + u_1 - u_2 = 0 \end{gathered} \tag{11.24}$$

The region $P_{[1]}$ is

$$u_1 \geq 0, \quad s_1 = -i - u_1 + 1 = 0, \quad u_2 = 0, \quad s_2 = i + u_1 \geq 0 \tag{11.25}$$

Hence, $u_1 = -i + 1$ and $s_2 = 1$ and $v = -i + i - 1 + 1 = 0$, while $i \leq 1$.

Finally, the region $P_{[2]}$ is

$$u_1 \geq 0, \quad s_1 = -i + u_2 + 1 \geq 0, \quad u_2 \geq 0, \quad s_2 = i - u_2 = 0$$

Hence

$$u_2 = i \quad \text{and} \quad s_1 = 1 \quad \text{and} \quad v = -i + i + 1 = 1, \quad \text{while } i \geq 0 \tag{11.26}$$

It is now easy to show in general that the canonical PWL representation is a special case of the LCP model. Just choose $u_j \geq 0$ and $s_j \geq 0$ for all j as follows:

$$\left| c_j^{\mathrm{T}} i - d_j \right| = \frac{1}{2}(u_j + s_j) \tag{11.27}$$

$$c_j^{\mathrm{T}} i - d_j = \frac{1}{2}(u_j - s_j) \tag{11.28}$$

then, u and s are complementary vectors, i.e.,

$$u \geq 0, \quad s \geq 0, \quad u^{\mathrm{T}} s = 0$$

Observe that the moduli in Equation 11.6 can be eliminated with Equation 11.27 to produce an equation of the form (Equation 11.10) and that (Equation 11.28) produces an equation of the form (Equation 11.11).

More generally, it has been proven [36] that the implicit model includes all explicit models. Because it also includes the parametric models, one obtains the general hierarchy of models as depicted in Figure 11.8.

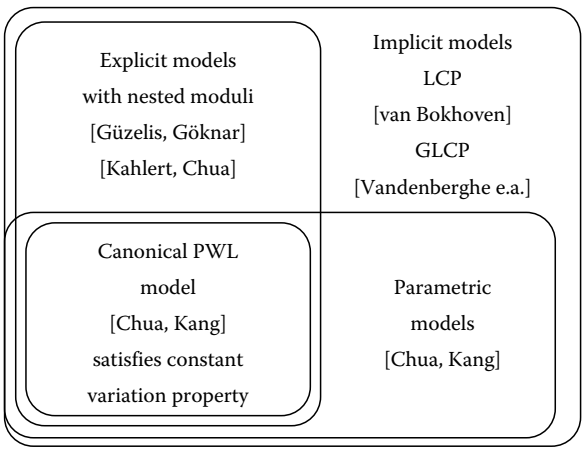

FIGURE 11.8 Interrelation of the PWL models.

A general remark should be made about all models that have been presented until now. Although the models have been given for resistive multiports where the voltages v at the ports are expressed in terms of the currents i, analogous equations can be given for the currents i in terms of the voltages, or hybrid variables. It can even be adapted for piecewise-linear capacitors, inductors, or memristors, where the variables are, respectively, q, v for capacitors, φ, i for inductors, and q, φ for memristors.

11.3 Piecewise-Linear Models for Electronic Components

In order to simulate nonlinear networks with a circuit or network simulator, the nonlinear behavior of the components must be modeled fist. During this modeling phase, properties of the component that are not considered important for the behavior of the system may be neglected. The nonlinear behavior is often important, therefore, nonlinear models have to be used. In typical simulators such as SPICE, nonlinear models often involve polynomials and transcendental functions for bipolar and MOS transistors. These consume a large part of the simulation time, so table lookup methods have been worked out. However, the table lookup methods need much storage for an accurate description of multiports and complex components.

The piecewise-linear models constitute an attractive alternative that is both efficient in memory use and in computation time. We discuss here the most important components. The derivation of a model usually requires two steps: first, the PWL approximation of constitutive equations, and second, the algebraic representation.

Two PWL models for an ideal diode (Figure 11.6) have been derived, that is, a parametric model (Equations 11.8 and 11.9) and an implicit model (Equations 11.13 through 11.15, while a canonical PWL model does not exist.

The piecewise-linear models for op-amps and OTAs are also simple and frequently used. The piecewise-line approximation of op-amps and OTAs of Figure 11.9 is quite accurate. It leads to the

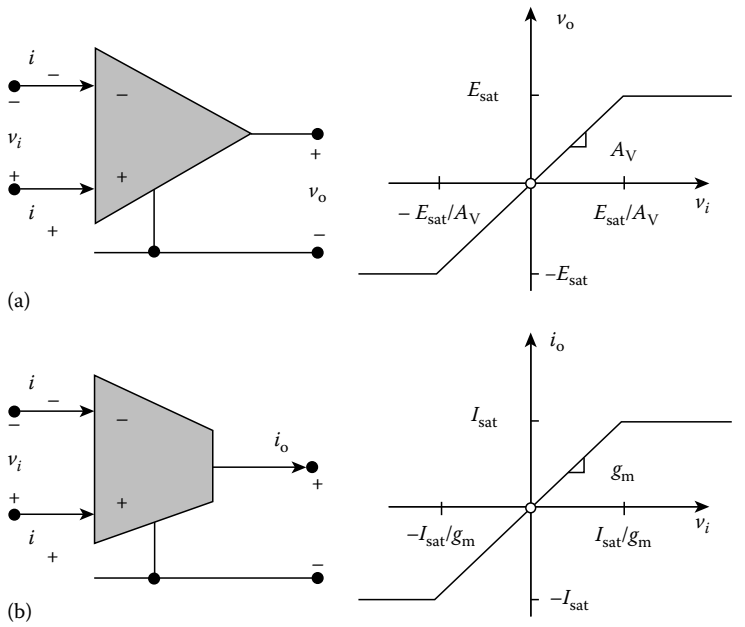

FIGURE 11.9 (a) Op-amp and PWL model and (b) OTA and PWL model.

following representation for the op-amp, which is in the linear region for $-E_{\text{sat}} \le v_0 \le E_{\text{sat}}$ with voltage amplification A_v and positive and negative saturation E_{sat} and $-E_{\text{sat}}$

$$v_0 = \frac{A_v}{2}\left(\left|v_i + \frac{E_{\text{sat}}}{A_v}\right| - \left|v_i - \frac{E_{\text{sat}}}{A_v}\right|\right) \tag{11.29}$$

$$i_- = i_+ = 0 \tag{11.30}$$

This is called the op-amp finite-gain model. In each of the three regions, the op-amp can be replaced by a linear circuit.

For the OTA, we have similarly in the linear region for $-I_{\text{sat}} \le i_0 \le I_{\text{sat}}$ with transconductance gain g_{m} and positive and negative saturation I_{sat} and $-I_{\text{sat}}$

$$i_0 = \frac{g_{\text{m}}}{2}\left(\left|v_i + \frac{I_{\text{sat}}}{g_{\text{m}}}\right| - \left|v_i - \frac{I_{\text{sat}}}{g_{\text{m}}}\right|\right) \tag{11.31}$$

$$i_- = i_+ = 0 \tag{11.32}$$

Next, for a tunnel diode, one can perform a piecewise-linear approximation for the tunnel-diode characteristic as shown in Figure 11.10. It clearly has three regions with conductances g_1, g_2, and g_3. This PWL characteristic can be realized by three components (Figure 11.10b) with conductances, voltage sources, and diodes. The three parameters G_0, G_1, and G_2 of Figure 11.10b must satisfy

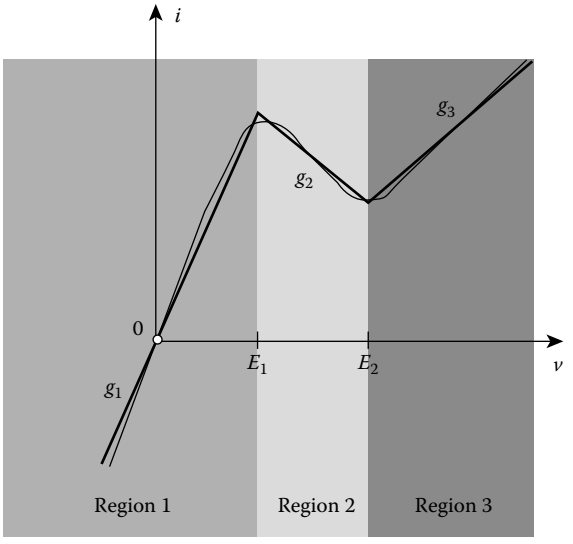
$$\text{In Region 1: } G_0 = g_1 \tag{11.33}$$

$$\text{In Region 2: } G_0 + G_1 = g_2 \tag{11.34}$$

$$\text{In Region 3: } G_0 + G_1 + G_2 = g_3 \tag{11.35}$$

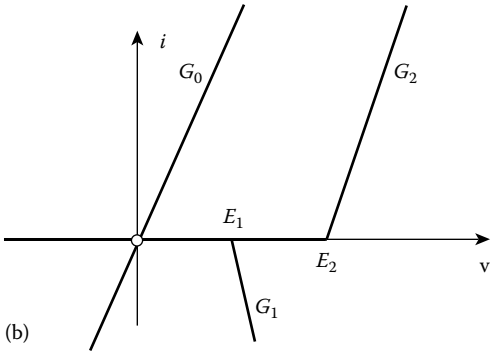
Thus, $G_0 = g_1$, $G_1 = -g_1 + g_2$, and $G_2 = -g_2 + g_3$. We can derive the canonical PWL representation as follows:

$$i = -\frac{1}{2}(G_1E_1 + G_2E_2) + \left(G_0 + \frac{1}{2}G_1 + \frac{1}{2}G_2\right)v + \frac{1}{2}G_1|v - E_1| + \frac{1}{2}G_2|v - E_2| \tag{11.36}$$



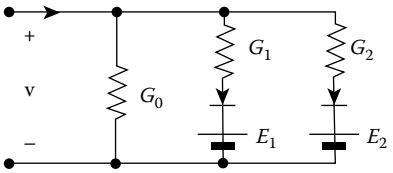
Next, we present a canonical piecewise-linear bipolar transistor model [12]. Assume a *npn*-bipolar transistor is connected in the common base configuration with $v_1 = v_{BE}$, $v_2 = v_{BC}$, $i_1 = i_E$, and $i_2 = i_C$, as shown in Figure 11.3. We consider data points in a square region defined by $0.4 \le v_1 \le 0.7$ and $0.4 \le v_2 \le 0.7$, and assume the terminal behavior of the transistor follows the Ebers–Moll equation; namely,

$$i_1 = \frac{I_{\text{s}}}{\alpha_{\text{f}}}\left(e^{v_1/V_{\text{T}}} - 1\right) - I_{\text{s}}\left(e^{v_2/V_{\text{T}}} - 1\right) \tag{11.37}$$



$$i_2 = \frac{I_{\text{s}}}{\alpha_{\text{r}}}\left(e^{v_2/V_{\text{T}}} - 1\right) - I_{\text{s}}\left(e^{v_1/V_{\text{T}}} - 1\right) \tag{11.38}$$

with $I_{\text{s}} = 10^{-14}$ A, $V_{\text{T}} = 26$ mV, $\alpha_{\text{f}} = 0.99$, and $\alpha_{\text{r}} = 0.5$. In Ref. [12], the following canonical piecewise-linear model is obtained, which optimally fits the data points (Figure 11.11)



$$\begin{bmatrix} i_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} + \begin{bmatrix} b_{11} & b_{21} \\ b_{12} & b_{22} \end{bmatrix}\begin{bmatrix} v_1 \\ v_2 \end{bmatrix} + \begin{bmatrix} c_{11} \\ c_{21} \end{bmatrix}|m_1v_1 - v_2 + t_1| + \begin{bmatrix} c_{12} \\ c_{22} \end{bmatrix}|m_2v_1 - v_2 + t_2| + \begin{bmatrix} c_{13} \\ c_{23} \end{bmatrix}|m_3v_1 - v_2 + t_3| \tag{11.39}$$

$$\begin{bmatrix} b_{12} \\ b_{22} \end{bmatrix} = \begin{bmatrix} -4.0897 \times 10^{-2} \\ 8.1793 \times 10^{-2} \end{bmatrix} \begin{bmatrix} c_{11} \\ c_{21} \end{bmatrix} = \begin{bmatrix} 3.1095 \times 10^{-6} \\ -3.0784 \times 10^{-6} \end{bmatrix}$$

$$\begin{bmatrix} c_{12} \\ c_{22} \end{bmatrix} = \begin{bmatrix} -9.9342 \times 10^{-3} \\ 1.9868 \times 10^{-2} \end{bmatrix} \begin{bmatrix} c_{13} \\ c_{23} \end{bmatrix} = \begin{bmatrix} -3.0471 \times 10^{-2} \\ 6.0943 \times 10^{-2} \end{bmatrix}$$

$$\begin{bmatrix} m_1 \\ m_2 \\ m_3 \end{bmatrix} = \begin{bmatrix} 1.002 \times 10^{4} \\ -1.4 \times 10^{-4} \\ 1.574 \times 10^{-6} \end{bmatrix} \begin{bmatrix} t_1 \\ t_2 \\ t_3 \end{bmatrix} = \begin{bmatrix} -6472 \\ 0.61714 \\ 0.66355 \end{bmatrix}$$

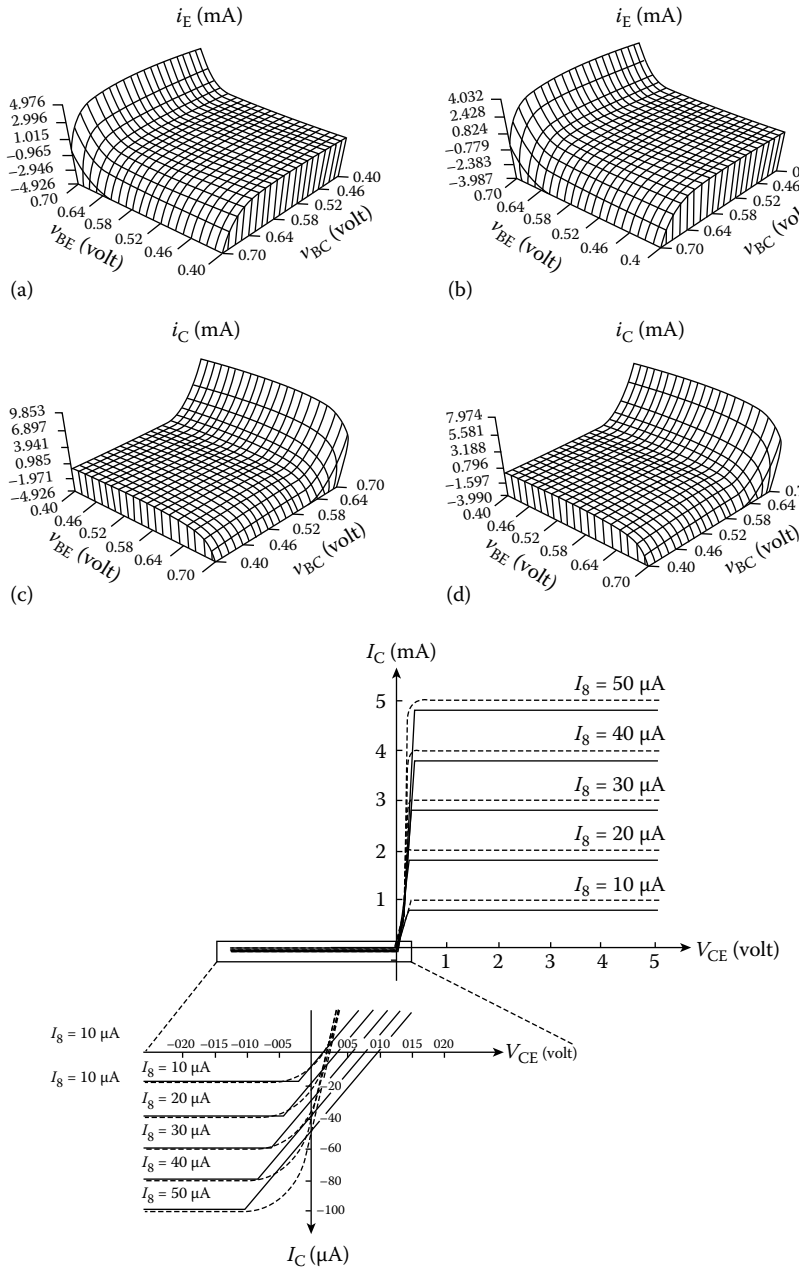

FIGURE 11.11 Three-dimensional plots for the emitter current in the Ebers–Moll model given by Equations 11.37 and 11.38. (b) Three-dimensional plot for the emitter current in the canonical piecewise-linear model given by Ref. [10, (B.1)] (low-voltage version). (c) Three-dimensional plot for the collector current in the Ebers–Moll model given by Equations 11.37 and 11.38. (d) Three-dimensional plot for the collector current in the canonical piecewise-linear model given by Ref. [10, (B.1)] (low-voltage version). (e) Comparison between the family of collector currents in the Ebers–Moll model (dashed line) and the canonical piecewise-linear model (solid line). (From Chua, L.O. and Deng, A., *IEEE Trans. Circuits Syst*., CAS-33, 519, 1986. With permission.)

Next, a canonical piecewise-linear MOS transistor model is presented. Assume the MOS transistor is connected in the common source configuration with $v_1 = v_{GS}$, $v_2 = v_{DS}$, $i_1 = i_G$, and $i_2 = i_D$, as illustrated, in Figure 11.12, where both v_1, v_2 are in volts, and i_1, i_2 are in microamperes. The data points are uniformly spaced in a grid within a rectangular region defined by $0 \le v_1 \le 5$, and $0 \le v_2 \le 5$. We assume the data points follow the Shichman–Hodges model, namely,

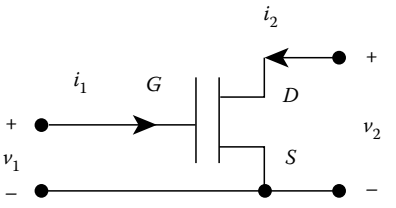

FIGURE 11.12 Two-port configuration of the MOSFET.

$$
\begin{aligned}
i_1 &= 0 \\
i_2 &= k\left[(v_1 - V_t)v_2 - 0.5v_2^2\right], \quad \text{if } v_1 - V_t \ge v_2
\end{aligned}
$$

or

$$
i_2 = 0.5k(v_1 - V_t)^2[1 + \lambda(v_2 - v_1 + V_t)], \quad \text{if } v_1 - V_t < v_2 \tag{11.40}
$$

with $k = 50\ \mu\text{A/V}^2$, $V_t = 1$ V, $\lambda = 0.02\ \text{V}^{-1}$. Applying the optimization algorithm of Ref. [11], we obtain the following canonical piecewise-linear model (see Figure 11.13):

$$
\begin{aligned}
i_2 = {} & a_2 + b_{21}v_1 + b_{22}v_2 + c_{21}|m_1v_1 - v_2 + t_1| \\
& + c_{22}|m_2v_1 - v_2 + t_2| + c_{23}|m_3v_1 - v_2 + t_3|
\end{aligned} \tag{11.41}
$$

where

$$
\begin{aligned}
a_2 &= -61.167, \quad b_{21} = 30.242, \quad b_{22} = 72.7925 \\
c_{21} &= -49.718, \quad c_{22} = -21.027, \quad c_{23} = 2.0348 \\
m_1 &= 0.8175, \quad m_2 = 1.0171, \quad m_3 = -23.406 \\
t_1 &= -2.1052, \quad t_2 = -1.4652, \quad t_3 = 69
\end{aligned}
$$

Finally, a canonical piecewise-linear model of GaAs FET is presented. The GaAs FET has become increasingly important in the development of microwave circuits and high-speed digital IC's due to its fast switching speed.

$$
\begin{aligned}
i_2 = {} & a_2 + b_{21}v_1 + b_{22}v_2 + c_{21}|m_1v_1 - v_2 + t_2| \\
& + c_{22}|m_2v_1 - v_2 + t_2| + c_{23}|m_3v_1 - v_2 + t_3|
\end{aligned} \tag{11.42}
$$

where $v_1 = v_{GS}$ (V), $v_2 = v_{DS}$ (V), $i_2 - i_D$ (mA), and

$$
\begin{aligned}
a_2 &= 6.3645, \quad b_{21} = 2.4961, \quad b_{22} = 32.339 \\
c_{21} &= 0.6008, \quad c_{22} = 0.9819, \quad c_{23} = -29.507 \\
m_1 &= -19.594, \quad m_2 = -6.0736, \quad m_3 = 0.6473 \\
t_1 &= -44.551, \quad t_2 = -8.9962, \quad t_3 = 1.3738
\end{aligned}
$$

Observe that this model requires only three absolute-value functions and 12 numerical coefficients and compares rather well to the analytical model (Figure 11.14).

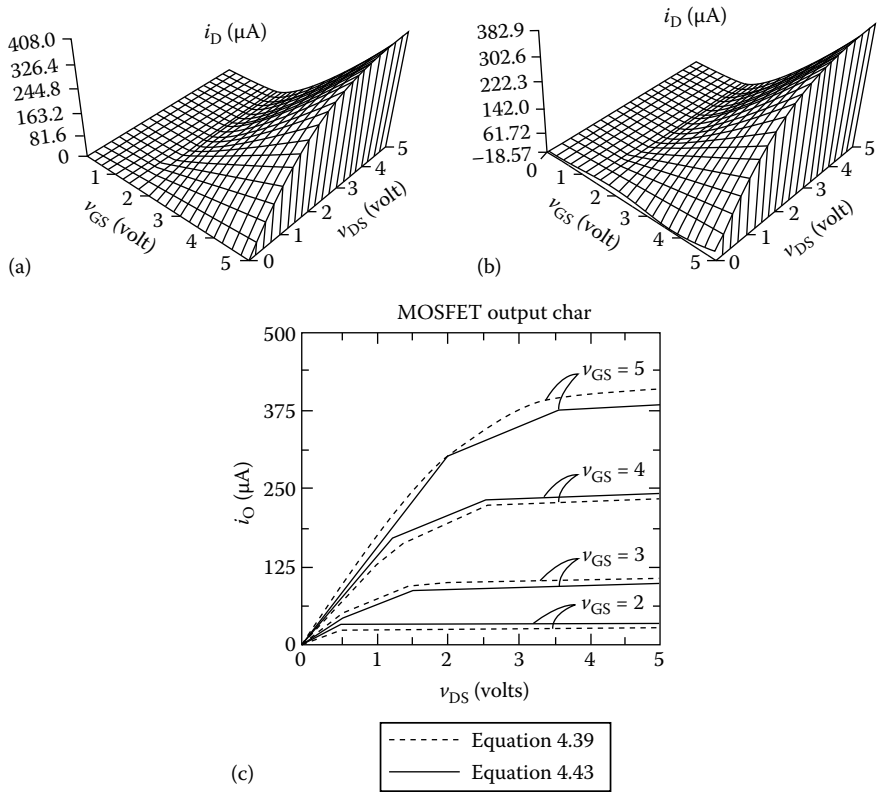

FIGURE 11.13 (a) Three-dimensional plot of drain current from the Shichman–Hodges model. (b) Three-dimensional plot of the drain current from the canonical piecewise-linear model. (c) Family of drain currents modeled by Equations 11.40 (dashed line) and 11.41 (solid line). (From Chua, L.O. and Deng, A., *IEEE Trans. Circuits Syst.*, CAS-33, 520, 1986. With permission.)

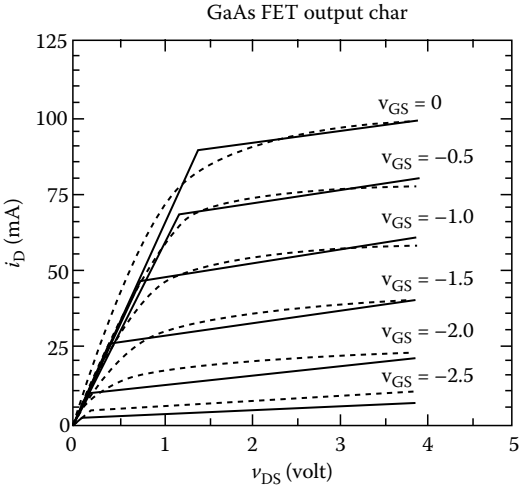

FIGURE 11.14 Comparison of the canonical piecewise linear described by Equation 11.42 (solid line) and the analytical model (dashed line) for the ion-implanted GaAs FET. (From Chua, L.O. and Deng, A., *IEEE Trans. Circuits Syst.*, CAS-33, 522, 1986. With permission.)

More piecewise-linear models for timing analysis of logic circuits can be found in Ref. [21]. In the context of analog computer design, even PWL models of other nonlinear relationships have been derived in Ref. [51].

11.4 Structural Properties of Piecewise-Linear Resistive Circuits

When considering interconnections of PWL resistors (components), it follows from the linearity of KVL and KCL that the resulting multiport is also a piecewise-linear resistor. However, if the components have a canonical PWL representation, the resulting multiport may not have a canonical PWL representation. This can be illustrated by graphically deriving the equivalent one port of the series connection of two tunnel diodes [3] (Figure 11.15). Both resistors have the same current, so we have to add the corresponding voltages $v = v_1 + v_2$ and obtain an $i-v$ plot with two unconnected parts. Values of i correspond to three values of v_1 for R_1 and three values of v_2 for R_2, and hence to nine values of the equivalent resistor (Figure 11.15d). This illustrates once more that nonlinear circuits may have more solutions than expected at first sight. Although the two tunnel diodes R_1 and R_2 have a canonical PWL representation, the equivalent one port of their series connection has neither a canonical PWL voltage description, nor a current one. It, however, has a GLCP description because KVL, KCL, and the LCP of R_1 and R_2 constitute a GLCP. If the v–i PWL relation is monotonic, the inverse i–v function exists and then some uniqueness properties hold.

These observations are, of course, also valid for the parallel connection of two PWL resistors and for more complicated interconnections.

In Section 11.3, we illustrated with an example how a PWL one-port resistor can be realized with linear resistors and ideal diodes. This can be proven in general. One essentially needs a diode for each breakpoint in the PWL characteristic. Conversely, each one port with diodes and resistors is a PWL one port resistor.

This brings us to an interesting class of circuits composed of linear resistors, independent sources, linear controlled sources, and ideal diodes. These circuits belong to the general class of circuits with PWL

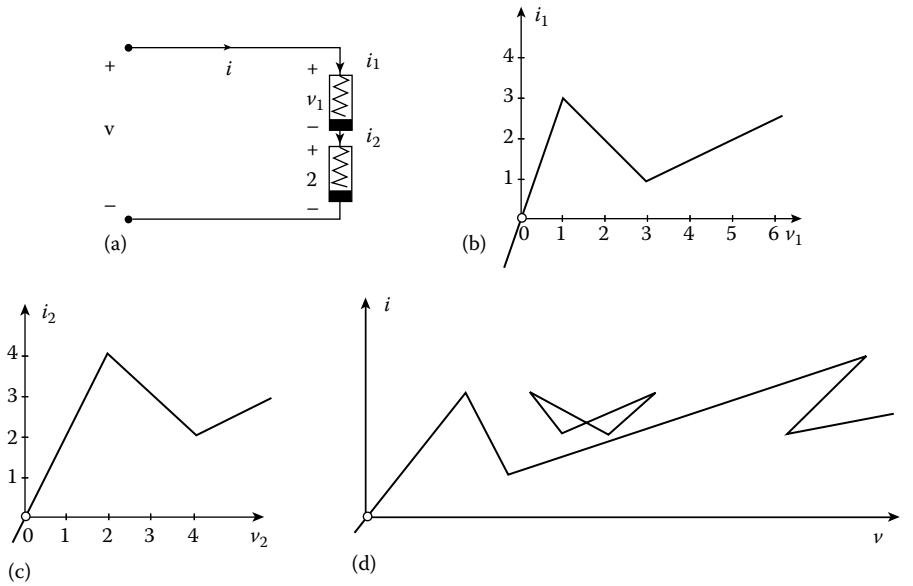

FIGURE 11.15 (a) The series connection of two tunnel diodes, (b) and (c), their $i-v$ characteristics, and (d) the composite $i-v$ plot, which consists of two unconnected parts.

components (see Figure 11.1a) and can be described by GLCP equations. Such networks have not only shown their importance in analysis but also in the topologic study of the number of solutions and more general qualitative properties. When only short-circuit and open-circuit branches are present, one independent voltage source with internal resistance and ideal diodes, an interesting loop cut set exclusion property holds that is also called the colored branch theorem or the arc coloring theorem (see Section 1.7 of *Fundamentals of Circuits and Filters*). It says that the voltage source either forms a conducting loop with forward-oriented diodes and some short circuits or there is a cut set of the voltage source, some open circuits, and blocking diodes. Such arguments have been used to obtain [23] topologic criteria for upper bounds of the number of solutions of PWL resistive circuits. In fact, diode resistor circuits have been used extensively in PWL function generators for analog computers [51]. These electrical analogs can also be used for mathematical programming problems (similar to linear programming) and have reappeared in the neural network literature.

11.5 Analysis of Piecewise-Linear Resistive Circuits

It is first demonstrated that all conventional network formulation methods (nodal, cut, set, hybrid, modified nodal, and tableau) can be used for PWL resistive circuits where the components are described with canonical or with LCP equations. These network equations may have one or more solutions. In order to find solutions, one can either search through all the polyhedral regions P_k by solving the linear equations for that region or by checking whether its solution is located inside that region P_k.

Because many regions often exist, this is a time-consuming method, but several methods can be used to reduce the search [28,61]. If one is interested in only one solution, one can use solution tracing methods, also called continuation methods or homotopy methods, of which the Katzenelson method is best known. If one is interested in all solutions, the problem is more complicated, but some algorithms exist.

11.5.1 Theorem Canonical PWL (Tableau Analysis)

Consider a connected resistive circuit N containing only linear two-terminal resistors, dc-independent sources, current-controlled and voltage-controlled piecewise-linear two-terminal resistors, linear- and piecewise-linear-controlled sources (all four types) and any linear multiterminal resistive elements. A composite branch of this circuit is given in Figure 11.16. If each piecewise-linear function is represented in the canonical form (Equation 11.6), then the *tableau formulation* also has the canonical PWL form

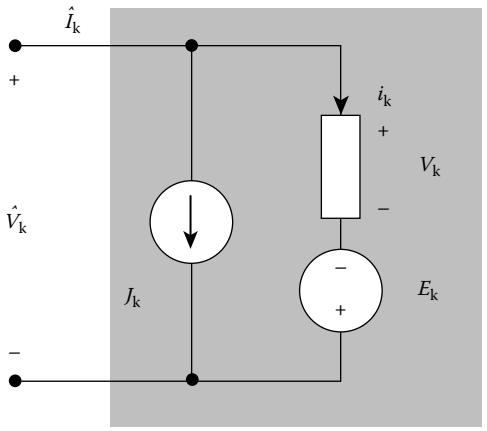

FIGURE 11.16 A composite branch.

$$f(x) = a + Bx + \sum_{i+1}^{p} c_i |\alpha_i^{\mathrm{T}} x - \beta_i| = 0 \qquad (11.43)$$

where $x = \left[i^{\mathrm{T}}, v^{\mathrm{T}}, v_n^{\mathrm{T}}\right]^{\mathrm{T}}$ and i, respectively v, is the branch current voltage vector (Figure 11.16) and v_n is the node-to-datum voltage vector.

PROOF. Let A be the reduced incidence matrix of N relative to some datum node, then KCL, KVL, and element constitutive relations give

$$Ai = AJ \qquad (11.44)$$

$$v = A^{\mathrm{T}} v_n + E \qquad (11.45)$$

$$f_1(i) + f_v(v) = S \qquad (11.46)$$

where we can express $f_{\mathrm{I}}(\cdot)$ and $f_{\mathrm{v}}(\cdot)$ in the canonical form (Equation 11.6)

$$f_I(i) = a_I + B_I i + C_I \mathrm{abs}\left(D_I^{\mathrm{T}} e - e_1\right) \tag{11.47}$$

$$f_{\mathrm{v}}(v) = a_{\mathrm{v}} + B_{\mathrm{v}} v + C_{\mathrm{v}} \mathrm{abs}\left(D_{\mathrm{v}}^{\mathrm{T}} v - e_{\mathrm{v}}\right) \tag{11.48}$$

Substituting Equations 11.47 and 11.48 into Equation 11.46, we obtain

$$\begin{bmatrix} -AJ \\ -E \\ a_I + a_{\mathrm{v}} - S \end{bmatrix} + \begin{bmatrix} A & 0 & 0 \\ 0 & 1 & A^{\mathrm{T}} \\ B_I & B_{\mathrm{v}} & 0 \end{bmatrix} \begin{bmatrix} i \\ v \\ v_n \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ C_{\mathrm{I}} & C_{\mathrm{v}} & 0 \end{bmatrix}$$
$$\mathrm{abs}\left(\begin{bmatrix} D_{\mathrm{I}} & 0 & 0 \\ 0 & D_{\mathrm{V}} & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} i \\ v \\ v_n \end{bmatrix} - \begin{bmatrix} e_{\mathrm{I}} \\ e_{\mathrm{V}} \\ 0 \end{bmatrix} \right) = 0 \tag{11.49}$$

Clearly, Equation 11.49 is in the canonical form of Equation 11.43.

Of course, an analogous theorem can be given when the PWL resistors are given in LCP form. Then the tableau constitute a GLCP. Moreover, completely in line with the section on circuit analysis (see Chapter 23 of *Fundamentals of Circuits and Filters*), one can derive nodal, cut set, loop, hybrid, and modified nodal analysis from the tableau analysis by eliminating certain variables. Alternatively, one can also directly derive these equations.

Whatever the description for the PWL components may be, one can always formulate the network equations as linear equations

$$0 = f(x) = a_k + B_k x, \quad x \in P_k \tag{11.50}$$

in the polyhedral region P_k defined by Equation 11.50. The map f is a continuous PWL map. A solution x of Equation 11.50 can then be computed in a finite number of steps with the Katzenelson algorithm [4,33], by tracing the map f from an initial point $(\mathrm{x}^{(1)}, \mathrm{y}^{(1)})$ to a value $(\mathrm{x}^*, 0)$ (see Figure 11.18).

11.5.2 Algorithm

STEP 1. Choose an initial point $x^{(1)}$ and determine its polyhedral region $P^{(1)}$, and compute

$$y^{(1)} = f\left(x^{(1)}\right) = a^{(1)} + B^{(1)} x \text{ and set} \quad j = 1$$

STEP 2. Compute

$$\hat{x} = x^{(j)} + \left(B^{(j)}\right)^{-1} \left(0 - y^{(j)}\right) \tag{11.51}$$

STEP 3. If $\hat{x} \in P^{(j)}$, we have obtained a solution $\hat{x}$ of $f(\hat{x}) = 0$. Stop.

STEP 4. Otherwise, compute

$$x^{(j+1)} = x^{(j)} + \lambda^{(j)} \left(\hat{x} - x^{(j)}\right) \tag{11.52}$$

where $\lambda^{(j)}$ is the largest number such that $x^{(j+1)} \in P^{(j)}$, i.e., $x^{(j+1)}$ is on the boundary between $P^{(j)}$ and $P^{(j+1)}$ (see Figure 11.17).

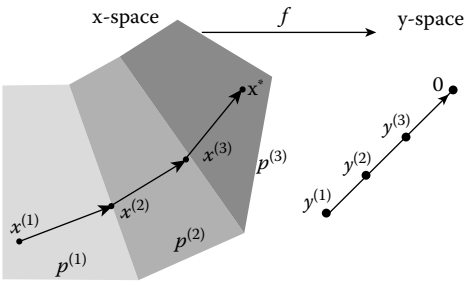

FIGURE 11.17 Iteration in the Katzenelson algorithm for solving $y = f(x) = 0$.

STEP 5. Identify $P^{(j+1)}$ and the linear map $y = a^{(j+1)} + B^{(j+1)}\,x$ in the polyhedral region $P^{(j+1)}$ and compute

$$y^{(j+1)} = y^{(j)} + \lambda^{(j)}\left(y^{\star} - y^{(j)}\right) \tag{11.53}$$

Set $j = j + 1$. Go to step 2.

This algorithm converges to a solution in a finite number of steps if the determinants of all matrices $B^{(j)}$ have the same sign. This condition is satisfied when the i–v curves for the PWL one port resistors are monotonic. The Katzenelson algorithm was extended in Ref. [45] by taking the sign of the determinants into account in Equations 11.52 and 11.53. This requires the PWL resistors to be globally coercive. If by accident in the iteration the point $x^{(j+1)}$ is not on a single boundary and instead is located on a corner, the region $P^{(j+1)}$ is not uniquely defined. However, with a small perturbation [1], one can avoid this corner and still be guaranteed to converge.

This algorithm was adapted to the canonical PWL Equation 11.49 in Ref. [8]. It can also be adapted to the GLCP. However, there exist circuits where this algorithm fails to converge. For the LCP problem, one can then use other algorithms [20,40,56]. One can also use other homotopy methods [43,57,60], which can be shown to converge based on eventual passivity arguments. In fact, this algorithm extends the rather natural method of source stepping, where the PWL circuit is solved by first making all sources zero and then tracing the solution for increasing (stepping up) the sources. It is instructive to observe here that these methods can be used successfully in another sequence of the steps in Figure 11.1a. Until now, we always first performed the horizontal step of PWL approximation or modeling and then the vertical step of network equation formulation. With these methods, one can first perform the network equation formulation and then the PWL approximation. The advantage is that one can use a coarser grid in the simplicial subdivision far away from the solution, and hence dynamically adapt the accuracy of the PWL approximation.

In any case, if all solutions are requested, all these homotopy-based methods are not adequate, because not all solutions can be found even if the homotopy method is started with many different $x^{(1)}$. Hence, special methods have been designed. It is beyond the scope of this text to give a complete algorithm [39,59], but the solution of the GLCP basically involves two parts. First, calculate the solution set of all nonnegative solutions to Equations 11.10 and 11.11. This is a polyhedral cone where extremal rays can be easily determined [44,54]. Second, this solution set is intersected with a hyperplane and the complementarity condition $u^{\mathrm{T}}s = 0$ implies the elimination of vertices (respectively, convex combinations) where these complementarity (respectively, cross complementarity) is not satisfied. This has allowed to systematically obtain the complete solution set for the circuit of Figure 11.15 and for circuits with infinitely many solutions.

A more recent method [46] covers the PWL i–v characteristic with a union of polyhedra and hierarchically solves the circuit with finer and finer polyhedra.

An important improvement in efficiency for the methods is possible when the PWL function $f(\cdot)$ is separable, i.e., there exist $f^i : \mathbb{R}^{\rightarrow} \mathbb{R}^n$ $i = 1, 2, \ldots, n$ such that

$$f(x) = \sum_{i=1}^{n} f^i(x_i) \tag{11.54}$$

This happens when there are only two terminal PWL resistors, linear resistors, and independent sources, and if the bipolar transistors are modeled by the Ebers–Moll model (see Equation 11.39). Then, the subdivision for x is rectangular and each rectangle is subdivided into simplices (see Figure 11.18). This

property can be used to eliminate certain polyhedral regions without solutions [62] and also to speed up the Katzenelson-type algorithm [60,62]. If there are MOS transistors, the map f is not separable but one can apply the extended concept of pairwise separable map [62].

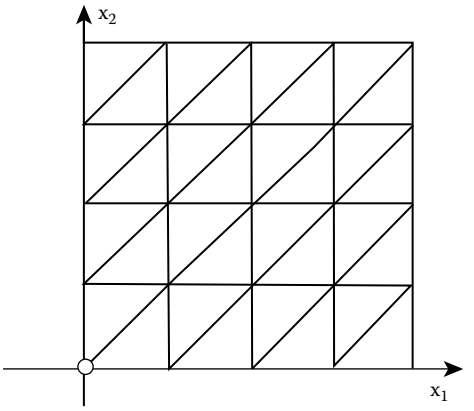

FIGURE 11.18 Simplicial subdivision.

11.6 Piecewise-Linear Dynamic Circuits

As mentioned at the end of Section 11.2, the piecewise-linear descriptions of Section 11.2 can be used also for PWL capacitors, respectively, inductors and memristors, by replacing the port voltages v and currents i by q, v, respectively, φ, i and φ, q. Whenever we have a network obtained by interconnecting linear and/or PWL resistors, inductors, capacitors, and memristors, we have a dynamic piecewise-linear circuits. Of course, such networks are often encountered because it includes the networks with linear R, L, C, and linear-dependent sources, diodes, switches, op-amps, and components such as bipolar and MOS transistors, and GaAs FETs with PWL resistive models. This includes several important and famous nonlinear circuits such as Chua's circuit [18,19], and the cellular neural networks (CNNs) [48], which are discussed in Chapter 13 and Section 14.2.

Of course, PWL dynamic circuits are much more interesting and much more complicated and can exhibit a much more complex behavior than resistive circuits and hence this subject is much less explored. It is clear from the definition of a PWL dynamic circuit that it can be described by linear differential equations over polyhedral regions. Hence, it can exhibit many different types of behavior. They may have many equilibria, which can essentially be determined by solving the resistive network (see Section 11.5 and Figure 11.1) obtained by opening the capacitive ports and short circuiting the inductive ports (dc analysis). When there is no input waveform, the circuit is said to be autonomous and has transients. Some transients may be periodic and are called limit cycles but they may also show chaotic behavior. Next, one may be interested in the behavior of the circuit for certain input waveforms (transient analysis). This can be performed by using integration rules in simulations.

For the analysis of limit cycles, chaos, and transients, one can of course use the general methods for nonlinear circuits, but some improvements can be made based on the PWL nature of the nonlinearities. Here, we only describe the methods briefly. If one is interested in the periodic behavior of a PWL dynamic circuit (autonomous or with a periodic input), then one can, for each PWL nonlinearity, make some approximations.

First, consider the case that one is only interested in the dc and fundamental sinusoidal contributions in all signals of the form $i(t) = A_0 + A_1 \cos \omega t$. The widely used describing function method [6] for PWL resistors $v = f(i)$ consists of approximating this resistor by an approximate resistor where $\hat{v}(t) = D_0 + D_1 \cos \omega t$ has only the dc and fundamental contribution of $v(t)$. This is often a good approximation since the remainder of the circuit often filters out all higher harmonics anyway. Using a Fourier series, one can then find D_0 and D_1 as

$$D_0(A_0, A_1) = \frac{1}{2\pi} \int_0^{2\pi} f(A_0 + A_1 \cos \phi) \mathrm{d}\phi$$

$$D_1(A_0, A_1) = \frac{1}{\pi A_1} \int_0^{2\pi} f(A_0 + A_1 \cos \phi) \mathrm{d}\phi$$

By replacing all PWL components by their describing functions, one can use linear methods to set up the network equations in the Laplace–Fourier domain. When this approximation is not sufficient, one can include more harmonics. Then, one obtains the famous harmonic balance method, because one is balancing more harmonic components.

Alternatively, one can calculate the periodic solution by simulating the circuit with a certain initial condition and considering the map F: $x_0 \rightarrow x_1$ from the initial condition x_0 to the state x_1 one period later. Of course, a fixed point $x^* = F(x^*)$ of the map corresponds to a periodic solution. It has been demonstrated [27] that the map F is differentiable for PWL circuits. This is very useful in setting up an efficient iterative search for a fixed point of F. This map is also useful in studying the eventual chaotic behavior and is then called the Poincaré return map.

In transient analysis of PWL circuits, one is often interested in the sensitivity of the solution to certain parameters in order to optimize the behavior. As a natural extension of the adjoint network for linear circuits in Ref. [22], the adjoint PWL circuit is defined and used to determine simple sensitivity calculations for transient analysis.

Another important issue is whether the PWL approximation of a nonlinear characteristic in a dynamic circuit has a serious impact on the transient behavior. In Ref. [63], error bounds were obtained on the differences of the waveforms.

11.7 Efficient Computer-Aided Analysis of PWL Circuits

Transient analysis and timing verification is an essential part of the VLSI system design process. The most reliable way of analyzing the timing performance of a design is to use analog circuit analysis methods. Here as well, a set of algebraic-differential equations has to be solved. This can be done by using implicit integration formulas that convert these equations into a set of algebraic equations, which can be solved by iterative techniques like Newton–Raphson (see Chapter 12). The computation time then becomes excessive for large circuits. It mainly consists of linearizations of the nonlinear component models and the solution of the linear equations. In addition, the design process can be facilitated substantially if this simulation tool can be used at many different levels from the top level of specifications over the logic and switch level to the circuit level. Such a hierarchical simulator can support the design from top to bottom and allow for mixtures of these levels. In limited space, we describe here the main simulation methods for improving the efficiency and supporting the hierarchy of models with piecewise-linear methods. We refer the reader to Chapter 8, *Computer Aided Design and Design Automation* for general simulation of VLSI circuits and to the literature for more details on the methods and for more descriptions on complete simulators.

It is clear from our previous discussion that PWL models and circuit descriptions can be used at many different levels. An op-amp, for example, can be described by the finite gain model (see Figure 11.9 and Equations 11.29 and 11.30), but when it is designed with a transistor circuit it can be described by PWL circuit equations as in Section 11.5. Hence, it is attractive to use a simulator that can support this top-down design process [35]. One can then even incorporate logic gates into the PWL models. One can organize the topological equations of the network hierarchically, so that it is easy to change the network topology. The separation between topological equations and model descriptions allows for an efficient updating of the model when moving from one polyhedral region into another. Several other efficiency issues can be built into a hierarchical PWL simulator.

An important reduction in computation time needed for solving the network equations can be obtained by using the consistent variation property. In fact, only a rank one difference exists between the matrices of two neighboring polyhedral regions, and hence, one inverse can be easily derived from the other [8,35]. In the same spirit, one can at the circuit level take advantage of the PWL transistor models (see Ref. [62] and separability discussion in Section 8.5). In Ref. [53], the circuit is partitioned dynamically into subcircuits during the solution process, depending on the transistor region of operation. Then, the subcircuits are dynamically ordered and solved with block Gauss–Seidel for minimal or no coupling among them.

Interesting savings can be obtained [34] by solving the linear differential equations in a polyhedral region with Laplace transformations and by partitioning the equations. However, the computation of the intersection between trajectories in neighboring polyhedral regions can be a disadvantage of this method.

This chapter deals with the simulation or analysis of a nonlinear electrical circuit by means of a computer program. The program creates and solves the differential-algebraic equations of a model of the circuit. The basic tools in the solution process are *linearization*, *difference approximation*, and *the solution of a set of linear equations*. The output of the analysis may consist of (1) all node and branch voltages and all branch currents of a bias point (dc analysis), (2) a linear small-signal model of a bias point that may be used for analysis in the frequency domain (ac analysis), or (3) all voltages and currents as functions of time in a certain time range for a certain excitation (transient analysis). A model is satisfactory if there is good agreement between measurements and simulation results. In this case, simulation may be used instead of measurement for obtaining a better understanding of the nature and abilities of the circuit. The crucial point is to set up a model that is as simple as possible, in order to obtain a fast and inexpensive simulation, but sufficiently detailed to give the proper answer to the questions concerning the behavior of the circuit under study. Modeling is the bottleneck of simulation.

The model is an equivalent scheme—"schematics-capture"—or a branch table—"net-list"—describing the basic components (n-terminal elements) of the circuit and their connection. It is always possible to model an n-terminal element by means of a number of 2-terminals (branches). These internal 2-terminals may be coupled. By pairing the terminals of an n-terminal element, a port description may be obtained. The branches are either admittance branches or impedance branches. All branches may be interpreted as controlled sources. An admittance branch is a current source primarily controlled by its own voltage or primarily controlled by the voltage or current of another branch (transadmittance). An impedance branch is a voltage source primarily controlled by its own current or primarily controlled by the current or voltage of another branch (transimpedance). Control by signal (voltage or current) and control by time-derivative of signal are allowed. Control by several variables is allowed. Examples of admittance branches are (1) the conductor is a current source controlled by its own voltage, (2) the capacitor is a current source controlled by the time-derivative of its own voltage, and (3) the open circuit is a zero-valued current source (a conductor with value zero). Examples of impedance branches are (1) the resistor is a voltage source controlled by its own current, (2) the inductor is a voltage source controlled by the time-derivative of its own current, and (3) the short circuit is a zero-valued voltage source (a resistor with value zero)

A component may often be modeled in different ways. A diode, for example, is normally modeled as a current source controlled by its own voltage such that the model can be linearized into a dynamic conductor in parallel with a current source during the iterative process of finding the bias point of the diode. The diode may also be modeled as (1) a voltage source controlled by its own current (a dynamic resistor in series with a voltage source), (2) a static conductor being a function of the voltage across the diode, or (3) a static resistor being a function of the current through the diode. Note that in the case where a small-signal model is wanted, for frequency analysis, only the dynamic model is appropriate.

The primary variables of the model are the currents of the impedance branches and the node potentials. The current law of Kirchhoff (the sum of all the currents leaving a node is zero) and the current–voltage relations of the impedance branches are used for the creation of the equations describing the relations between the primary variables of the model. The contributions to the equations from the branches are taken one branch at a time based on the question: Will this branch add new primary variables? If yes, then a new column (variables) and a new row (equations) must be created and updated, or else the columns and rows corresponding to the existing primary variables of the branch must be updated. This approach to equation formulation is called the extended nodal approach or the modified nodal approach (MNA).

In the following, some algorithms for solving a set of nonlinear algebraic equations and nonlinear differential equations are briefly described. Because we are dealing with physical systems and because we are responsible for the models, we assume that at least one solution is possible. The zero solution is, of course, always a solution. It might happen that our models become invalid if we, for example, increase the amplitudes of the exciting signals, diminish the risetime of the exciting signals, or by mistake create unstable models. It is important to define the range of validity for our models. What are the consequences of our assumptions? Can we believe in our models?

12.1 Numerical Solution of Nonlinear Algebraic Equations

Let the equation system to be solved be $f(x, u) = 0$, where x is the vector of primary variables and u is the excitation vector. Denote the solution by x_s. Then, if we define a new function $g(x) = \alpha(f(x, u)) + x$, where α may be some function of $f(x, u)$, which is zero for $f(x, u) = 0$, then we can define an iterative scheme where $g(x)$ converges to the solution x_s by means of the iteration: $x_{k+1} = g(x_k) = \alpha(f(x_k, u)) + x_k$ where k is the iteration counter.

If for all x in the interval $[x_a, x_b]$ the condition $\|g(x_a) - g(x_b)\| \leq L^* \|x_a - x_b\|$ for some $L < 1$ is satisfied, the iteration is called a contraction mapping. The condition is called a Lipschitz condition. Note that a function is a contraction if it has a derivative less than 1.

For $\alpha = -1$, the iterative formula becomes $x_{k+1} = g(x_k) = -f(x_k, u) + x_k$. This scheme is called the Picard method, the functional method, or the contraction mapping algorithm. At each step, each nonlinear component is replaced by a linear static component corresponding to the solution x_k. A nonlinear conductor, for example, is replaced by a linear conductor defined by the straight line through the origin and the solution point. Each iterative solution is calculated by solving a set of linear equations. All components are updated and the next iteration is made. When two consecutive solutions are within a prescribed tolerance, the solution point is accepted.

For $\alpha = -1/(\mathrm{d}f/\mathrm{d}x)$, the iterative formula becomes $x_{k+1} = g(x_k) = -f(x_k, u)/(\mathrm{d}f(x_k, u)/\mathrm{d}x) + x_k$. This scheme is called the Newton–Raphson method or the derivative method. At each step, each nonlinear component is replaced by a linear dynamic component plus an independent source corresponding to the solution x_k. A nonlinear conductor, for example, is replaced by a linear conductor defined by the derivative of the branch current with respect to the branch voltage (the slope of the nonlinearity) in parallel with a current source corresponding to the branch voltage of the previous solution. A new solution is then calculated by solving a set of linear equations. The components are updated and the next iteration is made. When the solutions converge within a prescribed tolerance, the solution point is accepted.

It may, of course, happen that the previously mentioned iterative schemes do not converge before the iteration limit k_{max} is reached. One reason may be that the nonlinearity $f(x)$ changes very rapidly for a small change in x. Another reason could be that $f(x)$ possess some kind of symmetry that causes cycles in the Newton–Raphson iteration scheme. If convergence problems are detected, the iteration scheme can be *modified* by introducing a limiting of the actual step size. Another approach may be to change the modeling of the nonlinear branches from voltage control to current control or vice versa. Often, the user of a circuit analysis program may be able to solve convergence problems by means of proper modeling and adjustment of the program options [1–5].

12.2 Numerical Integration of Nonlinear Differential Equations

The dynamics of a nonlinear electronic circuit may be described by a set of coupled first-order differential equations–algebraic equations of the form: $dx/dt = f(x, y, t)$ and $g(x, y, t) = 0$, where x is the vector of primary variables (node potentials and impedance branch currents), y is the vector of variables that cannot be explicitly eliminated, and f and g are nonlinear vector functions. It is always possible to express y as a function of x and t by inverting the function g and inserting it into the differential equations such that the general differential equation form $dx/dt = f(x, t)$ is obtained. The task is then to obtain a solution $x(t)$ when an initial value of x is given. The usual methods for solving differential equations reduce to the solution of difference equations, with either the derivatives or the integrals expressed *approximately* in terms of finite differences.

Assume, at a given time t_0, we have a known solution point $x_0 = x(t_0)$. At this point, the function f can be expanded in Taylor series: $dx/dt = f\ (x_0, t) + A\ (x_0)\ (x - x_0)\ + \cdots$ where $A(x_0)$ is the Jacobian of f evaluated at x_0. Truncating the series, we obtain a linearization of the equations such that the small-signal behavior of the circuit in the neighborhood of x_0 is described by $dx/dt = A * x + k$, where A is a constant matrix equal to the Jacobian and k is a constant vector.

The most simple scheme for the approximate solution of the differential equation $dx/dt = f(x, t) = Ax + k$ is the forward Euler formula $x(t) = x(t_0) + hA(t_0)$ where $h = t - t_0$ is the integration time step. From the actual solution point at time t_0, the next solution point at time t is found along the tangent of the solution curve. It is obvious that we will rapidly leave the vicinity of the exact solution curve if the integration step is too large. To guarantee stability of the computation, the time step h must be smaller than $2/|\lambda|$ where λ is the largest eigenvalue of the Jacobian A. Typically, h must not exceed $0.2/|\lambda|$.

The forward Euler formula is a linear *explicit* formula based on forward Taylor expansion from t_0. If we make backward Taylor expansion from t we arrive at the backward Euler formula: $x(t) = x(t_0) + hA(t)$. Because the unknown appears on both sides of the equation, it must in general be found by iteration so the formula is a linear *implicit* formula. From a stability point of view, the backward Euler formula has a much larger stability region than the forward Euler formula. The truncation error for the Euler formulas is of order h^2.

The two Euler formulas can be thought of as polynomials of degree 1 that approximate $x(t)$ in the interval $[t_0, t]$. If we compute $x(t)$ from a second-order polynomial $p(t)$ that matches the conditions that $p(t_0) = x(t_0)$, $dp/dt(t_0) = dx/dt(t_0)$ and $dp/dt(t) = dx/dt(t)$, we arrive at the trapezoidal rule: $x(t) = x(t_0) + 0.5hA(t_0) + 0.5hA(t)$. In this case, the truncation error is of order h^3.

At each integration step, the size of the local truncation error can be estimated. If it is too large, the step size must be reduced. An explicit formula such as the forward Euler may be used as a predictor giving a starting point for an implicit formula like the trapezoidal, which in turn is used as a corrector. The use of a predictor–corrector pair provides the base for the estimate of the local truncation error. The trapezoidal formula with varying integration step size is the main formula used in the Simulation Program with Integrated Circuit Emphasis (SPICE) program.

The two Euler formulas and the trapezoidal formula are special cases of a general linear multistep formula $\Sigma(a_i x_{n-i} + b_i h(dx/dt)_{n-i})$, where i goes from -1 to $m - 1$ and m is the degree of the polynomial

used for the approximation of the solution curve. The trapezoidal rule, for example, is obtained by setting $a_{-1} = -1$, $a_0 = +1$, and $b_{-1} = b_0 = 0.5$, all other coefficients being zero. The formula can be regarded as being derived from a polynomial of degree r which matches $r+1$ of the solution points x_{n-i} and their derivatives $(\mathrm{d}x/\mathrm{d}t)_{n-i}$.

Very fast transients often occur together with very slow transients in electronic circuits. We observe widely different time constants. The large spread in component values, for example, from large decoupling capacitors to small parasitic capacitors, implies a large spread in the modules of the eigenvalues. We say that the circuits are stiff. A family of implicit multistep methods suitable for stiff differential equations has been proposed by C.W. Gear. The methods are stable up to the polynomial of order 6. For example, the second-order Gear formula for fixed integration step size h may be stated as $x_{n+1} = -(1/3)x_{n-1} + (4/3)x_n + (2/3)h(\mathrm{d}x/\mathrm{d}t)_{n+1}$.

By changing both the *order* of the approximating polynomial and the integration *step size*, the methods adapt themselves dynamically to the performance of the solution curve. The family of Gear formulas is modified into a ''stiff-stable variable-order variable-step predictor–corrector'' method based on implicit approximation by means of backward difference formulas (BDFs). The resulting set of nonlinear equations is solved by modified Newton–Raphson iteration. Note that numerical integration, in a sense, is a kind of low-pass filtering defined by means of the minimum integration step [1–5].

12.3 Use of Simulation Programs

Since 1960, a large number of circuit-simulation programs have been developed by universities, industrial companies, and commercial software companies. In particular, the SPICE program has become a standard simulator both in the industry and in academia. Here, only a few programs, which together cover a very large number of simulation possibilities, are presented. Due to competition, there is a tendency to develop programs that are supposed to cover any kind of analysis so that only one program should be sufficient (the Swiss Army Knife Approach). Unfortunately this implies that the programs become very large and complex to use. Also, it may be difficult to judge the correctness and accuracy of the results of the simulation having only one program at your disposal. If you try to make the same analysis of the same model with different programs, you will frequently see that the results from the programs may not agree completely. By comparing the results, you may obtain a better feel for the correctness and accuracy of the simulation. The programs SPICE and Analysis Program for Linear Active Circuits (APLAC) supplemented with the programs Nonlinear Analysis Program version 2 (NAP2), Engineering System and Circuit Analysis (ESACAP), and DYNAmic Simulation Tool (DYNAST) have proven to be a good choice in the case where a large number of different kinds of circuits and systems are to be modeled and simulated (the Tool Box Approach). The programs are available in inexpensive evaluation versions running on IBM compatible personal computers. The ''net-list'' input languages are very close, making it possible to transfer input data easily between the programs. In order to make the programs more ''user-friendly'' graphics interphase language ''schematics-capture,'' where you draw the circuit on the screen, has been introduced. Unfortunately, this approach makes it a little more difficult for the user to transfer data between the programs. In the following, short descriptions of the programs are given and a small circuit is simulated in order to give the reader an idea of the capabilities of the programs.

12.3.1 SPICE

The first versions of SPICE (Simulation Program with Integrated Circuit Emphasis version 2), based on the MNA, were developed in 1975 at the Electronics Research Laboratory, College of Engineering, University of California, Berkeley, CA.

SPICE is a general-purpose circuit analysis program. Circuit models may contain resistors, capacitors, inductors, mutual inductors, independent sources, controlled sources, transmission lines, and the

most common semiconductor devices: diodes, bipolar junction transistors, and field effect transistors. SPICE has very detailed built-in models for the semiconductor devices, which may be described by about 50 parameters. Besides the normal dc, ac, and transient analyses, the program can make sensitivity, noise, and distortion analysis and analysis at different temperatures. In the various commercial versions of the program many other possibilities have been added; for example, analog behavior modeling (poles and zeros) and statistical analysis.

In order to give an impression of the ''net-list'' input language, the syntax of the statements describing controlled sources is the following:

```
Voltage Controlled Current Source: Gxxx N+ N− NC+ NC− VALUE
Voltage Controlled Voltage Source: Exxx N+ N− NC+ NC− VALUE
Current Controlled Current Source: Fxxx N+ N− VNAM VALUE
Current Controlled Voltage Source: Hxxx N+ N− VNAM VALUE
```

where the initial characters of the branch name G, E, F, and H indicate the type of the branch; $N+$ and $N-$ are integers (node numbers) indicating the placement and orientation of the branch, respectively; NC+, NC−, and VNAM indicate from where the control comes (VNAM is a dummy dc voltage source with value 0 inserted as an ammeter!); and VALUE specifies the numerical value of the control, which may be a constant or a polynomial expression in case of nonlinear dependent sources. Independent sources are specified with Ixxx for current and Vxxx for voltage sources.

The following input file describes an analysis of the Chua oscillator circuit. It is a simple harmonic oscillator with losses (C2, L2, and RL2) loaded with a linear resistor (R61) in series with a capacitor (C1) in parallel with a nonlinear resistor. The circuit is influenced by a sinusoidal voltage source VRS through a coil L1. Comments may be specified either as lines starting with an asterisk ''*'' or by means of a semicolon '';'' after the statement on a line. A statement may continue by means of a plus '' + '' as the first character on the following line.

The analysis is controlled by means of the statements: .TRAN, where, for example, the maximum integration step is fixed to 18 μs, and .OPTIONS, where, for example, the relative truncation error is set to 1e-3. The result of the analysis is presented in Figure 12.1. It is seen that transition from chaotic behavior to a period 5 limit cycle takes place at about 100 ms. A very important observation is that the result of the analysis may depend on (1) the choice of the control parameters and (2) the order of the branches in the "net-list," for example, if the truncation error is set to 1e-6 instead of 1e-3 previously, the result becomes quite different. This observation is valid for all programs [5–11].

12.3.2 APLAC

The program APLAC [5] has been under constant development at the Helsinki University of Technology, Finland, since 1972. Over time it has developed into an object-oriented analog circuits and systems simulation and design tool. Inclusion of a new model into APLAC requires only the labor of introducing the parameters and equations defining the model under the control of ''C-macros.'' The code of APLAC itself remains untouched. The APLAC *Interpreter* immediately understands the syntax of the new model. APLAC accepts SPICE ''net-lists'' by means of the program Spi2a (SPICE to APLAC net-list converter).

APLAC is capable of carrying out dc, ac, transient, noise, oscillator, and multitone harmonic steady-state analyses and measurements using IEEE-488 bus. Transient analysis correctly handles, through convolution, components defined by frequency-dependent characteristics. Monte Carlo analysis is available in all basic analysis modes and sensitivity analysis in dc and ac modes. *N*-port *z*, *y*, and *s* parameters, as well as two-port *h* parameters, are available in ac analysis. In addition, APLAC includes a versatile collection of system-level blocks for the simulation and design of analog and digital communication systems. APLAC includes seven different optimization methods. Any parameter in the design problem can be used as a variable, and any user-defined function may act as an objective. Combined time and frequency domain optimization is possible.

The file below is the APLAC ''net-list'' of the Chua oscillator circuit created by the Spi2a converter program with the PSpice file CRC-CHUA.CIR above as input. Comments are indicated by means of the dollar sign ''$'' or the asterisk ''*.'' Unfortunately, it is necessary to manually change the file. Comments semicolon '';'' and colon '':'' must be replaced with ''$;'' and ''$:''. Also, Spi2a indicates a few statements as ''$ not implemented.''

The result of the analysis is presented in Figure 12.2. It is observed that limit cycle behavior is not obtained in the APLAC analysis in the time interval from 0 to 200 ms.

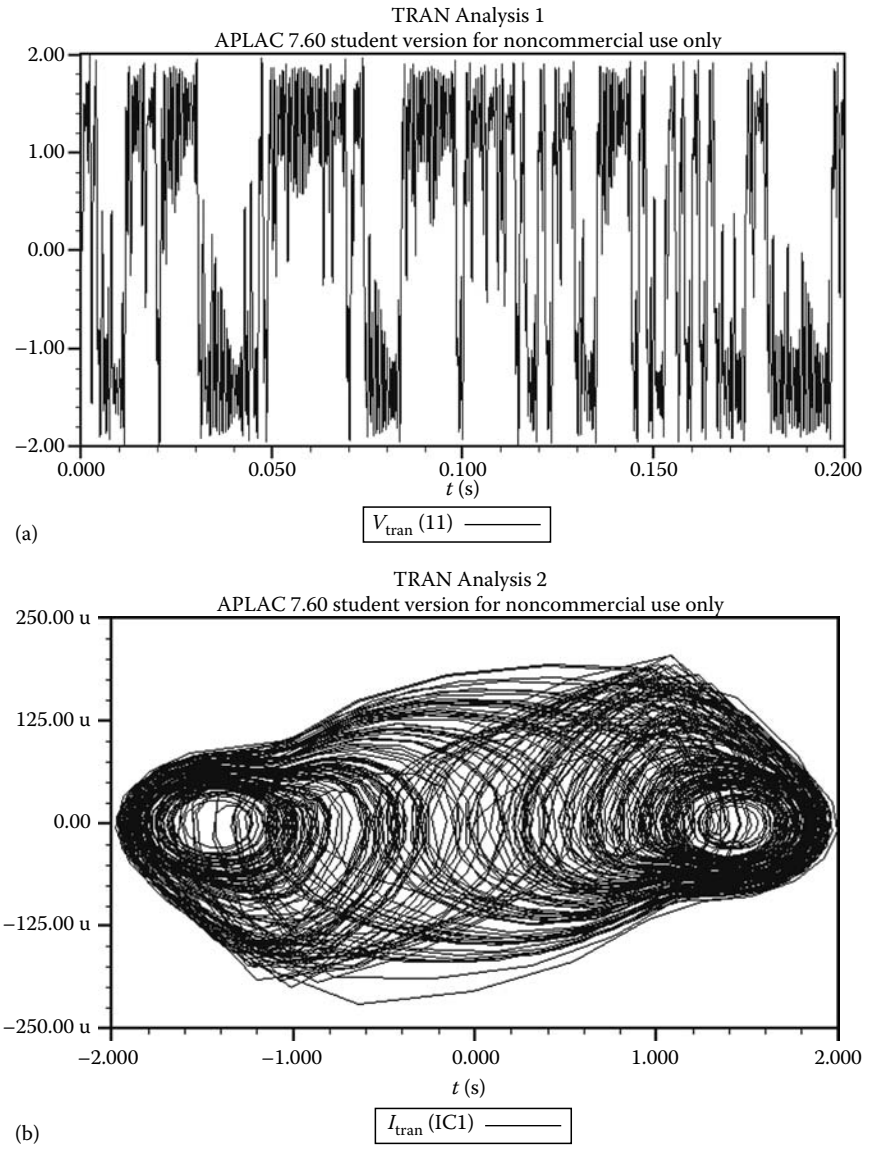

FIGURE 12.2 (a) The voltage of C1: $V(11)$ as function of time in the interval 0–200 ms. (b) The current of C1: $I(C1)$ as function of the voltage of C1: $V(11)$.

12.3.3 NAP2

The first versions of NAP2 (Nonlinear Analysis Program version 2) [10], based on the extended nodal equation formulation were developed in 1973 at the Institute of Circuit Theory and Telecommunication, Technical University of Denmark, Lyngby, Denmark.

NAP2 is a general-purpose circuit analysis program. Circuit models may contain resistors, conductors, capacitors, inductors, mutual inductors, ideal operational amplifiers, independent sources, controlled sources, and the most common semiconductor devices: diodes, bipolar junction transistors, and field effect transistors. NAP2 has only simple built-in models for the semiconductor devices, which require about 15 parameters. Besides the normal dc, ac, and transient analyses, the program can make parameter

variation analysis. Any parameter (e.g., component value or temperature) may be varied over a range in an arbitrary way and dc, ac, or transient analysis may be performed for each value of the parameter. Optimization of dc bias point (given: voltages, find: resistors) is possible. Event detection is included so that it is possible to interrupt the analysis when a certain signal, for example, goes from a positive to a negative value. The results may be combined into one output plot. It is also possible to calculate the poles and zeros of driving point and transfer functions for the linearized model in a certain bias point. Eigenvalue technique (based on the QR algorithm by J.G.F. Francis) is the method behind the calculation of poles and zeros. Group delay (i.e., the derivative of the phase with respect to the angular frequency) is calculated from the poles and zeros. This part of the program is available as an independent program named ANP3 (Analytical Network Program version 3).

In order to give an impression of the ''net-list'' input language, the syntax of the statements describing controlled sources is as follows:

```
Voltage Controlled Current Source:  Ixxx  N+  N−  VALUE VByyy
Voltage Controlled Voltage Source:  Vxxx  N+  N−  VALUE VByyy
Current Controlled Current Source:  Ixxx  N+  N−  VALUE IByyy
Current Controlled Voltage Source:  Vxxx  N+  N−  VALUE Ibyyy
```

where the initial characters of the branch name I and V indicate the type of the branch; *N*+ and *N*− are integers (node numbers) indicating the placement and orientation of the branch, respectively; and VALUE specifies the numerical value of the control, which may be a constant or an arbitrary functional expression in case of nonlinear control. IB and VB refer to the current or voltage of the branch, respectively, from where the control comes. If the control is the time derivative of the branch signal, SI or SV may be specified. Independent sources must be connected to a resistor R or a conductor G as follows: Rxxx N+ N− VALUE E = VALUE and Gxxx N+ N− VALUE J = VALUE, where VALUE may be any function of time, temperature, and components.

The input file ''net-list'' below describes the same analysis of the Chua oscillator circuit as performed by means of SPICE and APLAC. The circuit is a simple harmonic oscillator with losses (C2, L2, and RL2) loaded with a linear resistor (R61) in series with a capacitor (C1) in parallel with a nonlinear resistor. The circuit is excited by a sinusoidal voltage source through a coil L1. The frequency is specified as angular frequency in rps. It is possible to specify more than one statement on one line. Colon '':'' indicate start of a comment statement and semicolon '';'' indicates end of a statement. The greater than character ''>'' indicates continuation of a statement on the following line. It is observed that most of the lines are comment lines with the PSPICE input statements.

The program options are set by means of the statement *RUN, where, for example, the minimum integration step is set to 1e-20 s and the relative truncation error is set to 1e-6. The result of the analysis is presented in Figure 12.3. It can be observed that transition from chaotic behavior to a period 5 limit cycle takes place at about 50 ms. If we compare to the results obtained above by means of SPICE and APLAC,

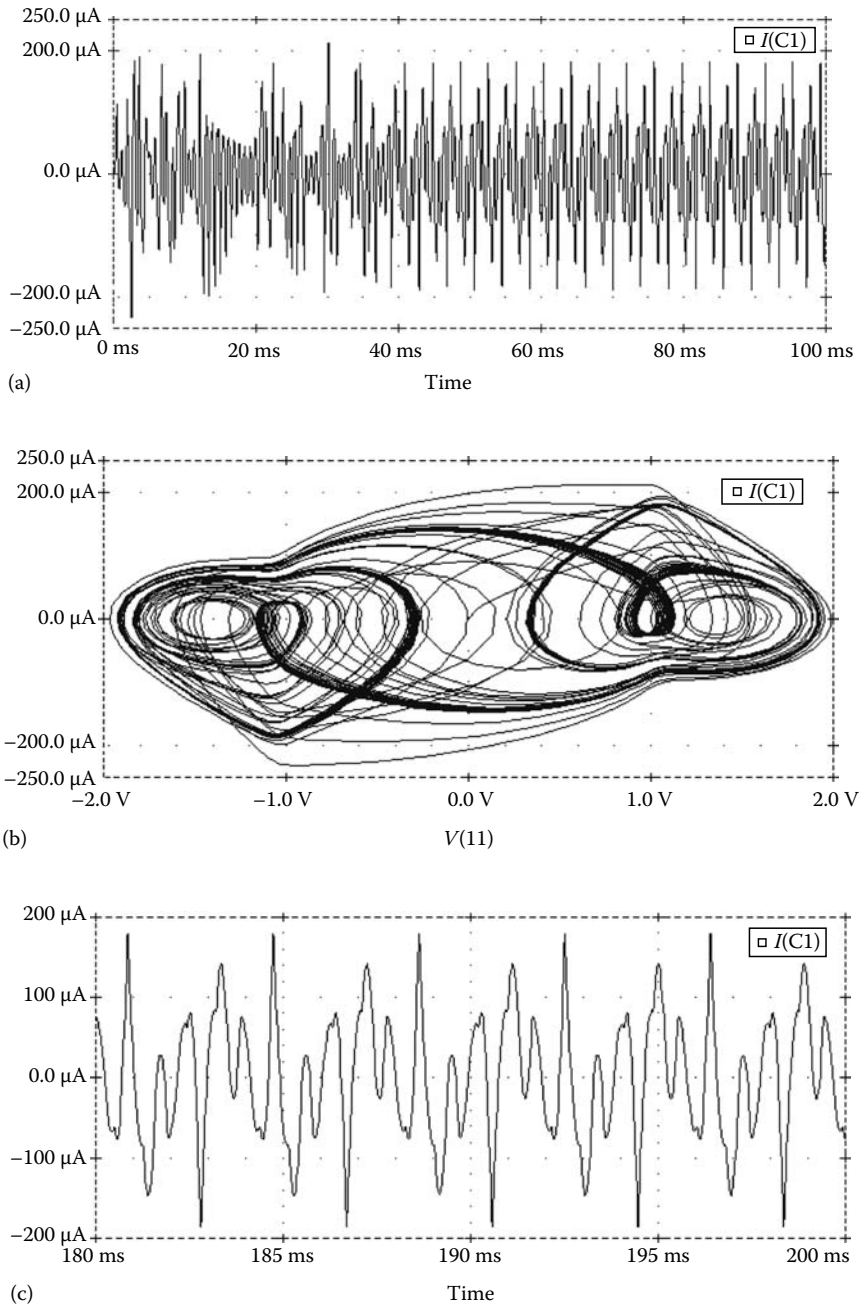

FIGURE 12.3 (a) NAP2 analysis. The current of C1: I(C1) as function of time in the interval 0–100 ms. (b) The current of C1: I(C1) as function of the voltage of C1: V(11) in the time interval 0–100 ms. (c) The current of C1: I(C1) as function of time in the interval 180–200 ms.

(*continued*)

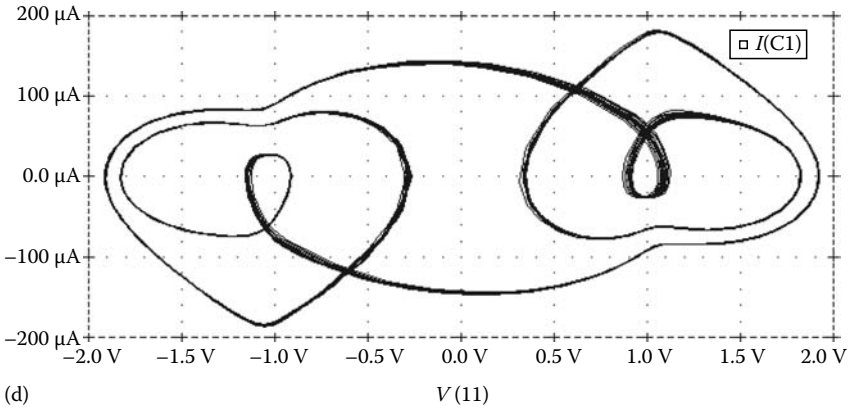

FIGURE 12.3 (continued) (d) The current of C1: I(C1) as function of the voltage of C1: V(11) in the time interval 100–200 ms.

we see that although the three programs are ''modeled and set'' the same way, for example, with the same relative tolerance 1e-3, the results are different due to the chaotic nature of the circuit and possibly also due to the different strategies of equation formulation and solution used in the three programs. For example, SPICE uses the trapezoidal integration method with variable step; APLAC and NAP2 use the Gear integration methods with variable order and variable step.

12.3.4 ESACAP

The first versions of ESACAP program based on the extended nodal equation formulation were developed in 1979 at Elektronik Centralen, Hoersholm, Denmark, for the European Space Agency as a result of a strong need for a simulation language capable of handling interdisciplinary problems (e.g., coupled electrical and thermal phenomena). ESACAP was therefore born with facilities that have only recently been implemented in other simulation programs (e.g., facilities referred to as behavioral or functional modeling).

ESACAP carries out analyses on nonlinear systems in dc and in the time domain. The nonlinear equations are solved by a hybrid method combining the robustness of the gradient method with the good convergence properties of the Newton–Raphson method. The derivatives required by the Jacobian matrix are symbolically evaluated from arbitrarily complex arithmetic expressions and are therefore exact. The symbolic evaluation of derivatives was available in the very first version of ESACAP. It has now become a general numerical discipline known as automatic differentiation. The time-domain solution is found by numerical integration implemented as BDFs of variable step and orders 1 through 6 (modified Gear method). An efficient extrapolation method (the epsilon algorithm) accelerates the asymptotic solution in the periodic steady-state case.

Frequency-domain analyses may be carried out on linear or linearized systems (e.g., after a dc analysis). Besides complex transfer functions, special outputs such as group delay and poles/zeros are available. The group delay is computed as the sum of the frequency sensitivities of all the reactive components in the system. Poles and zeros are found by a numerical interpolation of transfer functions evaluated on a circle in the complex frequency plane. ESACAP also includes a complex number postprocessor by means of which any function of the basic outputs can be generated (e.g., stability factor, s-parameters, complex ratios).

Sensitivities of all outputs with respect to all parameters are available in all analysis modes. The automatic differentiation combined with the adjoint network provides exact partial derivatives in the frequency domain. In the time domain, integration of a sensitivity network (using the already LUfactorized Jacobian) provides the partial derivatives as functions of time.

The ESACAP language combines procedural facilities, such as if-then-else, assignment statements, and do-loops, with the usual description by structure (nodes/branches). Arbitrary expressions containing system variables and their derivatives are allowed for specifying branch values thereby establishing any type of nonlinearity. System variables of nonpotential and noncurrent type may be defined and used everywhere in the description (e.g., for defining power, charge). The language also accepts the specification of nonlinear differential equations. Besides all the standard functions known from high-level computer languages, ESACAP provides a number of useful functions. One of the most important of these functions is the delay function. The delay function returns one of its arguments delayed by a specified value, which in turn may depend on system variables. Another important function is the threshold switch—the ZEROREF function—used in if-then-else constructs for triggering discontinuities. The ZEROREF function interacts with the integration algorithm that may be reinitialized at the exact threshold crossing. The ZEROREF function is an efficient means for separating cause and action in physical models thereby eliminating many types of causality problems. Causality problems are typical examples of bad modeling techniques and the most frequent reason for divergence in the simulation of dynamic systems.

Typical ESACAP applications include electronics as well as thermal and hydraulic systems. The frequency domain facilities have been a powerful tool for designing stable control systems including nonelectronics engineering disciplines.

In order to give an idea of the input language, the syntax of the statements describing sources is as follows:

```
Current  Source:  Jxxx(N+,  N−) = VALUE;
Voltage  Source:  Exxx(N+,  N−) = VALUE;
```

where the initial characters of the branch name: J and E indicate the type of the branch; $N+$ and $N-$ are node identifiers (character strings), which, as a special case, may be integer numbers (node numbers). The node identifiers indicate the placement and orientation of the branch. The VALUE specifies the numerical value of the source, which may be an arbitrary function of time, temperature, and parameters as well as system variables (including their time derivatives). Adding an apostrophe references the time derivative of a system variable. $V(\mathrm{N1,N2})'$, for example, is the time derivative of the voltage drop from node N1 to node N2.

The next input file—actually, a small program written in the ESACAP language—describes an analysis of a tapered transmission line. The example shows some of the powerful tools available in the ESACAP language such as (1) the delay function, (2) the do-loop, and (3) the sensitivity calculation. The description language of ESACAP is a genuine simulation and modeling language. However, for describing simple systems, the input language is just slightly more complicated than the languages of SPICE, APLAC, and NAP2. Data are specified in a number of blocks (“chapters” and “sections”) starting with $$ and $. Note how the line model is specified in a do-loop where ESACAP creates nodes and branches of a ladder network [11].

```

12.3.5 DYNAST

DYNAST [7] was developed in 1992 in a joint venture between the Czech Technical University, Prague, the Czech Republic and Katholieke Universiteit Leuven, Heverlee, Belgium. The program was developed as an interdisciplinary simulation and design tool in the field of "mechatronics" (mixed mechanical/electrical systems).

The main purpose of DYNAST is to simulate dynamic systems decomposed into subsystems defined independently of the system structure. The structure can be hierarchical. DYNAST is a versatile software tool for modeling, simulation, and analysis of general linear as well as nonlinear dynamic systems, both in time and frequency domain. Semisymbolic analysis is possible (poles and zeros of network functions, inverse Laplace transformation using closed-form formulas).

Three types of subsystem models are available in DYNAST. The program admits systems descriptions in the form of (1) a multipole diagram respecting physical laws, (2) a causal or an acausal block diagram, (3) a set of equations, or (4) in a form combining the above approaches.

1. In DYNAST the physical-level modeling of dynamic systems is based on subsystem multipole models or multiterminal models. These models respect the continuity and compatibility postulates that apply to all physical energy-domains. (The former postulate corresponds to the laws of conservation of energy, mass, electrical charge, etc.; the latter is a consequence of the system

connectedness.) The multipole poles correspond directly to those subsystem locations in which the actual energetic interactions between the subsystems take place (such as shafts, electrical terminals, pipe inlets, etc.). The interactions are expressed in terms of products of complementary physical quantity pairs: the through variables flowing into the multipoles via the individual terminals, and the across variables identified between the terminals.

2. The causal blocks, specified by explicit functional expressions or transfer functions, are typical for any simulation program. But the variety of basic blocks is very poor in DYNAST, as its language permits definition of the block behavior in a very flexible way. Besides the built-in basic blocks, user specified multi-input multi-output macroblocks are available as well. The causal block interconnections are restricted by the rule that only one block output may be connected to one or several block inputs. In the DYNAST block variety, however, causal blocks are also available with no restrictions imposed on their interconnections, as they are defined by implicit-form expressions.
3. DYNAST can also be used as an equation solver for systems of nonlinear first-order algebro-differential and algebraic equations in the implicit form. The equations can be submitted in a natural way (without converting them into block diagrams) using a rich variety of functions including the Boolean, event-dependent, and tabular ones. The equations, as well as any other input data, are directly interpreted by the program without any compilation.

The equation formulation approach used for both multipoles and block diagrams evolved from the extended method of nodal voltages (MNA) developed for electrical systems. Because all the equations of the diagrams are formulated simultaneously, no problems occur with the *algebraic loops*. As the formulated equations are in the implicit form, it does not create any problems with the *causality* of the physical models.

The integration method used to solve the nonlinear algebro-differential and algebraic equations is based on a stiff-stable implicit backward-differentiation formula (a modified Gear method). During the integration, the step length as well as the order of the method is varied continuously to minimize the computational time while respecting the admissible computational error. Jacobians necessary for the integration are computed by symbolic differentiation. Their evaluation as well as their LU decomposition, however, is not performed at each iteration step if the convergence is fast enough. Considerable savings of computational time and memory are achieved by a consistent matrix sparsity exploitation.

To accelerate the computation of periodic responses of weakly damped dynamic systems, the iterative epsilon-algorithm is utilized. Also, fast-Fourier transformation is available for spectral analysis of the periodic steady-state responses.

DYNAST runs under DOS- or WINDOWS-control on IBM-compatible PCs. Because it is coded in FORTRAN 77 and C-languages, it is easily implemented on other platforms. It is accompanied by a menu-driven *graphical environment*. The block and multiport diagrams can be submitted in a graphical form by a schematic capture editor. DYNAST can be easily augmented by various pre- and postprocessors because all its input and output data are available in the ASCII code. Free ''net-list'' access to DYNAST is possible by means of e-mail or online over the Internet [7].

13.1 Introduction: Definition and Classification

Current very-large-scale integration (VLSI) technologies provide for the fabrication of chips with several million transistors. With these technologies a single chip may contain one powerful digital processor, a huge memory containing millions of very simple units placed in a regular structure, and other complex functions. A powerful combination of a simple logic processor placed in a regular structure is the cellular automaton invented by John von Neumann. The cellular automaton is a highly parallel computer architecture. Although many living neural circuits resemble this architecture, the neurons do not function in a simple logical mode: they are analog ''devices.'' The cellular neural network architecture, invented by Chua and his graduate student Yang [1], has both the properties: the cell units are nonlinear continuous-time dynamic elements placed in a cellular array. Of course, the resulting nonlinear dynamics in space could be extremely complex. The inventors, however, showed that these networks can be designed and used for a variety of engineering purposes, while maintaining stability and keeping the dynamic range within well-designed limits. Subsequent developments have uncovered the many inherent capabilities of this architecture (IEEE conferences: CNNA-90, CNNA-92, CNNA-94, 96, 98, 00, 02; Special issues: *International Journal of Circuit Theory and Applications*, 1993, 1996, 1998, 2002; and *IEEE Transactions on Circuits and Systems*, *I and II*, 1993, 1999, etc.). In the circuit implementation, unlike analog computers or general neural networks, the cellular neural/nonlinear network (CNN) cells are not the ubiquitous high-gain operational amplifiers. In most practical cases, they are either simple unity-gain amplifiers or simple second- or third-order simple dynamic circuits with one to two simple nonlinear components. Tractability

in the design and the possibility for exploiting the complex nonlinear dynamic phenomena in space, as well as the trillion operations per second (TeraOPS) computing speed in a single chip are but some of the many attractive properties of cellular neural networks. The trade-off is in the accuracy; however, in many cases, the accuracy achieved with current technologies is enough to solve a lot of real-life problems.

The CNN is a new paradigm for multidimensional, nonlinear, dynamic processor arrays [1,2]. The mainly uniform processing elements, called cells or artificial neurons, are placed on a regular geometric grid (with a square, hexagonal, or other pattern). This grid may consist of several two-dimensional (2-D) layers packed upon each other (Figure 13.1). Each processing element or cell is an analog dynamical system, the state (x), the input (u), and the output (y) signals are analog (real-valued) functions of time (both continuous-time and discrete-time signals are allowed). The interconnection and interaction pattern assumed at each cell is mainly local within a neighborhood N_r, where N_r denotes the first "r" circular layers of surrounding cells. Figure 13.2 shows a 2-D layer with a square grid of interconnection

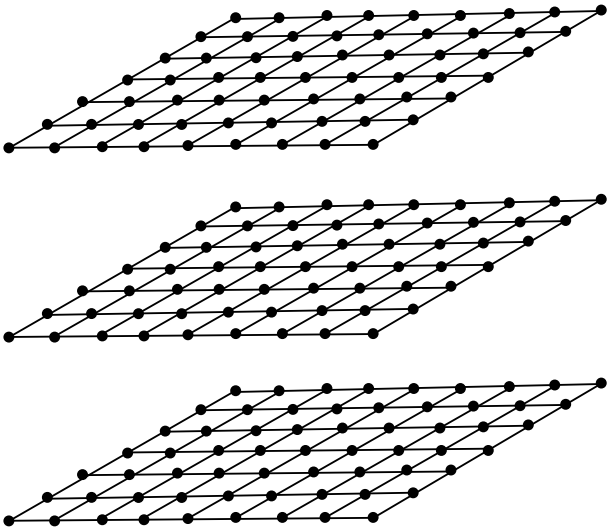

FIGURE 13.1 CNN grid structure with the processing elements (cells) located at the vertices.

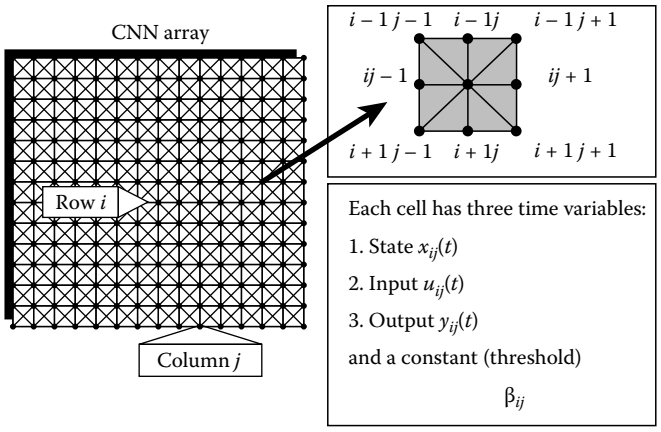

FIGURE 13.2 A single, 2-D CNN layer and a magnified cell with its neighbor cells with the normal neighborhood radius $r = 1$.

radius of 1 (nearest neighborhood). Each vertex contains a cell and the edges represent the interconnections between the cells. The pattern of interaction strengths between each cell and its neighbors is the ''program'' of the CNN array. It is called a cloning template (or just template).

Depending on the types of grids, processors (cells), interactions, and modes of operation, several classes of CNN architectures and models have been introduced. Although the summary below is not complete, it gives an impression of vast diversities.

13.1.1 Typical CNN Models

1. Grid type
   - Square
   - Hexagonal
   - Planar
   - Circular
   - Equidistant
   - Logarithmic
2. Processor type
   - Linear
   - Sigmoid
   - First-order
   - Second-order
   - Third-order
3. Interaction type
   - Linear memoryless
   - Nonlinear
   - Dynamic
   - Delay-type
4. Mode of operation
   - Continuous-time
   - Discrete-time
   - Equilibrium
   - Oscillating
   - Chaotic

13.2 Simple CNN Circuit Structure

The simplest first-order dynamic CNN cell used in the seminal paper [1] is illustrated in Figure 13.3. It is placed on the grid in the position *ij* (row *i* and column *j*). It consists of a single state capacitor with a parallel resistor and an amplifier $[f(x_{ij})]$. This amplifier is a voltage-controlled current source (VCCS), where the controlling voltage is the state capacitor voltage. To make the amplifier model self-contained, a parallel resistor of unit value is assumed to be connected across the output port. Hence, the voltage transfer characteristic of this amplifier is also equal to $f(\cdot)$. In its simplest form this amplifier has a unity-gain saturation characteristic (see Figure 13.7 for more details).

The aggregate feedforward and feedback interactions are represented by the current sources i_{input} and i_{output}, respectively. Figure 13.4 shows these interactions in more detail. In fact, the feedforward interaction term i_{input} is a weighted sum of the input voltages (u_{kl}) of all cells in the neighborhood (N_r). Hence, the feedforward template, the so-called $\boldsymbol{B}$ template, is a small matrix of size $(2r+1) \times (2r+1)$ containing the template elements b_{kl}, which can be implemented by an array of linear VCCSs. The controlling voltages of these controlled sources are the input voltages of the cells within the neighborhood of radius r. This means, for example, that b_{12} is the VCCS controlled by the input voltage of the cell lying

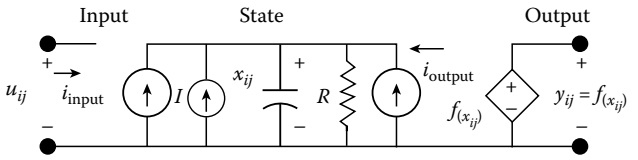

FIGURE 13.3 Simple first-order CNN cell.

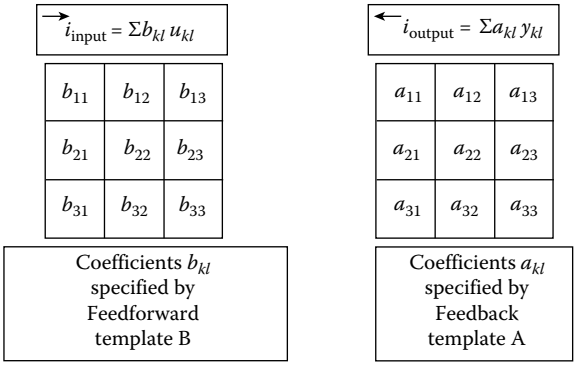

FIGURE 13.4 The 19 numbers (a program) that govern the CNN array (the 19th number is the constant bias term I, but it is not shown in the figure) define the cloning template (***A***, ***B***, and ***I***).

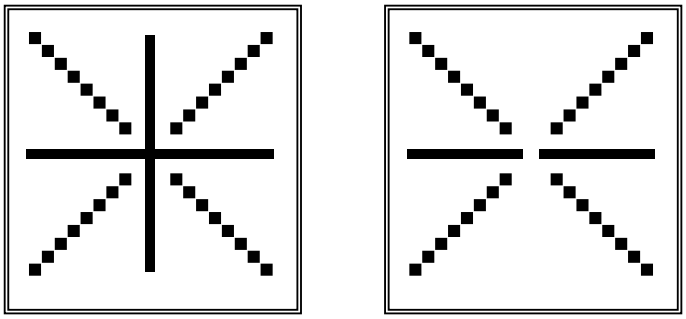

north from the cell ij. In most practical cases the ***B*** template is translation invariant, i.e., the interaction pattern (the ***B*** template) is the same for all cells. Hence, the chip layout will be very regular (as in memories or PLAs). The feedback interaction term i_{output} is a weighted sum of the output voltages (y_{kl}) of all cells in the neighborhood (N_r). The weights are the elements of a small matrix ***A*** called the ***A*** template (or feedback template). Similar arguments apply for the ***A*** template as for the ***B*** template discussed previously. If the constant threshold term is translation invariant as denoted by the constant current source ***I***, then in the case of $r = 1$, the complete cloning template contains only 19 numbers (***A*** and ***B*** and ***I***, i.e., $9 + 9 + 1$ terms), irrespective of the size of the CNN array. These 19 numbers define the task which the CNN array can solve.

What kind of tasks are we talking about? The simplest, and perhaps the most important, are image-processing tasks. In the CNN array computer, the input and output images are coded as follows. For each picture element (called pixel) in the image, a single cell is assigned in the CNN. This means that a one-to-one correspondence exists between the pixels and the CNN cells. Voltages in the CNN cells code the grayscale values of the pixels. Black is coded by $+1$ V, white is -1 V, and the grayscale values are in between. Two independent input images can be defined pixel-by-pixel: the input voltages u_{ij} and the initial voltage values of the capacitors x_{ij} (0) (cell-by-cell). Placing these input images onto the cell array and starting the transient, the steady-state outputs y_{ij} will encode the output image. The computing time is equal to the settling time of the CNN array. This time is below 1 μs using a CNN chip made with a 1.0–1.5 μm technology containing thousands of CNN processing elements, i.e., pixels, in an area of about 2 cm^2. This translates to a computing power of several 100 billion operations per second (GXPS). The first tested CNN chip [3] was followed by several others implementing a discrete-time CNN model [4] and chips with on-chip photosensors in each cell [5].

For example, if we place the array of voltage values defined by the image shown in Figure 13.5b as the input voltage and the initial state capacitor voltage values in the CNN array with the cloning template shown in Figure 13.5a, then after the transients have settled down, the output voltages will encode the output image of Figure 13.5c. Observe that the vertical line has been deleted. Since the image

$$\boldsymbol{A} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} 0 & -0.25 & 0 \\ 0 & 0 & 0 \\ 0 & -0.25 & 0 \end{bmatrix}, \quad \boldsymbol{I} = -1.5$$

(a)

(b) (c)

FIGURE 13.5 An input and output image where the vertical line was deleted.

contains 40×40 pixels, the CNN array contains 40×40 cells. It is quite interesting that if we had more than one vertical line, the computing time would be the same. Moreover, if we had an array of 100×100 cells on the chip, the computing time would remain the same as well. This remarkable result is due to the fully parallel nonlinear dynamics of the CNN computer. Some propagating-type templates induce wavelike phenomena. Their settling times increase with the size of the array.

For other image-processing tasks, processing form, motion, color, and depth, more than 100 cloning templates have been developed to date and the library of new templates is growing rapidly. Using the Cellular Neural Network Workstation Tool Kit [6], they can be called in from a CNN template library (CTL). New templates are being developed and published continually.

The dynamics of the CNN array is described by the following set of differential equations:

$$\begin{aligned} \mathrm{d}x_{ij}/\mathrm{d}t &= -x_{ij} + I + i_{\text{output}} + i_{\text{input}} \\ y_{ij} &= f(x_{ij}) \\ i &= 1, 2, \ldots, N \quad \text{and} \quad j = 1, 2, \ldots, M \text{ (the array has } N \times M \text{ cells)} \end{aligned}$$

where the last two terms in the state equation are given by the sums shown in Figure 13.4.

We can generalize the domain covered by the original CNN defined via linear and time-invariant templates by introducing the "nonlinear" templates (denoted by "$\wedge$") and the "delay" templates (indicated by τ in the superscript) as well, to obtain the generalized state equation shown below. The unity-gain nonlinear sigmoid characteristics f are depicted in Figure 13.6.

$$\begin{aligned} \frac{\mathrm{d}vx_{ij}}{\mathrm{d}t} = -vx_{ij} + I_{ij} &+ \sum_{kl \in N_r(ij)} \hat{A}_{ij;kl}\,(vy_{kl}(t), vy_{ij}(t)) + \sum_{kl \in N_r(ij)} \hat{B}_{ij;kl}(vu_{kl}(t), vu_{ij}(t)) \\ &+ \sum_{kl \in N_r(ij)} A^{\tau}_{ij;kl} vy_{kl}(t - \tau) + \sum_{kl \in N_r(ij)} B^{\tau}_{ij;kl} vu_{kl}(t - \tau) \end{aligned}$$

Several strong results have been proved that assure stable and reliable operations. If the $\boldsymbol{A}$ template is symmetric, then the CNN is stable. Several other results have extended this condition [4,7]. The sum of the absolute values of all the 19 template elements plus 1 defines the dynamic range within which the

  - All *state variables are continuous valued* signals

FIGURE 13.7 CNN definition.

state voltage remains bounded during the entire transient, if the input and initial state signals are <1 V in absolute value [1].

In a broader sense, the CNN is defined [8] as shown in Figure 13.7, see also Ref. [32].

13.3 Stored Program CNN Universal Machine and the Analogic Supercomputer Chip

For different tasks, say image-processing, we need different cloning templates. If we want to implement them in hardware, we would need different chips. This is inefficient except for dedicated, mass-production applications.

The invention of the CNN universal machine [9] has overcome the problem above. It is the first stored-program array computer with analog nonlinear array dynamics. One CNN operation, for example, solving thousands of nonlinear differential equations in a microsecond, is just one single instruction. In addition, a single instruction is represented by just a few analog (real) values (numbers). In the case when the nearest neighborhood is used, only 19 numbers are generated. When combining several CNN templates, for example, extracting first contours in a grayscale image, then detecting those areas where the contour has holes, etc., we have to design a flowchart logic that satisfies the correct sequence of the different templates. The simple flowchart for the previous example is shown in Figure 13.8. One key point is that, in order to exploit the high speed of the CNN chips, we have to store the intermediate results cell-by-cell (pixel-by-pixel). Therefore, we need a local analog memory (LAM). By combining several template actions we can write more complex flowcharts for implementing almost any analogic algorithms. The name analogic is an acronym for ''analog and logic.'' It is important to realize that analogic computation is completely different from hybrid computing. To cite just one point, among others, no A/D or D/A conversions occur during the computation of an analogic program. As with digital microprocessors, to control the execution of an analogic algorithm, we need a global programming unit. The global architecture of the CNN universal machine is shown in Figure 13.9.

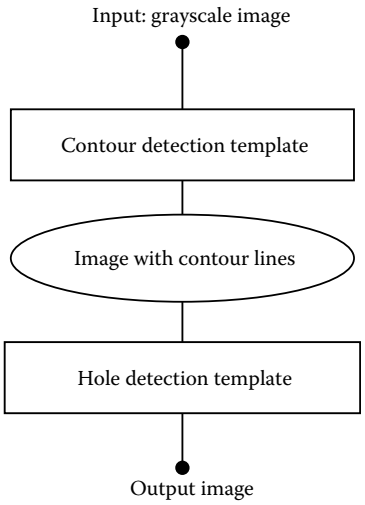

FIGURE 13.8 Flowchart representing the logic sequence of two templates.

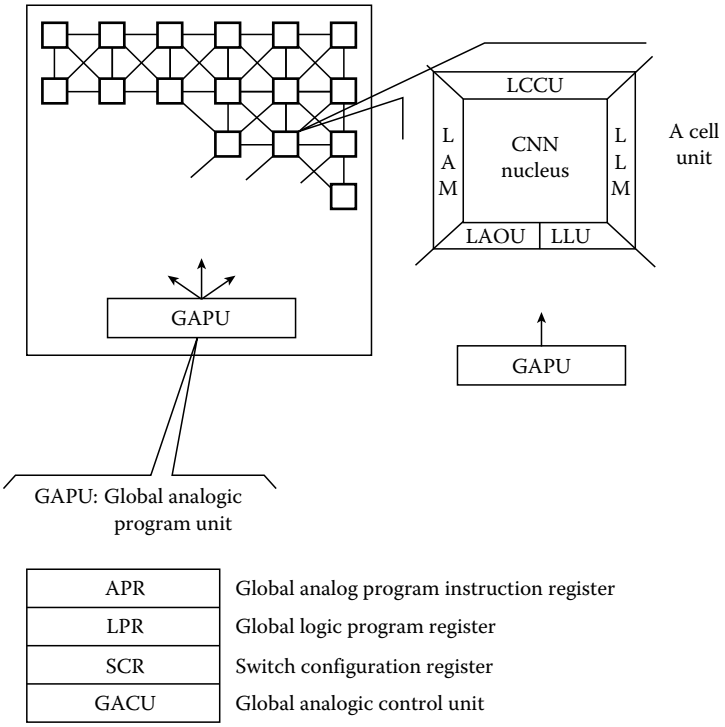

FIGURE 13.9 Global architecture of the CNN universal machine.

As we can see from this figure, the CNN nucleus described in Section 13.2 has been generalized to include several crucial functions depicted in the periphery. We have already discussed the role of the LAM that provides the local (on-chip) storage of intermediate analog results. Because the results of many detection tasks in applications involve only black-and-white logic values, adding a local logic memory (LLM) in each cell is crucial. After applying several templates in a sequence, it is often necessary to combine their results. For example, to analyze motion, consecutive snapshots processed by CNN templates are compared. The local analog output unit (LAOU) and the local logic unit (LLU) perform these tasks, both on the local analog (gray scale) and the logical (black-and-white) values. The local communication and control unit (LCCU) of each cell decodes the various instructions coming from the global analogic program unit (GAPU).

The global control of each cell is provided by the GAPU. It consists of four parts:

1. Analog program (instruction) register (APR) stores the CNN template values (19 values for each CNN template instruction in the case of nearest interconnection). The templates stored here will be used during the run of the prescribed analogical algorithm.
2. Global logic program register (LPR) stores the code for the LLUs.
3. Flexibility of the extended CNN cells is provided by embedding controllable switches in each cell. By changing the switch configurations of each cell simultaneously, we can execute many tasks using the same cell. For example, the CNN program starts by loading a given template, storing the results of this template action in the LAM, placing this intermediate result back on the input to prepare the cell, starting the action with another template, etc. The switch configurations of the cells are coded in the switch configuration register (SCR).
4. Finally, the heart of the GAPU is the global analogic control unit (GACU), which contains the physical machine code of the logic sequence of analogical algorithm. It is important to emphasize that here the control code is digital; hence, although its internal operation is analog and logical, a CNN universal chip can be programmed with the same flexibility and ease as a digital microprocessor—except the language is much simpler. Indeed, a high-level language, a compiler, an operating system, and an algorithm development system are available for CNN universal chip architectures. Moreover, by fabricating optical sensors cell-by-cell on the chip [5], the image input is directly interfaced.

The CNN universal chip is called supercomputer chip because the execution speed of an analogic algorithm falls in the same range as the computing power of today's average digital supercomputers (a TeraOPS). Another reason for this enormous computing power is that the reprogramming time of a new analog instruction (template) is of the same order, or less, than the analog array execution time (less than a microsecond). This is about 1 million times faster than some fully interconnected analog chips.

Based on the previously mentioned novel characteristics, the CNN universal chip can be considered to be an analogic microprocessor.

13.4 Applications

In view of its flexibility and its very high speed in image-processing tasks, the CNN universal machine is ideal for many applications. In the following, we briefly describe three areas. For more applications, the reader should consult the references at the end of this chapter.

13.4.1 Image Processing—Form, Motion, Color, and Depth

Image processing is currently the most popular application of CNN. Of the more than 100 different templates currently available, the vast majority are for image-processing tasks. Eventually, we will have templates for almost all conceivable local image-processing operations. Form (shape), motion, color, and depth can all be ideally processed via CNN. The interested reader can find many examples and

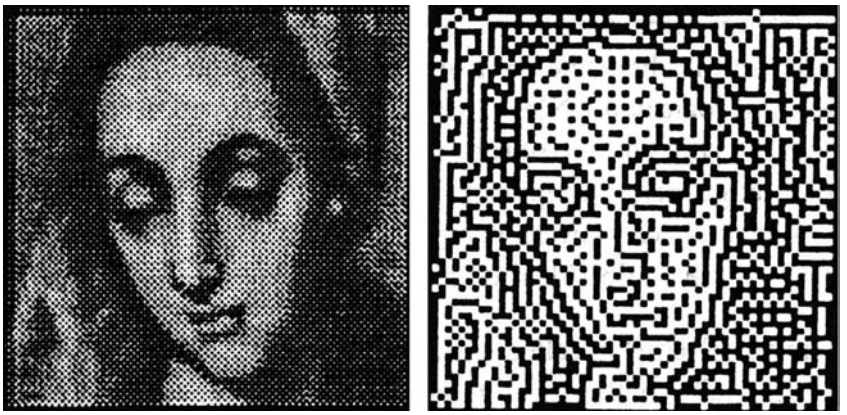

FIGURE 13.10 Halftoning: an original grayscale image (LHS) and its halftoned version (RHS). A low resolution is deliberately chosen in (b) in order to reveal the differing dot densities at various regions of the image.

applications in the references. CNN handles analog pixel values, so grayscale images are processed directly.

Many templates detect simple features like different types of edges, convex or concave corners, lines with a prescribed orientation, etc. Other templates detect semiglobal features like holes, groups of objects within a given size of area, or delete objects smaller than a given size. There are also many CNN global operations like calculating the shadow, histogram, etc. Halftoning is commonly used in fax machines, laser printers, and newspapers. In this case, the local gray level is represented by black dots of identical size, whose density varies in accordance with the gray level. CNN templates can do this job as well. A simple example is shown in Figure 13.10. The original grayscale image is shown on the left-hand side, the halftoned image is shown on the right-hand side. The ''smoothing'' function of our eye completes the image-processing task.

More complex templates detect patterns defined within the neighborhood of interaction. In this case, the patterns of the $\boldsymbol{A}$ and $\boldsymbol{B}$ templates somehow reflect the pattern of the object to be detected.

Because the simplest templates are translation invariant, the detection or pattern recognition is translation invariant as well. By clever design, however, some rotationally invariant detection procedures have been developed as well.

Combining several templates according to some prescribed logic sequence, more complex pattern detection tasks can be performed, e.g., halftoning.

Color-processing CNN arrays represent the three basis colors by single layers via a multilayer CNN. For example, using the red-green-blue (RGB) representation in a three-layer CNN, simple color-processing operations can be performed. Combining them with logic, conversions between various color representations are possible.

One of the most complex tasks that has been undertaken by an analogic CNN algorithm is the recognition of bank notes. Recognition of bank notes in a few milliseconds is becoming more and more important. Recent advances in the copy machine industry have made currency counterfeiting easier. Therefore, automatic bank note detection is a pressing need. Figure 13.11 shows a part of this process (which involves color processing as well). The dollar bill shown in the foreground is analyzed and the circles of a given size are detected (colors are not shown). The ''color cube'' means that each color intensity is within prescribed lower and upper limit values.

Motion detection can be achieved by CNN in many ways. One approach to process motion is to apply two consecutive snapshots to the input and the initial state of the CNN cell. The CNN array calculates the various combinations between the two snapshots. The simplest case is just taking the difference to detect

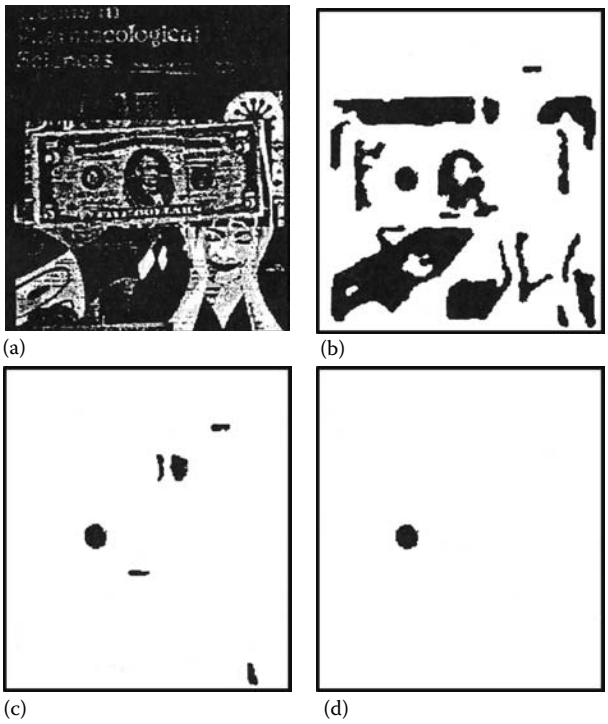

FIGURE 13.11 Some intermediate steps in the dollar bill recognition process. An input image (a) shown here in single color results in the ''color cube'' (b), the convex objects (c), and the size classification (d).* (From Zarándy, A., Werblin, F., Roska, T., Chua, L.O., and Novel type of analogical CNN algorithms for recognizing bank notes, Memorandum UCB/ERL, M94/29 1994, Electronics Research Laboratory, University of California, Berkeley, CA, 1994. With permission.)

motion. Detecting direction, shape, etc. of moving objects are only the simplest problems that can be solved via CNN. In fact, even depth detection can be included as well.

13.4.2 Partial Differential Equations

As noted in the original paper [1], even the simple-cell CNN with the linear template

$$\boldsymbol{A} = \begin{bmatrix} 0 & 1 & 0 \\ 1 & -3 & 1 \\ 0 & 1 & 0 \end{bmatrix}, \quad \boldsymbol{B} = 0, \quad \boldsymbol{I} = 0$$

can approximate the solution of a diffusion-type partial differential equation (PDE) on a discrete spatial grid. This solution maintains continuity in time, a nice property not possible in digital computers.

By adding just a simple capacitor to the output, i.e., by placing a parallel RC circuit across the output port of the cell of Figure 13.3, the following wave equation will be represented in a discrete space grid:

$$\mathrm{d}^2 p(t)/\mathrm{d}t^2 = \Delta p$$

* Figure 13.11 shows a part of this process [31] (which involves color processing as well). The dollar bill shown in the foreground is analyzed and the circles of a given size are detected (colors are not shown).

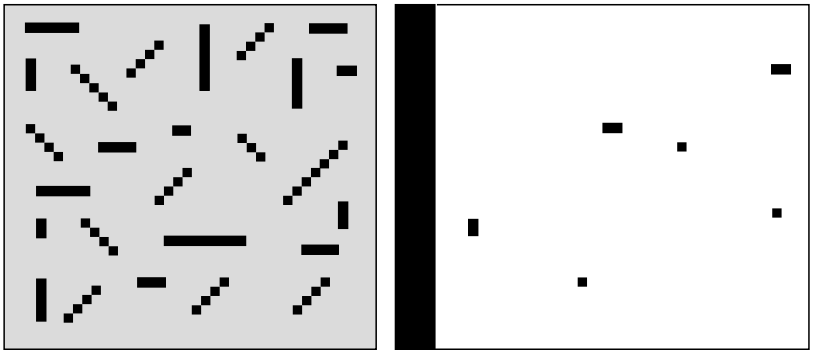

FIGURE 13.12 The length tuning effect. The input image on the LHS contains bars of different lengths. The out image on the RHS contains only those that are smaller than a given length. (From Roska, T., Hámori, J., Lábos, E., Lotz, K., Takács, J., Venetianer, P., Vidnyánszki, Z., and Zarándy, A., *IEEE Trans. Circuits Syst. I*, 40, 182, 1993. With permission.)

where

$p(t) = P(x, y, t)$ is the state (intensity) variable on a 2-D plane (x, y)

Δ is the Laplacian operator (the sum of the second derivatives related to x and y)

In some cases, it is useful to use a cell circuit that is chaotic. Using the canonical Chua's circuit, other types of PDEs can be modeled, generating effects like autowaves, spiral waves, Turing patterns, and so on (e.g., Perez-Munuzuri et al. in Ref. [7]).

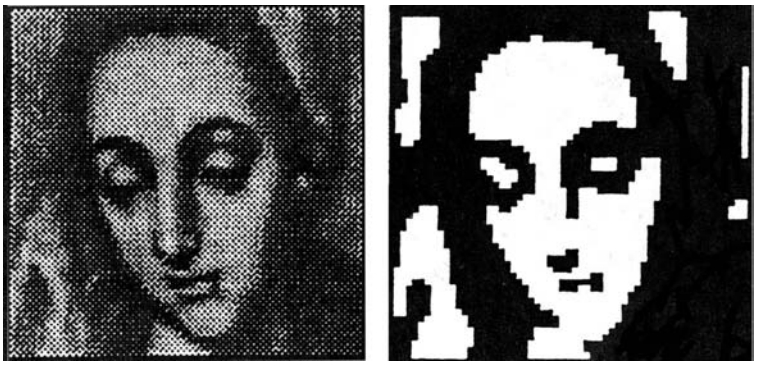
13.4.3 Relation to Biology

Many topographical sensory organs have processing neural-cell structures very similar to the CNN model. Local connectivity in a few sheets of regularly situated neurons is very typical. Vision, especially the retina, reflects these properties strikingly. It is not surprising that, based on standard neurobiological models, CNN models have been applied to the modeling of the subcortical visual pathway [10]. Moreover, a new method has been devised to use the CNN universal machine for combining retina models of different species in a programmed way. Modalities from other sensory organs can be modeled similarly and combined with the retina models [11]. This has been called bionic eye.

Many of these models are neuromorphic. This means that there is a one-to-one correspondence between the neuroanatomy and the CNN structure. Moreover, the CNN template reflects the interconnection pattern of the neurons (called receptive field organizations). Length tuning is such an example. A corresponding input and output picture of the neuromorphic length tuning model is shown in Figure 13.12. Those bars that have lengths smaller than or equal to three pixels are detected.

13.5 Template Library: Analogical CNN Algorithms

During the last few years, after the invention of the cellular neural network paradigm and the CNN universal machine, many new cloning templates have been discovered. In addition, the number of innovative analogical CNN algorithms, combining both analog cloning templates and local as well as global logic, is presently steadily increasing at a rapid rate.



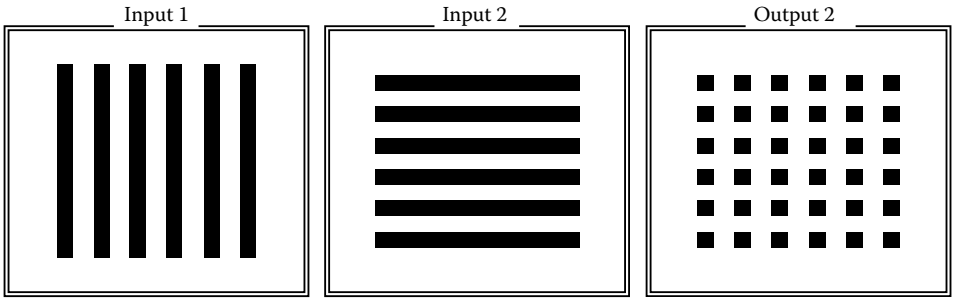
As an illustration, let us choose a couple of cloning templates from the CNN library [1,12]. In each case, a name, a short description of the function, the cloning templates, and a representative input–output image pair are shown. With regard to the inputs, the default case means that the input and initial state are the same. If $\boldsymbol{B} = 0$, then the input picture is chosen as the initial state.

Name: AVERAGE

Function. Spatial averaging of pixel intensities over the $r = 1$ convolutional window.

$$\boldsymbol{A} = \begin{bmatrix} 0 & 1 & 0 \\ 1 & 2 & 1 \\ 0 & 1 & 0 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \boldsymbol{I} = 0$$

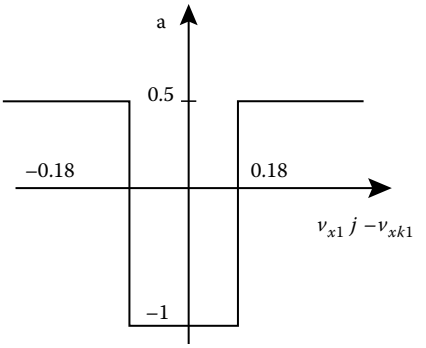
Example. Input and output picture.



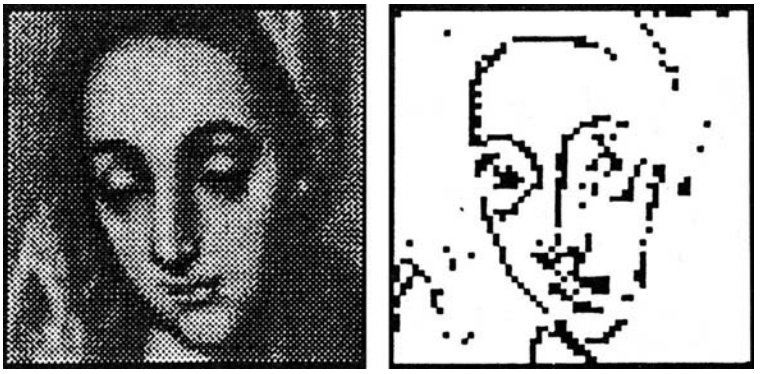
Name: AND

Function. Logical "AND" function of the input and the initial state pictures.

$$\boldsymbol{A} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1.5 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1.5 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \boldsymbol{I} = -1$$



Example. Input, initial state, and output picture.

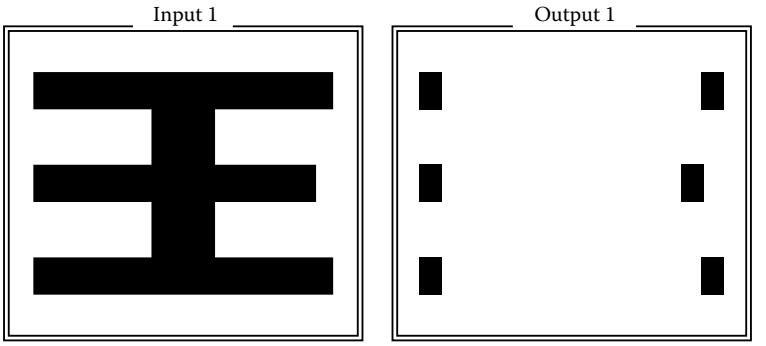


Name: CONTOUR

Function. Grayscale contour detector.

$$\boldsymbol{A} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} a & a & a \\ a & a & a \\ a & a & a \end{bmatrix}, \quad \boldsymbol{I} = 0.7$$

Example. Input and output picture.

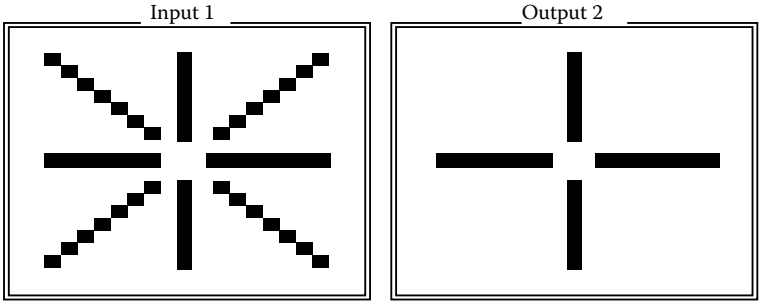


Name: CORNER

Function. Convex corner detector.

$$\boldsymbol{A} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} -0.25 & -0.25 & -0.25 \\ -0.25 & 2 & -0.25 \\ -0.25 & -0.25 & -0.25 \end{bmatrix}, \quad \boldsymbol{I} = -3$$

Example. Input and output picture.

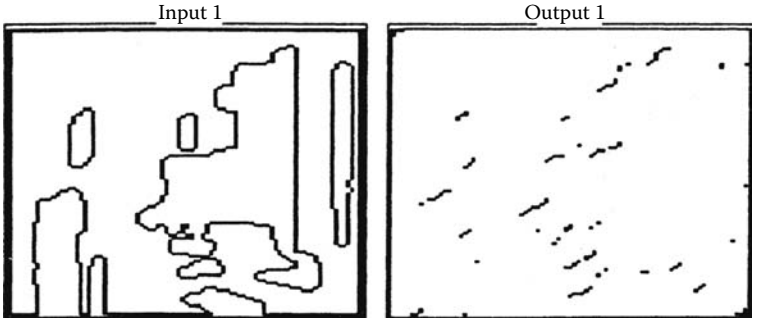


Name: DELDIAG1

Function. Deletes one pixel wide diagonal lines (5).

$$\boldsymbol{A} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} -0.25 & 0 & -0.25 \\ 0 & 0 & 0 \\ -0.25 & 0 & -0.25 \end{bmatrix}, \quad \boldsymbol{I} = -2$$

Example. Input and output picture.

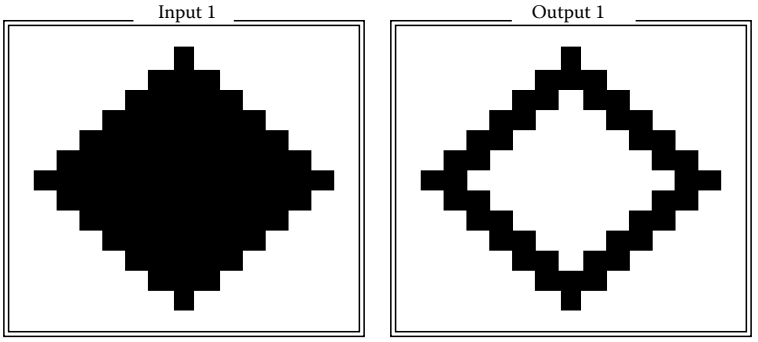


Name: DIAG

Function. Deletes the diagonal lines.

$$\boldsymbol{A} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} -1 & -1 & -0.5 & 0.5 & 1 \\ -1 & -0.5 & 1 & 1 & 0.5 \\ -0.5 & 1 & 5 & 1 & -0.5 \\ 0.5 & 1 & 1 & -0.5 & -1 \\ 1 & 0.5 & -0.5 & -1 & -1 \end{bmatrix}, \quad \boldsymbol{I} = -9$$

Example. Input and output picture.



Name: EDGE

Function. Black-and-white edge detector.

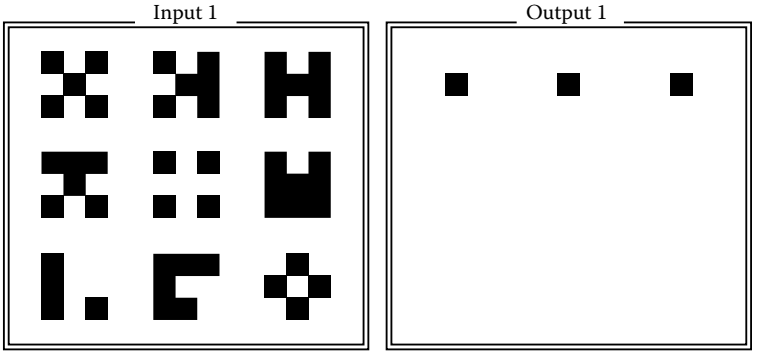
$$\boldsymbol{A} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} -0.25 & -0.25 & -0.25 \\ -0.25 & 2 & -0.25 \\ -0.25 & -0.25 & -0.25 \end{bmatrix}, \quad \boldsymbol{I} = -1.5$$

Example. Input and output picture.

Name: MATCH

Function. Detects 3×3 patterns matching exactly the one prescribed by the template $\boldsymbol{B}$, namely, having a black/white pixel where the template value is ± 1, respectively.

$$\boldsymbol{A} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} v & v & v \\ v & v & v \\ v & v & v \end{bmatrix}, \quad \boldsymbol{I} = -N + 0.5$$



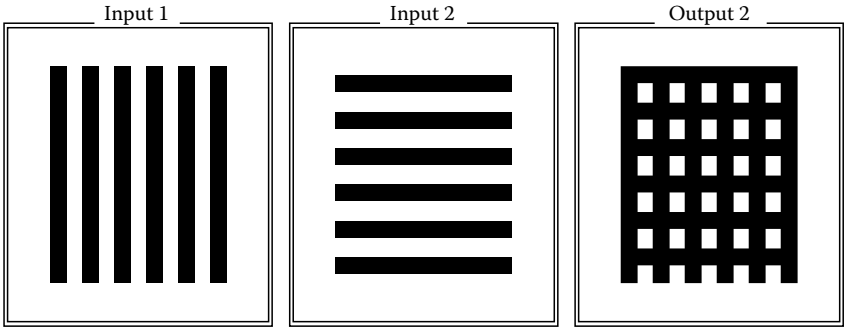
where

$v = +1$, if corresponding pixel is required to be black
$v = 0$, if corresponding pixel is don't care
$v = -1$, if corresponding pixel is required to be white

$N =$ number of pixels required to be either black or white, i.e., the number of nonzero values in the $\boldsymbol{B}$ template

Example. Input and output picture, using the following values:

$$\boldsymbol{A} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} 1 & -1 & 1 \\ 0 & 1 & 0 \\ 1 & -1 & 1 \end{bmatrix}, \quad \boldsymbol{I} = -6.5$$

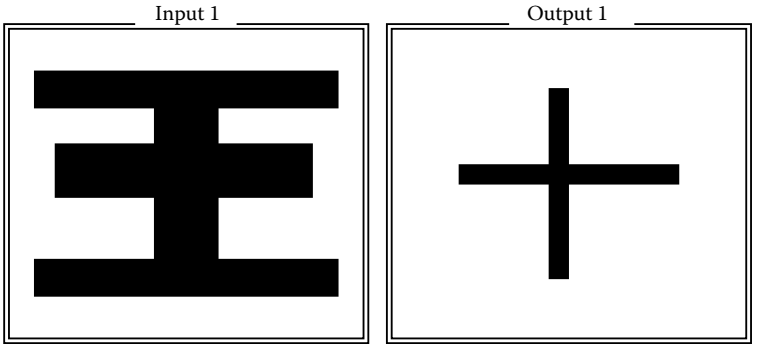


Name: OR

Function. Logical "OR" function of the input and the initial state.

$$\boldsymbol{A} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 3 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 3 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \boldsymbol{I} = 2$$

Example. Input, initial state, and output picture.



Name: PEELIPIX

Function. Peels one pixel from all directions.

$$\boldsymbol{A} = \begin{bmatrix} 0 & 0.4 & 0 \\ 0.4 & 1.4 & 0.4 \\ 0 & 0.4 & 0 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} 4.6 & -2.8 & 4.6 \\ -2.8 & 1 & -2.8 \\ 4.6 & -2.8 & 4.6 \end{bmatrix}, \quad \boldsymbol{I} = -7.2$$

Example. Input and output picture.

13.6 Recent Advances

After the first few integrated circuit implementations of the basic CNN circuits, stored programmable analogic CNN universal machine chips have been fabricated. Indeed, a full-fledged version of them [13] is the first visual microprocessor, all the 4096 cell processors of it contain an optical sensor right on the surface of the chip (a focal plane). This implementation represents, at the same time, the most complex operational, stored programmable analog CMOS integrated circuit ever reported, in terms of the number of transistors operating in analog mode (about 1 million). The equivalent digital computing power of this

visual microprocessor is about a few TeraOPS. It processes grayscale input images and has a grayscale output. A 128×128 processor version has recently been fabricated. A binary input/output CNN universal machine chip with 48×48 cell processors has a higher cell density [14], and another circuit design strategy [15] is aiming to implement 5×5 or even higher neighborhood templates.

These chips are the first examples of a new, analogic, topographic (spatial-temporal) computing technology. Its computational infrastructure (high-level language, called Alpha, compiler, operating system, etc.) has also been developed [16], and the industrial applications have been started in a couple of companies worldwide. Moreover, a key application area of this technology is sensor computing [17]. Integrating 2-D topographic sensor arrays with the CNN universal machine on a single chip, providing a direct, dynamic interaction with tuning of the sensors, this is a capability no other technology offers with comparable computational power.

Recently, it has been shown that PDE-based techniques, the most advanced methods for complex image-processing problems, could solve tasks intractable with other methods. Their only drawback is the excessive digital computing power they need. In our cellular computing technology, however, the elementary instruction could be a solution of a PDE. It has been shown that, in addition to the simple diffusion PDE implementation described previously, almost all PDEs can be implemented by CNN [18]. Indeed, active waves [2] have been successfully applied using operational analogic CNN universal machine chips with 4096 cell processors, manifesting at least three orders of magnitude speed advantage compared to fully digital chips of comparable IC technology feature size.

Following the first steps in modeling living sensory modalities, especially vision, motivated especially by a breakthrough in understanding the neurobiological constructs of the mammalian retina [19], new models and a modeling framework [20] have been developed based on CNNs. Their implementation in complex cell CNN universal machines [21] is under construction.

Studies on complexity related to CNN models and implementations have been emerging recently. Following the groundbreaking theoretical studies of Turing on the morphogenesis of CNN-like coupled nonlinear units [22] and a few experimental case studies of the well-publicized ''complex systems,'' as well as many exotic waves generated by coupled $\boldsymbol{A}$ template CNNs, the root of complexity in pattern formation at the edge of chaos has been discovered [23]. As far as the computational complexity is concerned, the study of a new quality of computational complexity has been explored [24], showing qualitatively different properties compared to the classical digital complexity theory as well as the complexity on reals [25].

To further explore the vast amount of literature on CNN technology and analogic cellular computing, the interested reader could consult the bibliography at the website of the technical committee on Cellular Neural Networks and Array Computing of the IEEE Circuits and Systems Society (http://www.ieee-cas.org/~cnnactc), some recent monographs [26–28], and an undergraduate textbook [29].

13.7 Recent Developments and Outlook

During the last few years, CNN technology, as well as its offsprings and generalizations, has generated several significant results and the first few companies have entered into the market. The main events are as follows.

The appearance of the first commercially available, stored programmable, visual microprocessor, the Q-Eye (with 176×144 cell processors and on-chip optical sensors, 10,000 frame per second, and $<$300 mW), embedded in the self-contained Eye-RIS system, both are from AnaFocus Ltd., Seville (www.anafocus.com). A new version of the Bi-i camera-computer, using emulated digital cellular array architecture, has also been developed, and applied in some mission critical tasks (Eutecus Inc., Berkeley, California, www.eutecus.com).

Several algorithmic and theoretical results as well as application case studies have been published. A new type of algorithmic thinking is emerging that is based on spatial-temporal waves as elementary instructions.

The CNN universal machine, with some extensions and diverse physical implementations became a general computational platform: the cellular wave computer. This has been happening in parallel with a dramatic new trend in microprocessor architecture development, namely the multi- and many core architectures on a single chip. The other side of the story is the cellular supercomputer development.

The essence of this new trend is that processor arrays on a single chip are becoming the next main direction in CMOS technology, when saturating the clock frequency due to the power dissipation constraints. Today, products are already on the market with about 100 processors and the trend is continuing, including the latest FPGAs. Hence, the cellular many-core processor arrays are becoming the major trend in computing in general, and in sensory computing, in particular. Since the wire delay is becoming greater than the gate delay, the communication speed is reduced dramatically far from a given processor. Hence, the mainly (not exclusively) locally connected cellular processor array architectures on a single chip become a physical necessity. Interestingly, the high-end supercomputers are also following this lead (the highest speed Blue Gene of IBM has a 3-D toroidal cellular architecture).

This new development has made the cellular wave computer architecture a must in many applications. As an example, a very efficient PDE implementation was made by using CNN models on an FPGA and on a CELL Multiprocessor (IBM, Sony, Toshiba) developed for a game console, as well.

Interestingly, the circuit hardware implementation issues (now at a 45 nm CMOS technology) are forcing the conversion of the computing architectures. The details can be found in a recent review article [30]. It seems that the cellular wave computer might become a prototype architecture, although the cell processors are of different forms and implementations (digital, analog, mixed mode, optical, etc.), and the spatial-temporal, mainly locally and sparsely globally connected communication framework is necessary. Interestingly, many different sensory organs, uncovered recently by neurobiologists, are following this architecture.

14.1 Introduction to Chaos

14.1.1 Electrical and Electronic Circuits as Dynamical Systems

A system is something having parts that may be perceived as a single entity. A dynamical system is one that changes with time; what changes is the state of the system. Mathematically, a dynamical system consists of a space of states (called the state space or phase space) and a rule, called the dynamic, for determining which state corresponds at a given future time to a given present state [8]. A deterministic dynamical system is one where the state, at any time, is completely determined by its initial state and dynamic. In this section, we consider only deterministic dynamical systems.

A deterministic dynamical system may have a continuous or discrete state space and a continuous-time or discrete-time dynamic.

A lumped* circuit containing resistive elements (resistors, voltage and current sources) and energy-storage elements (capacitors and inductors) may be modeled as a continuous-time deterministic dynamical system in $\mathbb{R}^n$. The evolution of the state of the circuit is described by a system of ordinary differential equations (ODEs) called state equations.

Discrete-time deterministic dynamical systems occur in electrical engineering as models of switched-capacitor (SC) and digital filters, sampled phase-locked loops, and sigma–delta modulators. Discrete-time dynamical systems also arise when analyzing the stability of steady-state solutions of continuous-time systems. The evolution of a discrete-time dynamical system is described by a system of *difference equations*.

14.1.1.1 Continuous-Time Dynamical Systems

THEOREM 14.1 (Existence and Uniqueness of Solution for a Differential Equation)

Consider a continuous-time deterministic dynamical system defined by a system of ordinary differential equations of the form

$$\dot{\mathbf{X}}(t) = \mathbf{F}(\mathbf{X}(t), t) \tag{14.1}$$

where $\mathbf{X}(t) \in \mathbb{R}^n$ *is called the state,* $\dot{\mathbf{X}}(t)$ *denotes the derivative of* $\mathbf{X}(t)$ *with respect to time,* $\mathbf{X}(t_0) = \mathbf{X}_0$ *is called the initial condition, and the map* $\mathbf{F}(\cdot, \cdot): \mathbb{R}^n \times \mathbb{R}_+ \to \mathbb{R}^n$ *is* (1) *continuous almost everywhere*† *on* $\mathbb{R}^n \times \mathbb{R}_+$ *and* (2) *globally Lipschitz*‡ *in* $\mathbf{X}$. *Then, for each* $(\mathbf{X}_0, t_0) \in \mathbb{R}^n \times \mathbb{R}_+$, *there exists a continuous function* $\phi(\cdot; \mathbf{X}_0, t_0): \mathbb{R}_+ \to \mathbb{R}^n$ *such that*

$$\phi(t_0; \mathbf{X}_0, t_0) = \mathbf{X}_0$$

and

$$\dot{\phi}(t; \mathbf{X}_0, t_0) = \mathbf{F}(\phi(t; \mathbf{X}_0, t_0), t) \tag{14.2}$$

Furthermore, this function is unique.

The function $\phi(\cdot; \mathbf{X}_0, t_0)$ *is called the solution or trajectory* $(\mathbf{X}_0, t_0)$ *of the differential Equation* 14.1.

The image $\{\phi(t; \mathbf{X}_0, t_0) \in \mathbb{R}^n | t \in \mathbb{R}_+\}$ of the trajectory through $(\mathbf{X}_0, t_0)$ is a continuous curve in $\mathbb{R}^n$ called the orbit through $(\mathbf{X}_0, t_0)$.

$\mathbf{F}(\cdot, \cdot)$ is called the vector field of Equation 14.1 because its image $\mathbf{F}(\mathbf{X}, t)$ is a vector that defines the direction and speed of the trajectory through $\mathbf{X}$ at time t.

The vector field $\mathbf{F}$ generates the *flow* ϕ, where $\phi(\cdot; \cdot, \cdot): \mathbb{R}_+ \times \mathbb{R}^n \times \mathbb{R}_+ \to \mathbb{R}^n$ is a collection of continuous maps $\{\phi(t; \cdot, \cdot): \mathbb{R}^n \times \mathbb{R}_+ \to \mathbb{R}^n | t \in \mathbb{R}_+\}$.

In particular, a point $\mathbf{X}_0 \in \mathbb{R}^n$ at t_0 is mapped by the flow into $\mathbf{X}(t) = \phi_t(t; \mathbf{X}_0, t_0)$ at time t.

---

* A *lumped* circuit is one with physical dimensions that are small compared with the wavelengths of its voltage and current waveforms [2].

† By *continuous almost everywhere*, we mean the following: let D be a set in $\mathbb{R}_+$ that contains a countable number of discontinuities and for each $\mathbf{X} \in \mathbb{R}^n$, assume that the function $t \in \mathbb{R}_+ \backslash D \to \mathbf{F}(\mathbf{X}, t) \in \mathbb{R}^n$ *is continuous* and for any $\tau \in D$ the left-hand and right-hand limits $\mathbf{F}(\mathbf{X}, \tau)$ and $\mathbf{F}(\mathbf{X}, \tau_+)$, respectively, are *finite* in $\mathbb{R}^n$ [1]. This condition includes circuits that contain switches and/or squarewave voltage and current sources.

‡ There is a piecewise continuous function $k(\cdot): \mathbb{R}_+ \to \mathbb{R}_+$ such that $\|\mathbf{F}(\mathbf{X}, t) - \mathbf{F}(\mathbf{X}', t)\| \leq k(t) \|\mathbf{X} - \mathbf{X}'\|$, $\forall t \in \mathbb{R}_+$, $\forall \mathbf{X}, \mathbf{X}' \in \mathbb{R}^n$.

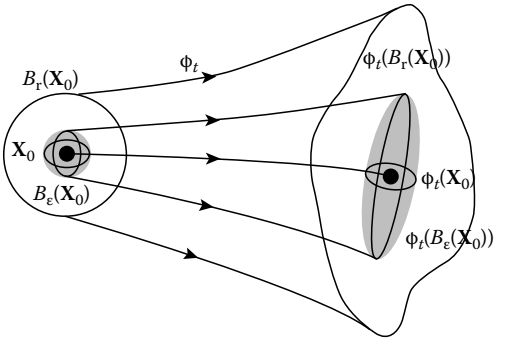

FIGURE 14.1 Vector field **F** of an autonomous continuous-time dynamical system generates a flow ϕ that maps a point $\mathbf{X}_0$ in the state space to its image $\phi_t(\mathbf{X}_0)$ t seconds later. A volume of state space $B_r(\mathbf{X}_0)$ evolves under the flow into a region $\phi_t[B_r(\mathbf{X}_0)]$. Sufficiently close to the trajectory $\phi_t(\mathbf{X}_0)$, the linearized flow maps a sphere of radius ε into an ellipsoid.

14.1.1.2 Autonomous Continuous-Time Dynamical Systems

If the vector field of a continuous-time deterministic dynamical system depends only on the state and is *independent* of time t, then the system is said to be *autonomous* and may be written as

$$\dot{\mathbf{X}}(t) = \mathbf{F}[\mathbf{X}(t)]$$

or simply

$$\dot{\mathbf{X}} = \mathbf{F}(\mathbf{X}) \tag{14.3}$$

If, in addition, the vector field $\mathbf{F}(\cdot)$: $\mathbb{R}^n \to \mathbb{R}^n$ is *Lipschitz*,* then there is a *unique* continuous function $\phi(\cdot, \mathbf{X}_0)$: $\mathbb{R}_+ \to \mathbb{R}^n$ (called the trajectory through $\mathbf{X}_0$), which satisfies,

$$\dot{\phi}(t, \mathbf{X}_0) = \mathbf{F}[\phi(t, \mathbf{X}_0)], \quad \phi(t_0, \mathbf{X}_0) = \mathbf{X}_0 \tag{14.4}$$

Because the vector field is independent of time, we choose $t_0 \equiv 0$. For shorthand, we denote the flow by ϕ and the map $\phi(t, \cdot)$: $\mathbb{R}^n \to \mathbb{R}^n$ by ϕ_t.

The t-advance map ϕ_t takes a state $\mathbf{X}_0 \in \mathbb{R}^n$ to state $\mathbf{X}(t) = \phi_t(\mathbf{X}_0)$ t seconds later. In particular, ϕ_0 is the identity mapping. Furthermore, $\phi_{t+s} = \phi_t\phi_s$, because the state $\mathbf{Y} = \phi_s(\mathbf{X})$ to which $\mathbf{X}$ evolves after time s evolves after an additional time t into the same state $\mathbf{Z}$ as that to which $\mathbf{X}$ evolves after time $t + s$:

$$\mathbf{Z} = \phi_t(\mathbf{Y}) = \phi_t[\phi_s(\mathbf{X})] = \phi_{t+s}(\mathbf{X})$$

A bundle of trajectories emanating from a ball $B_r(\mathbf{X}_0)$ of radius r centered at $\mathbf{X}_0$ is mapped by the flow into some region $\phi_t[B_r(\mathbf{X}_0)]$ after t seconds (see Figure 14.1). Consider a short segment of the trajectory ϕ_t $(\mathbf{X}_0)$ along which the flow is differentiable with respect to $\mathbf{X}$: in a sufficiently small neighborhood of this trajectory, the flow is almost linear, so the ball $B_\varepsilon(\mathbf{X}_0)$ of radius ε about $\mathbf{X}_0$ evolves into an ellipsoid $\phi_t[B_\varepsilon(\mathbf{X}_0)]$, as shown.

An important consequence of Lipschitz continuity in an autonomous vector field and the resulting uniqueness of solution of Equation 14.3 is that a trajectory of the dynamical system cannot go through the same point twice in two different directions. In particular, no two trajectories may cross each other; this is called the noncrossing property [18].

14.1.1.3 Nonautonomous Dynamical Systems

A nonautonomous, n-dimensional, continuous-time dynamical system may be transformed to an $(n+1)$-dimensional autonomous system by appending time as an additional state variable and writing

$$\begin{aligned} \dot{\mathbf{X}}(t) &= \mathbf{F}[\mathbf{X}(t), X_{n+1}(t)] \\ \dot{X}_{n+1}(t) &= 1 \end{aligned} \tag{14.5}$$

* There exists a finite $k \in \mathbb{R}^n$ such that $\|\mathbf{F}(\mathbf{X}) - \mathbf{F}(\mathbf{X}')\| \leq k \|\mathbf{X} - \mathbf{X}'\|$, $\forall \mathbf{X}, \mathbf{X}' \in \mathbb{R}^n$.

In the special case where the vector field is periodic with period T, as for example in the case of an oscillator with sinusoidal forcing, the periodically forced system Equation 14.5 is equivalent to the $(n+1)$ th-order autonomous system

$$\begin{aligned}\dot{\mathbf{X}}(t) &= \mathbf{F}(\mathbf{X}(t), \theta(t)T)\\ \dot{\theta}(t) &= \frac{1}{T}\end{aligned} \tag{14.6}$$

where $\theta(t) = X_{n+1}/T$.

By identifying the n-dimensional hyperplanes corresponding to $\theta = 0$ and $\theta = 1$, the state space may be transformed from $\mathbb{R}^n \times \mathbb{R}_+$ into an equivalent cylindrical state space $\mathbb{R}^n \times S^1$, where S^1 denotes the circle. In the new coordinate system, the solution through $(\mathbf{X}_0, t_0)$ of Equation 14.6 is

$$\begin{pmatrix} \mathbf{X}(t) \\ \theta_{S^1}(t) \end{pmatrix} = \begin{pmatrix} \phi_t(\mathbf{X}_0, t_0) \\ t/T \bmod 1 \end{pmatrix}$$

where $\theta(t) \in \mathbb{R}_+$ is identified with a point on S^1 (which has normalized angular coordinate $\theta_{S^1}(t) \in [0, 1)$) via the transformation $\theta_s^1(t) = \theta(t) \bmod 1$. Using this technique, periodically forced nonautonomous systems can be treated like autonomous systems.

14.1.1.4 Discrete-Time Dynamical Systems

Consider a discrete-time deterministic dynamical system defined by a system of difference equations of the form

$$\mathbf{X}(k+1) = \mathbf{G}(\mathbf{X}(k), k) \tag{14.7}$$

where

$\mathbf{X}(k) \in \mathbb{R}^n$ is called the state

$\mathbf{X}(k_0) = \mathbf{X}_0$ is the initial condition

$\mathbf{G}(\cdot, \cdot)$: $\mathbb{R}^n \times \mathbb{Z}_+ \to \mathbb{R}^n$ maps the current state $\mathbf{X}(k)$ into the next state $\mathbf{X}(k+1)$, where $k_0 \in \mathbb{Z}_+$

By analogy with the continuous-time case, there exists a function $\phi(\cdot, \mathbf{X}_0, k_0)$: $\mathbb{Z}_+ \to \mathbb{R}^n$ such that

$$\phi(k_0; \mathbf{X}_0, k_0) = \mathbf{X}_0$$

and

$$\phi(k+1; \mathbf{X}_0, k_0) = \mathbf{G}(\phi(k; \mathbf{X}_0, k_0), k)$$

The function $\phi(\cdot; \mathbf{X}_0, k_0)$: $\mathbb{Z}_+ \to \mathbb{R}^n$ is called the solution or trajectory through $(\mathbf{X}_0, k_0)$ of the difference Equation 14.7.

The image $\{\phi(k; \mathbf{X}_0, k_0) \in \mathbb{R}^n \mid k \in \mathbb{Z}_+\}$ in $\mathbb{R}^n$ of the trajectory through $(\mathbf{X}_0, k_0)$ is called an orbit through $(\mathbf{X}_0, k_0)$.

If the map $\mathbf{G}(\cdot, \cdot)$ of a discrete-time dynamical system depends only on the state $\mathbf{X}(k)$ and is independent of k then the system is said to be autonomous and may be written more simply as

$$\mathbf{X}_{k+1} = \mathbf{G}(\mathbf{X}_k) \tag{14.8}$$

where $\mathbf{X}_k$ is shorthand for $\mathbf{X}(k)$ and the initial iterate k_0 is chosen, without loss of generality, to be zero. Using this notation, $\mathbf{X}_k$ is the image $\mathbf{X}_0$ after k iterations of the map $\mathbf{G}(\cdot)$: $\mathbb{R}^n \to \mathbb{R}^n$.

Example: Nonlinear Parallel *RLC* Circuit

Consider the parallel *RLC* circuit in Figure 14.2. This circuit contains a linear inductor L, a linear capacitor C_2, and a nonlinear resistor N'_R, where the continuous piecewise-linear driving-point (DP) characteristic (see Figure 14.3) has slope G'_a for $|V'_R| \leq E$ and slope G'_b for $|V'_R| > E$. The DP characteristic of N'_R may be written explicitly

$$I'_R(V'_R) = G'_b V'_R + \frac{1}{2}(G'_a - G'_b)\left(|V'_R + E| - |V'_R - E|\right)$$

This circuit may be described by a pair of ODEs and is therefore a second-order, continuous-time dynamical system. Choosing I_3 and V_2 as state variables, we write

$$\frac{dI_3}{dt} = -\frac{1}{L}V_2$$
$$\frac{dV_2}{dt} = \frac{1}{C_2}I_3 - \frac{1}{C_2}I'_R(V_2)$$

with $I_3(0) = I_{3_0}$ and $V_2(0) = V_{2_0}$.

We illustrate the vector field by drawing vectors at uniformly spaced points in the two-dimensional state space defined by (I_3, V_2). Starting from a given initial condition (I_{3_0}, V_{2_0}), a solution curve in state space is the locus of points plotted out by the state as it moves through the vector field, following the direction of the arrow at every point. Figure 14.4 illustrates typical vector fields and trajectories of the circuit.

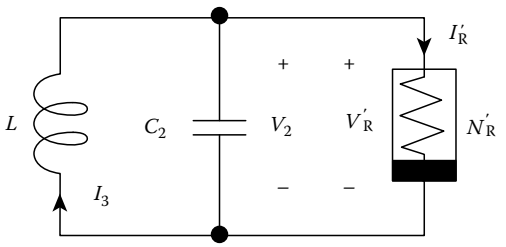

FIGURE 14.2 Parallel *RLC* circuit where the nonlinear resistor N'_R has a DP characteristic as illustrated in Figure 14.3. By Kirchhoff's voltage law, $V'_R = V_2$.

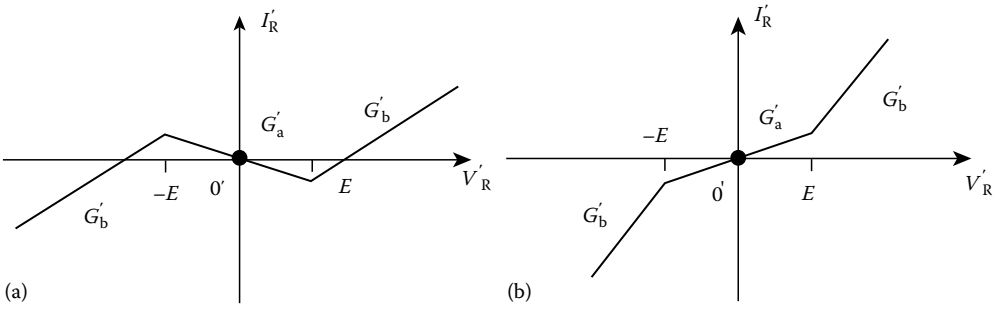

FIGURE 14.3 DP characteristic of N'_R in Figure 14.2 when (a) $G'_a < 0$ and (b) $G'_a > 0$.

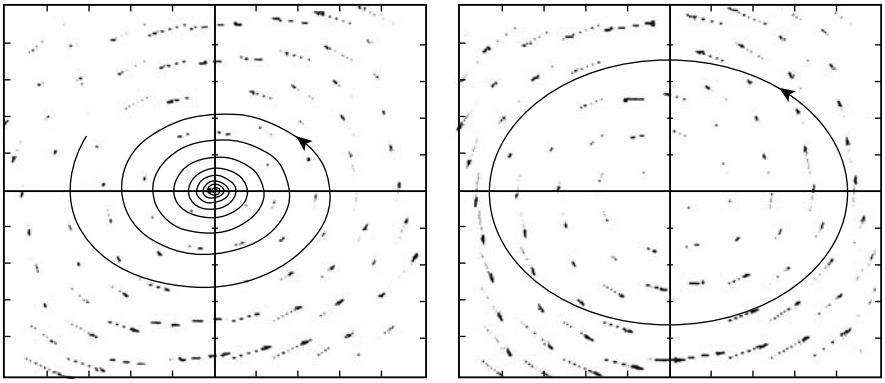

FIGURE 14.4 Vector fields for the nonlinear *RLC* circuit in Figure 14.2. $L = 18$ mH, $C_2 = 100$ nF, $E = 0.47$ V. (a) $G'_a = 242.424$ μS, $G'_b = 1045.455$ μS: all trajectories converge to the origin. (b) $G'_a = -257.576$ μS, $G'_b = 545.455$ μS: the unique steady-state solution is a limit cycle. Horizontal axis: I_3, 400 μA/div; vertical axis: V_2, 200 mV/div. (From Kennedy, M. P., *IEEE Trans. Circuits Syst. I Fundam. Theory Appl.*, 40, 647, Oct. 1993. With permission.)

If L, C_2, and G'_b are positive, the steady-state behavior of the circuit depends on the sign of G'_a. When $G'_a > 0$, the circuit is dissipative everywhere and all trajectories collapse toward the origin. The unique steady-state solution of the circuit is the stable dc equilibrium condition $I_3 = V_2 = 0$.

If $G'_a > 0$, N'_R looks like a negative resistor close to the origin and injects energy into the circuit, pushing trajectories away. Further out, where the characteristic has positive slope, trajectories are pulled in by the dissipative vector field. The resulting balance of forces produces a steady-state orbit called a *limit cycle*, which is approached asymptotically by all initial conditions of this circuit.

This limit cycle is said to be *attracting* because nearby trajectories move toward it and it is structurally stable in the sense that, for almost all values of G'_a, a small change in the parameters of the circuit has little effect on it. In the special case when $G'_a \equiv 0$, a perturbation of G'_a causes the steady-state behavior to change from an equilibrium point to a limit cycle; this is called a *bifurcation*.

In the following sections, we consider in detail steady-state behaviors, stability, structural stability, and bifurcations.

14.1.2 Classification and Uniqueness of Steady-State Behaviors

A trajectory of a dynamical system from an initial state $\mathbf{X}_0$ settles, possibly after some transient, onto a set of points called a *limit set*. The **ω**-limit set corresponds to the asymptotic behavior of the system as $t \to +\infty$ and is called the steady-state response. We use the idea of recurrent states to determine when the system has reached steady state.

A state $\mathbf{X}$ of a dynamical system is called recurrent under the flow ϕ if, for every neighborhood $B_\varepsilon(\mathbf{X})$ of $\mathbf{X}$ and for every $T > 0$, there is a time $t > T$ such that $\phi_t(\mathbf{X}) \cap B_\varepsilon(\mathbf{X}) \neq \emptyset$. Thus, a state $\mathbf{X}$ is recurrent if, by waiting long enough, the trajectory through $\mathbf{X}$ repeatedly returns arbitrarily close to $\mathbf{X}$ [7].

Wandering points correspond to transient behavior, while steady-state or asymptotic behavior corresponds to orbits of recurrent states.

A point $\mathbf{X}_\omega$ is an ω-limit point of $\mathbf{X}_0$ if and only if $\lim_{k\to+\infty} \phi_{t_k}(\mathbf{X}_0) = (\mathbf{X}_\omega)$ for some sequence $\{t_k | k \in \mathbb{Z}_+$ such that $t_k \to +\infty$. The set $L(\mathbf{X}_0)$ of ω-limit points of $\mathbf{X}_0$ is called ω-limit set of $\mathbf{X}_0$.*

A limit set L is called attracting if there exists a neighborhood U of L such that $L(\mathbf{X})_0 = L$ for all $\mathbf{X}_0 \in U$. Thus, nearby trajectories converge toward an attracting limit set as $t \to \infty$.

* The set of points to which trajectories converge from $\mathbf{X}_0$ as $t \to -\infty$ is called the α-limit set of $\mathbf{X}_0$. We consider only positive time, therefore, by *limit set*, we mean the ω-limit set.

An attracting set $\mathcal{A}$ that contains at least one orbit that comes arbitrarily close to every point in $\mathcal{A}$ is called an attractor [7].

In an asymptotically stable linear system the limit set is independent of the initial condition and unique so it makes sense to talk of the steady-state behavior. By contrast, a nonlinear system may possess several different limit sets and therefore may exhibit a variety of steady-state behaviors, depending on the initial condition.

The set of all points in the state space that converge to a particular limit set L is called the basin of attraction of L.

Because nonattracting limit sets cannot be observed in physical systems, the asymptotic or steady-state behavior of a real electronic circuit corresponds to motion on an attracting limit set.

14.1.2.1 Equilibrium Point

The simplest steady-state behavior of a dynamical system is an equilibrium point. An equilibrium point or stationary point of Equation 14.3 is a state $\mathbf{X_Q}$ at which the vector field is zero. Thus, $\mathbf{F}(\mathbf{X_Q}) = 0$ and $\phi_t(\mathbf{X_Q}) = \mathbf{X_Q}$; a trajectory starting from an equilibrium point remains indefinitely at that point.

In state space, the limit set consists of a single nonwandering point $\mathbf{X_Q}$. A point is a zero-dimensional object. Thus, an equilibrium point is said to have dimension zero.

In the time domain, an equilibrium point of an equilibrium circuit is simply a dc solution or operating point.

An equilibrium point or fixed point of a discrete-time dynamical system is a point $\mathbf{X_Q}$ that satisfies

$$\mathbf{G}(\mathbf{X_Q}) = \mathbf{X_Q}$$

Example: Nonlinear Parallel *RLC* Circuit

The nonlinear *RLC* circuit shown in Figure 14.2 has just one equilibrium point $(I_{3_Q}, V_{2_Q}) = (0,0)$. When G'_a is positive, a trajectory originating at any point in the state converges to this attracting dc steady-state (as shown in Figure 14.4a). The basin of attraction of the origin is the entire state space.

All trajectories, and not just those that start close to it, converge to the origin, so this equilibrium point is said to be a global attractor.

When $G'_a < 0$, the circuit possesses two steady-state solutions: the equilibrium point at the origin, and the limit cycle Γ. The equilibrium point is unstable in this case. All trajectories, except that which starts at the origin, are attracted to Γ.

14.1.2.2 Periodic Steady-State

A state $\mathbf{X}$ is called periodic if there exists $T > 0$ such that $\phi_T(\mathbf{X}) = \mathbf{X}$. A periodic orbit which is not a stationary point is called a cycle.

A limit cycle Γ is an isolated periodic orbit of a dynamical system (see Figure 14.5b). The limit cycle trajectory visits every point on the simple closed curve Γ with period T. Indeed, $\phi_t(\mathbf{X}) = \phi_{t+T}(\mathbf{X})\ \forall$ $\mathbf{X} \in \Gamma$. Thus, every point on the limit cycle Γ is a nonwandering point.

A limit cycle is said to have dimension one because a small piece of it looks like a one-dimensional object: a line. Then, n components $X_i(t)$ of a limit cycle trajectory $\mathbf{X}(t) = [X_1(t), X_2(t), \ldots, X_n(t)]^T$ in $\mathbb{R}^n$ are periodic time waveforms with period T.

Every periodic signal $X(t)$ may be decomposed into a Fourier series—a weighted sum of sinusoids at integer multiples of a fundamental frequency. Thus, a periodic signal appears in the frequency domain as a set of spikes at integer multiples (harmonics) of the fundamental frequency. The amplitudes of these spikes correspond to the coefficient in the Fourier series expansion of $X(t)$. The Fourier transform is an extension of these ideas to aperiodic signals; one considers the distribution of the signal's power over a continuum of frequencies rather than on a discrete set of harmonics.

The distribution of power in a signal $X(t)$ is most commonly quantified by means of the power density spectrum, often simply called the power spectrum. The simplest estimator of the power spectrum is the periodogram [17] which, given N uniformly spaced samples $X(k/f_s)$, $k = 0, 1, \ldots, N-1$ of $X(t)$, yields $N/2+1$ numbers $P(nf_s/N)$, $n = 0, 1, \ldots, N/2$, where f_s is the sampling frequency.

If one considers the signal $X(t)$ as being composed of sinusoidal components at discrete frequencies, then $P(nf_s/N)$ is an estimate of the power in the component at frequency nf_s/N. By Parseval's theorem, the sum of the power in each of these components equals the mean-squared amplitude of the N samples of $X(t)$ [17].

If $X(t)$ is periodic with period T, then its power will be concentrated in a dc component, a fundamental frequency component $1/T$, and harmonics. In practice, the discrete nature of the sampling process causes power to "leak" between adjacent frequency components; this leakage may be reduced by "windowing" the measured data before calculating the periodogram [17].

Example: Periodic Steady-State Solution

Figure 14.5b depicts a state-space orbit, time waveform, and power spectrum of a periodic steady-state solution of a third-order, autonomous, continuous-time dynamical system.

The orbit in state space is an asymmetric closed curve consisting of four loops. In the time domain, the waveform has four crests per period and a dc offset. In the power spectrum, the dc offset manifests itself as a spike at zero frequency. The period of approximately 270 Hz produces a fundamental component at that frequency. Notice that the fourth harmonic (arising from "four crests per period") has the largest magnitude. This power spectrum is reminiscent of subharmonic mode locking in a forced oscillator.

14.1.2.3 Subharmonic Periodic Steady-State

A subharmonic periodic solution or period-K orbit of a discrete-time dynamical system is a set of K points $\{\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_k\}$ that satisfy

$$\mathbf{X}_2 = \mathbf{G}(\mathbf{X}_1), \quad \mathbf{X}_3 = \mathbf{G}(\mathbf{X}_2) \cdots \mathbf{X}_K = \mathbf{G}(\mathbf{X}_{K-1}), \quad \mathbf{X}_1 = \mathbf{G}(\mathbf{X}_K)$$

More succinctly, we may write $\mathbf{X}_i = \mathbf{G}^{(K)}(\mathbf{X}_i)$, where $\mathbf{G}^{(K)} = \mathbf{G}[\mathbf{G}(\cdots[\mathbf{G}(\cdot)]\cdots)]$ denotes $\mathbf{G}$ applied K times to the argument of the map; this is called the Kth iterate of $\mathbf{G}$.

Subharmonic periodic solutions occur in systems that contain two or more competing frequencies, such as forced oscillators or sampled-data circuits. Subharmonic solutions also arise following period-doubling bifurcations (see Section 14.1.5).

14.1.2.4 Quasiperiodic Steady-State

The next most complicated form of steady-state behavior is called quasiperiodicity. In state space, this corresponds to a *torus* (see Figure 14.5a). Although a small piece of a limit cycle in $\mathbb{R}^3$ looks like a line, a small section of two-torus looks like a plane; a two-torus has dimension two.

A quasiperiodic function is one that may be expressed as a countable sum of periodic functions with incommensurate frequencies, i.e., frequencies that are not rationally related. For example, $X(t) = \sin(t) + \sin(2\pi t)$ is a quasiperiodic signal. In the time domain, a quasiperiodic signal may look like an amplitude-or phase-modulated waveform.

Although the Fourier spectrum of a periodic signal consists of a discrete set of spikes at integer multiples of a fundamental frequency, that of a quasiperiodic solution comprises a discrete set of spikes at incommensurate frequencies, as presented in Figure 14.5a.

In principle, a quasiperiodic signal may be distinguished from a periodic one by determining whether the frequency spikes in the Fourier spectrum are harmonically related. In practice, it is impossible to

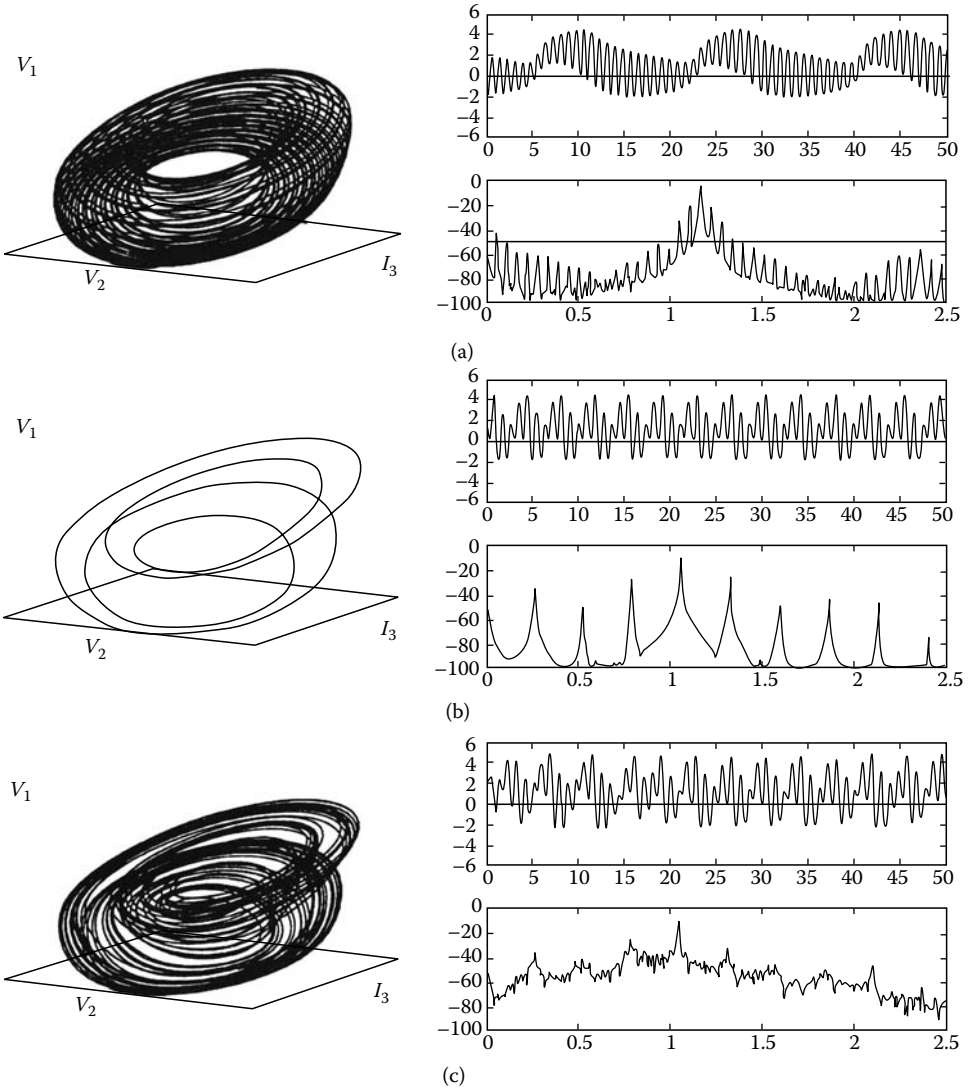

FIGURE 14.5 Quasiperiodicity (torus breakdown) route to chaos in Chua's oscillator. Simulated state-space trajectories, time waveforms $V_1(t)$, and power spectra of $V_2(t)$. (a) Quasiperiodic steady-state—the signal is characterized by a discrete power spectrum with incommensurate frequency components; (b) periodic window—all spikes in the power spectrum are harmonically related to the fundamental frequency; (c) chaotic steady-state following breakdown of the torus—the waveform has a broadband power spectrum. Time plots; horizontal axis—t (ms); vertical axis—V_1 (V). Power spectra: horizontal axis—frequency (kHz); vertical axis—power (mean-squared amplitude) of $V_2(t)$ (dB).

determine whether a measured number is rational or irrational; therefore, any spectrum that appears to be quasiperiodic may simply be periodic with an extremely long period.

A two-torus in a three-dimensional state space looks like a doughnut. Quasiperiodic behavior on a higher dimensional torus is more difficult to visualize in state space but appears in the power spectrum as a set of discrete components at incommensurate frequencies. A K-torus has dimension K.

Quasiperiodic behavior occurs in discrete-time systems where two incommensurate frequencies are present. A periodically forced or discrete-time dynamical system has a frequency associated with

the period of the forcing or sampling interval of the system; if a second frequency is introduced that is not rationally related to the period of the forcing or the sampling interval, then quasiperiodicity may occur.

Example: Discrete Torus

Consider a map from the circle S^1 onto itself. In polar coordinates, a point on the circle is parameterized by an angle $\boldsymbol{\theta}$. Assume that $\boldsymbol{\theta}$ has been normalized so that one complete revolution of the circle corresponds to a change in $\boldsymbol{\theta}$ of 1. The state of this system is determined by the normalized angle $\boldsymbol{\theta}$ and the dynamics by

$$\boldsymbol{\theta}_{k+1} = (\boldsymbol{\theta}_k + \boldsymbol{\Omega}) \bmod 1$$

If $\boldsymbol{\Omega}$ is a rational number (of the form J/K where $J, K \in \mathbb{Z}_+$), then the steady-state solution is a period-**K** (subharmonic) orbit. If $\boldsymbol{\Omega}$ is irrational, we obtain quasiperiodic behavior.

14.1.2.5 Chaotic Steady-State

DC equilibrium periodic as well as quasiperiodic steady-state behaviors have been correctly identified and classified since the pioneering days of electronics in the 1920s. By contrast, the existence of more exotic steady-state behaviors in electronic circuits has been acknowledged only in the past 30 years. Although the notion of chaotic behavior in dynamical systems has existed in the mathematics literature since the turn of the century, unusual behaviors in the physical sciences as recently as the 1960s were described as ''strange.'' Today, we classify as *chaos* the recurrent* motion in a deterministic dynamical system, which is characterized by a positive Lyapunov exponent (LE).

From an experimentalist's point of view, chaos may be defined as bounded steady-state behavior in a deterministic dynamical system that is not an equilibrium point, nor periodic, and not quasiperiodic [15].

Chaos is characterized by repeated stretching and folding of bundles of trajectories in state space. Two trajectories started from almost identical initial conditions diverge and soon become uncorrelated; this is called sensitive dependence on initial conditions and gives rise to long-term unpredictability.

In the time domain, a chaotic trajectory is neither periodic nor quasiperiodic, but looks ''random.'' This ''randomness'' manifests itself in the frequency domain as a broad ''noise-like'' Fourier spectrum, as presented in Figure 14.5c.

Although an equilibrium point, a limit cycle, and a K-torus each have integer dimension, the repeated stretching and folding of trajectories in a chaotic steady-state gives the limit set a more complicated structure that, for three-dimensional continuous-time circuits, is something more than a surface but not quite a volume.

14.1.2.6 Dimension

The structure of a limit set $L \subset \mathbb{R}^n$ of a dynamical system may be quantified using a generalized notion of dimension that considers not just the geometrical structure of the set, but also the time evolution of trajectories on L.

Capacity (D_0 *Dimension*)

The simplest notion of dimension, called capacity (or D_0 dimension), considers a limit set simply as set of points, without reference to the dynamical system that produced it.

* Because a chaotic steady-state does not settle down onto a single well-defined trajectory, the definition of recurrent states must be used to identify posttransient behavior.

To estimate the capacity of L, cover the set with n-dimensional cubes having side length ε. If L is a D_0-dimensional object, then the minimum number $N(\varepsilon)$ of cubes required to cover L is proportional to ε^{-D_0}. Thus, $N(\varepsilon) \propto \varepsilon^{-D_0}$.

The D_0 dimension is given by

$$D_0 = \lim_{\varepsilon \to 0} - \frac{\ln N(\varepsilon)}{\ln \varepsilon}$$

When this definition is applied to a point, a limit cycle (or line), or a two-torus (or surface) $\mathbb{R}^3$, the calculated dimensions are 0, 1, and 2, respectively, as expected. When applied to the set of nonwandering points that comprise a chaotic steady-state, the D_0 dimension is typically noninteger. An object that has noninteger dimension is called a fractal.

Example: The Middle-Third Cantor Set

Consider the set of points that is obtained by repeatedly deleting the middle third of an interval, as indicated in Figure 14.6a. At the first iteration, the unit interval is divided into 2^1 pieces of length 1/3 each; after k iterations, the set is covered by 2^k pieces of length $1/3^k$. By contrast, the set that is obtained by dividing the intervals into thirds but not throwing away the middle third each time (Figure 14.6b) is covered at the kth step by 3^k pieces of length $1/3^k$.

Applying the definition of capacity, the dimension of the unit interval is

$$\lim_{k \to \infty} \frac{k \ln 3}{k \ln 3} = 1.00$$

By contrast, the middle-third Cantor set has dimension

$$\lim_{k \to \infty} \frac{k \ln 2}{k \ln 3} \approx 0.63$$

The set is something more than a zero-dimensional object (a point) but not quite one-dimensional (like a line segment); it is a fractal.

Correlation (D_2) Dimension

The D_2 dimension considers not just the geometry of a limit set, but also the time evolution of trajectories on the set.

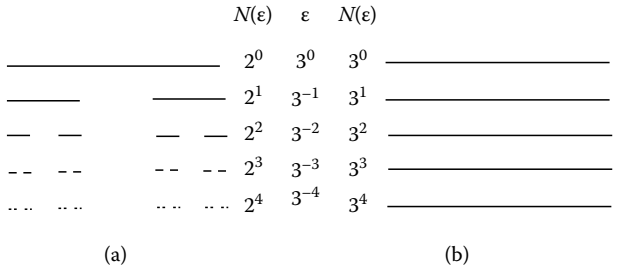

FIGURE 14.6 (a) The Middle-third Cantor set is obtained by recursively removing the central portion of an interval. At the kth step, the set consists of $N(\varepsilon) = 2^k$ pieces of length $\varepsilon = 3^{-k}$. The limit set has capacity 0.63. (b) By contrast, the unit interval is covered by 3^k pieces of length 3^{-k}. The unit interval has dimension 1.00.

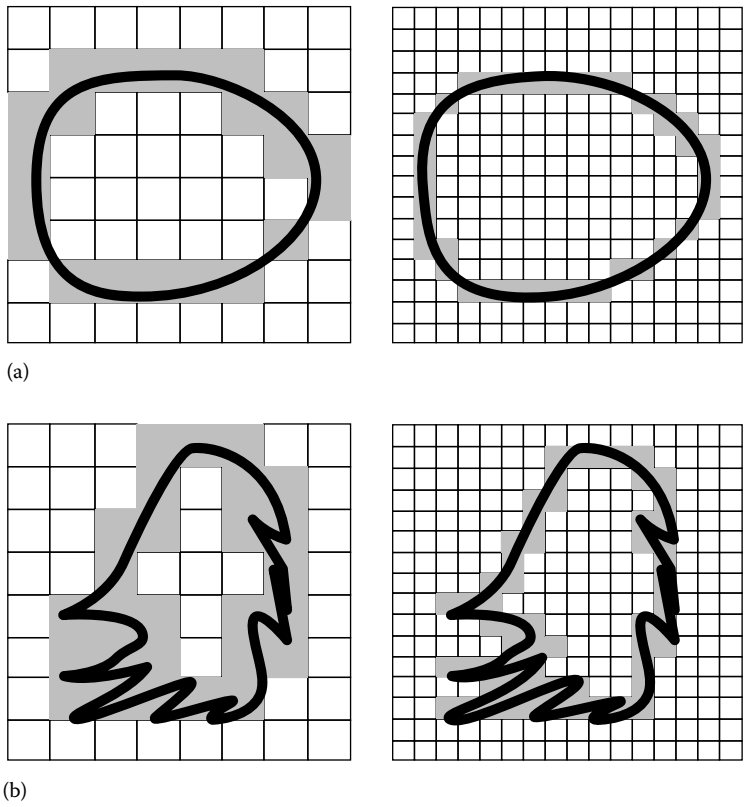

FIGURE 14.7 Coverings of two limit sets L_a (a) and L_b (b) with squares of side length ε_0 and $\varepsilon_0/2$, respectively.

Consider the two limit sets L_a and L_b in $\mathbb{R}^2$ shown in Figure 14.7a and b, respectively. The D_0 dimension of these sets may be determined by iteratively covering them with squares (two-dimensional "cubes") of side length $\varepsilon = \varepsilon_0/2^k$, $k = 0, 1, 2, \ldots$, counting the required number of squares $N(\varepsilon)$ for each ε, and evaluating the limit

$$D_0 = \lim_{k \to \infty} -\frac{\ln N(\varepsilon)}{\ln(\varepsilon)}$$

For the smooth curve L_a, the number of squares required to cover the set grows linearly with $1/\varepsilon$; hence $D_0 = 1.0$. By contrast, if the kinks and folds in set L_b are present at all scales, then the growth of $N(\varepsilon)$ versus $1/\varepsilon$ is superlinear and the object has a noninteger D_0 dimension between 1.0 and 2.0.

Imagine now that L_a and L_b are not simply static geometrical objects but are orbits of discrete-time dynamical systems. In this case, a steady-state trajectory corresponds to a sequence of points moving around the limit set.

Cover the limit set with the minimum number $N(\varepsilon)$ of "cubes" with side length ε, and label the boxes 1, 2, ..., i, ..., $N(\varepsilon)$. Count the number of times $n_i(N, \varepsilon)$ that a typical steady-state trajectory of length N visits box i and define

$$p_i = \lim_{N \to \infty} \frac{n_i(N, \varepsilon)}{N}$$

where p_i is the relative frequency with which a trajectory visits the ith cube. The D_2 dimension is defined as

$$D_2 = \lim_{\varepsilon \to 0} \frac{\ln \sum_{i=1}^{N(\varepsilon)} p_i^2}{\ln \varepsilon}$$

In general, $D_2 \leq D_0$ with equality when a typical trajectory visits all $N(\varepsilon)$ cubes with the same relative frequency $p = 1/N(\varepsilon)$. In this special case,

$$\begin{aligned} D_2 &= \lim_{\varepsilon \to 0} \frac{\ln \sum_{i=1}^{N(\varepsilon)} \frac{1}{N(\varepsilon)^2}}{\ln \varepsilon} \\ &= \lim_{\varepsilon \to 0} -\frac{\ln N(\varepsilon)}{\ln \varepsilon} \\ &= D_0 \end{aligned}$$

An efficient algorithm (developed by Grassberger and Procaccia) for estimating D_2 is based on the approximation $\sum_{i=1}^{N(e)} p_i^2 \approx C(\varepsilon)$ [15], where $C(\varepsilon) = \lim_{N \to 0} \frac{1}{N^2}$ (the number of pairs of points (X_i, X_j) such that $\|X_i - X_j\| < \varepsilon$) is called the correlation. The D_2 or correlation dimension is given by

$$D_2 = \lim_{\varepsilon \to 0} \frac{\ln C(\varepsilon)}{\ln \varepsilon}$$

Example: Correlation (D_2) Dimension

The correlation dimension of the chaotic attractor in Figure 14.5c, estimated using INSITE, is 2.1, while D_2 for the uniformly covered torus in Figure 14.5a is 2.0.

14.1.3 Stability of Steady-State Trajectories

Consider once more the nonlinear *RLC* circuit in Figure 14.2. If G'_a is negative, this circuit settles to a periodic steady-state from almost every initial condition. However, a trajectory started from the origin will, in principle, remain indefinitely at the origin since this is an equilibrium point. The circuit has two possible steady-state solutions. Experimentally, only the limit cycle will be observed. Why?

If trajectories starting from states close to a limit set converge to that steady state, the limit set is called an attracting limit set. If, in addition, the attracting limit set contains at least one trajectory that comes arbitrarily close to every point in the set, then it is an attractor. If nearby points diverge from the limit set, it is called a repellor.

In the nonlinear *RLC* circuit with $G'_a < 0$, the equilibrium point is a repellor and the limit cycle is an attractor.

14.1.3.1 Stability of Equilibrium Points

Qualitatively, an equilibrium point is said to be stable if trajectories starting close to it remain nearby for all future time and unstable otherwise. Stability is a local concept, dealing with trajectories in a small neighborhood of the equilibrium point.

To analyze the behavior of the vector field in the vicinity of an equilibrium point $\mathbf{X_Q}$, we write $\mathbf{X} = \mathbf{X_Q} + \mathbf{x}$ and substitute into Equation 14.3 to obtain

$$\begin{aligned} \dot{\mathbf{X}}_\mathbf{Q} + \dot{\mathbf{x}} &= \mathbf{F}(\mathbf{X}_\mathbf{Q} + \mathbf{x}) \\ \mathbf{F}(\mathbf{X}_\mathbf{Q}) + \dot{\mathbf{x}} &\approx \mathbf{F}(\mathbf{X}_\mathbf{Q}) + \mathbf{D}_\mathbf{x}\mathbf{F}(\mathbf{X}_\mathbf{Q})\mathbf{x} \end{aligned} \tag{14.9}$$

where we have kept just the first two terms of the Taylor series expansion of $\mathbf{F}(\mathbf{X})$ about $\mathbf{X}_\mathbf{Q}$. The Jacobian matrix $\mathbf{D}_\mathbf{x}\mathbf{F}(\mathbf{X})$ is the matrix of partial derivatives of $\mathbf{F}(\mathbf{X})$ with respect to $\mathbf{X}$:

$$\mathbf{D}_\mathbf{x}\mathbf{F}(\mathbf{X}) = \begin{bmatrix} \frac{\partial F_1(\mathbf{X})}{\partial X_1} & \frac{\partial F_1(\mathbf{X})}{\partial X_2} & \cdots & \frac{\partial F_1(\mathbf{X})}{\partial X_n} \\ \frac{\partial F_2(\mathbf{X})}{\partial X_1} & \frac{\partial F_2(\mathbf{X})}{\partial X_2} & \cdots & \frac{\partial F_2(\mathbf{X})}{\partial X_n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial F_n(\mathbf{X})}{\partial X_1} & \frac{\partial F_n(\mathbf{X})}{\partial X_2} & \cdots & \frac{\partial F_n(\mathbf{X})}{\partial X_n} \end{bmatrix}$$

Subtracting $\mathbf{F}(\mathbf{X}_\mathbf{Q})$ from both sides of Equation 14.9 we obtain the linear system

$$\dot{\mathbf{x}} = \mathbf{D}_\mathbf{x}\mathbf{F}(\mathbf{X}_\mathbf{Q})\mathbf{x}$$

where the Jacobian matrix is evaluated at $\mathbf{X}_\mathbf{Q}$. This linearization describes the behavior of the circuit in the vicinity of $\mathbf{X}_\mathbf{Q}$; we call this the local behavior.

Note that the linearization is simply the small-signal equivalent circuit at the operating point $\mathbf{X}_\mathbf{Q}$. In general, the local behavior of a circuit depends explicitly on the operating point $\mathbf{X}_\mathbf{Q}$. For example, a *pn*-junction diode exhibits a small incremental resistance under forward bias, but a large small-signal resistance under reverse bias.

14.1.3.2 Eigenvalues

If $\mathbf{X}_\mathbf{Q}$ is an equilibrium point of Equation 14.3, a complete description of its stability is contained in the eigenvalues of the linearization of Equation 14.3 about $\mathbf{X}_\mathbf{Q}$. These are defined as the roots λ of the characteristic equation

$$\det[\lambda\mathbf{I} - \mathbf{D}_\mathbf{x}\mathbf{F}(\mathbf{X}_\mathbf{Q})] = 0 \tag{14.10}$$

where $\mathbf{I}$ is the identity matrix.

If the real parts of all of the eigenvalues $\mathbf{D}_\mathbf{x}\mathbf{F}(\mathbf{X}_\mathbf{Q})$ are strictly negative, then the equilibrium point $\mathbf{X}_\mathbf{Q}$ is asymptotically stable and is called a sink because all nearby trajectories converge toward it.

If any of the eigenvalues has a positive real part, the equilibrium point is unstable; if all of the eigenvalues have positive real parts, the equilibrium point is called a source. An equilibrium point that has eigenvalues with both negative and positive real parts is called a saddle. A saddle is unstable.

An equilibrium point is said to be hyperbolic if all the eigenvalues of $\mathbf{D}_\mathbf{x}\mathbf{F}(\mathbf{X}_\mathbf{Q})$ have nonzero real parts. All hyperbolic equilibrium points are either unstable or asymptotically stable.

14.1.3.3 Discrete-Time Systems

The stability of a fixed point $\mathbf{X}_\mathbf{Q}$ of a discrete-time dynamical system

$$\mathbf{X}_{k+1} = \mathbf{G}(\mathbf{X}_k)$$

is determined by the eigenvalues of the linearization $\mathbf{D}_\mathbf{X}\mathbf{G}(\mathbf{X}_\mathbf{Q})$ of the vector field $\mathbf{G}$, evaluated at $\mathbf{X}_\mathbf{Q}$.

The equilibrium point is classified as stable if all of the eigenvalues of $\mathbf{D}_\mathbf{X}\mathbf{G}(\mathbf{X}_\mathbf{Q})$ are strictly less than unity in modulus, and unstable if any has modulus greater than unity.

14.1.3.4 Eigenvectors, Eigenspaces, Stable and Unstable Manifolds

Associated with each distinct eigenvalue λ of the Jacobian matrix $\mathbf{D_X F(X_Q)}$ is an eigenvector $\vec{\mathbf{v}}$ defined by

$$\mathbf{D_X F(X_Q)}\vec{v} = \lambda\vec{v}$$

A real eigenvalue γ has a real eigenvector $\vec{\eta}$. Complex eigenvalues of a real matrix occur in pairs of the form $\sigma \pm j\omega$. The real and imaginary parts of the associated eigenvectors $\vec{\eta}_r \pm j\vec{\eta}_c$ span a plane called a complex eigenplane.

The n_s-dimensional subspace of $\mathbb{R}^n$ associated with the stable eigenvalues of the Jacobian matrix is called the stable eigenspace, denoted $E^s(\mathbf{X_Q})$. The n_u-dimensional subspace corresponding to the unstable eigenvalues is called the unstable eigenspace, denoted $E^u(\mathbf{X_Q})$.

The analogs of the stable and unstable eigenspaces for a general nonlinear system are called the local stable and unstable *manifolds** $W^s(\mathbf{X_Q})$ and $W^u(\mathbf{X_Q})$.

The stable manifold $W^s(\mathbf{X_Q})$ is defined as the set of all states from which trajectories remain in the manifold and converge under the flow to $\mathbf{X_Q}$. The unstable manifold $W^u(\mathbf{X_Q})$ is defined as the set of all states from which trajectories remain in the manifold and diverge under the flow from $\mathbf{X_Q}$.

By definition, the stable and unstable manifolds are invariant under the flow (if $\mathbf{X} \in W^s$, then $\phi_t(\mathbf{X}) \in W^s$). Furthermore, the n_s- and n_u-dimensional tangent spaces to W^s and W^u at $\mathbf{X_Q}$ are E^s and E^u (as shown in Figure 14.8). In the special case of a linear or affine vector field **F**, the stable and unstable manifolds are simply the eigenspaces E^s and E^u.

Chaos is associated with two characteristic connections of the stable and unstable manifolds. A homoclinic orbit (see Figure 14.9a) joins an isolated equilibrium point $\mathbf{X_Q}$ to itself along its stable and unstable manifolds. A heteroclinic orbit (Figure 14.9b) joins two distinct equilibrium points, $\mathbf{X_{Q1}}$ and $\mathbf{X_{Q2}}$, along the unstable manifold of one and the stable manifold of the other.

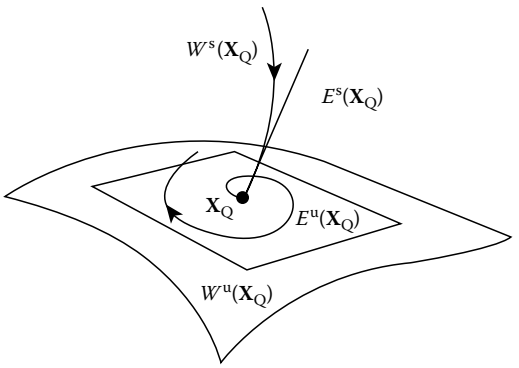

FIGURE 14.8 Stable and unstable manifolds $W^s(\mathbf{X_Q})$ and $W^u(\mathbf{X_Q})$ of an equilibrium point $\mathbf{X_Q}$. The stable and unstable eigenspaces $E^s(\mathbf{X_Q})$ and $E^u(\mathbf{X_Q})$ derived from the linearization of the vector field at $\mathbf{X_Q}$ are tangent to the corresponding manifolds W^s and W^u at $\mathbf{X_Q}$. A trajectory approaching the equilibrium point along the stable manifold is tangential to $E^s(\mathbf{X_Q})$ at $\mathbf{X_Q}$; a trajectory leaving $\mathbf{X_Q}$ along the unstable manifold is tangential to $E^u(\mathbf{X_Q})$ at $\mathbf{X_Q}$.

14.1.3.5 Stability of Limit Cycles

Although the stability of an equilibrium point may be determined by considering the eigenvalues of the linearization of the vector field near the point, how does one study the stability of a limit cycle, torus, or chaotic steady-state trajectory?

The idea introduced by Poincaré is to convert a continuous-time dynamical system into an equivalent discrete-time dynamical system by taking a transverse slice through the flow. Intersections of trajectories with this so-called Poincaré section define a Poincaré map from the section to themselves. Since the limit cycle is a fixed point $\mathbf{X_Q}$ of the associated discrete-time dynamical system, its stability may be determined by examining the eigenvalues of the linearization of the Poincaré map at $\mathbf{X_Q}$.

* An m-dimensional manifold is a geometrical object every small section of which looks like $\mathbb{R}^m$. More precisely, M is an m-dimensional manifold if, for every $x \in M$, there exists an open neighborhood U of x and a smooth invertible map which takes U to some open neighborhood of $\mathbb{R}^m$. For example, a limit cycle of a continuous-time dynamical system is a one-dimensional manifold.

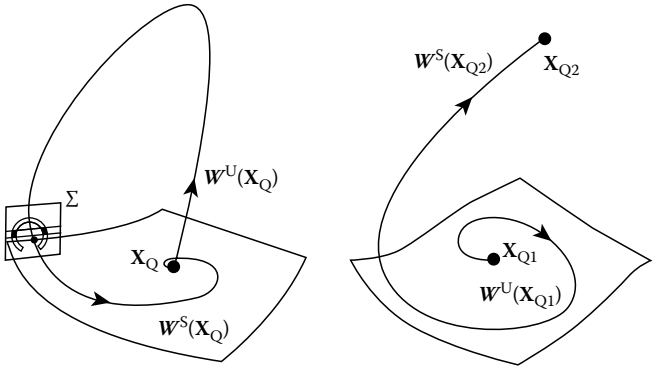

FIGURE 14.9 (a) Homoclinic orbit joins an isolated equilibrium point $\mathbf{X_Q}$ to itself along its stable and unstable manifolds. (b) A heteroclinic orbit joins two distinct equilibrium points, $\mathbf{X_{Q1}}$ and $\mathbf{X_{Q2}}$, along the unstable manifolds of one and the stable manifold of the other.

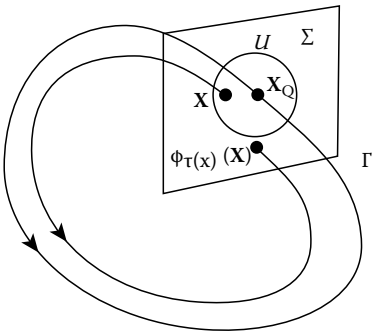

FIGURE 14.10 Transverse Poincaré section Σ through the flow of a dynamical system induces a discrete Poincaré map from a neighborhood U of the point of intersection X_Q to Σ.

14.1.3.6 Poincaré Sections

A Poincaré section of an n-dimensional autonomous continuous-time dynamical system is an $(n-1)$-dimensional hyperplane Σ in the state space that is intersected transversally* by the flow.

Let Γ be a closed orbit of the flow of a smooth vector field $\mathbf{F}$, and let $\mathbf{X_Q}$ be a point of intersection of Γ with Σ. If T is the period of Γ and $\mathbf{X} \in \Sigma$ is sufficiently close to $\mathbf{X_Q}$, then the trajectory $\phi_t(\mathbf{X})$ through $\mathbf{X}$ will return to Σ after a time $\tau(\mathbf{X}) \approx T$ and intersect the hyperplane at a point $\phi_{\tau(\mathbf{X})}(\mathbf{X})$, as illustrated in Figure 14.10.

This construction implicitly defines a function (called a Poincaré map or first return map) $\mathbf{G}$: $U \rightarrow \Sigma$

$$\mathbf{G}(\mathbf{X}) = \phi_{\tau(\mathbf{X})}(\mathbf{X})$$

where U is a small region of Σ close to $\mathbf{X_Q}$. The corresponding discrete-time dynamical system

$$\mathbf{X}_{k+1} = \mathbf{G}(\mathbf{X}_k)$$

has a fixed point at $\mathbf{X_Q}$.

The stability of the limit cycle is determined by the eigenvalues of the linearization $\mathbf{D_X G}(\mathbf{X_Q})$ of $\mathbf{G}$ at $\mathbf{X_Q}$. If all of the eigenvalues of $\mathbf{D_X G}(\mathbf{X_Q})$ have modulus less than unity, the limit cycle is asymptotically stable; if any has modulus greater than unity, the limit cycle is unstable.

Note that the stability of the limit cycle is independent of the position and orientation of the Poincaré plane, provided that the intersection is chosen *transverse* to the flow. For a nonautonomous system with periodic forcing, a natural choice for the hyperplane is at a fixed phase θ_o of the forcing.

* A *transverse* intersection of manifolds in $\mathbb{R}^n$ is an intersection of manifolds such that, from any point in the intersection, all directions in $\mathbb{R}^n$ can be generated by linear combinations of vectors tangent to the manifolds.

(a) (b) (c)

FIGURE 14.11 Experimental Poincaré sections corresponding to a torus breakdown sequence in Chua's oscillator. (a) Torus, (b) period-four orbit, (c) chaotic attractor resulting from torus breakdown. (From Chua, L.O., Wu, C.W., Hung, A., and Zhong, G.-Q., *IEEE Trans. Circuits Syst*., 40, 738, Oct. 1993. With permission.)

In the Poincaré section, a limit cycle looks like a fixed point. A period-K subharmonic of a non-autonomous system with periodic forcing appears as a period-K orbit of the corresponding map (see Figure 14.11b).

The Poincaré section of a quasiperiodic attractor consisting of two incommensurate frequencies looks like a closed curve—a transverse cut through a two-torus (Figure 14.11a).

The Poincaré section of chaotic attractor has fractal structure, as depicted in Figure 14.11c.

14.1.4 Horseshoes and Chaos

Chaotic behavior is characterized by sensitive dependence on initial conditions. This phrase emphasizes the fact that small differences in initial conditions are persistently magnified by the dynamics of the system so that trajectories starting from nearby initial conditions reach totally different states in a finite time.

Trajectories of the nonlinear *RLC* circuit in Figure 14.2 that originate near the equilibrium point are initially stretched apart exponentially by the locally negative resistance in the case $G'_a < 0$. Eventually, however, they are squeezed together onto a limit cycle, so the stretching is not persistent. This is a consequence of the noncrossing property and eventual passivity.

Although perhaps locally active, every physical resistor is eventually passive meaning that, for a large enough voltage across its terminals, it dissipates power. This in turn limits the maximum values of the voltages and currents in the circuit giving a bounded steady-state solution. All physical systems are bounded, so how can small differences be magnified persistently in a real circuit?

14.1.4.1 Chaos in the Sense of Shil'nikov

Consider a flow ϕ in $\mathbb{R}^3$ that has an equilibrium point at the origin with a real eigenvalue $\gamma > 0$ and a pair of complex conjugate eigenvalues $\sigma \pm j\omega$ with $\sigma < 0$ and $\omega \neq 0$. Assume that the flow has a homoclinic orbit Γ through the origin.

One may define a Poincaré map for this system by taking a transverse section through the homoclinic orbit, as illustrated in Figure 14.9a.

THEOREM 14.2 (Shil'nikov)

If $|\sigma/\gamma| < 1$, *the flow* ϕ *can be perturbed to* ϕ' *such that* ϕ' *has a homoclinic orbit* Γ' *near* Γ *and the Poincaré map of* ϕ' *defined in a neighborhood of* Γ' *has a countable number of horseshoes in its discrete dynamics.*

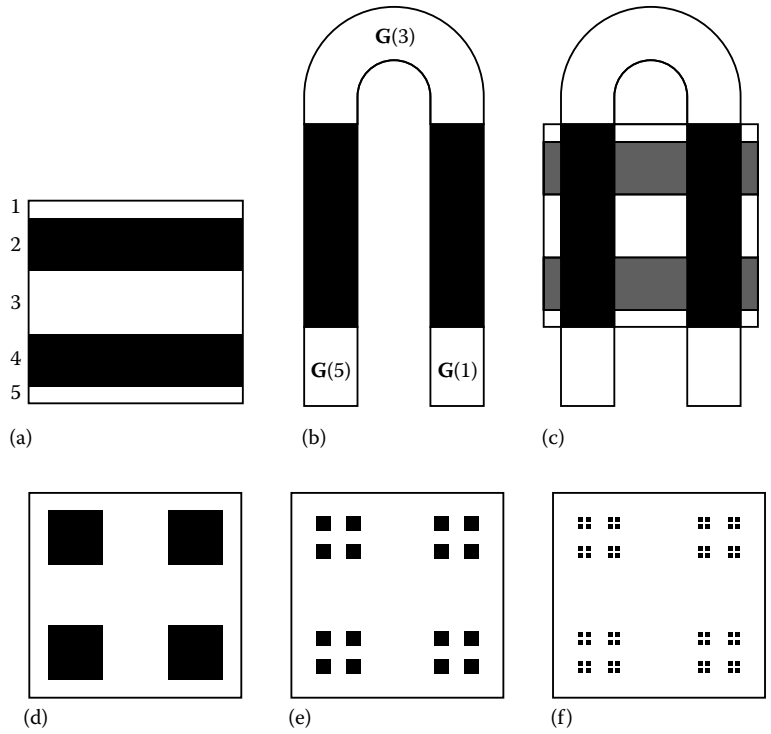

FIGURE 14.12 The Smale horseshoe map stretches the unit square (a), folds it into a horseshoe (b), and lays it back on itself (c), so that only points lying in bands 2 and 4 of (a) are mapped into the square. At the next iteration, only those points in $(\mathbf{G}(2) \cup \mathbf{G}(4)) \cap (2 \cup 4)$ (d) are mapped back to the square. Repeated iterations of the map (d)–(f) remove all points from the square except an invariant (fractal) set of fixed points.

The characteristic horseshoe shape in the Poincaré map stretches and folds trajectories repeatedly (see Figure 14.12). The resulting dynamics exhibit extreme sensitivity to initial conditions [7].

The presence of horseshoes in the flow of a continuous-time system that satisfies the assumptions of Shil'nikov's theorem implies the existence of countable numbers of unstable periodic orbits of arbitrarily long period as well as an uncountable number of complicated bounded nonperiodic chaotic solutions [7].

Horseshoes

The action of the Smale horseshoe map is to take the unit square (Figure 14.12a), stretch it, fold it into a horseshoe shape (Figure 14.12b), and lay it down on itself (Figure 14.12c). Under the action of this map, only four regions of the unit square are returned to the square.

Successive iterations of the horseshoe map return smaller and smaller regions of square to itself, as shown in Figure 14.12d through f. If the map is iterated *ad infinitum*, the unit square is ultimately mapped onto a set of points. These points form an invariant (fractal) limit set L that contains a countable set of periodic orbits of arbitrarily long periods, an uncountable set of bounded nonperiodic orbits, and at least one orbit that comes arbitrarily close to every point in L.

The properties of the map still hold if the horseshoe is distorted by a perturbation of small size but arbitrary shape. Thus, the dynamical behavior of the horseshoe map is structurally stable.*

Although the invariant limit set of a horseshoe map consists of nonwandering points, it is not attracting. Therefore, the existence of a horseshoe in the flow of a third-order system does not imply

* *Structural stability* is discussed in more detail in Section 14.1.5.

that the system will exhibit chaotic steady-state behavior. However if a typical trajectory in the Poincaré map remains in a neighborhood of the invariant set, then the system may exhibit chaos. Thus, although Shil'nikov's theorem is a strong indicator of choas, it does not provide definitive proof that a system is chaotic.

Example: Chaos in a Piecewise-Linear System

Although we have stated it for the case $\sigma < 0$, $\gamma > 0$, Shil'nikov's theorem also applies when the equilibrium point at the origin has an unstable pair of complex conjugate eigenvalues and a stable real eigenvalue. In that case, it is somewhat easier to visualize the stretching and folding of bundles of trajectories close to a homoclinic orbit.

Consider the trajectory in a three-region piecewise-linear vector field in Figure 14.13. We assume that the equilibrium point P_- has a stable real eigenvalue γ_1 (where the eigenvector is $E^r(P_-)$) and an unstable complex conjugate pair of eigenvalues $\sigma_1 \pm j\omega_1$, the real and imaginary parts of whose eigenvectors span the plane $E^c(P_-)$ [2], as illustrated. A trajectory originating from a point $\mathbf{X_0}$ on $E^c(P_-)$ spirals away from the equilibrium point along $E^c(P_-)$ until it enters the D_0 region, where it is folded back into D_{-1}. Upon reentering D_{-1}, the trajectory is pulled toward P_- roughly in the direction of the real eigenvector $E^r(P_-)$, as illustrated.

Now imagine what would happen if the trajectory entering D_{-1} from D_0 were in precisely the direction $E^r(P_-)$. Such a trajectory would follow $E^r(P_-)$ toward P_-, reaching the equilibrium point asymptotically as $t \to \infty$. Similarly, if we were to follow this trajectory backward in time through D_0 and back onto $E^c(P_-)$ in D_{-1}, it would then spiral toward P_-, reaching it asymptotically as $t \to -\infty$. The closed curve thus formed would be a homoclinic orbit, reaching the same equilibrium point P_- asymptotically in forward and reverse time.

Although the homoclinic orbit itself is not structurally stable, and therefore cannot be observed experimentally, horseshoes are structurally stable. A flow ϕ that satisfies the assumptions of Shil'nikov's theorem contains a countable infinity of horseshoes; for sufficiently small perturbations ϕ' of the flow, finitely many of the horseshoes will persist. Thus, both the original flow and the perturbed flow exhibit chaos in the sense of Shil'nikov.

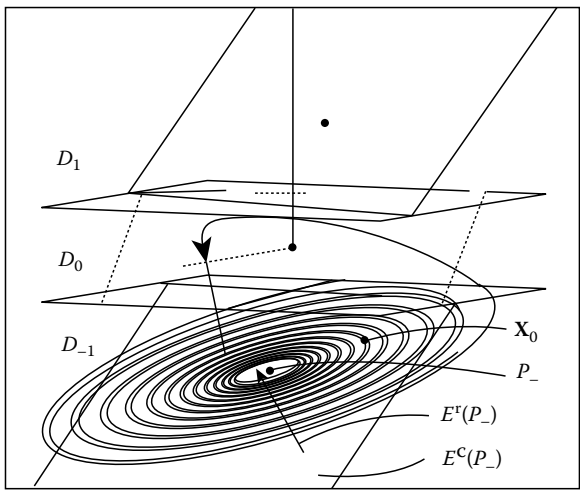

FIGURE 14.13 Stretching and folding mechanism of chaos generation in Chua's circult. A trajectory spirals away from the equilibrium point P_- along the eigenplane $E^c(P_-)$ until it enters the D_0 region, where it is folded back into D_{-1} and returns to the unstable eigenplane $E^c(P_-)$ close to P_-. (From Kennedy, M.P., *IEEE Trans. Circuits Syst. I Fundam. Theory Appl.*, 40, 657, Oct. 1993. With permission.)

In Figure 14.13, we see that a trajectory lying close to a homoclinic orbit exhibits similar qualitative behavior: it spirals away from P_- along the unstable complex plane $E^c(P_-)$, is folded in D_0, reenters D_{-1} above $E^c(P_-)$, and is pulled back toward $E^c(P_-)$, only to be spun away from P_- once more.

Thus, two trajectories starting from distinct initial states close to P_- on $E^c(P_-)$ are stretched apart exponentially along the unstable eigenplane before being folded in D_1 and reinjected close to P_-; this gives rise to sensitive dependence on initial conditions. The recurrent stretching and folding continues *ad infinitum*, producing a chaotic steady-state solution.

14.1.4.2 Lyapunov Exponents

The notion of sensitive dependence on initial conditions may be made more precise through the concept of LEs. LEs quantify the average exponential rates of separation of trajectories along the flow.

The flow in a neighborhood of asympototically stable trajectory is contracting so the LEs are zero or negative.* Sensitive dependence on initial conditions results from a positive LE.

To determine the stability of an equilibrium point, we consider the eigenvalues of the linearization of the vector field in the vicinity of equilibrium trajectory. This idea can be generalized to any trajectory of the flow.

The local behavior of the vector field along a trajectory $\phi_t(\mathbf{X}_0)$ of an autonomous continuous-time dynamical system (Equation 14.3) is governed by the linearized dynamics

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{D}_X\mathbf{F}(\mathbf{X})\mathbf{x}, \quad \mathbf{x}(0) = \mathrm{x}_0 \\ &= \mathbf{D}_X\mathbf{F}[\phi_t(\mathbf{X}_0)]\mathbf{x}\end{aligned}$$

This is a linear time-varying system where the state transition matrix, $\Phi_t(\mathbf{X}_0)$, maps a point $\mathbf{x}_0$ into $\mathbf{x}(t)$. Thus

$$\mathbf{x}(t) = \mathbf{\Phi}_t(\mathbf{X}_0)\mathbf{x}_0$$

Note that Φ_t is a linear operator. Therefore, a ball $B_\varepsilon(\mathbf{X}_0)$ of radius ε about $\mathbf{X}_0$ is mapped into an ellipsoid, as presented in Figure 14.1. The principal axes of the ellipsoid are determined by the singular values of Φ_t.

The singular values $\sigma_1(t), \sigma_2(t), \ldots, \sigma_n(t)$ of Φ_t are defined as the square roots of the eigenvalues of $\mathbf{\Phi}_t^H\mathbf{\Phi}_t$, where $\mathbf{\Phi}_t^H$ is the complex conjugate transpose of Φ_t. The singular values are ordered so that $\sigma_1(t) > \sigma_2(t) > \cdots > \sigma_n(t)$.

In particular, a ball of radius ε is mapped by the linearized flow into an ellipsoid (see Figure 14.1), the maximum and minimum radii of which are bounded by $\sigma_1(t)\varepsilon$ and $\sigma_n(t)\varepsilon$, respectively.

The stability of a steady-state orbit is governed by the average local rates of expansion and contraction of volumes of state space close to the orbit. The LEs λ_i are defined by

$$\lambda_i = \lim_{t\to\infty} \frac{1}{t} \ln \sigma_i(t)$$

whenever this limit exists. The LEs quantify the average exponential rates of separation of trajectories along the flow.

The LEs are a property of a steady-state trajectory. Any transient effect is averaged out by taking the limit as $t \to \infty$. Furthermore, the LEs are global quantities of an attracting set that depend on the local stability properties of a trajectory within the set.

* A continuous flow that has a bounded trajectory not tending to an equlibrium point has a zero LE (in the direction of flow).

The set $\{\lambda_i, i = 1, 2, \ldots, n\}$ is called the Lyapunov spectrum. An attractor has the property that the sum of its LEs is negative.

Lyapunov Exponents of Dicrete-Time Systems

The local behavior along an orbit of the autonomous discrete-time dynamical system (Equation 14.8) is governed by the linearized dynamics

$$\mathbf{x}_{k+1} = \mathbf{D}_x\mathbf{G}(\mathbf{x}_k)\mathbf{x}_k, \quad k = 0, 1, 2, \ldots$$

where the state transition matrix, $\Phi_k(\mathbf{X}_0)$, maps a point $\mathbf{x}_0$ into $\mathbf{x}_k$. Thus,

$$\mathbf{x}_k = \mathbf{\Phi}_k(\mathbf{X}_0)\mathbf{x}_0$$

The LEs λ_i for the discrete-time dynamical system (Equation 14.8) are defined by

$$\lambda_i = \lim_{t\to\infty} \frac{1}{k} \ln \sigma_i(k)$$

whenever this limit exists. $\sigma_i(k)$ denotes the ith singular value of $\Phi_k^H\Phi_k$.

Lyapunov Exponents of Steady-State Solutions

Consider once more the continuous-time dynamical system (Equation 14.3). If $\mathbf{D_xF}$ were constant along the flow, with n distinct eigenvalues $\tilde{\lambda}_i$,

$i = 1, 2, \ldots, n$, then

$$\Phi_t = \begin{pmatrix} \exp(\tilde{\lambda}_1 t) & 0 & \cdots & 0 \\ 0 & \exp(\tilde{\lambda}_2 t) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \exp(\tilde{\lambda} a_n t) \end{pmatrix}$$

and

$$\Phi_t^H\Phi_t = \begin{pmatrix} \exp\big(2\mathrm{Re}(\tilde{\lambda}_1)t\big) & 0 & \cdots & 0 \\ 0 & \exp\big(2\mathrm{Re}(\tilde{\lambda}_2)t\big) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \exp\big(2\mathrm{Re}(\tilde{\lambda}_n)t\big) \end{pmatrix}$$

giving $\sigma_i(t) = \exp(\mathrm{Re}(\tilde{\lambda}_i)t)$ and

$$\begin{aligned} \lambda_i &= \lim_{t\to\infty} \frac{1}{t} \ln\big(\exp\big[\mathrm{Re}(\tilde{\lambda}_i)t\big]\big) \\ &= \mathrm{Re}(\tilde{\lambda}_i) \end{aligned}$$

In this case, the LEs are simply the real parts of the eigenvalues of $\mathbf{D_XF}$.

All the eigenvalues of a stable equilibrium point have negative real parts and therefore the largest LE of an attracting equilibrium point is negative.

Trajectories close to a stable limit cycle converge onto the limit cycle. Therefore, the largest LE of a periodic steady-state is zero (corresponding to motion along the limit cycle [15]), and all its other LEs are negative.

TABLE 14.1 Classification of Steady-State Behaviors according to Their Limit Sets, Power Spectra, LEs, and Dimension

Steady State	Limit Set	Spectrum	LEs	Dimension
DC	Fixed point	Spike at DC	$0 > \lambda_1 \geq \cdots \geq \lambda_n$	0
Periodic	Closed curve	Fundamental plus	$\lambda_1 = 0$	1
		Integer harmonics	$0 > \lambda_2 \geq \cdots \geq \lambda_n$	
Quasiperiodic	K-torus	Incommensurate	$\lambda_1 = \cdots = \lambda_K = 0$	K
		Frequencies	$0 > \lambda_{K+1} \geq \cdots \geq \lambda_n$	
Chaotic	Fractal	Broad spectrum	$\lambda_1 > 0$	Noninteger
			$\sum_{i=1}^{n} \lambda_i < 0$	

A quasiperiodic K-torus has K zero LEs because the flow is locally neither contracting nor expanding along the surface of the K-torus.

A chaotic trajectory is locally unstable and therefore has a positive LE; this produces sensitive dependence on initial conditions. Nevertheless, in the case of a chaotic attractor, this locally unstable chaotic trajectory belongs to an attracting limit set to which nearby trajectories converge.

The steady-state behavior of a four-dimensional continuous-time dynamical system which has two positive, one zero, and one negative LE is called hyperchaos.

The Lyapunov spectrum may be used to identify attractors, as summarized in Table 14.1.

14.1.5 Structural Stability and Bifurcations

Structural stability refers to the sensitivity of a phenomenon to small changes in the parameter of a system. A structurally stable vector field $\mathbf{F}$ is one for which sufficiently close vector fields $\mathbf{F}'$ have equivalent* dynamics [18].

The behavior of a typical circuit depends on a set of parameters one or more of which may be varied in order to optimize some performance criteria. In particular, one may think of a one-parameter family of systems

$$\dot{\mathbf{X}} = \mathbf{F}_\mu(\mathbf{X}) \tag{14.11}$$

where the vector field is parametrized by a control parameter μ. A value μ_0 of Equation 14.11 for which the flow of Equation 14.11 is not structurally stable is a bifurcation value of μ [7].

The dynamics in the state space may be qualitatively very different from one value of μ to another. In the nonlinear *RLC* circuit example, the steady-state solution is a limit cycle if the control parameter G'_a is negative and an equilibrium point if G'_a is positive. If G'_a is identically equal to zero, trajectories starting from $I_{30} = 0$, $V_{20} < E$ yield sinusoidal solutions. These sinusoidal solutions are not structurally stable because the slightest perturbation of G'_a will cause the oscillation to decay to zero or converge to the limit cycle, depending on whether G'_a is made slightly larger or smaller than zero.

If we think of this circuit as being parametrized by G'_a, then its vector field is not structurally stable at $G'_a \equiv 0$. We say that the equilibrium point undergoes a bifurcation (from stability to instability) as the value of the bifurcation parameter G'_a is reduced through the bifurcation point $G'_a = 0$.

* Equivalent means that there exists a continuous invertible function h that transforms $\mathbf{F}$ into $\mathbf{F}'$.

14.1.5.1 Bifurcation Types

In this section, we consider three types of local bifurcation: the Hopf bifurcation, the saddle-node bifurcation, and the period-doubling bifurcation [18]. These bifurcations are called local because they may be understood by linearizing the system close to an equilibrium point or limit cycle.

Hopf Bifurcation

A Hopf bifurcation occurs in a continuous-time dynamical system (Equation 14.3) when a simple pair of complex conjugate eigenvalues of the linearization $\mathbf{D_x F}(\mathbf{X_Q})$ of the vector field at an equilibrium point $\mathbf{X_Q}$ crosses the imaginary axis.

Typically, the equilibrium point changes stability from stable to unstable and a stable limit cycle is born. The bifurcation at $G_a' \equiv 0$ in the nonlinear *RLC* circuit is Hopf-like.*

When an equilibrium point undergoes a Hopf bifurcation, a limit cycle is born. When a limit cycle undergoes a Hopf bifurcation, motion on a two-torus results.

Saddle-Node Bifurcation

A saddle-node bifurcation occurs when a stable and an unstable equilibrium point merge and disappear; this typically manifests itself as the abrupt disappearance of an attractor.

A common example of a saddle-node bifurcation in electronic circuits is switching between equilibrium states in a Schmitt trigger. At the threshold for switching, a stable equilibrium point corresponding to the ''high'' saturated state merges with the high-gain region's unstable saddle-type equilibrium point and disappears. After a switching transient, the trajectory settles to the other stable equilibrium point, which corresponds to the ''low'' state.

A saddle-node bifurcation may also manifest itself as a switch between periodic attractors of different sizes between a periodic attractor and a chaotic attractor, or between a limit cycle at one frequency and a limit cycle at another frequency.

Period-Doubling Bifurcation

A period-doubling bifurcation occurs in a discrete-time dynamical system (Equation 14.8) when a real eigenvalue of the linearization $\mathbf{D_X G}(\mathbf{X_Q})$ of the map $\mathbf{G}$ at an equilibrium point crosses the unit circle at -1 [7].

In a continuous-time system, a period-doubling bifurcation occurs only from a periodic solution (an equilibrium point of the Poincaré map). At the bifurcation point, a periodic orbit with period T changes smoothly into one with period $2T$, as illustrated in Figure 14.14a and b.

Blue Sky Catastrophe

A blue sky catastrophe is a global bifurcation that occurs when an attractor disappears ''into the blue,'' usually because of a collision with a saddle-type limit set. Hysteresis involving a chaotic attractor is often caused by a blue sky catastrophe [18].

14.1.5.2 Routes to Chaos

Each of the three local bifurcations may give rise to a distinct route to chaos, and all three have been reported in electronic circuits. These routes are important because it is often difficult to conclude from experimental data alone whether irregular behavior is due to measurement noise or to underlying chaotic dynamics. If, upon adjusting a control parameter, one of the three prototype routes is observed, this indicates that the dynamics might be chaotic.

---

* Note that the Hopf bifurcation theorem is proven for sufficiently smooth systems and does not strictly apply to piecewise-linear systems. However, a physical implementation of a piecewise-linear characteristic, such as that of N_R, is always smooth.

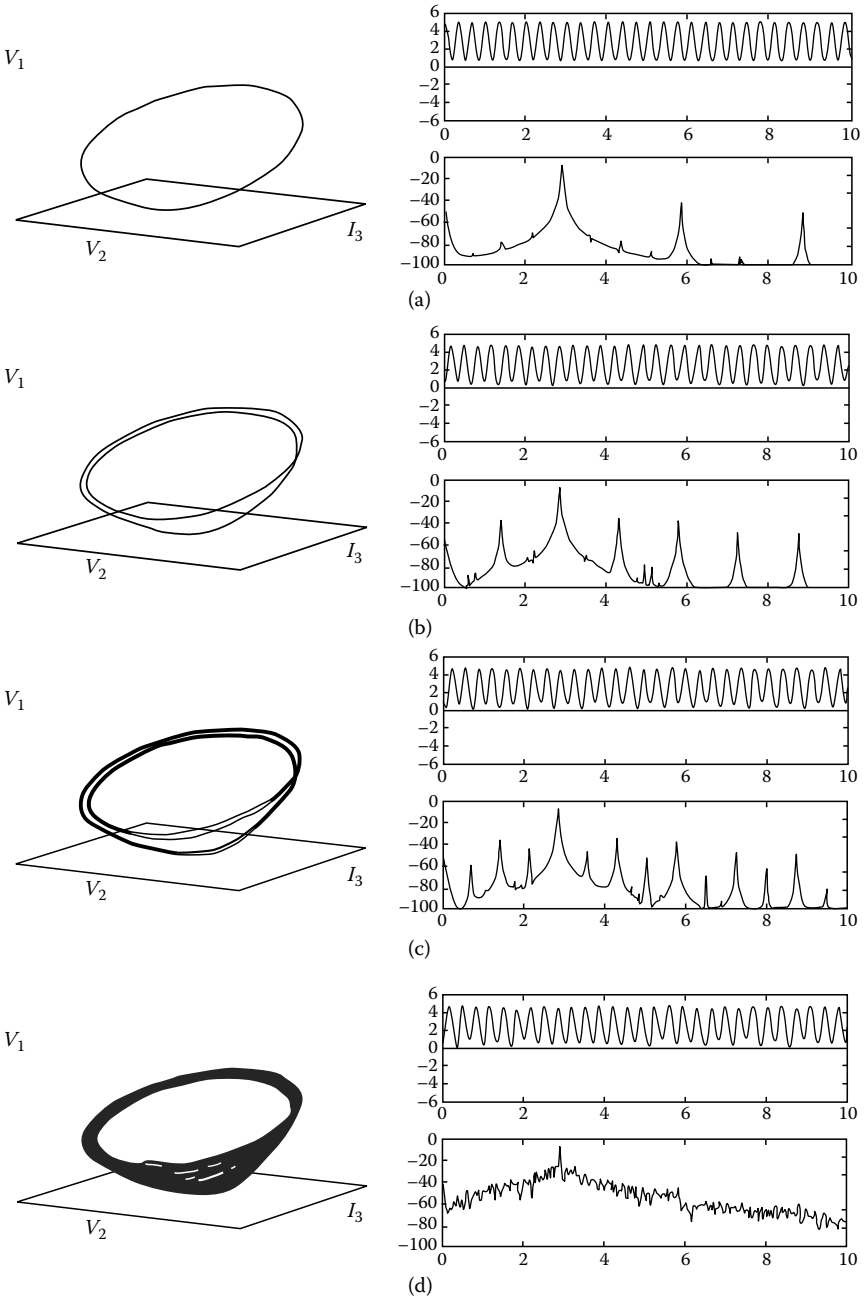

FIGURE 14.14 Period-doubling route to chaos in Chua's oscillator. Simulated state-space trajectories, time waveforms $V_1(t)$, and power spectra of $V_2(t)$ (a) $G = 530$ μS: periodic steady-state—the signal is characterized by a discrete power spectrum with energy at integer multiples of the fundamental frequency f_0; (b) $G = 537$ μS; period-two—after a period-doubling bifurcation, the period of the signal is approximately twice that of (a). In the power spectrum, a spike appears at the new fundamental frequency $\approx f_0/2$. (c) $G = 539$ μS: period-four—a second period-doubling bifurcation gives rise to a fundamental frequency of $\approx f_0/4$; (d) $G = 541$ μS: spiral Chua's attractor—a cascade of period doublings results in a chaotic attractor that has a broadband power spectrum. Time plots: horizontal axis—t (ms); vertical axis—V_1 (V). Power spectra: horizontal axis—frequency (kHz); vertical axis—power (mean-squared amplitude of $V_2(t)$) (dB).

Periodic-Doubling Route to Chaos

The period-doubling route to chaos is characterized by a cascade of period-doubling bifurcations. Each period-doubling transforms a limit cycle into one at half the frequency, spreading the energy of the system over a wider range of frequencies. An infinite cascade of such doublings results in a chaotic trajectory of infinite period and a broad frequency spectrum that contains energy at all frequencies. Figure 14.14 is a set of snapshots of the period-doubling route to chaos in Chua's oscillator.

An infinite number of period-doubling bifurcations to chaos can occur over a finite range of the bifurcation parameter because of a geometric relationship between the intervals over which the control parameter must be moved to cause successive bifurcations. Period-doubling is governed by a universal scaling law that holds in the vicinity of the bifurcation point to chaos μ_∞.

Define the ratio δ_k of successive intervals μ, in each of which there is a constant period of oscillation, as follows,

$$\delta_k = \frac{\mu_{2^k} - \mu_{2^{k-1}}}{\mu_{2^{k+1}} - \mu_{2^k}}$$

where μ_{2^k} is the bifurcation point for the period from $2^k T$ to $2^{k+1}T$. In the limit as $k \to \infty$, a universal constant called the Feigenbaum number δ is obtained:

$$\lim_{k\to\infty} \delta_k = \delta = 4.6692\ldots$$

The period-doubling route to chaos is readily identified from a state-space plot, time series, power spectrum, or a Poincaré map.

Intermittency Route to Chaos

The route to chaos caused by saddle-node bifurcations comes in different forms, the common feature of which is direct transition from regular motion to chaos. The most common type is the intermittency route and results from a single saddle-node bifurcation. This is a route and not just a jump because, straight after the bifurcation, the trajectory is characterized by long intervals of almost regular motion (called laminar phases) and short bursts of irregular motion. The period of the oscillations is approximately equal to that of the system just before the bifurcation. This is illustrated in Figure 14.15.

As the parameter passes through the critical value μ_c at the bifurcation point into the chaotic region, the laminar phases become shorter and the bursts become more frequent, until the regular intervals disappear altogether. The scaling law for the average interval of the laminar phases depends on $|\mu - \mu_c|$, so chaos is not fully developed until some distance from the bifurcation point [13].

Intermittency is best characterized in the time domain because its scaling law depends on the length of the laminar phases.

Another type of bifurcation to chaos associated with saddle-nodes is the direct transition from a regular attractor (fixed point or limit cycle) to a coexisting chaotic one, without the phenomenon of intermittency.

Quasiperiodic (Torus Breakdown) Route to Chaos

The quasiperiodic route to chaos results from a sequence of Hopf bifurcations. Starting from a fixed point, the three-torus generated after three Hopf bifurcations is not stable in the sense that there exists an arbitrarily small perturbation of the system (in terms of parameters) for which the three-torus gives way to chaos.

A quasiperiodic–periodic–chaotic sequence corresponding to torus breakdown in Chua's oscillator is given in Figure 14.5.

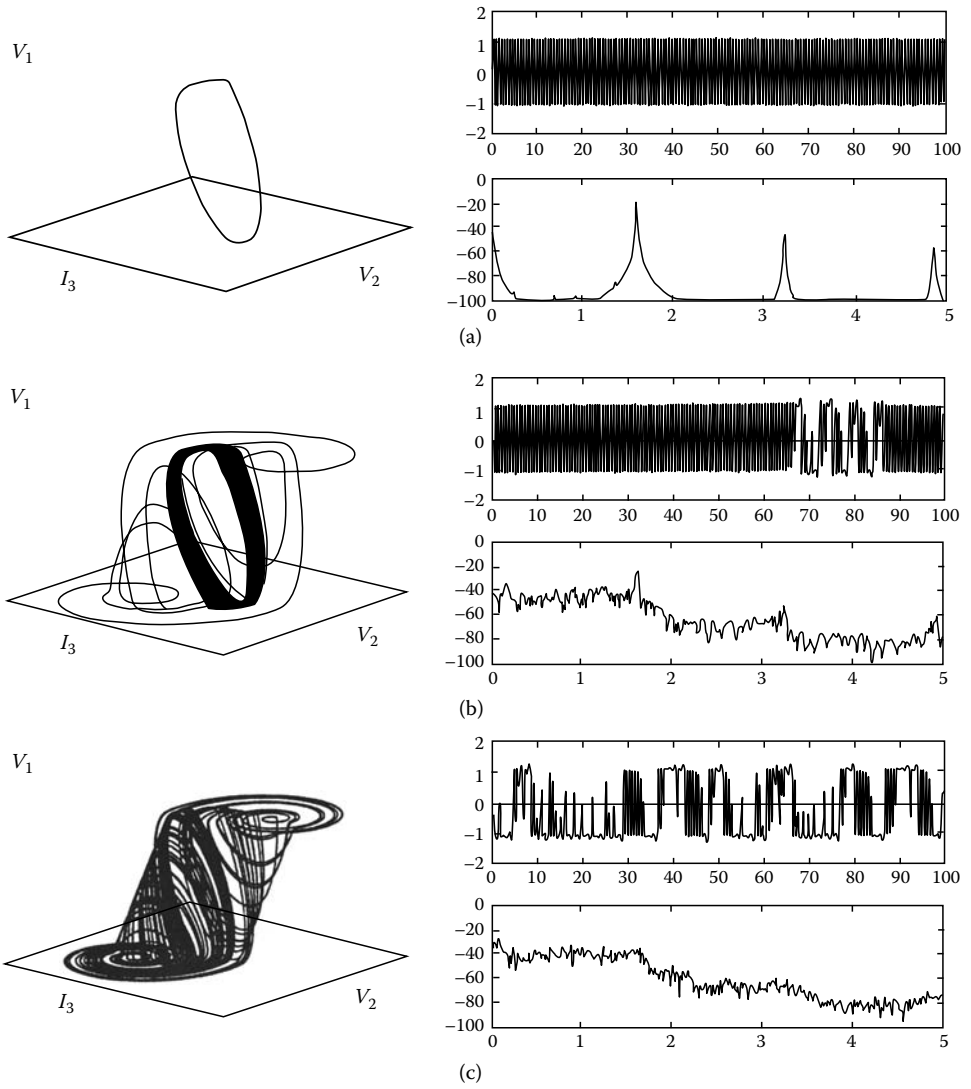

FIGURE 14.15 Intermittency route to chaos in Chua's oscillator. Simulated state-space trajectories, time waveforms $V_1(t)$ and power spectra of $V_2(t)$ (a) Periodic steady-state—the signal is characterized by a discrete power spectrum with energy at integer multiples of the fundamental frequency; (b) onset of intermittency—the time signal contains long regular laminar phases and occasional bursts of irregular motion—in the frequency domain, intermittency manifests itself as a raising of the noise floor; (c) fully developed chaos-laminar phases are infrequent and the power spectrum is broad. Time plots: horizontal axis—t (ms); vertical axis—V_1 (V). Power spectra: horizontal axis—frequency (kHz); vertical axis—power (mean-squared amplitude of $V_2(t)$) (dB).

Quasiperiodicity is difficult to detect from a time series; it is more readily identified by means of a power spectrum or Poincaré map (see Figure 14.11).

14.1.5.3 Bifurcation Diagrams and Parameter Space Diagrams

Although state-space, time- and frequency-domain measurements are useful for characterizing steady-state behaviors, nonlinear dynamics offers several other tools for summarizing qualitative information concerning bifurcations.

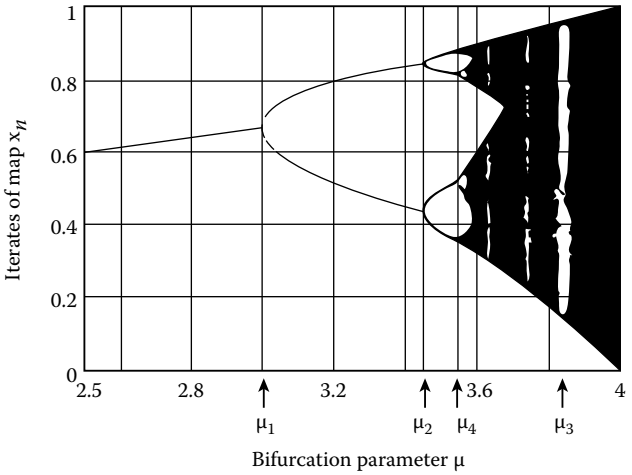

FIGURE 14.16 Bifurcation diagram for the logistic map: $X_{k+1} = \mu X_k(1-X_k)$. The first period-doubling bifurcation occurs at $\mu = \mu_1$, the second at μ_2, and the third at μ_4. μ_3 corresponds to a period-three window. When $\mu = 4$, the entire interval (0, 1) is visited by a chaotic orbit $\{X_k, k = 0, 1, \ldots\}$. (From Wu, C.W. and Rul'kov, N.R., *IEEE Trans. Circuits Syst. I Fundam. Theory Appl.*, 40, 708, Oct. 1993. With permission.)

A bifurcation diagram is a plot of the attracting sets of a system versus a control parameter. Typically, one chooses a state variable and plots this against a single control parameter. In discrete systems, one simply plots successive values of a state variable. In the continuous-time case, some type of discretization is needed, typically by means of a Poincaré section.

Figure 14.16 is a bifurcation diagram of the logistic map $X_{k+1} = \mu X_k(1 - X_k)$ for $\mu \in [2.5, 4]$ and $X_k \in [0, 1]$. Period doubling from period-one to period-two occurs at μ_2; the next two doublings in the period-doubling cascade occur at μ_2 and μ_4, respectively. A periodic window in the chaotic region is indicated by μ_3. The map becomes chaotic by the period-doubling route if μ is increased from μ_3 and by the intermittency route if μ is reduced out of the window.

When more than one control parameter is present in a system, the steady-state behavior may be summarized in a series of bifurcation diagrams, where one parameter is chosen as the control parameter, with the others held fixed, and only changed from one diagram to the next. This provides a complete but cumbersome representation of the dynamics [13].

A clearer picture of the global behavior is obtained by partitioning the parameter space by means of bifurcation curves, and labeling the regions according to the observed steady-state behaviors within these regions. Such a picture is called a parameter space diagram.

14.2 Chua's Circuit: A Paradigm for Chaos

Chaos is characterized by a stretching and folding mechanism; nearby trajectories of a dynamical system are repeatedly pulled apart exponentially and folded back together.

In order to exhibit chaos, as autonomous circuit consisting of resistors, capacitors, and inductors must contain (1) at least one locally active resistor, (2) at least one nonlinear element, and (3) at least three energy-storage elements. The active resistor supplies energy to separate trajectories, the nonlinearity provides folding, and the three-dimensional state space permits persistent stretching and folding in a bounded region without violating the noncrossing property of trajectories.

Chua's circuit (see Figure 14.17) is the simplest electronic circuit that satisfies these criteria. It consists of a linear inductor, a linear resistor, two linear capacitors, and a single nonlinear resistor N_R. The circuit is readily constructed at low cost using standard electronic components and exhibits a rich variety of bifurcations and chaos [10].

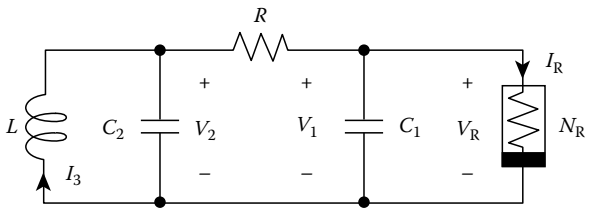

FIGURE 14.17 Chua's circuit consists of a linear inductor L, two linear capacitors (C_2, C_1), a linear resistor R, and a voltage-controlled nonlinear resistor N_R.

14.2.1 Dynamics of Chua's Circuit

14.2.1.1 State Equations

Chua's circuit may be described by three ODEs. Choosing V_1, V_2, and I_3 as state variables, we write

$$\begin{aligned}\frac{dV_1}{dt} &= \frac{G}{C_1}(V_2 - V_1) - \frac{1}{C_1}f(V_1)\\ \frac{dV_2}{dt} &= \frac{G}{C_2}(V_1 - V_2) + \frac{1}{C_2}I_3\\ \frac{dI_3}{dt} &= -\frac{1}{L}V_2\end{aligned} \tag{14.12}$$

where $G = 1/R$ and $f(V_R) = G_b V_R + 1/2(G_a + G_b)\,(|V_R + E| - |V_R - E|)$, as depicted in Figure 14.18.

Because of the piecewise-linear nature of N_R, the vector field of Chua's circuit may be decomposed into three distinct affine regions: $V_1 < -E$, $|V_1| \le E$, and $V_1 > E$. We call these the D_{-1}, D_0, and D_1 regions, respectively. The global dynamics may be determined by considering separately the behavior in each of the three regions (D_{-1}, D_0, and D_1) and then gluing the pieces together along the boundary planes U_{-1} and U_1.

14.2.1.2 Piecewise-Linear Dynamics

In each region, the circuit is governed by a three-dimensional autonomous affine dynamical system of the form

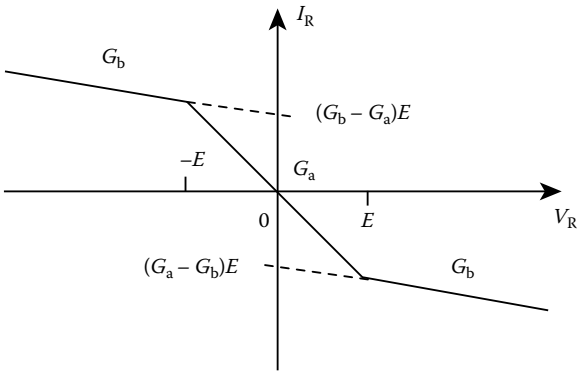

FIGURE 14.18 The DP characteristic of the nonlinear resistor N_R in Chua's circuit has breakpoints at $\pm E$ and slopes G_a and G_b in the inner and outer regions, respectively.

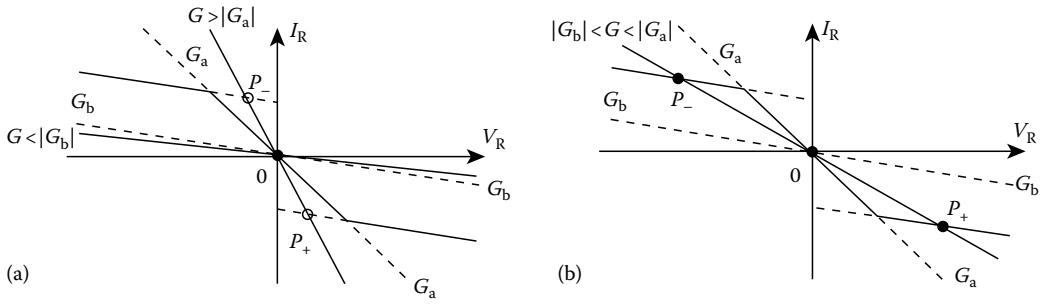

FIGURE 14.19 DC equilibrium points of Figure 14.17 may be determined graphically by intersecting the load line $I_R = -GV_R$ with the DP characteristic of N_R. (a) If $G > |G_a|$ or $G < |g_b|$, the circuit has a unique equilibrium point at the origin (P_- and P_+ are virtual equilibria in this case). (b) When $|G_b| < G < |G_a|$, the circuit has three equilibrium points at P_-, 0 and P_+.

$$\dot{\mathbf{X}} = \mathbf{AX} + \mathbf{b} \tag{14.13}$$

where

A is the (constant) system matrix

b is a constant vector

The equilibrium points of the circuit may be determined graphically by intersecting the load line $I_R = -GV_R$ with the DP characteristic $I_R = f(V_R)$ of the nonlinear resistor N_R, as presented in Figure 14.19 [2]. When $G > |G_a|$ or $G > |G_b|$, the circuit has a unique equilibrium point at the origin (and two virtual equilibria P_- and P_+); otherwise, it has three equilibrium points at P_-, 0, and P_+.

The dynamics close to an equilibrium point $\mathbf{X_Q}$ are governed locally by the linear system

$$\dot{\mathbf{x}} = \mathbf{Ax} \tag{14.14}$$

If the eigenvalues λ_1, λ_2, and λ_3 of **A** are distinct, then every solution $\mathbf{x}(t)$ of Equation 14.14 may be expressed in the form

$$\mathbf{x}(t) = c_1 \exp(\lambda_1 t)\vec{\xi}_1 + c_2 \exp(\lambda_2 t)\vec{\xi}_2 + c_3 \exp(\lambda_3 t)\vec{\xi}_3$$

where

$\vec{\xi}_1$, $\vec{\xi}_2$, and $\vec{\xi}_3$ are the (possibly complex) eigenvectors associated with the eigenvalues λ_1, λ_2, and λ_3, respectively

c_k's are (possibly complex) constants that depend on the initial state $\mathbf{X}_0$

In the special case when **A** has one real eigenvalue γ and a complex conjugate pair of eigenvalues $\sigma \pm j\omega$, the solution of Equation 14.14 has the form

$$\mathbf{x}(t) = c_r \exp(\gamma t)\vec{\xi}_\gamma + 2c_c \exp(\sigma t)[\cos(\omega t + \phi_c)\vec{\eta}_r - \sin(\omega t + \phi_c)\vec{\eta}_i]$$

where

$\vec{\eta}_r$ and $\vec{\eta}_i$ are the real and imaginary parts of the eigenvectors associated with the complex conjugate pair of eigenvalues

$\vec{\xi}_\gamma$ is the eigenvector defined by $\mathbf{A}\vec{\xi}_\gamma = \gamma\ \vec{\xi}_\gamma$

c_r, c_c, and ϕ_c are real constants that are determined by the initial conditions

Let us relabel the real eigenvector E^r, and define E^c as the complex eigenplane spanned by $\vec{\eta}_r$ and $\vec{\eta}_i$.

We can think of the solution $\mathbf{x}(t)$ of Equation 14.14 as being the sum of two distinct components $\mathbf{x}_r(t) \in E^r$ and $\mathbf{x}_c(t) \in E^c$:

$$\mathbf{x}_r(t) = c_r \exp(\gamma t)\vec{\xi}_\gamma$$
$$\mathbf{x}_c(t) = 2c_c \exp(\sigma t)[\cos(\omega t + \phi_c)\vec{\eta}_r - \sin(\omega t + \phi_c)\vec{\eta}_i]$$

The complete solution $\mathbf{X}(t)$ of Equation 14.13 may be found by translating the origin of the linearized coordinate system to the equilibrium point $\mathbf{X_Q}$. Thus,

$$\begin{aligned}\mathbf{X}(t) &= \mathbf{X_Q} + \mathbf{x}(t)\\ &= \mathbf{X_Q} + \mathbf{x}_r(t) + \mathbf{x}_c(t)\end{aligned}$$

We can determine the qualitative behavior of the complete solution $\mathbf{X}(t)$ by considering separately the components $\mathbf{x}_r(t)$ and $\mathbf{x}_c(t)$ along E^r and E^c, respectively.

If $\gamma > 0$, $\mathbf{x}_r(t)$ grows exponentially in the direction of E^r; if $\gamma < 0$ the component $\mathbf{x}_r(t)$ tends asymptotically to zero. When $\sigma > 0$ and $\omega \neq 0$, $\mathbf{x}_c(t)$ spirals away from $\mathbf{X_Q}$ along the complex eigenplane E^c, and if $\sigma < 0$, $\mathbf{x}_c(t)$ spirals toward $\mathbf{X_Q}$ and E^c.

We remark that the vector E^r and plane E^c are invariant under the flow of Equation 14.13: if $\mathbf{X}(0) \in E^r$, then $\mathbf{X}(t) \in E^r$ for all t; if $\mathbf{X}(0) \in E^c$ then $\mathbf{X}(t) \in E^c$ for all t. An important consequence of this is that a trajectory $\mathbf{X}(t)$ cannot cross through the complex eigenspace E^c; suppose $\mathbf{X}(t_0) \in E^c$ at some time t_0, then $\mathbf{X}(t) \in E^c$ for all $t > t_0$.

14.2.2 Chaos in Chua's Circuit

In the following discussion, we consider a fixed set of component values: $L = 18$ mH, $C_2 = 100$ nF, $C_1 = 10$ nF, $G_a = -50/66$ mS $= -757.576$ μS, $G_b = -9/22$ mS $= -409.091$ μS, and $E = 1$ V. When $G = 550$ μS, three equilibrium points occur at P_+, 0, and P_-. The equilibrium point at the origin (0) has one unstable real eigenvalue γ_0 and a stable complex pair $\sigma_0 \pm j\omega_0$. The outer equilibria (P_- and P_+) each have a stable real eigenvalue γ_1 and an unstable complex pair $\sigma_0 \pm j\omega_1$.

14.2.2.1 Dynamics of D_0

A trajectory starting from some initial state $\mathbf{X}_0$ in the D_0 region may be decomposed into its components along the complex eigenplane $E^c(0)$ and along the eigenvector $E^r(0)$. When $\gamma_0 > 0$ and $\sigma_0 < 0$, the component along $E^c(0)$ spirals toward the origin along this plane while the component in the direction $E^r(0)$ grows exponentially. Adding the two components, we see that a trajectory starting slightly above the stable complex eigenplane $E^c(0)$ spirals toward the origin along the $E^c(0)$ direction, all the while being pushing away from $E^c(0)$ along the unstable direction $E^r(0)$. As the (stable) component along $E^c(0)$ shrinks in magnitude, the (unstable) component grows exponentially, and the trajectory follows a helix of exponentially decreasing radius whose axis lies in the direction of $E^r(0)$; this is illustrated in Figure 14.20.

14.2.2.2 Dynamics of D_{-1} and D_1

The eigenvector $E^r(P_+)$ is associated with the stable real eigenvalue γ_1 in the D_1 region. The real and imaginary parts of the complex eigenvectors associated with $\sigma_1 \pm j\omega_1$ define a complex eigenplane $E^c(P_+)$.

A trajectory starting from some initial state $\mathbf{X}_0$ in the D_1 region may be decomposed into its components along the complex eigenplane $E^c(P_+)$ and the eigenvector $E^r(P_+)$. When $\gamma_1 < 0$ and $\sigma_1 > 0$, the component on $E^c(P_+)$ spirals away from P_+ along this plane while the component in the direction of $E^r(0)$ tends asymptotically toward P_+. Adding the two components, we see that a trajectory starting close to the stable real eigenvector $E^r(P_+)$ above the complex eigenplane moves toward $E^c(P_+)$

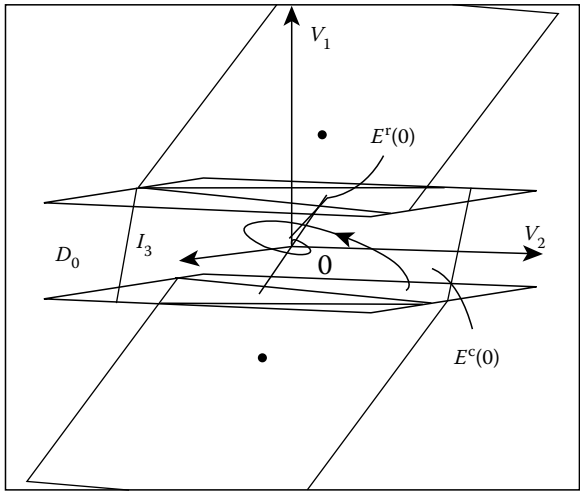

FIGURE 14.20 Dynamics of the D_0 region. A trajectory starting slightly above the stable complex eigenplane $E^c(0)$ spirals toward the origin along this plane and is repelled close to 0 in the direction of the unstabe eigenvector $E^r(0)$. (From Kennedy, M.P., *IEEE Trans. Circuits Syst. I Fundam. Theory Appl.*, 40, 660, Oct. 1993. With permission.)

along a helix of exponentially increasing radius. Because the component along $E^r(P_+)$ shrinks exponentially in magnitude and the component on $E^c(P_+)$ grows exponentially, the trajectory is quickly flattened onto $E^c(P_+)$, where it spirals away from P_+ along the complex eigenplane; this is illustrated in Figure 14.21.

By symmetry, the equilibrium point P_- in the D_{-1} region has three eigenvalues: γ_1 and $\sigma_1 \pm j\omega_1$. The eigenvector $E^r(P_-)$ is associated with the stable real eigenvalue γ_1; the real and imaginary parts of the eigenvectors associated with the unstable complex pair $\sigma_1 \pm j\omega_1$ define an eigenplane $E^c(P_-)$, along which trajectories spiral away from P_-.

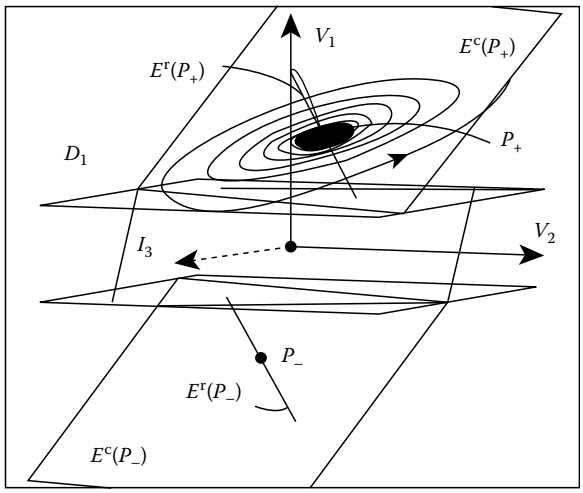

FIGURE 14.21 Dynamics of the D_1 region. A trajectory starting above the unstable complex eigenplane $E^c(P_+)$ close to the eigenvector $E^r(P_+)$ moves toward the plane and spirals away from P_+ along $E^c(P_+)$. By symmetry, the D_{-1} region has equivalent dynamics. (From Kennedy, M.P., *IEEE Trans. Circuits Syst.*, 40, 662, Oct. 1993. With permission.)

14.2.2.3 Global Dynamics

With the given set of parameter values, the equilibrium point at the origin has an unstable real eigenvalue and a stable pair of complex conjugate eigenvalues; the outer equilibrium point P_- has a stable real eigenvalue and an unstable complex pair.

In particular, P_- has a pair of unstable complex conjugate eigenvalues $\sigma_1 \pm \omega_1$ ($\sigma_1 > 0$, $\omega_1 \neq 0$) and a stable real eigenvalue γ_1, where $|\sigma_1| < |\omega_1|$. In order to prove that the circuit is chaotic in the sense of Shil'nikov, it is necessary to show that it possesses a homoclinic orbit for this set of parameter values.

A trajectory starting on the eigenvector $E^r(0)$ close to 0 moves away from the equilibrium point until it crosses the boundary U_1 and enters D_1, as illustrated in Figure 14.20. If this trajectory is folded back into D_0 by the dynamics of the outer region, and reinjected toward 0 along the stable complex eigenplane $E^c(0)$ then a homoclinic orbit is produced.

That Chua's circuit is chaotic in the sense of Shil'nikov was first proven by Chua et al. [21] in 1985. Since then, there has been an intensive effort to understand every aspect of the dynamics of this circuit with a view to developing it as a paradigm for learning, understanding, and teaching about nonlinear dynamics and chaos [3].

14.2.3 Steady-States and Bifurcations in Chua's Circuit

In the following discussion, we consider the global behavior of the circuit using our chosen set of parameters with R in the range $0 \leq R \leq 2000\ \Omega$ ($500\ \mu S \leq G < \infty S$).

Figure 14.14 is a series of simulations of the equivalent circuit in Figure 14.26 with the following parameter values: $L = 18$ mH, $C_2 = 100$ nF, $C_1 = 10$ nF, $G_a = -50/66$ mS $= -757.576$ μS, $G_b = -9/22$ mS $= -409.091$ μS, and $E = 1$ V. $R_0 = 12.5\ \Omega$, the parasitic series resistance of a real inductor. R is the bifurcation parameter.

14.2.3.1 Equilibrium Point and Hopf Bifurcation

When R is large (2000 Ω), the outer equilibrium points P_- and P_+ are stable ($\gamma_1 < 0$ and $\sigma_1 < 0$, $\omega_1 \neq 0$); the inner equilibrium point 0 is unstable ($\gamma_0 > 0$ and $\sigma_0 < 0$, $\omega_0 \neq 0$).

Depending on the initial state of the circuit, the system remains at one outer equilibrium point or the other. Let us assume that we start at P_+ in the D_1 region. This equilibrium point has one negative real eigenvalue and a complex pair with negative real parts. The action of the negative real eigenvalue γ_1 is to squeeze trajectories down onto the complex eigenplane $E^c(P_+)$, where they spiral toward the equilibrium point P_+.

As the resistance R is decreased, the real part of the complex pair of eigenvalues changes sign and becomes positive. Correspondingly, the outer equilibrium points become unstable as σ_1 passes through 0; this is a Hopf-like bifurcation.* The real eigenvalue of P_+ remains negative so trajectories in the D_1 region converge toward the complex eigenplane $E^c(P_+)$. However, they spiral away from the equilibrium point P_+ along $E^c(P_+)$ until they reach the dividing plane U_1 (defined by $V_1 + E$) and enter the D_0 region.

The equilibrium point at the origin in the D_0 region has a stable complex pair of eigenvalues and an unstable real eigenvalue. Trajectories that enter the D_0 region on the complex eigenplane $E^c(0)$ are attracted to the origin along this plane. Trajectories that enter D_0 from D_1 below or above the eigenplane either cross-over to D_{-1} or are turned back toward D_1, respectively. For R sufficiently large, trajectories that spiral away from P_+ along $E^c(P_+)$ and enter D_0 above $E^c(0)$ are returned to D_1, producing a stable period-one limit cycle. This is illustrated in Figure 14.14a.

---

* Recall that the Hopf bifurcation theorem strictly applies only for sufficiently smooth systems, but that physical implementations of piecewise-linear characteristics are typically smooth.

14.2.3.2 Period-Doubling Cascade

As the resistance R is decreased further, a period-doubling bifurcation occurs. The limit cycle now closes on itself after encircling P_+ twice; this is called a period-two cycle because a trajectory takes approximately twice the time to complete this closed orbit as to complete the preceding period-one orbit (see Figure 14.14b).

Decreasing the resistance R still further produces a cascade of period-doubling bifurcations to period-four (Figure 14.14c), period-eight, period-sixteen, and so on until an orbit of infinite period is reached, beyond which we have chaos (see Figure 14.14d). This is a spiral Chua's chaotic attractor.

The spiral Chua's attractor in Figure 14.14d looks like a ribbon or band that is smoothly folded on itself; this folded band is the simplest type of chaotic attractor [18]. A trajectory from an initial condition $\mathbf{X}_0$ winds around the strip repeatedly, returning close to $\mathbf{X}_0$, but never closing on itself.

14.2.3.3 Periodic Windows

Between the chaotic regions in the parameter space of Chua's circuit, there exist ranges of the bifurcation parameter R over which stable periodic motion occurs. These regions of periodicity are called periodic windows and are similar to those that exist in the bifurcation diagram of the logistic map (see Figure 14.16).

Periodic windows of periods three and five are readily found in Chua's circuit. These limit cycles undergo period-doubling bifurcations to chaos as the resistance R is decreased.

For certain sets of parameters, Chua's circuit follows the intermittency route to chaos as R is increased out of the period-three window.

14.2.3.4 Spiral Chua's Attractor

Figure 14.22 outlines three views of another simulated spiral Chua's chaotic attractor. Figure 14.22b is a view along the edge of the outer complex eigenplanes $E^c(P_+)$ and $E^c(P_-)$; notice how trajectories in the D_1 region are compressed toward the complex eigenplane $E^c(P_+)$ along the direction of the stable real eigenvector $E^c(P_+)$ and they spiral away from the equilibrium point P_+ along $E^c(P_+)$.

When a trajectory enters the D_0 region through U_1 from D_1, it is twisted around the unstable real eigenvector $E^r(0)$ and returned to D_1.

Figure 14.22c illustrates clearly that when the trajectory enters D_0 from D_1, it crosses U_1 above the eigenplace $E^c(0)$. The trajectory cannot cross through this eigenplane and therefore it must return to the D_1 region.

14.2.3.5 Double-Scroll Chua's Attractor

Because we chose a nonlinear resistor with a symmetric nonlinearity, every attractor that exists in the D_1 and D_0 regions has a counterpart (mirror image) in the D_{-1} and D_0 regions. As the coupling resistance R is decreased further, the spiral Chua's attractor "collides" with its mirror image and the two merge to form a single compound attractor called a double-scroll Chua's chaotic attractor [10], as presented in Figure 14.23.

Once more, we show three views of this attractor in order to illustrate its geometrical structure. Figure 14.23b is a view of the attractor along the edge of the outer complex eigenplanes $E^c(P_+)$ and $E^c(P_-)$. Upon entering the D_1 region form D_0, the trajectory collapses onto $E^c(P_+)$ and spirals away from P_+ along this plane.

Figure 14.23c is a view of the attractor along the edge of the complex eigenplane $E^c(0)$ in the inner region. Notice once more that when the trajectory crosses U_1 into D_0 above $E^c(0)$, it must remain above $E^c(0)$ and so returns to D_1. Similarly, if the trajectory crosses U_1 below $E^c(0)$, it must remain below $E^c(0)$ and therefore crosses over to the D_{-1} region. Thus, $E^c(0)$ presents a knife-edge to the trajectory as it crosses U_1 into the D_0 region, forcing it back toward D_1 or across D_0 to D_{-1}.

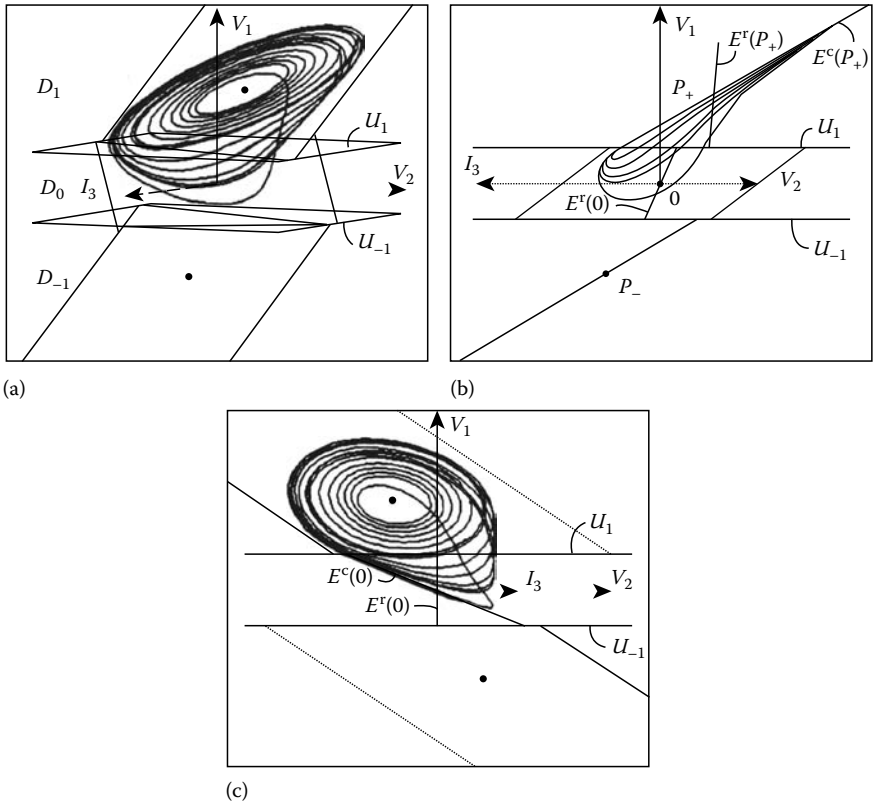

FIGURE 14.22 Three views of a simulated spiral Chua's attractor in Chua's oscillator with $G = 550$ μS. (a) Reference view (compare with Figure 14.14d). (b) View of the edge of the outer complex eigenplanes $E^c(P_+)$ and $E^c(P_-)$; note how trajectory in D_1 is flattened onto $E^c(P_+)$. (c) View along the edge of the complex eigenplane $E^c(0)$; trajectories cannot cross this plane. (From Kennedy, M.P., *IEEE Trans. Circuits Syst. I Fundam. Theory Appl.*, 40, 664, Oct. 1993. With permission.)

14.2.3.6 Boundary Crisis

Reducing the resistance R still further produces more regions of chaos, interspersed with periodic windows. Eventually, for a sufficiently small value of R, the unstable saddle trajectory that normally resides outside the stable steady-state solution collides with the double-scroll Chua's attractor and a blue sky catastrophe called a boundary crisis [10] occurs. After this, all trajectories become unbounded.

14.2.4 Manifestations of Chaos

14.2.4.1 Sensitive Dependence on Initial Conditions

Consider once more the double-scroll Chua's attractor shown in Figure 14.23. Two trajectories starting from distinct but almost identical initial states in D_1 will remain "close together" until they reach the separating plane U_1. Imagine that the trajectories are still "close" at the knife-edge, but that one trajectory crosses into D_0 slightly above $E^c(0)$ and the other slightly below $E^c(0)$. The former trajectory returns to D_1 and the latter crosses over to D_1: their "closeness" is lost.

The time-domain waveforms $V_1(t)$ for two such trajectories are shown in Figure 14.24. These are solutions of Chua's oscillator with the same parameters as in Figure 14.23; the initial conditions are $(I_3, V_2, V_1) = (1.810$ mA, 222.014 mV, -2.286 V) [solid curve] and $(I_3, V_2, V_1) = (1.810$ mA,

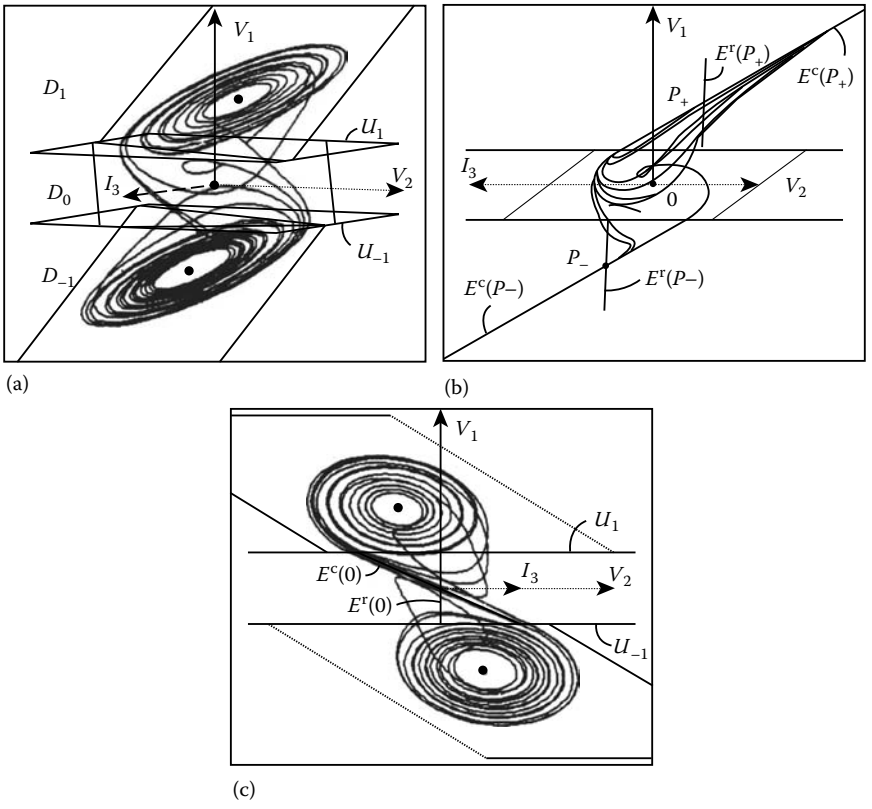

FIGURE 14.23 Three views of a simulated double-scroll Chua's attractor in Chua's oscillator with $G = 565$ μS. (a) Reference view (compare with Figure 14.14d). (b) View along the edge of the outer complex eigenplanes $E^c(P_+)$ and $E^c(P_-)$; note how the trajectory in D_1 is flattened onto $E^c(P_+)$ and onto $E^c(P_-)$ in D_{-1}. (c) View along the edge of the complex eigenplane $E^c(0)$; a trajectory entering D_0 from D_1 above this plane returns to D_1 while one entering D_0 below $E^c(0)$ crosses to D_{-1}. (From Kennedy, M.P., *IEEE Trans. Circuits Syst. I Fundam. Theory Appl.*, 40, 665, Oct. 1993. With permission.)

222.000 mV, −2.286 V) [dashed curve]. Although the initial conditions differ by less than 0.01% in just one component (V_2), the trajectories diverge and become uncorrelated within 5 ms because one crosses the knife-edge before the other.

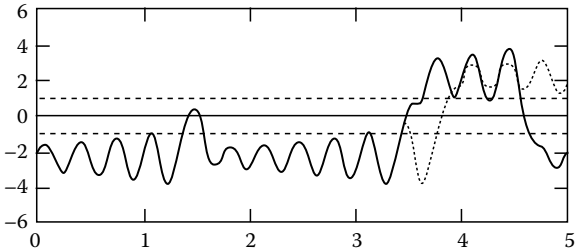

FIGURE 14.24 Sensitive dependence on initial conditions. Two time waveforms $V_1(t)$ from Chua's oscillator with $G = 550$ μS, starting from $(I_3, V_2, V_1) = (1.810$ mA, 222.01 mV, −2.286 V) [solid line] and $(I_3, V_2, V_1) = (1.810$ mA, 222.000 mV, −2.286 V) [dashed line]. Note that the trajectories diverge within 5 ms. Horizontal axis: t (ms); vertical axis: V_1 (V). Compare with Figure 14.23.

This rapid decorrelation of trajectories that originate in nearby initial states, commonly called sensitive dependence on initial conditions, is a generic property of chaotic systems. It gives rise to an apparent randomness in the output of the system and long-term unpredictability of the state.

14.2.4.2 ''Randomness'' in the Time Domian

Figures 14.14a through d show the state-space trajectories of period-one, period-two, and period-four periodic attractors, a spiral Chua's chaotic attractor, respectively, and the corresponding voltage waveforms $V_1(t)$.

The ''period-one'' waveform is periodic; it looks like a slightly distorted sinusoid. The ''period-two'' waveform is also periodic. It differs qualitatively from the ''period-one'' in that the pattern of a large peak followed by a small peak repeats approximately once every two cycles of the period-one signal; that is why it is called period-two.

In contrast with these periodic time waveforms, $V_1(t)$ for the spiral Chua's attractor is quite irregular and does not appear to repeat itself in any observation period of finite length. Although it is produced by a third-order deterministic differential equation, the solution looks ''random.''

14.2.4.3 Broadband ''Noise-Like'' Power Spectrum

In the following discussion, we consider 8192 samples of $V_2(t)$ recorded at 200 kHz; leakage in the power spectrum is controlled by applying a Welch window [17] to the data.

We remarked earlier that the period-one time waveform corresponding to the attractor in Figure 14.14a, is almost sinusoidal; we expect, therefore, that most of its power should be concentrated at the fundamental frequency. The power spectrum of the period-one waveform $V_2(t)$ shown in Figure 14.14a consists of a sharp spike at approximately 3 kHz and higher harmonic components that are over 30 dB below the fundamental.

Because the period-two waveform repeats roughly once every 0.67 ms, this periodic signal has a fundamental frequency component at approximately 1.5 kHz (see Figure 14.14b). Notice, however, that most of the power in the signal is concentrated close to 3 kHz.

The period-four waveform repeats roughly once every 1.34 ms, corresponding to a fundamental frequency component at approximately 750 Hz (see Figure 14.14c). Note once more that most of the power in the signal is still concentrated close to 3 kHz.

The spiral Chua's attractor is qualitatively different from these periodic signals. The aperiodic nature of its time-domain waveforms is reflected in the broadband noise-like power spectrum (Figure 14.14d). No longer is the power of the signal concentrated in a small number of frequency components; rather, it is distributed over a broad range of frequencies. This broadband structure of the power spectrum persists even if the spectral resolution is increased by sampling at a higher frequency f_s. Notice that the spectrum still contains a peak at approximately 3 kHz that corresponds to the average frequency of rotation of the trajectory about the fixed point.

14.2.5 Practical Realization of Chua's Circuit

Chua's circuit can be realized in a variety of ways using standard or custom-made electronic components. All the linear elements (capacitor, resistor, and inductor) are readily available as two-terminal devices. A nonlinear resistor N_R with the prescribed DP characteristic (called a Chua diode [10]) may be implemented by connecting two negative resistance converters in parallel as outlined in Figure 14.25. A complete list of components is given in Table 14.2.

The op-amp subcircuit consisting of A_1, A_2, and R_1–R_6 functions as a negative resistance converter N_R with DP characteristic as shown in Figure 14.28b. Using two 9 V batteries to power the op-amps gives $V^+ = 9$ V and $V^- = -9$ V. From measurements of the saturation levels of the AD712 outputs, $E_{sat} \approx 8.3$ V, giving $E \approx 1$ V. With $R_2 = R_3$ and $R_5 = R_6$, the nonlinear characteristic is defined by $G_a = -1/R_1 - 1/R_4 = -50/66$ mS, $G_b = 1/R_3 - 1/R_4 = -9/22$ mS, and $E = R_1 E_{sat}/(R_1 + R_2) \approx 1$ V [10].

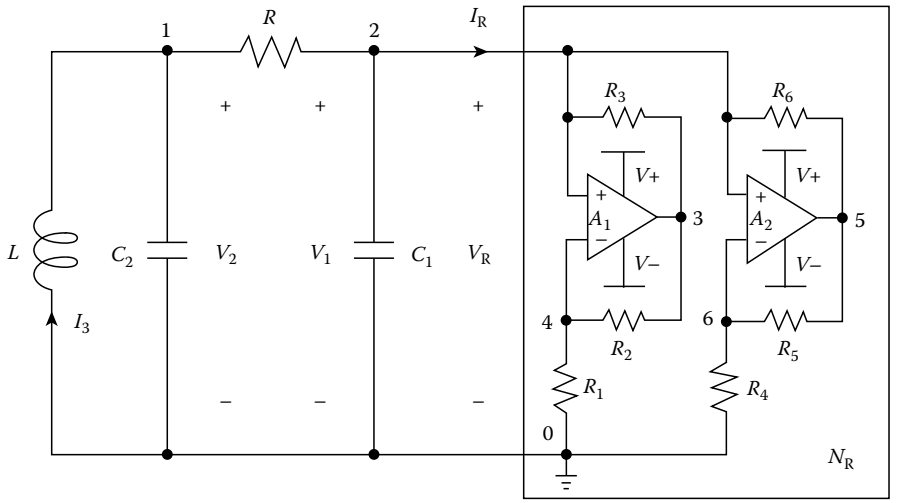

FIGURE 14.25 Practical implementation of Chua's circuit using two op-amps and six resistors to realize the Chua diode. Component values are listed in Table 14.2. (From Kennedy, M.P., *IEEE Trans. Circuits Syst. I Fundam. Theory Appl.*, 40, 640–656, 657–674, Oct. 1993. With permission.)

TABLE 14.2 Component List for the Practical Implementation of Chua's Circuit, Depicted in Figure 14.25

Element	Description	Value	Tolerance (%)
A_1	Op-amp ($\frac{1}{2}$ AD712, TL082, or equivalent)	—	—
A_2	Op-amp ($\frac{1}{2}$ AD712, TL082, or equivalent)	—	—
C_1	Capacitor	10 nF	±5
C_2	Capacitor	100 nF	±5
R	Potentiometer	2 kΩ	—
R_1	$\frac{1}{4}$ W resistor	3.3 kΩ	±5
R_2	$\frac{1}{4}$ W resistor	22 kΩ	±5
R_3	$\frac{1}{4}$ W resistor	22 kΩ	±5
R_4	$\frac{1}{4}$ W resistor	2.2 kΩ	±5
R_5	$\frac{1}{4}$ W resistor	220 Ω	±5
R_6	$\frac{1}{4}$ W resistor	220 Ω	±5
L	Inductor (TOKO-type 10 RB, or equivalent)	118 mH	±10

The equivalent circuit of Figure 14.25 is presented in Figure 14.26, where the real inductor is modeled as a series connection of an ideal linear inductor L and a linear resistor R_0. When the inductor's resistance is modeled explicitly in this way, the circuit is called Chua's oscillator [5].

14.2.6 Experimental Steady-State Solutions

A two-dimensional projection of the steady-state attractor in Chua's circuit may be obtained by connecting V_2 and V_1 to the X and Y channels, respectively, of an oscilloscope in X–Y mode.

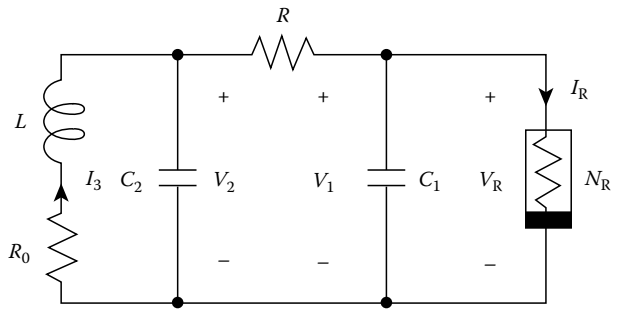

FIGURE 14.26 Chua's oscillator.

14.2.6.1 Bifurcation Sequence with *R* as Control Parameter

By reducing the variable resistor R in Figure 14.25 from 2000 Ω to 0, Chua's circuit exhibits a Hopf bifurcation from dc equilibrium, a sequence of period-doubling bifurcations to a spiral Chua's attractor, periodic windows, a double-scroll Chua's chaotic attractor, and a boundary crisis, as illustrated in Figure 14.27.

Notice that varying R in this way causes the size of the attractors to change: the period-one orbit is large, period-two is smaller, the spiral Chua's attractor is smaller again, and the double-scroll Chua's attractor shrinks considerably before it dies. This shrinking is due to the equilibrium points P_+ and P_- moving closer toward the origin as R is decreased. Consider the load line in Figure 14.19b: as R is decreased, the slope G increases, and the equilibrium points P_- and P_+ move toward the origin. Compare also the positions of P_+ in Figures 14.22a and 14.23a.

14.2.6.2 Outer Limit Cycle

No physical system can have unbounded trajectories. In particular, any physical realization of a Chua diode is eventually passive, meaning simply that for a large enough voltage across its terminals, the instantaneous power $P_R(t)$ $[= V_R(t)I_R(t)]$ consumed by the device is positive.

Hence, the DP characteristic of a real Chua diode must include at least two outer segments with positive slopes which return the characteristic to the first and third quadrants (see Figure 14.28b). From a practical point of view, as long as the voltages and currents on the attractor are restricted to the negative resistance region of the characteristic, these outer segments will not affect the circuit's behavior.

The DP characteristic of the op-amp-based Chua diode differs from the desired piecewise-linear characteristic depicted in Figure 14.28a in that it has five segments, the outer two of which have positive slopes $G_c = 1/R_5 = 1/220$ S.

The "unbounded" trajectories that follow the boundary crisis in the ideal three-region system are limited in amplitude by these dissipative outer segments and a large limit cycle results, as illustrated in Figure 14.27i. This effect could, of course, be simulated by using a five-segment DP characteristic for N_R as illustrated in Figure 14.28b.

The parameter value at which the double-scroll Chua's attractor disappears and the outer limit cycle appears is different from that at which the outer limit cycle disappears and the chaotic attractor reappears. This "hysteresis" in parameter space is the characteristic of a blue sky catastrophe.

14.2.7 Simulation of Chua's Circuit

Our experimental observations and qualitative descriptive description of the global dynamics of Chua's circuit may be confirmed by simulation using a general purpose ODE solver such as MATLAB® [22] or by employing a customized simulator such as "ABC++" [23].

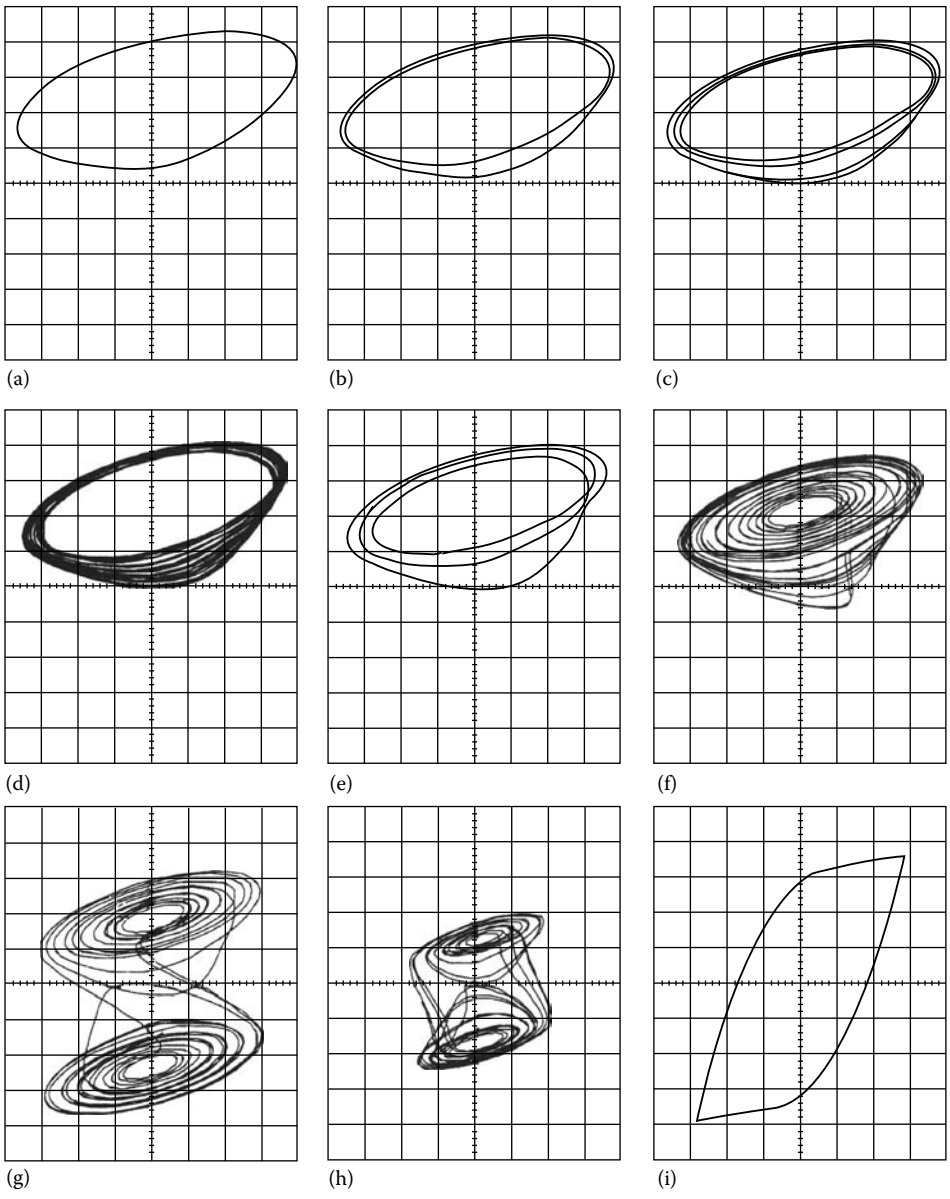

FIGURE 14.27 Typical experimental bifurcation sequence in Chua's circuit (component values as in Table 14.2) recorded using a digital storage oscilloscope. Horizontal axis V_2 (a)–(h) 200 mV/div, (i) 2 V/div; vertical axis V_1 (a)–(h) 1 V/div, (i) 2 V/div. (a) $R = 1.83$ kΩ, period–one; (b) $R = 1.82$ kΩ, period-two; (c) $R = 1.81$ kΩ, period-four; (d) $R = 1.80$ kΩ, spiral Chua's attractor; (e) $R = 1.797$ kΩ, period-three window; (f) $R = 1.76$ kΩ, spiral Chua's attractor; (g) $R = 1.73$ kΩ, double-scroll Chua's attractor; (h) $R = 1.52$ kΩ, double-scroll Chua's attractor; (i) $R = 1.42$ kΩ, large limit cycle corresponding to the outer segments of the Chua diode's DP characteristic. (From Kennedy, M.P., *IEEE Trans. Circuits Syst. I Fundam. Theory Appl.*, 40, 669, Oct. 1993. With permission.)

For electrical engineers who are familiar with the SPICE circuit simulator but perhaps not with chaos, we present a net-list and simulation results for a robust op-amp-based implementation of Chua's circuit. The AD712 op-amps in this realization of the circuit are modeled using Analog Devices' AD712 macromodel. The TOKO 10RB inductor has a nonzero series resistance that we have included in the

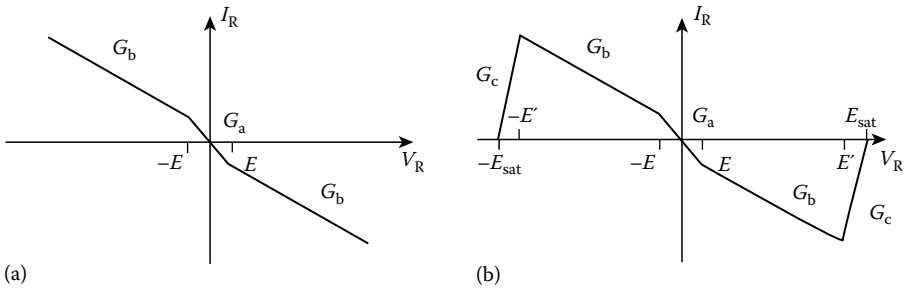

FIGURE 14.28 (a) Required three-segment piecewise-linear DP characteristic for the Chua diode in Figure 14.17. (b) Every physically realizable nonlinear resistor N_R is eventually passive—the outermost segments (while not necessarily linear as presented here) must lie completely within the first and third quadrants of the $V_R - I_R$ place for sufficiently large $|V_R|$ and $|I_R|$.

SPICE net-list; a typical value of RO for this inductor is 12.5 Ω. Node numbers are as Figure 14.25: the power rails are 111 and 222; 10 is the ''internal'' node of the physical inductor, where its series inductance is connected to its series resistance.

A double-scroll Chua's attractor results from a PSPICE simulation using the input deck shown in Figure 14.29; this attractor is plotted in Figure 14.30.

14.2.8 Dimensionless Coordinates and the α–β Parameter-Space Diagram

Thus far, we have discussed Chua's circuit equations in terms of seven parameters: L, C_2, G, C_1, E, G_a, and G_b. We can reduce the number of parameters by normalizing the nonlinear resistor such that its breakpoints are at ± 1 V instead of $\pm E$ V. Furthermore, we may write Chua's circuit Equation 14.12 in normalized dimensionless form by making the following change of variables: $X_1 = V_1/E$, $X_2 = V_2/E$, $X_3 = I_3/(EG)$, and $\tau = tG/C_2$. The resulting state equations are

$$\begin{aligned} \frac{dX_1}{d\tau} &= \alpha[X_2 - X_1 - f(X_1)] \\ \frac{dX_2}{d\tau} &= X_1 - X_2 + X_3 \\ \frac{dX_3}{d\tau} &= -\beta X_2 \end{aligned} \tag{14.15}$$

where $\alpha = C_2/C_1$, $\beta = C_2/(LG^2)$, and $f(X) = bX + 1/2(a-b)(|X+1| - |X-1|)$; $a = G_a/G$ and $b = G_b/G$. Thus, each set of seven circuit parameters has an equivalent set of four normalized dimensionless parameters $\{\alpha, \beta, a, b\}$. If we fix the values of a and b (which correspond to the slopes G_a and G_b of the Chua diode), we can summarize the steady-state dynamical behavior of Chua's circuit by means of a two-dimensional parameter-space diagram.

Figure 14.31 presents the (α, β) parameter-space diagram with $a = -8/7$ and $b = -5/7$. In this diagram, each region denotes a particular type of steady-state behavior: for example, an equilibrium point, period-one orbit, period-two, spiral Chua's attractor, double-scroll Chua's attractor. Typical state-space behaviors are shown in the insets. For clarity, we show chaotic regions in a single shade; it should be noted that these chaotic regions are further partitioned by periodic windows and ''islands'' of periodic behavior.

To interpret the α–β diagram, imagine fixing the value of $\beta = C_2/(LG_2)$ and increasing $\alpha = C_2/C_1$ from a positive value to the left of the curve labeled ''Hopf at $P^{\pm}$''; experimentally, this corresponds to fixing the parameters L, C_2, G, E, G_a, and G_b, and reducing the value of C_1—this is called a ''C_1 bifurcation sequence.''

FIGURE 14.29 SPICE deck to simulate the transient response of the dual op-amp implementation of Chua's circuit. Node numbers are as in Figure 14.25. The op-amps are modeled using the Analog Devices AD712 macromodel. R0 models the series resistance of the real inductor L.

Initially, the steady-state solution is an equilibrium point. As the value of C_1 is reduced, the circuit undergoes a Hopf bifurcation when α crosses the "Hopf at $P^{\pm}$" curve. Decreasing C_1 still further, the steady-state behavior bifurcates from period-one to period-two to period-four and so on to chaos, periodic windows, and a double-scroll Chua's attractor. The right-hand side edge of the chaotic region is delimited by a curve corresponding to the boundary crisis and "death" of the attractor.

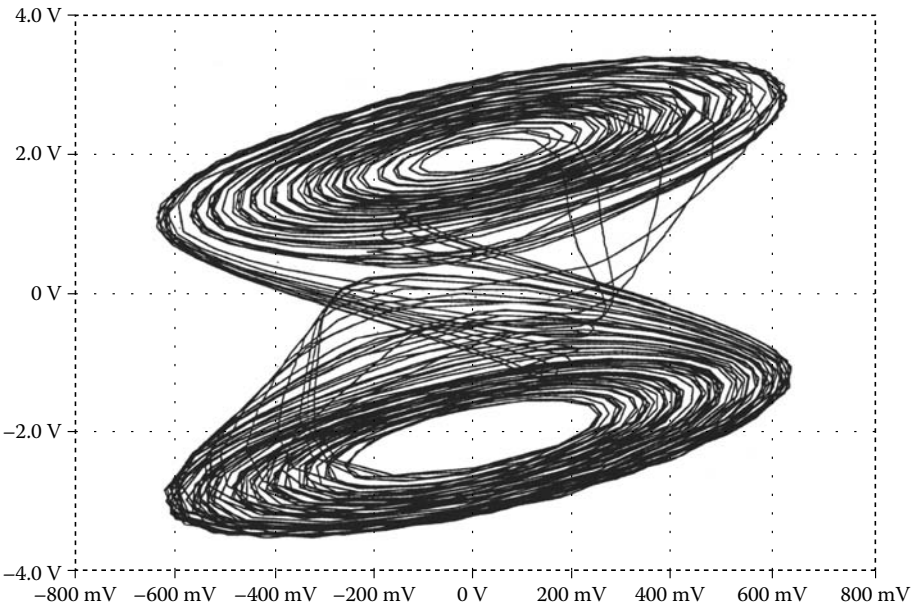

FIGURE 14.30 PSPICE (evaluation version 5.4, July 1993) simulation of Figure 14.25 using the input deck from Figure 14.29 yields this double-scroll Chua's attractor. Horizontal axis V_2 (V) and vertical axis V_1 (V).

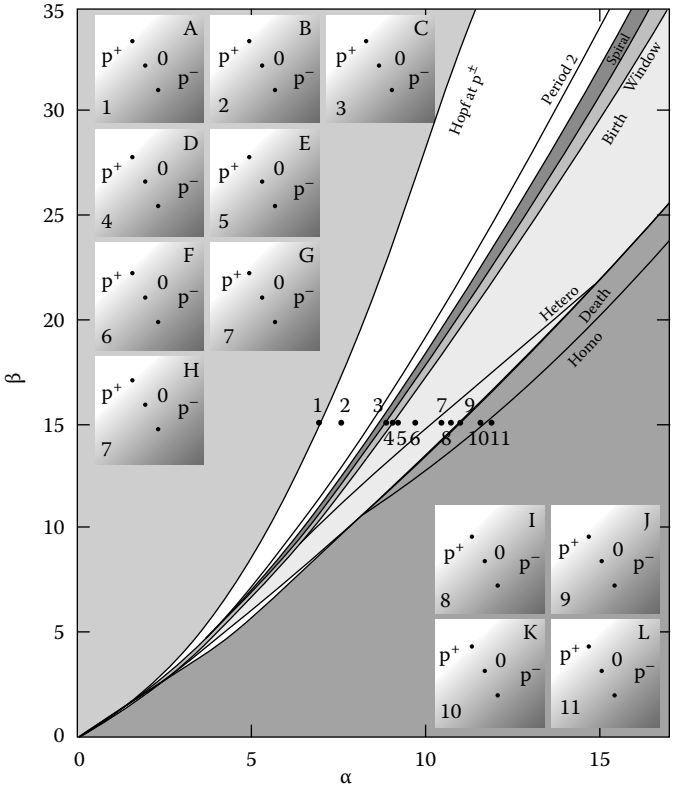

FIGURE 14.31 α–β parameter space diagram for the normalized dimensionless Chua's circuit Equation 14.31 with $a = -8/7$ and $b = -5/7$. (From Kennedy, M.P., *IEEE Trans. Circuits Syst. I Fundam. Theory Appl.*, 40, 673, Oct. 1993. With permission.)

Beyond this curve, trajectories diverge toward infinity. Because of eventual passivity in a real circuit, these divergent trajectories will of course converge to a limit cycle in any physical implementation of Chua's circuit.

14.3 Chua's Oscillator

Chua's oscillator [5] (see Figure 14.26) is derived from Chua's circuit by adding a resistor R_0 in series with the inductor L. The oscillator contains a linear inductor, two linear resistors, two linear capacitors, and a single Chua diode N_R. N_R is a voltage-controlled piecewise-linear resistor whose continuous odd-symmetric three-segment DP characteristic (see Figure 14.18) is described explicitly by the relationship

$$I_R = G_b V_R + \frac{1}{2}(G_a - G_b)(|V_R + E| - |V_R - E|)$$

The primary motivation for studying this circuit is that the vector field of Chua's oscillator is topologically conjugate to the vector field of a large class of three-dimensional, piecewise-linear vector fields. In particular, the oscillator can exhibit every dynamical behavior known to be possible in an autonomous three-dimensional, continuous-time dynamical system described by a continuous odd-symmetric three-region piecewise-linear vector field. With appropriate choices of component values, the circuit follows the period-doubling, intermittency, and quasiperiodic routes to chaos.

14.3.1 State Equations

Choosing V_1, V_2, V, and I_3 as state variables, Chua's oscillator may be described by three ODEs:

$$\frac{dV_1}{dt} = \frac{G}{C_1}(V_2 - V_1) - \frac{1}{C_1}f(V_1)$$
$$\frac{dV_2}{dt} = \frac{G}{C_2}(V_1 - V_2) + \frac{1}{C_2}I_3$$
$$\frac{dI_3}{dt} = -\frac{1}{L}V_2 - \frac{R_0}{L}I_3$$

where

$G = 1/R$

$f(V_R) = G_b V_R + 1/2\ (G_a - G_b)\ (|V_R + E| - |V_R - E|)$

The vector field is parameterized by eight constants: L, C_2, G, C_1, R_0, E, G_a, and G_b. We can reduce the number of parameters by normalizing the nonlinear resistor such that its breakpoints are at ± 1 V instead of $\pm EV$, scaling the state variables, and scaling time.

By making the following change of variables: $X_1 = V_1/E$, $X_2 = V_2/E$, $X_3 = I_3/(EG)$, $\tau = t|G/C_2|$, and $k = \text{sgn}(G/C_2)$,* we can rewrite the state Equations 14.16 in normalized dimensionless form:

$$\frac{dX_1}{d\tau} = k\alpha[X_2 - X_1 - f(X_1)]$$
$$\frac{dX_2}{d\tau} = k(X_1 - X_2 + X_3)$$
$$\frac{dX_3}{d\tau} = -k(\beta X_2 + \gamma X_3)$$

* The signum function is defined by $\text{sgn}(x) = x$ if $x > 0$, $\text{sgn}(x) = -x$ if $x < 0$, and $\text{sgn}(0) = 0$.

where $\alpha = C_2/C_1$, $\beta = C_2/(LG^2)$, $\gamma = R_0C_2/(LG)$, and $f(x) = bX + 1/2(a-b)(|X+1| - |X-1|)$ with $a = G_a/G$ and $b = G_b/G$. Thus, each set of eight circuit parameters has an equivalent set of six normalized dimensionless parameters $\{\alpha, \beta, \gamma, a, b, k\}$.

14.3.2 Topological Conjugacy

Two vector fields **F** and **F′** are topologically conjugate if there exists a continuous map h (which has a continuous inverse) such that h maps trajectories of **F** into trajectories of **F′**, preserving time orientation and parametrization of time. If ϕ_t and ϕ'_t are the flows of **F** and **F′**, respectively, then $\phi_t \circ h = h \circ \phi'_t$ for all t. This means that the dynamics of **F** and **F′** are qualitatively the same. If h is linear, then **F** and **F′** are said to be linearly conjugate.

14.3.2.1 Class $\mathscr{C}$

The three-dimensional, autonomous, continuous-time dynamical system defined by the state equation

$$\dot{\mathbf{X}} = \mathbf{F}(\mathbf{X}),\ \mathbf{X} \in \mathbb{R}^3$$

is said to belong to class $\mathscr{C}$ iff

1. $\mathbf{F}$: $\mathbb{R}^3 \to \mathbb{R}^3$ is continuous
2. $\mathbf{F}$ is odd-symmetric, i.e., $\mathbf{F}(-X) = -\mathbf{F}(X)$
3. $\mathbb{R}^3$ is partitioned by two parallel boundary planes U_1 and U_{-1} into an inner region D_0, which contains the origin, and two outer regions D_1 and D_{-1}, and $\mathbf{F}$ is affine in each region.

Without loss of generality, the boundary planes and the regions they separate can be chosen as follows:

$$\begin{aligned} D_{-1} &= \{\mathbf{X}: \mathbf{X}_1 \le -1\} \\ U_{-1} &= \{\mathbf{X}: \mathbf{X}_1 = -1\} \\ D_0 &= \{\mathbf{X}: |\mathbf{X}_1| \le 1\} \\ U_1 &= \{\mathbf{X}: \mathbf{X}_1 = 1\} \\ D_1 &= \{\mathbf{X}: \mathbf{X}_1 \ge 1\} \end{aligned}$$

Any vector field in the family $\mathscr{C}$ can then be written in the form

$$\dot{\mathbf{X}} = \begin{cases} \mathbf{A}_{-1}\mathbf{X} - \mathbf{b} & \mathbf{X}_1 \le -1 \\ \mathbf{A}_0\mathbf{X} & -1 \le \mathbf{X}_1 \le 1 \\ \mathbf{A}_1\mathbf{X} + \mathbf{b} & \mathbf{X}_1 \ge 1 \end{cases}$$

where

$$\mathbf{A}_{-1} = \mathbf{A}_1 = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix} \quad \text{and} \quad \mathbf{b} = \begin{bmatrix} b_1 \\ b_2 \\ b_3 \end{bmatrix}$$

By continuity of the vector field across the boundary planes,

$$\mathbf{A}_0 = \begin{bmatrix} (a_{11} + b_1) & a_{12} & a_{13} \\ (a_{21} + b_2) & a_{22} & a_{23} \\ (a_{31} + b_3) & a_{32} & a_{33} \end{bmatrix}$$

14.3.2.2 Equivalent Eigenvalue Parameters

Let (μ_1, μ_2, μ_3) denote the eigenvalues associated with the linear vector field in the D_0 region and let (ν_1, ν_2, ν_3) denote the eigenvalues associated with the affine vector fields in the outer regions D_1 and D_{-1}. Define

$$\left.\begin{aligned} p_1 &= \mu_1 + \mu_2 + \mu_3 \\ p_2 &= \mu_1\mu_2 + \mu_2\mu_3 + \mu_3\mu_1 \\ p_3 &= \mu_1\mu_2\mu_3 \\ \\ q_1 &= \nu_1 + \nu_2 + \nu_3 \\ q_2 &= \nu_1\nu_2 + \nu_2\nu_3 + \nu_3\nu_1 \\ q_3 &= \nu_1\nu_2\nu_3 \end{aligned}\right\} \tag{14.16}$$

Because the six parameters $\{p_1, p_2, p_3, q_1, q_2, q_3\}$ are uniquely determined by the eigenvalues $\{\mu_1, \mu_2, \mu_3, \nu_1, \nu_2, \nu_3\}$ and vice versa, the former are called the equivalent eigenvalue parameters. Note that the equivalent eigenvalues are real; they are simply the coefficients of the characteristic polynomials:

$$(s-\mu_1)(s-\mu_2)(s-\mu_3) = s^3 - p_1 s^2 + p_2 s - p_3$$
$$(s-\nu_1)(s-\nu_2)(s-\nu_3) = s^3 - q_1 s^2 + q_2 s - q_3$$

THEOREM 14.3 (Chua et al.) [5]

Let $\{\mu_1, \mu_2, \mu_3, \nu_1, \nu_2, \nu_3\}$ be the eigenvalues associated with a vector field $\mathbf{F(X)} \in \mathscr{C}/\mathscr{E}_0$, *where $\mathscr{E}_0$ is the set of measure zero in the space of equivalent eigenvalue parameters where one of the five conditions in Equation* 14.17 *is satisfied. Then, Chua's oscillator with parameters defined by Equations* 14.18 *and* 14.19 *is linearly conjugate to this vector field.*

$$\left.\begin{aligned} p_1 - q_1 &= 0 \\ p_2 - \left(\frac{p_3 - q_3}{p_1 - q_1}\right) - \left(\frac{p_2 - q_2}{p_1 - q_1}\right)\left(p_1 - \frac{p_2 - q_2}{p_1 - q_1}\right) &= 0 \\ -\left(\frac{p_2 - q_2}{p_1 - q_1}\right) - \frac{k_1}{k_2} &= 0 \\ -k_1 k_3 + k_2\left(\frac{p_3 - q_3}{p_1 - q_1}\right) &= 0 \\ \det \mathbf{K} = \det\begin{bmatrix} 1 & 0 & 0 \\ a_{11} & a_{12} & a_{13} \\ K_{31} & K_{32} & K_{33} \end{bmatrix} &= a_{12}k_{33} - a_{13}k_{32} = 0 \end{aligned}\right\} \tag{14.17}$$

where

$$K_{3i} = \sum_{j=i}^{3} a_{1j}a_{ji}, \quad i = 1, 2, 3$$

We denote by $\tilde{\mathscr{C}}$ the set of vector fields $\mathscr{C}/\mathscr{E}_0$. Two vector fields in $\tilde{\mathscr{C}}$ are linearly conjugate if they have the same eigenvalues in each region.

14.3.3 Eigenvalues-to-Parameters Mapping Algorithm for Chua's Oscillator

Every continuous, third-order, odd-symmetric, three-region, piecewise-linear vector field $\mathbf{F}'$ in $\mathcal{C}$ may be mapped onto a Chua's oscillator (where the vector field $\mathbf{F}$ is topologically conjugate to $\mathbf{F}'$) by means of the following algorithm [5]:

1. Calculate the eigenvalues (μ_1', μ_2', μ_3') and (ν_1', ν_2', ν_3') associated with the linear and affine regions, respectively, of the vector field $\mathbf{F}'$ of the circuit or system whose attractor is to be reproduced (up to linear conjugacy) by Chua's oscillator.
2. Find a set of circuit parameters $\{C_1, C_2, L, R, R_0, G_a, G_b, E\}$ (or dimensionless parameters $\{\alpha, \beta, \gamma, a, b, k\}$) so that the resulting eigenvalues μ_j and ν_j for Chua's oscillator satisfy $\mu_j = \mu_j'$ and $\nu = \nu_j'$, $j = 1, 2, 3$.

Let $\{p_1, p_2, p_3, q_1, q_2, q_3\}$ be the equivalent eigenvalue parameters defined by Equation 14.16. Furthermore, let

$$\left.\begin{aligned} k_1 &= -p_3 + \left(\frac{p_3 - q_3}{p_1 - q_1}\right)\left(p_1 - \frac{p_2 - q_2}{p_1 - q_1}\right) \\ k_2 &= p_2 - \left(\frac{p_3 - q_3}{p_1 - q_1}\right) - \left(\frac{p_2 - q_2}{p_1 - q_1}\right)\left(p_1 - \frac{p_2 - q_2}{p_1 - q_1}\right) \\ k_3 &= -\left(\frac{p_2 - q_2}{p_1 - q_1}\right) - \frac{k_1}{k_2} \\ k_4 &= -k_1 k_3 + k_2\left(\frac{p_3 - q_3}{p_1 - q_1}\right) \end{aligned}\right\} \tag{14.18}$$

The corresponding circuit parameters are given by

$$\left.\begin{aligned} C_1 &= 1 \\ C_2 &= -\frac{k_2}{k_3^2} \\ L &= -\frac{k_3^2}{k_4} \\ R &= -\frac{k_3}{k_2} \\ R_0 &= -\frac{k_1 k_3^2}{k_2 k_4} \\ G_a &= -p_1 + \left(\frac{p_2 - q_2}{p_1 - q_1}\right) + \frac{k_2}{k_3} \\ G_b &= -q_1 + \left(\frac{p_2 - q_2}{p_1 - q_1}\right) + \frac{k_2}{k_3} \end{aligned}\right\} \tag{14.19}$$

The breakpoint E of the piecewise-linear Chua diode can be chosen arbitrarily because the choice of E does not affect either the eigenvalues or the dynamics; it simply scales the circuit variables. In a practical

realization of the circuit, one should scale the voltages and currents so that they lie within the inner three segments of the nonlinear resistor N_R.

The dimensionless parameters can be calculated as follows:

$$\left.\begin{aligned}
\alpha &= -\frac{k_2}{k_3^2} \\
\beta &= \frac{k_4}{k_2 k_3^2} \\
\gamma &= \frac{k_1}{k_2 k_3} \\
a &= -1 + \frac{k_3}{k_2}\left(p_1 - \frac{p_2 - q_2}{p_1 - q_1}\right) \\
b &= -1 + \frac{k_3}{k_2}\left(q_1 - \frac{p_2 - q_2}{p_1 - q_1}\right) \\
k &= \mathrm{sgn}(k_3)
\end{aligned}\right\} \tag{14.20}$$

Example: Torus

Figure 14.32 shows a practical implementation of Chua's oscillator that exhibits a transition to chaos by torus breakdown. A complete list of components is given in Table 14.3.

A SPICE simulation of this circuit produces a quasiperiodic voltage $\nu(2)$ $(= -V_1)$, as expected (see Figure 14.33). The resistor R0 is not explicitly added to the circuit, but models the dc resistance of the inductor.

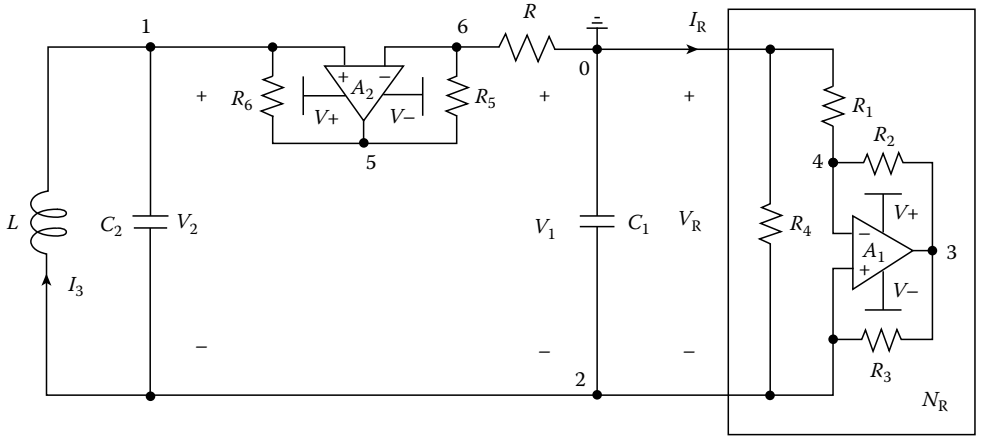

FIGURE 14.32 Practical implementation of Chua's oscillator using an op-amp and four resistors to realize the Chua diode. (From Kennedy, M.P., *IEEE Trans. Circuits Syst. I Fundam. Theory Appl.*, 40, 640, 657, Oct. 1993. With permission.) The negative resistor G is realized by means of a negative resistance converter (A_2, R_5, R_6, and positive resistor R). If $R_2 = R_3$ and $R_5 = R_6$, and $G_a = 1/R_4 - 1/R_1$, $G_b = 1/R_4 + 1/R_2$, and $G = -1/R$. Component values are listed in Table 14.3.

TABLE 14.3 Component List for the Chua Oscillator in Figure 14.32

Element	Description	Value	Tolerance (%)
A_1	Op-amp ($\frac{1}{2}$ AD712, TL082, or equivalent)	—	—

14.4 van der Pol Neon Bulb Oscillator

In a paper titled "Frequency demultiplication," the eminent Dutch electrical engineer Balthazar van der Pol described an experiment in which, by tuning the capacitor in a neon bulb *RC* relaxation oscillator driven by a sinusoidal voltage source (see Figure 14.34), "currents and voltages appear in the system which are whole submultiples of the driving frequency" [11].

The circuit consists of a high-voltage dc source E attached via a large series resistance R to a neon bulb and capacitor C that are connected in parallel; this forms the basic relaxation oscillator. Initially, the capacitor is discharged and the neon bulb is nonconducting. The dc source charges C with time constant RC until the voltage across the neon bulb is

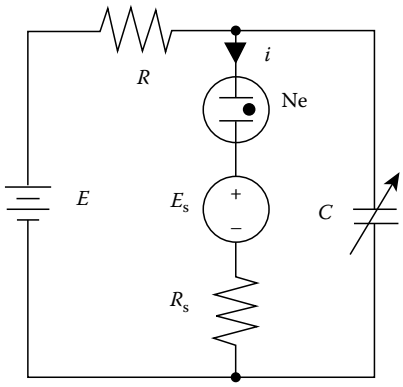

FIGURE 14.34 Sinusoidally driven neon bulb relaxation oscillator. Ne is the neon bulb.

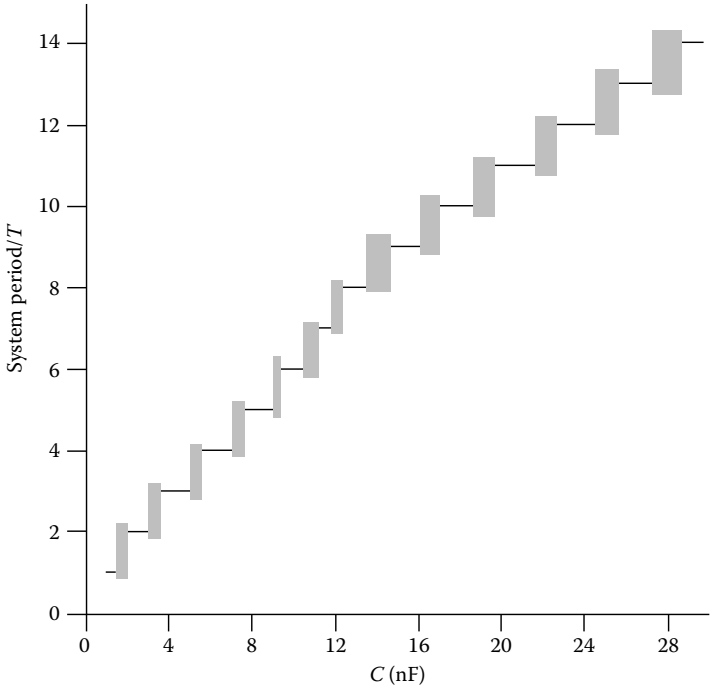

FIGURE 14.35 Normalized current pulse pattern repetition rate versus C for the sinusoidally driven neon relaxation oscillator in Figure 14.34, showing a coarse staircase structure of mode-lockings. (From Kennedy, M.P. and Chua, L.O., *IEEE Trans. Circuits Syst.*, CAS-33, 975, Oct. 1986. With permission.)

sufficient to turn it on. Once lit, the bulb presents a shunt low resistance path to the capacitor. The voltage across the capacitor falls exponentially until the neon arc is quenched, the bulb is returned to its "off" state, and the cycle repeats.

A sinusoidal voltage source $E_s = E_0 \sin(2\pi f_s t)$ is inserted in series with the neon bulb. Its effect is to perturb the "on" and "off" switching thresholds of the capacitor voltage.

Experimental results for this circuit are summarized in Figure 14.35, where the ratio of the system period (time interval before the pattern of current pulses repeats itself) to the period T of the forcing is plotted versus the capacitance C.

van der Pol noted that as the capacitance was increased from that value (C_0) for which the natural frequency f_0 of the undriven relaxation oscillator equaled that of the sinusoidal source (system period/$T = 1$), the system frequency made "discrete jumps from one whole submultiple of the driving frequency to the next" (detected by means of "a telephone coupled loosely in some way to the system"). van der Pol noted that "often an irregular noise is heard in the telephone receiver before the frequency jumps to the next lower value"; van der Pol had observed chaos. Interested primarily in frequency demultiplication, he dismissed the "noise" as "a subsidiary phenomenon."

Typical current waveforms, detected by means of a small current-sensing resistor R_s placed in series with the bulb are shown in Figure 14.36. These consist of a series of sharp spikes, corresponding to the periodic firing of the bulb. Figure 14.36c shows a nonperiodic "noisy" signal of the type noticed by van der Pol.

The frequency locking behavior of the driven neon bulb oscillator circuit is characteristic of forced oscillators that contain two competing frequencies: the natural frequency f_0 of the undriven oscillator and the driving frequency f_s. If the amplitude of the forcing is small, either quasiperiodicity or mode-locking occurs. For a sufficiently large amplitude of the forcing, the system may exhibit chaos.

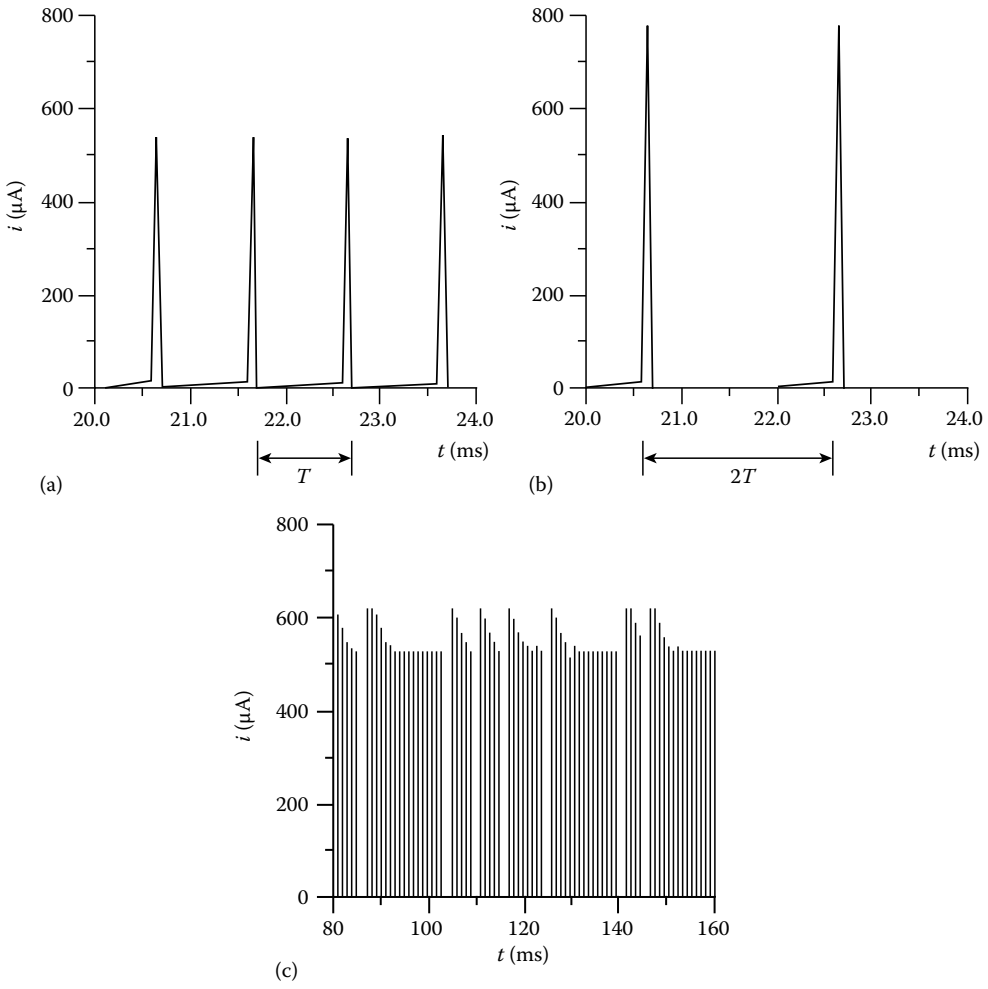

FIGURE 14.36 Periodic and chaotic neon bulb current waveforms. (a) One current pulse per cycle of E_s: $f_s/f_d = 1/1$; (b) one current pulse every two cycles of E_s: $f_s/f_d = 2/1$; (c) "noisy" current waveform.

14.4.1 Winding Numbers

Subharmonic frequency locking in a forced oscillator containing two competing frequencies f_1 and f_2 may be understood in terms of a winding number. The concept of a winding number was introduced by Poincaré to describe periodic and quasiperiodic trajectories on a torus.

A trajectory on a torus that winds around the minor axis of the torus with frequency f_1 revolutions per second, and completes revolutions of the major axis with frequency f_2, may be parametrized by two angular coordinates $\theta_1 \equiv f_1 t$ and $\theta_2 \equiv f_2 t$, as illustrated in Figure 14.37 [6]. The angles of rotation θ_1 and θ_2 about the major and minor axes of the torus are normalized so that one revolution corresponds to a change in θ of 1.

A Poincaré map for this system can be defined by sampling the state θ_1 with period $\tau = 1/f_2$. Let $\theta_k = \theta_1(k\tau)$. The Poincaré map has the form

$$\theta_{k+1} = G(\theta_k), \quad k = 0, 1, 2, \ldots$$

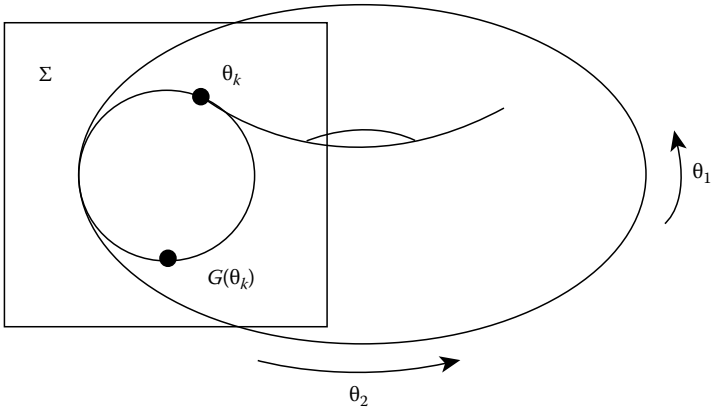

FIGURE 14.37 A trajectory on a torus is characterized by two normalized angular coordinates. $\theta_1 = f_1 t$ is the angle of rotation about the minor axis of the torus, while $\theta_2 = f_2 t$ is the angle of rotation along the major axis, where f_1 and f_2 are the frequencies of rotation about the corresponding axes. A Poincaré map $\theta_{k+1} = G(\theta_k)$ is defined by sampling the trajectory with frequency $1/f_2$. The winding number w counts the average number of revolutions in the Poincaré section per iteration of the map.

If $f_1/f_2 = p/q$ is rational, then the trajectory is periodic, closing on itself after completing q revolutions about the major axis of the torus. In this case, we say that the system is periodic with period q and completes p cycles per period. If the ratio p/q is irrational then the system is quasiperiodic; a trajectory covers the surface of the torus, coming arbitrarily close to every point on it, but does not close on itself.

The winding number w is defined by

$$w = \lim_{k \to \infty} \frac{G^{(k)}(\theta_0)}{k}$$

where $G^{(k)}$ denotes the k-fold iterate of G and θ_0 is the initial state.

The winding number counts the average number of revolutions in the Poincaré section per iteration. Equivalently, w equals the average number of turns about the minor axis per revolution about the major axis of the torus.* Periodic orbits possess rational winding numbers and are called resonant; quasiperiodic trajectories have irrational winding numbers.

14.4.2 Circle Map

A popular paradigm for explaining the behavior of coupled nonlinear oscillators with two competing frequencies is the circle map:

$$\theta_{k+1} = \left(\theta_k + \frac{K}{2\pi} \sin(2\pi\theta_k) + \Omega \right) \bmod 1, \quad k = 0, 1, 2, \ldots \tag{14.21}$$

so-called because it maps the circle into itself. The sinusoidal term represents the amplitude of the forcing, and Ω is the ratio of the natural frequency of the unperturbed system and the forcing frequency [18].

When $K \equiv 0$, the steady state of the discrete-time dynamical system (Equation 14.22) is either periodic or quasiperiodic, depending on whether Ω is rational or irrational.

* Either frequency may be chosen to correspond to the major axis of the torus, so the winding number and its reciprocal are equivalent.

If the amplitude K of the forcing is nonzero but less than unity, the steady-state is q-periodic when $\Omega = p/q$ is rational. In this case, a nonzero mode-locked window $[\Omega_{\min}(w), \Omega_{\max}(w)]$ occurs, over which $w = p/q$. A mode-locked region is delimited by saddle-node bifurcations at $\Omega_{\min}(w)$ and $\Omega_{\max}(w)$ [18].

The function $w(\Omega)$ in Figure 14.38 is monotone increasing and forms a Devil's staircase with plateaus at every rational value of w—for example, the step with winding number 1/2 is centered at $\Omega = 0.5$. An experimental Devil's staircase for the driven neon bulb circuit, with low-amplitude forcing, is shown in Figure 14.39.

As the amplitude k is increased, the width of each locked interval in the circle map increases so that mode-locking becomes more common and quasiperiodicity occurs over smaller ranges of driving frequencies. The corresponding (K, Ω) parameter space diagram (see Figure 14.40) consists of a series of distorted triangles, known as Arnold Tongues, with apexes that converge to rational values of Ω at $K = 0$.

Within a tongue, the winding number is constant, yielding one step of the Devil's staircase. The winding numbers of adjacent tongues are related by a *Farey tree* structure. Given two periodic windows with winding number $w_1 = p/q$ and $w_2 = r/s$, another periodic window with winding number $w = (\alpha p + \beta r)/(\alpha q + \beta s)$ can always be found, where p, q, r, and s are relatively prime and α and β are strictly positive integers. Furthermore, the widest mode-locked window between w_1 and w_2 has winding number $(p + r)/(q + s)$. For example, the widest step between those with winding numbers 1/2 and 2/3 in Figure 14.38 has $w = 3/5$.

The sum of the widths of the mode-locked states increases monotonically from zero at $K = 1$ to unity at $K = 1$. Below the critical line $K = 1$, the tongues bend away from each other and do not overlap. At $K = 1$, tongues begin to overlap, a kink appears in the Poincaré section and the Poincaré map develops a horseshoe; this produces coexisting attractors and chaos.

The transition to chaos as K is increased through $K = 1$ may be by a period-doubling cascade within a tongue, intermittency, or directly from a quasiperiodic trajectory by the abrupt disappearance of that trajectory (a blue sky catastrophe). This qualitative behavior is observed in van der Pol's neon bulb circuit.

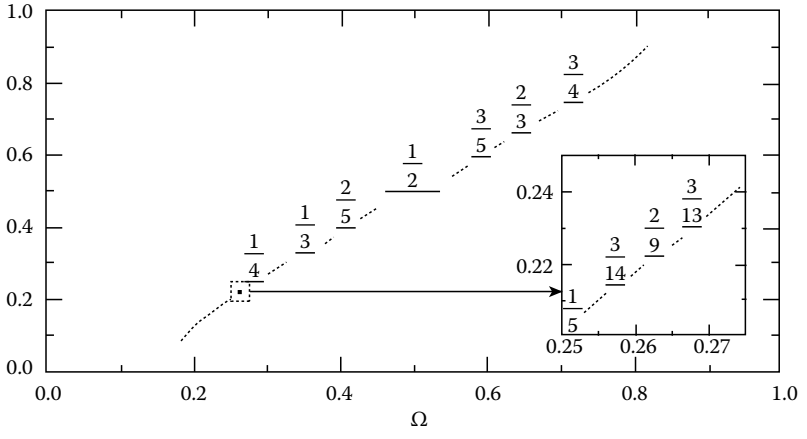

FIGURE 14.38 Devil's staircase for the circle map with $K = 1$. The steps indicate the regions in which w is constant. The staircase is self-similar in the sense that its structure is reproduced qualitatively at smaller scales (see inset). (From Glazier, J.A. and Libchaber, A., *IEEE Trans. Circuits Syst.*, 35, 793, July 1988. With permission.)

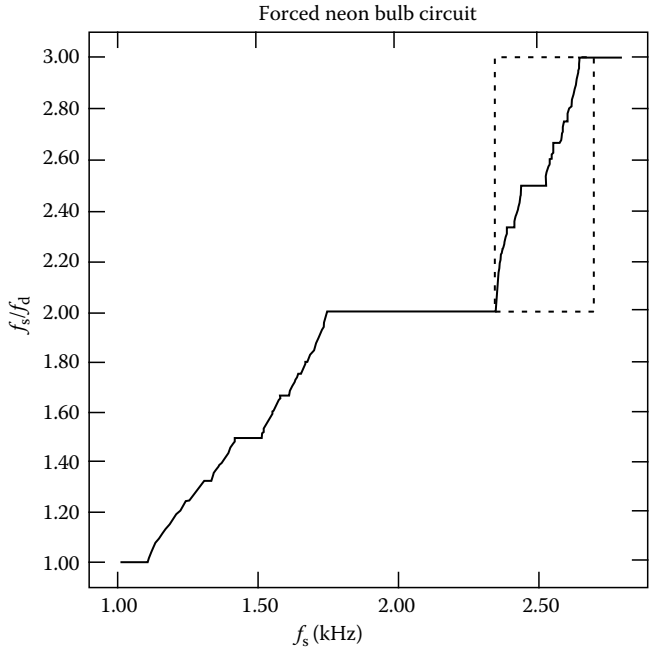

FIGURE 14.39 Experimentally measured staircase structure of lockings for a forced neon bulb relaxation oscillator. The winding number is given by f_s/f_d, the ratio of the frequency of the sinusoidal driving signal to the average frequency of current pulses through the bulb. (From Kennedy, M.P., Krieg, K.R., and Chua, L.O., *IEEE Trans. Circuits Syst*., 36, 1137, Aug. 1989. With permission.)

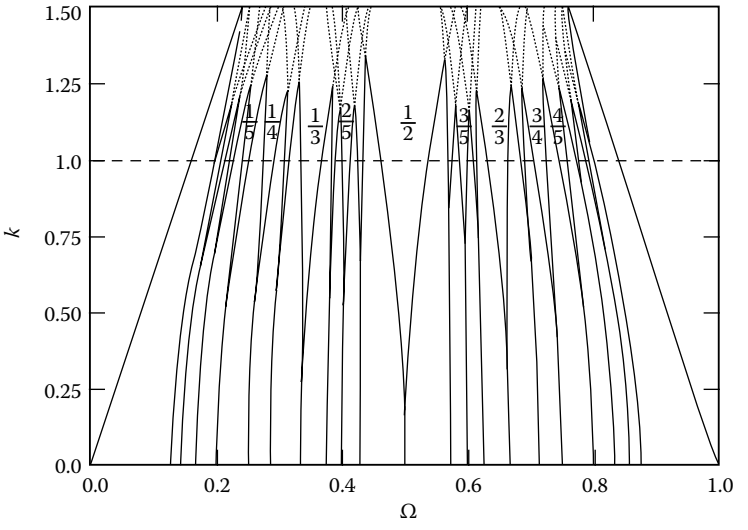

FIGURE 14.40 Parameter space diagram for the circle map showing Arnold tongue structure of lockings in the K–Ω plane. The relative widths of the tongues decrease as the denominator of the winding number increases. Below the critical line $K = 1$, the tongues bend away from each other and do not overlap; for $K > 1$, the Poincaré map develops a fold and chaos can occur. (From Glazier, J.A. and Libchaber, A., *IEEE Trans. Circuits Syst*., 35, 793, July 1988. With permission.)

14.4.3 Experimental Observations of Mode-Locking and Chaos in van der Pol's Neon Bulb Circuit

With the signal source E_s zeroed, the natural frequency of the undriven relaxation oscillator is set to 1 kHz by tuning capacitance C to C_0. A sinusoidal signal with frequency 1 kHz and amplitude E_0 is applied as shown in Figure 14.34. The resulting frequency of the current pulses (detected by measuring the voltage across R_s) is recorded with C as the bifurcation parameter.

14.4.3.1 C Bifurcation Sequence

If a fixed large-amplitude forcing E_s is applied and C is increased slowly, the system at first continues to oscillate at 1 kHz (Figure 14.36a) over a range of C, until the frequency "suddenly" drops to 1000/2 Hz (Figure 14.36b), stays at that value over an additional range of capacitance, drops to 1000/3 Hz, then 1000/4, 1000/5, and so on as far as 1000/20 Hz. These results are summarized in Figure 14.35.

Between each two submultiples of the oscillator driving frequency, a further rich structure of submultiples is found. At the macroscopic level (the coarse structure examined by van der Pol) increasing the value of C causes the system periods to step from T (1 ms) to $2T$, $3T$, $4T, \ldots$, where the range of C for which the period is fixed is much greater than that over which the transitions occur (Figure 14.35).

Examining the shaded transition regions more closely, one finds that between any two "macroscopic" regions where the period is fixed at $(n-1)T$ and nT $(n>1)$, respectively, there lies a narrower region over which the system oscillates with stable period $(2n-1)T$. Further, between $(n-1)T$ and $(2n-1)T$, one finds a region of C for which the period is $(3n-2)T$, and between $(2n-1)T$ and nT, a region with period $(3n-1)T$. Indeed, between any two stable regions with periods $(n-1)T$ and nT, respectively, a region with period $(2n-1)T$ can be found. Figure 14.41 depicts an enlargement of the C axis in the region of the T to $2T$ macrotransition, showing the finer period-adding structure.

Between T and $2T$ is a region with stable period $3T$. Between this and $2T$, regions of periods $5T$, $7T$, $9T, \ldots$, $25T$ are detected. Current waveforms corresponding to period-three and period-five steps, with winding numbers 3/2 and 5/3, respectively, are shown in Figure 14.42.

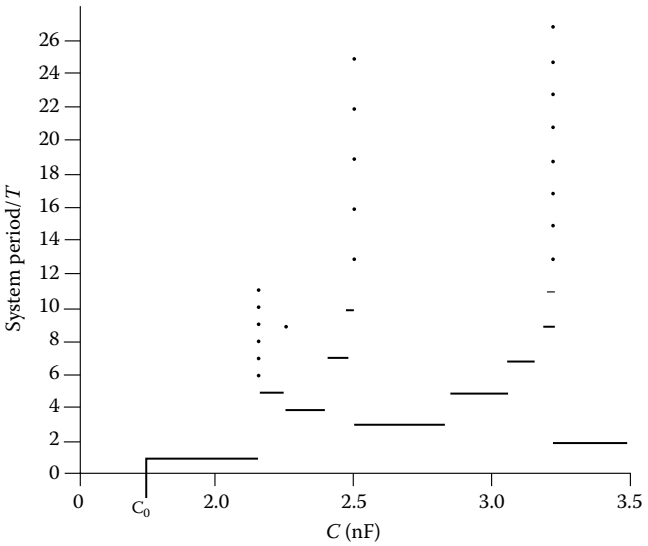

FIGURE 14.41 Experimental pulse pattern repetition rate versus C for van der Pol's forced neon bulb oscillator, showing fine period-adding structure. (From Kennedy, M.P. and Chua, L.O., *IEEE Trans. Circuits Syst.*, CAS-33, 975, Oct. 1986. With permission.)

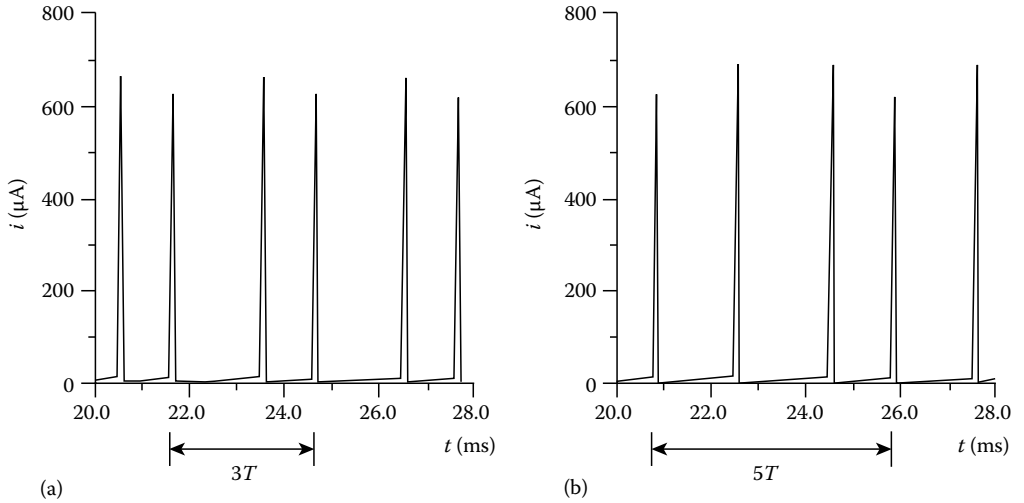

FIGURE 14.42 Neon bulb current waveforms. (a) Two pulses every three cycles of f_s: $f_s/f_d = 3/2$; (b) three pulses every five cycles $f_s/f_d = 5/3$.

A region of period $4T$ lies between T and $3T$, with steps $7T$, $10T$, $13T, \ldots,$ $25T$ between that and $3T$.

In practice, it becomes difficult to observe cycles with longer periods because stochastic noise in the experimental circuit can throw the solution out of the narrow window of existence of a high period orbit.

14.4.3.2 Experimental f_s Bifurcation Sequence with Low-Amplitude Forcing

An experimental Devil's staircase may be plotted for this circuit by fixing the parameters of the relaxation oscillator and the amplitude of the sinusoidal forcing signal, and choosing the forcing frequency f_s as the bifurcation parameter. The quantity f_s/f_d is the equivalent winding number in this case, where f_d is the average frequency of the current pulses through the neon bulb.

Experimental results for the neon bulb circuit with low-amplitude forcing are presented in Figures 14.39 and 14.43. The monotone staircase of lockings is consistent with a forcing signal of small amplitude. Note that the staircase is self-similar in the sense that its structure is reproduced qualitatively at smaller scales of the bifurcation parameter. If the amplitude of the forcing is increased, the onset of chaos is indicated by a nonmonotonicity in the staircase.

14.4.4 Circuit Model

The experimental behavior of van der Pol's sinusoidally driven neon bulb circuit may be reproduced in simulation by an equivalent circuit (see Figure 14.44) in which the only nonlinear element (the neon bulb) is modeled by a nonmonotone current-controlled resistor with a series parasitic inductor L_p.

The corresponding state equations are

$$\frac{dV_C}{dt} = -\frac{1}{RC}V_C - \frac{1}{C}I_L + \frac{E}{RC}$$

$$\frac{dI_L}{dt} = \frac{1}{L_p}V_C - \frac{R_s}{L_p}I_L - \frac{f(I_L)}{L_p} - \frac{E_0 \sin(2\pi f_s t)}{L_p}$$

where $V = f(I)$ is the DP characteristic of the current-controlled resistor (see Figure 14.45).

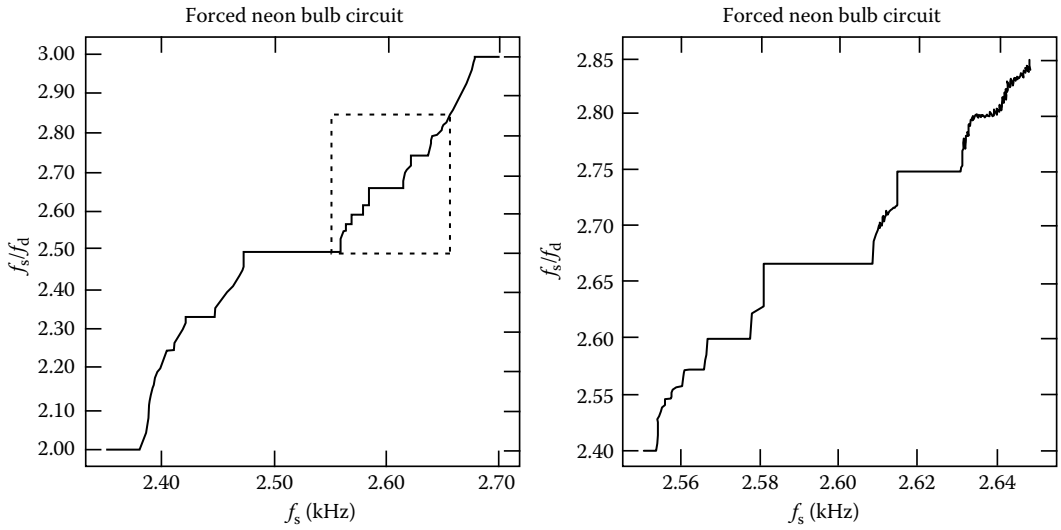

FIGURE 14.43 Magnification of Figure 14.39 showing self-similarity. (From Kennedy, M.P., Krieg, K.R., and Chua, L.O., *IEEE Trans. Circuits Syst.*, 36, 1137, Aug. 1989. With permission.)

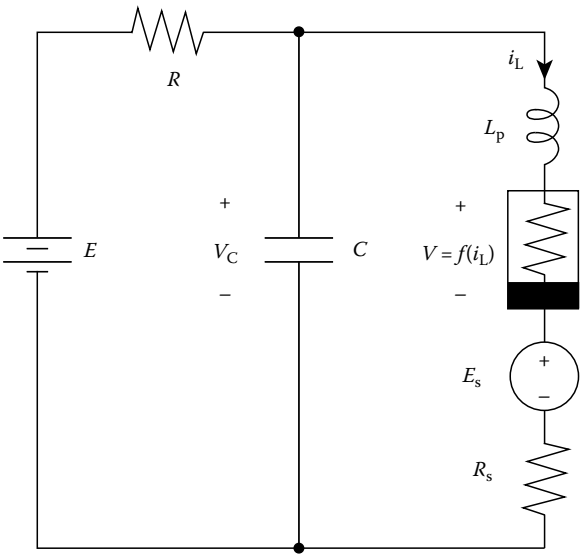

FIGURE 14.44 van der Pol's neon bulb circuit—computer model. The bulb is modeled by a nonmonotonic current-controlled nonlinear resistor with parasitic transit inductance L_p.

14.5 Synchronization of Chaotic Circuits

Chaotic steady-state solutions are characterized by sensitive dependence on initial conditions; trajectories of two identical autonomous continuous-time dynamical systems started from slightly different initial conditions quickly become uncorrelated. Surprisingly perhaps, it is nevertheless possible to synchronize these systems in the sense that a trajectory of one asymptotically approaches that of the other. Two trajectories $X_1(t)$ and $X_2(t)$ are said to *synchronize* if

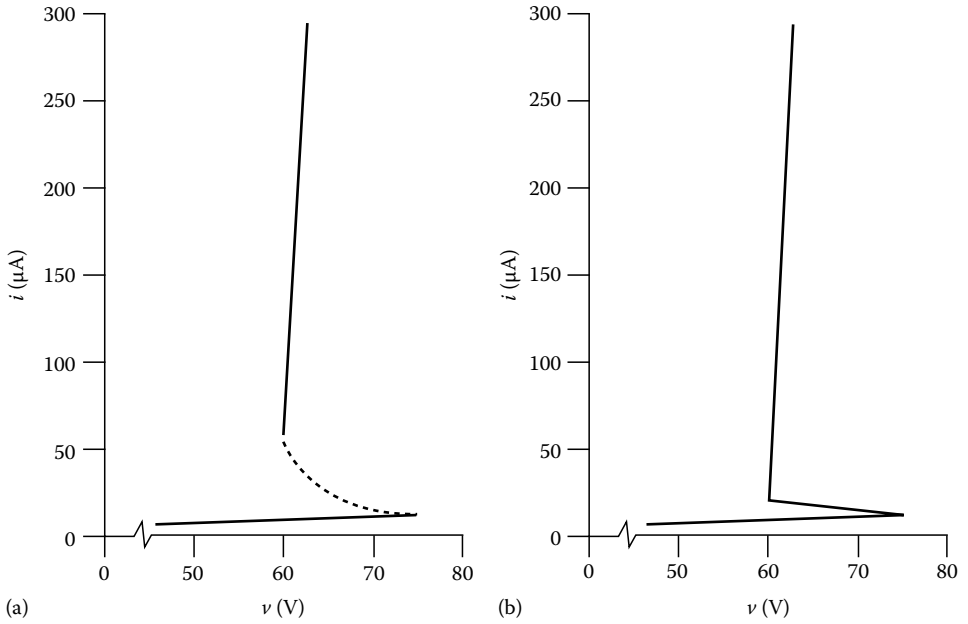

FIGURE 14.45 Neon bulb DP characteristics: (a) measured and (b) simulated. (From Kennedy, M.P. and Chua, L. O., *IEEE Trans. Circuits Syst*., CAS-33, 976, Oct. 1986. With permission.)

$$\lim_{t\to\infty} \|\mathbf{X}_1(t) - \mathbf{X}_2(t)\| = 0$$

In this section, we describe two techniques for synchronizing chaotic trajectories.

14.5.1 Linear Mutual Coupling

The simplest technique for synchronizing two dynamical systems

$$\begin{aligned}\dot{\mathbf{X}}_1 &= \mathbf{F}_1(\mathbf{X}_1), \quad \mathbf{X}_1(0) = \mathbf{X}_{1_0}\\ \dot{\mathbf{X}}_2 &= \mathbf{F}_2(\mathbf{X}_2), \quad \mathbf{X}_2(0) = \mathbf{X}_{2_0}\end{aligned}$$

is by linear mutual coupling of the form

$$\begin{aligned}\dot{\mathbf{X}}_1 &= \mathbf{F}_1(\mathbf{X}_1) + \mathbf{K}(\mathbf{X}_2 - \mathbf{X}_1), \quad \mathbf{X}_1(0) = \mathbf{X}_{1_0}\\ \dot{\mathbf{X}}_2 &= \mathbf{F}_2(\mathbf{X}_2) + \mathbf{K}(\mathbf{X}_2 - \mathbf{X}_1), \quad \mathbf{X}_2(0) = \mathbf{X}_{2_0}\end{aligned} \tag{14.22}$$

where $\mathbf{X}_1, \mathbf{X}_2 \in \mathbb{R}^n$ and $K = \text{diag}\,(K_{11}, K_{22}, \ldots, K_{nn})^{\mathrm{T}}$.

Here, $\mathbf{X}_1(t)$ is called the goal dynamics. The synchronization problem may be stated as follows: find $\mathbf{K}$ such that

$$\lim_{t\to\infty} \|\mathbf{X}_1(t) - \mathbf{X}_2(t)\| = 0$$

that is, that the solution $\mathbf{X}_2(t)$ synchronizes with the goal trajectory $\mathbf{X}_1(t)$.

In general, it is difficult to prove that synchronization occurs, unless an appropriate Lyapunov function* of the error system $\mathbf{E}(t) = \mathbf{X}_1(t) - \mathbf{X}_2(t)$ can be found. However, several examples exist in the literature where mutually coupled chaotic systems synchronize over particular ranges of parameters.

Example: Mutually Coupled Chua's Circuits

Consider a linear mutual coupling of two Chua's circuits. In dimensionless coordinates, the system under consideration is

$$\frac{dX_1}{dt} = \alpha[X_2 - X_1 - f(X_1)] + K_{11}(X_4 - X_1)$$
$$\frac{dX_2}{dt} = X_1 - X_2 - X_3 + K_{22}(X_5 - X_2)$$
$$\frac{dX_3}{dt} = -\beta y + K_{33}(X_6 - X_3)$$
$$\frac{dX_4}{dt} = \alpha(X_5 - X_4 - f(X_4)) + K_{11}(X_1 - X_4)$$
$$\frac{dX_5}{dt} = X_4 - X_5 - X_6 + K_{22}(X_2 - X_5)$$
$$\frac{dX_6}{dt} = -\beta X_5 + K_{33}(X_3 - X_6)$$

Two mutually coupled Chua's circuits characterized by $\alpha = 10.0$, $\beta = 14.87$, $a = -1.27$, and $b = -0.68$ will synchronize (the solutions of the two systems will approach each other asymptotically) for the following matrices K:

X_1 – coupling $K_{11} > 0.5$, $K_{22} = K_{33} = 0$
X_2 – coupling $K_{22} > 5.5$, $K_{11} = K_{33} = 0$
X_3 – coupling $0.7 < K_{33} < 2$, $K_{11} = K_{22} = 0$

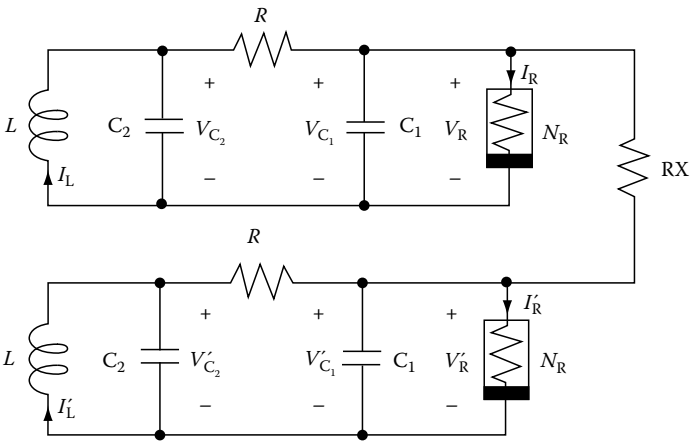

FIGURE 14.46 Synchronization of two Chua's circuits by means of resistive coupling between V_{C_1} and V'_{C_1}.

* For a comprehensive exposition of Lyapunov stability theory, see Ref. [19].

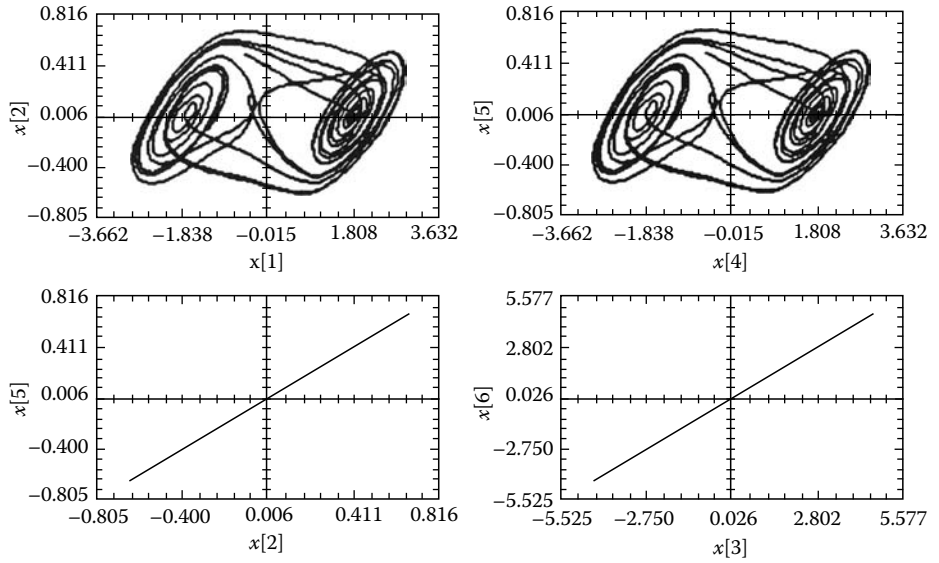

FIGURE 14.47 Simulation of the normalized dimensionless form of Figure 14.46, illustrating synchronization by mutual coupling of state variables. Identify $\{x[1], x[2], x[3]\}$ with $\{V_{C_1}\ V_{C_2}\ I_L\}$ and $\{x[4], x[5], x[6]\}$ with $\{V'_{C_1}\ V'_{C_2}\ I'_L\}$ synchronizes with $V_{C_2}(t)$ and $I'_L(t)$ synchronizes with $I_L(t)$. (From Chua, L.O., Itoh, M., Kočarev, L., and Eckert, K., *J. Circuits Syst. Comput.*, 3, 1, 99, Mar. 1993. With permission.)

Coupling between states X_1 and X_4 may be realized experimentally by connecting a resistor between the tops of the nonlinear resistors, as shown in Figure 14.46. States X_2 and X_5 may be coupled by connecting the tops of capacitors C_2 by means of a resistor.

A simulation of the system, which confirms synchronization of the two chaotic Chua's circuits in the case of linear mutual coupling between state V_{C_1} and V'_{C_1} is presented in Figure 14.47.

14.5.2 Pecora–Carroll Drive-Response Concept

The drive-response synchronization scheme proposed by Pecora and Carroll applies to systems that are drive-decomposable [16]. A dynamical system is called drive-decomposable if it can be partitioned into two subsystems that are coupled so that the behavior of the second (called the response subsystem) depends on that of the first, but the behavior of the first (called the drive subsystem) is independent of that of the second.

To construct a drive-decomposable system, an n-dimensional autonomous continuous-time dynamical system

$$\dot{\mathbf{X}} = \mathbf{F}(\mathbf{X}), \quad \mathbf{X}(0) = \mathbf{X}_0 \tag{14.23}$$

where $\mathbf{X} = (X_1,\ X_2, \ldots,\ X_n)^T$ and $\mathbf{F}(\mathbf{X}) = [F_1(\mathbf{X}),\ F_2(\mathbf{X}), \ldots,\ F_n(\mathbf{X})]^T$, is first partitioned into two subsystems

$$\dot{\mathbf{X}}_1 = \mathbf{F}_1(\mathbf{X}_1, \mathbf{X}_2), \quad \mathbf{X}_1(0) = \mathbf{X}_{1_0} \tag{14.24}$$

$$\dot{\mathbf{X}}_2 = \mathbf{F}_2(\mathbf{X}_1, \mathbf{X}_2), \quad \mathbf{X}_2(0) = \mathbf{X}_{2_0} \tag{14.25}$$

where $\mathbf{X}_1 = (X_1, X_2, \ldots, X_m)^T$, $\mathbf{X}_2 = (X_{m+1}, X_{m+2}, \ldots, X_n)^T$,

$$\mathbf{F}_1(\mathbf{X}_1, \mathbf{X}_2) = \begin{pmatrix} F_1(\mathbf{X}_1, \mathbf{X}_2) \\ F_2(\mathbf{X}_1, \mathbf{X}_2) \\ \vdots \\ F_m(\mathbf{X}_1, \mathbf{X}_2) \end{pmatrix}$$

and

$$\mathbf{F}_2(\mathbf{X}_1, \mathbf{X}_2) = \begin{pmatrix} F_{m+1}(\mathbf{X}_1, \mathbf{X}_2) \\ F_{m+2}(\mathbf{X}_1, \mathbf{X}_2) \\ \vdots \\ F_n(\mathbf{X}_1, \mathbf{X}_2) \end{pmatrix}$$

An identical $(n - m)$-dimensional copy of the second subsystem, with $\mathbf{X}_3$ as state variable and $\mathbf{X}_1$ as input, is appended to form the following $(2n - m)$-dimensional coupled drive-response system:

$$\dot{\mathbf{X}}_1 = \mathbf{F}_1(\mathbf{X}_1, \mathbf{X}_2), \quad \mathbf{X}_1(0) = \mathbf{X}_{1_0} \tag{14.26}$$

$$\dot{\mathbf{X}}_2 = \mathbf{F}_2(\mathbf{X}_1, \mathbf{X}_2), \quad \mathbf{X}_2(0) = \mathbf{X}_{2_0} \tag{14.27}$$

$$\dot{\mathbf{X}}_3 = \mathbf{F}_2(\mathbf{X}_1, \mathbf{X}_3), \quad \mathbf{X}_3(0) = \mathbf{X}_{3_0} \tag{14.28}$$

The n-dimensional dynamical system defined by Equations 14.26 and 14.27 is called the drive system and Equation 14.28 is called the response subsystem.

Note that the second drive subsystem (Equation 14.27) and the response subsystem (Equation 14.28) lie in state spaces of dimension $\mathbb{R}^{(n-m)}$ and have identical vector fields $\mathbf{F}_2$ and inputs $\mathbf{X}_1$.

Consider a trajectory $\mathbf{X}_3(t)$ of Equation 14.29 that originates from an initial state $\mathbf{X}_{3_0}$ "close" to $\mathbf{X}_{2_0}$. We may think of $\mathbf{X}_2(t)$ as a perturbation of $\mathbf{X}_3(t)$. In particular, define the error $\mathbf{X}_3(t) = \mathbf{X}_2(t) - \mathbf{X}_3(t)$. The trajectory $\mathbf{X}_2(t)$ approaches $\mathbf{X}_3(t)$ asymptotically (synchronizes) if $\|\mathbf{X}_2\| \to 0$ as $t \to \infty$. Equivalently, the response subsystem (Equation 14.29) is asymptotically stable when driven with $\mathbf{X}_1(t)$.

The stability of an orbit of a dynamical system may be determined by examining the linearization of the vector field along the orbit. The linearized response subsystem is governed by

$$\dot{\mathbf{x}}_3 = \mathbf{D}_{\mathbf{X}_3}\mathbf{F}_2(\mathbf{X}_1(t), \mathbf{X}_3)\mathbf{x}_3, \quad \mathbf{x}_3(0) = \mathbf{x}_{3_0}$$

where $\mathbf{D}_{\mathbf{x}_3}\mathbf{F}_2(\mathbf{X}_1(t), \mathbf{X}_3)$ denotes the partial derivatives of the vector field $\mathbf{F}_2$ of the response subsystem with respect to $\mathbf{X}_3$. This is a linear time-varying system whose state transition matrix $\Phi_t(\mathbf{X}_{1_0}, \mathbf{X}_{3_0})$ maps a point $\mathbf{x}_{3_0}$ into $\mathbf{X}_3(t)$. Thus,

$$\mathbf{x}_3(t) = \Phi_t(\mathbf{X}_{1_0}, \mathbf{X}_{3_0})\mathbf{x}_{3_0}$$

Note that Φ_t is a linear operator. Therefore, an $(n - m)$-dimensional ball $B_\varepsilon(\mathbf{X}_{3_0})$ of radius ε about $\mathbf{X}_{3_0}$ is mapped into an ellipsoid whose principal axes are determined by the singular values of Φ_t. In particular, a ball of radius ε is mapped by Φ_t into an ellipsoid, the maximum and minimum radii of which are bounded by the largest and smallest singular values, respectively, of Φ_t.

The conditional LEs $\lambda_i(\mathbf{X}_{1_0}, \mathbf{X}_{2_0})$ (hereafter denoted CLE) are defined by

$$\lambda_i(\mathbf{X}_{1_0}, \mathbf{X}_{2_0}) = \lim_{t\to\infty} \frac{1}{t} \ln \sigma_i[\phi_t(\mathbf{X}_{1_0}, \mathbf{X}_{2_0})], \quad i = 1, 2, \ldots, (n - m)$$

whenever the limit exists.

The term conditional refers to the fact that the exponents depend explicitly on the trajectory $\phi_t(\mathbf{X}_{1_0}, \mathbf{X}_{2_0})$ of the drive system.

Given that ε remains infinitesimally small, one needs only to consider the local linearized dynamics along the flow determined by $\phi_t(\mathbf{X}_{1_0}, \mathbf{X}_{2_0})$ and to determine the average local exponential rates of expansion and contraction along the principal axes of an ellipsoid. If all CLEs are negative, the response subsystem is asymptotically stable. A subsystem, where all the CLEs are negative, is called a stable subsystem.

A stable subsystem does not necessarily exhibit dc steady-state behavior. For example, while an asymptotically stable linear parallel *RLC* circuit has all negative LEs, the system settles to a periodic steady-state solution when driven with a sinusoidal current. Although the *RLC* subcircuit has negative CLEs in this case, the complete forced circuit has one nonnegative LE corresponding to motion along the direction of the flow.

THEOREM 14.4 (Pecora and Carroll)

The trajectories $\mathbf{X}_2(t)$ *and* $\mathbf{X}_3(t)$ *will synchronize only if the CLEs of the response system* (*Equation* 14.28) *are all negative.*

Note that this is a necessary but not sufficient condition for synchronization. If the response and second drive subsystems are identical and the initial conditions $\mathbf{X}_{2_0}$ and $\mathbf{X}_{3_0}$ are sufficiently close, and the CLEs of Equation 14.28 are all negative, synchronization will occur. However, if the systems are not identical or the initial conditions are not sufficiently close, synchronization might not occur, even if all of the CLEs are negative.

Although we have described it only for an autonomous continuous-time system, the drive-response technique may also be applied for synchronizing nonautonomous and discrete-time circuits.

14.5.2.1 Cascaded Drive-Response Systems

The drive-response concept may be extended to the case where a dynamical system can be partitioned into more than two parts. A simple two-level drive-response cascade is constructed as follows. Divide the dynamical system

$$\dot{\mathbf{X}} = \mathbf{F}(\mathbf{X}), \quad \mathbf{X}(0) = \mathbf{X}_0 \tag{14.29}$$

into three parts:

$$\dot{\mathbf{X}}_1 = \mathbf{F}_1(\mathbf{X}_1, \mathbf{X}_2, \mathbf{X}_3), \quad \mathbf{X}_1(0) = \mathbf{X}_{1_0} \tag{14.30}$$

$$\dot{\mathbf{X}}_2 = \mathbf{F}_2(\mathbf{X}_1, \mathbf{X}_2, \mathbf{X}_3), \quad \mathbf{X}_2(0) = \mathbf{X}_{2_0} \tag{14.31}$$

$$\dot{\mathbf{X}}_3 = \mathbf{F}_3(\mathbf{X}_1, \mathbf{X}_2, \mathbf{X}_3), \quad \mathbf{X}_3(0) = \mathbf{X}_{3_0} \tag{14.32}$$

Now, construct an identical copy of the subsystems corresponding to Equations 14.31 and 14.32 with $\mathbf{X}_1(t)$ as input:

$$\dot{\mathbf{X}}_4 = \mathbf{F}_2(\mathbf{X}_1, \mathbf{X}_4, \mathbf{X}_5), \quad \mathbf{X}_4(0) = \mathbf{X}_{4_0} \tag{14.33}$$

$$\dot{\mathbf{X}}_5 = \mathbf{F}_3(\mathbf{X}_1, \mathbf{X}_4, \mathbf{X}_5), \quad \mathbf{X}_5(0) = \mathbf{X}_{5_0} \tag{14.34}$$

If all the CLEs of the driven subsystem composed of Equations 14.33 and 14.34 are negative then, after the transient decays, $\mathbf{X}_4(t) = \mathbf{X}_2(t)$ and $\mathbf{X}_5(t) = \mathbf{X}_3(t)$.

Note that Equations 14.30 through 14.34 together define one large coupled dynamical system. Hence, the response subsystem can exhibit chaos even if all of its CLEs are negative.

Proceeding one step further, we reproduce subsystem (Equation 14.30):

$$\dot{\mathbf{X}}_6 = \mathbf{F}_1(\mathbf{X}_6, \mathbf{X}_4, \mathbf{X}_5), \quad \mathbf{X}_6(0) = \mathbf{X}_{6_0} \tag{14.35}$$

As before, if all of the conditional LEs of Equation 14.35 are negative, then $\|\mathbf{X}_6(t) - \mathbf{X}_1(t) \to 0\|$.

If the original system could be partitioned so that Equation 14.30 is one-dimensional, then using Equations 14.33 through 14.35 as a driven response system, *all* of the variables in the drive system could be reproduced by driving with just *one* variable $X_1(t)$. It has been suggested that chaotic synchronization might be useful in chaotic communications.

Example: Synchronization of Chua's Circuits Using the Drive-Response Concept

Chua's circuit may be partitioned in three distinct ways to form five-dimensional, drive-decomposable systems:

X_1-drive configuration:

$$\frac{dX_1}{dt} = \alpha[X_2 - X_1 - f(X_1)]$$
$$\frac{dX_2}{dt} = X_1 - X_2 - X_3$$
$$\frac{dX_3}{dt} = -\beta X_2$$
$$\frac{dX_4}{dt} = X_1 - X_4 - X_5$$
$$\frac{dX_5}{dt} = -\beta X_5$$

With $\alpha = 10.0$, $\beta = 14.87$, $a = -1.27$, and $b = -0.68$, the CLEs for the (X_2, X_3) subsystem are $(-0.5, -0.5)$.

X_2-drive configuration:

$$\frac{dX_2}{dt} = X_1 - X_2 - X_3$$
$$\frac{dX_1}{dt} = \alpha[X_2 - X_1 - f(X_1)]$$
$$\frac{dX_2}{dt} = -\beta X_2$$
$$\frac{dX_4}{dt} = \alpha[X_2 - X_4 - f(X_4)]$$
$$\frac{dX_5}{dt} = -\beta X_5$$

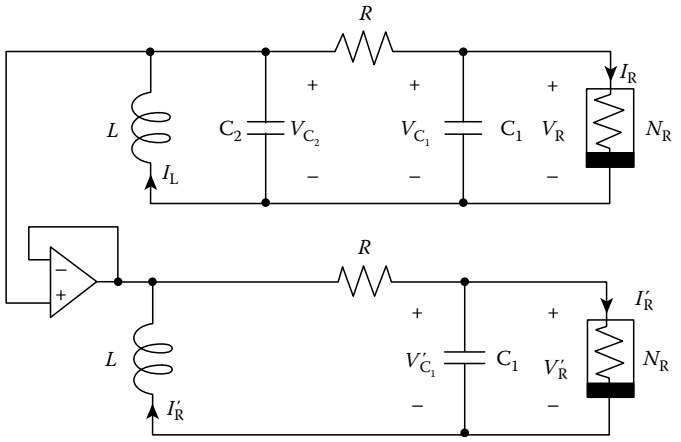

FIGURE 14.48 Synchronization of two Chua's circuits using the Pecora–Carroll drive-response method with V_{C_2} as the drive variable.

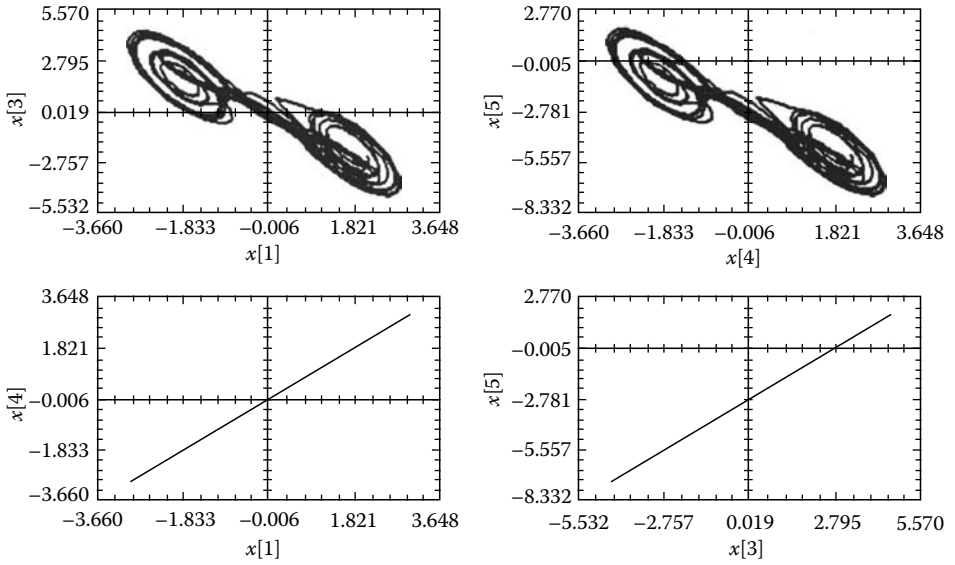

FIGURE 14.49 Simulation of the normalized dimensionless form of Figure 14.48, illustrating synchronization of state variables. Identify $\{x[1], x[2], x[3]\}$ with $\{V_{C_1}\ V_{C_2}\ I_L\}$, and $\{x[4], x[5]\}$ with $\left\{V'_{C_1}\ I'_L\right\} \cdot V'_{C_1}(t)$ synchronizes with $V'_{C_1}(t)$, and $I'_L(t)$ synchronizes with $I_L(t)$. Because one of the CLEs of the response subsystem is zero, the difference in the initial conditions $I_{L_0} - I_{L_0}$ does not decay to zero. (From Chua, L.O., Itoh, M., Kočarev, L., and Eckert, K., *J. Circuits Syst. Comput.*, 3, 1, 106, Mar. 1993. With permission.)

This case is illustrated in Figure 14.48. The CLEs of the (X_1, X_3) subsystem are 0 and -2.5 ± 0.05. Because of the zero CLE, states $X_5(t)$ and $X_3(t)$ remain a constant distance $|X_{3_0} - X_{5_0}|$ apart, as depicted in Figure 14.49.

X_3-drive configuration:

$$\frac{dX_3}{dt} = -\beta X_2$$
$$\frac{dX_1}{dt} = \alpha[X_2 - X_1 - f(X_1)]$$
$$\frac{dX_2}{dt} = X_1 - X_2 - X_3$$
$$\frac{dX_4}{dt} = \alpha[X_5 - X_4 - f(X_4)]$$
$$\frac{dX_5}{dt} = X_4 - X_5 - X_3$$

The CLEs in this case are 1.23 ± 0.03 and -5.42 ± 0.02. Because the (X_1, X_2) subsystem has a positive CLE, the response subsystem does not synchronize.

14.6 Applications of Chaos

14.6.1 Pseudorandom Sequence Generation

One of the most widely used deterministic "random" number generators is the linear congruential generator, which is a discrete-time dynamical system of the form

$$X_{k+1} = (AX_k + B) \bmod M, \quad k = 0, 1, \ldots \tag{14.36}$$

where A, B, and M are called the multiplier, increment, and modulus, respectively.

If $A > 1$, then all equilibrium points of Equation 14.36 are unstable. With the appropriate choice of constants, this system exhibits a chaotic solution with a positive LE equal to ln A. However, if the state space is discrete, for example in the case of digital implementations of Equation 14.37, then every steady-state orbit is periodic with a maximum period equal to the number of distinct states in the state space; such orbits are termed pseudorandom.

By using an analog state space, a truly "random" chaotic sequence can be generated. A discrete-time chaotic circuit with an analog state space may be realized in SC technology. Figure 14.50 is an SC realization of the parabolic map

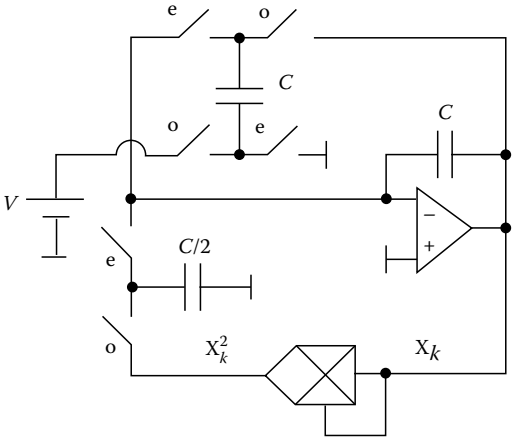

FIGURE 14.50 SC realization of the parabolic map $x_{k+1} = V - 0.5X_k^2$. The switches labeled o and e are driven by the odd and even phases, respectively, of a nonoverlapping two-phase clock.

$$x_{k+1} = V - 0.5x_k^2 \tag{14.37}$$

which, by the change of variables

$$X_k = Ax_k + B$$

with $\mu = 1/(2A)$, $B = 0.5$, and $A = (-1 \pm \sqrt{1 + 2V})/(4V)$, is equivalent to the logistic map

$$X_{k+1} = \mu X_k(1 - X_k) \tag{14.38}$$

The logistic map is chaotic for $\mu = 4$ with LE ln 2 [18]. Figure 14.16 is a bifurcation diagram of Equation 14.38 with $0 \leq \mu \leq 4$.

For $V < 1.5$, the steady-state solution of the SC parabolic map described by Equation 14.37 is a fixed point. As the bifurcation parameter V is increased from 1.5 to 3 V, the circuit undergoes a series of period-doubling bifurcations to chaos. $V = 4$ corresponds to fully developed chaos on the open interval $(0 < X_k < 1)$ in the logistic map with $\mu = 4$.

14.6.2 Communicating with Chaos

Modulation and coding techniques for mobile communication systems are driven by two fundamental requirements: that the communication channel should be secure and the modulation scheme should be tolerant of multipath effects. Security is ensured by coding and immunity from multipath degradation may be achieved by using a spread-spectrum transmission.

With appropriate modulation and demodulation techniques, the ''random'' nature and ''noise-like'' spectral properties of chaotic circuits can be exploited to provide simultaneous coding and spreading of a transmission.

14.6.2.1 Chaotic Masking

Chaotic masking is a method of hiding an information signal by adding it to a chaotic carrier at the transmitter. The drive-response synchronization technique is used to recover the carrier at the receiver.

Figure 14.51 is a block diagram of a communication system using matched Chua's circuits. The receiver has the same two-layer structure as in the previous example. The first subcircuit, which has very negative CLEs, synchronizes with the incoming signal, despite the perturbation $s(t)$, and recovers V_{C_2}. The second subcircuit, when driven by V_{C_2}, produces the receiver's copy of V_{C_1}. The information signal $r(t)$ is recovered by subtracting the local copy of V_{C_1} from the incoming signal $V_{C_1} + s(t)$.

Chaotic masking is not suitable for practical communications applications for two reasons:

- The signal is indistinguishable from additive noise in the channel; this results in a poor signal to noise ratio in the received signal and therefore poor overall noise performance
- The received signal is corrupted not only by noise in the channel but by the message itself; this makes synchronization of the receiver, and therefore coherent demodulation using synchronized chaos, difficult

Another possibility is to use chaotic signals as the basis functions in a digital communications system.

14.6.2.2 Chaos Shift Keying

The simplest idea for data transmission (digital communications) using a chaotic circuit is use the data to modulate some parameter(s) of the transmitter. This technique is called parameter modulation, chaotic switching, or chaos shift keying (CSK).

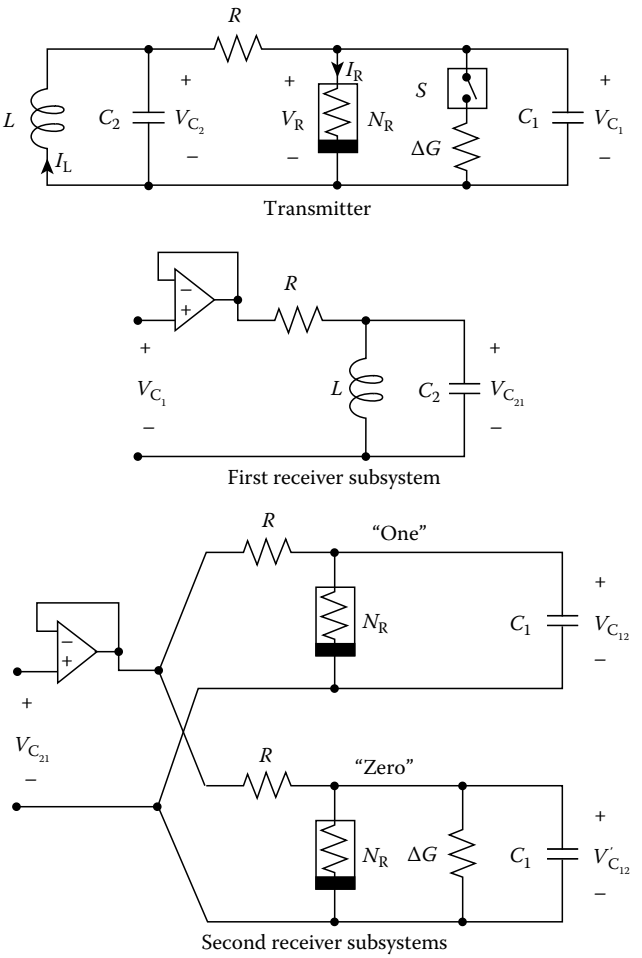

FIGURE 14.51 CSK communication system using Chua's circuit. When a ''one'' is transmitted, switch S remains open, $V_{C_{21}}(t)$ synchronizes with $V_{C_2}(t)$, $V_{C_{12}}(t)$ synchronizes with $V_{C_1}(t)$, and $V'_{C_{12}}(t)$ falls out of synchronization with $V_{C_1}(t)$. When a ''zero'' is transmitted, switch S is closed, $V_{C_{21}}(t)$ synchronizes with $V_{C_2}(t)$, $V_{C_{12}}(t)$ falls out of synchronization with $V_{C_1}(t)$, and $V'_{C_{12}}(t)$ synchronizes with $V_{C_1}(t)$.

In the case of binary data, the information signal is encoded as a pair of circuit parameter sets which produce distinct attractors in a dynamical system (the transmitter). In particular, a single control parameter μ may be switched between two values μ_0, corresponding to attractor $\mathcal{A}_0$ and μ_1, corresponding to $\mathcal{A}_1$. By analogy with frequency shift keying (FSK) and phase shift keying (PSK), this technique is known as CSK.

The binary sequence to be transmitted is mapped into the appropriate control signal $\mu(t)$ and the corresponding trajectory switches, as required, between $\mathcal{A}_1$ and $\mathcal{A}_0$.

One of the state variables of the transmitter is conveyed to the receiver, where the remaining state variables are recovered by drive-response synchronization. These states are then applied to the second stage of a drive-response cascade.

At the second level, two matched receiver subsystems are constructed, one of which synchronizes with the incoming signal if a ''zero'' was transmitted, the other of which synchronizes only if a ''one'' was transmitted. The use of two receiver circuits with mutually exclusive synchronization properties improves the reliability of the communication system.

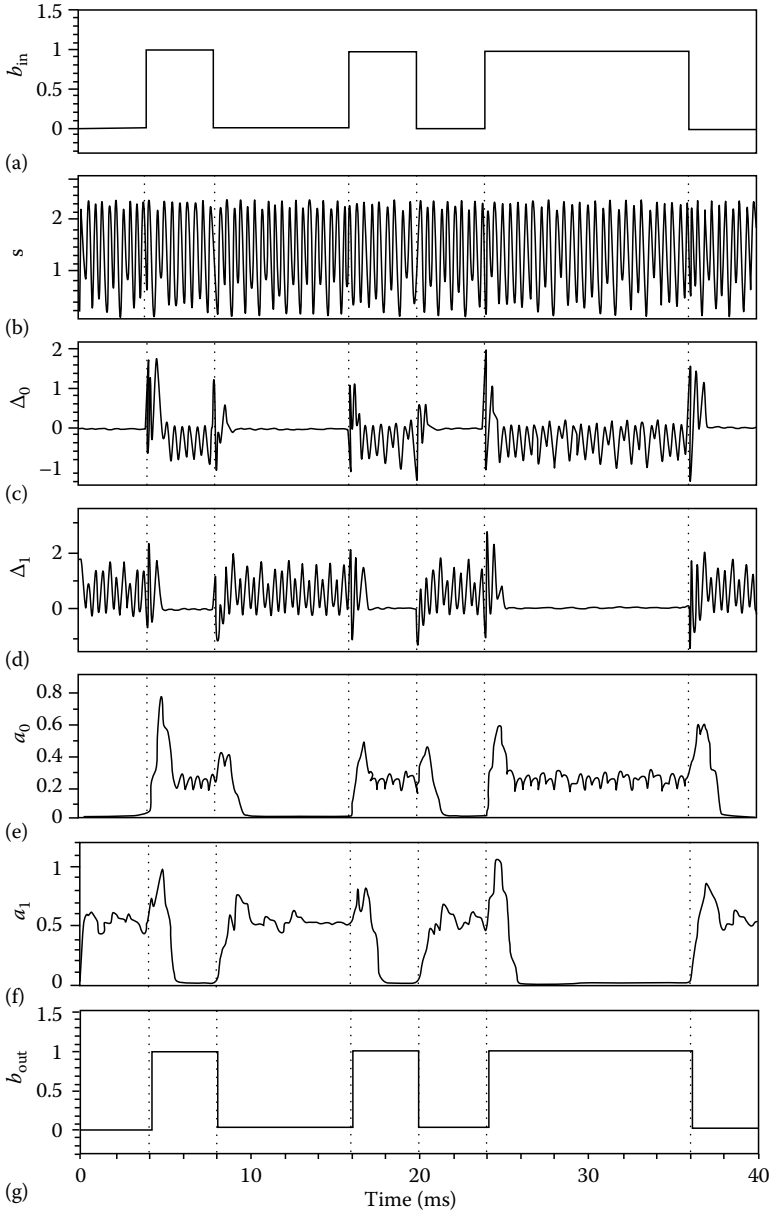

FIGURE 14.52 CSK waveforms. (a) Binary input signal b_{in}; (b) transmitted signal $s(t)$; (c) response $\Delta_0 = V_{C_{12}} - V_{C_1}$; (d) response $\Delta_0 = V'_{C_{12}} - V_{C_1}$; (e) 40-point moving average of Δ_0; (f) 40-point moving average of Δ_1; (g) output binary signal b_{out} when $\varepsilon = 0.1$. (From Ogorzalek, M., *IEEE Trans. Circuits Syst. I*, 40, 696, Oct. 1993. With permission.)

CSK has been demonstrated both theoretically and experimentally. Figure 14.52 depicts a CSK transmitter and receiver based on Chua's circuit. The control parameter is a resistor with conductance ΔG whose effect is to modulate the slopes G_a and G_b of the Chua diode. Switch S is opened and closed by the binary data sequence and V_{C_1} is transmitted. At the receiver, the first subsystem (a copy of the (V_{C_2}, I_L) subsystem of the transmitter) synchronizes with the incoming signal, recovering $V_{C_2}(t)$. Thus, $V_{C_{21}}(t) \rightarrow V_{C_2}(t)$.

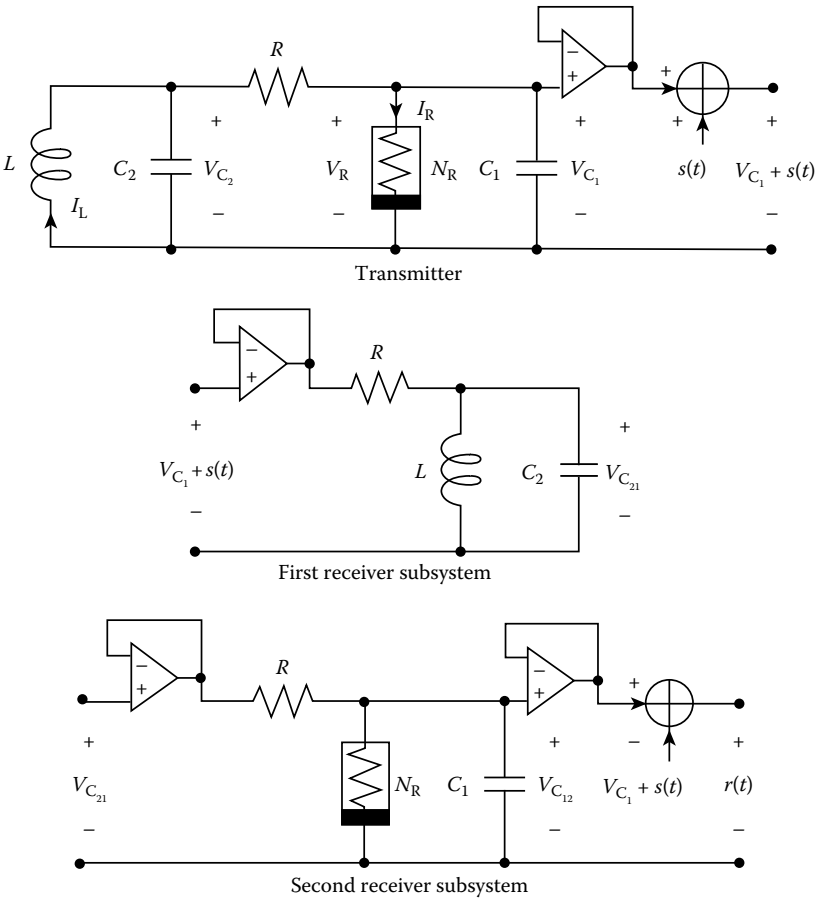

FIGURE 14.53 Chaos masking using Chua's circuits. At the transmitter, the information signal $s(t)$ is added to the chaotic carrier signal $V_{C_1}(t)$. Provided $s(t)$ is sufficiently small and the first receiver subsystem is sufficiently stable, $V_{C_{12}}(t)$ synchronizes with $V_{C_2}(t)$. This signal is applied to a second receiver subsystem, from which an estimate $V_{C_{12}}(t)$ of the unmodulated carrier $V_{C_1}(t)$ is derived. $V_{C_{12}}$ is subtracted from the incoming signal $V_{C_1} + s(t)$ to yield the received signal $r(t)$. The method works well only if $s(t)$ is much smaller than $V_{C_1}(t)$.

The synchronized local copy of $V_{C_1}(t)$ is then used to synchronize two further subsystems corresponding to the V_{C_1} subsystem of the transmitter with and without the resistor ΔG.

If the switch is closed at the transmitter, $V'_{C_{12}}$ (but not $V_{C_{12}}$) synchronizes with V_{C_1} and if the switch is open, $V_{C_{12}}$ (but not $V'_{C_{12}}$) synchronizes with V_{C_1}.

Figure 14.53 presents simulated results for a similar system consisting of two Chua's circuits. At the receiver, a decision must be made as to which bit has been transmitted. In this case, b_{out} was derived using the rule

$$b_{\text{out}} = \begin{pmatrix} 0, b_{\text{old}} = 0 & \text{for} & a_0 < \varepsilon,\ a_1 > \varepsilon \\ 1, b_{\text{old}} = 1 & \text{for} & a_0 > \varepsilon,\ a_1 < \varepsilon \\ b_{\text{old}} & \text{for} & a_0 < \varepsilon,\ a_1 < \varepsilon \\ 1 - b_{\text{old}} & \text{for} & a_0 > \varepsilon,\ a_1 > \varepsilon \end{pmatrix}$$

where b_{old} is the last bit received and b_{out} is the current bit [14].

As with chaos masking, noise in the channel perturbs the transmitted signal, making coherent demodulation using synchronized chaos difficult; this degrades the overall system performance.

An alternative to regenerating the chaotic basis functions at the receiver by means of synchronization is to transmit a chaotic reference signal as part of the message and to recover the information by correlating the received signal with the transmitted reference. An example of this is differential chaos shift keying (DCSK).

14.6.2.3 Differential Chaos Shift Keying

In chaotic modulation schemes, the transmitted signal is a wideband signal. The objectives of using a wideband signal as the carrier are twofold:

- To overcome the multipath propagation problem
- To reduce the transmitted power spectral density in order to reduce the interference caused in adjacent radio communications channels

Of the chaotic modulation schemes published to date, DCSK with orthonormal basis functions, also referred in the literature as to FM-DCSK [24] offers the best robustness against multipath and channel imperfections. In an FM-DCSK signal, symbol "0" is represented by a piece of FM-modulated chaotic waveform for time $T/2$, followed by a copy of itself; symbol "1" comprises a piece of FM-modulated chaotic waveform for time $T/2$, followed by an inverted copy of itself, where T is the symbol duration. Correlating the two halves of the waveform at the receiver yields $+1$ in the case of "0" and -1 in the case of "1."

It is frequently asked whether chaotic modulation schemes can offer any advantages over conventional narrow band systems. If the propagation conditions are so good that the basis function(s) can be regenerated at the receiver, then digital modulation schemes using conventional orthonormal (typically periodic) basis functions and orthonormal chaotic basis functions can achieve similar levels of noise performance.

The main question from an implementation perspective is the ease with which the basis functions can be regenerated. It is fundamentally easier to regenerate a periodic basis function than a chaotic one. Therefore, the noise performance of digital chaotic modulation with coherent correlation receivers will always lag behind that of equivalent modulation schemes using periodic basis functions.

If the propagation conditions are such that coherent detection is impossible, then chaotic switching with orthonormal DCSK basis functions and a differentially coherent receiver (DCSK, for short), offers the best possible performance for a chaotic digital modulation scheme. In the limit, the noise performance of DCSK lags only 3 dB behind that of DPSK with autocorrelation demodulation [24].

In this case, the choice of periodic or chaotic basis functions is determined by the propagation conditions. In particular, the multipath performance of a DCSK system can be improved by increasing the transmission bandwidth.

Figure 14.54 shows the simulated best case noise performance for CSK, chaotic on–off keying (COOK), and DCSK. The noise performance of binary phase shift keying (BPSK) and frequency shift keying (FSK) are also shown, for comparison.

Another important issue is interference. If the operating environment is such that interference with other narrow band radio systems working in the same frequency band should be minimized, then a spread spectrum system must be used; this can be implemented using chaotic basis functions, where the chaotic waveform is the spreading signal. For a fixed transmitted power, the wider the bandwidth of the chaotic signal, the lower the interference caused.

While signal spreading in a chaotic communications scheme reduces the interfering signal level for narrow band systems sharing the same frequency band, the converse is not necessarily true. Interference to a chaotic communications system caused by other users in the same band can be suppressed only by using coherent demodulation techniques.

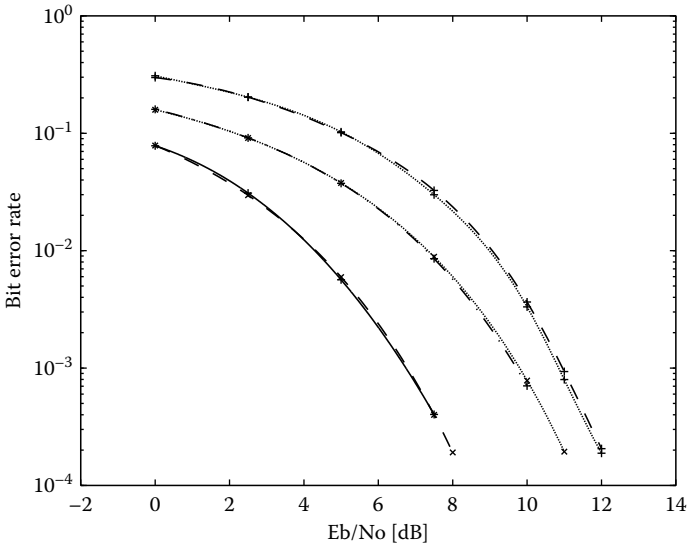

FIGURE 14.54 Simulated optimum noise performance of antipodal CSK modulation with coherent demodulation (solid curve with "+" marks [left]), COOK with noncoherent demodulation (dashed curve with "+" marks [right]), chaotic switching with orthonormal basis functions and coherent demodulation (dash-dot curve with "+" marks [center]), and chaotic switching with DCSK basis functions and a differentially coherent receiver (dotted curve with "o" marks [right]). The noise performance curves for BPSK (dashed curve with "o" marks [left]) and coherent FSK (dotted curve with "×" marks [center]) are also shown, for comparison. (From Kolumban, G., Kennedy, M.P., Jako, Z., and Kis, G., *Proc. IEEE*, 90(5), 711, May 2002. With permission.)

Although it performs worse than conventional narrowband modulation schemes in a simple additive white Gaussian noise (AWGN) channel, the advantage of DCSK is that the fall off in its performance in a multipath channel is more gradual than that of an equivalent narrow band modulation scheme.

This result is highlighted dramatically in Figure 14.55, where the performance degradation in a narrow band DPSK system; (classical DPSK with the optimum receiver configuration, referred as to "optimum DPSK") is compared with that of a wideband differentially coherent FM-DCSK system. The bit duration T was set to 2 μs in both cases and the RF bandwidth of the DCSK signal was 17 MHz. The solid and dashed curves give the noise performance of optimum DPSK and FM-DCSK, respectively, over a single-ray AWGN channel.

The noise performance of these modulation schemes was evaluated over a two-ray multipath channel with an excess delay of 100 ns that is typical of WLAN applications in large warehouses.

Although the single-ray performance of differentially coherent FM-DCSK is worse than that of DPSK, its multipath performance is significantly better, despite the fact that the carrier recovery problem which would accentuate the problem further does not appear in optimum DPSK.

In summary, FM-DCSK offers a performance advantage over conventional communications schemes in multipath environments when the propagation conditions are so poor that coherent detection or detection of DPSK with an optimum receiver configuration is not possible [24].

14.6.2.4 Miscellaneous

Chaotic circuits may also be used for suppressing spurious tones in ΣΔ modulators, for modeling musical instruments, fractal pattern generation, image processing, and pattern recognition [3].

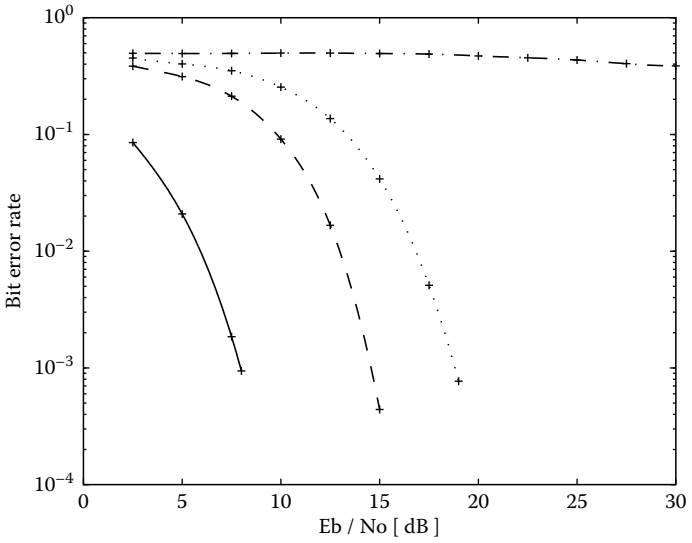

FIGURE 14.55 Simulated noise performance curves for optimum DPSK and wideband FM-DCSK in a single-ray channel (solid and dashed, respectively) and in a two-ray multipath channel (dash-dot and dotted, respectively). While FM-DCSK disimproves by about 4 dB, DPSK fails completely. (From Kolumban, G., Kennedy, M.P., Jako, Z., and Kis, G., *Proc. IEEE*, 90, 711, 2002. With permission.)

A chaotic attractor contains an infinite number of unstable periodic trajectories of different periods. Various control schemes for stabilizing particular orbits in chaotic circuits have been successfully demonstrated [14].

There has also been significant interest in using chaos for cryptographic purposes. An analog chaotic system with a continous state space has potentially greater complexity (in terms of crpytographic keys) than a digital finite state machine. However, many practical difficulties aris in trying to implement identical analog systems. An overview of the subject can be found in Ref. [25].

Further Information

Current Research in Chaotic Circuits. The August 1987 issue of the *Proceedings of the IEEE* is devoted to ''Chaotic Systems.'' The *IEEE Transactions on Circuits and Systems*, July 1988, focuses on ''Chaos and Bifurcations of Circuits and Systems.''

A three-part special issue of the *IEEE Transactions on Circuits and Systems* on ''Chaos in Electronic Circuits'' appeared in October (Parts I and II) and November 1993 (Part I). This special issue contains 42 papers on various aspects of bifurcations and chaos.

Two special issues (March and June 1993) of the *Journal of Circuits, Systems and Computers* are devoted to ''Chua's Circuit: A Paradigm for Chaos.'' These works, along with several additional papers, a pictorial guide to 45 attractors in Chua's oscillator, and the Adventures in Bifurcations and Chaos (ABC) simulator, have been compiled into a book of the same name—*Chua's Circuit: A Paradigm for Chaos*, R.N. Madan, Ed. Singapore: World Scientific, Singapore, 1993.

Developments in the field of bifurcations and chaos, with particular emphasis on the applied sciences and engineering, are reported in *International Journal of Bifurcation and Chaos*, which is published quarterly by World Scientific, Singapore.

Research in chaos in electronic circuits appears regularly in the *IEEE Transactions on Circuits and Systems*.

Simulation of Chaotic Circuits. A variety of general-purpose and custom software tools has been developed for studying bifurcations and chaos in nonlinear circuits systems.

ABC++ is a graphical simulator of Chua's oscillator. ABC++ contains a database of component values for all known attractors in Chua's oscillator, initial conditions, and parameter sets corresponding to homoclinic and heteroclinic trajectories, and bifurcation sequences for the period-doubling, intermittency, and quasiperiodic routes to chaos.

In "Learning about Chaotic Circuits with SPICE," *IEEE Transactions on Education*, Vol. 36, pp. 28–35, Jan. 1993, David Hamill describes how to simulate a variety of smooth chaotic circuits using the general-purpose circuit simulator SPICE. A commercial variant of SPICE, called PSpice, is available from http://www.cadence.com/orcad/index.html.

The free student evaluation version of this program is sufficiently powerful for studying simple chaotic circuits. PSpice runs on both workstations and PCs.

15.1 Generic Relations

15.1.1 Equivalent Circuit

The equivalent circuit of a generic transmission line in monochromatic single frequency operation is shown in Figure 15.1 [1–3], where $\dot{Z}$ is a series impedance per unit length of the transmission line (Ω/m) and $\dot{Y}$ is a shunt admittance per unit length of the transmission line (S/m). For a uniform, nonlinear transmission line, either $\dot{Z}$ or $\dot{Y}$ or both $\dot{Z}$ and $\dot{Y}$ are functions of the transmission line voltage and current, but both $\dot{Z}$ and $\dot{Y}$ are not functions of location on the transmission line. For a nonuniform, linear transmission line, both $\dot{Z}$ and $\dot{Y}$ are functions of location, but not functions of voltage and current on the transmission line. For a nonuniform and nonlinear transmission line, both $\dot{Z}$ and $\dot{Y}$ or $\dot{Z}$ or $\dot{Y}$ are functions of the voltage, the current, and the location on the transmission line.

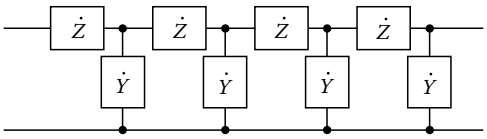

FIGURE 15.1 Equivalent circuit of a generic transmission line.

15.1.2 Transmission Line Equations

Ohm's law of a transmission line, which is the amount of voltage drop on a transmission line per unit distance of voltage transmission is expressed as

$$\frac{d\dot{V}}{dz} = -\dot{I}\dot{Z} \text{ (V/m)} \tag{15.1}$$

where

$\dot{V}$ is the transmission line voltage (V)
$\dot{I}$ is the transmission line current (A)
Z is the series impedance per unit length of the transmission line (Ω)
z is a one-dimensional coordinate placed in parallel to the transmission line (m)

The equation of current decrease per unit length is

$$\frac{d\dot{I}}{dz} = -\dot{Y}\dot{V} \text{ (A/m)} \tag{15.2}$$

where $\dot{Y}$ is the shunt admittance per unit distance of the transmission line (S/m).

Combining Equations 15.1 and 15.2, the Telegrapher's equation or Helmholtz's wave equation for the transmission line voltage is [1–3]

$$\frac{d^2\dot{V}}{dz^2} - \dot{Z}\dot{Y}\dot{V} = 0 \text{ (V/m)}^2 \tag{15.3}$$

The Telegrapher's equation or Helmholtz's wave equation for the transmission line current is [1–3]

$$\frac{d^2\dot{I}}{dz^2} - \dot{Z}\dot{Y}\dot{I} = 0 \text{ (A/m}^2\text{)} \tag{15.4}$$

15.1.3 General Solutions and Propagation Constant

The general solution of the Telegrapher's equation for transmission line voltage is [1–3]

$$\dot{V} = \dot{V}_F\varepsilon^{-\dot{\gamma}z} + \dot{V}_R\varepsilon^{\dot{\gamma}z} \tag{15.5}$$

where

$|\dot{V}_F|$ is the amplitude of the voltage waves propagating in $+z$-direction
$|\dot{V}_R|$ is the amplitude of the voltage waves propagating $-$z-direction
$\dot{\gamma}$ is the propagation constant of the transmission line [1]

$$\dot{\gamma} = \pm\sqrt{\dot{Z}\dot{Y}} = \alpha + \dot{\gamma}\beta \ (\mathrm{m}^{-1}) \tag{15.6}$$

where
+ sign is for forward propagation or propagation in $+z$-direction
− sign is for the backward propagation or propagation in $-z$-direction
α is the attenuation constant and it is the real part of propagation constant $\dot{\gamma}$

$$\alpha = \Re\dot{\gamma} = \Re\sqrt{\dot{Z}\dot{Y}} \ (\mathrm{m}^{-1}) \tag{15.7}$$

In Equation 15.6, β is the phase constant and it is the imaginary part of the propagation constant $\dot{\gamma}$:

$$\beta = \Im\dot{\gamma} = \Im\sqrt{\dot{Z}\dot{Y}} \ (\mathrm{m}^{-1}) \tag{15.8}$$

15.1.4 Characteristic Impedance

The characteristic impedance of the transmission line is [1–3]

$$Z_0 = \sqrt{\frac{\dot{Z}}{\dot{Y}}} \ (\Omega) \tag{15.9}$$

15.1.5 Wavelength

The wavelength of the transmission line voltage wave and transmission line current wave is

$$\lambda = \frac{2\pi}{\beta} = \frac{2\pi}{\Im\sqrt{\dot{Z}\dot{Y}}} \ (\mathrm{m}) \tag{15.10}$$

15.1.6 Phase Velocity

The phase velocity of voltage wave propagation and current wave propagation is

$$v_\mathrm{p} = f\lambda = \frac{\omega}{\beta} \ (\mathrm{m/s}) \tag{15.11}$$

where f is the frequency of operation, and the phase constant is

$$\beta = \frac{2\pi}{\lambda} \ (\mathrm{m}^{-1}) \tag{15.12}$$

15.1.7 Voltage Reflection Coefficient at the Load

If a transmission line of characteristic impedance Z_0 is terminated by a mismatched load impedance $\dot{Z}_\mathrm{L}$, as shown in Figure 15.2, a voltage wave reflection occurs at the load impedance $\dot{Z}_\mathrm{L}$. The voltage reflection coefficient is [1–3]

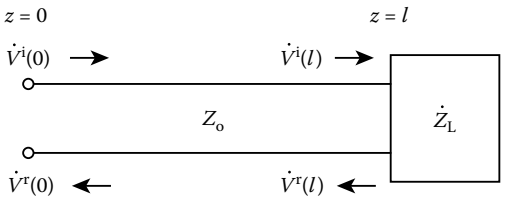

FIGURE 15.2 Incident wave $\dot{V}^{i}$ and reflected wave $\dot{V}^{r}$.

$$\dot{\rho}(l) = \frac{\dot{V}^{r}(l)}{\dot{V}^{i}(l)} = \frac{\dot{Z}_L - Z_0}{\dot{Z}_L + Z_0} = \frac{\tilde{\dot{Z}}_L - 1}{\tilde{\dot{Z}}_L + 1} \tag{15.13}$$

where

$\dot{\rho}(l)$ is the voltage reflection coefficient at $z = l$
$\tilde{\dot{Z}} = \tilde{\dot{Z}}_L / Z_0$ is the normalized load impedance
$\dot{V}^{i}(l)$ is the incident voltage at the load at $z = l$

When Z_0 is a complex quantity $\dot{Z}_0$, then

$$\dot{\rho}(l) = \frac{\dot{Z}_L - Z_0^{*}}{\dot{Z}_L + Z_0^{*}} \tag{15.14}$$

where Z_0^{*} is a conjugate of $\dot{Z}_0$.

15.1.8 Voltage Reflection Coefficient at the Input

Input Figure 15.2 $\dot{V}^{i}(l)$ is caused by $\dot{V}^{i}(0)$, which is the incident voltage at the input $z = 0$ of the transmission line. $\dot{V}^{r}(l)$ produces, $\dot{V}^{r}(0)$, which is the reflected voltage at the input $z = 0$. The voltage reflection coefficient at the input occurs, then, by omitting transmission line loss [1–3]

$$\dot{\rho} = \frac{\dot{V}^{r}(0)}{\dot{V}^{i}(0)} = \dot{\rho}(l)\varepsilon^{-2j\beta l} \tag{15.15}$$

15.1.9 Input Impedance

At the load $z = l$, from Equation 15.13,

$$\tilde{\dot{Z}}_L = \frac{1 + \dot{\rho}(l)}{1 - \dot{\rho}(l)} \tag{15.16}$$

or

$$\dot{Z}_L = Z_0 \frac{1 + \dot{\rho}(l)}{1 - \dot{\rho}(l)} \tag{15.17}$$

At the input of the transmission line $z = 0$

$$\tilde{\dot{Z}}(0) = \frac{1 + \dot{\rho}(0)}{1 - \dot{\rho}(0)} \tag{15.18}$$

Using Equation 15.15,

$$\tilde{\dot{Z}}(0) = \frac{1 + \dot{\rho}(l)\varepsilon^{-2j\beta l}}{1 - \dot{\rho}(l)\varepsilon^{-2j\beta l}} \tag{15.19}$$

Inserting Equation 15.13 [1–3]

$$\tilde{\dot{Z}}(0) = \frac{\tilde{\dot{Z}} + j\tan\beta l}{1 + j\tilde{\dot{Z}}_{\mathrm{L}}\tan\beta l} \tag{15.20}$$

or

$$\tilde{\dot{Z}}(0) = \frac{\dot{Z}_{\mathrm{L}} + jZ_0\tan\beta l}{Z_0 + j\dot{Z}_{\mathrm{L}}\tan\beta l} \tag{15.21}$$

If the line is lossy and

$$\dot{\gamma} = \alpha + j\beta \tag{15.22}$$

then [1]

$$\dot{Z}(0) = \dot{Z}_0^{\star}\frac{\dot{Z}_{\mathrm{L}} + \dot{Z}_0^{\star}\tanh\dot{\gamma}l}{\dot{Z}_0^{\star} + \dot{Z}_{\mathrm{L}}\tanh\dot{\gamma}l} \tag{15.23}$$

where $\dot{Z}_0^{\star}$ is the complex conjugate of $\dot{Z}_0$.

15.1.10 Input Admittance

The input admittance at $z = 0$ is

$$\dot{Y}(0) = \dot{Y}_0^{\star}\frac{\dot{Y}_{\mathrm{L}} + \dot{Y}_0^{\star}\tanh\dot{\gamma}l}{\dot{Y}_0^{\star} + \dot{Y}_{\mathrm{L}}\tanh\dot{\gamma}l} \tag{15.24}$$

where

$\dot{Y}(0)$ is the input admittance of the transmission line

$\dot{Y}_0$ is the characteristic admittance of the transmission line, which is

$$\dot{Y}_0 = \frac{1}{\dot{Z}_0} \tag{15.25}$$

and $\dot{Y}_0^*$ is the conjugate of $\dot{Y}_0 \cdot \dot{Y}_L$ is the load admittance; i.e.,

$$\dot{Y}_L = \frac{1}{\dot{Z}_L} \tag{15.26}$$

When the line is lossless,

$$\dot{\gamma} = j\beta \tag{15.27}$$

then [1–3]

$$\dot{Z}(0) = \frac{\dot{Z}_L + jZ_0 \tan \beta l}{Z_0 + jZ_L \tan \beta l} \tag{15.28}$$

15.2 Two-Wire Lines

15.2.1 Geometric Structure

A structural diagram of the cross-sectional view of a commercial two-wire line is shown in Figure 15.3. As observed in this figure, two parallel conductors, in most cases made of hard-drawn copper, are positioned by a plastic dielectric cover.

15.2.2 Transmission Line Parameters

In a two-wire line

$$\dot{Z} = R + jX = R + j\omega L \ (\Omega/\text{m}) \tag{15.29}$$

where
$\dot{Z}$ is the impedance per unit length of the two-wire line (Ω/m)
R is the resistance per unit length (Ω/m)
X is the reactance per unit length (Ω/m)
$\omega = 2\pi f$ is the operating angular frequency (s^{-1})
L is the inductance per unit length (H/m)

For a two-wire line made of hard-drawn copper [4]

$$R = 8.42 \frac{\sqrt{f}}{a} \ (\mu\Omega/\text{m}) \tag{15.30}$$

where f is the operating frequency and a is the radius of the conductor [4]:

$$L = 0.4 \ \ln \frac{b}{a} \ (\mu\text{H/m}) \tag{15.31}$$

where b is the wire separation or the center-to-center distance of the two-wire line as illustrated in Figure 15.3.

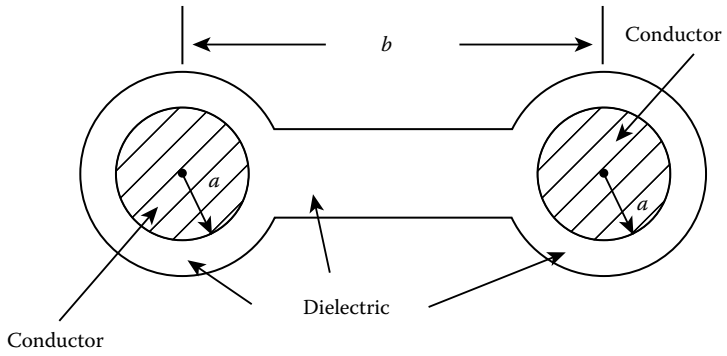

FIGURE 15.3 Cross-sectional view of a two-wire line.

$$\dot{Y} = G + jB = G + j\omega C \text{ (S/m)} \tag{15.32}$$

where

$\dot{Y}$ is a shunt admittance per unit length of the two-wire line (S/m)
G is a shunt conductance per unit length of the two-wire line (S/m)
B is a shunt susceptance per unit length (S/m)
C is a shunt capacitance per unit length (F/m)

$$G = \frac{3.14\sigma_d}{\cosh^{-1}\left(\frac{b}{2a}\right)} \text{ (pS/m)} \tag{15.33}$$

where σ_d is the insulation conductivity of the plastic dielectric surrounding the two parallel conductors, and

$$C = \frac{27.8\varepsilon_r}{\cosh^{-1}\left(\frac{b}{2a}\right)} \text{ (pF/m)} \tag{15.34}$$

where ε_r is the relative permittivity of the plastic insulating material [5].

If R and G are negligibly small, the characteristic impedance is [6]

$$Z_0 = 277 \log_{10} \frac{b}{a} \ (\Omega) \tag{15.35}$$

The attenuation constant of a generic two-wire line is, including both R and G [1],

$$\alpha = \frac{R}{2Z_0} + \frac{GZ_0}{2} \ (\text{m}^{-1}) \tag{15.36}$$

and the phase constants is [1]

$$\beta = \left\{ \frac{(\omega LB - RG) + \sqrt{(RG - \omega LB)^2 + (\omega LG + BR)^2}}{2} \right\}^{\frac{1}{2}} (\text{m}^{-1}) \tag{15.37}$$

15.2.3 Wavelength and Phase Velocity

The wavelength on a lossless two-wire line ($R = 0$, $G = 0$) is

$$\lambda_0 = \frac{\omega}{\beta_0} = \frac{1}{\sqrt{LC}} \text{ (m)} \tag{15.38}$$

where β_0 is the phase constant of the lossless two-wire line

$$\beta_0 = \omega\sqrt{LC} \text{ (m}^{-1}\text{)} \tag{15.39}$$

The wavelength on a lossy two-wire line ($R \neq 0$, $G \neq 0$) is

$$\lambda = \frac{2\pi}{\beta} = \left\{\frac{8\pi^2}{(\omega LB - RG) + \sqrt{(RG - \omega LB)^2 + (\omega LG + BR)^2}}\right\}^{\frac{1}{2}} \text{ (m)} \tag{15.40}$$

The phase velocity of transverse electromagnetic (TEM) waves on a lossless two-wire line is

$$v_0 = f\lambda_0 = \frac{\omega}{\beta_0} = \frac{1}{\sqrt{LC}} \text{ (m/s)} \tag{15.41}$$

The phase velocity of TEM waves on a lossy two-wire line is

$$v = f\lambda = \frac{\omega}{\beta} = \left\{\frac{2\omega^2}{(\omega LB - RG) + \sqrt{(RG - \omega LB)^2 + (\omega LG + BR)^2}}\right\}^{\frac{1}{2}} \text{ (m/s)} \tag{15.42}$$

15.3 Coaxial Lines

15.3.1 Geometric Structure

A generic configuration of a coaxial line is shown in Figure 15.4. The center and outer conductors are coaxially situated and separated by a coaxial insulator. Generally, coaxial lines are operated in the TEM mode, in which both the electric and magnetic fields are perpendicular to the direction of propagation. The propagating electric fields are in the radial direction and propagating magnetic fields are circumferential to the cylindrical surfaces.

In Figure 15.4, a is the radius of the center conductor, b is the inner radius of the outer conductor, and c is the outer radius of the outer conductor.

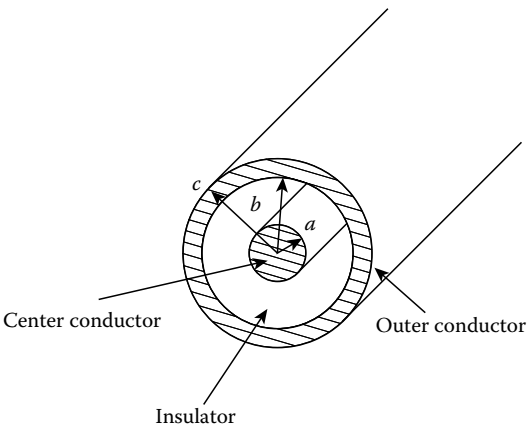

FIGURE 15.4 Generic configuration of a coaxial line.

15.3.2 Transmission Line Parameters

The series resistance per unit length of the line for copper is [7],

$$R = 4.16\sqrt{f}\left(\frac{1}{a} + \frac{1}{b}\right) \text{ } (\mu\Omega/\text{m}) \tag{15.43}$$

The series inductance per unit length is

$$L = 0.2 \ \ln\frac{b}{a} \ (\mu\text{H/m}) \tag{15.44}$$

The shunt conductance per unit length is

$$G = \frac{6.28\sigma_i}{\ln(b/a)} \ (\text{S/m}) \tag{15.45}$$

where σ_i is the conductivity of the *insulator* between the conductors. The shunt capacitance per unit length is

$$C = \frac{55.5\varepsilon_r}{\ln(b/a)} \ (\text{pF/m}) \tag{15.46}$$

where ε_r is the relative permittivity of the insulator. When the loss of the line is small, the characteristic impedance of the coaxial line is

$$Z_0 = \frac{138}{\sqrt{\varepsilon_r}} \ \log_{10}\frac{b}{a} \ (\Omega) \tag{15.47}$$

when the line is lossy [1]

$$\dot{Z}_0 = \sqrt{\frac{\dot{Z}}{\dot{Y}}} = \sqrt{\frac{R + j\omega L}{G + j\omega C}} = R_0 + jX_0 \tag{15.48}$$

$$R_0 = \frac{\left\{RG + \omega^2 LC + \sqrt{(RG + \omega^2 LC)^2 + (\omega LG - \omega RC)^2}\right\}^{\frac{1}{2}}}{\sqrt{G^2 + \omega^2 C^2}} \tag{15.49}$$

$$X_0 = \frac{1}{2R_0} \cdot \frac{\omega LG - \omega CR}{G^2 + \omega^2 C^2} \tag{15.50}$$

The propagation constant of the coaxial line is

$$\dot{\gamma} = \alpha + j\beta \tag{15.51}$$

The attenuation constant is [1]

$$\alpha = \frac{\omega LG + \omega CR}{2\beta} \tag{15.52}$$

where the phase constant is

$$\beta = \left\{\frac{(\omega^2 LC - RG) + \sqrt{(RG - \omega^2 LC)^2 + (\omega LG + \omega RC)^2}}{2}\right\}^{\frac{1}{2}} \tag{15.53}$$

15.3.3 Wavelength and Phase Velocity

The phase velocity on the coaxial line is

$$v_p = \frac{\omega}{\beta} \tag{15.54}$$

The wavelength on the line is

$$\lambda_1 = \frac{2\pi}{\beta} \tag{15.55}$$

15.4 Waveguides

15.4.1 Rectangular Waveguides

15.4.1.1 Geometric Structure

A rectangular waveguide is a hollow conducting pipe of rectangular cross section as depicted in Figure 15.5. Electromagnetic microwaves are launched inside the waveguide through a coupling antenna at the transmission site. The launched waves are received at the receiving end of the waveguide by a coupling antenna. In this case, a rectangular coordinate system is set up on the rectangular waveguide (Figure 15.5). The *z*-axis is parallel to the axis of the waveguide and is set coinciding with the lower left corner of the waveguide. The wider dimension of the cross section of the waveguide *a* and the narrower dimension of the cross section of the waveguide is *b*, as shown in the figure.

15.4.1.2 Modes of Operation

The waveguide can be operated in either *H*- or *E*-mode, depending on the excitation configuration. An *H*-mode is a propagation mode in which the magnetic field, *H*, has a *z*-component, *Hz*, as referred to in

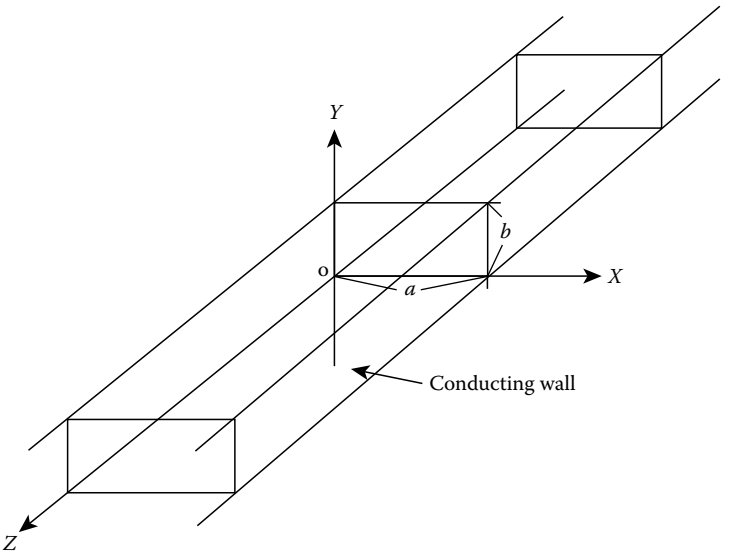

FIGURE 15.5 A rectangular waveguide and rectangular coordinate system.

Figure 15.5. In this mode, the electric field, E, is perpendicular to the direction of propagation, which is the $+z$-direction. Therefore, an H-mode is also called a transverse electric (TE) mode. An E-mode is a propagation mode in which the electric field, E, has a z-component, E_z, as referred to in Figure 15.5. In this mode, the magnetic field, H, is perpendicular to the direction of propagation, which is the $+z$-direction. Therefore, an E-mode is also called a transverse magnetic (TM) mode.

Solving Maxwell's equations for H-modes [1],

$$\dot{H}_z = \dot{H}_0 \cos\frac{m\pi x}{a} \cos\frac{n\pi y}{b} \varepsilon^{-\dot{\gamma}z+j\omega t} \tag{15.56}$$

where $|\dot{H}_0|$ is the amplitude of $\dot{H}_z$. Waveguide loss was neglected. Constants m and n are integral numbers 0, 1, 2, 3, ... and are called the mode number, and $\dot{\gamma}$ is the propagation constant. Both m and n cannot equal 0 simultaneously. Solving Maxwell's equations for E-modes [1],

$$\dot{E}_z = \dot{E}_0 \sin\frac{m\pi x}{a} \sin\frac{n\pi y}{b} \varepsilon^{-\dot{\gamma}z+j\omega t} \tag{15.57}$$

where $|\dot{E}_0|$ is the amplitude of $\dot{E}_z$. Neither m nor n can equal 0. The waveguide loss was neglected.

An H-mode is expressed as the H_{mn}-mode or TE_{mn}-mode. An E-mode is expressed as the E_{mn}- or TM_{mn}-mode.

15.4.2 Waveguide Parameters

Propagation constant $\dot{\gamma}$ of a rectangular waveguide made of a good conductor [1]:

$$\dot{\gamma} = j\beta_0\sqrt{1-\left(\frac{\lambda}{\lambda_c}\right)^2} \ (\mathrm{m}^{-1}) \tag{15.58}$$

where β_0 is the phase constant of free space, which is

$$\beta_0 = \frac{2\pi}{\lambda} \ (\mathrm{m}^{-1}) \tag{15.59}$$

where

λ is the wavelength in free space

λ_c is the cutoff wavelength of the waveguide

Electromagnetic waves with $\lambda > \lambda_c$ cannot propagate inside the waveguide. It is given for both E_{mn}-mode and H_{mn}-mode operation by [1]

$$\lambda_c = \frac{2}{\sqrt{\left(\frac{m}{a}\right)^2+\left(\frac{n}{b}\right)^2}} \ (\mathrm{m}) \tag{15.60}$$

This means that if the waveguide is made of a good conductor, the attenuation constant

$$\alpha \approx 0 \ (\mathrm{m}^{-1}) \tag{15.61}$$

and the phase constant is

$$\beta_g = \beta_0\sqrt{1-\left(\frac{\lambda}{\lambda_c}\right)^2} \tag{15.62}$$

The wavelength in the waveguide, i.e., waveguide wavelength λ_g, is longer than the free-space wavelength λ:

$$\lambda_g = \frac{\lambda}{\sqrt{1 - \left(\frac{\lambda}{\lambda_c}\right)^2}} \tag{15.63}$$

Then, the speed of propagation $v_p > c = f\lambda$.

$$v_p = f\lambda_g = \frac{f\lambda}{\sqrt{1 - \left(\frac{\lambda}{\lambda c}\right)^2}} = \frac{c}{\sqrt{1 - \left(\frac{\lambda}{\lambda c}\right)^2}} \tag{15.64}$$

For an H_{mn}-mode, the wave impedance is

$$\eta_H = \frac{-\dot{E}_y}{\dot{H}_x} = \frac{\dot{E}_x}{\dot{H}_y} = \frac{\sqrt{\frac{\mu_0}{\varepsilon_0}}}{\sqrt{1 - \left(\frac{\lambda}{\lambda_c}\right)^2}} \ (\Omega) \tag{15.65}$$

For an E_{mn}-mode the wave impedance is

$$\eta_E = \frac{-\dot{E}_y}{\dot{H}_x} = \frac{\dot{E}_x}{\dot{H}_y} = \sqrt{1 - \left(\frac{\lambda}{\lambda_c}\right)^2} \Big/ \sqrt{\frac{\mu_0}{\varepsilon_0}} \ (\Omega) \tag{15.66}$$

15.4.3 Circular Waveguides

15.4.3.1 Geometric Structure

A circular waveguide is a hollow conducting pipe of circular cross section, as depicted in Figure 15.6. Electromagnetic microwaves are launched inside the waveguide through a coupling antenna at the transmission site. The launched waves are received at the receiving end of the waveguide by a coupling

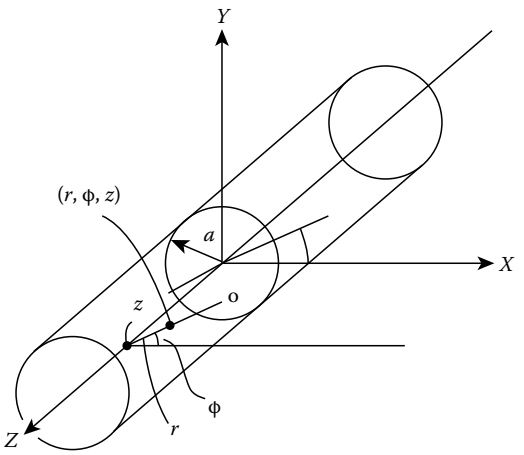

FIGURE 15.6 A circular waveguide and cylindrical coordinate system.

antenna. In this case, a circular coordinate system (r, ϕ, z) is set up in the circular waveguide, as depicted in Figure 15.6. The z-axis is coincident with the axis of the cylindrical waveguide. The inside radius of the circular waveguide is a.

15.4.3.2 Modes of Operation

The circular waveguide can be operated in either H- or E-mode, depending on the excitation configuration. An H-mode is a propagation mode in which the magnetic field, H, has a z-component, H_z, as referred to in Figure 15.6. In this mode the electric field, E, is perpendicular to the direction of propagation, which is the $+z$-direction. Therefore, an H-mode is also called a TE mode. In the mode $E_z = 0$. An E-mode is a propagation mode in which the electric field, E, has a z-component, E_z, as referred to in Figure 15.6. In this mode the magnetic field, H, is perpendicular to the direction of propagation, which is the $+z$-direction. Therefore, an E-mode is also called a TM mode.

Solving Maxwell's equations [1],

$$\dot{H}_z = \dot{H}_0 J_n\left(k'_{cm} r\right) \cos n\phi \varepsilon^{-\dot{\gamma}z + j\omega t} \tag{15.67}$$

where

$|\dot{H}_0|$ is the amplitude of $\dot{H}_z$

n and m are integral numbers 0, 1, 2, 3, ... and are called the mode number

$J_n(k'_{cm}r)$ is the Bessel function of nth order, with the argument that $k'_{cm}r$

k'_{cm} is the mth root of $J'_n(k_{cm}a) = 0$, which is

$$k'_{cm} = \frac{u'_{nm}}{a} \tag{15.68}$$

where u'_{nm} is the mth root of the derivative of the Bessel function of order n, i.e., $J'_n(x) = 0$, where x is a generic real argument. The propagation constant is $\dot{\gamma}$.

Solving Maxwell's equations for E-modes,

$$\dot{E}_z = \dot{E}_0 J_n(k_{cm} r) \cos n\phi \varepsilon^{-\dot{\gamma}z + j\omega t} \tag{15.69}$$

k_{cm} is an mth root of $J_n(k_c a) = 0$, which is

$$k_{cm} = \frac{u_{nm}}{a} \tag{15.70}$$

where u_{nm} is the mth root of the Bessel function of order n, i.e., $J_n(x) = 0$, where x is a generic real argument.

An H-mode in a circular waveguide is expressed as the H_{nm}-mode or the TM_{nm}-mode. An E-mode is expressed as the E_{nm}-mode or the TM_{nm}-mode.

15.4.3.3 Waveguide Parameters

The propagation constant $\dot{\gamma}$ of a circular waveguide made of a good conductor is [1]

$$\dot{\gamma} = j\beta_0 \sqrt{1 - \left(\frac{\lambda}{\lambda_c}\right)} \ (\mathrm{m}^{-1}) \tag{15.71}$$

where β_0 is the phase constant of free space, which is

$$\beta_0 = \frac{2\pi}{\lambda} \ (\mathrm{m}^{-1}) \tag{15.72}$$

where
λ is the wavelength in free space
λ_c is the cutoff wavelength of the waveguide

Electromagnetic waves with $\lambda > \lambda_c$ cannot propagate inside the waveguide. It is given for an H_{nm}-mode [1]

$$\lambda_{CH} = \frac{2\pi a}{u'_{nm}} \ (\mathrm{m}) \tag{15.73}$$

For E_{nm}-mode operation,

$$\lambda_{CE} = \frac{2\pi a}{u_{nm}} \ (\mathrm{m}) \tag{15.74}$$

This means that if the waveguide is made of a good conductor, the attenuation constant is

$$\alpha \approx 0 \ (\mathrm{m}^{-1}) \tag{15.75}$$

and the phase constant is

$$\beta_g = \beta_0 \sqrt{1 - \left(\frac{\lambda}{\lambda_c}\right)^2} \ (\mathrm{m}^{-1}) \tag{15.76}$$

The waveguide wavelength is

$$\lambda_g = \frac{\lambda}{\sqrt{1 - \left(\frac{\lambda}{\lambda_c}\right)^2}} \ (\mathrm{m}^{-1}) \tag{15.77}$$

The speed of propagation (phase velocity) is

$$v_p = f\lambda_g = \frac{c}{\sqrt{1 - \left(\frac{\lambda}{\lambda_c}\right)^2}} \ (\mathrm{m/s}) \tag{15.78}$$

For an H_{nm}-mode, the wave impedence is

$$\begin{aligned} \eta_H &= \frac{\dot{E}_r}{\dot{H}_\phi} = \frac{-\dot{E}\phi}{\dot{H}_r} = \frac{j\omega\mu_0}{\dot{\gamma}} \\ &= \frac{\omega\mu_0}{\beta_0 \sqrt{1 - \left(\frac{\lambda}{\lambda_c}\right)^2}} \ (\Omega) \end{aligned} \tag{15.79}$$

For an E_{nm}-mode, the wave impedance is

$$\eta_E = \frac{\dot{E}_r}{\dot{H}_\phi} = \frac{-\dot{E}_\phi}{\dot{H}_r} = \frac{\dot{\gamma}}{j\omega\varepsilon_0} = \frac{\beta_0\sqrt{1-\left(\frac{\lambda}{\lambda_c}\right)^2}}{\omega\varepsilon_0}\ (\Omega) \tag{15.80}$$

15.5 Microstrip Lines

15.5.1 Geometric Structure

Figure 15.7 presents a general geometric structure of a microstrip line. A conducting strip of width, w, and thickness, t, is laid on an insulating substrate of thickness, H, and permittivity, $\varepsilon = \varepsilon_0\varepsilon_r$. The dielectric substrate has a groundplate underneath, as presented in Figure 15.7.

15.5.2 Transmission Line Parameters

The characteristic impedance, Z_0, of a microstrip line, as shown in Figure 15.7, is given by [8–10]

$$Z_0 = \frac{42.4}{\sqrt{\varepsilon_r+1}}\ln\left\{1+\left(\frac{4H}{w'}\right)\left[\left(\frac{14+8/\varepsilon_r}{11}\right)\left(\frac{4H}{W'}\right)+\sqrt{\left(\frac{14+8\varepsilon_r}{11}\right)^2\left(\frac{4H}{w'}\right)+\frac{1+1/\varepsilon_r}{2}\pi^2}\right]\right\} \tag{15.81}$$

where w' is an effective width of the microstrip, which is given by

$$w' = w + \frac{1+1/\varepsilon_r}{2}\cdot\frac{t}{\pi}\ln\frac{10.87}{\sqrt{\left(\frac{t}{H}\right)^2+\left(\frac{1/\pi}{w/t+1.10}\right)^2}} \tag{15.82}$$

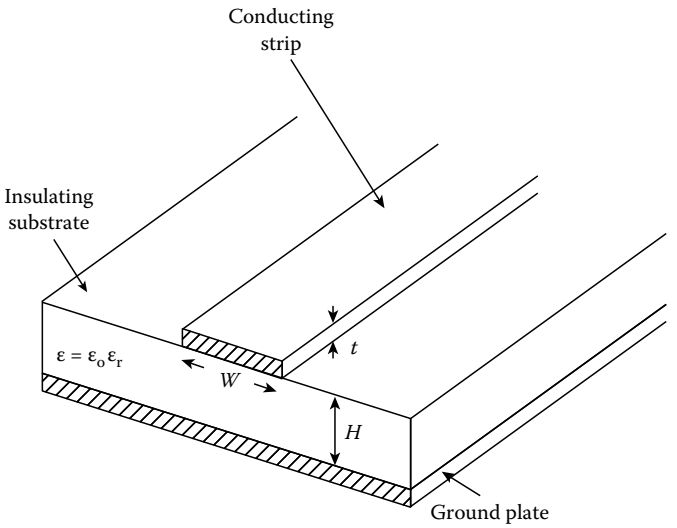

FIGURE 15.7 Geometric structure of a microstrip line.

The attenuation constant of a microstrip line is

$$\alpha = \frac{p + p'}{2} \frac{Z_{01}}{Z_0} \frac{2\pi}{\lambda_0} \text{ (Np/m)} \tag{15.83}$$

where

$$Z_{01} \equiv 30 \ \ln \left\{ 1 + \frac{1}{2} \left(\frac{8H}{w'} \right) \left[\frac{8H}{w'} + \sqrt{\left(\frac{8H}{w'} \right)^2 + \pi^2} \right] \right\} \tag{15.84}$$

and

$$p \equiv 1 - \frac{Z_{01}}{Z_{0\delta}} \tag{15.85}$$

where

$$Z_{0\delta} \equiv 30 \ \ln \left\{ 1 + \frac{1}{2} \left(\frac{8(H + \delta)}{w'} \right) \left[\frac{8H + \delta)}{w'} + \sqrt{\left(\frac{8H + \delta}{w'} \right)^2 + \pi^2} \right] \right\} \tag{15.86}$$

and

$$\delta = \frac{1}{\sqrt{\pi f \mu \sigma}} \tag{15.87}$$

is the skin depth of the conducting strip of conductivity σ

$$p' \equiv \frac{P_k}{1 - \frac{1/q - 1}{\varepsilon_r}} \tag{15.88}$$

where

$$\varepsilon_r = \varepsilon_r' - j\varepsilon_r'' \tag{15.89}$$

and

$$P_K = \sin \left[\tan^{-1} \frac{\varepsilon_r''}{\varepsilon_r'} \right] \tag{15.90}$$

and

$$q = \frac{1}{\varepsilon_r - 1} \left[\left(\frac{Z_{01}}{Z_0} \right)^2 - 1 \right] \tag{15.91}$$

15.5.3 Wavelength and Phase Velocity

The transmission line wavelength is

$$\lambda_1 = \frac{Z_0}{Z_{01}}\lambda_0 \tag{15.92}$$

The phase constant of the microstrip line is then

$$\beta = \frac{2\pi}{\lambda_0}\frac{Z_{01}}{Z_0} \tag{15.93}$$

The phase velocity of electromagnetic waves on the microstrip line is

$$v_p = 3 \times 10^8 \frac{Z_0}{Z_{01}} \tag{15.94}$$

15.6 Coplanar Waveguide

15.6.1 Geometric Structure

A cross-sectional view of a coplanar waveguide (CPW) is given in Figure 15.8. The waveguide consists of a narrow, central conducting strip of width $s(m)$ and very wide conducting plates on both sides of the central conducting strip, with gap widths w. These conductors are developed on a surface of dielectric substrate of thickness d, as presented in Figure 15.8. The electromagnetic waves propagate in the gap between the outer conducting plates and the center conducting strip.

15.6.2 Transmission Line Parameters

The attenuation constant of a CPW is given by [11]

$$\alpha = \left(\frac{\pi}{2}\right)^5 \cdot 2 \cdot \frac{1 - \frac{\varepsilon_{\text{eff}(f)}}{\varepsilon_r}}{\sqrt{\frac{\varepsilon_{\text{eff}(f)}}{\varepsilon_r}}} \cdot \frac{(s+2w)^2 \varepsilon_r^{3/2}}{c^3 K'(k) K(k)} \text{ (Np/m)} \tag{15.95}$$

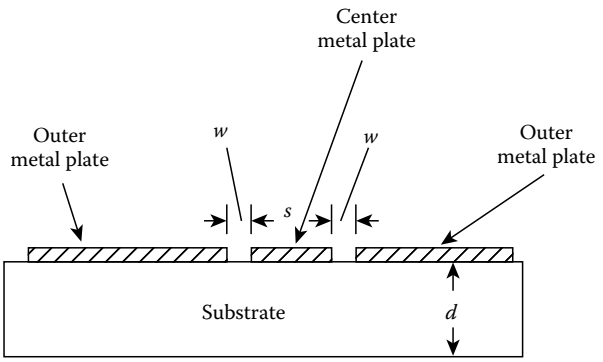

FIGURE 15.8 Cross-sectional view of a CPW.

where the effective dielectric constant is given by

$$\sqrt{\varepsilon_{\text{eff}}(f)} = \sqrt{\varepsilon_q} + \frac{\sqrt{\varepsilon_{\text{r}}} - \sqrt{\varepsilon_q}}{1 + a\left(\frac{f}{f_{\text{TE}}}\right)^{-b}} \tag{15.96}$$

and

$$\varepsilon_q = \frac{\varepsilon_{\text{r}} + 1}{2} \tag{15.97}$$

ε_{r} is the relative permittivity of the substrate material,

$$f_{\text{TE}} = \frac{c}{4d\sqrt{\varepsilon_{\text{r}} - 1}} \tag{15.98}$$

is the TE mode cutoff frequency,

$$k \equiv s/(s + 2w) \tag{15.99}$$

$K(k)$ is the complete elliptic integral of the first kind of the argument k, and c is the speed of light in vacuum, which is 3×10^8 m/s. The parameter a is [11]

$$a \approx \log^{-1}\left[u \log\frac{s}{w} + v\right] \tag{15.100}$$

$$u \approx 0.54 - 0.64q + 0.015q^2 \tag{15.101}$$

$$v \approx 0.43 - 0.86q + 0.54q^2 \tag{15.102}$$

$$q \approx \log\frac{s}{d} \tag{15.103}$$

The parameter b is an experimentally determined constant

$$b \approx 1.8 \tag{15.104}$$

$$K'(k) = K\left(\sqrt{1 - k^2}\right) \tag{15.105}$$

The phase constant of the CPW is

$$\beta(f) = 2\pi\frac{f}{c}\sqrt{\varepsilon_{\text{eff}}(f)}\ (\text{rad/m}) \tag{15.106}$$

The characteristic impedance of the CPW is [11]

$$Z_0 = \frac{120\pi}{\sqrt{\varepsilon_{\text{eff}}(f)}}\ \frac{K'(k)}{4K(k)}\ (\Omega) \tag{15.107}$$

15.6.3 Wavelength and Phase Velocity

The wavelength of electromagnetic waves propagating on a CPW is obtained from Equation 15.106:

$$\lambda_l = \frac{2\pi}{\beta(f)} = \frac{c}{f} \cdot \frac{1}{\sqrt{\varepsilon_{\text{eff}}}(f)} = \frac{\lambda}{\sqrt{\varepsilon_{\text{eff}}(f)}} \text{ (m)} \tag{15.108}$$

The phase velocity of the waves on the CPW is, then,

$$v_{\text{p}} = f\lambda_1 = \frac{c}{\sqrt{\varepsilon_{\text{eff}}(f)}} \text{ (m/s)} \tag{15.109}$$

16.1 Introduction: Frequency versus Time Domain Analysis

Multiconductor transmission lines (MTL), or multiconductor buses as they are also often called, are found in almost every electrical packaging technology and on every technology level from digital chips, over MMICs (monolithic microwave integrated circuits) to MCMs (multichip modules), boards, and backplanes. MTL are electrical conducting structures with a constant cross section (the x-, y-plane) which propagates signals in the direction perpendicular to that cross section (the z-axis) (see also Figure 16.1). Being restricted to a constant cross section we are in fact dealing with the so-called uniform MTL. The more general case using a nonuniform cross section is much more difficult to handle and constitutes a fully three-dimensional problem.

It is not the purpose of this chapter to give a detailed account of the physical properties and the use of the different types of MTL. The literature on this subject is abundant and any particular reference is bound to be both subjective and totally incomplete. Hence, we put forward only Refs. [1–3] as references here, as they contain a wealth of information and additional references.

In the frequency domain, i.e., for harmonic signals, solution of Maxwell's sourceless equations yields a number of (evanescent and propagating) modes characterized by modal propagation factors $\exp(\pm j \cdot \beta z)$ and by a modal field distribution, which depends only upon the (x, y) coordinates of the cross section. In the presence of losses and for evanescent modes β can take complex values, and $j\beta$ is then replaced by $\gamma = \alpha + j\beta$ (see Equation 16.3). In the propagation direction, the modal field amplitudes essentially behave as voltage and current along a transmission line. This immediately suggests that MTL should be represented on the circuit level by a set of coupled circuit transmission lines. The relationship between the typical circuit quantities, such as voltages, currents, coupling impedances, and signal velocities, on the one hand, and the original field quantities (modal fields and modal propagation factors) is not straightforward [4]. In general, the circuit quantities will be frequency dependent. The frequency domain circuit model parameters can be used as the starting point for time domain analysis of

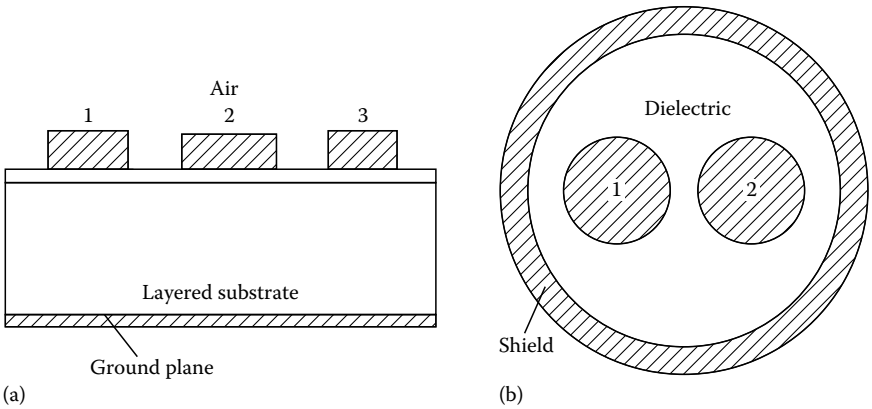

FIGURE 16.1 Two examples of cross sections of multiconductor lines.

networks, including multiconductor lines. This is, again, a vast research topic with important technical applications.

Section 16.2 describes the circuit modeling in the frequency domain of uniform MTL based on the Telegrapher's equations. The meaning of the voltages and currents in these equations is explained both at lower frequencies in which the quasi transverse electromagnetic (TEM) approach is valid as well as in the so-called full-wave regime valid for any frequency. The notions TEM, quasi-TEM, and full wave are elucidated. We introduce the capacitance, inductance, resistance, and conductance matrices together with the characteristic impedance matrix of the coupled transmission line model. Finally, for some simple MTL configurations analytical formulas are presented expressing the previous quantities and the propagation factors as a function of the geometric and electrical parameters of these configurations.

It would be a formidable task to give a comprehensive overview of all the methods that are actually used for the time domain analysis of MTL. In the remaining part of this paragraph a very short overview (both for uniform and nonuniform structures) is presented along with some references. In the case of linear loads and drivers, frequency domain methods in combination with (fast) Fourier transform techniques are certainly most effective [5–7]. In the presence of nonlinear loads and drivers other approaches must be used. Simulations based on harmonic balance techniques [8,9] are, again, mainly frequency domain methods. All signals are approximated by a finite sum of harmonics and the nonlinear loads and drivers are taken into account by converting their time domain behavior to the frequency domain. Kirchhoff laws are then imposed for each harmonic in an iterative way. Harmonic balance techniques are not very well suited for transient analysis or in the presence of strong nonlinearities, but are excellent for mixers, amplifiers, filters, etc. Many recent efforts were directed toward the development of time domain simulation methods (for both uniform and nonuniform interconnection structures) based on advanced convolution-type approaches. It is, of course, impossible to picture all the ramifications in this research field. We refer the reader to a recent special issue of *IEEE Circuits and Systems Transactions* [10], to the ''Simulation techniques for passive devices and structures'' section of a special issue of *IEEE Microwave Theory and Techniques Transactions* [11], and to a 1994 special issue of the *Analog Integrated Circuits and Signal Processing Journal* [12] and to the wealth of references therein.

Both frequency and time domain experimental characterization techniques for uniform and nonuniform multiconductor structures can be found in Chapter 17.

16.2 Telegrapher's Equations for Uniform Multiconductor Transmission Lines

16.2.1 Generalities

Figures 10.1a and b show the cross sections of two general coupled lossy MTLs consisting of $N+1$ conductors. These conductors either can be perfectly conducting or exhibit finite conductivity. Their cross section remains constant along the propagation or longitudinal direction z. The $(N+1)$th conductor is taken as reference conductor. In many practical cases, this will be the ground plane at the top or bottom (Figure 16.1a) of the layered dielectric in which the conductors are embedded or is the shielding surrounding the other conductors (Figure 16.1b). We restrict the analysis to the frequency domain, i.e., all field components and all voltages and currents have a common time dependence, exp $(j\omega t)$, which is suppressed in the sequel. The generalized Telegrapher's equations governing the circuit representation of the MTL of Figure 16.1 in terms of a set of C-coupled circuit transmission lines is given by Ref. [4]:

$$\begin{aligned} \frac{\mathrm{d}\mathbf{V}}{\mathrm{d}z} + \mathbf{Z}\mathbf{I} &= 0 \\ \frac{\mathrm{d}\mathbf{I}}{\mathrm{d}z} + \mathbf{Y}\mathbf{V} &= 0 \end{aligned} \tag{16.1}$$

where

- $\mathbf{V}$ and $\mathbf{I}$ are column vectors, the C elements of which are the voltages and currents of the circuit model
- $\mathbf{Z}$ and $\mathbf{Y}$ are the $C \times C$ impedance and admittance matrices

Equation 16.1 is a good circuit description of the wave phenomena along a MTL if only the fundamental modes of the corresponding field problem are of importance. In that case $C = N$ ($C = 3$ in Figure 16.1a and $C = 2$ in Figure 16.1b) if a ground plane is present, and $C = N - 1$ in the absence of a ground plane. For the relationship between the actual electromagnetic field description in terms of modes and the circuit model (Equation 16.1), we refer the reader to Refs. [4,13]. The general solution to Equation 16.1 is given by

$$\begin{aligned} \mathbf{V}(z) &= 2\left(\mathbf{I}_{\mathrm{m}}^{\mathrm{T}}\right)^{-1} e^{-j\boldsymbol{\beta}z}\mathbf{K}^{+} + 2\left(\mathbf{I}_{\mathrm{m}}^{\mathrm{T}}\right)^{-1} e^{j\boldsymbol{\beta}z}\mathbf{K}^{-} \\ \mathbf{I}(z) &= \mathbf{I}_{\mathrm{m}} e^{-j\boldsymbol{\beta}z}\mathbf{K}^{+} - \mathbf{I}_{\mathrm{m}} e^{j\boldsymbol{\beta}z}\mathbf{K}^{-} \end{aligned} \tag{16.2}$$

where

- $\mathbf{K}^{+}$ and $\mathbf{K}^{-}$ are column vectors with C elements
- $\boldsymbol{\beta}$ is a diagonal $C \times C$ matrix with the propagation factors β_f ($f = 1, 2, \ldots, C$) of the C fundamental eigenmodes as diagonal elements

This matrix $\boldsymbol{\beta}$ reduces to a single propagation factor for a single transmission line (see Equation 15.6). For the calculation of the fields and of the propagation constants many different methods can be found in the literature [14]. Solution (Equation 16.2) of the differential equations (Equation 16.1) is the extension of the corresponding Equation 15.5 for a single transmission line to the coupled line case. It also consists of waves respectively traveling in positive and negative z-directions. The $\mathbf{I}_{\mathrm{m}}$ is a $C \times C$ matrix, the columns of which are the current eigenvectors of the circuit model. The following relationships hold:

$$\begin{aligned}\mathbf{Z} &= j\omega\mathbf{L} + \mathbf{R} = 2j\left(\mathbf{I}_{\mathrm{m}}^{\mathrm{T}}\right)^{-1}\beta(\mathbf{I}_{\mathrm{m}})^{-1}\\ \mathbf{Y} &= j\omega\mathbf{C} + \mathbf{G} = \frac{j}{2}\mathbf{I}_{\mathrm{m}}\beta\mathbf{I}_{\mathrm{m}}^{\mathrm{T}}\end{aligned} \tag{16.3}$$

L, **R**, **C**, and **G** are the $C \times C$ (frequency-dependent) inductance, resistance, capacitance, and conductance matrices. The $C \times C$ characteristic impedance matrix of the transmission line models is given by $Z_{\mathrm{char}} = 2\left(\mathbf{I}_{\mathrm{m}}^{\mathrm{T}}\right)^{-1}(\mathbf{I}_{\mathrm{m}})^{-1}$. The matrix $\mathbf{Z}_{\mathrm{char}}$ replaces the simple characteristic impedance number of Equation 15.9. In general the mapping of the wave phenomenon onto the circuit model equations (Equations 16.1 through 16.3) depends on the choice of $\mathbf{I}_{\mathrm{m}}$. We refer the reader to the detailed discussions in Ref. [4]. For MTLs the most adopted definition for the elements of $\mathbf{I}_{\mathrm{m}}$ is [15]

$$I_{\mathrm{m},jf} = \oint_{\mathrm{c}_j} \mathbf{H}_{\mathrm{tr},f} \cdot \mathrm{d}\mathbf{l}, \quad j, f = 1, 2, \ldots, C \tag{16.4}$$

where

c_j is the circumference of conductor j

$\mathbf{H}_{\mathrm{tr},f}$ is the transversal component of the magnetic field of eigenmode f

This means that $I_{\mathrm{m},jf}$ is the total current through conductor j due to eigenmode f. This definition is used in the power-current impedance definition for microstrip and stripline problems [9]. For slotline circuits, a formulation that parallels the one given above must be used, but in this case it makes much more sense to introduce the voltage eigenvectors and to define them as line integrals of the electric field (see Appendix B of Ref. [16]).

As **Z** and **Y** in Equation 16.3 are frequency dependent, the time domain equivalent of Equation 16.1 involves convolution integrals between **Z** and **I** on the one hand and **Y** and **V** on the other hand. The propagation factors β_f are also frequency dependent, hence the signal propagation will show dispersion, i.e., the signal waveform becomes distorted while propagating.

16.2.2 Low-Frequency or Quasitransverse Electromagnetic Description

In the previous section, the reader was given a very general picture of the MTL problem, valid for any frequency. This analysis is the so-called full-wave analysis. The present section is restricted to the low-frequency or quasistatic regime. Here, the cross section of the MTL is small with respect to the relevant wavelengths, the longitudinal field components can be neglected and the transversal field components can be found from the solution of an electrostatic or magnetostatic problem in the cross section of the MTL. A detailed discussion of the theoretical background can be found in Ref. [17]. In the quasi-TEM limit and in the absence of losses **R** and **G** are zero and **L** and **C** become frequency independent and take their classical meaning. Both skin-effect losses and small dielectric losses can be accounted for by a perturbation approach [18]. In that case a frequency dependent **R** and **G** must be reintroduced. If **R** and **G** are zero and **L** and **C** are frequency independent, the following Telegrapher's equations hold:

$$\begin{aligned}\frac{\partial \mathbf{v}}{\partial z} &= -\mathbf{L} \cdot \frac{\partial \mathbf{i}}{\partial t}\\ \frac{\partial \mathbf{i}}{\partial z} &= -\mathbf{C} \cdot \frac{\partial \mathbf{v}}{\partial t}\end{aligned} \tag{16.5}$$

Equation 16.5 is the time domain counterpart of Equation 16.1. We have replaced the capital letters for voltages and currents with lower case letters to distinguish between time and frequency domains. **L** and **C** are related to the total charge Q_i per unit length carried by each conductor and to the total magnetic flux F_i between each conductor and the reference conductor:

$$\mathbf{Q} = \mathbf{C} \cdot \mathbf{V}$$
$$\mathbf{F} = \mathbf{L} \cdot \mathbf{I} \tag{16.6}$$

where $\mathbf{Q}$ and $\mathbf{F}$ are $C \times 1$ column vectors with elements Q_i and F_i, respectively. For a piecewise homogeneous medium, one can prove that the inductance matrix $\mathbf{L}$ can be derived from an equivalent so-called vacuum capacitance matrix $\mathbf{C}_v$ with $\mathbf{L} = \mathbf{C}_v^{-1}$ and where $\mathbf{C}_v$ is calculated in the same way as $\mathbf{C}$, but with the piecewise constant ε everywhere replaced by the corresponding value of $1/\mu$. For nonmagnetic materials, this operation corresponds with taking away all dielectrics and working with vacuum, thus explaining the name of the matrix $\mathbf{C}_v$. Other properties of $\mathbf{C}$ and $\mathbf{L}$ are

$\mathbf{C}$ and $\mathbf{L}$ are symmetric, i.e., $C_{ij} = C_{ji}$ and $L_{ij} = L_{ji}$.
$\mathbf{C}$ is real, $C_{ii} > 0$ and $C_{ij} < 0$ $(i \neq j)$.
$\mathbf{l}$ is real, $L_{ii} > 0$ and $L_{ij} > 0$.

The propagation factors β_f which form the elements of β in Equation 16.2 are now given by the eigenvalues of $(\mathbf{LC})^{1/2}$ or equivalently of $(\mathbf{CL})^{1/2}$. The current eigenvectors which form the columns of $\mathbf{I}_m$ are now solutions of the following eigenproblem (where ω is the circular frequency):

$$\omega^2(\mathbf{CL})\mathbf{I} = (\beta_f)^2\mathbf{I} \tag{16.7}$$

The corresponding eigenvoltages are solutions of

$$\omega^2(\mathbf{LC})\mathbf{V} = (\beta_f)^2\mathbf{V} \tag{16.8}$$

Hence, corresponding voltage and current eigenmodes propagate with the same propagation factors and as $\mathbf{L}$, $\mathbf{C}$, $\mathbf{V}$, and $\mathbf{I}$ are frequency independent, β_f is proportional with ω and can be rewritten as $\beta_f = \omega\beta'_f$ proving that the propagation is nondispersive with velocity $v_f = 1/\beta'_f$. Remember that the subindex f takes the values 1, 2,..., C, i.e., for a three-conductor problem above a ground plane ($N = C = 3$, see Figure 16.1a), three distinct propagation factors and corresponding eigenmode profiles exist for currents and voltages. Note, however, that for the same β_f the eigenvector for the currents differs from the eigenvector of the voltages.

We conclude this section by remarking that, for MTL embedded in a homogeneous medium (such as the simple stripline or the coaxial cable with homogeneous filling), $(LC) = \varepsilon\mu\mathbf{1}$, where $\mathbf{1}$ is the unity matrix. Thus, the eigenmodes are purely TEM, i.e., electric and magnetic fields have only transversal components and the longitudinal ones are exactly zero. All propagation factors β_f take the same value $[c/(\varepsilon, \mu_r)^{1/2}]$, where c is the velocity of light in vacuum. Note, however, that even for identical β_f different eigenmodes will be found.

Numerical calculation of $\mathbf{L}$ and $\mathbf{C}$ can be performed by many different numerical methods (see the reference section of [18]), and for sufficiently simple configurations analytical formulas are available. For a line with one conductor and a ground plane ($N = C = 1$) the characteristic impedance $Z_0 = (L/C)^{1/2}$ and the signal velocity v_p is $v_p = (LC)^{-1/2}$.

16.2.3 Analytical Expressions for Some Simple Multiconductor Transmission Line Configurations

16.2.3.1 Symmetric Stripline

Sections 15.3 through 15.6 presented a number of MTL consisting of a single conductor and a ground plane ($N = C = 1$). Here, we add another important practical example, the symmetric stripline configuration of Figure 16.2. We restrict ourselves to the lossless case. A perfectly conducting strip of width w and

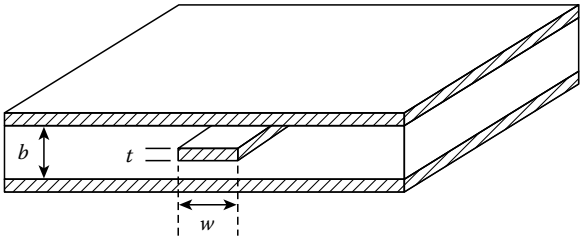

FIGURE 16.2 Stripline configuration.

thickness t is symmetrically placed between two perfectly conducting ground planes with spacing b. The insulating substrate has a permittivity $\varepsilon = \varepsilon_0\varepsilon_r$, and is nonmagnetic. This case has a single fundamental mode. The characteristic impedance Z_0 is given by Ref. [19]:

$$Z_0\sqrt{\varepsilon_r} = 30\ln\left\{1+\frac{4}{\pi}\frac{b-t}{W'}\left[\frac{8}{\pi}\frac{b-t}{W'}+\sqrt{\left(\frac{8}{\pi}\frac{b-t}{W'}\right)^2+6.27}\right]\right\} \tag{16.9}$$

with

$$\frac{W'}{b-t} = \frac{W}{b-t}+\frac{\Delta W}{b-t} \tag{16.10}$$

where

$$\frac{\Delta W}{b-t} = \frac{x}{\pi(1-x)}\left\{1-\frac{1}{2}\ln\left[\left(\frac{x}{2-x}\right)^2+\left(\frac{0.0796x}{W/b+1.1x}\right)^m\right]\right\} m = 2\left[1+\frac{2}{3}\frac{x}{1-x}\right]^{-1},\ x = t/b$$

For $W'/(b-t) < 10$ (Equation 16.9) is 0.5% accurate. The signal velocity v_p is given by $c/(\varepsilon_r)^{1/2}$, where c is the velocity of light in vacuum. The corresponding L and C are given by $L = Z_0/v_p$ and $C = 1/(Z_0 v_p)$.

16.2.3.2 Coupled Striplines

The configuration is depicted in Figure 16.3. It consists of the symmetric combination of the structure of Figure 16.2. There are now two fundamental TEM modes ($N = C = 2$). The even mode (index e) corresponds to the situation in which both central conductors are placed at the same voltage (speaking in low-frequency terms, of course). The odd mode (index o) corresponds to the situation where the

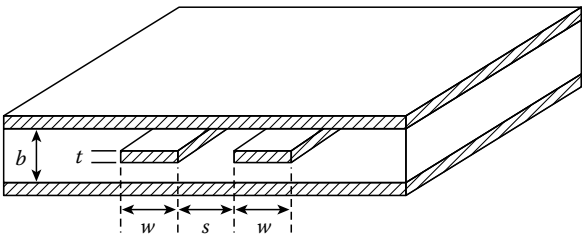

FIGURE 16.3 Coupled, symmetric stripline configuration.

central conductors are placed at opposite voltages. The impedances of the modes (respectively, $Z_{0,e}$ and $Z_{0,o}$) are given by

$$Z_{0e,o} = \frac{30\pi(b-t)}{\sqrt{\varepsilon_r}\left(W + \frac{bC_f}{2\pi}A_{e,o}\right)} \tag{16.11}$$

with

$$A_e = 1 + \frac{\ln(1 + \tanh\ \theta)}{\ln\ 2}$$

$$A_o = 1 + \frac{\ln(1 + \coth\ \theta)}{\ln\ 2}$$

$$\theta = \frac{\pi S}{2b}$$

$$C_f(t/b) = 2\ln\left(\frac{2b-t}{b-t}\right) - \frac{t}{b}\ln\left[\frac{t(2b-t)}{(b-t)^2}\right]$$

The signal velocity is the same for both modes ($c/(\varepsilon_r)^{1/2}$), and the L and C of both modes can be found by replacing Z_0 in Section 16.2.3.1 by $Z_{0,e}$ and $Z_{0,o}$, respectively.

16.2.3.3 Coupled Microstrip Lines

The configuration is depicted in Figure 16.4. It consists of the symmetric combination of the structure of Figure 15.7. Again, we have two fundamental modes, but the modes are hybrid, i.e., not purely TEM. Much work has been done on this configuration. The formulas proposed in the literature are quite lengthy; and we refer the reader to Refs. [20,21]. Reference [20] gives a very good overview together with some simple approximations, and Ref. [21] gives the most accurate formulas, taking into account the frequency dependence. It is important to remark here that the two impedances, $Z_{0,e}$ and $Z_{0,o}$, can be found. They depend upon frequency. Both modes now have a different velocity. The data found in literature are typically expressed in terms of the effective dielectric constant. The modal field lines are both found in the air above the substrate and in the substrate itself. Hence, the field experiences an effective dielectric constant that is smaller than the dielectric constant of the substrate. The effective dielectric constant for the even mode ($\varepsilon_{r,e}$) will be higher than for the odd mode ($\varepsilon_{r,o}$), and are frequency dependent. The corresponding modal velocities are given by $c/(\varepsilon_{r,e})^{1/2}$ and $c/(\varepsilon_{r,o})^{1/2}$.

17.1 Time-Domain Reflectometry

17.1.1 Principles

Time-domain reflectometry (TDR) is used to characterize interconnections in the time domain. The setup essentially consists of a time domain step generator and a digital sampling oscilloscope (Figure 17.1) [1]. The generator produces a positive-going step signal with a well-defined rise time. The step is applied to the device under test. The reflected and the transmitted signals are shown on the oscilloscope. Measuring the reflected signal is called TDR; the transmitted signal is measured using the time-domain transmission (TDT) option.

The characteristic impedance levels and delay through an interconnection structure can be derived from the TDR measurements. The TDT measurement gives information about the losses (decrease of magnitude) and degradation of the rise time (filtering of high-frequency components). The TDR/TDT measurements also are used to extract an equivalent circuit consisting of transmission lines and lumped elements.

The fundamentals of TDR are discussed in detail in Refs. [2,3]. Reference [4] describes the applications of TDR in various environments including PCB/backplane, wafer/hybrids, IC packages, connectors, and cables.

17.1.2 One-Port Time-Domain Reflectometry

Figure 17.2 demonstrates that the device under test is a simple resistor with impedance Z_L. In this case, a mismatch with respect to the reference or system impedance Z_0 exists. A reflected voltage wave will appear on the oscilloscope display algebraically added to the incident wave. The amplitude of the reflected voltage wave, E_r, is determined by the reflection coefficient of the load impedance, Z_L, with respect to the system impedance Z_0:

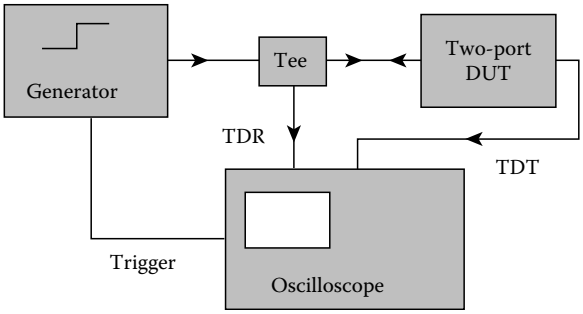

FIGURE 17.1 Setup of TDR/TDT measurements. DUT = device under test.

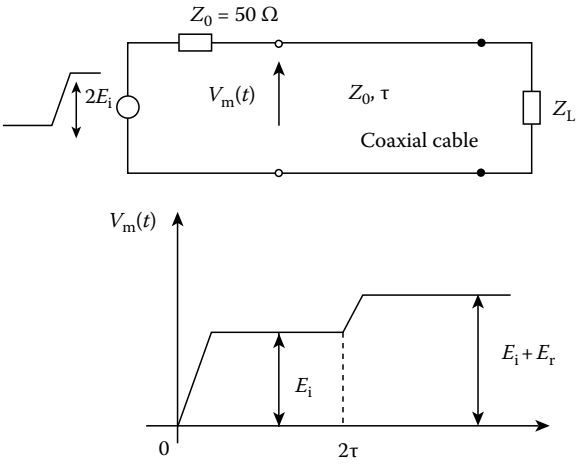

FIGURE 17.2 TDR measurement of an impedance Z_L.

$$E_r = \rho E_i = \frac{Z_L - Z_0}{Z_L + Z_0} E_i \tag{17.1}$$

Figure 17.2 also depicts the time-domain picture shown on the oscilloscope for a load, the impedance Z_L that is larger than Z_0. From the measurement of the magnitude E_r of the reflected voltage wave, the load impedance Z_L can be derived.

17.1.3 Time-Domain Reflectometry Pictures for Typical Loads

The simplest loads to be measured are the open circuit and the short circuit. For ideal open-circuit and short-circuit loads the reflection coefficient is, respectively, 1 and −1. This means that the measured voltage doubles in the first case and goes to zero in the second case, when the reflected voltage wave arrives at the oscilloscope (Figure 17.3).

For any other real load impedance, the reflection coefficient lies between −1 and 1. If the real load impedance is larger than the reference impedance, the reflected voltage wave is a positive-going step signal. In this case the amplitude of the voltage is increased when the reflected wave is added to the input step (Figure 17.4). The reverse happens when the load impedance is lower than the reference impedance.

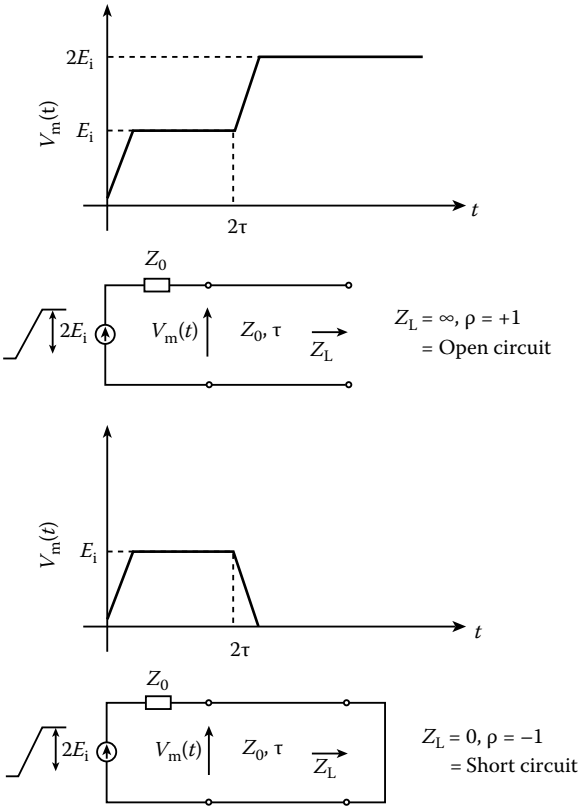

FIGURE 17.3 TDR pictures of an open- and a short-circuit termination.

For complex load impedances, the step response is more complicated. For example, in the case of a series connection of a resistance and an inductance or a parallel connection of a resistance and a capacitance, a first-order step response is obtained. From the two pictures in Figure 17.5, we learn that a series inductance gives a positive dip, while the capacitance produces a negative dip.

17.1.4 Time-Domain Reflectometric Characterization of an Interconnection Structure

One of the advantages of TDR is its ability to determine impedance levels and delays through an interconnection structure with multiple discontinuities. An example is shown in Figure 17.6 for a microstrip line connected to the measurement cable. We assume a perfect junction of the two transmission lines. The line is terminated in a load with impedance Z_L. Observe that two mismatches produce reflections that can be analyzed separately. The mismatch at the junction of the two transmission lines generates a reflected wave $E_{r1} = \rho_1 E_i$. Similarly, the mismatch at the load creates a reflection due to its reflection coefficient ρ_2. Both reflection coefficients are defined as:

$$\rho_1 = \frac{Z_0' - Z_0}{Z_0' + Z_0}$$
$$\rho_2 = \frac{Z_L - Z_0'}{Z_L + Z_0'} \tag{17.2}$$

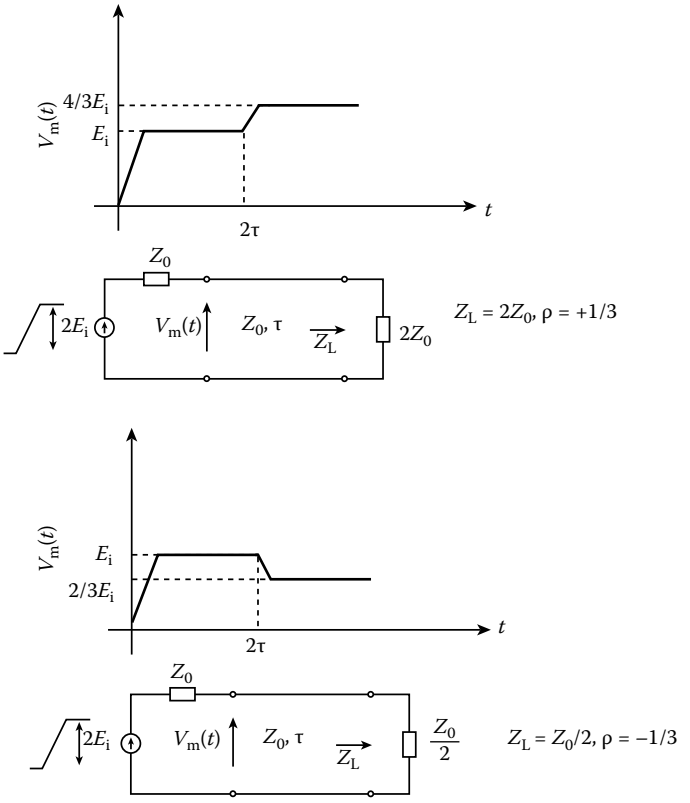

FIGURE 17.4 TDR pictures of real impedance terminations ($Z_L = 2Z_0$ and $Z_L = Z_0/2$).

After a time τ, the reflection at the junction of the transmission lines occurs. The voltage wave associated with this reflection adds to the oscilloscope's picture at the time instant 2τ. The voltage wave that propagates further in the microstrip line is $(1 + \rho_1)\, E_i$ and is incident on Z_L. The reflection at Z_L occurs at the time $\tau + \tau'$ and is given by

$$E_{rL} = \rho_2(1 + \rho_1)E_i \tag{17.3}$$

After a time $\tau + 2\tau'$, a second reflection is generated at the junction. The reflection is now determined by the reflection coefficient $\rho_1' = -\rho_1$. The voltage wave E_{r2} that is transmitted through the junction and propagates in the direction of the generator adds to the time-domain picture at time instant $2\tau + 2\tau'$ and is given by

$$E_{r2} = (1 + \rho_1)E_{rL} = (1 - \rho_1)\rho_2(1 + \rho_1)E_i = \left(1 - \rho_1^2\right)\rho_2 E_i \tag{17.4}$$

If ρ_1 is small in comparison to 1, then

$$E_{r2} \approx \rho_2 E_i \tag{17.5}$$

which means that ρ_2 can be determined from the measurement of E_{r2}.

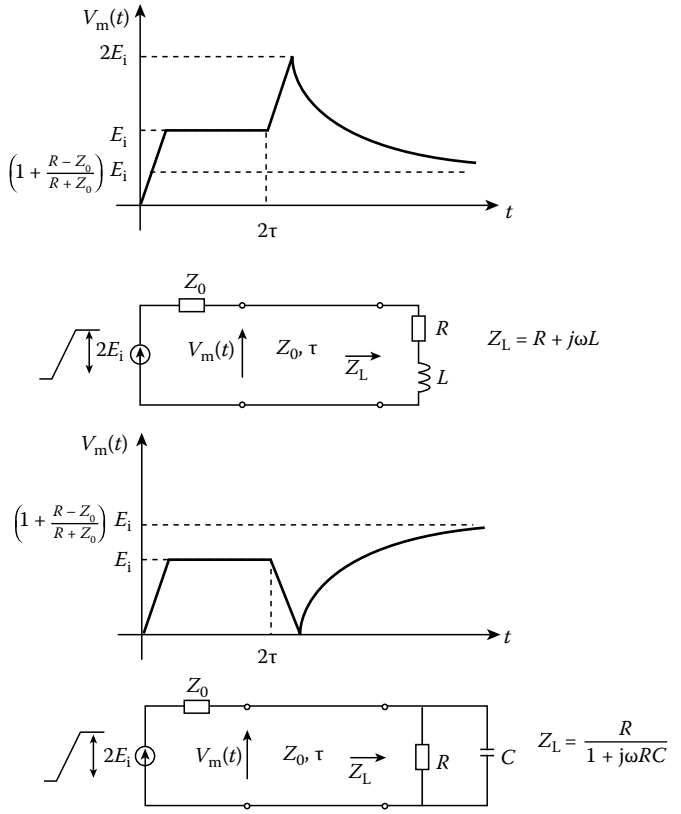

FIGURE 17.5 TDR pictures of two complex impedance terminations.

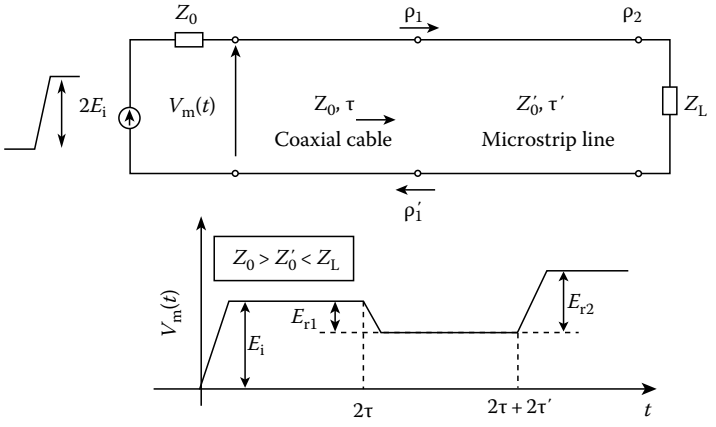

FIGURE 17.6 TDR measurement of a microstrip line terminated in an impedance Z_L.

In this example, the measurement cable was perfectly matched to the generator impedance so that no reflection occurred at the generator side, which simplifies the time-domain picture. In the case of an interconnection with many important discontinuities (high reflection coefficient), multiple reflections can prevent a straightforward interpretation of the oscilloscope's display.

17.2 Frequency-Domain Network Analysis

17.2.1 Introduction

A distributed circuit can also be analyzed in the frequency domain. At low frequencies the circuits are characterized by their *Z*- or *Y*-parameters. At high frequencies, circuits are better characterized by *S*-parameters. We focus only on *S*-parameter characterization.

The network analyzer is an instrument that measures the *S*-parameters of a two-port device (Figure 17.7) [5]. The reference impedance for the *S*-matrix is the system impedance, which is the standard 50 Ω. A sinusoidal signal is fed to the device under test and the reflected and transmitted signals are measured. If the network analyzer is of the vectorial type, it measures the magnitude as well as the phase of the signals.

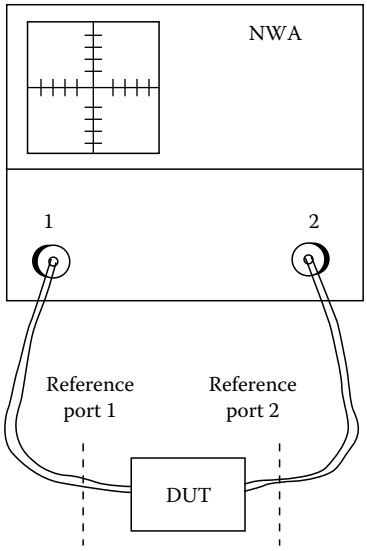

FIGURE 17.7 Network analyzer (NWA) setup.

17.2.2 Network Analyzer: Block Diagram

In operation, the source is usually set to sweep over a specified bandwidth (maximally 45 MHz to 26.5 GHz for the HP8510B network analyzer). A four-port reflectometer samples the incident, reflected, and transmitted waves, and a switch allows the network analyzer to be driven from either port 1 or port 2.

A powerful internal computer is used to calculate and display the magnitude and phase of the *S*-parameters or other quantities such as voltage standing wave radio, return loss, group delay, impedance, etc. A useful feature is the capability of determining the time-domain response of the circuit by calculating the inverse Fourier transform of the frequency-domain data.

Figure 17.8 depicts the network analyzer in the reflection measurement configuration. A sinusoidal signal from a swept source is split by a directional coupler into a signal that is fed to a reference channel and a signal that is used as input for the device under test. The reflected signal is fed back through the directional coupler to the test channel. In the complex ratio measuring unit, the amplitude and phase of the test and reference signals are compared.

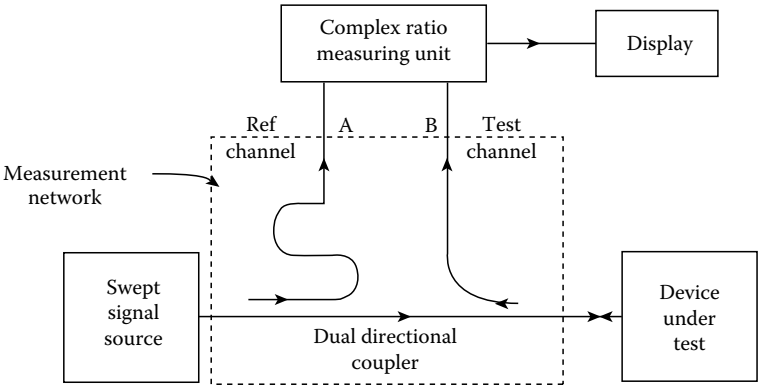

FIGURE 17.8 Block diagram for reflection measurements with the network analyzer.

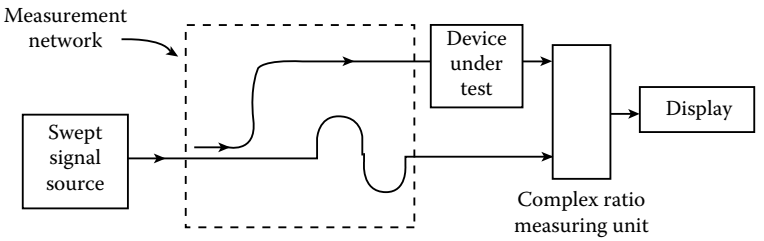

FIGURE 17.9 Block diagram for transmission measurements with the network analyzer.

The principle of the transmission measurement is the same as for the reflection configuration (Figure 17.9). In this setup the signal transmitted through the device under test is fed to the test channel. The other part of the signal of the swept source is transmitted through the directional coupler and fed to the reference channel. Again, amplitude and phase of the two signals are compared.

An important issue concerning the measurement of *S*-parameters is the calibration of the results. In order to perform a good calibration, the nature of the measurement errors must be well understood. These items are the subject of Section 17.2.3.

17.2.3 Measurement Errors and Calibration

17.2.3.1 Measurement Errors

The network analyzer measurement errors [6] can be classified in two categories:

1. *Random errors*—These are nonrepeatable measurement variations that occur due to noise, environmental changes, and other physical changes in the test setup. These are any errors that the system itself may not be able to measure.
2. *Systematic errors*—These are repeatable errors. They include the mismatch and leakage terms in the test setup, the isolation characteristic between the reference and test signal paths, and the system frequency response.

In most *S*-parameters measurements, the systematic errors are those that produce the most significant measurement uncertainty. Because each of these errors produces a predictable effect upon the measured data, their effects can be removed to obtain a corrected value for the test device response. The procedure of removing these systematic errors is called calibration. We illustrate here the calibration for one-port measurements. The extension to two-ports is mathematically more involved, but the procedure is fundamentally the same.

17.2.3.2 One-Port Calibration: Error Correction Network

In the configuration for one-port measurements, the real network analyzer can be considered as a connection of a ''perfect'' network analyzer and a two-port whose parameters are determined by the systematic errors. ρ_m is the measured reflection coefficient, while ρ_a is the actual one (Figure 17.10). The three independent coefficients of the error correction network [7] are

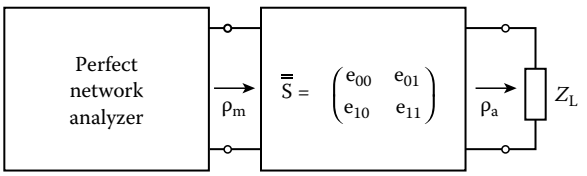

FIGURE 17.10 Error correction network for calibration of the *S*-parameter measurements.

1. *Directivity* e_{00}—The vector sum of all leakage signals appearing at the network analyzer test input due to the inability of the signal separation device to absolutely separate incident and reflected waves, as well as residual effects of cables and adapters between the signal separation device and the measurement plane
2. *Source impedance mismatch* e_{11}—The vector sum of the signals appearing at the network analyzer test input due to the inability of the source to maintain absolute constant power at the test device input as well as cable and adaptor mismatches and losses outside the source leveling loop
3. *Tracking or frequency response* $e_{10}e_{01}$—The vector sum of all test setup variations in the magnitude and phase frequency response between the reference and test signal paths

The relations between ρ_m and ρ_a are given by

$$\rho_m = e_{00} + \frac{e_{01}e_{10}\rho_a}{1 - e_{11}\rho_a} \tag{17.6}$$

$$\rho_a = \frac{\rho_m - e_{00}}{e_{11}(\rho_m - e_{00}) + e_{10}e_{01}} \tag{17.7}$$

The error coefficients are determined by measuring standard loads. In the case of the short-open-load (SOL) calibration, a short-circuit, open-circuit, and matched load are measured [5]. The standards are characterized over a specified frequency range (e.g., from 45 MHz to 26.5 GHz for the network analyzer HP8510B). The best-specified standards are coaxial. The quality of the coaxial standards is determined by the precision of the mechanical construction. The short circuit and the load are in most cases nearly perfect ($\rho_a^1 = -1$ and $\rho_a^3 = 0$, respectively). The open circuit behaves as a frequency-dependent capacitance:

$$\rho_a^2 = e^{-j2\ \mathrm{arctg}(\omega C Z_0)} \quad \text{with } C = C_0 + f^2 C_2 \tag{17.8}$$

where

Z_0 is the characteristic impedance of the coaxial part of the standard

C_0 and C_2 are specified by the constructor of the hardware

Once the reflection coefficients of the standards are specified and the standards are measured, a set of linear equations in the error coefficients is derived:

$$a\rho_a^i + b - c\rho_a^i\rho_m^i = \rho_m^i, \quad i = 1, 2, 3 \tag{17.9}$$

where $a = e_{01}e_{10} - e_{00}e_{11}$, $b = e_{00}$, and $c = -e_{11}$. This set is easily solved in the error coefficients which are then used together with the measurement of ρ_m to determine ρ_a.

Other calibration methods (thru-reflect-line [TRL], line-reflect-match [LRM]) are described in Refs. [8,9]. Analogous calibration techniques also were developed for time-domain measurements (TDR/TDT) [10]. Applications of *S*-parameter measurements on circuits on PCBs are described in Ref. [11].

17.2.3.3 Error Checking and Verification of the Calibration

Checking errors in the calibration is done by applying the calibration to a measured standard. The specified reflection response of the standard must be found. In Figure 17.11, the uncalibrated measurement of the open-circuit standard is shown. After calibration, we obtain the specified response (capacitance model) of the standard (Figure 17.11). The calibration can be further verified on a standard transmission line.

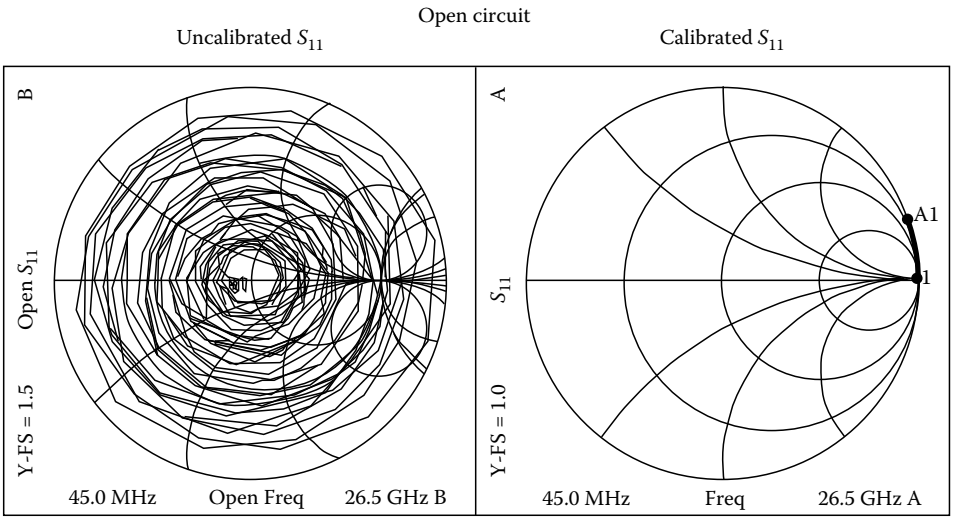

FIGURE 17.11 Smith chart representation of the uncalibrated and calibrated S_{11} data of an open circuit (measurements in the range of 45 MHz to 26.5 GHz).

Budapest University of Technology and Economics

In everyday practice, we often encounter RC networks that are inherently distributed (DRC lines). All the resistors and the interconnection lines of an IC, the channel regions of the FET, and MOS transistors are DRC lines. The electrical behavior of such networks is discussed in the current section.

18.1 Uniform Distributed RC Lines

First, let us consider the so-called lossless RC lines. The structure in Figure 18.1 has only serial resistance and parallel capacitance. Both the resistance and the capacitance are distributed along the x axis. r and c denote the resistance and the capacitance pro unit length, respectively. In this section, these values are considered constants, which means that the RC line is uniform.

Consider a Δx length section of the structure. Using the notations of Figure 18.1, the following relations can be given between the currents and voltages:

$$\Delta v = -ir\Delta x, \quad \Delta i = -\frac{\partial v}{\partial t} c\Delta x \tag{18.1}$$

By taking the limit as $\Delta x \to 0$, we obtain a pair of differential equations

$$\frac{\partial v}{\partial x} = -ri, \quad \frac{\partial i}{\partial x} = -c\frac{\partial v}{\partial t} \tag{18.2}$$

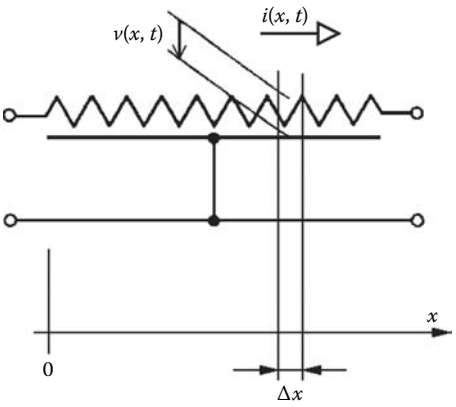

FIGURE 18.1 Lossless DRC line.

which describe the behavior of the lossless RC line. Substituting the first equation of Equation 18.2 after derivation into the second equation of Equation 18.2 results in

$$\frac{\partial v}{\partial t} = \frac{1}{rc}\frac{\partial^2 v}{\partial x^2} \tag{18.3}$$

This shows that the time-dependent voltage along the line $v(x, t)$ is determined by a homogeneous, constant-coefficient, second-order partial differential equation, with the first time derivative on one side and the second spatial derivative on the other side. This kind of equation is called a "diffusion equation," as diffusion processes are described using such equations.

18.1.1 Solution in the Time Domain

The differential Equation 18.3 is fulfilled by the simple, spatially Gauss-like function

$$v(x, t) = \frac{Q/c}{2\sqrt{\pi t/rc}} \exp\left(-\frac{x^2}{4t/rc}\right) \tag{18.4}$$

This can be proved easily by substituting the function into Equation 18.3.

Equation 18.4 describes the physical situation in which the uniform RC structure is of infinite length in both directions, and a short, impulse-like Q charge injection is applied at $x = 0$ in the $t = 0$ instant. This means a Dirac-δ excitation at $x = 0$ both in charge and voltage. As time elapses, the charge spreads equally in both directions. The extension of the charge and voltage wave is ever increasing, but their amplitude is decreasing (see Figure 18.2a).

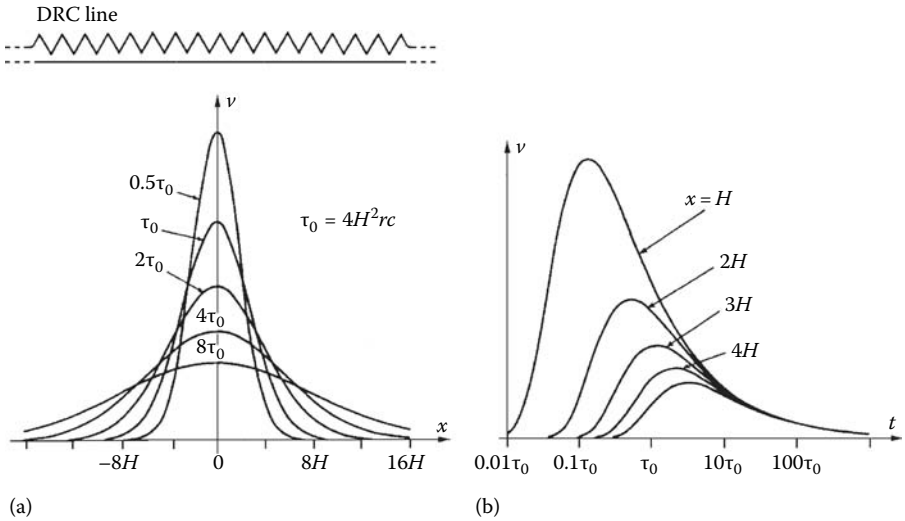

FIGURE 18.2 Effect of an impulse-like charge injection at $x = 0$. (a) Voltage distribution in subsequent time instants. (b) Voltage transients in different distances from the injection point.

The same result is represented in a different way in Figure 18.2b. The time dependence of the voltage is shown at the $x = H$, $x = 2H$, etc., spatial positions. As we move away from the $x = 0$ point, the maximum of the impulse appears increasingly later in time, and the originally sharp impulse is increasingly extended. This means that the RC line delays the input pulse and at the same time strongly spreads it. The RC line is dispersive.

18.1.1.1 Superposition

Equation 18.3 is homogeneous and linear. This means that any sum of the solutions is again a solution. Based on this fact, the problem of Figure 18.3a can be solved. At $t = 0$, the voltage distribution of the RC line is given by an arbitrary $U(x)$ function. For $t > 0$, the distribution can be calculated by dividing the $U(x)$ function into $\Delta\xi \to 0$ elementary slices. These may be considered to be individual Dirac-δ excitations and the responses given to them can be summarized by integration:

$$v(x,t) = \frac{1}{2\sqrt{\pi t/rc}} \int_{-\infty}^{\infty} U(\xi) \exp\left(-\frac{(x-\xi)^2}{4t/rc}\right) d\xi \tag{18.5}$$

Evaluating this equation for the special case of having $2U_0$ voltage on the $x < 0$ side at $t = 0$, while $x > 0$ is voltage less, results in

$$v(x,t) = \frac{2U_0}{2\sqrt{\pi t/rc}} \int_{-\infty}^{0} \exp\left(-\frac{(x-\xi)^2}{4t/rc}\right) d\xi = U_0 \operatorname{erfc}\left(\frac{x}{2\sqrt{t/rc}}\right) \tag{18.6}$$

where the integral of the Gauss function is notated by erfc(x), the complementary error function.* The originally abrupt voltage step is getting increasingly less steep with time (Figure 18.3b). In the middle at $x = 0$, the voltage remains U_0.

18.1.1.2 Semi-Infinite Line

Our next model is a bit closer to practice; the uniform RC line extends to $x \geq 0$ only. At $x = 0$ the port is characterized by the $V(t)$ voltage and the $I(t)$ current (Figure 18.4). If the line is relaxed and a $I(t) = \delta(t)$ current (a Dirac-δ current pulse) is forced to the port, a unit charge is introduced at $x = 0$. The result will

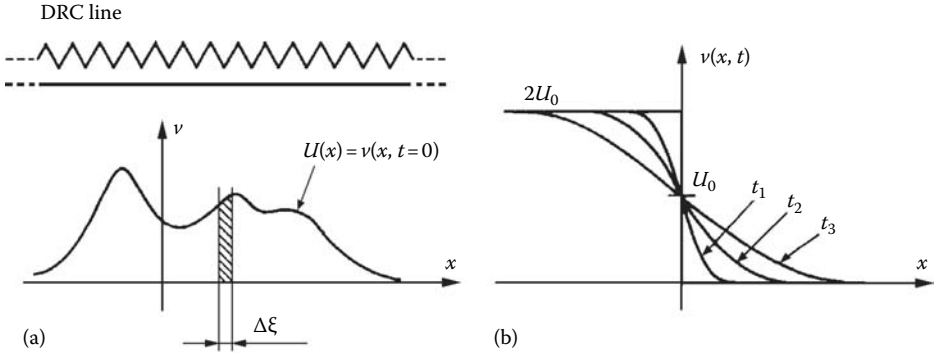

FIGURE 18.3 DRC line transients. (a) An arbitrary initial voltage distribution. (b) Solution for the initial step-function case.

* $\operatorname{erfc}(x) = 1 - \frac{2}{\sqrt{\pi}} \int_0^x \exp(-y^2)dy = \frac{2}{\sqrt{\pi}} \int_x^\infty \exp(-y^2)dy$.

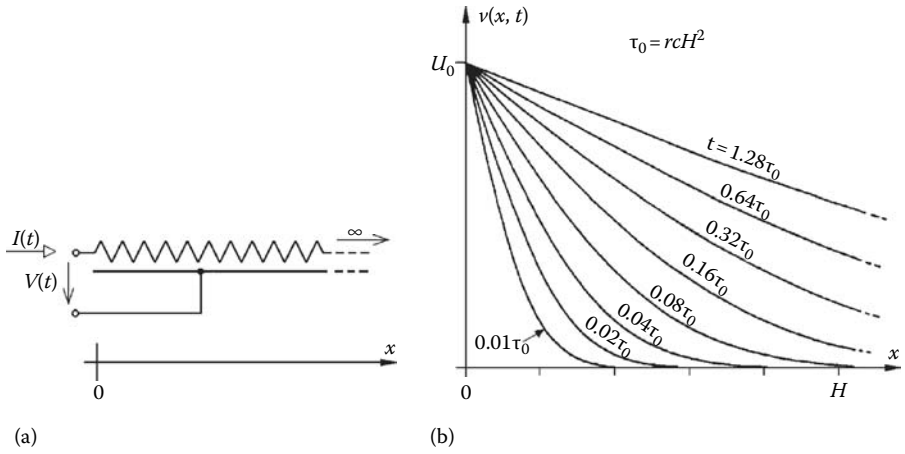

FIGURE 18.4 Semi-infinite uniform DRC line. (a) Notation. (b) Normalized solution for the initially relaxed line.

be similar to that of Figure 18.2a, but instead of symmetrical spreading the charge moves towards the positive x direction only. This means that a unit charge generates a twice-larger voltage wave

$$v(x,t) = \frac{1/c}{\sqrt{\pi t/rc}} \exp\left(-\frac{x^2}{4t/rc}\right) \tag{18.7}$$

Let us consider the case in which step function excitation is given to the port of Figure 18.4. At $t<0$, the port and the whole line are voltage free; at $t \geq 0$ a constant U_0 voltage is forced to the port. Comparing this situation with the problem of Figure 18.3b, it can be observed that the boundary conditions for the $x>0$ semi-infinite line are the same as in our current example, so that the solution must to be similar as well (see Figure 18.4b):

$$v(x,t) = U_0 \mathrm{erfc}\left(\frac{x}{2\sqrt{t/rc}}\right) \tag{18.8}$$

Applying at the $t=0$ instant an arbitrary $W(t)$ forced voltage excitation to the initially relaxed line, the response is given by the Duhamel integral as follows:

$$w(x,t) = \int_0^t \frac{\mathrm{d}W(\tau)}{\mathrm{d}\tau} \mathrm{erfc}\left(\frac{x}{2\sqrt{(t-\tau)/rc}}\right) \mathrm{d}\tau \tag{18.9}$$

18.1.1.3 Finite DRC Line

Let the DRC line of length L of Figure 18.5a be closed at $x=L$ with a short circuit. Let the line at $t<0$ be relaxed and assume a W $(t>0)$ voltage excitation at the $x=0$ port. Using the $w(x,t)$ voltage response of the semi-infinite line Equation 18.9, the response function for the short-terminated line of length L

$$\begin{aligned} v(x,t) &= \sum_{i=0}^{\infty} (-1)^i \cdot w\big(2iL + (-1)^i x, t\big) \\ &= \sum_{k=0}^{\infty} \big(w(2kL + x, t) - w(2kL + 2L - x, t)\big) \end{aligned} \tag{18.10}$$

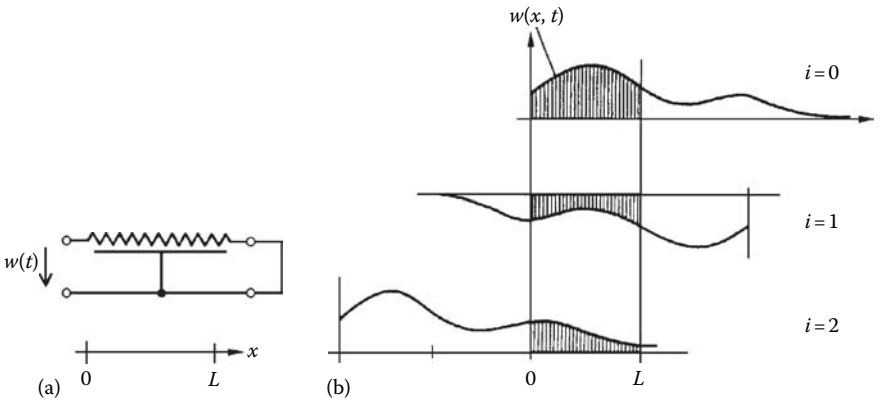

FIGURE 18.5 Finite-length uniform DRC line. (a) DRC line with short-circuit at $x = L$. (b) Visualization of the mirroring procedure.

This result is illustrated in Figure 18.5b. The $v(x, t)$ function is given as the sum of the shifted, negated, and mirrored replicas of the $w(x, t)$ function, so that it is a valid solution as well. The $x = L$ boundary condition is the short circuit $v(x = L, t) = 0$. The $i = 0$ and $i = 1$ functions are the same size with different signs at $x = L$, so they cancel each other. The same is true for $i = 2$ and 3, and so on. The $x = 0$ boundary condition $v = W(t)$ is fulfilled by the $i = 0$ function, while the further functions cancel each other in pairs (the $i = 1$ and 2, etc.).

The result can be interpreted as the response of the semi-infinite line being mirrored with negative sign on the short termination. In the case of Figure 18.5a, the termination on both the $x = 0$ and $x = L$ ends is assured by zero impedance short circuit; the resultant voltage function comes from the successive back and forth mirroring between these two ''mirrors.''

It is easy to understand that a termination with an open circuit results in mirroring without sign change. (At this termination the current equals to zero so that the dv/dx derivative equals to zero as well. This requirement is always fulfilled in the mirroring point summarizing the continuous incident function with its mirrored version.) According to this, the voltage on the open-terminated line of Figure 18.6a is

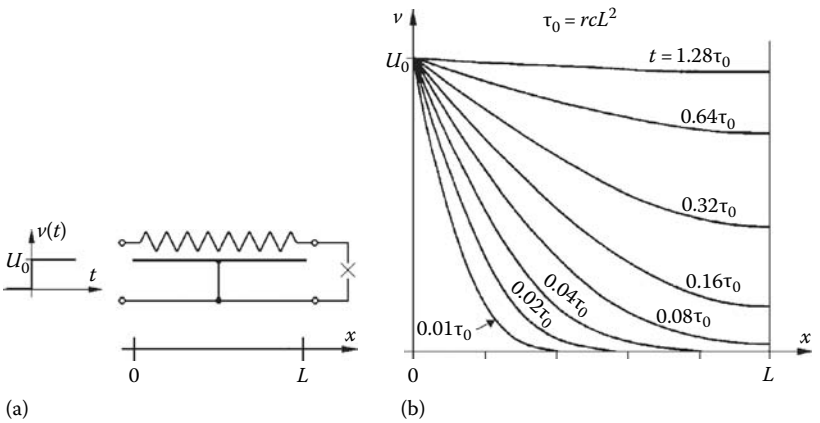

FIGURE 18.6 Finite-length uniform DRC line. (a) Open-circuit at the far end. (b) Normalized solution for the initially relaxed line.

$$v(x,t) = \sum_{k=0}^{\infty} (-1)^k (w(2kL + x, t) + w(2kL + 2L - x, t)) \tag{18.11}$$

which in the case of step function excitation with U_0 amplitude is

$$v(x,t) = U_0 \sum_{k=0}^{\infty} (-1)^k \left[\text{erfc}\left(\frac{2kL + x}{2\sqrt{t/rc}}\right) + \text{erfc}\left(\frac{2kL + 2L - x}{2\sqrt{t/rc}}\right)\right] \tag{18.12}$$

This function is given in Figure 18.6b for some time instants.

18.1.2 Solution in the Frequency Domain

To find the solution of the differential Equation 18.3, the following trial function can be used

$$v(x,t) = v \cdot \exp(j\omega t) \cdot \exp(\gamma x) \tag{18.13}$$

Substituting this function into (18.3) results in the following so-called dispersion equation:

$$\gamma = \sqrt{j\omega rc} = (1 + j)\frac{1}{\sqrt{2}}\sqrt{\omega rc} \tag{18.14}$$

This means that a wavelike solution exists as well. However, it is strongly collapsing because the real and imaginary parts of γ are always equal, which means that the attenuation on a path of λ wavelength is $\exp(-2\pi) \cong 1/535$.

The lossless DRC line can be considered to be a special telegraph line having neither serial inductance nor shunt conductance. The telegraph line theory can be conveniently used at the calculation of uniform DRC networks. The γ propagation constant and the $\mathbf{Z}_0$ characteristic impedance for the present case are

$$\gamma = \sqrt{\mathbf{s}rc}, \quad \mathbf{Z}_0 = \sqrt{\frac{r}{\mathbf{s}c}} \tag{18.15}$$

With these the two-port impedance parameters and chain parameters of an RC line of length L can be given as follows:

$$\mathbf{Z}_{ij} = \mathbf{Z}_0 \begin{bmatrix} \text{cth}\ \gamma L & 1/\text{sh}\ \gamma L \\ 1/\text{sh}\ \gamma L & \text{cth}\ \gamma L \end{bmatrix}, \quad \begin{bmatrix} A & B \\ C & D \end{bmatrix} = \begin{bmatrix} \text{ch}\ \gamma L & \mathbf{Z}_0 \text{sh}\ \gamma L \\ \frac{1}{\mathbf{Z}_0}\text{sh}\ \gamma L & \text{ch}\ \gamma L \end{bmatrix} \tag{18.16}$$

If one of the ports is terminated by the impedance of $\mathbf{Z}_t$, the following impedance can be "seen" on the opposite port

$$\mathbf{Z}_{in} = \mathbf{Z}_0 \frac{\mathbf{Z}_t\ \text{ch}\ \gamma L + \mathbf{Z}_0\ \text{sh}\ \gamma L}{\mathbf{Z}_t\ \text{sh}\ \gamma L + \mathbf{Z}_0\ \text{ch}\ \gamma L} \tag{18.17}$$

18.1.3 Uniform, Lossy DRC Lines

In some cases, the DRC structure also has shunt conductance, which means that it is lossy. The value of this conductance for the unit length is notated by g. In such a case, without giving the details of the calculation, the $v(x,t)$ line voltage can be determined by the solution of the equation

$$\frac{\partial v}{\partial t} = \frac{1}{rc}\frac{\partial^2 v}{\partial x^2} - \frac{g}{c}v \tag{18.18}$$

The following forms of the characteristic impedance and the propagation constant can be used now in the frequency domain

$$\gamma = \sqrt{r(g + \mathbf{s}c)}, \quad \mathbf{Z}_0 = \sqrt{\frac{r}{g + \mathbf{s}c}} \tag{18.19}$$

It is an interesting fact that the charge carrier motion in the base region of homogeneously doped bipolar transistors can be described by formally similar equations, so that the intrinsic transients of the bipolar transistors can be exactly modeled by lossy DRC two-ports [5].

Example 18.1. Wiring delays

Neither the series resistance nor the stray capacitances of the interconnection leads of integrated circuits are negligible. As an example, in the case of a polysilicon line of 1 μm width $r \cong 50$ kΩ/mm, $c \cong 0.04$ pF/mm. This means that these wires should be considered to be DRC lines. The input logical levels appear on their output with a finite delay. Let us determine the delay of a wire of length L. From Equation 18.12,

$$v(L,t) = U_0 \sum_{k=0}^{\infty} 2(-1)^k \mathrm{erfc}((2k+1)\vartheta)$$

where

$$\vartheta = \frac{L}{2\sqrt{t/rc}}$$

The value of the summation over k will reach 0.9 at $\vartheta = 0.5$, so that the voltage at the end of the line will reach the 90% of U_0 after a time delay of

$$t_{\mathrm{delay}} \cong rcL^2 \tag{18.20}$$

Note that the time delay increases with the square of the length of the wire. In the case of $L = 1$ mm the time delay of this polysilicon wire is already 2 ns, which is more than the time delay of a CMOS logical gate. For lengthy wires ($>0.2 \div 0.5$ mm), metal wiring must be applied with its inherently small resistivity.

Example 18.2. Parasitic effects of IC resistors

In an IC amplifier stage the transistor is loaded with, e.g., $R = 10$ kΩ (Figure 18.7a). This resistor has been fabricated by the base diffusion, the sheet resistance is 200 Ω, and the parasitic capacitance is 125 pF/mm^2. The width of the resistor is 4 μm. Let us determine the impedance of the resistor in the 1 to 1000 MHz range.

The resistance can be realized in 4×200 μm size. The total parasitic capacitance is $C_p = 0.1$ pF. The impedance of the transistor-side port can be calculated according to Equation 18.17, considering that the opposite port is short-terminated, as

$$\mathbf{Z}_{\mathrm{port}} = \mathbf{Z}_0 \ \mathrm{th}\ \gamma L = \sqrt{\frac{r}{\mathbf{s}c}}\mathrm{th}\left(\sqrt{\mathbf{s}rc}L\right) = \sqrt{\frac{R}{\mathbf{s}C_p}}\mathrm{th}\sqrt{\mathbf{s}RC_p} \tag{18.21}$$

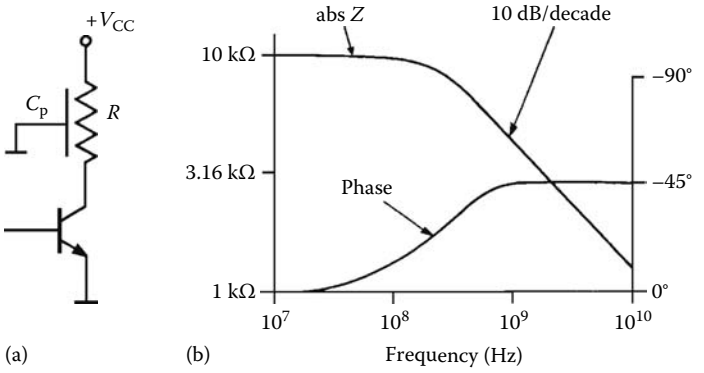

FIGURE 18.7 A simple IC amplifier stage. (a) The load resistor is in fact a DRC line. (b) The amplitude and phase plot of the load.

Using the $\mathbf{s} = j\omega$ substitution, along with the actual data, the amplitude and phase functions of Figure 18.7b can be obtained for the impedance. At 10 MHz, the phase shift caused by the parasitic capacitance is negligible, but at 100 MHz it is already considerable.

It is important to recognize that in the case of half size linewidths the size of the resistor will be only 2×100 μm, which results in one-fourth of the previous value in C_p. This means that the capacitance becomes disturbing only at four times larger frequencies.

Note in Figure 18.7b that the amplitude function shows a 10 dB/decade decay and the phase keeps to 45°, as if the load would be characterized by a "half pole." This 10 dB/decade frequency dependence often can be experienced at DRC lines.

18.2 Nonuniform Distributed RC Lines

In some cases, the capacitance and/or the resistance of the DRC line shows a spatial dependency. This happens if the width of the lead strip is modulated in order to reach some special effects (Figure 18.8a, tapered RC line). In case of a biased IC resistance, the capacitance changes along the length of the structure as well because of the voltage dependency of the junction capacitance. These structures are referred to as nonuniform DRC lines.

Let the spatially dependent resistance and capacitance pro unit length be notated by $r(x)$ and $c(x)$, respectively. The following equations can be given for the structure:

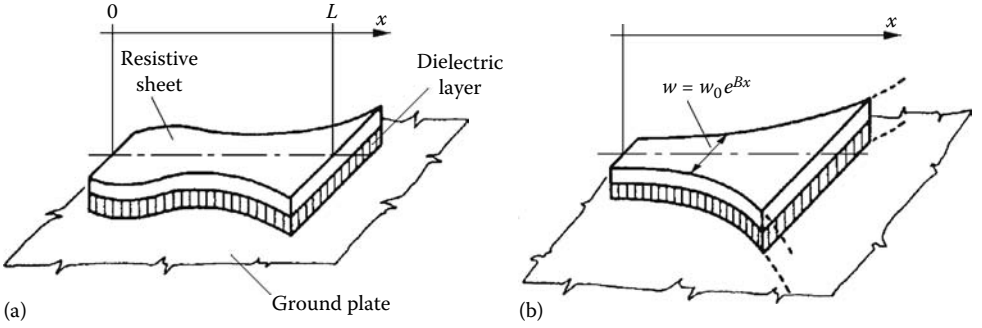

FIGURE 18.8 Nonuniform distributed RC lines. (a) Tapered line. (b) Exponentially tapered line.

$$\frac{\partial v}{\partial x} = -r(x)i, \quad \frac{\partial i}{\partial x} = -c(x)\frac{\partial v}{\partial t} \tag{18.22}$$

With these, the following differential equation can be written:

$$\frac{\partial v}{\partial t} = \frac{1}{c(x)}\frac{\partial}{\partial x}\left(\frac{1}{r(x)}\frac{\partial v}{\partial x}\right) \tag{18.23}$$

We can obtain a more convenient form if we consider as an independent variable (instead of the x spatial co-ordinate) the total ρ resistance related to a given reference point (e.g., to the $x = 0$ point), as follows:

$$\rho(x) = \int_0^x r(\xi)\mathrm{d}\xi, \quad r(x) = \frac{\partial \rho}{\partial x} \tag{18.24}$$

The variable defined this way can be considered as a kind of arc-length parameter. It has been introduced by Protonotarious and Wing [2]. With this new variable

$$\frac{\partial v}{\partial t} = \frac{1}{K(\rho)}\frac{\partial^2 v}{\partial \rho^2} \tag{18.25}$$

where

$$K(\rho) = K(\rho(x)) = \frac{c(x)}{r(x)} \tag{18.26}$$

The $K(\rho)$ function describes well the spatial parameter changes of the RC line; that is, the structure of the line. Therefore, the $K(\rho)$ function is called the **structure function.** Those DRC structures for which the $K(\rho)$ functions are the same are considered to be electrically equivalent.

Reference [2] uses the $\sigma(\rho)$ integral or cumulative version of the structure function:

$$\sigma(\rho) = \int_0^\rho K(\rho)\mathrm{d}\rho = \int_0^{x(\rho)} \frac{c(x)}{r(x)}\frac{\mathrm{d}\rho}{\mathrm{d}x}\mathrm{d}x = \int_0^{x(\rho)} c(x)\mathrm{d}x \tag{18.27}$$

This is the total capacitance related to the $x = 0$ point. This means that the cumulative structure function is the total capacitance versus total resistance map of the structure. An example of such a map is plotted in Figure 18.9.

The differential Equation 18.25 is homogeneous and linear; therefore, superposition can be used. Because this equation is of variable coefficient type, however, analytic solution can be expected only rarely. Such a case is that of the $K = K_0/\rho^4$ structure function for which

$$v(\rho, t) = \mathrm{const}\frac{1}{t^{3/2}}\exp\left(-\frac{K_0}{4\rho^2 t}\right) \tag{18.28}$$

Another form of Equation 18.25 is also known. To obtain this form, we should turn to the **s** domain with

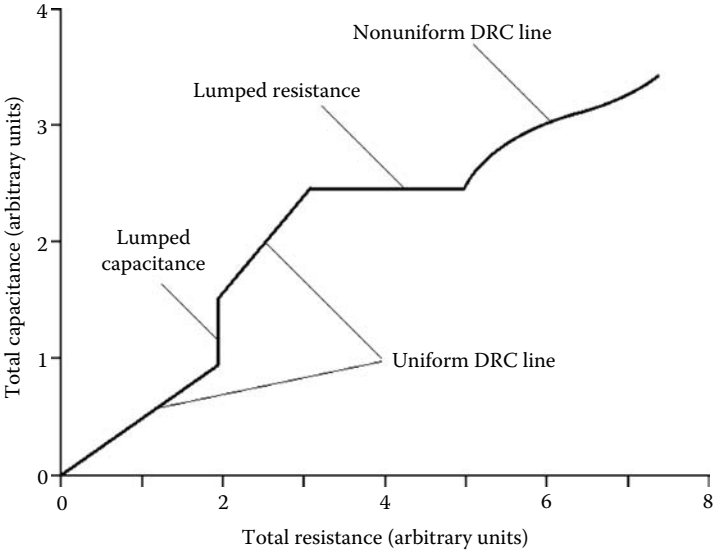

FIGURE 18.9 Cumulative structure function.

$$\mathbf{s}v = \frac{1}{K(\rho)}\frac{\partial^2 v}{\partial \rho^2} \tag{18.29}$$

Let us introduce the following new variable:

$$\mathbf{Z}(\rho) = \frac{v(\mathbf{s},\rho)}{i(\mathbf{s},\rho)} = \frac{v}{-\frac{1}{r}\frac{\partial v}{\partial x}} = -\frac{v}{\frac{\partial v}{\partial \rho}} \tag{18.30}$$

This variable is in fact the impedance of the line at the location of ρ. After rearrangements, the

$$\frac{d\mathbf{Z}}{d\rho} = 1 + \mathbf{s}K(\rho)\mathbf{Z}^2 \tag{18.31}$$

equation can be obtained. This is called the Riccati differential equation. In the case of a known $K(\rho)$ structure function, the one-port impedance of the nonuniform line can be determined from it by integration. In some cases, even the analytic solution is known. Such a case is the exponentially tapered line of Figure 18.8b, for which

$$r(x) = \frac{R_s}{w_0}\exp(-Bx), \quad c(x) = C_p w_0 \exp(Bx), \quad K(\rho) = \frac{R_s C_p}{B^2}\frac{1}{\rho^2} \tag{18.32}$$

where R_s is the sheet resistance of the structure, C_p is the capacitance per unit area, and ρ is related to the point in the infinity. If the port in the infinity is shorted, the impedance of the location of ρ is

$$\mathbf{Z}(\mathbf{s}) = \frac{\sqrt{1 + 4\mathbf{s}R_s C_p/B^2} - 1}{2\mathbf{s}R_s C_p/B^2}\rho \tag{18.33}$$

In other cases, numerical integration of Equation 18.31 leads to the solution.

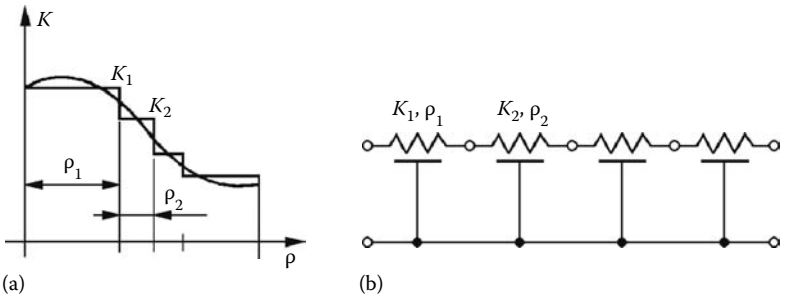

FIGURE 18.10 Approximation with concatenated uniform sections. (a) Stepwise approximation of the structure function. (b) Approximate model.

18.2.1 Approximation with Concatenated Uniform Sections

The following model can be used for approximate calculation of nonuniform structures. We split the structure function into sections (see Figure 18.10a) and use stepwise approximation. Inside the sections, $K =$ constant, so that they are uniform sections. Concatenating them according to Figure 18.10b an approximate model is obtained.

In the frequency domain, the overall parameters of the resultant two-port can be easily calculated. The chain parameter matrices of the concatenated sections have to be multiplied in the appropriate order. The time domain behavior can be calculated by inverse Laplace transformation.

18.2.2 Asymptotic Approximation for Large "s"

The chain parameters of a nonuniform DRC line can be approximately written as

$$\begin{bmatrix} A & B \\ C & D \end{bmatrix} \cong \frac{1}{2} \exp\left(\Delta\sqrt{\mathbf{s}}\right) \begin{bmatrix} \lambda & \mu/\sqrt{\mathbf{s}} \\ \sqrt{\mathbf{s}}/\mu & 1/\lambda \end{bmatrix} \tag{18.34}$$

where

$$\Delta = \int_0^{R_0} \sqrt{K(\rho)}\,d\rho, \quad R_0 = \rho(L), \quad \lambda = \left(\frac{K(R_0)}{K(0)}\right)^{1/4}, \quad \mu = (K(R_0)K(0))^{-1/4}$$

This approximation is valid for large **s** values and for sufficiently smooth function $K(\rho)$ [2].

18.2.3 Lumped Element Approximation

Distributed RC networks can be approximated by lumped element RC networks as well. The case of a lossless line is depicted in Figure 18.11a. The element values can be determined in either of the following two ways.

1. In the case of a known structure spatial discretization can be used. The nonuniform line must be split into sections of width h (see Figure 18.11b). A node of the network is associated with the middle of each section. The total capacitance of the section must be calculated, and this gives the value of the lumped capacitance connected to the node of the section. The resistance between the middle points of two adjacent sections must be calculated, and this has to be connected

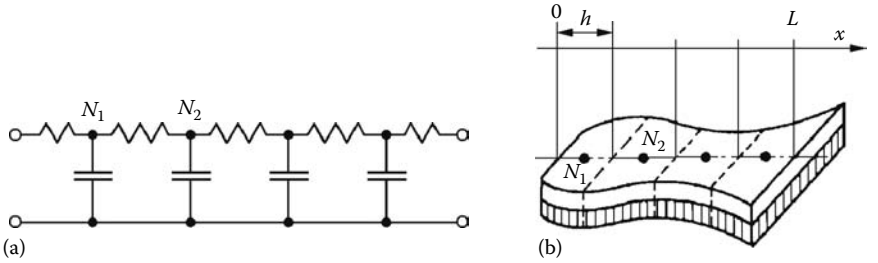

FIGURE 18.11 Lumped element approximation. (a) Network model. (b) The line split into sections.

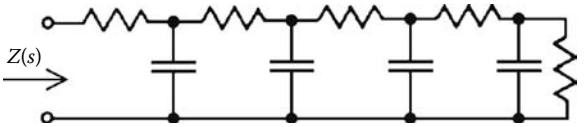

FIGURE 18.12 Cauer equivalent circuit (ladder structure).

between the nodes of the appropriate sections. It is obvious that the accuracy can be increased by decreasing h. The price is the increasing number of lumped elements. With $h \to 0$, we obtain the exact model.

2. When we know the impedance function, we can build the model using the pole-zero pattern of the network. For example, let us investigate a uniform RC line of finite length L, short-circuited at the far end. The corresponding impedance expression, according to Equation 18.21, is

$$\mathbf{Z}(\mathbf{s}) = \frac{1}{\sqrt{\mathbf{s}K_0}} \text{th}\, R_0\sqrt{\mathbf{s}K_0} \tag{18.35}$$

where $K_0 = c/r$, $R_0 = r \cdot L$. This function has poles and zeroes on the negative real axis in an infinite number. The zero and pole frequencies are

$$\sigma_{zi} = (2i)^2 \frac{\pi^2}{4} \frac{1}{R_0^2 K_0}, \quad \sigma_{pi} = (2i+1)^2 \frac{\pi^2}{4} \frac{1}{R_0^2 K_0} \tag{18.36}$$

where $i = 1, 2, \ldots, \infty$. Neglecting all the poles and zeroes situated well above the frequency range of interest and eliminating successively the remainder poles and zeroes from Equation 18.37 impedance function the element values of the ladder network in Figure 18.12 (Cauer equivalent) can be obtained from

$$\mathbf{Z}(\mathbf{s}) = R_0 \frac{\prod_{i=1}^{z} (1 + \mathbf{s}/\sigma_{zi})}{\prod_{i=1}^{p} (1 + \mathbf{s}/\sigma_{pi})} \tag{18.37}$$

18.3 Infinite-Length RC Lines

It was demonstrated earlier in the chapter that the DRC network can be described with the help of the pole-zero set of its impedance, as in the case of lumped element circuits. However, the number of these

poles and zeroes is infinite. The infinite-length DRC lines generally do not have this property. For this network category the exact description by discrete poles and zeroes is not possible.

For example, let us consider an infinitely long uniform DRC line. Its input impedance is the characteristic impedance:

$$\mathbf{Z}(\mathbf{s}) = \sqrt{\frac{r}{\mathbf{s}c}} \tag{18.38}$$

Evidently, this impedance function does not have poles and zeroes on the negative σ axis. This is the general case for a more complex, nonuniform distributed network if the length of the structure is infinite. The characteristic feature of these impedance functions is that $\sqrt{j\omega}$ factors appear in them. This is why in the logarithmic amplitude vs. frequency diagram (Bode plot) regions with 10 dB/decade slope appear, as pointed out in Ref. [1].

This section provides a generalization of the pole and zero notions and the time-constant representation in order to make them suitable to describe infinitely long distributed one-ports as well.

Before developing new ideas let us summarize the normal, well-known descriptions of a lumped element RC one-port. The port impedance of such a circuit is described by a rational function with real coefficients, as

$$\mathbf{Z}(\mathbf{s}) = R_0 \frac{(1+\mathbf{s}/\sigma_{z1})(1+\mathbf{s}/\sigma_{z2})\cdots(1+\mathbf{s}/\sigma_{zn-1})}{(1+\mathbf{s}/\sigma_{p1})(1+\mathbf{s}/\sigma_{p2})\cdots(1+\mathbf{s}/\sigma_{pn})} \tag{18.39}$$

where R_0 is the overall resistance, σ_p are the poles, and σ_z are the zeroes (as absolute values). The pole and zero values, together with the overall resistance value, hold all the information about the one-port impedance. Thus, an unambiguous representation of this impedance is given by a set of pole and zero values, and an overall resistance value. This will be called the "pole–zero representation."

Expression 18.39 can be rearranged as

$$\mathbf{Z}(\mathbf{s}) = \sum_{i=1}^{n} \frac{R_i}{1+\mathbf{s}/\sigma_{pi}} = \sum_{i=1}^{n} \frac{R_i}{1+\mathbf{s}\tau_i} \tag{18.40}$$

where

$$\tau_i = 1/\sigma_{pi} \tag{18.41}$$

which corresponds directly to the $v(t)$ voltage response for a step-function current excitation:

$$v(t) = \sum_{i=1}^{n} R_i(1-\exp(-t/\tau_i)) \tag{18.42}$$

In this case, the impedance is described in terms of the τ_i time-constants of its response and of the R_i magnitudes related to it. This will be called the time-constant representation.

18.3.1 Generalization of the Time Constant Representation*

A lumped element one-port can be represented by a finite number of τ time-constants and R magnitudes. A graphic representation of this is demonstrated in Figure 18.13. Each line of this plot represents a time constant, and the height of the line is proportional to the magnitude. This figure can be regarded as some

* Portions reprinted with permission from Székely, V., *IEEE Trans. Circuits Syst.*, 38, 711, 1991. © 1991 IEEE.

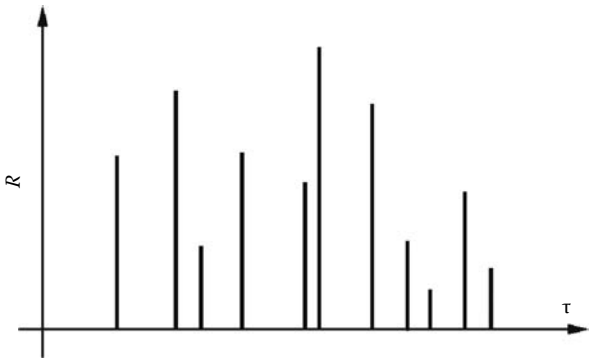

FIGURE 18.13 A lumped element one-port can be represented with a discrete set of time constants. (From Székely, V., *IEEE Trans. Circuits Syst.*, 38, 711, 1991. With permission.)

kind of a spectrum, the spectrum of the time constants that appeared in the step-function response of the network.

The port-impedance of a lumped element network has discrete ''spectrum lines'' in finite number. An infinite distributed network has no discrete lines, but it can be described with the help of a continuous time constant spectrum. The physical meaning of this idea is that in a general response any time constant can occur in some amount, some density, so that a density spectrum may suitably represent it.

We define the spectrum function by first introducing a new, logarithmic variable for the time and the time constants:

$$z = \ln t, \quad \zeta = \ln \tau \tag{18.43}$$

Let us consider a DRC one-port, the response of which contains numerous exponentials having different time constants and magnitudes. The ''time constant density'' is defined as

$$R(\zeta) = \lim_{\Delta\zeta \to 0} \frac{\text{sum of magnitudes between } \zeta \text{ and } \zeta + \Delta\zeta}{\Delta\zeta} \tag{18.44}$$

From this definition directly follows the fact that the step-function response can be composed from the time-constant density:

$$v(t) = \int_{-\infty}^{\infty} R(\zeta)[1 - \exp(-t/\exp(\zeta))]\mathrm{d}\zeta \tag{18.45}$$

This integral is obviously the generalization of the summation in Equation 18.42. If the $R(\zeta)$ density function consists of discrete lines (Dirac-δ pulses), Equation 18.42 is given back.

Using the logarithmic time variable in the integral of Equation 18.45

$$v(z) = \int_{-\infty}^{\infty} R(\zeta)[1 - \exp(-\exp(z - \zeta))]\mathrm{d}\zeta \tag{18.46}$$

a convolution-type differential equation is obtained. Differentiating both sides with respect to z, we obtain

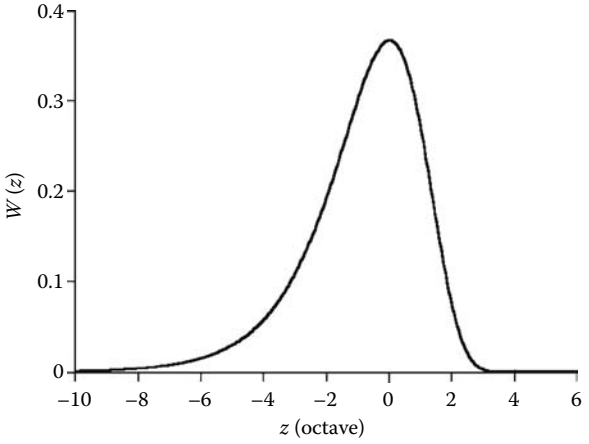

FIGURE 18.14 The shape of the $W(z)$ function. (From Székely, V., *IEEE Trans. Circuits Syst.*, 38, 711, 1991. With permission.)

$$\frac{\mathrm{d}}{\mathrm{d}z}\nu(z) = R(z) \otimes W(z) \tag{18.47}$$

where

$$W(z) = \exp(z - \exp(z)) \tag{18.48}$$

is a fixed weighting function with shape depicted in Figure 18.14, and $\otimes$ is the symbol of the convolution operation [3].

It can be proved that the area under the function $W(z)$ is equal to unity

$$\int_{-\infty}^{\infty} W(z)\mathrm{d}z = 1 \tag{18.49}$$

This means that

$$\int_{-\infty}^{\infty} R(z)\mathrm{d}z = \nu(t \to \infty) = R_0 \tag{18.50}$$

where R_0 is the zero-frequency value of the impedance. In other words, the finite step-function response guarantees that the time-constant density has finite integral.

18.3.2 Generalization of the Pole-Zero Representation

The task is now to substitute the pole-zero pattern of the lumped network with a continuous (eventually excepting some discrete points) function to describe the general distributed parameter network.

As emphasized above, the Bode plot of a distributed parameter network frequently shows regions with a 10 dB/decade slope. Figure 18.15 presents such an amplitude diagram. Using poles and zeroes, we can only approximate this behavior. If we place to point ω_1 a pole, the Bode plot turns to the decay of 20 dB/decade, which is too steep. If a zero is placed, the diagram returns to the zero-slope. However, if we alternate poles and zeroes in a manner that the mean value of the slope should give the prescribed one,

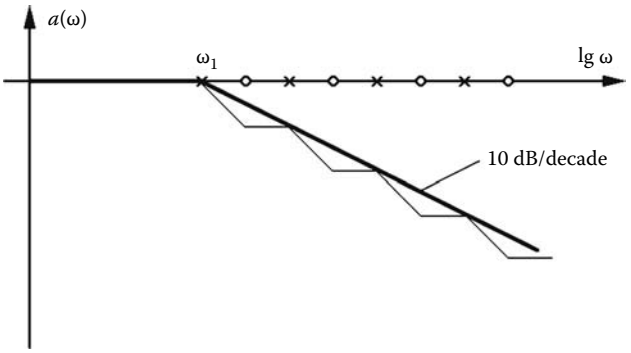

FIGURE 18.15 The 10 dB/decade decay of a DRC line amplitude plot can be approximated with an alternative sequence of poles and zeroes. (From Székely, V., *IEEE Trans. Circuits Syst.*, 38, 711, 1991. With permission.)

then any slope can be approximated. (For the previously-mentioned case, if the zeroes are situated exactly midway between the adjacent poles, then the mean slope is 10 dB/decade.) The suitability of the approximation depends on the density of poles and zeroes and can be improved by increasing the density. In this case, the network-specific information is not carried by the number of poles and zeroes (their number tends to infinity), but by the relative position of the zeroes between the adjacent poles.

An alternative interpretation is also possible. The pair of a neighboring pole and zero constitutes a dipole. The ''intensity'' of that dipole depends on the distance between the pole and the zero. If they coincide and cancel each other, then the intensity is equal to zero. If the zero is situated at the maximal distance from the pole (i.e., it is at the next pole), the intensity reaches its maximal value. We choose this to be the unity.

For later convenience, we turn to a logarithmic variable on the negative σ-axis:

$$\Sigma = \ln(-\sigma) \tag{18.51}$$

Let us investigate a $\Delta\Sigma$ interval of the logarithmic Σ-axis bounded by two adjacent poles. The distance between the left-hand pole and the inner zero is $\delta\Sigma$. Now, suppose that the density of the poles tends to infinity; i.e., $\Delta\Sigma$ becomes infinitely small. In this case the ''dipole intensity function'' is

$$I_d(\Sigma) = \lim_{\Delta\Sigma \to 0} \frac{\delta\Sigma}{\Delta\Sigma} \tag{18.52}$$

Considering that the poles and zeros of an RC port-impedance alternate, it follows that $0 \leq I_d \leq 1$. For an infinite, distributed RC two-pole the dipole intensity generally has regions in which the I_d value is between 0 and 1. For example, if the Bode plot shows a slope of 10 dB/decade, the value of I_d equals 0.5. This occurs in the case of an infinite, uniform RC line. For discrete circuits, the I_d function has only two possible values: 0 or 1.

18.3.3 Relations among $R(\zeta)$, $I_d(\Sigma)$, and the Impedance Function

Obviously, we needed one-to-one relations between the time constant density or the dipole intensity representation and the impedance expression of the one-port. (For the lumped element case Equations 18.39 and 18.40 give these correspondences).

Rather simple relations exist among the $R(\zeta)$, $I_d(\Sigma)$, and the $\mathbf{Z}(\mathbf{s})$ impedance function (see below). An interesting feature of these relations is a striking mathematical symmetry: the same expression couples

the time constant density to the impedance and the dipole intensity to the logarithmic impedance. The detailed proofs of the relations presented here are given in Ref. [4].

If the $\mathbf{Z}(\mathbf{s})$ complex impedance function is known, $R(\zeta)$ or $I_d(\Sigma)$ can be calculated as*

$$R(\zeta) = \frac{1}{\pi} \operatorname{Im} \mathbf{Z}(\mathbf{s} = -\exp(-\zeta)) \tag{18.53}$$

$$I_d(\Sigma) = \frac{1}{\pi} \operatorname{Im} (\ln \mathbf{Z}(\mathbf{s} = -\exp(\Sigma))) \tag{18.54}$$

If the $R(\zeta)$ or $I_d(\Sigma)$ function is known

$$\mathbf{Z}(\mathbf{S}) = R_0 - \int_{-\infty}^{\infty} R(-x) \frac{\exp(\mathbf{S} - x)}{1 + \exp(\mathbf{S} - x)} dx \tag{18.55}$$

$$\ln \mathbf{Z}(\mathbf{S}) = \ln R_0 - \int_{-\infty}^{\infty} I_d(x) \frac{\exp(\mathbf{S} - x)}{1 + \exp(\mathbf{S} - x)} dx \tag{18.56}$$

where $\mathbf{S}$ is the complex-valued logarithm of the complex frequency:

$$\mathbf{S} = \ln \mathbf{s} \tag{18.57}$$

Using the integral Equations 18.55 and 18.56, however, we must keep at least one from the two conditions:

1. $\mathbf{s}$ is not located on the negative real axis.
2. If $\mathbf{s}$ is located on the negative real axis then, at this point, and in a $\varepsilon \to 0$ neighborhood, $R(\zeta)$ or $I_d(\Sigma)$ must be equal to 0.

Note that Equations 18.53 through 18.56 are closely related to the Cauchy integral formula of the complex function theory. Substituting Equation 18.53 into 18.55 and exploiting some inherent properties of the RC impedance functions after some mathematics, the Cauchy integral results. The same is true for Equations 18.54 and 18.56.

An important feature of the transformations of Equations 18.53 and 18.55 is that they are linear. This means that the $\mathbf{Z}(\mathbf{s}) \times R(\zeta)$ transformation and the summation are interchangeable.

18.3.4 Practical Calculation of the $R(\zeta)$ Function†

Equation 18.53 suggests that only the $j\omega$ imaginary frequency has to be replaced by the $\mathbf{s} = -\exp(-z)$ complex frequency, and then the imaginary part of the calculated complex response multiplied by $1/\pi$ provides the time-constant spectrum.

However, the procedure is not as simple as that because of the use of Equation 18.53. This equation requires a great amount of caution. As the equation shows, the imaginary part of the $\mathbf{Z}$ impedance has to be calculated along the negative real axis of the complex plane. Along this axis, singularities usually lie: the poles of the network equation of lumped circuits or some singular lines in the case of distributed

* For Equation 12.53 $\mathbf{Z}(\mathbf{s} \to \infty) = 0$ is supposed.

† Portions reprinted, with permission, from Székely, V. and Rencz, M., *IEEE Trans. Compon. Pack. Technol.*, 23(3), 587, 2000. © 2000 IEEE.

systems. These singularities can prevent the use of Equation 18.53 for the calculation of the time-constant spectrum.

We can overcome these difficulties by adapting an approximate solution. In order to walk around the ''dangerous'' area, we have to avoid following the negative real axis. A line that is appropriately close to this axis might be used instead [9], like

$$\mathbf{s} = -(\cos\delta + j\sin\delta)\exp(-z) \tag{18.58}$$

Obviously, the δ angle has to be very small, not more than 2°–5°. Even if this angle is small, an error is introduced into the calculation. It can be proven that the calculated $R_C(z)$ time-constant spectrum can be expressed with the exact one by the following convolution equation:

$$R_C(z) = \frac{\pi - \delta}{\pi} R(z) \otimes e_r(z) \tag{18.59}$$

where

$$e_r(z) = \frac{1}{\pi - \delta} \frac{\sin\delta \exp(-z)}{1 - 2\cos\delta\exp(-z) + \exp(-2z)} \tag{18.60}$$

This function is a narrow pulse of unity area. The error of the calculation is represented by this function. Diminishing δ the $e_r(z)$ function becomes narrower and narrower. Thus, any accuracy requirement can be fulfilled by choosing an appropriately small δ angle. The half-value width, which is a measure of the resolution, is given by

$$\Delta_e = 2\ln\left(2 - \cos\delta + \sqrt{(2-\cos\delta)^2 - 1}\right) \cong 2\delta \tag{18.61}$$

If, for example, $\delta = 2°$, then the resolution is 0.1 octave, which means that two poles can be distinguished if the ratio between their frequencies is greater than 1.072.

Obviously, the calculated result has to be corrected with the factor of $\pi/(\pi - \delta)$.

Example 18.3

A tight analogy exists between electrical conductance and heat flow. Heat-conducting media, which can be characterized with distributed heat resistance and distributed heat capacitance, behave similarly to the electrical DRC networks. The analogous quantities are as follows:

Voltage → Temperature
Current → Power flow
Resistance → Thermal resistance
Capacitance → Heat capacitance

In the simplest model law, 1 V voltage corresponds to 1°C, 1 A current to 1 W power, etc., but different mapping can be applied as well.

The described analogy means that the tool set that is used to treat DRC networks can be applied to the calculation of heat-flow problems as well. This fact provides a direct way to calculate time-constant spectra in thermal field solver programs. These are thermal simulation tools suitable to solve the model equations in the **s**-domain. By using the substitution of Equation 18.58, some of these programs calculate directly the thermal time-constant spectrum of different structures [9]. As an example, a transistor package, presented in Figure 18.16a, was simulated. The time-constant spectrum calculated by the field

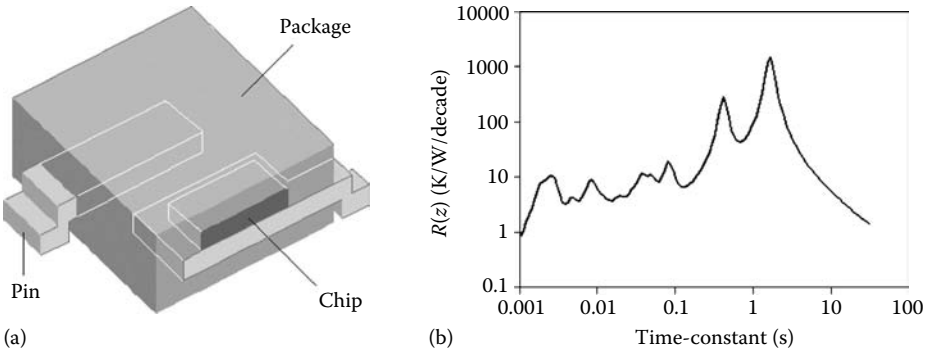

FIGURE 18.16 A transistor package and its time-constant spectrum. (a) Simulated transistor package. (b) Time-constant spectrum calculated by the field solver. (From Székely, V. and Rencz, M., *IEEE Trans. Compon. Pack. Technol.*, 23, 587, 2000. With permission.)

solver is plotted in Figure 18.16b. It is clearly visible that besides the two dominant time-constants a large number of further time-constants appear in the spectrum.

18.4 Inverse Problem for Distributed RC Circuits

Equation 18.47 offers a direct way to determine the time-constant density from the (measured or calculated) response function, which means that it is a method for the identification of RC one-ports. Using Equation 18.47 for a measured time domain response function, the time-constant density of the one-port impedance can be determined. By using this method, equivalent circuits can be constructed easily. This possibility is of considerable practical importance [8]; however, only approximate results can be obtained because the calculation leads to the inverse operation of the convolution. This operation can be done only approximately.

A possibility exists for identification in the frequency domain as well. Introducing the $\Omega = \ln \omega$ notation for the frequency axis, convolution-type equations can be found [8] between the $R(\zeta)$ time-constant density and the $\mathbf{Z}(\omega)$ complex impedance:

$$-\frac{\mathrm{d}}{\mathrm{d}\Omega}\mathrm{Re}\,\mathbf{Z}(\Omega) = R(\zeta = -\Omega) \otimes W_{\mathrm{R}}(\Omega) \tag{18.62}$$

$$-\mathrm{Im}\,\mathbf{Z}(\Omega) = R(\zeta = -\Omega) \otimes W_{\mathrm{I}}(\Omega) \tag{18.63}$$

where the weight-functions are

$$W_{\mathrm{R}}(\Omega) = \frac{2 \cdot \exp(2\ \Omega)}{(1 + \exp(2\ \Omega))^2} \tag{18.64}$$

$$W_{\mathrm{I}}(\Omega) = \frac{\exp(\Omega)}{1 + \exp(2\ \Omega)} \tag{18.65}$$

Moreover, a direct convolution relation exists between the Bode diagram of the impedance and the dipole intensity. Considering the Bode amplitude and phase diagrams, i.e., by using $\ln(\mathbf{Z}(\Omega)) = \ln \mathrm{abs}(\mathbf{Z}(\Omega)) + j \cdot \mathrm{arcus}(\mathbf{Z}(\Omega))$, we obtain

$$-\frac{\mathrm{d}}{\mathrm{d}\Omega}\ln \mathrm{abs}(\mathbf{Z}(\Omega)) = I_{\mathrm{d}}(\Omega) \otimes W_{\mathrm{R}}(\Omega) \tag{18.66}$$

$$-\text{arcus}(\mathbf{Z}(\Omega)) = I_d(\Omega) \otimes W_I(\Omega) \tag{18.67}$$

These equations may also be used for identification.

18.4.1 Network Identification by Deconvolution

All the relations between the $R(\zeta)$ time-constant spectrum and the different network responses are of convolution type Equations 18.47, 18.62, and 18.63. Knowing some kind of network responses the inverse operation of the convolution: the deconvolution leads to the $R(\zeta)$ function. The same is true for Equations 18.66 and 18.67 of the $I_d(\Sigma)$ dipole intensity. This means that the problem of identification of DRC networks is reduced to a deconvolution step. This method, called network identification by deconvolution (NID), is discussed in detail in Ref. [8], together with the appropriate deconvolution methods.

An important fact is that if we know the time response or only the real or the imaginary part of the frequency response, the network can be completely identified. (Noise effects produce practical limits—see later.)

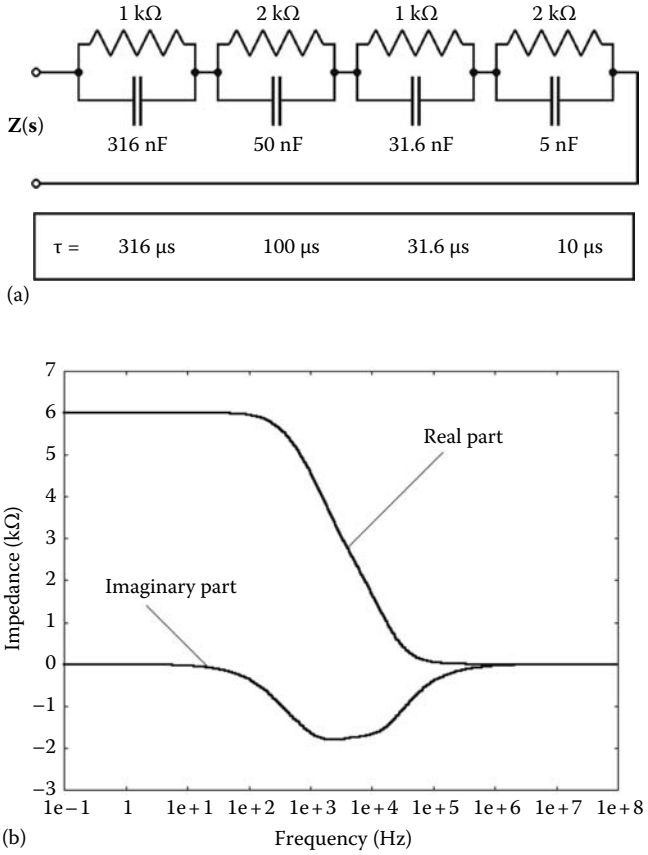

FIGURE 18.17 RC ladder and the frequency response of the $\mathbf{Z}(\omega)$ impedance. (a) Investigated RC network. (b) Real and the imaginary parts of the impedence. (From Székely, V., *IEEE Trans. Circuits Syst.—I. Theory Appl.*, 45, 244, 1998. With permission.)

Example 18.4

For the sake of simplicity, a "lumped circuit problem" will be discussed first. The investigated RC network is given in Figure 18.17a. We have calculated the frequency response of the **Z**(**s**) port-impedance of this circuit by using a standard circuit-simulator program, with a 40 point/frequency-decade resolution. Both the real and the imaginary parts of this impedance are plotted in Figure 18.17b.

In order to apply Equation 18.62, the derivative of the real part was calculated numerically. The result is shown in Figure 18.18a. In the next step, this function was deconvolved by the $W_R(\Omega)$ function. The result is plotted in Figure 18.18b. This function is the approximate time-constant density of the network. We expect that this function depicts the pole-pattern of the circuit. This is in fact obtained: the four peaks of the function are lying at $f = 497.7$, 1,585, 4,908, and 15,850 Hz. These

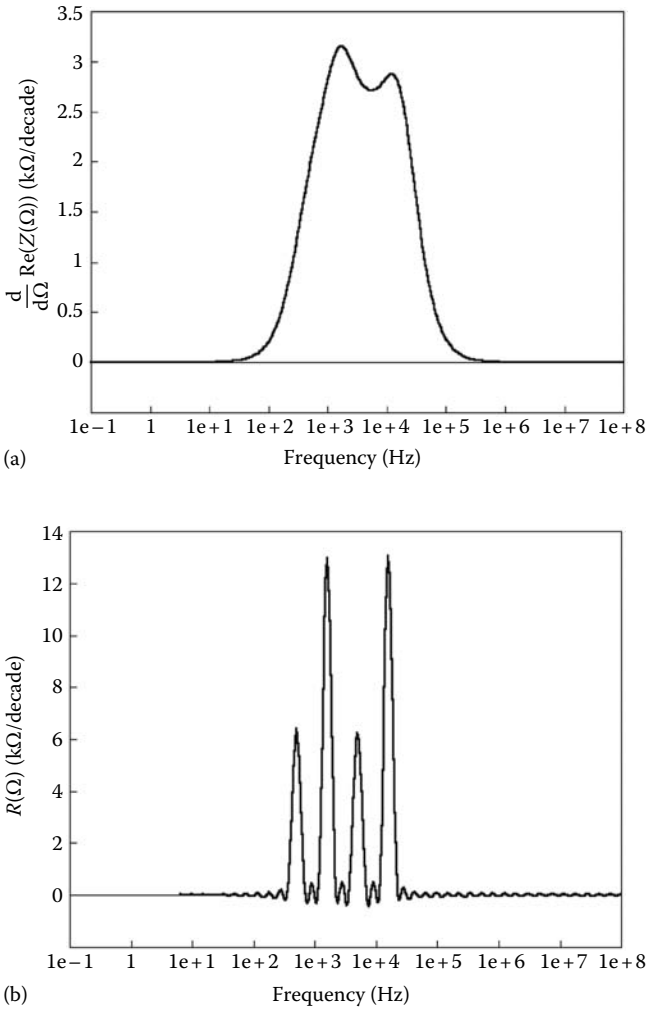

FIGURE 18.18 Identification steps. (a) Derivative of Real(**Z**). (b) The identified time-constant spectrum. (From Székely, V., *IEEE Trans. Circuits Syst.—I. Theory Appl.*, 45, 244, 1998. With permission.)

values correspond to the time constants of 320, 100.4, 32.43, and 10.04 μs, respectively. The ratios of the peak areas are about 1:2:1:2. These data agree well with the actual parameters of the circuit in Figure 18.17a.*

Notice that the noise corrupting the $\mathbf{Z}(\omega)$ function considerably affects the result of the identification. In order to reach 1 octave resolution of $R(\zeta)$ along the frequency axis, about 68 dB noise separation is needed in $\mathbf{Z}(\omega)$. Detailed discussion of the noise effects on the identification can be found in Ref. [8].

Example 18.5

As a second example, let us discuss the thermal identification of a semiconductor package + heat sink structure. The analogy between electrical current and heat flow introduced in Example 18.3 will be applied again.

Between a semiconductor chip and its ambient a complex distributed thermal structure exists consisting of many elements. The main parts of it are the chip itself, the soldering, the package, mounting to the heat sink, the heat sink itself, and the ambience. This is obviously a distributed thermal RC network, the input-port of which is the top surface of the chip and the far end is the ambience (the world). Thus, the structure can be considered practically infinite. This means that we have to examine a nonuniform infinite-length DRC network.

Investigations in the time domain require recording the thermal step-response of the system. A thermal test chip can be used for this purpose, containing appropriate heating elements that can assure step-function power excitation. The temperature rise is measured by the forward voltage change of a pn junction integrated into the test chip as well. This is the thermal response function. Such a thermal response is plotted in Figure 18.19a. The time range of the measurement is strikingly wide: 9 decades, from 10 μs to some thousand s. This is indispensable since the thermal time constants of the heat-flow structure vary over a wide range.

According to Equation 18.47, after numerical derivation of the step-response and by a consecutive deconvolution, the time constant density function $R(z)$ can be obtained (see Figure 18.19b). Because of the quantization noise and measuring error the deconvolution operation can be done only approximately with a $1 \div 1.5$ octave resolution. A suitable algorithm is discussed in Ref. [7]. Figure 18.19b illustrates that, in the 100 μs to 10 s interval, time constants spread over a relative wide range. This refers to the distributed structure of the chip and the package. At $\tau \approx 1000$ s, a relatively sharp, distinct time constant appears. This can be identified as originating from the heat capacitance of the whole heat sink and the heat sink-ambience thermal resistance.

Splitting the resultant time constant spectrum into $\Delta\tau$ time slots, each of these slots can be approximated by a Dirac-δ spectrum line proportional in height to the appropriate slot area. These give the data of a lumped element approximation according to Equation 18.40. Now, the equivalent circuit of the heat-flow structure can be generated either in Foster or in Cauer normal form.

Using the Cauer-approximation of the DRC line we can calculate the approximate $K(\rho)$ and $\sigma(\rho)$ structure functions. From these functions, the heat-conducting cross-section areas, the heat flow path length, etc. can be derived. This means that geometric and physical data of the heat-flow structure can be extracted and checked with the help of an electrical measurement. The structure function calculated from the measurement results of Figure 18.19 is plotted in Figure 18.20. It is easy to read out, e.g., the C_{hs} heat capacitance of the heat sink. For more details, see Refs. [6,10].

19.1 Generic Relations

The starting procedure for the synthesis of distributed circuits is the same as for the conventional synthesis of lumped parameter circuits. If a one-port network is to be synthesized, then a desired driving-point immittance $H(s)$ must be defined first, where

$$s = \sigma + j\omega \tag{19.1}$$

is the complex frequency, σ is the damping coefficient of the operating signal, and ω is the operating angular frequency. If a two-port network is to be synthesized, then a desired transmittance $T(s)$ must be defined first.

According to conventional principles of network synthesis [1], for the one-port network, $H(s)$ is represented by

$$H(s) = \frac{P(s)}{Q(s)} = \frac{a_n s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0}{b_m s^m + b_{m-1}s^{m-1} + \cdots + b_1 s + b_0} \tag{19.2}$$

where

a_n and b_m are constants determined by the network parameters
$Q(s)$ is a driving function
$P(s)$ is the response function

for a two-port network

$$T(s) = \frac{P(s)}{Q(s)} = \frac{a_n s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0}{b_m s^m + b_{m-1}s^{m-1} + \cdots + b_1 s + b_0} \tag{19.3}$$

Both $H(s)$ and $T(s)$ should be examined for realizability [1] before proceeding.

If the summation of even-order terms of $P(s)$ is $M_1(s)$ and the summation of odd-order terms of $P(s)$ is $N_1(s)$, then

$$P(s) = M_1(s) + N_1(s) \tag{19.4}$$

Similarly,

$$Q(s) = M_2(s) + N_2(s) \tag{19.5}$$

For a one-port network the driving-point impedance is synthesized by [1]

$$Z(s) = \frac{N_1(s)}{M_2(s)} \tag{19.6}$$

or

$$Z(s) = \frac{M_1(s)}{N_2(s)} \tag{19.7}$$

For a two-port network [1], if $P(s)$ is even, the transadmittance is

$$y_{21} = \frac{P(s)/N_2(s)}{1 + [M_2(s)/N_2(s)]} \tag{19.8}$$

the open-circuit transfer admittance is

$$y_{21} = \frac{P(s)}{N_2(s)} \tag{19.9}$$

and the open-circuit output admittance is

$$y_{22} = \frac{M_2(s)}{N_2(s)} \tag{19.10}$$

If $P(s)$ is odd,

$$y_{21} = \frac{P(s)/N_2(s)}{1 + [M_2(s)/N_2(s)]} \tag{19.11}$$

$$y_{21} = \frac{P(s)}{M_2(s)} \tag{19.12}$$

and

$$y_{22} = \frac{N_2(s)}{M_2(s)} \tag{19.13}$$

In both cases,

$$y_{11} = \frac{y_{21}(s)}{n} \tag{19.14}$$

where n is the current-ratio transfer function from port 1 to port 2. From these y- or z-parameters, the required values for the network components, i.e., L, C, and R, can be determined [1].

In high-frequency circuits the L, C, and R may be synthesized using distributed circuit components. The synthesis of distributed components in microstrip line and circuits is the emphasis of this chapter.

19.2 Synthesis of a Capacitance

If the required capacitive impedance is $-jX_C\ \Omega$, the capacitance is

$$C = \frac{1}{\omega X_C} \tag{19.15}$$

where

$$X_C > 0 \tag{19.16}$$

and ω is the operating angular frequency. In a distributed circuit the capacitance C is often synthesized using a short section of a short-circuited transmission line of negligibly small transmission line loss. If the characteristic impedance of such a transmission line is Z_0, the operating transmission line wavelength is λ_l, and the length of the transmission line is l in meters, then [2]

$$jX_C = jZ_0 \tan\frac{2\pi l}{\lambda_l} \tag{19.17}$$

where

$$\frac{\lambda_l}{4} < l < \frac{\lambda_l}{2}$$

or, more generally,

$$\frac{n\lambda_l}{2} + \frac{\lambda_l}{4} < l < \frac{n\lambda_l}{2} + \frac{\lambda_l}{2} \tag{19.18}$$

and n is an integer. Detailed information on Z_0 and λ_l is given in Chapter 15. Combining Equations 19.15 and 19.17,

$$C = \frac{1}{\omega Z_0 \tan\frac{2\pi l}{\lambda_l}} \tag{19.19}$$

In practical synthesis, the transmission line length must be determined. The design equation is

$$l = \frac{\lambda_l}{2\pi} \tan^{-1}\left(\frac{1}{\omega C Z_0}\right) \tag{19.20}$$

Thus, the capacitance C can be synthesized using a section of a short-circuited transmission line.

If an open-circuited transmission line is used instead, then

$$l = \frac{\lambda_l}{2}\left[\frac{1}{\pi}\tan^{-1}\frac{1}{\omega C Z_0} + \frac{1}{2}\right] \tag{19.21}$$

Equation 19.19 is valid provided that Equation 19.20 is used for l or,

$$l = \frac{\lambda_l}{2}\tan^{-1}\ \omega C Z_0 \tag{19.22}$$

where

$$\frac{n\lambda_l}{2} < l < \frac{\lambda_l}{4} + \frac{n\lambda_l}{2} \tag{19.23}$$

If an open-circuited transmission line section is used instead of the short-circuited transmission line section, just add $\lambda_l/4$ to the line length.

19.3 Synthesis of an Inductance

If the required inductive impedance is $+jX_L\ \Omega$, the inductance is

$$L = \frac{X_L}{\omega} \tag{19.24}$$

where

$$X_L > 0 \tag{19.25}$$

and ω is the operating angular frequency. In a distributed circuit the inductance L is often synthesized using a short section of a short-circuited transmission line of negligibly small transmission line loss. If the characteristic impedance of such a transmission line is Z_0, the operating transmission line wavelength is λ_l, and the length of transmission line is l meters, then [2]

$$jX_L = jZ_0 \tan\frac{2\pi l}{\lambda_l} \tag{19.26}$$

where

$$0 < l < \frac{\lambda_l}{4} \tag{19.27}$$

or, more generally,

$$\frac{n\lambda_l}{2} < l < \frac{n\lambda_l}{2} + \frac{\lambda_l}{4} \tag{19.28}$$

and n is an integer. Detailed information on Z_0 and λ_l is given in Chapter 15.

Combining Equations 19.24 and 19.26

$$L = \frac{Z_0}{\omega} \tan 2\pi \frac{l}{\lambda_l} \tag{19.29}$$

In practical synthesis, the transmission line length must be designed. The design equation is

$$l = \frac{\lambda_l}{2\pi} \tan^{-1} \frac{\omega L}{Z_0} \tag{19.30}$$

Thus, the inductance L can be synthesized using a section of a short-circuited transmission line.

If an open-circuited transmission line is used instead, then

$$l = \frac{\lambda_l}{2} \left(\frac{1}{\pi} \tan^{-1} \frac{\omega L}{Z_0} + \frac{1}{2} \right) \tag{19.31}$$

Equation 19.29 is valid for the open-circuited transmission line provided that Equation 19.31 is used for l or

$$l = \frac{\lambda_l}{2\pi} \tan^{-1} \frac{Z_0}{\omega L} \tag{19.32}$$

where

$$\frac{n\lambda_l}{2} + \frac{\lambda_l}{4} < l < \frac{\lambda_l}{2} + \frac{n\lambda_l}{2} \tag{19.33}$$

If an open-circuited transmission line is used instead of the short-circuited transmission line section, just add $\lambda_l/4$ to the short-circuited transmission line design.

19.4 Synthesis of a Resistance

A distributed circuit resistance can be synthesized using a lossy transmission line of length l with the line end short or open-circuited. When the line end is short-circuited, the input impedance of the line of length l and characteristic impedance $\dot{Z}_0$ is [2]

$$\dot{Z}_i = \dot{Z}_0 \tanh \dot{\gamma} l \tag{19.34}$$

where the propagation constant is

$$\dot{\gamma} = \alpha + j\beta \tag{19.35}$$

α is the attenuation constant, and β is the phase constant of the line. Assuming Z_0 is real, the input impedance becomes a pure resistance, i.e., the reactance becomes zero, when

$$\beta l = \frac{2\pi l}{\lambda_l} = \frac{1}{2}\pi, \frac{3}{2}\pi, \frac{5}{2}\pi, \ldots \tag{19.36}$$

When

$$\beta l = (2n+1)\frac{\pi}{2} \tag{19.37}$$

and where

$$n = 0, 1, 2, 3, \ldots \tag{19.38}$$

the short-circuited transmission line is at antiresonance. When

$$\beta l = 2n\frac{\pi}{2} \tag{19.39}$$

and where

$$n = 1, 2, 3, \ldots \tag{19.40}$$

the transmission line is at resonance.

When the transmission line is at antiresonance, the input impedance is [2]

$$\dot{Z}_{\mathrm{i}} = \dot{Z}_0 \frac{1 + \varepsilon^{-\alpha(2n+1)\frac{\lambda_{\mathrm{l}}}{2}}}{1 - \varepsilon^{-\alpha(2n+1)\frac{\lambda_{\mathrm{l}}}{2}}} \tag{19.41}$$

If

$$\dot{Z}_0 \approx Z_0 \tag{19.42}$$

the input resistance is

$$R_{\mathrm{i}} \approx Z_0 \frac{1 + \varepsilon^{-\alpha(2n+1)\frac{\lambda_{\mathrm{l}}}{2}}}{1 - \varepsilon^{-\alpha(2n+1)\frac{\lambda_{\mathrm{l}}}{2}}} \tag{19.43}$$

where

$$l = (2n + 1)\frac{\lambda_{\mathrm{l}}}{4} \tag{19.44}$$

When the transmission line section is at resonance, the input resistance is

$$R_{\mathrm{i}} \approx Z_0 \frac{1 - \varepsilon^{-\alpha n\lambda_{\mathrm{l}}}}{1 + \varepsilon^{-\alpha n\lambda_{\mathrm{l}}}} \tag{19.45}$$

if Equation 13.41 holds, where

$$l = n\frac{\lambda_{\mathrm{l}}}{2} \tag{19.46}$$

From transmission line theory, α and β can be determined from the transmission line model parameters as [2]

$$\alpha = \frac{\omega LG + BR}{2\beta} \tag{19.47}$$

$$\beta = \left\{ \frac{\omega LB - RG + \sqrt{(RG - \omega LB)^2 + (\omega LG + BR)^2}}{2} \right\}^{\frac{1}{2}} \tag{19.48}$$

where

L is the series inductance per meter
G is the shunt conductance per meter
B is the shunt susceptance per meter
R is the series resistance per meter of the transmission line section

The characteristic impedance of a lossy line is [2]

$$\dot{Z}_0 = R_0 + jX_0 \tag{19.49}$$

$$R_0 = \frac{\left\{ RG + \omega LB + \sqrt{(RG - \omega LB)^2 + (\omega LG - BR)^2} \right\}^{\frac{1}{2}}}{\sqrt{2}\sqrt{G^2 + B^2}} \tag{19.50}$$

$$X_0 = \frac{1}{2R_0} \cdot \frac{\omega LG - BR}{G^2 + B^2} \tag{19.51}$$

or simply from Equation 13.34

$$l = \frac{1}{\dot{\gamma}} \tanh^{-1} \frac{R_i}{\dot{Z}_0} \tag{19.52}$$

to determine l for desired R_i for synthesis.

In practical circuit synthesis, convenient, commercially available, surface-mountable chip resistors are often used. Integrated circuit resistors are monolithically developed. Therefore, the technique described here is seldom used.

19.5 Synthesis of Transformers

An impedance $\dot{Z}_1$ can be transformed into another impedance $\dot{Z}_2$ using a lossless or low-loss transmission line of length l and characteristic impedance Z_0 [2]:

$$\dot{Z}_2 = Z_0 \frac{\dot{Z}_1 + jZ_0 \tan \frac{2\pi l}{\lambda_l}}{Z_0 + j\dot{Z}_1 \tan \frac{2\pi l}{\lambda_l}} \tag{19.53}$$

where λ_l is the wavelength on the transmission line. Solving Equation 19.53 for l,

$$l = \frac{\lambda_l}{2\pi} \tan^{-1} \frac{Z_0(\dot{Z}_2 - \dot{Z}_1)}{j\left(Z_0^2 - \dot{Z}_1\dot{Z}_2\right)} \tag{19.54}$$

In Equation 19.53, if

$$l = \frac{\lambda_l}{4} \tag{19.55}$$

then

$$\dot{Z}_2 = Z_0^2/\dot{Z}_1 \tag{19.56}$$

This is a quarter wavelength transmission line transformer. A low-impedance $\dot{Z}_1$ is transformed into a new high-impedance $\dot{Z}_2$, or vice versa. A capacitive $\dot{Z}_1$ is transformed into an inductive $\dot{Z}_2$, or vice versa. However, Z_0 is usually real, which restricts the available transformed impedances.

An admittance $\dot{Y}_1$ can be transformed into another admittance $\dot{Y}_2$ using a lossless or low-loss transmission line of length l and characteristic admittance $\dot{Y}_0$ [2]

$$\dot{Y}_2 = Y_0 \frac{\dot{Y}_1 + jY_0 \tan\frac{2\pi l}{\lambda_l}}{Y_0 + j\dot{Y}_1 \tan\frac{2\pi l}{\lambda_l}} \tag{19.57}$$

Solving Equation 19.56 for l,

$$l = \frac{\lambda_l}{2\pi} \tan^{-1} \frac{Y_0\left(\dot{Y}_2 - \dot{Y}_1\right)}{j\left(Y_0^2 - \dot{Y}_1\dot{Y}_2\right)} \tag{19.58}$$

In Equation 19.57, if

$$l = \frac{\lambda_1}{4} \tag{19.59}$$

then

$$\dot{Y}_2 = Y_0^2/\dot{Y}_1 \tag{19.60}$$

This is a one quarter-wavelength transmission line transformer. A low-admittance $\dot{Y}_1$ is transformed into a new high-admittance $\dot{Y}_2$, or vice versa. A capacitive $\dot{Y}_1$ is transformed into an inductive $\dot{Y}_2$, or vice versa. However, Y_0 is usually real, which restricts the available transformed admittances.

The transforming method Equations 19.53 and 19.57 cannot transform $\dot{Z}_1$ to every possible value of $\dot{Z}_2$, especially when the value of Z_0 is given. In practice, this is often the case. If this is the case and $\dot{Z}_1$ is complex, use Equation 19.53 first to transform $\dot{Z}_1$ to $\dot{Z}_2'$, where

$$\dot{Z}_2' = R_2' + jX_2' \tag{19.61}$$

and

$$R_2' = R_2 \tag{19.62}$$

where

$$\dot{Z}_2 = R_2 + jX_2 \tag{19.63}$$

Then, synthesize $X_2 - X_2'$ and add it in series at the input of the transmission line, as depicted in Figure 19.1. Then,

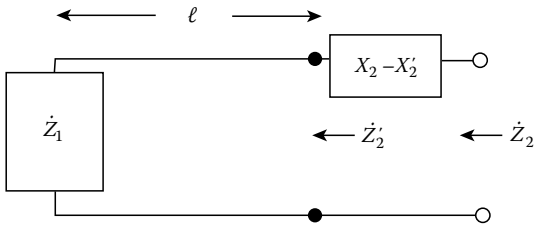

FIGURE 19.1 Synthesis of $\dot{Z}_1$ to any $\dot{Z}_2$ transformer.

$$\begin{aligned}\dot{Z}_2 &= \dot{Z}_2' + j(X_2 - X_2') \\ &= R_2' + jX_2' + jX_2 - jX_2' \\ &= R_2' + jX_2 \\ &= R_2 + jX_2 \end{aligned} \tag{19.64}$$

Thus, $\dot{Z}_1$ can be transformed to any $\dot{Z}_2$ desired.

In a similar manner, to transform a shunt admittance $\dot{Y}_1$ to any other shunt admittance $\dot{Y}_2$, first transform $\dot{Y}_1$ to $\dot{Y}_2'$ so that

$$\dot{Y}_2' = G_2' + jB_2' \tag{19.65}$$

and

$$G_2' = G_2 \tag{19.66}$$

where

$$\dot{Y}_2 = G_2 + jB_2 \tag{19.67}$$

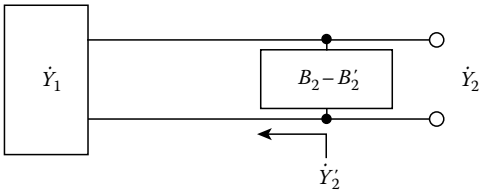

FIGURE 19.2 Synthesis of any $\dot{Y}_2$, from $\dot{Y}_1$ transformation.

Then, synthesize $B_2 - B_2'$ and add it in shunt at the input of the transmission line as depicted in Figure 19.2. Then,

$$\begin{aligned}\dot{Y}_2 &= \dot{Y}_2' + j(B_2 - B_2') \\ &= G_2' + jB_2' + jB_2 - jB_2' \\ &= G_2' + jB_2 = G_2 + jB_2 \end{aligned} \tag{19.68}$$

Thus, $\dot{Y}_1$ can be transformed to any $\dot{Y}_2$ desired.

19.6 Synthesis Examples

Distributed circuits can be synthesized using a number of transmission line sections. The transmission line sections include waveguides, coaxial lines, two-wire lines, and microstrip lines and coplanar waveguides. In this section, distributed circuit synthesis examples of distributed circuits using microstrip lines are presented for convenience. Similar techniques can be utilized for other types of transmission lines.

19.6.1 Series *L–C* Circuit

A series *L–C* circuit as illustrated in Figure 19.3 is considered to be a phase delay line in distributed line technology. The series impedance of an *L–C* circuit is $j(\omega L - 1/\omega C)$. If the load is a resistance of R_L Ω, then the phase delay in the output voltage is

$$\Delta\theta = \tan^{-1} \frac{\omega L - \frac{1}{\omega C}}{R_L} \tag{19.69}$$

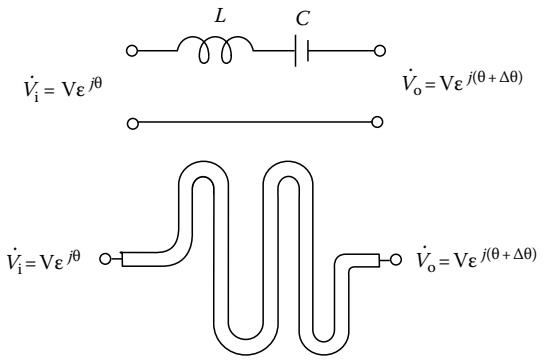

FIGURE 19.3 Synthesis of a series *L–C* circuit using a microstrip meander line.

The phase "delay" should be interpreted algebraically. Depending on the size of ωL and ωC, $\Delta\theta$ can be either "+" or "−." If it is delay, the sign of $\Delta\theta$ is "−" and if it is advance, the sign of $\Delta\theta$ must be "+" in Figure 19.3.

If the phase constant of the microstrip line is

$$\beta = \frac{2\pi}{\lambda_i} \tag{19.70}$$

where λ_1 is the wavelength on the line, then the synthesizing equation is

$$\Delta\theta = \beta l \tag{19.71}$$

or

$$l = \frac{\Delta\theta}{\beta} = \frac{\lambda_1}{2\pi}\tan^{-1}\frac{\omega L - \frac{1}{\omega C}}{R_L} \tag{19.72}$$

Usually, the delay line takes the form of a meander line in microstrip line, as illustrated in Figure 19.3.

19.6.2 Parallel *L–C* Circuit

A parallel *L–C* circuit (see Figure 19.4) can be synthesized using distributed circuit components. In this figure, the open-circuited microstrip line length l_1 represents inductive shunt admittance and the synthesis equation is given by Equation 19.31. In Figure 19.4 another open-circuited microstrip line length l_2 represents capacitive shunt admittance. The synthesis equation for this part is given by Equation 19.21.

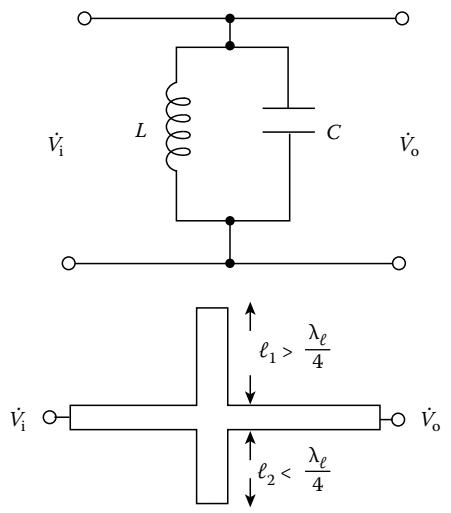

FIGURE 19.4 Synthesis of a parallel *L–C* circuit using a microstrip line circuit.

19.6.3 Series *L–C–R* Circuit

If the load resistance connected to the output circuit of a series *L–C–R* circuit (see Figure 19.5) is R_L, then the output voltage $\dot{V}_o$ of this network across R_L due to the input voltage $\dot{V}_i$ is

$$V_o = \frac{R_L\dot{V}_i}{R_L + R + j\left(\omega L - \frac{1}{\omega C}\right)} = \frac{R_L\dot{V}_i}{Z\varepsilon^{j\phi}} \tag{19.73}$$

where

$$Z = \sqrt{(R_L + R)^2 + \left(\omega L - \frac{1}{\omega C}\right)^2} \tag{19.74}$$

$$\phi = \tan^{-1} \frac{\omega L - \frac{1}{\omega C}}{R_L + R} \tag{19.75}$$

Thus,

$$\dot{V}_o = \frac{R_L}{Z} \dot{V}_i \varepsilon^{-j\phi} \tag{19.76}$$

In a distributed circuit, such as the microstrip line in Figure 19.5,

$$V_o = \dot{V}_i \varepsilon^{-\alpha l} \varepsilon^{-j\beta l} \tag{19.77}$$

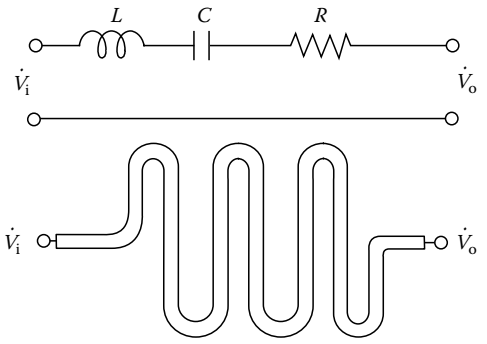

FIGURE 19.5 Synthesis of a series *L–C–R* circuit.

where

- α is the attenuation constant
- β is the phase constant
- l is the total length of the microstrip line

Then, comparing Equations 13.76 with 13.75,

$$\varepsilon^{-\alpha l} = \frac{R_L}{Z} \tag{19.78}$$

or

$$\alpha l = \ln \frac{Z}{R_L} \tag{19.79}$$

and

$$\beta l = \phi \tag{19.80}$$

19.6.4 Parallel *L–C–R* Circuit

A parallel *L–C–R* circuit can be synthesized using the microstrip line (see Figure 19.6). In this figure, the microstrip of length l_1, characteristic impedance $\dot{Z}_{01}$, attenuation constant α_1, and phase constant β_1 represents a parallel circuit of inductance L and $2R$. Another microstrip line of length l_2, characteristic impedance $\dot{Z}_{02}$, attenuation constant α_2, and phase constant β_2 represents a parallel circuit of capacitance C and $2R$.

The input admittance of the open-circuited lossy microstrip line is

$$\dot{Y}_i = \frac{1}{\dot{Z}_{01}} \tanh(\alpha_1 + j\beta_1) l_1 \tag{19.81}$$

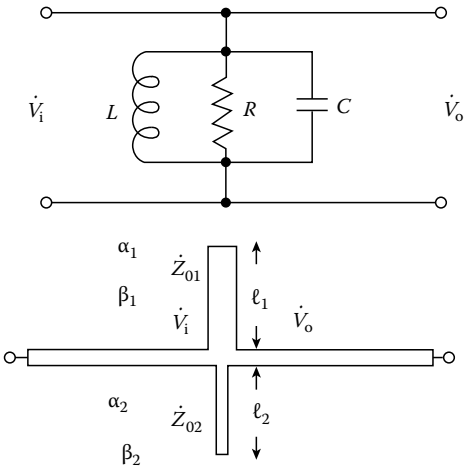

FIGURE 19.6 Synthesis of a parallel *L–C–R* circuit.

In a parallel L–$2R$ circuit, the parallel admittance is

$$Y_{\mathrm{i}} = \frac{1}{2R} + \frac{1}{j\omega L} \tag{19.82}$$

The synthesis equation for the inductive microstrip line is

$$(\alpha_1 + j\beta_1)l_1 = \tanh^{-1}\dot{Z}_{01}\left(\frac{1}{2R} - j\frac{1}{\omega L}\right) \tag{19.83}$$

Similarly, for the capacitive microstrip line,

$$(\alpha_2 + j\beta_2)l_2 = \tanh^{-1}\dot{Z}_{02}\left(\frac{1}{2R} + j\omega C\right) \tag{19.84}$$

To synthesize this distributed circuit, Equations 19.82 and 19.83 must be solved. These are transcendental equations of an excess number of unknowns to be determined by trial and error. Therefore, a digital computer is needed. In many cases, lossless lines are used for L and C and a shunt chip resistor is used for R to avoid complications.

19.6.5 Low-Pass Filters

If the load resistance of a low-pass filter, as presented in Figure 19.7 is R_{L}, then the admittance across R_{L} is

$$\dot{Y}_{\mathrm{L}} = \frac{1}{R_{\mathrm{L}}} + j\omega C \tag{19.85}$$

If this is synthesized using the microstrip line shown in Figure 19.7, then the normalized admittance of the microstrip line is

$$\tilde{\dot{Y}}_{\mathrm{L}} \equiv \frac{\dot{Y}_{\mathrm{L}}}{Y_0} = \frac{\frac{1}{R_{\mathrm{L}}} + j\omega C}{Y_0} \tag{19.86}$$

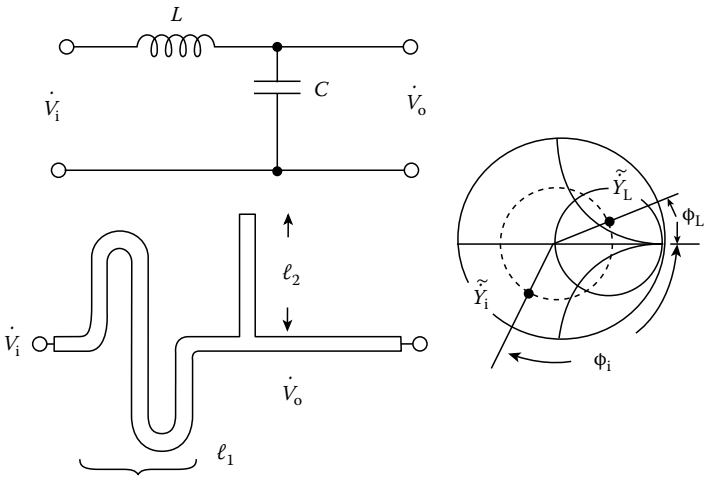

FIGURE 19.7 Synthesis of a low-pass filter.

where Y_0 is the characteristic admittance of the microstripline. $\tilde{\dot{Y}}_L$ should be plotted on a Smith chart as presented in Figure 19.7, and its angle of reflection coefficient ϕ_L must be noted. The input admittance of this circuit is

$$\begin{aligned}\dot{Y}_i &= \frac{1}{j\omega L + \frac{R_L\frac{1}{j\omega C}}{R_L+\frac{1}{j\omega C}}} \\ &= \frac{R_L + j\{\omega C R_C^2(1-\omega^2 LC) - \omega L\}}{R_L^2(1-\omega^2 LC)^2 + (\omega L)^2}\end{aligned} \tag{19.87}$$

This admittance is normalized as

$$\tilde{\dot{Y}}_i = \dot{Y}_i / Y_0 \tag{19.88}$$

and it must be plotted on the Smith chart (Figure 19.7). The phase angle of the reflection coefficient ϕ_i at this point must be noted. Therefore, the synthesis equation is

$$\beta_1 l_1 = \phi_L + \phi_i \tag{19.89}$$

In Figure 19.7, the meander line of length l_1, representing the inductance L, and a straight microstrip line of length l_2, representing the capacitance C, are joined to synthesize a microwave low-pass filter. The synthesis of the shunt capacitance C in Figure 19.7 is accomplished using an open-circuited microstrip line of the phase constant β_2. The length of the microstrip line l_2 is determined from Equation 19.21. If the low-pass filter takes on a π-shape, the microstrip version of synthesis will be similar to Figure 19.8. The microstrip line stub l_3 can be synthesized in the same way as the capacitive stub l_2.

19.6.6 High-Pass Filters

If a high-pass filter consists of a capacitance C and an inductance L, as shown in Figure 19.9, then normalized admittance across the load resistance R_L is

$$\tilde{\dot{Y}}_L = \dot{Y}_L / Y_0 = \left(\frac{1}{R_L} - j\frac{1}{\omega L}\right) \Big/ Y_0 \tag{19.90}$$

where Y_0 is the characteristic admittance of the microstrip line to be used for synthesis. This must be plotted on the Smith chart, as depicted in Figure 19.9, and the angle of reflection coefficient ϕ_L should be noted.

Normalized admittance at the input is

$$\begin{aligned}\tilde{\dot{Y}}_i \equiv \dot{Y}_i / Y_0 &= \frac{1}{\frac{1}{j\omega C} + \frac{(j\omega L)R_L}{j\omega L + R_L}} \Big/ Y_0 \\ &= \frac{(\omega^2 LC)^2 R_L + j\omega\{R_L^2 C(1-\omega^2 LC) + \omega^2 L^2 C\}}{R_L^2(1-\omega^2 LC)^2 + (\omega L)^2} \Big/ Y_0\end{aligned} \tag{19.91}$$

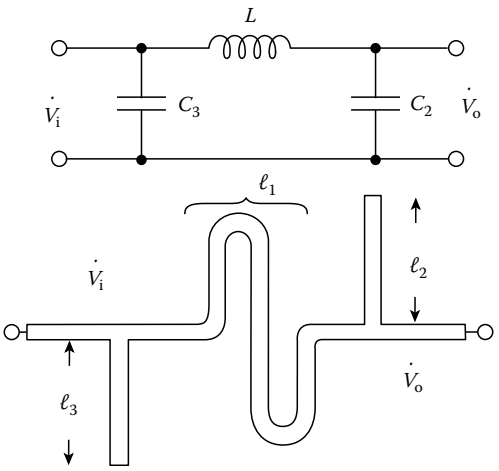

FIGURE 19.8 Synthesis of a π-network low-pass filter.

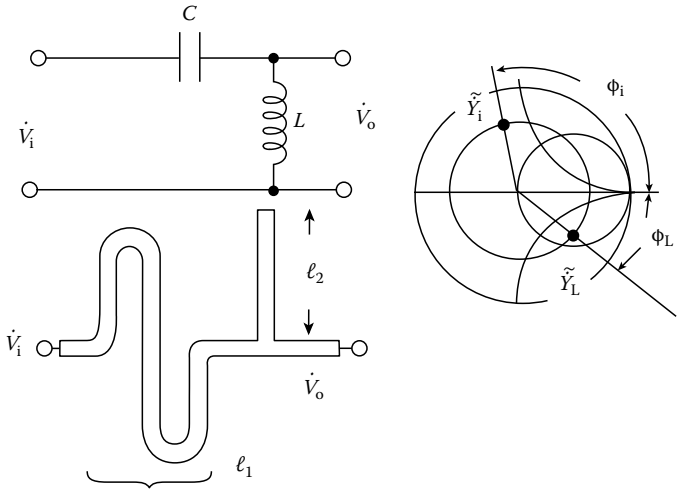

FIGURE 19.9 Synthesis of a high-pass filter.

Plot this on the Smith chart (Figure 19.9), and the angle of the voltage reflection coefficient ϕ_i should be noted.

The phase delay of the distributed microstrip line is

$$\dot{v}_0 = \dot{v}_i \varepsilon^{-j\beta l_1} \tag{19.92}$$

where β is a phase constant of the microstrip line and

$$\beta = 2\pi/\lambda_l \tag{19.93}$$

where λ_l is the wavelength on the microstrip line.

In Equation 19.91, l_1 is the length of microstrip line representing the *C*-section of the low-pass filter. Then, the synthesis equation is

$$\beta l_1 = 360^\circ - (\phi_i + \phi_L) \tag{19.94}$$

The shunt inductance *L* in Figure 19.9 is synthesized using Equation 19.31. Thus, a high-pass filter can be synthesized using a distributed microstrip line section. If the low-pass filter is in a π-network form, then microstrip line configuration will be at the designed frequency (see Figure 19.10).

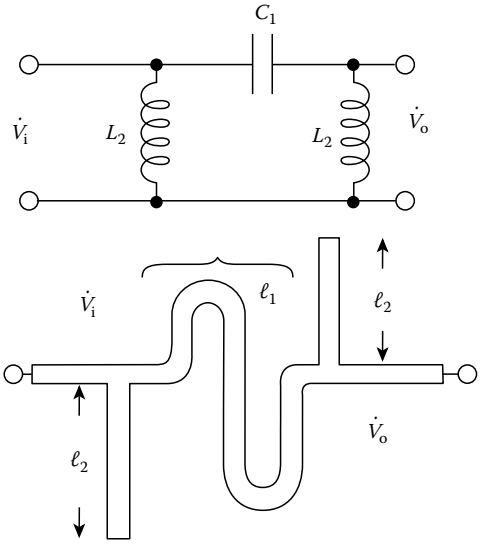

FIGURE 19.10 Synthesis of a π-network high-pass filter.

19.6.7 Bandpass Filters

A bandpass filter may be a series connection of an inductor *L* and a capacitor of capacitance *C*, as shown in Figure 19.11. This figure is identical to Figure 19.3.

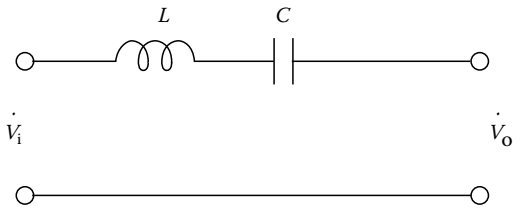

FIGURE 19.11 Configuration of a series *L*–*C* bandpass filter.

Therefore, the microstrip line synthesis equation is Equation 19.72.

If the bandpass filter is in the shape of a π-network (Figure 19.12a), then the series L_1C_1, represented by the meander microstrip line of length l_5, can be designed using Equation 19.72. Both of the shunt L_2 and C_2 arms are identical to Figure 19.4. Therefore, this part is synthesized by utilizing the technique in Section 19.6.2, which results in the configuration presented in Figure 19.12b. An alternative distributed version of Figure 19.12a is given in Figure 19.12c. In this figure, the technique in λ_l is the microstrip line wavelength at the center of the desired passband. The frequency bandwidth is determined by the quality factor of the resonating element.

19.6.8 Bandstop Filters

Various types of bandstop filters are available. A schematic diagram of a series type bandstop filter is shown in Figure 13.13. It is basically a resonant circuit inserted in series with the transmission line. The center frequency of the bandstop is the resonant frequency of the resonant circuit. The loaded quality factor of the resonator determines the bandstop width.

In the distributed microstrip line the resonator is a section of a half-wavelength microstrip line resonator of either low impedance (Figure 19.13a) or high impedance (Figure 19.13b), or a dielectric resonator placed in proximity to the microstrip line, (see Figure 19.13c) or a ring resonator placed in

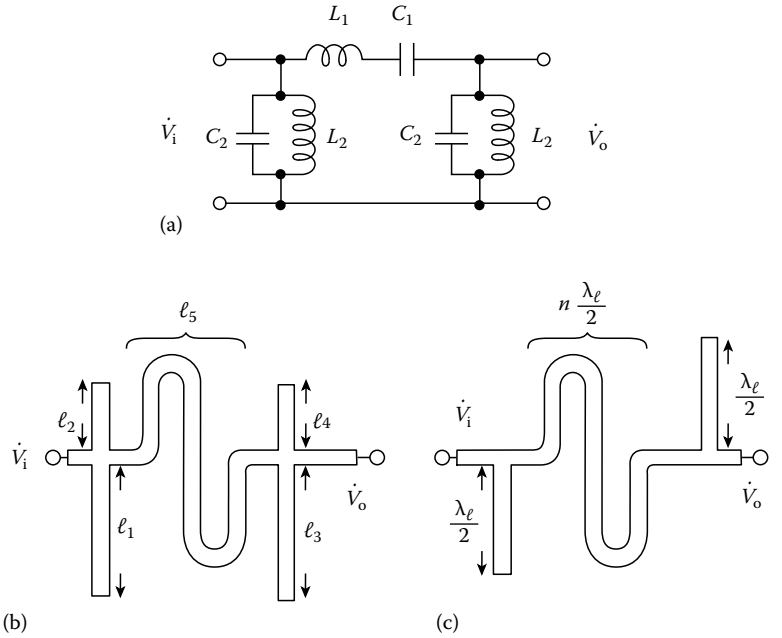

FIGURE 19.12 Synthesis of a distributed microstrip line π-network bandpass filter. (a) π-network. (b) Configuration of (a). (c) Alternative distributed version of (a).

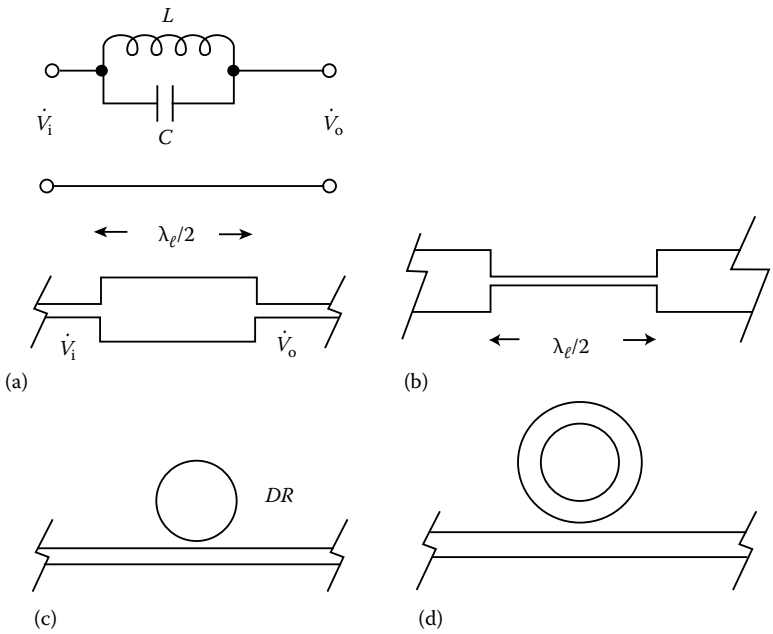

FIGURE 19.13 Synthesis of distributed series type bandstop filters. (a) A section of a half-wavelength microstrip line resonator of low impedance. (b) A section of a half-wavelength microstrip line resonator of high impedance. (c) A dielectric resonator placed in proximity to the microstrip line. (d) A ring resonator placed in proximity to the microstrip line.

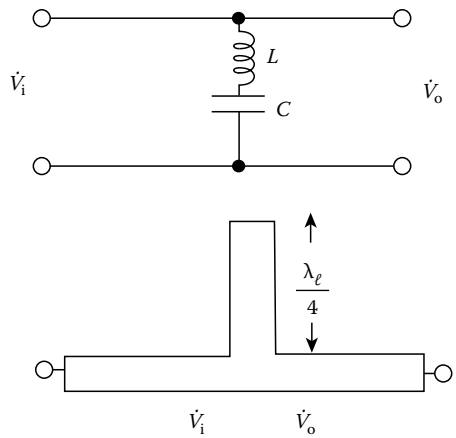

FIGURE 19.14 Synthesis of distributed parallel type bandstop filters.

proximity to the microstrip line (Figure 19.13d). The resonant frequency of the resonators is the center frequency of the bandstop. The bandwidth is determined by the loaded Q and coupling of the resonator.

A bandstop filter can also be synthesized in microstrip line if the filter is a parallel type (Figure 19.14). Simply attaching a one quarter-wavelength, open-circuited stub will create a bandstop filter. The center of the bandstop has a wavelength of λ_l (Figure 19.14).

A bandstop filter may take a π-network form, as illustrated in Figure 19.15, by the combination of the $\lambda_l/2$ resonator and $\lambda_l/4$ open-circuited stubs. The frequency bandwidth of the filter depends on the quality factor of the resonating elements.

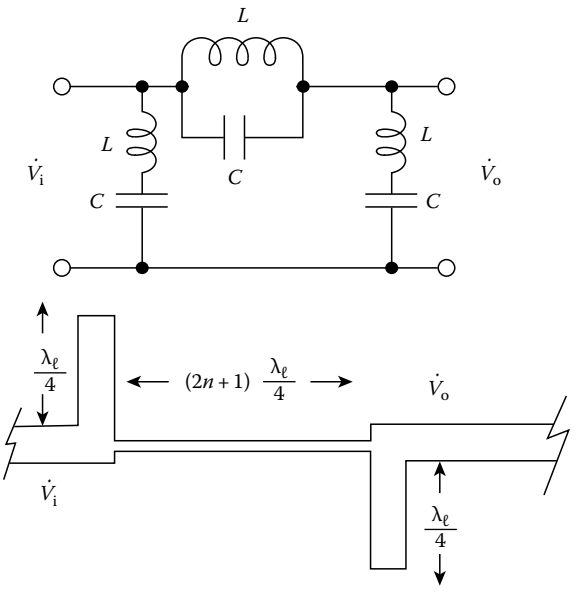

FIGURE 19.15 Synthesis of distributed π-network bandstop filters.

19.6.9 Further Comments on Distributed Circuit Filters

If the unit sections of filters previously described are treated as lumped parameter filters, they can be cascaded into a number of stages to obtain desired filter characteristics, as exemplified by Chebyshev and Butterworth filters. The center frequencies of the stages can be staggered to obtain the desired frequency bandwidth [5].

A radio frequency choke is a special case of a bandstop filter. Cascading of alternate $\lambda_l/2$ sections of high and low impedance (Figure 19.16a) is common. This is called the high-low filter. A microstrip line bandpass filter can be made using a number of $\lambda_l/2$ microstrip line resonators, as shown in Figure 19.16b [5].

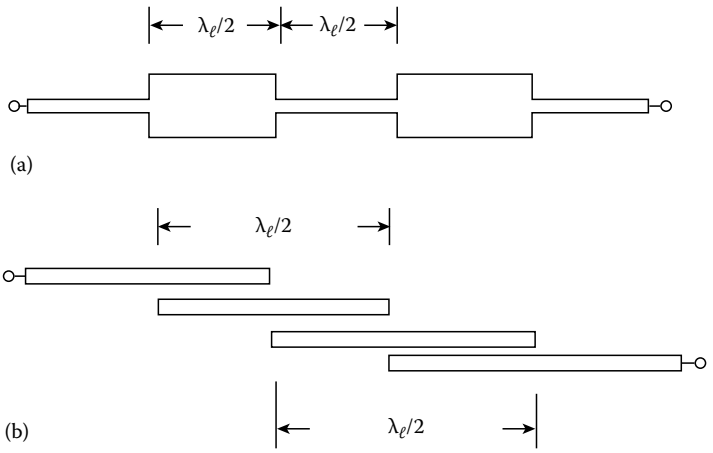

FIGURE 19.16 Microstrip line filters. (a) Bandstop high-low filter. (b) Bandpass coupled resonator filter.

19.7 Synthesis of Couplers

19.7.1 Generic Relations

A coupler is a circuit with coupling between a primary circuit and a secondary circuit. In distributed circuit technology, it often takes the form of coupling between two transmission line circuits. The coupling may be done by simply placing the secondary transmission line in proximity to the primary transmission line, as presented in Figure 19.17a and c, or both the primary and the secondary transmission lines are physically connected, as shown in Figure 19.17b. These examples of distributed coupler circuits are shown in microstrip line forms. No lumped parameter equivalent circuit exists for these distributed coupler circuits. Therefore, the previously described synthesis techniques cannot be used.

19.7.2 Proximity Couplers

Coupling of two transmission lines is accomplished simply by existing proximity to each other. If the transmission lines are microstrip lines (Figure 19.17a or 19.18), the coupler is also called an edge coupler.

The coupling factor (CF) of a coupler is defined as [3]

$$\mathrm{CF} = \frac{P_4}{P_1} \tag{19.95}$$

where

P_1 is the microwave power fed to port 1

P_4 is the microwave power output at port 4.

If the power coupling factor per meter of the line edge is $k(x)$ in the coupling region of length l, then [3]

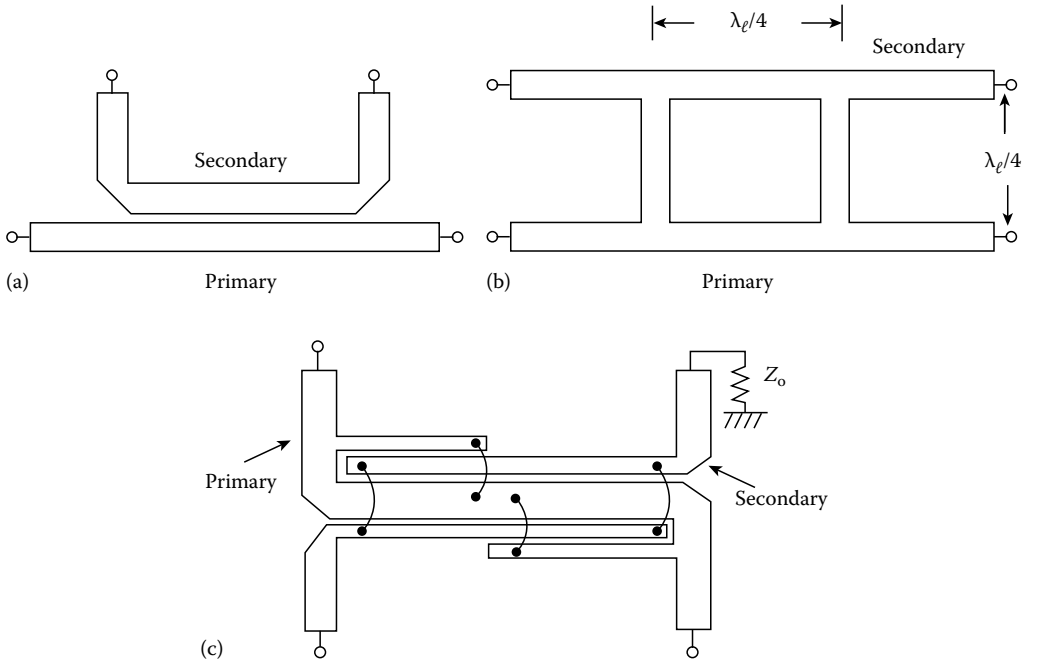

FIGURE 19.17 Distributed circuit couplers. (a) Proximity coupler. (b) Quarter-wavelength coupler. (c) Lange coupler.

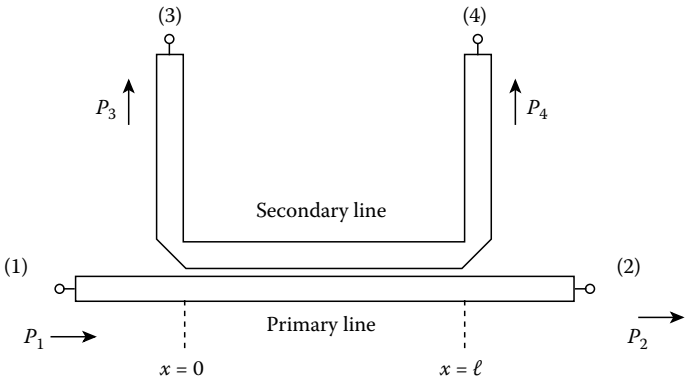

FIGURE 19.18 Microstrip line proximity coupler.

$$\mathrm{CF} = \left| \int_0^l k(x)\varepsilon^{-j\beta x} \mathrm{d}x \right| \tag{19.96}$$

This can be expressed in decibels as

$$\mathrm{CF\ (dB)} = 10 \log \frac{P_4}{P_1} = 10 \log \left| \int_0^l k(x)\varepsilon^{-j\beta x} \mathrm{d}x \right| \tag{19.97}$$

The directivity of a coupler is defined as [3]

$$\mathrm{dir} = \frac{P_3}{P_4} \tag{19.98}$$

$$\mathrm{dir} = \frac{1}{\mathrm{CF}} \left| \int_0^l k(x)\varepsilon^{-j2\beta x} \mathrm{d}x \right| \tag{19.99}$$

The decibel expression of directivity, then, is

$$\begin{aligned} \mathrm{dir\ (dB)} &= 10 \log_{10} \frac{P_3}{P_4} \\ &= 10 \log_{10} \frac{1}{\mathrm{CF}} \left| \int_0^l k(x)\varepsilon^{-j2\beta x} \mathrm{d}x \right| \end{aligned} \tag{19.100}$$

Generally, $P_3 \neq P_4$; therefore, the coupling has a directional property. This is the reason that this type of coupler is termed the directional coupler.

Insertion loss (IL) of a coupler is defined as

$$\mathrm{IL} = \frac{P_2}{P_1} = \frac{P_1 - (P_3 + P_4)}{P_1} \tag{19.101}$$

Inserting Equations 13.95 and 13.98 into Equation 19.101,

$$\text{IL} = 1 - \text{CF}(1 + \text{dir}) \tag{19.102}$$

or

$$\text{IL (dB)} = 10\log\{1 - \text{CF}(1 + \text{dir})\} \tag{19.103}$$

A complete analytical synthesis of microstrip line couplers is not available. However, computer software based on semiempirical equations is commercially available [5].

19.7.3 Quarter-Wavelength Couplers

The coupling factor of a quarter-wavelength coupler (Figure 19.19) is defined as [3]

$$\text{CF} = \frac{P_4}{P_1} \tag{19.104}$$

The amount of P_4 or coupling factor can be controlled by the width of microstrip lines connecting the secondary line to the primary line.

$$\text{CF (dB)} = 10\log_{10} P_4/P_1 \tag{19.105}$$

The directivity is

$$\text{dir} = \frac{P_3}{P_4} \tag{19.106}$$

or

$$\text{dir (dB)} = 10\log\frac{P_3}{P_4} \tag{19.107}$$

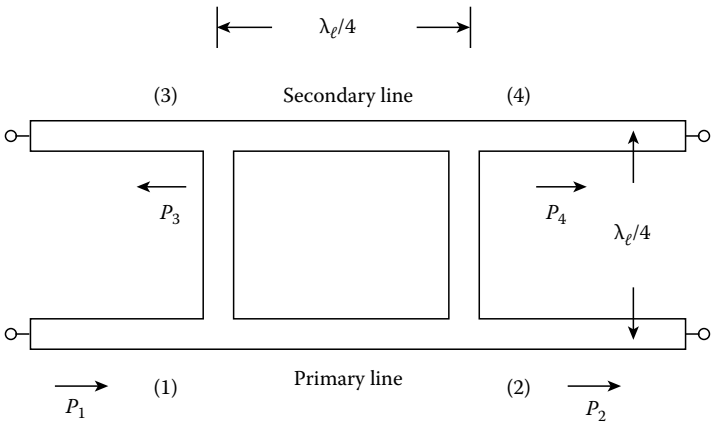

FIGURE 19.19 Quarter-wavelength coupler.

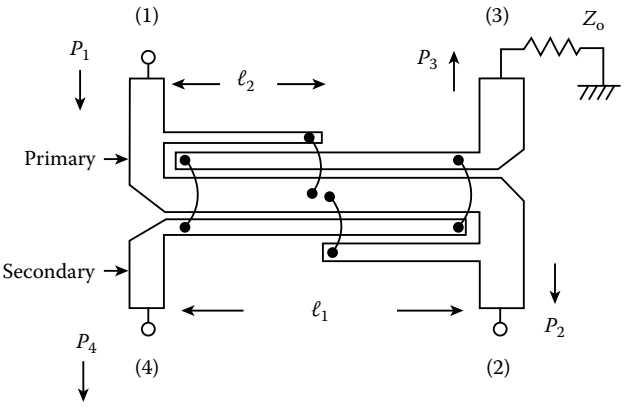

FIGURE 19.20 Lange coupler.

At the precise design operating frequency, P_3 should be zero. The insertion loss for this coupler is

$$\text{IL} = \frac{P_1 - (P_3 + P_4)}{P_1} = 1 - \text{CF}(1 + \text{dir}) \tag{19.108}$$

19.7.4 Lange Couplers

A schematic diagram of a generic Lange coupler [4] is given in Figure 19.20. In this figure, the primary transmission line is from port (1) to port (2). The secondary transmission line is from port (3) to port (4). In Lange couplers, both the primary and the secondary lines are coupled by edge coupling or proximity coupling. It should be noted that the transmission lines are not physically connected to each other by bonding wires. The bond wires on both ends form connections of the secondary transmission line from port (3) to port (4). The bond wires in the middle of the structure are the electrical potential equalizing bonding in the primary transmission line. Adjusting the values of l_1 and l_2 creates a variety of coupling factors. One of the objectives of Lange couplers is to increase the coupling factor between the primary lines and the secondary line. By comparing the structure to that of a straight edge-coupled coupler (see Figure 19.18), the Lange coupler in Figure 19.20 has more length of coupling edge. Therefore, a higher coupling factor is obtainable [5].

capacitive and inductive *n*-ports, 10-16

Chua's synthesis approach, 10-17
Δ−Y/Y−Δ transformations, 10-16
passive *i–v* curve, 10-17
Nonlinear systems identification
dynamic systems, time series embedding theory, 9-31
Gaussian white noise, 9-30
Poincaré map, 9-31
Fock space, Volterra series, 9-29–9-30
least-squares approximation technique, 9-28
Volterra polynomial, 9-29
Nonmonotone current-controlled resistor, 14-55
Nonuniform distributed RC lines
approximate calculation, 18-11
cumulative structure function, 18-9–18-10
lumped element approximation, 18-11–18-12
Riccati differential equation, 18-10
Nullator–*I*-resistor–voltage source tree, 7-9–7-10
Null return difference matrix, 6-6–6-7
Null return ratio, 1-4–1-5, 3-12, 6-6

O

Open-circuit ouput admittance, 19-2
Open-circuit reverse voltage gain, 2-3
Open-circuit transfer admittance, 19-2
Open-loop amplifier
group delay, 1-13
volt–ampere characteristics, 1-11
y-parameter model, 1-12–1-13
Open-loop gain-bandwidth product, 1-10, 1-12
Operational transconductance amplifier (OTA), 11-9
Ordinary differential equations (ODE), 14-2

P

Parallel *L–C* circuit, 19-10
Parallel *L–C–R* circuit, 19-11–19-12
Partial differential equations, 13-10–13-11
Period-doubling bifurcation, 14-23–14-24
Phase shift keying (PSK), 14-66
Picard method, 12-2
Piecewise-linear Chua diode, 14-46
Piecewise-linear (PWL) circuits
advantages, 11-1
computed-aided analysis, 11-19–11-20
current transfer, 8-18–8-20
dynamic circuits, 11-18–11-19
electronic components, 11-8–11-14
GaAs FET model, 11-12–11-13
MOS transistor model, 11-12
op-amp finite-gain model, 11-9
transistor model, 11-9–11-11
hierarchy and representations, 11-3–11-8
bipolar transistor, two-port configuration, 11-3
consistent variation property, 11-5
hysteresis one port resistor, 11-6–11-7
linear complementarity property, 11-5
resistive *n*-port, 11-3
interrelation of methods, 11-2
resistive circuits
algorithm, 11-16–11-18
structural properties, 11-14–11-15
theorem canonical PWL, 11-15–11-16
transresistance, 8-20–8-21
voltage-to-charge transfer characteristics, 8-21–8-22
π-network form, 19-16
Poincaré–Andronov–Hopf bifurcation, 10-8
Poincaré map, 14-15–14-16
Primitive circuit component catalog, 8-34
Propagation constant, 19-5
Pseudorandom sequence generation, 14-64–14-65
PSK, *see* Phase shift keying

Q

Q-factor, 10-10
Qualitative circuit analysis
autonomous dynamic circuits
DC-operating points, convergence, 7-14–7-19
nonlinear capacitor and inductor, 7-13
nonautonomous dynamic circuits
solutions, boundedness, 7-19–7-20
time-dependent voltage and current source, 7-19
unique asymptotic behavior, 7-20–7-21
resistive circuits
DC-operating points, 7-2
Ebers–Moll equations, 7-3
equilibrium points, 7-2
feedback structure, 7-7
monotonic dependent, 7-12–7-13
nonlinear resistor characteristics, 7-6
nullator and norator, 7-3
short–open circuit combinations, 7-7–7-8
V- and *I*-resistors, 7-9
voltage-controlled current source (VCCS), 7-3–7-4
voltage-controlled voltage source (VCVS), 7-2
voltages and currents, bounds, 7-11–7-12
zener diode, 7-2
Quarter-wavelength coupler, 19-20

R

Random chaotic sequence generation, 14-64
Reciprocal nonlinear dynamical circuits, equivalence
Brayton–Moser equations, 10-18–10-19
decomposition, 10-21–10-22
diffeomorphism, 10-19
mixed-potential function, 10-18
piecewise-linear *i–v* characteristics, 10-20
Resistive circuits
DC-operating points, 7-2
Ebers–Moll equations, 7-3

equilibrium points, 7-2
monotonic dependent, 7-12–7-13
nullator and norator, 7-3
solutions, number
feedback structure, 7-7
nonlinear resistor characteristics, 7-6
short–open circuit combinations, 7-7–7-8
V- and *I*-resistors, 7-9
voltage-controlled current source (VCCS), 7-3–7-4
voltage-controlled voltage source (VCVS), 7-2
voltages and currents, bounds, 7-11–7-12
zener diode, 7-2
Return difference
Blecher's procedure
short circuit admittance matrix, 5-3
transistor, common emitter configuration, 5-2–5-3
driving-point impedances
forward transfer admittance, 5-5
indefinite-admittance matrix, 5-4
feedback amplifier theory
amplifier voltage gain, 3-11
definition, 3-7
loop transmission, 3-9
returned voltage, 3-8–3-9
return ratio, 3-9–3-10
voltage-controlled current source, 3-7, 3-9
natural frequencies, 5-1
Return difference matrix, 6-5–6-6, 6-13
Return ratio, 1-4–1-5, 3-9–3-10, 6-5
Riccati differential equation, 18-10

S

Saddle-node bifurcation, 14-23
Scaling and aggregation circuitry
current scaling, mirror concept, 8-17
signal aggregation, Kirchhoff's current law, 8-18
voltage scaling mechanisms, 8-16
Sensitivity matrix
closed-loop transfer function matrix, 6-12
general feedback structure, 6-11
loop-transmission matrix, 6-13
multivariable open-loop control system, 6-11
return difference matrix, 6-13
Series *L*–*C* circuit, 19-9–19-10
Series *L*–*C*–*R* circuit, 19-10–19-11
Series–series feedback amplifier
AC schematic diagram, 2-16–2-17
balanced differential version, 2-20
closed-loop transconductance, 2-18
frequency-dependent feedback factor, 2-19
open-loop transconductance, 2-18
small signal equivalent circuit, 2-17–2-18
volt–ampere characteristics, 2-19
wye feedback subcircuit transformation, 2-20
z-parameter modeling, feedback network, 2-17
Series–series/shunt–shunt feedback amplifier
closed-loop transconductance, 2-21
closed-loop transresistance, 2-22
closed-loop voltage gain, 2-22, 2-24
loop gain, 2-21
Norton equivalent input, 2-23
open-loop transresistance, 2-21–2-22
output and input resistances, 2-22, 2-25
Thévenin equivalent output circuit, 2-23
Series–shunt feedback amplifier
circuit modeling and analysis
AC schematic diagram, 2-2
closed-loop voltage gain, 2-3, 2-6
current-controlled current source, 2-3
h-parameter equivalent circuit, 2-3–2-4
modified small-signal model, 2-5
open-circuit reverse voltage gain, 2-3
open-loop voltage gain, 2-8
resultant closed-loop amplifier, 2-2
short-circuit forward current gain, 2-4
short-circuit input resistance, 2-3
feed-forward compensation
driving-point input and output impedances, 2-9
open-loop voltage gain, 2-8
pertinent small-signal model, 2-7–2-8
resultant frequency-domain feedback factor, 2-9
Series–shunt/shunt–series feedback amplifier
AC schematic diagram, 2-28
circuit voltage gain, 2-25
current gain, 2-27
driving-point input and output resistance, 2-27–2-28
h-parameters, 2-25
system-level diagram, 2-25–2-26
voltage gain, 2-27–2-28
Shil'nikov's theorem, 14-17–14-18
Short-circuit forward current gain, 2-4
Shunt–series feedback amplifier
AC schematic diagram, 2-10
closed-loop current gain, 2-11–2-12
h-parameter and feedback network current, 2-11
open-loop current gain and loop gain, 2-12
Shunt–shunt feedback amplifier
circuit modeling and analysis
AC schematic diagram, 2-12–2-13
closed-loop transresistance, 2-14
feedback factor, 2-13
open-loop transresistance and loop gain, 2-14
y-parameter modeling, feedback network, 2-12
design considerations
balanced differential architecture, 2-16

open-loop amplifier interstage, 2-15
pole splitting, 2-14
Signal (functions) approximation
Chebyshev system, 9-18
general formulation, 9-17
interpolation, approximation
algebraic polynomial interpolation, 9-21
Hermite interpolant, 9-22
Walsh theorem, 9-23
polynomial and rational approximations, 9-18–9-19
splines and radial functions, approximation, 9-20–9-21
Simulated Program with Integrated Circuit Emphasis (SPICE) program, 12-4–12-7
Simulation, nonlinear electrical circuit
circuit-simulation programs
APLAC, 12-8–12-10

polynomial, 9-9
state transition matrix, 9-8

W

Walsh theorem, 9-23
Winding number, 14-50–14-51

Z

Zener diode, 7-2

Upon its initial publication, *The Circuits and Filters Handbook* broke new ground. It quickly became **the** resource for comprehensive coverage of issues and practical information that can be put to immediate use. Not content to rest on his laurels, in addition to updating the second edition, editor Wai-Kai Chen divided it into tightly focused texts that made the information easily accessible and digestible. These texts have been revised, updated, and expanded so that they continue to provide solid coverage of standard practices and enlightened perspectives on new and emerging techniques.

Feedback, Nonlinear, and Distributed Circuits draws together international contributors who discuss feedback amplifier theory and explore feedback amplifier configurations. They develop Bode's feedback theory as an example of general feedback theory. The coverage then moves on to the importance of complementing numerical analysis with qualitative analysis to get a global picture of a circuit's performance. After reviewing a wide range of approximation techniques and circuit design styles for discrete and monolithic circuits, the book presents a comprehensive description of the use of piecewise-linear methods in modeling, analysis, and structural properties of nonlinear circuits. It describes the analysis and synthesis of distributed circuits, and the circuit modeling in the frequency domain of uniform multiconductor transmission lines based on the Telegrapher's equations and covers frequency and time domain experimental characterization techniques for uniform and nonuniform multiconductor structures.

Features:

- Covers single-loop and multiple-loop feedback amplifiers
- Provides a brief description of mathematical representation, approximation, and identification of nonlinear systems
- Discusses general methods for the analysis of vector fields that have at least one nonhyperbolic fixed point
- Examines the simulation or analysis of a nonlinear electrical circuit by means of a computer program
- Presents a comprehensive analysis and synthesis of distributed circuits

This volume will undoubtedly take its place as the engineer's first choice in looking for solutions to problems encountered when dealing with feedback, linear, and distributed circuits.

SECTION III Digital Filters

18 FIR Filters **18**-1
M. H. Er, Andreas Antoniou, Yong Ching Lim, and Tapio Saramäki

19 IIR Filters **19**-1
Sawasd Tantaratana, Chalie Charoenlarpnopparut, Phakphoom Boonyanant, and Yong Ching Lim

20 Finite Wordlength Effects **20**-1
Bruce W. Bomar

21 VLSI Implementation of Digital Filters **21**-1
Joseph B. Evans and Timothy R. Newman

22 Two-Dimensional FIR Filters **22**-1
Rashid Ansari and A. Enis Cetin

23 Two-Dimensional IIR Filters **23**-1
A. G. Constantinides and Xiaojian Xu

24 1-D Multirate Filter Banks **24**-1
Nick G. Kingsbury and David B. H. Tay

25 Directional Filter Banks **25**-1
Jose Gerardo Rosiles and Mark J. T. Smith

26 Nonlinear Filtering Using Statistical Signal Models **26**-1
Kenneth E. Barner, Tuncer C. Aysal, and Gonzalo R. Arce

27 Nonlinear Filtering for Image Denoising **27**-1
Nasir M. Rajpoot, Zhen Yao, and Roland G. Wilson

28 Video Demosaicking Filters **28**-1
Bahadir K. Gunturk and Yucel Altunbasak

Index **IN**-1

Preface

As circuit complexity continues to increase, the microelectronic industry must possess the ability to quickly adapt to the market changes and new technology through automation and simulations. The purpose of this book is to provide in a single volume a comprehensive reference work covering the broad spectrum of filter design from passive, active, to digital. The book is written and developed for the practicing electrical engineers and computer scientists in industry, government, and academia. The goal is to provide the most up-to-date information in the field.

Over the years, the fundamentals of the field have evolved to include a wide range of topics and a broad range of practice. To encompass such a wide range of knowledge, this book focuses on the key concepts, models, and equations that enable the design engineer to analyze, design, and predict the behavior of large-scale systems that employ various types of filters. While design formulas and tables are listed, emphasis is placed on the key concepts and theories underlying the processes.

This book stresses fundamental theory behind professional applications and uses several examples to reinforce this point. Extensive development of theory and details of proofs have been omitted. The reader is assumed to have a certain degree of sophistication and experience. However, brief reviews of theories, principles, and mathematics of some subject areas are given. These reviews have been done concisely with perception.

The compilation of this book would not have been possible without the dedication and efforts of Professor Rashid Ansari and Dr. A. Enis Cetin, and most of all the contributing authors. I wish to thank them all.

Wai-Kai Chen

Editor-in-Chief

Wai-Kai Chen is a professor and head emeritus of the Department of Electrical Engineering and Computer Science at the University of Illinois at Chicago. He received his BS and MS in electrical engineering at Ohio University, where he was later recognized as a distinguished professor. He earned his PhD in electrical engineering at the University of Illinois at Urbana–Champaign.

Professor Chen has extensive experience in education and industry and is very active professionally in the fields of circuits and systems. He has served as a visiting professor at Purdue University, the University of Hawaii at Manoa, and Chuo University in Tokyo, Japan. He was the editor-in-chief of the *IEEE Transactions on Circuits and Systems, Series I and II*, the president of the IEEE Circuits and Systems Society, and is the founding editor and the editor-in-chief of the *Journal of Circuits, Systems and Computers*. He received the Lester R. Ford Award from the Mathematical Association of America; the Alexander von Humboldt Award from Germany; the JSPS Fellowship Award from the Japan Society for the Promotion of Science; the National Taipei University of Science and Technology Distinguished Alumnus Award; the Ohio University Alumni Medal of Merit for Distinguished Achievement in Engineering Education; the Senior University Scholar Award and the 2000 Faculty Research Award from the University of Illinois at Chicago; and the Distinguished Alumnus Award from the University of Illinois at Urbana–Champaign. He is the recipient of the Golden Jubilee Medal, the Education Award, and the Meritorious Service Award from the IEEE Circuits and Systems Society, and the Third Millennium Medal from the IEEE. He has also received more than a dozen honorary professorship awards from major institutions in Taiwan and China.

A fellow of the Institute of Electrical and Electronics Engineers (IEEE) and the American Association for the Advancement of Science (AAAS), Professor Chen is widely known in the profession for the following works: *Applied Graph Theory* (North-Holland), *Theory and Design of Broadband Matching Networks* (Pergamon Press), *Active Network and Feedback Amplifier Theory* (McGraw-Hill), *Linear Networks and Systems* (Brooks/Cole), *Passive and Active Filters: Theory and Implements* (John Wiley), *Theory of Nets: Flows in Networks* (Wiley-Interscience), *The Electrical Engineering Handbook* (Academic Press), and *The VLSI Handbook* (CRC Press).

1.1 Introduction

An electrical filter is a system that can be used to modify, reshape, or manipulate the frequency spectrum of an electrical signal according to some prescribed requirements. For example, a filter may be used to amplify or attenuate a range of frequency components, reject or isolate one specific frequency component, and so on. The applications of electrical filters are numerous, for example,

- To eliminate signal contamination such as noise in communication systems
- To separate relevant from irrelevant frequency components
- To detect signals in radios and TV's
- To demodulate signals
- To bandlimit signals before sampling
- To convert sampled signals into continuous-time signals
- To improve the quality of audio equipment, e.g., loudspeakers
- In time-division to frequency-division multiplex systems

- In speech synthesis
- In the equalization of transmission lines and cables
- In the design of artificial cochleas

Typically, an electrical filter receives an input signal or *excitation* and produces an output signal or *response*. The frequency spectrum of the output signal is related to that of the input by some rule of correspondence. Depending on the type of input, output, and internal operating signals, three general types of filters can be identified, namely, continuous-time, sampled-data, and discrete-time filters.

A continuous-time signal is one that is defined at each and every instant of time. It can be represented by a function $x(t)$ whose domain is a range of numbers (t_1, t_2), where $-\infty \leq t_1$ and $t_2 \leq \infty$. A sampled-data or impulse-modulated signal is one that is defined in terms of an infinite summation of continuous-time impulses (see Ref. [1, Chapter 6]). It can be represented by a function

$$\hat{x}(t) = \sum_{n=-\infty}^{\infty} x(nT)\delta(t - nT)$$

where $\delta(t)$ is the impulse function. The value of the signal at any instant in the range $nT < t < (n+1)T$ is zero. The frequency spectrum of a continuous-time or sampled-data signal is given by the Fourier transform.*

A discrete-time signal is one that is defined at discrete instants of time. It can be represented by a function $x(nT)$, where T is a constant and n is an integer in the range (n_1, n_2) such that $-\infty \leq n_1$ and $n_2 \leq \infty$. The value of the signal at any instant in the range $nT < t < (n+1)T$ can be zero, constant, or undefined depending on the application. The frequency spectrum in this case is obtained by evaluating the z transform on the unit circle $|z| = 1$ of the z plane.

Depending on the format of the input, output, and internal operating signals, filters can be classified either as analog or digital filters. In analog filters the operating signals are varying voltages and currents, whereas in digital filters they are encoded in some binary format. Continuous-time and sampled-data filters are always analog filters. However, discrete-time filters can be analog or digital.

Analog filters can be classified on the basis of their constituent components as

- Passive *RLC* filters
- Crystal filters
- Mechanical filters
- Microwave filters
- Active *RC* filters
- Switched-capacitor filters

Passive *RLC* filters comprise resistors, inductors, and capacitors. Crystal filters are made of piezoelectric resonators that can be modeled by resonant circuits. Mechanical filters are made of mechanical resonators. Microwave filters consist of microwave resonators and cavities that can be represented by resonant circuits. Active *RC* filters comprise resistors, capacitors, and amplifiers; in these filters, the performance of resonant circuits is simulated through the use of feedback or by supplying energy to a passive circuit. Switched-capacitor filters comprise resistors, capacitors, amplifiers, and switches. These are discrete-time filters that operate like active filters but through the use of switches the capacitance values can be kept very small. As a result, switched-capacitor filters are amenable to VLSI implementation.

This section provides an introduction to the characteristics of analog filters. Their basic characterization in terms of a differential equation is reviewed in Section 1.2 and by applying the Laplace transform, an algebraic equation is deduced that leads to the s-domain representation of a filter. The representation of analog filters in terms of the transfer function is then developed. Using the transfer function, one can

* See Chapter 4 of *Fundamentals of Circuits and Filters*.

obtain the time-domain response of a filter to an arbitrary excitation, as shown in Section 1.3. Some important time-domain responses, i.e., the impulse and step responses, are examined. Certain filter parameters related to the step response, namely, the overshoot, delay time, and rise time, are then considered. The response of a filter to a sinusoidal excitation is examined in Section 1.4 and is then used to deduce the basic frequency-domain representations of a filter, namely, its frequency response and loss characteristic. Some idealized filter characteristics are then identified and the differences between idealized and practical filters are delineated in Section 1.5. Practical filters tend to introduce signal degradation through amplitude and/or delay distortion. The causes of these types of distortion are examined in Section 1.6. In Section 1.7, certain special classes of filters, e.g., minimum-phase and allpass filters, are identified and their applications mentioned. This chapter concludes with a review of the design process and the tasks that need to be undertaken to translate a set of filter specifications into a working prototype.

1.2 Characterization

A linear causal analog filter with input $x(t)$ and output $y(t)$ can be characterized by a differential equation of the form

$$b_n \frac{\mathrm{d}^n y(t)}{\mathrm{d}t^n} + b_{n-1} \frac{\mathrm{d}^{n-1} y(t)}{\mathrm{d}t^{n-1}} + \cdots + b_0 y(t) = a_n \frac{\mathrm{d}^n x(t)}{\mathrm{d}t^n} + a_{n-1} \frac{\mathrm{d}^{n-1} x(t)}{\mathrm{d}t^{n-1}} + \cdots + a_0 x(t)$$

The coefficients $a_0, a_1, \ldots, a_n$ and $b_0, b_1, \ldots, b_n$ are functions of the element values and are real if the parameters of the filter (e.g., resistances, inductances, etc.) are real. If they are independent of time, the filter is time invariant. The input $x(t)$ and output $y(t)$ can be either voltages or currents. The order of the differential equation is said to be the *order* of the filter.

An analog filter must of necessity incorporate reactive elements that can store energy. Consequently, the filter can produce an output even in the absence of an input. The output on such an occasion is caused by the initial conditions of the filter, namely,

$$\left.\frac{\mathrm{d}^{n-1} y(t)}{\mathrm{d}t^{n-1}}\right|_{t=0}, \left.\frac{\mathrm{d}^{n-2} y(t)}{\mathrm{d}t^{n-2}}\right|_{t=0}, \ldots, y(0)$$

The response in such a case is said to be the *zero-input response*. The response obtained if the initial conditions are zero is sometimes called the *zero-state response*.

1.2.1 Laplace Transform

The most important mathematical tool in the analysis and design of analog filters is the Laplace transform. It owes its widespread application to the fact that it transforms differential into algebraic equations that are a lot easier to manipulate. The Laplace transform of $x(t)$ is defined as*

$$X(s) = \int_{-\infty}^{\infty} x(t) e^{-st} \mathrm{d}t$$

where s is a complex variable of the form $s = \sigma + j\omega$. Signal $x(t)$ can be recovered from $X(s)$ by applying the inverse Laplace transform, which is given by

* See Chapter 3 by J. R. Deller, Jr. in *Fundamentals of Circuits and Filters*.

$$x(t) = \frac{1}{2\pi j} \int_{C-j\infty}^{C+j\infty} X(s)e^{st}\,\mathrm{d}s$$

where C is a positive constant. A shorthand notation of the Laplace transform and its inverse are

$$X(s) = \mathcal{L}x(t) \quad \text{and} \quad x(t) = \mathcal{L}^{-1}X(s)$$

Alternatively,

$$X(s) \leftrightarrow x(t)$$

A common practice in the choice of symbols for the Laplace transform and its inverse is to use upper case for the s domain and lower case for the time domain.

On applying the Laplace transform to the nth derivative of some function of time $y(t)$, we find that

$$\mathcal{L}\left[\frac{\mathrm{d}^n y(t)}{\mathrm{d}t^n}\right] = s^n Y(s) - s^{n-1}y(0) - s^{n-2}\left.\frac{\mathrm{d}y(t)}{\mathrm{d}t}\right|_{t=0} - \cdots - \left.\frac{\mathrm{d}^{n-1}y(t)}{\mathrm{d}t^{n-1}}\right|_{t=0}$$

Now, on applying the Laplace transform to an nth-order differential equation with constant coefficients, we obtain

$$\left(b_n s^n + b_{n-1}s^{n-1} + \cdots + b_0\right)Y(s) + \Psi_y(s) = \left(a_n s^n + a_{n-1}s^{n-1} + \cdots + a_0\right)X(s) + \Psi_x(s)$$

where

$X(s)$ and $Y(s)$ are the Laplace transforms of the input and output, respectively

$\Psi_x(s)$ and $\Psi_y(s)$ are functions that combine all the initial-condition terms that depend on $x(t)$ and $y(t)$, respectively

1.2.2 Transfer Function

An important s-domain characterization of an analog filter is its *transfer function*, as for any other linear system. This is defined as the ratio of the Laplace transform of the response to the Laplace transform of the excitation.

An arbitrary linear, time-invariant, continuous-time filter, which may or may not be causal, can be represented by the convolution integral

$$y(t) = \int_{-\infty}^{\infty} h(t-\tau)x(\tau)\mathrm{d}\tau = \int_{-\infty}^{\infty} h(\tau)x(t-\tau)\mathrm{d}\tau$$

where $h(t)$ is the impulse response of the filter. The Laplace transform yields

$$\begin{aligned} Y(s) &= \int_{-\infty}^{\infty}\left[\int_{-\infty}^{\infty} h(t-\tau)x(\tau)\mathrm{d}\tau\right]e^{-st}\mathrm{d}t \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(t-\tau)e^{-st}x(\tau)\mathrm{d}\tau\ \mathrm{d}t \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(t-\tau)e^{-st}\cdot e^{s\tau}\cdot e^{-s\tau}x(\tau)\mathrm{d}\tau\ \mathrm{d}t \end{aligned}$$

Changing the order of integration, we obtain

$$Y(s) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} h(t-\tau)e^{-s(t-\tau)} \cdot x(\tau)e^{-s\tau} \mathrm{d}t \ \mathrm{d}\tau$$
$$= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} h(t-\tau)e^{-s(t-\tau)} \mathrm{d}t \cdot x(\tau)e^{-s\tau} \mathrm{d}\tau$$

Now, if we let $t = t' + \tau$, then $\mathrm{d}t/\mathrm{d}t' = 1$ and $t - \tau = t'$; hence,

$$Y(s) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} h(t')e^{-st'} \mathrm{d}t' \cdot x(\tau)e^{-s\tau} \mathrm{d}\tau$$
$$= \int_{-\infty}^{\infty} h(t')e^{-st'} \mathrm{d}t' \cdot \int_{-\infty}^{\infty} x(\tau)e^{-s\tau} \mathrm{d}\tau$$
$$= H(s)X(s)$$

Therefore, the transfer function is given by

$$H(s) = \frac{Y(s)}{X(s)} = \mathcal{L}h(t) \tag{1.1}$$

In effect, the transfer function is equal to the Laplace transform of the impulse response.

Some authors define the transfer function as the Laplace transform of the impulse response. Then through the use of the convolution integral, they show that the transfer function is equal to the ratio of the Laplace transform of the response to the Laplace transform of the excitation. The two definitions are, of course, equivalent.

Typically, in analog filters the input and output are voltages, e.g., $x(t) + v_i(t)$ and $y(t) + v_o(t)$. In such a case the transfer function is given by

$$\frac{V_o(s)}{V_i(s)} = H_V(s)$$

or simply by

$$\frac{V_o}{V_i} = H_V(s)$$

However, on occasion the input and output are currents, in which case

$$\frac{I_o(s)}{I_i(s)} \equiv \frac{I_o}{I_i} = H_I(s)$$

The transfer function can be obtained through network analysis using one of several classical methods,* e.g., by using

* See Chapters 18 through 27 of this volume.

- Kirchhoff's voltage and current laws
- Matrix methods
- Flow graphs
- Mason's gain formula
- State-space methods

A transfer function is said to be *realizable* if it characterizes a stable and causal network. Such a transfer function must satisfy the following constraints:

1. It must be a rational function of s with real coefficients.
2. Its poles must lie in the left-half s plane.
3. The degree of the numerator polynomial must be equal to or less than that of the denominator polynomial.

A transfer function may represent a network comprising elements with real parameters only if its coefficients are real. The poles must be in the left-half s plane to ensure that the network is stable and the numerator degree must not exceed the denominator degree to assure the existence of a causal network.

1.3 Time-Domain Response

From Equation 1.1,

$$Y(s) = H(s)X(s)$$

Therefore, the time-domain response of a filter to some arbitrary excitation can be deduced by obtaining the inverse Laplace transform of $Y(s)$, i.e.,

$$y(t) = \mathcal{L}^{-1}\{H(s)X(s)\}$$

1.3.1 General Inversion Formula

If

1. the singularities of $Y(s)$ in the finite plane are poles,* and
2. $Y(s) \to 0$ uniformly with respect to the angle of s as $|s| \to \infty$ with $\sigma \leq C$, where C is a positive constant, then [2]

$$y(t) = \begin{cases} 0 & \text{for } t < 0 \\ \frac{1}{2\pi j} \int_{C-j\infty}^{C+j\infty} Y(s)e^{st}\,ds = \frac{1}{2\pi j} \int_{\Gamma} Y(s)e^{st}\,ds & \text{for } t \geq 0 \end{cases} \tag{1.2}$$

where Γ is a contour in the counterclockwise sense make up of the part of the circle $s = Re^{j\theta}$ to the left of line $s = C$ and the segment of the line $s = C$ that overlaps the circle, as depicted in Figure 1.1; C and R are sufficiently large to ensure that Γ encloses all the finite poles of $Y(s)$.

From the residue theorem [3] and Equation 1.2, we have

$$y(t) = \begin{cases} 0 & \text{for } t < 0 \\ \frac{1}{2\pi j} \int_{\Gamma} Y(s)e^{st}\,ds = \sum_{i=1}^{K} \operatorname*{res}_{s=p_i} Y_0(s) & \text{for } t \geq 0 \end{cases}$$

* Such a function is said to be meromorphic [2,3].

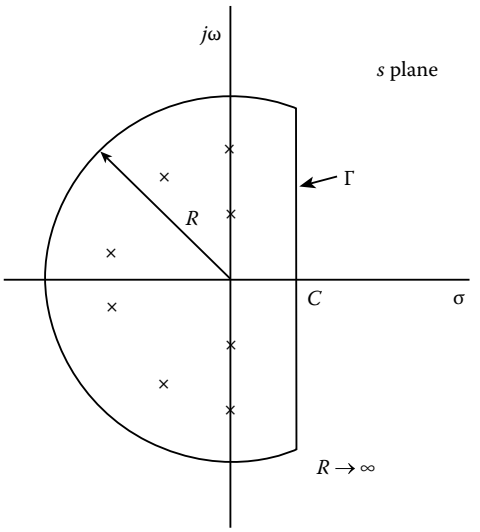

FIGURE 1.1 Contour Γ for the evaluation of the inverse Laplace transform.

where $Y_0(s) = Y(s)e^{st}$ and K is the number of poles in $Y(s)$. If $Y_0(s)$ has a pole p_i of order m_i, the residue can be obtained by using the general formula [3]

$$\operatorname*{res}_{z=p_i} Y_0(s) = \frac{1}{(m_i - 1)!} \lim_{s \to p_i} \frac{\mathrm{d}^{m_i - 1}}{\mathrm{d}s^{m_i - 1}} [(s - p_i)^{m_i} Y_0(s)]$$

Note that complex poles yield complex residues. Hence, like the poles of $Y_0(s)$, its residues occur in complex–conjugate pairs. For this reason, $y(t)$ is found to be a real function of t, as can be easily verified.

Condition 1 listed previously may not be satisfied sometimes, for example, if

$$\lim_{s \to \infty} Y(s) = A_0$$

where A_0 is a constant. In such a case, we can express $Y(s)$ as

$$Y(s) = A_0 + Y'(s)$$

where $Y'(s)$ satisfies conditions 1 and 2. Thus,

$$y(t) = A_0 \delta(t) + \mathcal{L}^{-1} Y'(s)$$

The inverse Laplace transform of $Y'(s)$ can now be obtained by using the inversion formula.

1.3.2 Inverse by Using Partial Fractions

The simplest way to obtain the time-domain response of a filter is to express $H(s)X(s)$ as a partial-fraction expansion and then invert the resulting fractions individually. If $Y(s)$ has simple poles, we can write

$$Y(s) = A_0 + \sum_{i=1}^{K} \frac{A_i}{s - p_i}$$

where A_0 is a constant and

$$A_i = \lim_{s \to p_i} [(s - p_i) Y(s)]$$

is the residue of pole $s = p_i$. On applying the general inversion formula to each partial fraction, we obtain

$$y(t) = A_0 \delta(t) + u(t) \sum_{i=1}^{K} A_i e^{p_i t}$$

where $\delta(t)$ and $u(t)$ are the impulse function and unit step, respectively.

1.3.3 Impulse and Step Responses

The response of a filter to an impulse $\delta(t)$ designated as

$$y(t) = \mathcal{R}\delta(t) \equiv h(t)$$

where $\mathcal{R}$ is an operator, is of considerable importance. Its absolute integrability guarantees the stability of the filter* and its Laplace transform, namely, $H(s)$, is the transfer function as has been shown in the section on the transfer function.

For an Nth-order, causal, linear, and time-invariant filter

$$H(s) = \frac{a_0 + a_1 s + a_2 s^2 + \cdots + a_M s^M}{b_0 + b_1 s + b_2 s^2 + \cdots + b_N s^N}$$

where $M \leq N$.

The step (or unit-step) response is the output of a filter to the signal

$$u(t) = \begin{cases} 1 & \text{for } t \geq 0 \\ 0 & \text{for } t < 0 \end{cases}$$

The Laplace transform of $u(t)$ is $1/s$. Hence, the step response of an arbitrary filter is obtained as

$$y(t) = \mathcal{R}u(t) \equiv y_u(t) = \mathcal{L}^{-1}\left[\frac{H(s)}{s}\right]$$

1.3.4 Overshoot, Delay Time, and Rise Time

Three time-domain parameters of a filter are usually associated with the step response [4], namely, the overshoot, delay time, and rise time. The *overshoot* γ is the difference between the peak value and the asymptotic value of the step response in percent as $t \to \infty$. The *delay time* τ_d is the time required for the step response to reach 50% of the asymptotic value. The *rise time* τ_r is the time required for the step response to increase from 10% to 90% of the asymptotic value. These three parameters are illustrated in Figure 1.2, where $K = a_0/b_0$ is a scaling constant that normalizes the asymptotic value of the step response as $t \to \infty$ to unity.

The delay and rise times defined in terms of the step response entail quite a bit of computation. Alternative definitions of these parameters that are easier to use have been proposed by Elmore [4]. These are based on the impulse response and give accurate results if the overshoot is small. The delay time is defined as

$$\tau_{\mathrm{D}} = \int_0^\infty t h(t)\mathrm{d}t$$

and the rise time assumes the form

$$\tau_{\mathrm{R}} = \left[2\pi \int_0^\infty (t - \tau_{\mathrm{D}})^2 h(t)\mathrm{d}t\right]^{1/2} = \sqrt{2\pi}\left[\int_0^\infty t^2 h(t)\mathrm{d}t - \tau_{\mathrm{D}}^2\right]^{1/2}$$

* See Section 22.1 of *Fundamentals of Circuits and Filters.*

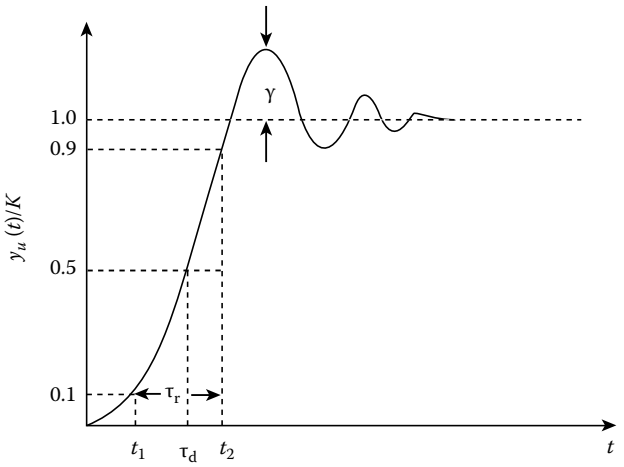

FIGURE 1.2 Overshoot, delay time, and rise time.

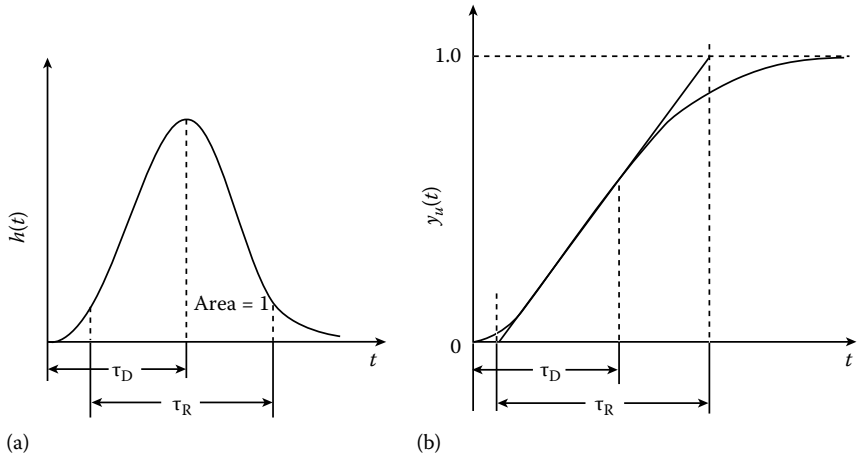

FIGURE 1.3 Physical interpretation of Elmore's definitions of delay and rise times: (a) impulse response $h(t)$ and (b) unit-step response $y_u(t)$.

The physical interpretation of these parameters is illustrated in Figure 1.3a and b. If the overshoot is small, say less than 1%, then

$$\tau_D \approx \tau_d \quad \text{and} \quad \tau_R \approx \tau_r$$

The simplification brought about by Elmore's definitions can be easily demonstrated. Consider a filter whose step response approaches unity as $t \to \infty$. Such a filter has a transfer function of the form

$$H(s) = \frac{1 + a_1 s + a_2 s^2 + \cdots + a_M s^M}{1 + b_1 s + b_2 s^2 + \cdots + b_N s^N} \tag{1.3}$$

that is, $a_0 = b_0 = 1$. From the definition of the Laplace transform,

$$\begin{aligned} H(s) &= \int_0^\infty h(t)e^{-st}\mathrm{d}t \\ &= \int_0^\infty h(t)\left(1 - st + \frac{s^2t^2}{2!} - \cdots\right)\mathrm{d}t \\ &= \int_0^\infty h(t)\mathrm{d}t - s\int_0^\infty th(t)\mathrm{d}t + \frac{s^2}{2!}\int_0^\infty t^2h(t)\mathrm{d}t - \cdots \\ &= \int_0^\infty h(t)\mathrm{d}t - s\tau_\mathrm{D} + \frac{s^2}{2!}\left(\frac{\tau_\mathrm{R}^2}{2\pi} + \tau_\mathrm{D}^2\right) - \cdots \end{aligned} \tag{1.4}$$

Alternatively, from Equation 1.3, direct division gives

$$H(s) = 1 - (b_1 - a_1)s + \left(b_1^2 - a_1b_1 + a_2 - b_2\right)s^2 + \cdots \tag{1.5}$$

Now by comparing Equations 1.4 and 1.5, we deduce

$$\int_0^\infty h(t)\mathrm{d}t = 1, \quad \tau_\mathrm{D} = b_1 - a_1$$

and

$$\tau_\mathrm{R} = \left\{2\pi\left[b_1^2 - a_1^2 + 2(a_2 - b_2)\right]\right\}^{1/2}$$

The previous definitions are based on the assumption that the unit-step response approaches unity as $t \to \infty$. If this is not the case, i.e., coefficients a_0 and b_0 are not equal to unity, then we can write

$$H(s) = KH'(s)$$

where $K = a_0/b_0$ and

$$H'(s) = \frac{1 + a_1's + a_2's^2 + \cdots + a_M's^M}{1 + b_1's + b_2's^2 + \cdots + b_N's^N}$$

Using the coefficients of $H'(s)$ in the formulas for τ_D and τ_R yields approximate values for the delay time and rise time, since these parameters are independent of the absolute value of the step response.

1.4 Frequency-Domain Analysis

The frequency response of an analog filter is deduced by finding its steady-state sinusoidal response, as we shall now demonstrate.

1.4.1 Sinusoidal Response

Consider an *N*th-order analog filter characterized by a transfer function $H(s)$. The sinusoidal response of such a filter is

$$y(t) = \mathcal{L}^{-1}[H(s)X(s)]$$

where

$$X(s) = \mathcal{L}[u(t)\sin\omega t] = \frac{\omega}{(s+j\omega)(s-j\omega)} \tag{1.6}$$

The product $H(s)X(s)$ satisfies conditions 1 and 2 imposed on the general inversion formula of Equation 1.2. Hence, for $t \geq 0$, we have

$$y(t) = \frac{1}{2\pi j}\int_{\Gamma} Y(s)e^{st}\,ds = \sum \text{res}[H(s)X(s)e^{st}] \tag{1.7}$$

where Γ is a contour enclosing the poles of $H(s)$ and $X(s)$ as in Figure 1.1.

Assuming simple poles for the transfer function, Equations 1.6 and 1.7 give

$$y(t) = \sum_{i=1}^{N} X(p_i)e^{p_i t}\operatorname*{res}_{s=p_i} H(s) + \frac{1}{2j}\left[H(j\omega)e^{j\omega t} - H(-j\omega)e^{-j\omega t}\right] \tag{1.8}$$

If the filter is assumed to be stable, then the poles are in the left-half s plane, i.e., $p_i = \sigma_i + j\omega_i$ with $\sigma_i < 0$.* As a consequence

$$\lim_{t\to\infty} e^{p_i t} = \lim_{t\to\infty}\left(e^{\sigma_i t}\cdot e^{j\omega_i t}\right) = 0$$

and since the residues of $H(s)$ are finite, the steady-state sinusoidal response is obtained from Equation 1.8 as

$$\tilde{y}(t) = \lim_{t\to\infty} y(t) = \frac{1}{2j}\left[H(j\omega)e^{j\omega t} - H(-j\omega)e^{-j\omega t}\right] \tag{1.9}$$

Equation 1.9 was deduced on the assumption that the poles of the transfer function are simple. However, it also applies for transfer functions with higher-order poles.

Now from the definition of the Laplace transform

$$H(s) = \int_{-\infty}^{\infty} h(t)e^{-st}\,dt$$

and hence

$$H(-j\omega) = \int_{-\infty}^{\infty} h(t)e^{j\omega t}\,dt = \left[\int_{-\infty}^{\infty} h(t)e^{-j\omega t}\,dt\right]^{*} = H^{*}(j\omega) \tag{1.10}$$

* See Chapter 22.1 of *Fundamentals of Circuits and Filters*.

If we write

$$H(j\omega) = M(\omega)e^{j\theta(\omega)} \tag{1.11}$$

where

$$M(\omega) = |H(j\omega)| \quad \text{and} \quad \theta(\omega) = \arg H(j\omega) \tag{1.12}$$

the steady-state sinusoidal response of the filter is obtained from Equations 1.9 through 1.12 as

$$\begin{aligned}\tilde{y}(t) &= \frac{1}{2j}\left[M(\omega)e^{j\theta(\omega)}e^{j\omega t} - M(\omega)e^{-j\theta(\omega)}e^{-j\omega t}\right] \\ &= M(\omega)\frac{1}{2j}\left[e^{j[\omega t+\theta(\omega)]} - e^{-j[\omega t+\theta(\omega)]}\right] \\ &= M(\omega)\sin[\omega t + \theta(\omega)]\end{aligned}$$

The preceding analysis has shown that the steady-state response of an analog filter to a sinusoid of unit amplitude is a sinusoid of amplitude $M(\omega)$, shifted by an angle $\theta(\omega)$. In effect, for a given frequency ω, the filter introduces a *gain* $M(\omega)$ and a *phase shift* $\theta(\omega)$.

As functions of frequency, $M(\omega)$ and $\theta(\omega)$ are known as the amplitude (or magnitude) response and phase response of the filter, respectively. The transfer function evaluated on the imaginary axis, namely, $H(j\omega)$ is the frequency response and, as was shown, its magnitude and angle are the amplitude response and phase response, respectively.

Two other quantities of a filter, which are of significant interest, are its *phase* and *group delays* These are defined as

$$\tau_p(\omega) = -\frac{\theta(\omega)}{\omega} \quad \text{and} \quad \tau_g(\omega) = -\frac{d\theta(\omega)}{d\omega}$$

respectively. For filters, the group delay is the more important of the two. As a function of frequency, $\tau_g(\omega)$ is usually referred to as the delay characteristic.

1.4.2 Graphical Construction

Consider a filter characterized by a transfer function of the form

$$H(s) = H_0\frac{N(s)}{D(s)} = H_0\frac{\prod_{i=1}^{M}(s - z_i)}{\prod_{i=1}^{N}(s - p_i)^{m_i}} \tag{1.13}$$

where H_0 is a constant. The frequency response of the filter is obtained as

$$H(j\omega) = M(\omega)e^{j\theta(\omega)} = \frac{H_0\prod_{i=1}^{M}(j\omega - z_i)}{\prod_{i=1}^{N}(j\omega - p_i)^{m_i}}$$

By letting

$$j\omega - z_i = M_{z_i} e^{j\psi_{z_i}} \tag{1.14}$$

$$j\omega - p_i = M_{p_i} e^{j\psi_{p_i}} \tag{1.15}$$

we obtain

$$M(\omega) = \frac{|H_0| \prod_{i=1}^{M} M_{z_i}}{\prod_{i=1}^{N} M_{p_i}^{m_i}} \tag{1.16}$$

and

$$\theta(\omega) = \arg H_0 + \sum_{i=1}^{M} \psi_{z_i} - \sum_{i=1}^{N} m_i \psi_{p_i} \tag{1.17}$$

where arg $H_0 = \pi$ if H_0 is negative.

The gain and phase shift $M(\omega)$ and $\theta(\omega)$ for some frequency $\omega = \omega_i$ can be determined graphically by using the following procedure:

1. Mark the zeros and poles of the filter in the s plane.
2. Draw the phasor $s = j\omega_i$, where ω_i is the frequency of interest.
3. Draw a phasor of the type in Equation 1.14 for each simple zero of $H(s)$.
4. Draw m_i phasor of the type in Equation 1.15 for each pole of order m_i.
5. Measure the magnitudes and angles of the phasors in steps 3 and 4 and use them in Equations 1.16 and 1.17 to calculate the gain $M(\omega_i)$ and phase shift $\theta(\omega_i)$, respectively.

The amplitude and phase responses of a filter can be determined by repeating the preceding procedure for frequencies $\omega = \omega_1, \omega_2, \ldots$, in the range 0 to ∞. The procedure is illustrated in Figure 1.4.

It should be mentioned that the modern approach for the analysis of filters is through the use of the many circuit analysis programs such as SPICE.* Nevertheless, the above graphical method is of interest and merits consideration for two reasons. First, it illustrates some of the fundamental properties of filters. Second, it provides a certain degree of intuition about the expected amplitude or phase response of a filter. For example, if a filter has pole close to the $j\omega$ axis, then as ω approaches the neighborhood of the pole, the magnitude of the phasor from the pole to the $j\omega$ axis decreases rapidly to a very small value and then increases as ω increases above this value. As a result, the amplitude response will exhibit a large peak in the frequency range close to the pole. On the other hand, a zero close to or on the $j\omega$ axis will lead to a notch in the amplitude response when ω is in the neighborhood of the zero.

Other situations are of interest, for example, if the poles of a filter are located in a band of the s plane below the horizontal line $s = \omega_c$ and its zeros are located above this line, then the filter will pass low-frequency and attenuate high-frequency components since $M_{zi} < M_{pi}$ if $\omega > \omega_c$ for all i. Such a filter is said to be a *low-pass* filter. If the zeros are located below the line $s = \omega_c$ and the poles above it, then the filter will pass high-frequency and attenuate low-frequency components, i.e., the filter will be a *high-pass* one.

* See Chapter 8 of *Computer Aided Design and Design Automation*, contribution of J.G. Rollins.

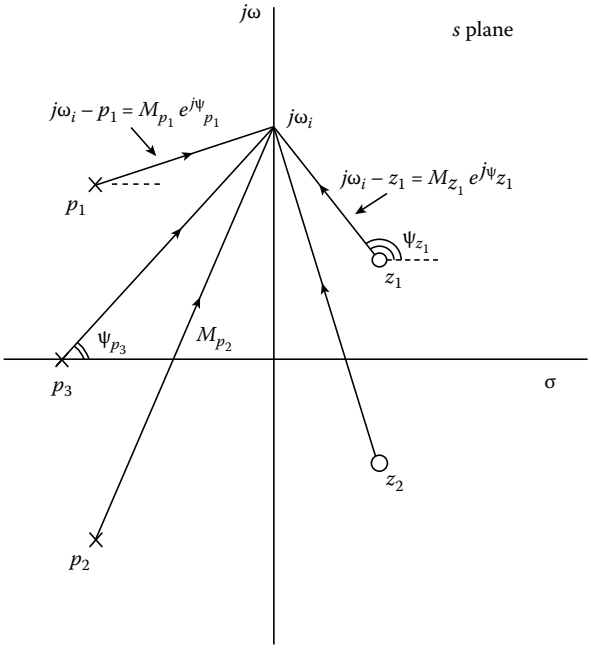

FIGURE 1.4 Graphical method for the evaluation of the frequency response.

1.4.3 Loss Function

Quite often, it is desirable to represent a filter in terms of its loss function. Consider a filter represented by the voltage transfer function

$$\frac{V_o(s)}{V_i(s)} = H(s) = \frac{N(s)}{D(s)}$$

where

$V_i(s)$ and $V_o(s)$ are the Laplace transforms of the input and output voltages, respectively
$N(s)$ and $D(s)$ are polynomials in s

The loss (or attenuation) of the filter in decibels is defined as

$$A(\omega) = 20\log\left|\frac{V_i(j\omega)}{V_o(j\omega)}\right| = 20\log\frac{1}{|H(j\omega)|} = 10\log L(\omega^2) \tag{1.18}$$

where

$$L(\omega^2) = \frac{1}{H(j\omega)H(-j\omega)}$$

$A(\omega)$ as a function of ω is the *loss characteristic*.

With $\omega = s/j$ in Equation 1.18, the function

$$L(-s^2) = \frac{D(s)D(-s)}{N(s)N(-s)}$$

can be formed. This is called the *loss function* of the filter and, as is evident, its zeros are the poles of $H(s)$ and their negatives, whereas its poles are the zeros of $H(s)$ and their negatives.

1.5 Ideal and Practical Filters

An ideal low-pass filter is one that will pass only low-frequency components. Its loss characteristic is given by

$$A(\omega) = \begin{cases} 0 & \text{for } 0 \le \omega < \omega_c \\ \infty & \text{for } \omega_c < \omega < \infty \end{cases}$$

The frequency ranges 0 to ω_c and ω_c to ∞ are the *passband* and *stopband*, respectively. The boundary between the passband and stopband, namely, ω_c, is the *cutoff frequency*. An ideal high-pass filter will pass all components with frequencies above the cutoff frequency and reject all components with frequencies below the cutoff frequency, i.e.,

$$A(\omega) = \begin{cases} \infty & \text{for } 0 \le \omega < \omega_c \\ 0 & \text{for } \omega_c < \omega < \infty \end{cases}$$

Idealized loss characteristics can similarly be identified for bandpass and bandstop filters as

$$A(\omega) = \begin{cases} \infty & \text{for } 0 \le \omega < \omega_{c1} \\ 0 & \text{for } \omega_{c1} < \omega < \omega_{c2} \\ \infty & \text{for } \omega_{c2} \le \omega < \infty \end{cases}$$

and

$$A(\omega) = \begin{cases} 0 & \text{for } 0 \le \omega < \omega_{c1} \\ \infty & \text{for } \omega_{c1} < \omega < \omega_{c2} \\ 0 & \text{for } \omega_{c2} \le \omega < \infty \end{cases}$$

respectively.

Practical filters differ from ideal ones in that the passband loss is not zero, the stopband loss is not infinite, and the transition between passband and stopband is gradual. Practical loss characteristics for low-pass, high-pass, bandpass, and bandstop filters assume the forms

$$A_{LP}(\omega)\begin{cases} \le A_p & \text{for } 0 \le \omega < \omega_p \\ \ge A_a & \text{for } \omega_a \le \omega \le \infty \end{cases}$$

$$A_{HP}(\omega)\begin{cases} \ge A_a & \text{for } 0 \le \omega \le \omega_a \\ \le A_p & \text{for } \omega_p \le \omega < \infty \end{cases}$$

$$A_{BP}(\omega)\begin{cases} \ge A_a & \text{for } 0 \le \omega \le \omega_{a1} \\ \le A_p & \text{for } \omega_{p1} \le \omega \le \omega_{p2} \\ \ge A_a & \text{for } \omega_{a2} \le \omega \le \infty \end{cases}$$

and

$$A_{BS}(\omega) = \begin{cases} \leq A_p & \text{for } 0 \leq \omega \leq \omega_{p1} \\ \geq A_a & \text{for } \omega_{a1} \leq \omega \leq \omega_{a2} \\ \leq A_p & \text{for } \omega_{p2} \leq \omega \leq \infty \end{cases}$$

respectively, where ω_p, ω_{p1}, and ω_{p2} are passband edges, ω_a, ω_{a1}, and ω_{a2} are stopband edges, A_p is the maximum passband loss, and A_a is the minimum stopband loss. In practice, A_p is determined from the allowable amplitude distortion (see Section 1.6) and A_a is dictated by the allowable adjacent channel interference and the desirable signal-to-noise ratio.

It should be mentioned that in practical filters the cutoff frequency ω_c is not a very precise term. It is often used to identify some hypothetical boundary between passband and stopband such as the 3 dB frequency in Butterworth filters, the passband edge in Chebyshev filters, the stopband edge in inverse-Chebyshev filters, or the geometric mean of the passband and stopband edges in elliptic filters.

If a filter is required to have a piecewise constant loss characteristic (or amplitude response) and the shape of the phase response is not critical, the filter can be fully specified by its band edges, the minimum passband and maximum stopband losses A_p and A_a, respectively.

1.6 Amplitude and Delay Distortion

In practice, a filter can distort the information content of the signal. Consider a filter characterized by a transfer function $H(s)$ and assume that its input and output signal are $v_i(t)$ and $v_o(t)$. The frequency response of the filter is given by

$$H(j\omega) = M(\omega)e^{j\theta(\omega)}$$

where $M(\omega)$ and $\theta(\omega)$ are the amplitude and phase responses, respectively.

The frequency spectrum of $v_i(t)$ is its Fourier transform, namely, $V_i(j\omega)$. Assume that the information content of $v_i(t)$ is concentrated in frequency band B given by

$$B = \{\omega: \omega_L \leq \omega \leq \omega_H\}$$

and that its frequency spectrum is zero elsewhere.

Let us assume that the amplitude response is constant with respect to band B, i.e.,

$$M(\omega) = G_0 \quad \text{for } \omega \in B \tag{1.19}$$

and that the phase response is linear, i.e.,

$$\theta(\omega) = -\tau_g\omega + \theta_o \quad \text{for } \omega \in B \tag{1.20}$$

where τ_g is a constant. This implies that the group delay is constant with respect to band B, i.e.,

$$\tau(\omega) = -\frac{d\theta(\omega)}{d\omega} = \tau_g \quad \text{for } \omega \in B$$

The frequency spectrum of the output signal $v_o(t)$ can be obtained from Equations 1.19 and 1.20 as

$$\begin{aligned} V_o(j\omega) &= H(j\omega)V_i(j\omega) = M(\omega)e^{j\theta(\omega)}V_i(j\omega) \\ &= \left[G_0 e^{-j\omega\tau_g + j\theta_0}\right]V_i(j\omega) = G_0 e^{j\theta_0}\left[e^{-j\omega\tau_g}V_i(j\omega)\right] \end{aligned}$$

and from the time-shifting theorem of the Fourier transform

$$v_o(t) = G_0 e^{j\theta_0} v_i\left(t - \tau_g\right)$$

We conclude that the amplitude response of the filter is flat and its phase response is a linear function of ω (i.e., the delay characteristic is flat) in band B, then the output signal is a delayed replica of the input signal except that a gain G_o and a constant phase shift θ_0 are introduced.

If the amplitude response of the filter is not flat in band B, then *amplitude distortion* will be introduced since different frequency components of the signal will be amplified by different amounts.

If the delay characteristic is not flat in band B, then *delay* (or *phase*) *distortion* will be introduced since different frequency components will be delayed by different amounts.

Amplitude distortion can be quite objectionable in practice and, consequently, in each frequency band that carries information, the amplitude response is required to be constant to within a prescribed tolerance. The amount of amplitude distortion allowed determines the maximum passband loss A_p.

If the ultimate receiver of the signal is the human ear, e.g., when a speech or music signal is to be processed, delay distortion is quite tolerable. However, in other applications it can be as objectionable as amplitude distortion and the delay characteristic is required to be fairly flat. Applications of this type include data transmission, where the signal is to be interpreted by digital hardware, and image processing, where the signal is used to reconstruct an image that is to be interpreted by the human eye. The allowable delay distortion dictates the degree of flatness in the delay characteristic.

1.7 Minimum-Phase, Nonminimum-Phase, and Allpass Filters

Filters satisfying prescribed loss specifications for applications where delay distortion is unimportant can be readily designed with transfer functions whose zeros are on the $j\omega$ axis or in the left-half s plane. Such transfer functions are said to be minimum-phase since the phase response at a given frequency ω is increased if any one of the zeros is moved into the right-half s plane, as will now be demonstrated.

1.7.1 Minimum-Phase Filters

Consider a filter where the zeros z_i for $i = 1, 2, \ldots, M$ are replaced by their mirror images and let the new zeros be located at $z = \bar{z}_i$, where

$$\text{Re}\ \bar{z}_i = -\text{Re}\ z_i \quad \text{and} \quad \text{Im}\ \bar{z}_i = \text{Im}\ z_i$$

as depicted in Figure 1.5. From the geometry of the new zero-pole plot, the magnitude and angle of each phasor $j\omega - \bar{z}_i$ are given by

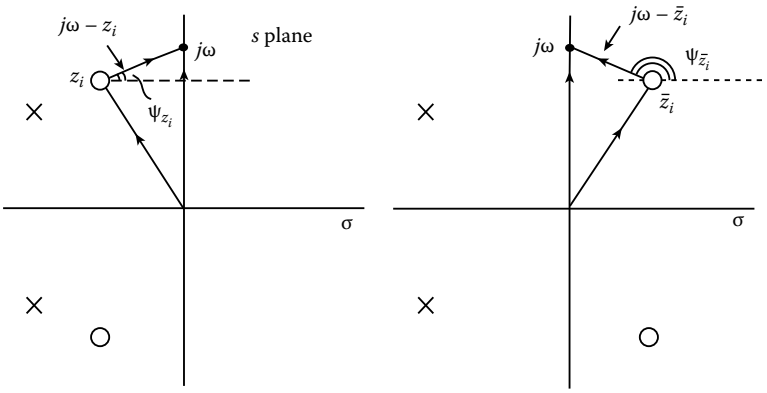

FIGURE 1.5 Zero-pole plots of minimum-phase and corresponding nonminimum-phase filter.

$$M_{\bar{z}_i} = M_{z_i} \quad \text{and} \quad \psi_{\bar{z}_i} = \pi - \psi_{z_i}$$

respectively. The amplitude response of the modified filter is obtained from Equation 1.16 as

$$\overline{M}(\omega) = \frac{|H_0| \prod_{i=1}^{M} M_{\bar{z}_i}}{\prod_{i=1}^{N} M_{p_i}^{m_i}} = \frac{|H_0| \prod_{i=1}^{M} M_{z_i}}{\prod_{i=1}^{N} M_{p_i}^{m_i}} = M(\omega)$$

Therefore, replacing the zeros of the transfer function by their mirror images leaves the amplitude response unchanged.

The phase response of the original filter is given by Equation 1.17 as

$$\theta(\omega) = \arg H_0 + \sum_{i=1}^{M} \psi_{z_i} - \sum_{i=1}^{N} m_i \psi_{p_i} \tag{1.21}$$

and since $\psi_{\bar{z}_i} = \pi - \psi_{z_i}$, the phase response of the modifier filter is given by

$$\begin{aligned} \bar{\theta}(\omega) &= \arg H_0 + \sum_{i=1}^{M} \psi_{\bar{z}_i} - \sum_{i=1}^{N} m_i \psi_{p_i} \\ &= \arg H_0 + \sum_{i=1}^{M} (\pi - \psi_{z_i}) - \sum_{i=1}^{N} m_i \psi_{p_i} \end{aligned} \tag{1.22}$$

that is, the phase response of the modified filter is different from that of the original filter. Furthermore, from Equations 1.21 and 1.22

$$\bar{\theta}(\omega) - \theta(\omega) = \sum_{i=1}^{M} (\pi - 2\psi_{z_i})$$

and since $-\pi/2 \leq -\psi_{z_i} \leq \pi/2$, we have

$$\bar{\theta}(\omega) - \theta(\omega) \geq 0$$

or

$$\bar{\theta}(\omega) \geq \theta(\omega)$$

As a consequence, the phase response of the modified filter is equal to or greater than that of the original filter for all ω.

A frequently encountered requirement in the design of filters is that the delay characteristic be flat to within a certain tolerance within the passband(s) in order to achieve tolerable delay distortion, as was demonstrated in Section 1.6. In these and other filters in which the specifications include constraints on the phase response or delay characteristic, a nonminimum-phase transfer function is almost always required.

1.7.2 Allpass Filters

An allpass filter is one that has a constant amplitude response. Consider a transfer function of the type given by Equation 1.13. From Equation 1.10, $H(-j\omega)$ is the complex conjugate of $H(j\omega)$, and hence a constant amplitude response can be achieved if

$$M^2(\omega) = H(s)H(-s)|_{s=j\omega} = H_0^2 \frac{N(s)}{D(s)} \times \left.\frac{N(-s)}{D(-s)}\right|_{s=j\omega} = H_0^2$$

Hence, an allpass filter can be obtained if

$$N(-s) = D(s)$$

that is, the zeros of such a filter must be the mirror images of the poles and vice versa. A typical zero-pole plot for an allpass filter is illustrated in Figure 1.6. A second-order allpass transfer function is given by

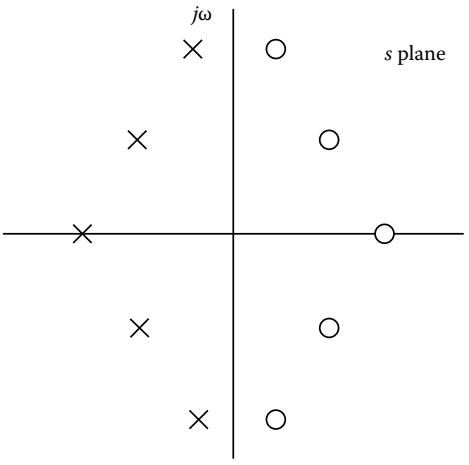

FIGURE 1.6 Typical zero-pole plot of an allpass filter.

$$H_{AP}(s) = \frac{s^2 - bs + c}{s^2 + bs + c}$$

where $b > 0$ for stability. As described previously, we can write

$$M^2(\omega) = H_{AP}(s)H_{AP}(-s)|_{s=j\omega} = \frac{s^2 - bs + c}{s^2 + bs + c} \times \left.\frac{s^2 + bs + c}{s^2 - bs + c}\right|_{s=j\omega} = 1$$

Allpass filters can be used to modify the phase responses of filters without changing their amplitude responses. Hence, they are used along with minimum-phase filters to obtain nonminimum-phase filters that satisfy amplitude and phase response specifications simultaneously.

1.7.3 Decomposition of Nonminimum-Phase Transfer Functions

Some methods for the design of filters satisfying amplitude and phase response specifications, usually methods based on optimization, yield a nonminimum-phase transfer function. Such a transfer function can be easily decomposed into a product of a minimum-phase and an allpass transfer function, i.e.,

$$H_N(s) = H_M(s)H_{AP}(s)$$

Consequently, a nonminimum-phase filter can be implemented as a cascade arrangement of a minimum-phase and an allpass filter.

The preceding decomposition can be obtained by using the following procedure:

1. For each zero in the right-half s plane, augment the transfer function by a zero and a pole at the mirror image position of the zero.
2. Assign the left-half s-plane zeros and the original poles to the minimum-phase transfer function $H_M(s)$.
3. Assign the right-half s-plane zeros and the left-hand s-plane poles generated in step 1 to the allpass transfer function $H_{AP}(s)$.

This procedure is illustrated in Figure 1.7. For example, if

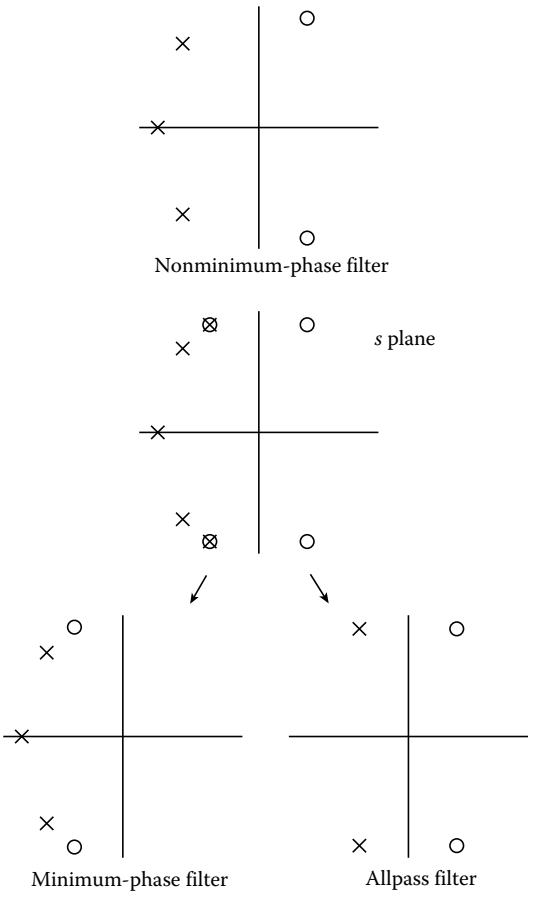

FIGURE 1.7 Decomposition of nonminimum-phase transfer function.

$$H_N(s) = \frac{(s^2+4s+5)(s^2-3s+7)(s-5)}{(s^2+2s+6)(s^2+4s+9)(s+2)}$$

then, we can write

$$H_N(s) = \frac{(s^2+4s+5)(s^2-3s+7)(s-5)}{(s^2+2s+6)(s^2+4s+9)(s+2)} \times \frac{(s^2+3s+7)(s+5)}{(s^2+3s+7)(s+5)}$$

Hence,

$$H_N(s) = \frac{(s^2+4s+5)(s^2+3s+7)(s+5)}{(s^2+2s+6)(s^2+4s+9)(s+2)} \times \frac{(s^2-3s+7)(s-5)}{(s^2+3s+7)(s+5)}$$

or

$$H_N(s) = H_M(s)H_{AP}(s)$$

where

$$H_M(s) = \frac{(s^2+4s+5)(s^2+3s+7)(s+5)}{(s^2+2s+6)(s^2+4s+9)(s+2)}$$
$$H_{AP}(s) = \frac{(s^2-3s+7)(s-5)}{(s^2+3s+7)(s+5)}$$

1.8 Introduction to the Design Process

The design of filters starts with a set of specifications and ends with the implementation of a prototype. It comprises four general steps, as follows:

1. Approximation
2. Realization
3. Study of imperfections
4. Implementation

1.8.1 The Approximation Step

The approximation step is the process of generating a transfer function that satisfies the desired specifications, which may concern the amplitude, phase, and possibly the time-domain response of the filter.

The available methods for the solution of the approximation problem can be classified as closed-form or iterative. In closed-form methods, the problem is solved through a small number of design steps using a set of closed-form formulas or transformations. In iterative methods, an initial solution is assumed and, through the application of optimization methods, a series of progressively improved solutions are obtained until some design criterion is satisfied. Closed-form solutions are very precise and entail a minimal amount of computation. However, the available solutions are useful in applications where the loss characteristic is required to be piecewise constant to within some prescribed tolerances. Iterative methods, on the other hand, entail a considerable amount of computation but can be used to design filters

with arbitrary amplitude and phase response characteristics (see Ref. [1, Chapter 14]) for the application of these methods for the design of digital filters). Some classical closed-form solutions are the so-called Butterworth, Chebyshev, and elliptic* approximations to be described in Chapter 2 by A.M. Davis.

In general, the designer is interested in simple and reliable approximation methods that yield precise designs with the minimum amount of computation.

1.8.2 The Realization Step

The *synthesis* of a filter is the process of converting some characterization of the filter into a network. The process of converting the transfer function into a network is said to be the realization step and the network obtained is sometimes called the realization.

The realization of a transfer function can be accomplished by expressing it in some form that allows the identification of an interconnection of elemental filter subnetworks and/or elements. Many realization methods have been proposed in the past that lead to structures of varying complexity and properties. In general, the designer is interested in realizations that are economical in terms of the number of elements, do not require expensive components, and are not seriously affected by variations in the element values such as may be caused by variations in temperature and humidity, and drift due to element aging.

1.8.3 Study of Imperfections

During the approximation step, the coefficients of the transfer function are determined to a high degree of precision and the realization is obtained on the assumption that elements are ideal, i.e., capacitors are lossless, inductors are free of winding capacitances, amplifiers have infinite bandwidths, and so on. In practice, however, the filter is implemented with nonideal elements that have finite tolerances and are often nonlinear. Consequently, once a realization is obtained, sometimes referred to as a *paper design*, the designer must embark on the study of the effects of element imperfections. Several types of analysis are usually called for ranging from tolerance analysis, study of parasitics, time-domain analysis, sensitivity analysis, noise analysis, etc. Tight tolerances result in high-precision filters but the cost per unit would be high. Hence the designer is obliged to determine the highest tolerance that can be tolerated without violating the specifications of the filter throughout its working life. Sensitivity analysis is a related study that will ascertain the degree of dependence of a filter parameter, e.g., the dependence of the amplitude response on a specific element. If the loss characteristic of a filter is not very sensitive to certain capacitance, then the designer would be able to use a less precise and cheaper capacitor, which would, of course, decrease the cost of the unit.

1.8.4 Implementation

Once the filter is thoroughly analyzed and found to meet the desired specifications under ideal conditions, a prototype is constructed and tested. Decisions to be made involve the type of components and packaging, and the methods are to be used for the manufacture, testing, and tuning of the filter. Problems may often surface at the implementation stage that may call for one or more modifications in the paper design. Then the realization and possibly the approximation may have to be redone.

---

* To be precise, the elliptic approximation is not a closed-form method, since the transfer function coefficients are given in terms of certain infinite series. However, these series converge very rapidly and can be treated as closed-form formulas for most practical purposes (see Ref. [1, Chapter 5]).

1.9 Introduction to Realization

Realization tends to depend heavily on the type of filter required. The realization of passive *RLC* filters differs quite significantly from that of active filters which, in turn, is entirely different from the realization of microwave filters.

1.9.1 Passive Filters

Passive *RLC* filters have been the mainstay of communications since the 1920s and, furthermore, they continue to be of considerable importance today for frequencies in the 100–500 kHz range.

The realization of passive *RLC* filters has received considerable attention through the years and it is, as a consequence, highly developed and sophisticated. It can be accomplished by using available filter-design packages such as FILSYN [5] and FILTOR [6]. In addition, several filter-design handbooks and published design tables are available [7–10].

The realization of passive *RLC* filters starts with a resistively terminated *LC* two-port network such as that in Figure 1.8. Then through one of several approaches, the transfer function is used to generate expressions for the *z* or *y* parameters of the *LC* two-port. The realization of the *LC* two-port is achieved by realizing the *z* or *y* parameters. The realization of passive filters is considered in Section I.

1.9.2 Active Filters

Since the reactance of an inductor is ωL, increased inductance values are required to achieve reasonable reactance values at low frequencies. For example, an inductance of 1 mH which will present a reactance of 6.28 kΩ at 1 MHz will present only 0.628 Ω at 100 Hz. Thus, as the frequency range of interest is reduced, the inductance values must be increased if a specified impedance level is to be maintained. This can be done by increasing the number of turns on the inductor coil and to some extent by using ferromagnetic cores of high permeability. Increasing the number of turns increases the resistance, the size, and the cost of the inductor. The resistance is increased because the length of the wire is increased [$R = (\rho \times length)/Area$], and hence the *Q* factor is reduced. The cost goes up because the cost of materials as well as the cost of labor go up, since an inductor must be individually wound. For these reasons, inductors are generally incompatible with miniaturization or microcircuit implementation.

The preceding physical problem has led to the invention and development of a class of inductorless filters known collectively as active filters. Sensitivity considerations, which will be examined in Chapter 4 by I. Filanovsky, have led to two basic approaches to the design of active filters. In one approach, the active filter is obtained by simulating the inductances in a passive *RLC* filter or by realizing a signal flow graph of the passive *RLC* filter. In another approach, the active filter is obtained by cascading a number of low-order filter sections of some type, as depicted in Figure 1.9a where Z_{o0} is the output impedance of the signal source.

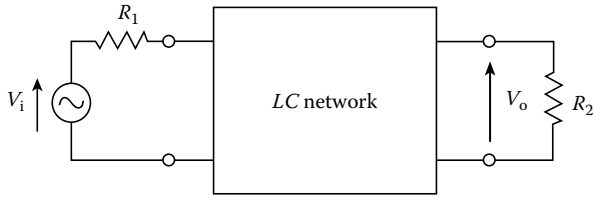

FIGURE 1.8 Passive *RLC* filter.

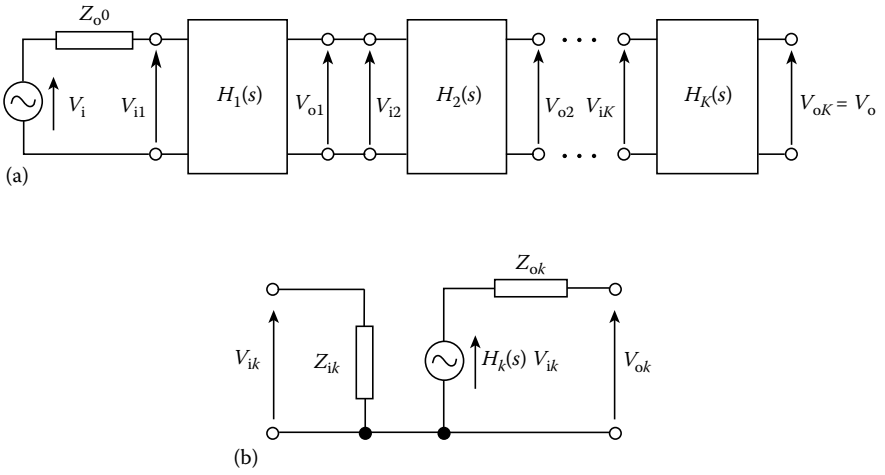

FIGURE 1.9 (a) Cascade realization and (b) Thévenin equivalent circuit of filter section.

Each filter section is made up of an interconnection of resistors, capacitors, and active elements, and by Thévenin's theorem, it can be represented by its input impedance, open-circuit voltage transfer function, and output impedance as shown in Figure 1.9b. The voltage transfer function of the configuration is given by

$$H(s) = \frac{V_o}{V_i}$$

and since the input voltage of section k is equal to the output voltage of section $k-1$, i.e., $V_{ik} = V_{o(k-1)}$ for $k = 2, 3, \ldots, K$, and $V_o = V_{oK}$ we can write

$$H(s) = \frac{V_o}{V_i} = \frac{V_{i1}}{V_i} \times \frac{V_{o1}}{V_{i1}} \times \frac{V_{o2}}{V_{i2}} \times \cdots \times \frac{V_{oK}}{V_{iK}} \tag{1.23}$$

where

$$\frac{V_{i1}}{V_i} = \frac{Z_{i1}}{Z_{o0} + Z_{i1}} \tag{1.24}$$

and

$$\frac{V_{ok}}{V_{ik}} = \frac{Z_{i(k+1)}}{Z_{ok} + Z_{i(k+1)}} H_k(s) \tag{1.25}$$

is the transfer function of the kth section. From Equations 1.23 through 1.25, we obtain

$$H(s) = \frac{V_o}{V_i} = \frac{Z_{i1}}{Z_{o0} + Z_{i1}} \prod_{k=1}^{K} \frac{Z_{i(k+1)}}{Z_{ok} + Z_{i(k+1)}} H_k(s)$$

Now if

$$|Z_{ik}| \gg |Z_{o(k-1)}|$$

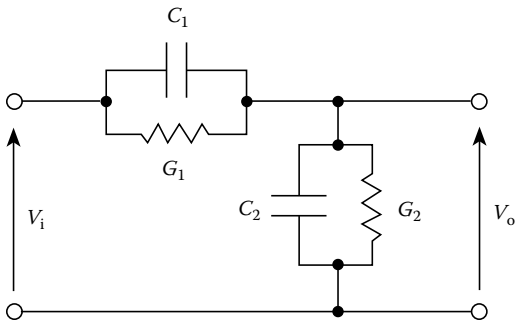

FIGURE 1.10 First-order *RC* network.

for $k = 1, 2, \ldots, K$, then the loading effect produced by section $k+1$ on section k can be neglected and hence

$$H(s) = \frac{V_o}{V_i} = \prod_{k-1}^{K} H_k(s)$$

Evidently, a highly desirable property in active filter sections is that the magnitude of the input impedance be large and/or that of the output impedance be small since in such a case the transfer function of the cascade structure is equal to the product of the transfer functions of the individual sections.

An arbitrary *N*th-order transfer function obtained by using the Butterworth, Bessel, Chebyshev, inverse-Chebyshev, or elliptic approximation can be expressed as

$$H(s) = H_0(s) \prod_{k=1}^{K} \frac{a_{2k}s^2 + a_{1k}s + a_{0k}}{s^2 + b_{1k}s + b_{0k}}$$

where

$$H_0(s) = \begin{cases} \frac{a_{10}s + a_{00}}{b_{10}s + b_{00}} & \text{for odd } N \\ 1 & \text{for even } N \end{cases}$$

The first-order transfer function $H_0(s)$ for the case of an odd-order can be readily realized using the *RC* network of Figure 1.10.

1.9.3 Biquads

From the above analysis, we note that all we need to be able to realize an arbitrary transfer function is a circuit that realizes the biquadratic transfer function

$$H_{BQ}(s) = \frac{a_2s^2 + a_1s + a_0}{s^2 + b_1s + b_0} = \frac{a_2(s + z_1)(s + z_2)}{(s + p_1)(s + p_2)} \tag{1.26}$$

where zeros and poles occur in complex conjugate pairs, i.e., $z_2 = z_1^*$ and $p_2 = p_1^*$. Such a circuit is commonly referred to as a *biquad*.

After some manipulation, the transfer function in Equation 1.26 can be expressed as

$$H_{BQ}(s) = K\frac{s^2 + (2\text{Re } z_1)s + (\text{Re } z_1)^2 + (\text{Im } z_1)^2}{s^2 + (2\text{Re } p_1)s + (\text{Re } p_1)^2 + (\text{Im } p_1)^2}$$
$$= K\frac{s^2 + (\omega_z/Q_z)s + \omega_z^2}{s^2 + (\omega_p/Q_p)s + \omega_p^2}$$

where

$K = a_2$

ω_z and ω_p are the zero and pole frequencies, respectively

Q_z and Q_p are the zero and pole *quality factors* (or Q factors for short), respectively

The formulas for the various parameters are as follows:

$$\omega_z = \sqrt{(\text{Re } z_1)^2 + (\text{Im } z_1)^2}$$
$$\omega_p = \sqrt{(\text{Re } p_1)^2 + (\text{Im } p_1)^2}$$
$$Q_z = \frac{\omega_z}{2\text{ Re } z_1}$$
$$Q_p = \frac{\omega_p}{2\text{ Re } p_1}$$

The zero and pole frequencies are approximately equal to the frequencies of minimum gain and maximum gain, respectively. The zero and pole Q factors have to do with the selectivity of the filter. A high zero Q factor results in a deep notch in the amplitude response, whereas a high pole Q factor results in a very peaky amplitude response.

The dc gain and the gain as $\omega \to \infty$ in decibels are given by

$$M_0 = 20\log|H_{BQ}(0)| = 20\log\left(K\frac{\omega_z^2}{\omega_p^2}\right)$$

and

$$M_\infty = 20\log|H_{BQ}(j\infty)| = 20\log K$$

respectively.

1.9.4 Types of Basic Filter Sections

Depending on the values of the transfer function coefficients, five basic types of filter sections can be identified, namely, low-pass, high-pass, bandpass, notch (sometimes referred to as bandreject), and allpass. These sections can serve as building blocks for the design of filters that can satisfy arbitrary specifications. They are actually sufficient for the design of all the standard types of filters, namely, Butterworth, Chebyshev, inverse-Chebyshev, and elliptic filters.

1.9.4.1 Low-Pass Section

In a *low-pass* section, we have $a_2 = a_1 = 0$ and $a_0 = K\omega_p^2$. Hence, the transfer function assumes the form

$$H_{LP}(s) = \frac{a_0}{s^2 + b_1 s + b_0} = \frac{K\omega_p^2}{s^2 + (\omega_p/Q_p)s + \omega_p^2}$$

(see Figure 1.11a)

1.9.4.2 High-Pass Section

In a *high-pass* section, we have $a_2 = K$ and $a_1 = a_0 = 0$. Hence, the transfer function assumes the form

$$H_{\mathrm{HP}}(s) = \frac{a_2 s^2}{s^2 + b_1 s + b_0} = \frac{Ks^2}{s^2 + \left(\omega_{\mathrm{p}}/Q_{\mathrm{p}}\right)s + \omega_{\mathrm{p}}^2}$$

(see Figure 1.11b)

1.9.4.3 Bandpass Section

In a *bandpass* section, we have $a_1 = K\omega_{\mathrm{p}}/Q_{\mathrm{p}}$ and $a_2 = a_0 = 0$. Hence the transfer function assumes the form

$$H_{\mathrm{BP}}(s) = \frac{a_1 s}{s^2 + b_1 s + b_0} = \frac{K\left(\omega_p/Q_{\mathrm{p}}\right)s}{s^2 + \left(\omega_{\mathrm{p}}/Q_{\mathrm{p}}\right) + \omega_{\mathrm{p}}^2}$$

(see Figure 1.11c)

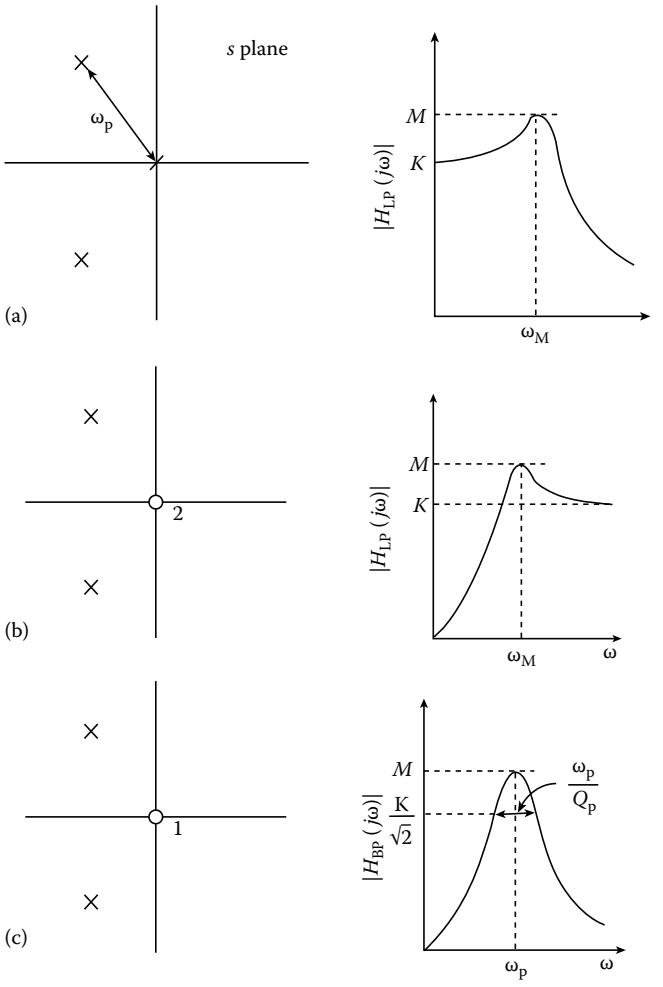

FIGURE 1.11 Basic second-order filter sections: (a) low-pass, (b) high-pass, (c) bandpass,

(*continued*)

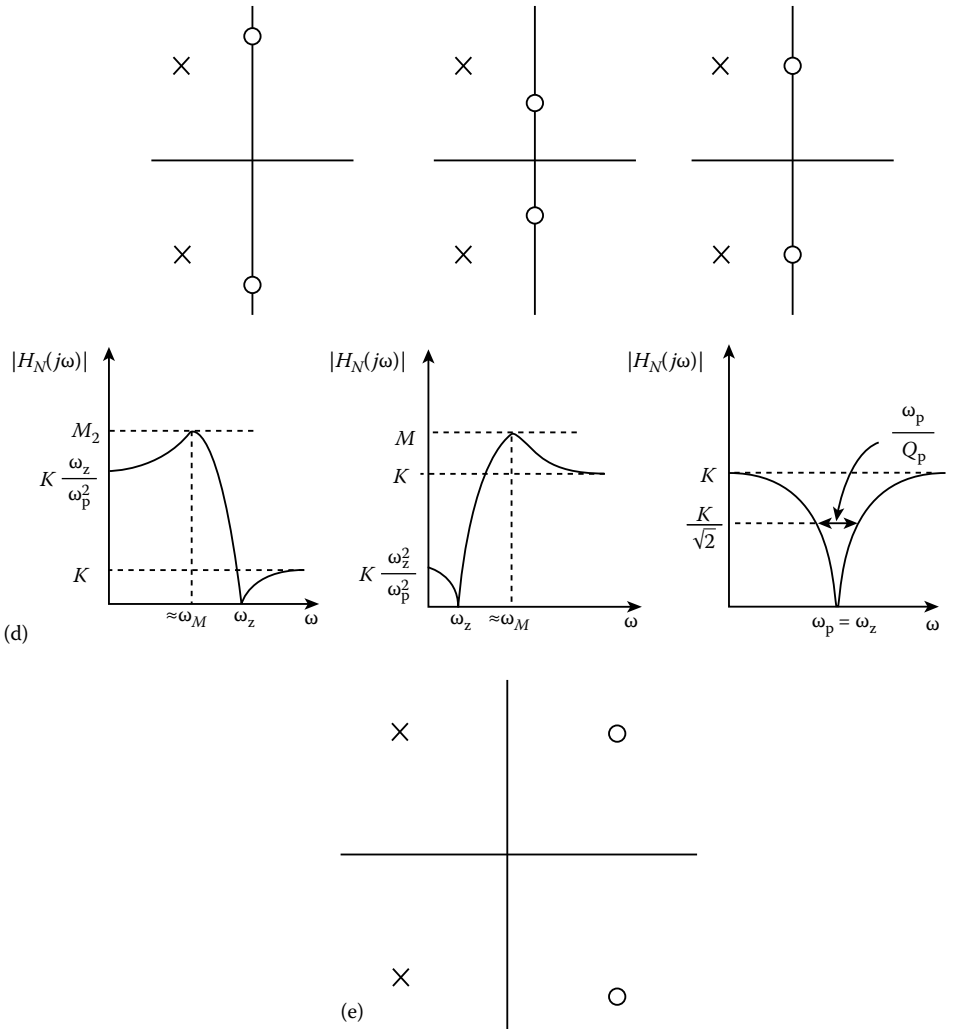

FIGURE 1.11 (continued) (d) notch, and (e) allpass.

1.9.4.4 Notch Section

In a *notch* section, we have $a_2 = K$, $a_1 = 0$, and $a_0 = K\omega_p^2$. Hence, the transfer function assumes the form

$$H_N(s) = \frac{a_2 s^2 + a_0}{s^2 + b_1 s + b_0} = \frac{K\left(s^2 + \omega_z^2\right)}{s^2 + \left(\omega_p/Q_p\right)s + \omega_p^2}$$

(see Figure 1.11d)

1.9.4.5 Allpass Section

In an *allpass* section, we have $a_2 = K$, $a_1 = -Kw_p/Q_p$, and $a_0 = K\omega_p^2$. Hence the transfer function assumes the form

$$H_{AP}(s) = \frac{a_2 s^2 + a_1 s + a_0}{s^2 + b_1 s + b_0} = \frac{K\left[s^2 - \left(\omega_p/Q_p\right)s + \omega_p^2\right]}{s^2 + \left(\omega_p/Q_p\right)s + \omega_p^2}$$

(see Figure 1.11e)

The design of active and switched-capacitor filters is treated in some detail in Section II.

2.1 Introduction

The approximation problem for filters is illustrated in Figure 2.1. A filter is often desired to produce a given slope of gain over one or more frequency intervals, to remain constant over other intervals, and to completely reject signals having frequencies contained in still other intervals. Thus, in the example shown in the figure, the desired gain is zero for very low and very high frequencies. The centerline, shown dashed, is the nominal behavior and the shaded band shows the permissible variation in the gain characteristic. Realizable circuits must always generate smooth curves and so cannot exactly meet the piecewise linear specification represented by the centerline. Thus, the realizable behavior is shown by the smooth, dark curve that lies entirely within the shaded tolerance band.

What type of frequency response function can be postulated that will meet the required specifications and, at the same time, be realizable: constructible with a specified catalog of elements? The answer depends upon the types of elements allowed. For instance, if one allows pure delays with a common delay time, summers, and scalar multipliers, a trigonometric polynomial will work; this, however, will cause the gain function to be repeated in a periodic manner. If this is permissible, one can then realize the filter in the form of an FIR digital filter or as a commensurate transmission line filter, and in fact, it can be realized in such a fashion that the resulting phase behavior is precisely linear. If one fits the required behavior with a rational trigonometric function, a function that is the ratio of two trigonometric polynomials, an economy of hardware will result. The phase, however, will unfortunately no longer be linear. These issues are discussed at greater length in Ref. [1].

Another option would be to select an ordinary polynomial in ω as the approximating function. Polynomials, however, behave badly at infinity. They approach infinity as $\omega \to \pm\infty$, a highly undesirable solution. For this reason, one must discard polynomials. A rational function of ω, however, will work nicely for the ratio of two polynomials will approach zero as $\omega \to \pm\infty$ if the degree of the numerator polynomial is selected to be of lower degree than that of the denominator. Furthermore, by the Weierstrass theorem, such a function can approximate any continuous function arbitrarily closely over any closed interval of finite length [2]. Thus, one sees that the rational functions in ω offer a suitable approximation for analog filter design and, in fact, do not have the repetitive nature of the trigonometric rational functions.

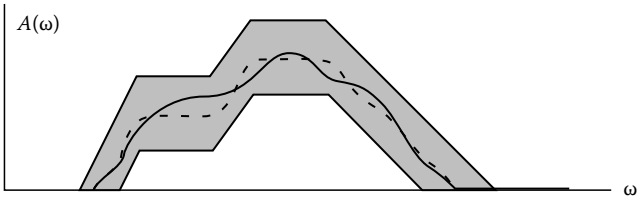

FIGURE 2.1 General approximation problem.

Suppose, therefore, that the gain function is of the form

$$A(\omega) = \frac{N(\omega)}{D(\omega)} = \frac{a_0 + a_1\omega + a_2\omega^2 + \cdots + a_r\omega^r}{b_0 + b_1\omega + b_2\omega^2 + \cdots + b_q\omega^q} \tag{2.1}$$

where $r \leq q$ for reasons mentioned above. Assuming that the filter to be realized is constrained to be constructable with real* elements, one must require that $A(-\omega) = A(\omega)$, that is, that the gain be an event function of frequency. But then, as it is straightforward to show, one must require that all the odd coefficients of both numerator and denominator be zero. This means that the gain is a function of ω^2:

$$A(\omega) = \frac{N(\omega^2)}{D(\omega^2)} = \frac{a_0 + a_1\omega^2 + \cdots + a_m\omega^{2m}}{b_0 + b_1\omega^2 + \cdots + b_n\omega^{2n}} = A(\omega^{-2}) \tag{2.2}$$

The expression has been reindexed and the constants redefined in an obvious manner. The net result is that one must approximate the desired characteristic by the ratio of two polynomials in ω^2; the objective is to determine the numerator and denominator coefficients to meet the stated specifications. Once this is accomplished one must compute the filter transfer function $G(s)$ in order to synthesize the filter [4,5]. Assuming that $G(s)$ is real (has real coefficients), then its complex conjugate satisfies $G^*(s) = G(s^*)$, from which it follows that $G(s)$ is related to $A(\omega^2)$ by the relationship

$$[G(s)G(-s)]_{s=j\omega} = G(j\omega)G^*(j\omega) = |G(j\omega)|^2 = A^2(\omega^2) \tag{2.3}$$

In fact, it is more straightforward to simply cast the original approximation problem in terms of $A^2(\omega^2)$, rather than in terms of $A(\omega)$. In this case, Equation 2.2 becomes

$$A^2(\omega^2) = \frac{N(\omega^2)}{D(\omega^2)} = \frac{a_0 + a_1\omega^2 + \cdots + a_m\omega^{2m}}{b_0 + b_1\omega^2 + \cdots + b_n\omega^{2n}} \tag{2.4}$$

Thus, one can assume that the approximation process produces $A^2(\omega^2)$ as the ratio of two real polynomials in ω^2. Since Equation 2.3 requires the substitutions $s \rightarrow j\omega$, one also has $s^2 \rightarrow -\omega^2$, and conversely. Thus, Equation 2.3 becomes

$$G(s)G(-s) = A^2(-s^2) \tag{2.5}$$

Though this has been shown to hold only on the imaginary axis, it continues to hold for other complex values of s as well by analytic continuation.†

* Complex filters are quite possible to construct, as recent work [3] shows.

† A function analytic in a region is completely determined by its values along any line segment in that region—in this case, by its value along the $j\omega$ axis.

The problem now is to compute $G(s)$ from Equation 2.5, a process known as the factorization problem. The solution is not unique; in fact, the phase is arbitrary—subject only to certain realizability conditions. To see this, just let $G(j\omega) = A(\omega)e^{j\phi(\omega)}$, where $\phi\omega$ is an arbitrary phase function. Then, Equation 2.3 implies that

$$G(j\omega)G^{*}(j\omega) = A(\omega)e^{j\phi(\omega)} \cdot A(\omega)e^{-j\phi(\omega)} = A^2(\omega) \tag{2.6}$$

If the resulting structure is to have the property of minimum phase [6], the phase function is determined completely by the gain function. If not, one can simply perform the factorization and accept whatever phase function results from the particular process chosen. As has been pointed out earlier in this chapter, it is often desirable that the phase be a linear function of frequency. In this case, one must follow the filter designed by the above process with a phase equalization filter, one that has constant gain and a phase characteristic that, when summed with that of the first filter, produces linear phase. As it happens, the human ear is insensitive to phase nonlinearity, so the phase is not of much importance for filters designed to operate in the audio range. For those intended for video applications, however, it is vitally important. Nonlinear phase produces, for instance, the phenomenon of multiple edges in a reproduced picture.

If completely arbitrary gain characteristics are desired, computer optimization is necessary [6]. Indeed, if phase is of great significance, computer algorithms are available for the simultaneous approximation of both gain and phase. These are complex and unwieldy to use, however, so for more modest applications the above approach relying upon gain approximation only suffices. In fact, the approach arose historically in the telephone industry in its earlier days in which voice transmission was the only concern, data and video transmission being unforeseen at the time. Furthermore, the frequency division multiplexing of voice signals was the primary concern; hence, a number of standard desired shapes of frequency response were generated: low pass, high pass, bandpass, and bandreject (or notch). Typical but stylized specification curves are shown in Figure 2.2. This figure serves to define the following parameters: the minimum passband gain A_p, the maximum stopband gain A_s, the passband cutoff frequency ω_p, the stopband cutoff frequency ω_s (the last two parameters are for low-pass and high-pass filters only), the center frequency ω_o, upper passband and stopband cutoff frequencies ω_{pu} and ω_{su}, and lower passband and stopband cutoff frequencies ω_{pl} and ω_{sl} (the last four parameters are for the bandpass

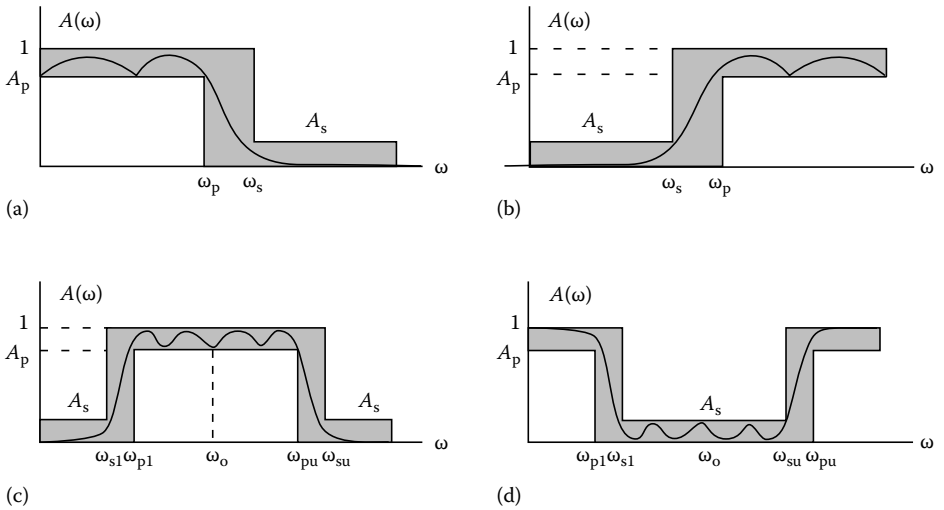

FIGURE 2.2 Catalog of basic filter types: (a) low pass, (b) high pass, (c) bandpass, and (d) bandreject.

and band-reject filters only). As shown in the figure, the maximum passband gain is usually taken to be unity. In the realization process, the transfer function scale factor is often allowed to be a free parameter that is resolved in the design procedure. The resulting "flat gain" (frequency independent) difference from unity is usually considered to be of no consequence, as long as it is not too small, thus creating signal-to-noise ratio problems. There is a fifth standard type that we have not shown: the allpass filter. It has a constant gain for all frequencies, but with a phase characteristic that can be tailored to fit a standard specification in order to compensate for phase distortion. Frequency ranges where the gain is relatively large are called passbands and those where the gain is relatively small, stopbands. Those in between—where the gain is increasing or decreasing—are termed transition bands.

In order to simplify the design even more, one bases the design of all other types of filter in terms of only one: the low pass. In this case, one says that the low-pass filter is a prototype. The specifications of the desired filter type are transformed to those of an equivalent low-pass prototype, and the transfer function for this filter is determined to meet the transformed specifications. Letting the low-pass frequency be symbolized by Ω and the original by ω, one sets

$$\Omega = f(\omega) \tag{2.7}$$

The approximation problem is then solved in terms of Ω. Letting

$$p = j\Omega \tag{2.8}$$

one then has $G(p)$, the desired transfer function.

Two approaches are now possible. One is to apply the inverse transformation, letting

$$s = j\omega = jf^{-1}(\Omega) = jf^{-1}(p/j) \tag{2.9}$$

thus obtaining the desired transfer function

$$G(s) = G(j\omega) = G[jf^{-1}(\Omega)] = G[jf^{-1}(p/j)] \tag{2.10}$$

The other consists of designing the circuit to realize the low-pass prototype filter, then transform *each of the elements* from functions of p to functions of s by means of the complex frequency transformation

$$s = j\omega = jf^{-1}(\Omega) = jf^{-1}(p/j) \tag{2.11}$$

As it happens, the transformation $p = f(s)$ has a special form. It can be shown that if f is real for real values of s, thereby having real parameters, and maps the imaginary axis of the p plane into the imaginary axis of the s plane then it must be an odd function; furthermore, if it is to map *positive real rational functions* into those of like kind (necessary for realizability with R, L, and C elements, as well as possibly ideal transformers*), it must be a *reactance function*. (See Ref. [7] for details.) Since it is always desirable from an economic standpoint to design filters of minimum order, it is desirable that the transformation be of the smallest possible degree. As a result, the following transformations are used:

$$(\text{lpp} \leftrightarrow \text{lp}) \quad p = ks \tag{2.12}$$

$$(\text{lpp} \leftrightarrow \text{hp}) \quad p = \frac{k}{s} \tag{2.13}$$

* For active realizations, those containing dependent sources, this condition is not necessary.

$$(\text{lpp} \leftrightarrow \text{bp}) \quad p = \frac{s^2 + \omega_o^2}{Bs} \tag{2.14}$$

$$(\text{lpp} \leftrightarrow \text{br}) \quad p = \frac{Bs}{s^2 + \omega_o^2} \tag{2.15}$$

where the parameters k, B, and ω_o are real constants to be determined by the particular set of specifications. We have used the standard abbreviations of lpp for *low-pass prototype*, lp for *low pass*, hp for *high pass*, bp for *bandpass*, and br for *bandreject*. Often the letter *f* is added; for example, one might use the acronym brf for *bandreject filter*. The reason for including the transformation in Equation 2.12 is to allow standardization of the lpp. For instance, one can transform from an lpp with, say, a passband cutoff frequency of 1 rad/s to a low-pass filter with a passband cutoff of perhaps 1 kHz.

As a simple example, suppose a bandreject filter were being designed and that the result of the approximation process were

$$H(p) = \frac{1}{p+1} \tag{2.16}$$

Then the br transfer function would be

$$H(s) = [H(p)]_{p=[Bs/(s^2+\omega_o^2)]} = \frac{1}{\frac{Bs}{s^2+\omega_o^2} + 1} = \frac{s^2 + \omega_o^2}{s^2 + Bs + \omega_o^2} \tag{2.17}$$

(The parameters ω_o and B would be determined by the bandreject specifications.) As one can readily see, a first-order lpp is transformed into a second-order brf. In general, for bandpass and bandreject design, the object transfer function is of twice the order of the lpp. Since the example is so simple, it can readily be seen that the circuit in Figure 2.3 realizes the lpp voltage gain function in Equation 2.16. If one applies the transformation in Equation 2.15 the 1-Ω resistor maps into a 1-Ω resistor, but the 1 F capacitor maps into a combination of elements having the admittance

$$Y(p) = p = \frac{1}{\frac{s}{B} + \frac{\omega_o^2}{Bs}} \tag{2.18}$$

But this is simply the series connection of a capacitor of value B/ω_o^2 farads and an inductor of value $1/B$ henrys. The resulting bandreject filter is shown in Figure. 2.4.

The only remaining "loose end" is the determination of the constant(s) in the appropriate transformation equation selected appropriately from Equations 2.12 through 2.15. This will be done here for the

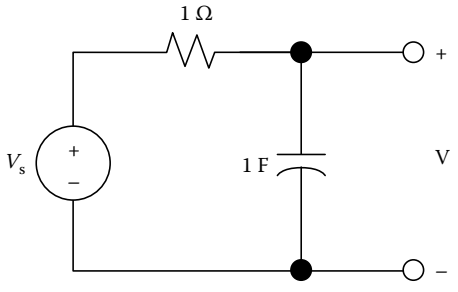

FIGURE 2.3 Low-pass prototype.

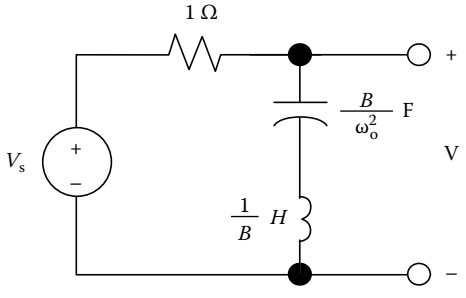

FIGURE 2.4 Resulting bandreject filter.

lpp × bp transformation (Equation 2.14). It is typical, and the reader should have no difficulty working out the other cases. Substituting $p = j\Omega$ and $s = j\omega$ in Equation 2.14, one gets

$$j\Omega = \frac{-\omega^2 + \omega_o^2}{jB\omega} \tag{2.19}$$

or

$$\Omega = \frac{\omega^2 - \omega_o^2}{B\omega} = \frac{\omega}{B} - \frac{\omega_o^2}{B\omega} \tag{2.20}$$

This clearly shows that $\omega = \pm\omega_o$ maps into $\Omega = 0$ and $\omega = \pm\infty$ into $\Omega = \pm\infty$. However, as $\omega \to 0+$, $\Omega \to -\infty$ and as $\omega \to 0-$, $\Omega \to +\infty$. Of perhaps more interest is the inverse transformation. Solving Equation 2.20 for ω in terms of Ω, one finds that*

$$\omega = \frac{B\Omega}{2} + \sqrt{\left[\frac{B\Omega}{2}\right] + \omega_o^2} \tag{2.21}$$

Now, consider pairs of values of Ω, of which one is the negative of the other. Letting ω_+ be the image of Ω with $\Omega > 0$ and ω_- be the image of $-\Omega$, one has

$$\omega_+ = \frac{B\Omega}{2} + \sqrt{\left[\frac{B\Omega}{2}\right] + \omega_o^2} \tag{2.22}$$

and

$$\omega_- = \frac{-B\Omega}{2} + \sqrt{\left[\frac{B\Omega}{2}\right] + \omega_o^2} \tag{2.23}$$

Subtracting, one obtains

$$\omega_+ - \omega_- = B\Omega \tag{2.24}$$

$$\omega_+\omega_- = \omega_o^2 \tag{2.25}$$

Thus, the geometric mean of ω_+ and ω_- is the parameter ω_o; furthermore, the lpp frequencies $\Omega = 1$ rad/s map into points whose difference is the parameter B. Recalling that $A(\Omega)$ has to be an even function of Ω, one sees that the gain magnitudes at these two points must be identical. If the lpp is designed so that $\Omega = 1$ rad/s is the "bandwidth" (single-sided), then the object bpf will have a (two-sided) bandwidth of B rad/s.

An example should clarify things. Figure 2.5 shows a set of bandpass filter gain specifications. Some slight generality has been allowed over those shown in Figure 2.2 by allowing the maximum stopband gains to be different in the two stopbands.

The graph is semilog: the vertical axis is linear with a dB scale and the horizontal axis is a log scale (base 10). The −0.1 dB minimum passband gain, by the way, is called the *passband ripple* because actual

* The negative sign on the radical gives $\omega < 0$ and the preceding treatment only considers positive ω.

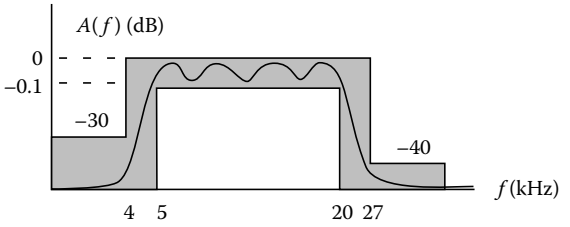

FIGURE 2.5 Bandpass filter specifications.

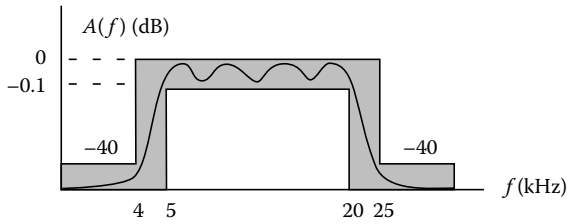

FIGURE 2.6 Bandpass filter specifications.

realized response is permitted to "ripple" back and forth between 0 and −0.1 dB. Notice that the frequency has been specified in terms of kilohertz—often a practical unit. Equation 2.20, however, can be normalized to any unit without affecting Ω. Thus, by normalizing ω to $2\pi \times 10^3$, one can substitute f in kilohertz for ω; the parameters ω_o (replaced of f_o symbolically) and B will then be in kilohertz also.

Now, notice that $5 \times 20 = 100 \neq 4 \times 27 = 108$, so the specifications are not geometrically symmetric relative to any frequency. Somewhat arbitrarily choosing $f_0 = \sqrt{5 \times 20} = 10$ kHz, one can force the specifications to have geometric symmetry by the following device: simply reduce the upper stopband cutoff frequency from 27 to 25 kHz. Then force the two stopband attenuations to be identical by decreasing the −30 dB lower stopband figure to −40 dB. This results in the modified specifications shown in Figure 2.6. If one chooses to map the upper and lower passband cutoff frequencies to $\Omega = 1$ rad/s (a quite typical choice, as many filter design catalogs are tabulated under this assumption), one then has

$$B = 20 - 5 = 15\,\text{kHz} \tag{2.26}$$

This fixes the parameters in the transformation and the lpp stopband frequency can be determined from Equation 2.20:

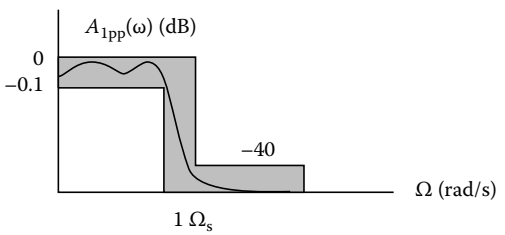

FIGURE 2.7 Bandpass filter specifications.

$$\Omega_s = \frac{25^2 - 10^2}{15 \times 25} = \frac{25}{15} - \frac{100}{375} = 1.498\,\text{rad/s} \tag{2.27}$$

The lpp specifications then assume the form shown in Figure 2.7. Once the lpp approximation problem is solved, one can then transform either the derived transfer function or the synthesized circuit back up to bandpass form since the parameters of the transformation are known.

2.2 Butterworth LPP Approximation

For performing lpp approximations, it is more convenient to work with the *characteristic function* $k(\omega)$ than with the gain function. It is defined by the equation

$$A^2(\omega) = \frac{1}{1 + K^2(\omega)} \tag{2.28}$$

Although Ω was used in Section 2.1 to denote lpp frequency, the lower case ω is used here and throughout the remainder of the section. No confusion should result because frequency will henceforth always mean lpp frequency. The main advantage in using the characteristic function is simply that it approximates zero over any frequency interval for which the gain function approximates unity. Further, it becomes infinitely large when the gain becomes zero. These ideas are illustrated in Figure 2.8. Notice that $K(\omega)$ can be either positive or negative in the passband for it is squared in the defining equation. The basic problem in lpp filter approximation is therefore to find a characteristic function that approximates zero in the passband, approximates infinity in the stopband, and makes the transition from one to the other rapidly. Ideally, it would be exactly zero in the passband, then become abruptly infinity for frequencies in the stopband.

The *n*th-order Butterworth approximation is defined by

$$K(\omega) = \omega^n \tag{2.29}$$

This characteristic function is sketched in Figure 2.9 for two values of n—one small and the other large. As is easily seen, the larger order provides a better approximation to the idea "brick wall" lpp response. Notice, however, that $K(1) = 1$ regardless of the order; hence $A(1) = 0.5$ (-3 dB) regardless of the order.

It is conventional to define the *loss function* $H(s)$ to be reciprocal of the gain function:

$$H(s) = \frac{1}{G(s)} \tag{2.30}$$

Letting $s = j\omega$ and applying Equation 2.28 results in

$$|H(j\omega)|^2 - K^2(\omega) = 1 \tag{2.31}$$

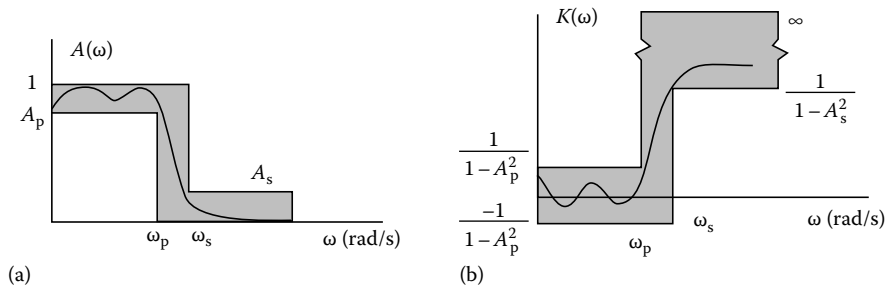

FIGURE 2.8 Filter specifications in terms of the characteristic function: (a) gain and (b) characteristic function.

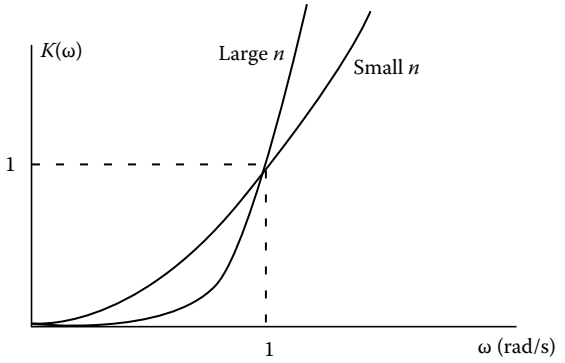

FIGURE 2.9 Butterworth characteristic function.

which is one form of *Feldtkeller's equation*, a fundamental equation in the study of filters. The loss approximates unity wherever the characteristic function approximates zero and infinity when the latter approximates infinity.

The loss function can be used to illustrate a striking property of the Butterworth approximation. Taking the kth derivative of Equation 2.31, one has

$$\frac{d^k|H(j\omega)|^2}{d\omega^k} = \frac{d^k K^2(\omega)}{d\omega^k} = \frac{d^k \omega^{2n}}{d\omega^k} = \frac{(2n)!}{k!}\omega^{2n-k} \tag{2.32}$$

This has the value zero at $\omega = 0$ for $k \leq 2n - 1$. It is the unique polynomial having this property among the set of all monic* polynomials of order $2n$ or lower having the value zero at the origin. But this means that the square of the Butterworth characteristic function $K(\omega)$ is the flattest of all such polynomials at $\omega = 0$. Since adding one to $K^2(\omega)$ produces the loss function $|H(j\omega)|^2$, the same is true of it relative to the set of all loss functions having the value unity at the origin. For this reason, the Butterworth approximation is often called the *maximally flat magnitude* (or MFM) approximation.

The passband ripple parameter A_p is always $1/\sqrt{2}$ for a Butterworth lpp; note that if a different ripple parameter is desired, one must treat the corresponding filter as a general low-pass filter, then apply Equation 3.8 of this book. The value of the parameter in that frequency transformation is determined by the requirement that the frequency at which the desired filter assumes the value $1/\sqrt{2}$ map into a lpp passband frequency of 1 rad/s. The required order is determined from the equation

$$\frac{1}{\sqrt{1+\omega_s^{2n}}} \leq A_s \tag{2.33}$$

or, rearranged,

$$n \geq \frac{\log\left[\frac{1}{A_s^2} - 1\right]}{2\log(\omega_s)} \tag{2.34}$$

The value of n is, of course, chosen to be the smallest integer greater than the expression on the right-hand side of Equation 2.34.

* A monic polynomial is one where the leading coefficient (highest power of ω) is unity.

Since only one parameter is in the Butterworth approximation, Equation 2.34 completely determines $A(\omega)$. That is, the MFM is a one-parameter approximation. The only remaining item of concern is the determination of $G(s)$, for synthesis of the actual filter requires knowledge of the transfer function. As was pointed out in Section 2.1, this is the factorization problem. In general, the solution is given by Equation 2.5, repeated here for convenience as Equation 2.35:

$$G(s)G(-s) = A^2(-s^2) \tag{2.35}$$

In the present case, we have

$$G(s)G(-s) = \frac{1}{1+(-s^2)^n} = \frac{1}{1+(-1)^n s^{2n}} \tag{2.36}$$

How does one find $G(s)$ from this equation? The solution merely lies in applying the restriction that the resulting filter is to be stable. This means that the poles of $G(s)G(-s)$ that lie in the right-half plane must be discarded and the remaining ones assigned to $G(s)$. In this connection, observe that any poles on the imaginary axis must be off even multiplicity since $G(s)G(-s)$ is an even function (or, equivalently, since $A^2(\omega^2) = |G(j\omega)|^2$ is nonnegative). Furthermore, any even-order poles of $G(s)G(-s)$ on the imaginary axis could only result from one or more poles of $G(s)$, itself, at the same location. But such a $G(s)$ represents a filter that is undesirable because, at best, it is only marginally stable. As will be shown, this situation does not occur for Butterworth filters.

The problem now is merely to find all the poles of $G(s)G(-s)$, then to sort them. These poles are located at the zeros of the denominator in Equation 2.36. Thus, one must solve

$$1 + (-s^2)^n = 0 \tag{2.37}$$

or, equivalently,

$$s^{2n} = (-1)^{n-1} \tag{2.38}$$

Representing s in polar coordinates by

$$s = \rho e^{j\phi} \tag{2.39}$$

one can write Equation 2.38 in the form

$$\rho^{2n} e^{j2n\phi} = e^{j(n-1)\pi} \tag{2.40}$$

This has the solution

$$\rho = 1 \tag{2.41}$$

and

$$\phi = \frac{\pi}{2} + (2k-1)\frac{\pi}{2n} \tag{2.42}$$

where k is any integer. Of course, only those values of ϕ between 0 and 2π rad are to be considered unique.

As an example, suppose that $n = 2$; that is, one is interested in determining the transfer function of a second-order Butterworth filter. Then the unique values of ϕ determined from Equation 2.42 are $\pi/4$, $3\pi/4$, $5\pi/4$, and $7\pi/4$. All other values are simply these four with integer multiples of 2π added. The last two represent poles in the right-half plane, so are simply discarded. The other two correspond to poles at $s = -0.707 \pm j0.707$. Letting $D(s)$ be the numerator polynomial of $G(s)$, then, one has

$$D(s) = s^2 + \sqrt{2}s + 1 \tag{2.43}$$

The poles of $G(s)G(-s)$ are sketched in Figure 2.10. Notice that if one assigns the left-half plane poles to $G(s)$, then those in the right-half plane will be those of $G(-s)$.

Perhaps another relatively simple example is in order. To this end, consider the third-order Butterworth transfer function $n = 3$. In this case, the polar angles of the poles of $G(s)$ are at $\pi/3$, $2\pi/3$, π, $4\pi/3$, $5\pi/3$, and 2π. This pole pattern is shown in Figure 2.11. The denominator polynomial corresponds to those in the left-half plane. It is

$$D(s) = (s+1)\left(s^2 + s + 1\right) = s^3 + 2s^2 + 2s + 1 \tag{2.44}$$

The pattern for the general nth order case is similar—all the poles of $G(s)G(-s)$ lie on the unit circle and are equally spaced at intervals of π/n radians, but are offset by $\pi/2$ radians relative to the positive real axis. A little thought will convince one that this means that no poles ever fall on the imaginary axis.

The factorization procedure determines the denominator polynomial in $G(s)$. But what about the numerator? Since the characteristic function is a polynomial, it is clear that $G(j\omega)$, and hence $G(s)$ itself, will have a constant numerator. For this reason, the Butterworth approximation is referred to as an *all-pole* filter. Sometimes it is also called a *polynomial* filter, referring to the fact that the characteristic function is a polynomial. As was mentioned earlier, the constant is usually allowed to float freely in the synthesis process and is determined only at the conclusion of the design process. However, more can be said. Writing

$$G(s) = \frac{a}{D(s)} \tag{2.45}$$

one can apply Equation 2.36 to show that $a^2 = 1$, provided that $|G(0)|$ is to be one, as is the case for the normalized lpp. This implies that

$$a = \pm 1 \tag{2.46}$$

If a passive unbalanced (grounded) filter is desired the positive sign must be chosen. Otherwise, one can opt for either.

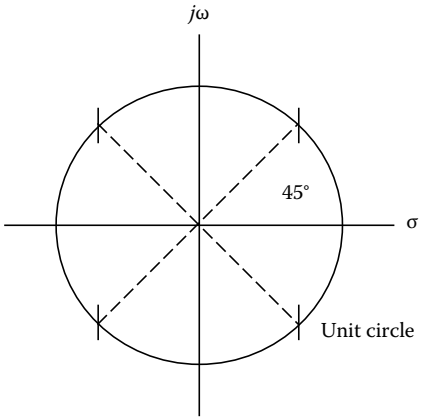

FIGURE 2.10 Poles of the second-order Butterworth transfer function.

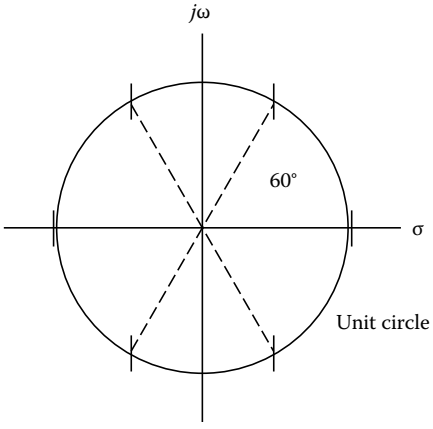

FIGURE 2.11 Poles of the third-order Butterworth transfer function.

2.3 Chebyshev LPP Approximation

The main advantage of the Butterworth approximation is that it is simple. It does not, however, draw upon the maximum approximating power of polynomials. In fact, a classical problem in mathematics is to approximate a given continuous function on a closed bounded interval with a polynomial of a specified maximum degree. One can choose to define the error of approximation in many ways, but the so-called minimax criterion seems to be the most suitable for filter design. It is the minimum value, computed over all polynomials of a specified maximum degree, of the maximum difference between the polynomial values and those of the specified function. This is illustrated in Figure 2.12. The minimax error in this case occurs at ω_x. It is the largest value of the magnitude of the difference between the function values $f(\omega)$ and those of a given candidate polynomial $p_n(\omega)$. The polynomial of best fit is the one for which this value is the smallest.

The basic lpp approximation problem is to pick the characteristic function to be that polynomial of a specified maximum degree no more than, say, n, which gives the smallest maximum error of approximation *to the constant value* 0 over the interval $0 \leq \omega \leq 1$ (arbitrarily assuming that the passband cutoff is to be 1 rad/s). In this special case, the solution is known in closed form: it is the Chebyshev* polynomial of degree n. Then, $K(\omega)$ is polynomial $\varepsilon T_n(\omega)$, where

$$T_n(\omega) = \cos\left[n \cos^{-1}(\omega)\right] \tag{2.47}$$

and ε is the minimax error (a constant).

It is perhaps not clear that $T_n(\omega)$ is actually a polynomial; however, upon computing the first few by applying simple trigonometric identities one has the results shown in Table 2.1. In fact, again by calling upon simple trigonometric identities, one can derive the general recurrence relation

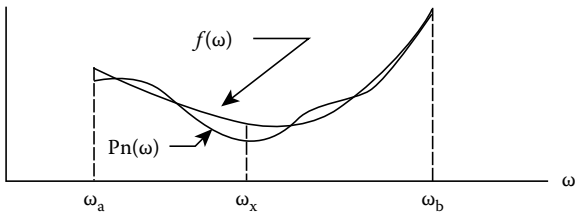

FIGURE 2.12 Minimax error criterion.

TABLE 2.1 Chebyshev Polynomial of Degree n

n	$T_n(\omega)$
0	1
1	ω
2	$2\omega^2 - 1$
3	$4\omega^3 - 3\omega$
4	$8\omega^4 - 8\omega^2 + 1$

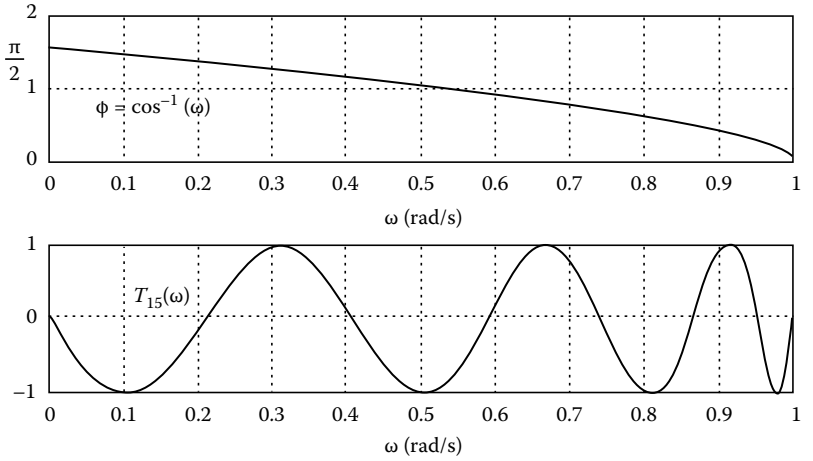

FIGURE 2.13 Behavior of the Chebyshev polynomials.

$$T_n(\omega) = 2\omega T_{n-1}(\omega) - T_{n-2}(\omega); \quad n \geq 2 \tag{2.48}$$

The Chebyshev polynomials have an enormous number of interesting properties and to explore them all would require a complete monograph. Among those of the most interest for filtering applications, however, are these. First, from the recursion relationship (Equation 2.48) one can see that $T_n(\omega)$ is indeed a polynomial of order n; furthermore, its leading coefficient is 2^{n-1}. If n is even, $T_n(\omega)$ is an even polynomial in ω and if n is odd, $T_n(\omega)$ is an odd polynomial. The basic definition in Equation 2.47 clearly shows that the extreme values of $T_n(\omega)$ over the interval $0 \leq \omega \leq 1$ are ± 1. Some insight into the behavior of the Chebyshev polynomials can be obtained by making the transformation $\phi = \cos^{-1}(\omega)$. Then, $T_n(\phi) = \cos(n\phi)$, a trigonometric function that is quite well known. The behavior of T_{15}, for example, is shown in Figure 2.13. The basic idea is this: the Chebyshev polynomial of nth order is merely a cosine of "frequency" $n/4$, which "starts" at $\omega = 1$ and "runs backward" to $\omega = 0$. Thus, it is always 1 at $\omega = 1$ and as ω goes from 1 rad/s to 0 rad/s backward, it goes through n quarter-periods (or $n/4$ full periods). Thus, at $\omega = 0$ the value of this polynomial will be either 0 or ± 1, depending upon the specific value of n. If n is even, an integral number of half-periods will have been described and the resulting value will be ± 1; if n is odd, an integral number of half-periods plus a quarter-period will have been described and the value will be zero.

Based on the foregoing theory, one sees that the best approximation to the ideal lpp characteristic over the passband is, for a given passband tolerance, ε, given by

$$A^2(\omega) = \frac{1}{1 + \varepsilon^2 T_n^2(\omega)} \tag{2.49}$$

It is, of course, known as the Chebyshev approximation and the resulting filter as the Chebyshev lpp of order n. The gain magnitude $A(\omega)$ is plotted for $n = 5$ and $\varepsilon = 0.1$ in Figure 2.14. The passband behavior looks like ripples in a container of water, and since the crests are equally spaced above and below the average value, it is called equiripple behavior. In the passband, the maximum value is 1 and the minimum value is

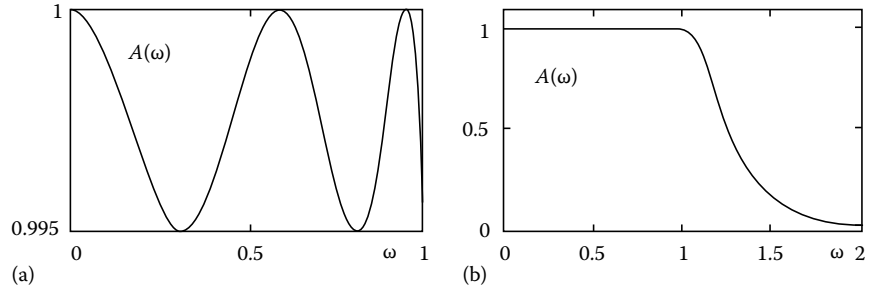

FIGURE 2.14 Frequency response of a fifth-order Chebyshev lpp: (a) passband and (b) overall.

$$A_{\min} = \frac{1}{\sqrt{1+\varepsilon^2}} \tag{2.50}$$

The passband ripple is usually specified as the peak to peak variation in dB. Since the maximum value is one, that is 0 dB, this quantity is related to the *ripple parameter* ε through the equation

$$\text{passband ripple in dB} = 20\log\sqrt{1+\varepsilon^2} \tag{2.51}$$

The Chebyshev approximation is the best possible among the class of all-pole filters—*over the passband*. But what about its stopband behavior? As was pointed out previously, it is desirable that—in addition to approximating zero in the passband—the characteristic function should go to infinity as rapidly as possible in the stopband. Now it is a happy coincidence that the Chebyshev polynomial goes to infinity for $\omega > 1$ faster than any other polynomial of the same order. Thus, the Chebyshev approximation is the best possible among the class of polynomial, or all-pole, filters.

The basic definition of the Chebyshev polynomial works fine for values of ω in the passband, where $\omega \leq 1$. For larger values of ω, however, $\cos^{-1}(\omega)$ is a complex number. Fortunately, there is an alternate form that avoids complex arithmetic. To derive this form, simply recognize the complex nature of $\cos^{-1}(\omega)$ explicitly and write

$$x = \cos^{-1}(\omega) \tag{2.52}$$

One then has*

$$\omega = \cos(x) = \cos[\,j(jx)] = \cosh(jx) \tag{2.53}$$

so

$$jx = \cosh^{-1}(\omega) \tag{2.54}$$

Thus, one can also write

$$T_n(\omega) = \cos[jn(jx)] = \cosh[n(jx)] = \cosh[n\cosh^{-1}(\omega)] \tag{2.55}$$

* Since $\cos(x) = \cosh(jx)$.

This result is used to compute the required filter order. Assuming as usual that A_s is the maximum allowed stopband gain, one uses the square root of Equation 2.49 to get

$$A(\omega_s) = \frac{1}{\sqrt{1 + \varepsilon^2 T_n^2(\omega_s)}} \leq A_s \tag{2.56}$$

Solving, one has

$$T_n(\omega_s) \geq \frac{1}{\varepsilon}\sqrt{\frac{1}{A_s^2} - 1} \tag{2.57}$$

Since $\omega_s \geq 1$, it is most convenient to use the hyperbolic form in Equation 2.55:

$$n \geq \frac{\cosh^{-1}\left[\frac{1}{\varepsilon}\sqrt{\frac{1}{A_s^2} - 1}\right]}{\cosh^{-1}(\omega_s)} \tag{2.58}$$

To summarize, one first determines the parameter ε from the allowed passband ripple, usually using Equation 2.51; then one determines the minimum order required using Equation 2.58. The original filter specifications must, of course, be mapped into the lpp domain through appropriate choice(s) of the constant(s) in the transformation Equations 2.12 through 2.15. Notice that the definition of passband for the Chebyshev filter differs from that of the Butterworth unless the passband ripple is 3 dB. For the Chebyshev characteristic, the passband cutoff frequency is that frequency at which the gain goes through the value $1/\sqrt{1+\varepsilon^2}$ for the last time as ω increases.

The only remaining item is the determination of the transfer function $G(s)$ by factorization. Again, this requires the computation of the poles of $G(s)G(-s)$. Using Equation 2.49, one has

$$G(s)G(-s) = \left[A^2(\omega)\right]_{s=j\omega} = \frac{1}{1 + \varepsilon^2\left[T_n^2(\omega)\right]_{s=j\omega}} \tag{2.59}$$

Thus, the poles are at those values of s for which

$$\left[T_n^2(\omega)\right]_{s=j\omega} = \frac{-1}{\varepsilon^2} \tag{2.60}$$

or*

$$\cos\left[n\ \cos^{-1}\left(\frac{s}{j}\right)\right] = \pm j\frac{1}{\varepsilon} \tag{2.61}$$

Letting

$$\cos^{-1}(s/j) = a + jb, \text{ there results} \tag{2.62}$$

$$\cos(na)\cosh(nb) - j\sin(na)\sinh(nb) = \pm j\frac{1}{\varepsilon} \tag{2.63}$$

* Since s is complex anyway, nothing is to be gained from using the hyperbolic form.

Equating real and imaginary parts, one has

$$\cos(na)\cos(nb) = 0 \tag{2.64a}$$

and

$$\sin(na)\sinh(nb) = \pm\frac{1}{\varepsilon} \tag{2.64b}$$

Since $\cosh(nb) > 0$ for any b, one must have

$$\cos(na) = 0 \tag{2.65}$$

which can hold only if

$$a = (2k+1)\frac{\pi}{2n} \quad k \text{ any integer} \tag{2.66}$$

But, in this case, $\sin[(2k+1)\pi/2] = \pm 1$, so application of Equation 2.64b gives

$$\sinh(nb) = \pm\frac{1}{\varepsilon} \tag{2.67}$$

One can now solve for b:

$$b = \pm\frac{1}{n}\sinh^{-1}\left[\frac{1}{\varepsilon}\right] \tag{2.68}$$

Equations 2.66 through 2.68 together determine a and b, hence $\cos^{-1}(s/j)$. Taking the cosine of both sides of Equation 2.62 and using Equations 2.65 and 2.68 gives

$$\begin{aligned} s = &\pm\sin\left[(2k+1)\frac{\pi}{2n}\right]\sinh\left[\frac{1}{n}\sinh^{-1}\left(\frac{1}{\varepsilon}\right)\right] \\ &+ j\cos\left[(2k+1)\frac{\pi}{2n}\right]\cosh\left[\frac{1}{n}\sinh^{-1}\left(\frac{1}{\varepsilon}\right)\right] \end{aligned} \tag{2.69}$$

Letting $s = \sigma + j\omega$ as usual, one can rearrange Equation 2.69 into the form

$$\left[\frac{\sigma}{\sinh\left[\frac{1}{n}\sinh^{-1}\left(\frac{1}{\varepsilon}\right)\right]}\right]^2 + \left[\frac{\omega}{\cosh\left[\frac{1}{n}\sinh^{-1}\left(\frac{1}{\varepsilon}\right)\right]}\right]^2 = 1 \tag{2.70}$$

which is the equation of an ellipse in the s plane with real axis intercepts of

$$\sigma_o = \pm\sinh\left[\frac{1}{n}\sinh^{-1}\left(\frac{1}{\varepsilon}\right)\right] \tag{2.71}$$

and imaginary axis intercepts of

$$\omega_o = \pm\cosh\left[\frac{1}{n}\sinh^{-1}\left(\frac{1}{\varepsilon}\right)\right] \tag{2.72}$$

This is shown in Figure 2.15.

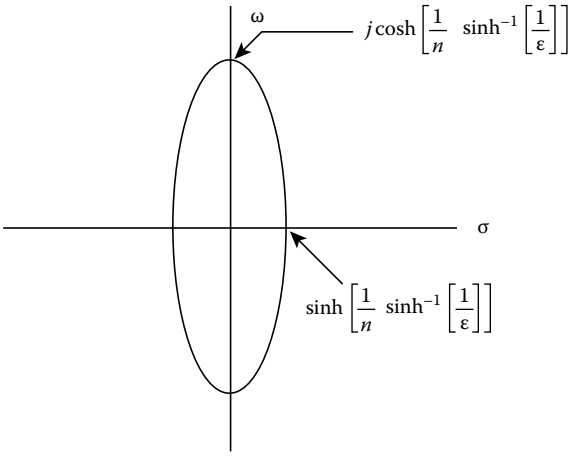

FIGURE 2.15 Pole locations for $G(s)G(-s)$ for the Chebyshev filter.

As an example, suppose that a Chebyshev lpp is to be designed that has a passband ripple of 0.1 dB, a maximum stopband gain of −20 dB, and $\omega_s = 2$ rad/s. Then, one can use Equation 2.51 to find* the ripple parameter ε:

$$\varepsilon = \sqrt{10^{0.1/10} - 1} = 0.1526 \tag{2.73}$$

Equation 2.58 gives the minimum order required:

$$n \geq \frac{\cosh^{-1}\left[\frac{1}{0.1526}\sqrt{\frac{1}{(0.1)^2} - 1}\right]}{\cosh^{-1}(2)} = \frac{\cosh^{-1}(65.20)}{\cosh^{-1}(2)} = 3.70 \tag{2.74}$$

In doing this computation by hand, one often uses the identity

$$\cosh^{-1}(x) = \ln\left[x + \sqrt{x^2 - 1}\right] \tag{2.75}$$

which can be closely approximated by

$$\cosh^{-1}(x) = \ln(2x) \tag{2.76}$$

if $x \gg 1$. In the present case, a fourth-order filter is required. The poles are shown in Table 2.2 and graphed in Figure 2.16.

By selecting the left-half plane poles and forming the corresponding factors, then multiplying them, one finds the denominator polynomial of $G(s)$ to be

$$D(s) = s^4 + 1.8040s^3 + 2.2670s^2 + 2.0257s + 0.8286 \tag{2.77}$$

* For practical designs, a great deal of precision is required for higher-order filters.

TABLE 2.2 Pole Locations

k	Real Part	Imaginary Part
0	0.2642	1.1226
1	0.6378	0.4650
2	0.6378	−0.4650
3	0.2642	−1.1266
4	−0.2642	−1.1266
5	−0.6378	−0.4650
6	−0.6378	0.4650
7	−0.2642	1.1226

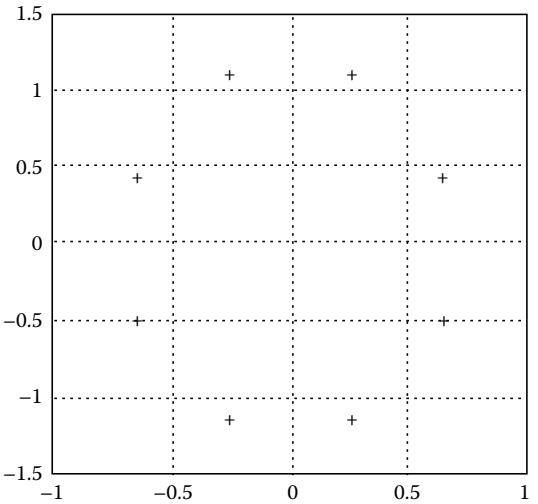

FIGURE 2.16 Pole locations for example filter.

As for the Butterworth example of Section 2.2, one finds the scale factor:

$$k = 0.8286 \tag{2.78}$$

Therefore, the complete transfer function is

$$G(s) = \frac{k}{D(s)} = \frac{0.8286}{s^4 + 1.8040s^3 + 2.2670s^2 + 2.0257s + 0.8286} \tag{2.79}$$

Of course, if completely automated algorithms are not being used to design such a filter as the one in our example, numerical assistance is required. The computation in the preceding example was performed in MATLAB®—a convenient package for many computational problems in filter design.

2.4 Bessel–Thompson LPP Approximation

Thus far, two all-pole approximations have been presented. As was pointed out in Section 2.3, the Chebyshev is better than the Butterworth—in fact, it is the best all-pole approximation available. So why bother with the Butterworth at all, other than as an item of historical interest? The answer lies in the phase. The Chebyshev filter has a phase characteristic that departs farther from linearity than that of the

Butterworth; put differently, its group delay deviates from a constant by a greater amount. Thus, the Butterworth approximation is still a viable approximation in applications where phase linearity is of some importance.

The question naturally arises as to whether there is an lpp approximation that has better phase characteristics than that of the Butterworth. The answer is yes, and that is the topic of this section, which will follow [8]—perhaps the simplest development of all.

Recall that the gain function $G(s)$ is the inversion of the loss function $H(s)$:

$$G(s) = \frac{1}{H(s)} \tag{2.80}$$

Also, recall that it was the loss function $|h(j\omega)| = 1/A(\omega)$ (or, rather, its square $|h(j\omega)|^2$) that was required to have MFM property at $\omega = 0$,

$$\left[\frac{\mathrm{d}^k |H(j\omega)|^2}{\mathrm{d}\omega^k}\right]_{\omega=0} = \left[\frac{\mathrm{d}^k \omega^{2n}}{\mathrm{d}\omega^k}\right]_{\omega=0} = \left[\frac{(2n)!}{k!}\omega^{2n-k}\right]_{\omega=0} = 0 \tag{2.81}$$

for $k = 0, 1, \ldots, 2n-1$. The question to be asked and answered in this section is whether there exists a similar approximation for the group delay $\tau_g(\omega)$ a maximally flat delay (MFD) approximation.

To answer this question, the phase will be written in terms of the loss function $H(j\omega)$. Since the latter quantity can be written in polar form as

$$H(j\omega) = \frac{1}{G(j\omega)} = \frac{1}{A(\omega)e^{j\phi(\omega)}} = \frac{1}{A(\omega)}e^{-j\phi(\omega)} \tag{2.82}$$

the (complex) logarithm is

$$\ln H(j\omega) = -\ln A(\omega) - j\phi(\omega) \tag{2.83}$$

Thus,

$$\phi(\omega) = -\mathrm{Im}\{\ln H(j\omega)\} \tag{2.84}$$

The group delay is merely the negative of the derivative of the phase, so one has

$$\begin{aligned}\tau_g(\omega) &= -\frac{\mathrm{d}\phi}{\mathrm{d}\omega} = \frac{\mathrm{d}}{\mathrm{d}\omega}\mathrm{Im}\{\ln H(j\omega)\} = \mathrm{Im}\left\{\frac{\mathrm{d}}{\mathrm{d}\omega}\ln H(j\omega)\right\} \\ &= \mathrm{Im}\left\{j\frac{\mathrm{d}}{\mathrm{d}(j\omega)}\ln H(j\omega)\right\} = \mathrm{Re}\left\{\frac{\mathrm{d}}{\mathrm{d}(j\omega)}\ln H(j\omega)\right\}\end{aligned} \tag{2.85}$$

Recalling that the even part of a complex function $F(s)$ is given by

$$\mathrm{Ev}\{F(s)\} = \frac{F(s) + F(-s)}{2} \tag{2.86}$$

one can use the symmetry property for real $F(s)$ (in the present context, $F(s)$ is assumed to be a rational function, so a real $F(s)$ is one with real coefficients) to show that

$$\mathrm{Ev}\{F(s)\}_{s=j\omega} = \frac{F(j\omega) + F(-j\omega)}{2} = \frac{F(j\omega) + F^{*}(j\omega)}{2} = \mathrm{Re}\{F(j\omega)\} \tag{2.87}$$

In this manner, one can analytically extend the group delay function $\tau_g(j\omega)$ so that it becomes a function of s:

$$\tau_g(s) = \mathrm{Ev}\left\{\frac{\mathrm{d}}{\mathrm{d}s}\ln H(s)\right\} = \mathrm{Ev}\left[\frac{H'(s)}{H(s)}\right] = \frac{1}{2}\left[\frac{H'(s)}{H(s)} + \frac{H'(-s)}{H(-s)}\right] \tag{2.88}$$

In the present case, it will be assumed that $H(s)$ is a polynomial. In this manner, an all-pole (or polynomial) filter will result. Thus, one can write

$$H(s) = \sum_{k=0}^{n} a_k^n s^k \tag{2.89}$$

The superscript on the (assumed real) coefficient matches the upper limit on the sum and is the assumed filter order. The group delay function is, thus, a real rational function:

$$\tau_g(s) = \frac{N(s)}{D(s)} \tag{2.90}$$

where $N(s)$, the numerator polynomial, and $D(s)$, the denominator polynomial, have real coefficients and are of degrees no greater than $2n-1$ and $2n$, respectively, by inspection of Equation 2.88. But, again according to Equation 2.88, $\tau_g(s)$ is an even function. Thus,

$$\tau_g(-s) = \frac{N(-s)}{D(-s)} = \tau_g(s) = \frac{N(s)}{D(s)} \tag{2.91}$$

The last equation, however, implies that

$$\frac{N(-s)}{N(s)} = \frac{D(-s)}{D(s)} = 1 \tag{2.92}$$

The last equality is arrived at by the following reasoning. $N(s)$ and $D(s)$ are assumed to have no common factors—any such have already been cancelled in the formation of $\tau_g(s)$. Thus, the two functions of s in Equation 2.92 are independent; since they must be equal for s, they must therefore equal a constant. But this constant is unity, as is easily shown by allowing s to become infinite and noting that the degrees and leading coefficients of $N(-s)$ and $N(s)$ are the same.

The implication of the preceding development is simply that $N(s)$ and $D(s)$ consist of only even powers of s. Looking at $N(s)$, for example, and letting it be written

$$N(s) = \sum_{k=0}^{2n-1} \rho_k s^k \tag{2.93}$$

one has

$$N(-s) = \sum_{k=0}^{2n-1} \rho_k (-s)^k = N(s) = \sum_{k=0}^{m} \rho_k (s)^k \tag{2.94}$$

This however implies that the ρ_k are zero for odd k. Hence $N(s)$ consists of only even powers of s. The same is true of $D(s)$ and therefore of $\tau_g(s)$. Clearly, therefore $\tau_g(\omega)$ will consist of only even powers of ω, that is, it will be a function of ω^2. Now there is to be an MFD approximation one must have by analogy with the MFM approximation in Section 2.2,

$$\frac{d^k \tau_g(\omega)}{d(\omega^2)^k} = 0 \tag{2.95}$$

for $k = 1, 2, \ldots, n-1$. The constraint is, of course, that τ_g must come from a polynomial loss function $H(s)$ whose zeros [poles of $G(s)$] all lie in the left-half plane.

It is convenient to normalize time so that the group delay T, say, at $\omega = 0$ is 1 s; this is equivalent to scaling the frequency variable ω to be ωT. Here, it will be assumed that this has been performed already. A slight difference exists between the MFD and MFM approximations; the latter approximates zero at $\omega = 0$, while the former approximates $T = 1s$ at $\omega = 0$. The two become the same, however, if one considers the function

$$\tau_g(s) - 1 = \frac{P(s)}{2H(s)H(-s)} \tag{2.96}$$

where $P(s)$ has a maximum order of $2n$. The form on the right-hand side of this expression can be readily verified by consideration of Equation 2.88, the basic result for the following derivation. Furthermore, writing $P(s)$ in the form

$$P(s) = \sum_{k=0}^{n} P_k \left(s^2\right)^k \tag{2.97}$$

it is readily seen that

$$p_o = p_1 = \cdots = p_{n-1} = 0 \tag{2.98}$$

The lowest-order coefficient is clearly zero because $\tau_g(0) = 1$; furthermore, all odd coefficients are zero since τ_g is even. Finally, all other coefficients in Equation 2.98 have to be zero if one imposes the MFD condition in Equation 2.95.*

At this stage, one can write the group delay function in the form

$$\tau_g(s) = \frac{N(s)}{D(s)} = 1 + \frac{p_n s^{2n}}{2H(s)H(-s)} = \frac{2H(s)H(-s) + p_n s^{2n}}{2H(s)H(-s)} \tag{2.99}$$

It was pointed out immediately after Equation 2.90, however, that the degree of $N(s)$ is at most $2n-1$. Hence, the coefficient of s^{2n} in the numerator of Equation 2.99 have vanished, and one therefore also has

$$2(-1)^n a_n + p_n = 0 \tag{2.100}$$

or, equivalently,

$$p_n = 2(-1)^{n+1} a_n \tag{2.101}$$

* The derivatives are easy to compute, but this is omitted here for reasons of space.

Finally, this allows one to write Equation 2.99 in the form

$$\tau_g(s) = \frac{H(s)H(-s) + (-1)^{n+1}a_n s^{2n}}{H(s)H(-s)} \tag{2.102}$$

If one now equates Equations 2.102 and 2.88 and simplifies, there results

$$H'(s)H(-s) + H'(-s)H(s) - 2H(s)H(-s) = 2(-1)^{n+1}a_n s^{2n} \tag{2.103}$$

Multiplying both sides by s^{-2n}, taking the derivative (noting that $(\mathrm{d}/\mathrm{d}s)H(-s) = -H'(-s)$), one obtains (after a bit of algebra)

$$\mathrm{Ev}\{[sH''(s) - 2(s+n)H'(s) + 2nH(s)]H(-s)\} = 0 \tag{2.104}$$

Now, if s_o is a zero of this even function, the $-s_o$ will also be a zero. Further, since all of the coefficients in $H(s)$ are real, s_0^* and $-s_0^*$ must also be zeros as well; that is, the zeros must occur in a *quadrantally symmetric* manner. Each zero must belong either to $H(-s)$, or to the factor it multiplies, or to both. The degree of the entire expression in Equation 2.40 is $2n$ and $H(-s)$ has n zeros. Thus, the expression in square brackets must have n zeros. Now here is the crucial step in the logic: if the filter being designed is to be stable, then all n zeros $H(-s)$ must be in the (open) right-half plane. This implies that the factor in square brackets must have n zeros in the (open) left-half plane. Since the expression has degree n, these zeros can be found from the equation

$$sH''(s) - 2(s+n)H'(s) + 2nH(s) = 0 \tag{2.105}$$

This differential equation can be transformed into that of Bessel; here, however, the solution will be derived directly by recursion. Using Equation 2.89 for $H(s)$, computing its derivatives, reindexing, and using Equation 2.105, one obtains, for $0 \le k \le n-1$,

$$(k+1)ka_{k+1}^n - 2n(k+1)a_{k+1}^n - 2ka_k^n + 2na_k^n = 0 \tag{2.106}$$

This produces the recursion formula

$$a_{k+1}^n = \frac{2(n-k)}{(2n-k)(k+1)}a_k^n; \quad 0 \le k \le n-1 \tag{2.107}$$

or, normalizing the one free constant so that $a_n^n = 1$ and reindexing, gives

$$a_{k+1}^n = \frac{2(n-k)}{(2n-k)(k+1)}; \quad 0 \le k \le n-1 \tag{2.108}$$

The resulting polynomials for $H(s)$ are closely allied with the Bessel polynomials. The first several are given in Table 2.3 and the corresponding gain and group delay characteristics are plotted (using MATLAB) in Figure 2.17. Notice that the higher the order, the more accurately the group delay approximates a constant and the better the gain approximates the ideal lpp; the latter behavior, however, is fairly poor. A view of the group delay behavior in the passband is shown for the third-order filter in Figure 2.18.

TABLE 2.3 Bessel Polynomials of Order n

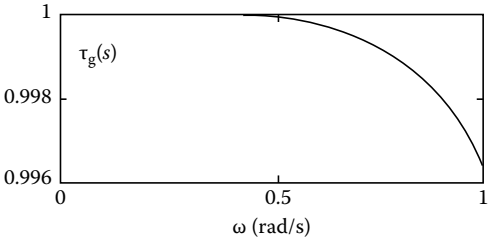

FIGURE 2.18 Group delay of third-order Bessel filter.

2.5 Elliptic Approximation

The Butterworth approximation provides a very fine approximation to the ideal "brick wall" lpp response at $\omega = 0$, but is poor for other frequencies; the Chebyshev, on the other hand, spreads out the error of approximation throughout the passband and thereby achieves a much better amplitude approximation. This is one concrete application of a general result in approximation theory known as the Weierstrass theorem [2], which asserts the possibility of uniformly approximating a continuous function on a compact set by a polynomial or by a rational function.

A compact set is the generalization of a closed and bounded interval—the setting for the Chebyshev approximation sketched in Figure 2.19. The compact set is the closed interval $[-1, 1]$,* the continuous

* Here, we are explicitly observing that the characteristic function to be approximated is even in ω.

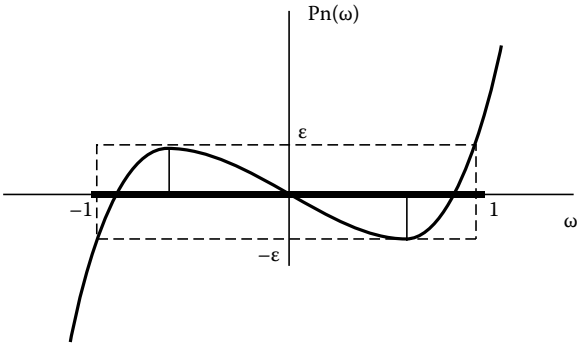

FIGURE 2.19 Chebyshev approximation.

function to be approximated is the constant 0, and the approximating function is a polynomial of degree n (in the figure n is three). A careful inspection of this figure reveals that the maximum error of approximation occurs exactly four times on a set of four discrete points within the interval and the *sign* of this maximum error alternates from one such point to its adjacent neighbor. This is no coincidence; in fact, the polynomial of best approximation of degree n is characterized by this alternation or *equiripple* property: the error function achieves its maximum value exactly $n+1$ times on the interval of approximation and the signs at these points alternate. If one finds a polynomial by any means that has this property it is the unique polynomial of best approximation.

In the present case, one simply notes that the cosine function has the required equiripple behavior. That is, as ϕ varies between $-\pi/2$ and $\pi/2$, $\cos(n\phi)$ varies between its maximum and minimum values of ± 1 a total of $n+1$ times. But $\cos(n\phi)$ is not a polynomial, and the problem (for reasons stated in the introduction) is to determine a *polynomial* having this property. At this point, one observes that if one makes the transformation

$$\phi = \cos^{-1}(\omega) \tag{2.109}$$

then, as ω varies from -1 to $+1$, ϕ varies from $-\pi/2$ to $+\pi/2$. This transformation is, fortunately, one-to-one over this range; furthermore, even more fortunately, the overall function

$$T_n(\omega) = \cos[n\cos^{-1}(\omega)] \tag{2.110}$$

is a polynomial as desired. Of course, the maximum error is ± 1, an impractically large value. This is easily rectified by requiring that the approximating polynomial be

$$p_n(\omega) = \varepsilon T_n(\omega) = \varepsilon\cos[n\cos^{-1}(\omega)] \tag{2.111}$$

In terms of gain and characteristic functions, therefore, one has

$$G(\omega) = \frac{1}{1+K^2(\omega)} = \frac{1}{1+\varepsilon^2 T_n^2(\omega)} \tag{2.112}$$

That is, $p_n(\omega) = \varepsilon T_n(\omega)$ is the best approximation to the characteristic function $K(\omega)$.

Since the gain function to be approximated is even in ω, $K(\omega)$—and, therefore, $p_n(\omega) = \varepsilon T_n(\omega)$—must be either even or odd. As one can recall, the Chebyshev polynomials have this property. For this reason, it is only necessary to discuss the situation for $\omega \geq 0$ for the extension to negative ω is then obvious.

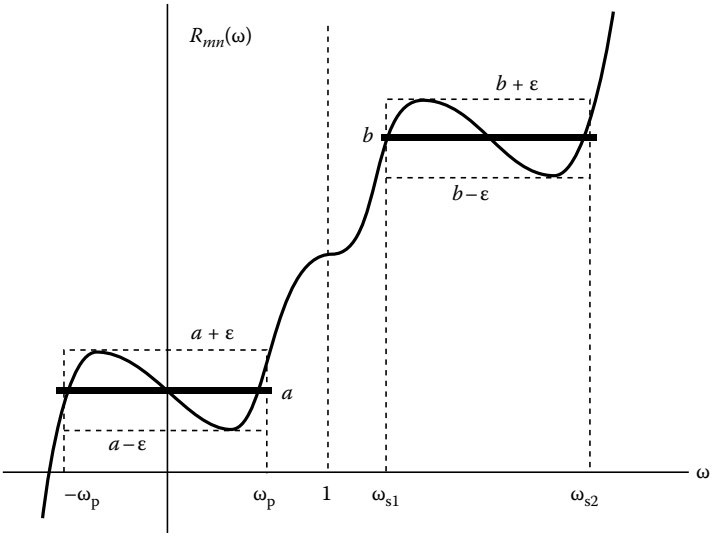

FIGURE 2.20 Chebyshev rational approximation.

The foregoing sets the stage for the more general problem, which will now be addressed. As noted previously, the Weierstrass theorem holds for more general compact sets. Thus, as a preliminary exercise, the approximation problem sketched in Figure 2.20 will be discussed. That figure shows two closed intervals as the compact set on which the approximation is to occur. The function to be approximated is assumed to be the constant a on the first interval and the constant b on the second.* In order to cast this into the filtering context, it will be assumed that the constant a is small and the constant b large. The sharpness of the transition characteristic can then be set to any desired degree by allowing ω_p to approach unity from below and ω_s^1 to approach unity from above. Notice that the frequency scaling will be different here than for the all-pole case in which the right-hand interval endpoint was allowed to be unity.

In addition to more general compact sets, the Weierstrass theorem allows the approximating function to be a general real rational function, which has been denoted by $R_{mn}(\omega)$ in the figure. This notation means that the numerator and denominator polynomials have maximum degree m and n, respectively. Now suppose that one specifies that $b = 1/a$ and suppose $R_{mn}(\omega)$ is a reciprocal function, that is, one having the property that

$$R_{mn}\left(\frac{1}{\omega}\right) = \frac{1}{R_{mn}(\omega)} \tag{2.113}$$

Then, if one determines its coefficients such that the equiripple property holds on the interval $-\omega_p \leq \omega \leq \omega_p$, it will also hold on the interval $\omega_{s1} \leq \omega \leq \omega_{s2}$. Of course, this interval is constrained such that $\omega_{s1} = 1/\omega_p$. The other interval endpoint will then extend to $+\infty$ (and, by symmetry, there will also be an interval on the negative frequency axis with one endpoint at $-1/\omega_p$ and the other at $-\infty$). This is, of course, not a compact set but the approximation theorem continues to hold anyway because it is equivalent to approximating $a = 1/b$ on the low-pass interval $[-\omega_p, \omega_p)$. Thus, one can let $a = 0$ and $b = \infty$ and simultaneously approximate the ideal characteristic function

* One should note that this function is continuous on the compact set composed of the two closed intervals.

$$K(\omega) = \begin{cases} 0; & |\omega| \le \omega_p \\ \infty; & |\omega| \ge \frac{1}{\omega_p} \end{cases} \tag{2.114}$$

with the real and even or odd (for realizability) rational function $R_{mn}(\omega)$ having the aforementioned reciprocal property. The Weierstrass theorem equiripple property for such rational functions demands that the total number of error extrema* on the compact set be $m+n+2$. (This assumes the degree of both polynomials to be relative to the variable ω^2.)

Based on the preceding discussion, one has the following form for $R_{mn}(\omega)$:

$$R_{2n,2n}(\omega) \equiv R_{2n}(\omega) = \frac{(\omega_1^2 - \omega^2)(\omega_3^2 - \omega^2)\cdots(\omega_{2n-1}^2 - \omega^2)}{(1 - \omega_1^2\omega^2)(1 - \omega_2^2\omega^2)\cdots(1 - \omega_{2n-1}^2\omega^2)} \tag{2.115}$$

$$R_{2n+1,2n}(\omega) \equiv R_{2n+1}(\omega) = \omega\frac{(\omega_2^2 - \omega^2)(\omega_4^2 - \omega^2)\cdots(\omega_{2n}^2 - \omega^2)}{(1 - \omega_2^2\omega^2)(1 - \omega_4^2\omega^2)\cdots(1 - \omega_{2n}^2\omega^2)} \tag{2.116}$$

The first is clearly an even rational function and latter odd. The problem now is to find the location of the pole and zero factors such that equiripple behavior is achieved in the passband. The even case is illustrated in Figure 2.21 for $n=2$. Notice that the upper limit of the passband frequency interval has been taken for convenience to be equal to $\sqrt{k}$; hence, the lower limit of the stopband frequency interval is $1/\sqrt{k}$. Thus,

$$k = \frac{\omega_p}{\omega_s} \tag{2.117}$$

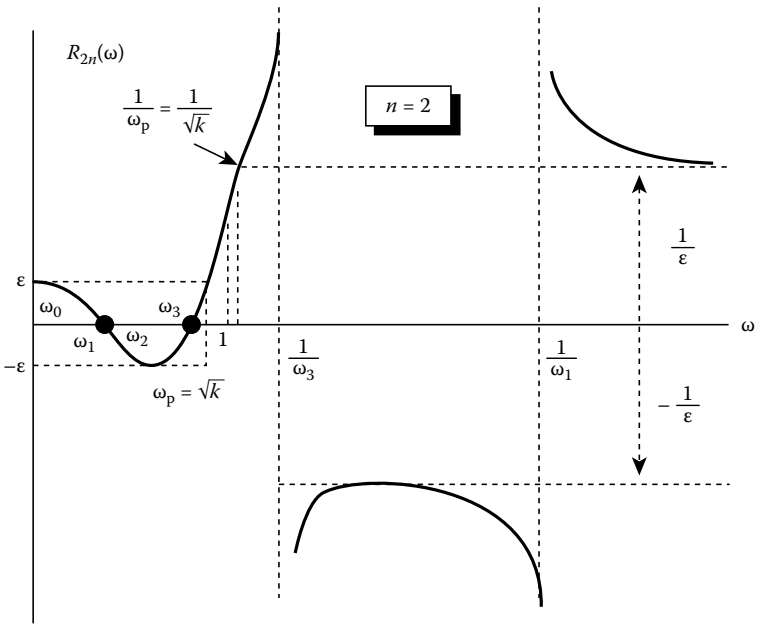

FIGURE 2.21 Typical plot of an even-order Chebyshev rational function.

* There can be degeneracy in the general approximation problem, but the constraints of the problem being discussed here preclude this from occurring.

is a measure of the sharpness of the transition band rolloff and is always less than unity. The closer it is to one, the sharper the rolloff. It is an arbitrarily specified parameter in the design. Notice that equiripple behavior in the passband implies equiripple behavior in the stopband—in the latter, the approximation is to the constant whose value is infinity and the minimum value (which corresponds to a maximum value of gain) is $1/\varepsilon$, while the maximum deviation from zero in the passband is ε. The zeros are all in the passband and are mirrored in poles, or infinite values, in the stopband. The notation ω_0 and ω_2 for the passband frequencies of maximum error has been introduced. In general, their indices will be even for even approximations and odd for odd approximations.

A sketch for the odd case would differ only in that the plot would go through the origin, that is, the origin would be a zero rather than a point of maximum error. Notice that the resulting filter will have finite gain unlike the Butterworth or Chebyshev, which continue to rolloff toward zero as ω becomes infinitely large. As noted in the figure, the approximating functions are called the *Chebyshev rational functions*.

The procedure [9] now is quite analogous to the Chebyshev polynomial approximation, though rather more complicated. One looks for a continuous periodic waveform that possess the desired equiripple behavior. Since the Jacobian elliptic functions are generalizations of the more ordinary sinusoids, it is only natural that they be investigated with an eye toward solving the problem under attack. With that in mind, some of the more salient properties will now be reviewed.

Consider the function

$$I(\phi, k) = -\frac{1}{\sqrt{1 - k^2 \sin^2(\phi)}} \tag{2.118}$$

which is plotted for two values of k in Figure 2.22. If $k = \pm 1$, the peak value is infinite; in this case, $I(\phi, k) = \sec(\phi)$. For smaller values of k the peak value depends upon k with smaller values of k resulting lower peak values. The peaks occur at odd multiples of $\pi/2$. Note that $I(\phi, k)$ has the constant value one for $k = 0$. Figure 2.23 shows the running integral of $I(\phi, k)$ for $k^2 = 0.99$ and for $k^2 = 0$. For $k^2 = 0$ the curve is a straight line (shown dashed); or other values of k^2, it deviates from a straight line by an amount that depends upon the size of k^2. Observe that the running integral has been plotted over one full period of $I(k, \phi)$, that is, from 0 to π. The running integral is given in analytical form by

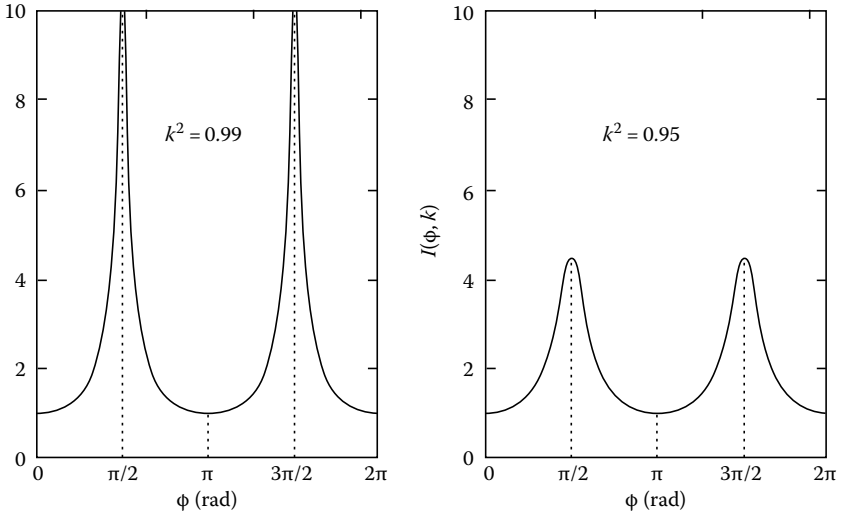

FIGURE 2.22 Plot of $I(\phi, k)$.

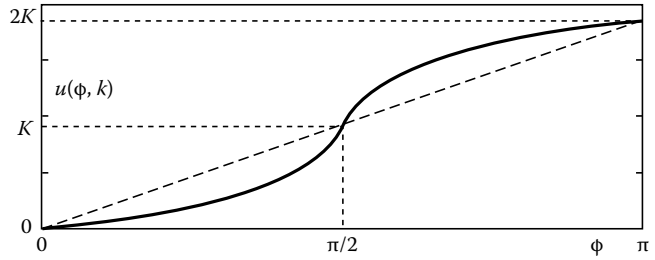

FIGURE 2.23 Running integral of I normalized to K.

$$u(\phi, k) = \int_0^{\phi} I(\alpha, k)\mathrm{d}\alpha = \int_0^{\phi} \frac{1}{\sqrt{1 - k^2 \sin^2(\alpha)}}\mathrm{d}\alpha \tag{2.119}$$

The quantity K, shown by the lowest dashed horizontal line in Figure 2.23, is the integral of $I(\phi, k)$ from 0 to $\pi/2$; that is, it is the area beneath the $I(\phi, k)$ curve in Figure 2.22 from 0 to $\pi/2$. Thus, it is the area beneath the curve to the left of the first vertical dashed line in that figure. It is given by

$$u\left(\frac{\pi}{2}, k\right) = \int_0^{\pi/2} I(\alpha, k)\mathrm{d}\alpha = \int_0^{\pi/2} \frac{1}{\sqrt{1 - k^2 \sin^2(\alpha)}}\mathrm{d}\alpha = K \tag{2.120}$$

and is referred to as the *complete elliptic integral of the first kind.*

The sine generalization sought can now be defined. Since the running integral $u(\phi, k)$ is monotonic, it can be inverted and thereby solved for ϕ in terms of u; for each value of u there corresponds a unique value of ϕ. The elliptic sine function is defined to be the ordinary sine function of ϕ:

$$\mathrm{sn}(u, k) = \sin(\phi, k) \tag{2.121}$$

Now, inspection of Figure 2.23 shows that, as ϕ progresses from 0 to 2π, $u(\phi, k)$ increases from 0 to $4K$; since angles are unique only to within multiples of 2π, therefore, it is clear that $\mathrm{sn}(u, k)$ is periodic with period $4K$. Hence, K is a quarter-period of the elliptic sine function.

The integral in Equation 2.119 cannot be evaluated in closed form; thus, there is not a simple, compact expression for the required inverse. Therefore, the elliptic sine function can only be tabulated in numerical form or computer using numerical techniques. It is shown for $k^2 = 0.99$ in Figure 2.24 and compared with a conventional sine function having the same period ($4K$).

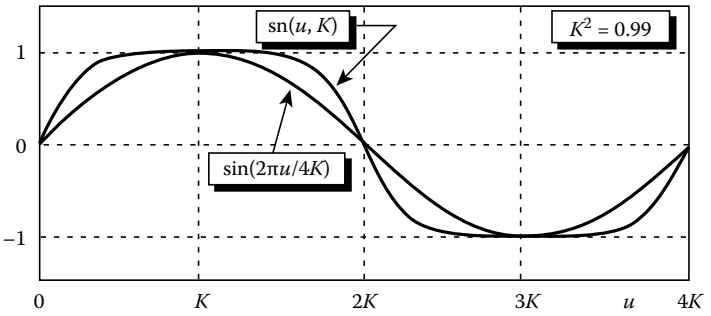

FIGURE 2.24 Plots of the elliptic and ordinary sine functions.

Recall, now, the objective of exploring the preceding generalization of the sinusoid: one is looking for a transformation that will convert the characteristic function given by Equations 2.115 and 2.116 into equivalent waveforms having the equiripple property. As one might suspect (since so much time has been spent on developing it), the elliptic sine function is precisely the transformation desired. The crucial aspect of showing this is the application of a fundamental property of sn(u, k), known as an additional formula:

$$\mathrm{sn}(u+a,k)\mathrm{sn}(u-a,k)=\frac{\mathrm{sn}^2(u,k)-\mathrm{sn}^2(a,k)}{1-k^2\mathrm{sn}^2(u,k)\mathrm{sn}^2(a,k)} \tag{2.122}$$

The right-hand side of this identity has the same form as one factor in Equations 2.115 and 2.116, that is of one zero factor coupled with its corresponding pole factor. This suggests the transformation

$$\omega=\sqrt{k}\mathrm{sn}(u,k) \tag{2.123}$$

The passband zeros then are given by

$$\omega_i=\sqrt{k}\mathrm{sn}(u_i,k) \tag{2.124}$$

and the factors mentioned previously map into

$$\frac{\omega_i^2-\omega^2}{1-\omega_i^2\omega^2}=\frac{k[\mathrm{sn}^2(u_i,k)-\mathrm{sn}^2(u,k)]}{1-k^2\mathrm{sn}^2(u_i,k)\mathrm{sn}^2(u,k)}=k\mathrm{sn}(u+u_i)\mathrm{sn}(u-u_i) \tag{2.125}$$

For specificity, the even-order case will be discussed henceforth. The odd-order case is the same if minor notational modifications are made. Thus, one sees that

$$R_{2n}(\omega)=\prod_{i=1,3,\ldots,2n-1}\frac{\omega_i^2-\omega^2}{1-\omega_i^2\omega^2}=\prod_{i=1,3,\ldots,2n-1}k\mathrm{sn}(u+u_i)\mathrm{sn}(u-u_i) \tag{2.126}$$

The u_i are to be chosen. Before doing this, it helps to simplify the preceding expression by defining $u_{-i}=-u_i$ and reindexing. Calling the resulting function $G(u)$, one has

$$G(u)=\prod_{i=-1,-3,\ldots,-(2n-1)}^{i=1,3,\ldots,2n-1}k\mathrm{sn}(u+u_i) \tag{2.127}$$

Refer now to Figure 2.24. Each of the sn functions is periodic with period $4K$ and is completely defined by its values over one quarter-period $[0, K]$. Suppose that one defines

$$u_i=i\frac{K}{2n} \tag{2.128}$$

Figure 2.25 shows the resulting transformation corresponding to Equations 2.123 and 2.124. As u progresses from $-K$ to $+K$, ω increases from $-\sqrt{k}$ to $+\sqrt{k}$ as desired. Furthermore, because of the symmetry of sn(u), the set $\{u_i\}$ forms an additive group—adding $K/2n$ to the index of any u_i results in another u_i in the set. This means that $G(u)$ in Equation 2.127 is periodic with period $K/2n$. Thus, as ω increases from $-\sqrt{k}$ to $+\sqrt{k}$, $R_{2n}(\omega)$ achieves $2n+2$ extrema, that is, positive and negative peak values. But this is sufficient for $R_{2n}(\omega)$ to be the Chebyshev rational function of best approximation.

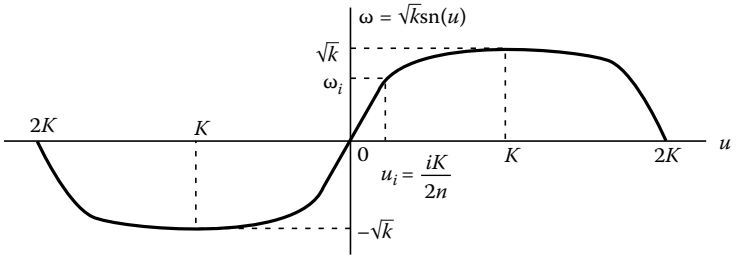

FIGURE 2.25 Elliptic sine transformation.

The symmetry of the zero distribution around the peak value of $\mathrm{sn}(u)$, that is, around $u = K$, reveals that the peak values of $R_{2n}(\omega)$ occur between the zeros; that is, recalling that in Figure 2.21 the peak values have been defined by the symbols ω_i for even i, one has

$$\omega_i = \sqrt{k}\,\mathrm{sn}\left(\frac{iK}{2n}\right); \quad i = 0, 1, 2, \ldots, 2n \tag{2.129}$$

where the odd indices correspond to the zeros and the even ones to the peak values. Note that $i = 0$ corresponds to $\omega = 0$ and $i = 2n$ to $\omega = \sqrt{k}$. This permits one to compute the minimax error:

$$\varepsilon = |R_{2n}(0)| = (\omega_1 \omega_3 \cdots \omega_{2n-1})^2 \tag{2.130}$$

As pointed out previously, the analysis for odd-order filters proceeds quite analogously. The only difference lies in the computation of ε. In this case, $R_{2n+1}(0) = 0$; thus, $\omega = 0$ is a zero—not a point of maximum deviation. One can, however, note that the quantity $\varepsilon^2 - R_{2n+1}^2(\omega)$ has double zeros at the frequencies of maximum deviation (except at $\omega = \omega_{2n+1} = \sqrt{k}$) and the same denominator as $R_{2n+1}^2(\omega)$. Hence,

$$\varepsilon^2 - R_{2n+1}^2(\omega) = \frac{\left(\omega_1^2 - \omega^2\right)^2 \left(\omega_3^2 - \omega^2\right)^2 \cdots \left(\omega_{2n+1}^2 - \omega^2\right)}{\left(1 - \omega_2^2\omega^2\right)^2 \left(1 - \omega_4^2\omega^2\right)^2 \cdots \left(1 - \omega_{2n}^2\omega^2\right)^2} \tag{2.131}$$

Notice here that $\omega_{2n+1} = \sqrt{k}$. Since $R_{2n+1}(0) = 0$, one can evaluate this expression at $\omega = 0$ to get

$$\varepsilon = (\omega_1 \omega_3 \cdots \omega_{2n-1})^2 \sqrt{k} \tag{2.132}$$

Note that one uses the zero frequencies in the even-order case and the frequencies of maximum deviation in the odd-order case.

As an example, suppose that the object is to design an elliptic filter of order $n = 2$. Further, suppose that the passband ripple cutoff frequency is to be 0.95. Then, one has

$$\omega_\mathrm{p} = \sqrt{k} = 0.95 \tag{2.133}$$

The quarter period of the elliptic sine function is

$$K = 2.9083 \tag{2.134}$$

TABLE 2.4 Zeros of Elliptic Rational Functions

i	ω_i
0	0.0000
1	0.5923
2	0.8588
3	0.9352
4	0.9500

Evaluating the zeros and points of maximum deviation of the Chebyshev rational function numerically using Equation 2.129, one obtains the values shown in Table 2.4. Thus, the required elliptic rational function is

$$R_4(\omega) = \frac{(0.3508 - \omega^2)(0.8746 - \omega^2)}{(1 - 0.3508\omega^2)(1 - 0.8746\omega^2)} \tag{2.135}$$

Finally, the maximum error is given by Equation 2.130:

$$\varepsilon = (\omega_1\omega_2)^2 = (0.5923 \times 0.9352)^2 = 0.3078 \tag{2.136}$$

Figure 2.26 shows the resulting gain plot. Observe the transmission zero at $\omega = 1/0.9352 = 1.069$, corresponding to the pole of the Chebyshev rational function located at the inverse of the largest passband zero. Also, as anticipated, the minimum gain in the passband is

$$A_p = \frac{1}{\sqrt{1+\varepsilon^2}} = \frac{1}{\sqrt{1+(0.3078)^2}} = 0.9558 \tag{2.137}$$

and the maximum stopband gain is

$$A_s = \frac{1}{\sqrt{1+\frac{1}{\varepsilon^2}}} = \frac{1}{\sqrt{1+\frac{1}{(0.3078)^2}}} = 0.2942 \tag{2.138}$$

Perhaps a summary of the various filter types is in order at this point. The elliptic filter has more flexibility than the Butterworth or the Chebyshev because one can adjust its transition band rolloff independently of the passband ripple. However, as the sharpness of this rolloff increases, as a more detailed analysis shows, the stopband gain increases and the passband ripple increases. Thus, if these

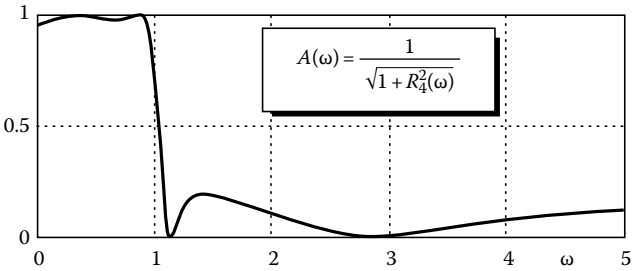

FIGURE 2.26 Gain plot for the example elliptic filter.

parameters are to be independently specified—as is often the desired approach—one must allow the order of the filter to float freely. In this case, the design becomes a bit more involved. The reader is referred to Ref. [10], which presents a simple curve for use in determining the required order. It proceeds from the result that the filter order is the integer greater than or equal to the following ratio:

$$n \geq \frac{f(M)}{f(\Omega)} \tag{2.139}$$

where

$$f(x) = \frac{K\left(\sqrt{1 - x^{-2}}\right)}{K(1/x)} \tag{2.140}$$

Lin [10] presents a curve of this function $f(x)$. K is the complete elliptic integral given in Equation 2.120. The parameters M and Ω are defined by

$$M = \sqrt{\frac{1 - 10^{-0.1A_s}}{1 - 10^{-0.1A_p}}} \tag{2.141}$$

and

$$\Omega = 1/k \tag{2.142}$$

Of course, there is still the problem of factorization. That is, now that the appropriate Chebyshev rational function is known, one must find the corresponding $G(s)$ transfer function of the filter. The overall design process is explained in some detail in Ref. [11], which develops a numerically efficient algorithm for directly computing the parameters of the transfer function.

The Butterworth and Chebyshev filters are of the all-pole variety, and this means that the synthesis of such filters is simpler than is the realization of elliptic filters, which requires the realization of transmission zeros on the finite $j\omega$ axis.

Finally, a word about phase (or group delay). Table 2.5 shows a rank ordering of the filters in terms of both gain and phase performance. As one can see, the phase behavior is inverse to the gain performance. Thus, the elliptic filter offers the very best standard approximation to be ideal lpp "brickwall" gain behavior, but its group delay deviates considerably from a constant. On the other end of the spectrum, one notes that the Bessel–Thompson filters offers excellent phase performance, but a quite high order is required to achieve a reasonable gain characteristic.

If both excellent phase and gain performance are absolutely necessary, two approaches are possible. One either uses computer optimization techniques to simultaneously approximate gain and phase, or one uses one of the filters described in this section followed by an *allpass* filter, one having unity gain over the frequency range of interest, but whose phase can be designed to have the inverse characteristic to the filter providing the desired gain. This process is known as *phase compensation*.

TABLE 2.5 A Rank Ordering of the Filters in Terms of Both Gain and Phase Performance

Filter Type	Gain Rolloff	Phase Linear
Bessel	Worst	Best
Butterworth	Poor	Better
Chebyshev	Better	Poor
Elliptic	Best	Worst

3.1 Low-Pass Prototype

As discussed in Chapter 2, conventional approximation techniques (Butterworth, Chebyshev, Elliptic, Bessel, etc.) lead to a normalized transfer function denoted low-pass prototype (LPP). The LPP is characterized by a passband frequency $\Omega_P = 1.0$ rad/s, a maximum passband ripple A_P (or A_{max}), a minimum stopband attenuation A_s (or A_{min}), and a stopband frequency Ω_s. A_p and A_s are usually specified in decibels. Tolerance bounds (also called box constraints) for the magnitude response of an LPP are illustrated in Figure 3.1a. The ratio Ω_s/Ω_p is called the selectivity factor and it has a value Ω_s for an LPP filter. The passband and stopband edge frequencies are defined as the maximum frequency with the maximum passband attenuation A_p and the minimum frequency with the minimum stopband attenuation A_s, respectively. The passband ripple and the minimum passband attenuation are expressed by

$$A_P = 20\log\left|\frac{K}{H(\omega_P)}\right|, \quad A_s = 20\log\left|\frac{K}{H(\omega_s)}\right| \tag{3.1}$$

where K is the maximum value of the magnitude response in the passband (usually unity). Figure 3.1b shows the magnitude response of a Chebyshev LPP transfer function with specifications $A_P = 2$ dB, $A_s = 45$ dB, and $\Omega_s = 1.6$.

Transformation of transfer function. Low-pass, high-pass, bandpass, and band-reject transfer functions (denoted in what follows LP, HP, BP, and BR, respectively) can be derived from an LPP transfer function through a transformation of the complex frequency variable. For convenience, the transfer function of the LPP is expressed in terms of the complex frequency variable s, where $s = u + j\Omega$ while the transfer functions obtained through the frequency transformation (low-pass, high-pass, bandpass, or band-reject) are expressed in terms of the transformed complex frequency variable $p = \sigma + j\omega$.

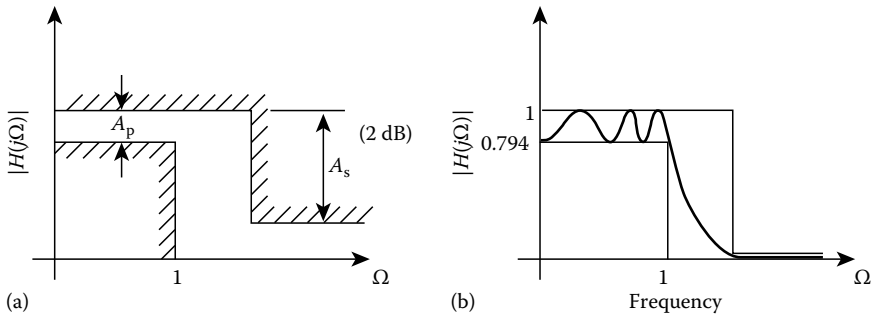

FIGURE 3.1 (a) Tolerance bounds for magnitude response of low-pass prototype and (b) Chebyshev LPP response.

The approximation of an LP, HP, BP, or BR transfer function with passband ripple (*s*) A_p and stopband attenuation (*s*) A_s involves three steps:

1. Determination of the stopband edge frequency or selectivity factor Ω_s of an LPP, which can be transformed into the desired LP, HP, BP, or BR filter.
2. Approximation of an LPP transfer function $T_{LPP}(s)$ with selectivity factor Ω_s and with same passband ripple and stopband attenuation A_p and A_s are the desired LP, HP, BP, or BR filter, respectively
3. Transformation of the LPP transfer function $T_{LPP}(s)$ into the desired transfer function (LP, HP, BP, or BR) $T(p)$ through a frequency transformation of the form

$$s = f(p) \tag{3.2}$$

Transformation of a network with LPP magnitude response into a low-pass, high-pass, bandpass, or band-rejection network can be done directly on the elements of the network. This procedure is denoted network transformation. It is very convenient in practice because element values for double terminated lossless ladder networks with LPP specifications have been extensively tabulated for some common values of A_p, A_s, and Ω_s. Also, a host of personal computer programs have become available in recent years that allow one to determine the component values of LPP ladder networks for arbitrary values A_p, A_s, and Ω_s. In what follows we study the frequency transformation $s = f(p)$ for each specific type of filter response (LP, HP, BP, and BR). We show how to calculate the selectivity factor of the equivalent LPP based on box constraint specifications for each type of filter. We then show how mapping of the imaginary frequency axis from *s* to *p* leads to LP, HP, BP, or BR magnitude responses. We analyze how poles and zeros are mapped from the *s*-plane to the *p*-plane for each transformation and finally we show the element transformations required to directly transform LPP networks into any of the filter types addressed previously.

3.2 Frequency and Impedance Scaling

3.2.1 Frequency Scaling

The simplest frequency transformation is a scaling operation expressed by

$$s = \frac{p}{\omega_o} \tag{3.3}$$

where ω_o is a frequency scaling parameter. This transformation is denoted frequency scaling and it allows one to obtain a low-pass transfer function with a nonunity passband frequency edge from an LPP transfer function.

Transformation of poles and zeros of transfer function. Consider an LPP factorized transfer function $T_{LPP}(s)$ with n poles $s_{p1}, s_{p2}, \ldots, s_{pn}$ and m zeros $s_{z1}, s_{z2}, \ldots, s_{zm}$

$$T_{LPP}(s) = K\frac{(1 - s/s_{z1})(1 - s/s_{z2})\cdots(1 - s/s_{zm})}{(1 - s/s_{p1})(1 - s/s_{p2})\cdots(1 - s/s_{pn})} \tag{3.4}$$

Using Equation 3.3, this transfer function becomes

$$T_{LP}(p) = K\frac{(1 - p/p_{z1})(1 - p/p_{z2})\cdots(1 - p/p_{zm})}{(1 - p/p_{p1})(1 - p/p_{p2})\cdots(1 - p/p_{pn})} \tag{3.5}$$

where poles and zeros (s_{zi} and s_{pj}) of the LPP transfer function $P_{LPP}(s)$ become simply poles and zeros in $T_{LP}(p)$, which are related to those of $T_{LPP}(s)$ by the scaling factor ω_o:

$$p_{pi} = \omega_o s_{pi}, \quad p_{zj} = \omega_o s_{zj} \tag{3.6}$$

To determine the magnitude (or frequency) response of the LP filter we evaluate the magnitude of the transfer function on the imaginary axis (for $s = j\Omega$). The magnitude response of the transformed transfer function $|T_{LP}(j\omega)|$ preserves a low-pass characteristic as illustrated in Figure 3.2. The frequency range from 0 to ∞ in the Ω-axis is mapped to the range 0 to ∞ in the ω-axis. A frequency and its mirror image in the negative axis $\pm\Omega$ is mapped to frequencies $\omega = \pm\omega_o\Omega$ with the same magnitude response: $|T_{LPP}(j\Omega)| = |T_{LP}(j\omega_o\Omega)|$. The passband and stopband edge frequencies $\Omega_P = 1$ rad/s and Ω_s of the LPP are mapped into passband and stopband edge frequencies $\omega_p = \omega_o$ and $\omega_s = \omega_o\Omega_s$, respectively. From this, it can be seen that for given low-pass filter specifications ω_s, ω_p the equivalent LPP is determined based on the relation $\Omega_s = \omega_s/\omega_p$, while the frequency scaling parameter ω_o corresponds to the passband edge frequency of the desired LP.

LP network transformation. Capacitors and inductors are the only elements that are frequency dependent and that can be affected by a change of frequency variable. Capacitors and inductors in an LPP network have impedances $z_c = 1/sc_n$ and $z_1 = sl_n$, respectively. Using Equation 3.3 these become $Z_c(p) = 1/pC$ and $Z_L(p) = pL$, where $C = c_n/\omega_o$ and $L = l_n/\omega_o$. The LPP to LP frequency transformation is performed directly on the network by simply dividing the values of all capacitors and inductors by the frequency scaling factor ω_o. This is illustrated in Figure 3.3a. The transformation expressed by Equation 3.3 can be applied to any type of filter and it has the effect of scaling the frequency axis without changing the shape of its magnitude response. This is illustrated in Figure 3.3, where the elements of an LPP with $A_p = 2$ dB, $A_s = 45$ dB, and selectivity $\Omega_s = 1.6$ rad/s are scaled (Figure 3.3b) to transform the network into an LP network with passband and stopband edge frequencies $\omega_p = 2\pi$ 10 krad/s and $\omega_s = 2\pi$ 16 krad/s (or $f_p = 10$ kHz and $f_s = 16$ kHz), respectively.

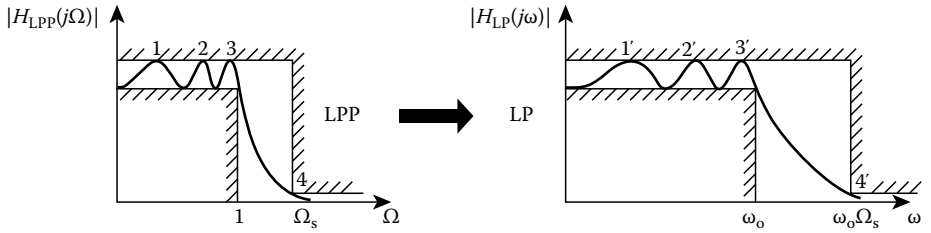

FIGURE 3.2 Derivation of low-pass response from a low-pass prototype by frequency scaling.

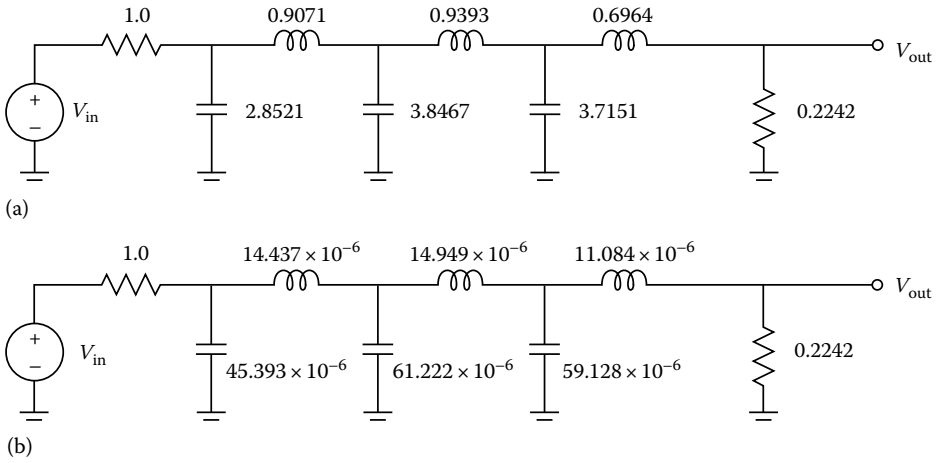

FIGURE 3.3 (a) Low-pass prototype ladder network and (b) LP network with passband frequency $f_p = 10$ kHZ derived from (a).

3.2.2 Impedance Scaling

Dimensionless transfer functions defined by ratios of voltages (V_{out}/V_{in}) or currents (I_{out}/I_{in}) remain unchanged if all impedances of a network are scaled by a common scaling factor "*a*." On the other hand, transfer functions of the transresistance type (V_{out}/I_{in}) or of the transconductance type (I_{out}/V_{in}) are simply modified by the impedance scaling factor a and $1/a$, respectively. If we denote a normalized impedance by z_n, then the impedance scaling operation leads to an impedance $Z = az_n$. When applied to resistors (r_n), capacitors (c_n), inductors (l_n), transconductance gain coefficients (g_n), and transresistance gain coefficients (r_n) result in the following relations for the elements (R, C, L, g, and r) of the impedance scaled network.

$$\begin{aligned} R &= ar_n \\ L &= al_n \\ C &= \frac{1}{a}c_n \\ g &= \frac{1}{a}g_n \\ r &= ar_n \end{aligned} \tag{3.7}$$

Dimensionless voltage-gain and current-gain coefficients are not affected by impedance scaling. Technologies for fabrication of microelectronic circuits (CMOS, bipolar, BiCMOS monolithic integrated circuits, thin-film and thick-film hybrid circuits) only allow elements values and time constants (or pole and zero frequencies) within certain practical ranges. Frequency and impedance scaling are very useful to scale normalized responses and network elements resulting from standard approximation procedures to values within the range achievable by the implementation technology. This is illustrated in the following example.

Example 3.1

The amplifier of Figure 3.4. is characterized by a one-pole low-pass voltage transfer function given by $H(s) = V_{out}/V_{in} = K(1+s/\omega_p)$, where $K = g_m r_L r_1/(r_1 + r_2)$, and $\omega_p = 1/r_L C_L$. Perform frequency and impedance scaling so that the circuit pole takes a value $\omega_p = 2\pi \times 10$ Mrad/s (or $f_p = 10$ MHz) and resistance,

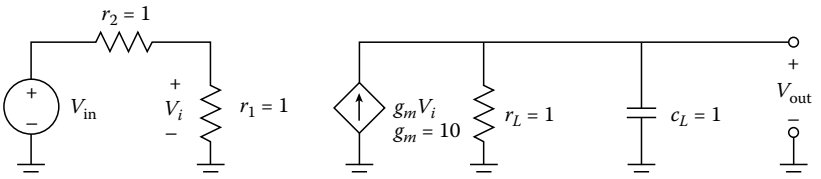

FIGURE 3.4 Normalized transconductance amplifier.

capacitance, and transconductance gain values are in the range of kΩ, pF, and μA/V, which are appropriate for the implementation of the circuit as an integrated circuit in CMOS technology.

Solution

The required location of the pole and range of values for the circuit elements can be achieved using frequency and impedance scaling factors $\omega_o = 2\pi \times 10^7$ and $a = 10^4$, respectively. These result in $R_1 = ar_1 = 10$ kΩ, $R_2 = ar_2 = 10$ kΩ, $g = g_m/a = 1000$ μA/V, $R_L = ar_L = 10$ kΩ, and $C_L = c_L/a\omega_o = 1.59$ pF.

3.3 Low-Pass to High-Pass Transformation

The LPP to high-pass transformation is defined by

$$s = \frac{\omega_o^2}{p} \tag{3.8}$$

Using this substitution in the LPP transfer function (Equation 3.4), it becomes

$$T_{HP}(P) = K\frac{p^{n-m}(p - p_{z1})(p - p_{z2})\cdots(p - p_{zm})}{(p - p_{p1})(p - p_{p2})\cdots(p - p_{pn})} \tag{3.9}$$

where the poles and zeros of Equation 3.8 are given by

$$\begin{aligned} p_{zi} &= \frac{\omega_o^2}{s_{zi}} \quad \text{for } i \in \{1, 2, \ldots, m\} \\ p_{pj} &= \frac{\omega_o^2}{s_{pj}} \quad \text{for } j \in \{1, 2, \ldots, n\} \end{aligned} \tag{3.10}$$

It can be seen that zeros and poles of $T_{HP}(p)$ are reciprocal to those of $T_{LPP}(s)$ and scaled by the factor ω_o^2. $T_{HP}(p)$ has $n - m$ zeros at $s = 0$, which can be considered to originate from $n - m$ zeros at ∞ in $T_{LPP}(s)$.

Let us consider now the transformation of the imaginary axis in s to the imaginary axis in p. For $s = j\Omega$, p takes the form $p = j\omega$ where

$$\omega = \frac{-\omega_o^2}{\Omega} \tag{3.11}$$

From Equation 3.11, it can be seen that positive frequencies in the LPP transform to reciprocal and scaled frequencies of the HP filter. Specifically, the frequency range from 0 to ∞ in Ω maps to the frequency range $-\infty$ to 0 in ω, while the range $-\infty$ to 0 in Ω maps to 0 to ∞ in ω. The passband edge frequency

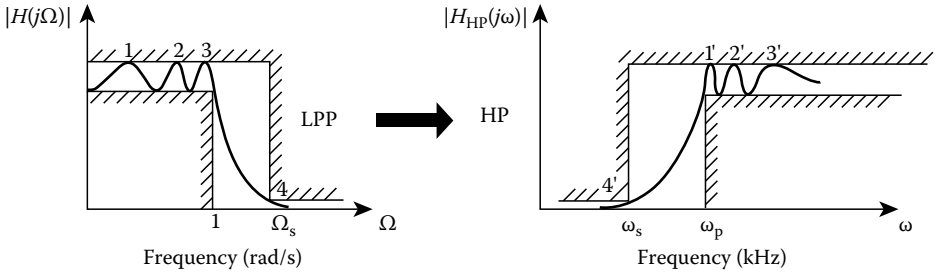

FIGURE 3.5 Transformation of a low-pass into a high-pass response.

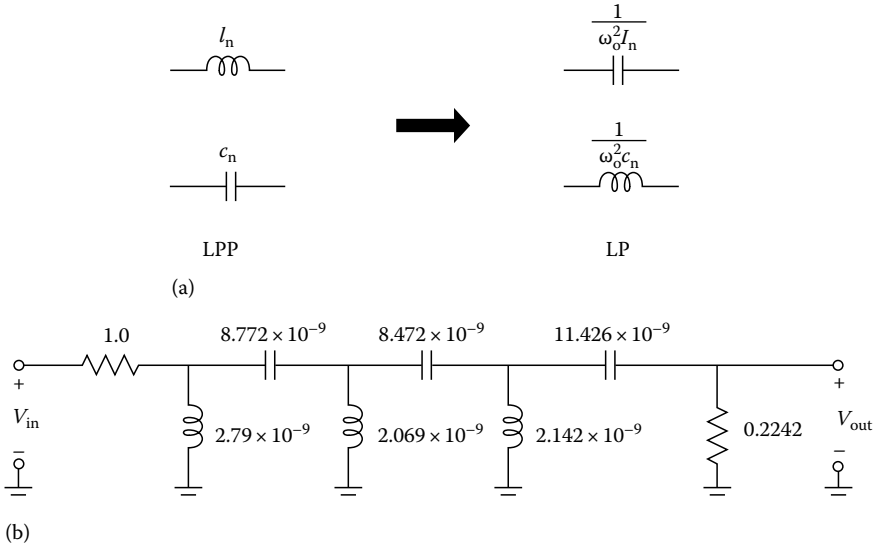

FIGURE 3.6 (a) LPP to high-pass network element transformations and (b) high-pass network derived from LPP of Figure 3.3a.

($\Omega_p = \pm 1$) and the stopband edge frequency $\pm\,\Omega_s$ of the LPP is mapped to $\omega_p = \pm\omega_o^2$ and $\omega_s = \pm\omega_o^2/\Omega_s$ in the high-pass response. This is illustrated in Figure 3.5.

The procedure to obtain the specifications of the equivalent LPP given specifications ω_p and ω_s for a HP circuit can be outlined as follows:

1. Calculate the selectivity factor of the LPP according to $\Omega_s = \omega_p/\omega_s$.
2. Approximate an LPP transfer function $T_{LPP}(s)$ with the selectivity Ω_s and the passband ripple and stopband attenuation of the desired high-pass response.
3. Perform an LPP to HP transformation either by direct substitution $p = \omega_o^2/s$ in $T_{LPP}(s)$ or by transforming poles and zeros of $T_{LPP}(s)$ using Equation 3.10.

Network transformation. Consider a capacitor c_n and an inductor l_n in an LPP network. They have impedances $z_c(s) = 1/sc_n$, $z_1(s) = sl_n$, respectively. Using Equation 3.8, these become impedances $Z_L(p) = pL$ and $Z_c = 1/pC$ in the high-pass network, where $L = 1/\omega_o^2\ c_n$ and $C = 1/\omega_o^2\ l_n$. It can be seen that an LPP to HP transformation can be done directly on an LPP network by replacing capacitors by inductors and inductors by capacitors. For illustration, Figure 3.6 shows a high-pass network with a passband edge frequency $\omega_p = 2\pi$ 20 Mrad/s or ($fp = 20$ MHz) derived from the LPP network shown in Figure 3.6a.

3.4 Low-Pass to Bandpass Transformation

If the LPP transfer function is expressed now as a rational function

$$H_{\mathrm{LPP}}(s) = K\frac{b_0 + b_1 s + b_2 s^2 + \cdots + b_m s_m}{a_0 + a_1 s + a_2 s^2 + \cdots + a_n s^n} \tag{3.12}$$

then through the substitution

$$s = \frac{1}{\mathrm{BW}}\frac{p^2 + \omega_{\mathrm{o}}^2}{p} \tag{3.13}$$

$H_{\mathrm{LPP}}(s)$ transformed into a bandpass transfer function $H_{\mathrm{BP}}(p)$ with the form

$$H_{\mathrm{BP}}(P) = K' P^{n-m}\frac{1 + B_1 p + B_2 p^2 + \cdots + B_2 p^{2m-2} + B_1 p^{2m-1} + p^{2m}}{1 + A_1 p + A_2 p^2 + \cdots + A_2 p^{2m-2} + A_1 p^{2m-1} + p^{2m}} \tag{3.14}$$

From Equation 3.14, it can be seen that the bandpass transfer function has twice as many poles and zeros as the LPP transfer function. In addition it has $n - m$ zeros at the origin. The coefficients of the numerator and denominator polynomials are symmetric and are a function of the coefficients of $H_{\mathrm{LPP}}(s)$.

In order to obtain poles and zeros of the bandpass transfer function from the poles and zeros of $T_{\mathrm{LPP}}(p)$, three points must be considered.

First, a real pole (or zero) $s_{\mathrm{p}} = -u_{\mathrm{p}}$ of $H_{\mathrm{LPP}}(s)$ maps into a complex conjugate pair with frequency ω_{o} and Q (or selectivity) factor in $H_{\mathrm{BP}}(p)$, where $Dq = \omega_{\mathrm{o}}/(U_{\mathrm{p}}BW)$.*

Second, a pair of complex conjugate pole (or zeros) of $H_{\mathrm{LPP}}(s)$ with frequency Ω_{o} and pole-quality factor q denoted by (Ω_{o}, q) is mapped into two pairs of complex conjugate poles (or zeros) $(\omega_{\mathrm{o1}}, Q)$ and $(\omega_{\mathrm{o2}}, Q)$, where the following relations apply:

$$\begin{aligned} \omega_{\mathrm{o1}} &= \omega_{\mathrm{o}} M \\ \omega_{\mathrm{o2}} &= \frac{\omega_{\mathrm{o}}}{M} \\ Q &= \frac{a}{c}\left(M + \frac{1}{M}\right) \end{aligned} \tag{3.15a}$$

and the definitions

$$\begin{aligned} a &= \frac{\omega_{\mathrm{o}}}{\mathrm{BW}} \\ b &= \frac{\Omega_{\mathrm{o}}}{2a} \\ c &= \frac{\Omega_{\mathrm{o}}}{q} \\ M &= \sqrt{b^2 + \sqrt{(1+b^2)^2 - \frac{c}{(2a)^2}} + \sqrt{2b}\sqrt{1 + b^2 - \frac{c}{2\Omega_{\mathrm{o}}^2} + \sqrt{(1+b^2)^2 - \frac{c}{(2a)^2}}}} \end{aligned} \tag{3.15b}$$

apply.

* A complex conjugate pole pair can be expressed as $s_{\mathrm{p}}, S_{\mathrm{p}}^* = u_{\mathrm{p}} \pm j\omega_{\mathrm{p}} = \omega_{\mathrm{c}}\, e^{\pm j\theta} = (\omega_{\mathrm{c}}, Q)$, where the pole quality factor Q is given by $Q = \frac{1}{2}\cos\theta$ and $\omega_{\mathrm{c}} = (G_{\mathrm{p}}^2 + \omega_{\mathrm{p}}^2)^{\frac{1}{2}}$, $\theta = tg^{-1}\frac{\omega_{\mathrm{p}}}{G_{\mathrm{p}}}$.

Narrow-band approximation. If the condition $BW/\omega_o \ll 1$ is satisfied, then following simple transformations known as the narrow band approximation* can be used to map directly poles (or zeros) from the *s*-plane to the *p*-plane

$$p_p \approx \frac{BW}{2} s_p + j\omega_o, \quad p_z \approx \frac{BW}{2} s_z + j\omega_o \tag{3.16}$$

These approximations are valid only if the transformed poles and zeros are in the vicinity of $j\omega_o$, that is, if $|s_p - \omega_o|/\omega_o \ll 1$.

Third, in order to obtain poles and zeros of the bandpass transfer function, mapping of complex zeros on the imaginary Ω axis (s_2, $s_x^* = \pm j\Omega_z$) takes place using the same mapping relations discussed next.

Mapping of imaginary frequency axis. Consider a frequency $s = j\Omega$ and its mirror image $s = -j\Omega$ in the LPP. Using Equation 3.13, these two frequencies are mapped into four frequencies: $\pm\omega_1$ and $\pm\omega_2$, where ω_1 and ω_2 are given by

$$\begin{aligned} \omega_2 &= \Omega\frac{BW}{2} + \sqrt{\omega_o^2 + \left(\Omega\frac{BW}{2}\right)^2} \\ \omega_1 &= -\Omega\frac{BW}{2} + \sqrt{\omega_o^2 + \left(\Omega\frac{BW}{2}\right)^2} \end{aligned} \tag{3.17}$$

From Equation 3.17, the following relations can be derived:

$$\begin{aligned} \omega_2 - \omega_1 &= BW\Omega \\ \omega_1\omega_2 &= \omega_o^2 \end{aligned} \tag{3.18}$$

It can be seen that with the LPP to bandpass transformation frequencies are mapped into bandwidths. A frequency Ω and its mirror image $-\Omega$ are mapped into two pairs of frequency points that have ω_0 as center of geometry. The interval from 0 to ∞ in the positive Ω axis maps into two intervals in the ω axis: the first from ω_o to $+\infty$ on the positive ω axis and the second from $-\omega_o$ to 0 to in the negative ω axis. The interval $-\infty$ to 0 on the negative Ω axis maps into two intervals: from $-\infty$ to $-\omega_o$ in the negative ω axis and from 0 to ω_o in the positive ω axis. The LPP passband and stopband edge frequencies $\Omega_p = \pm 1$ and $+\Omega_s$ are mapped into passband edge frequencies ω_{p1}, ω_{p2}, and into stopband edge frequencies ω_{s1}, ω_{s2} that satisfy

$$\begin{aligned} \omega_{p2} - \omega_{p1} &= BW \\ \omega_{s2} - \omega_{s1} &= BW\Omega_s \end{aligned} \tag{3.19}$$

and

$$\omega_{p1}\omega_{p2} = \omega_{s1}\omega_{s2} = \omega_o^2 \tag{3.20}$$

Figure 3.7 shows mapping of frequency points 1, 2, 3, and 4 in the Ω axis to points 1′, 2′, 3′, and 4′ and 1″, 2″, 3″, 4″ in the ω axis of the bandpass response.

If the bandpass filter specifications do not satisfy Equation 3.20 (which is usually the case), then either one of the stopband frequencies or one of the passband frequencies has to be redefined so that they become symmetric w.r.t. ω_o and an equivalent LPP filter can be specified. For given passband and

* L.P. Huelsman, An algorithm for the low-pass to bandpass transformation, *IEEE Trans. Education,* EH, 72, March 1968.

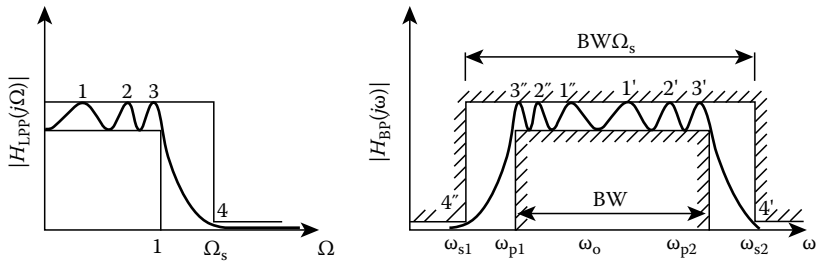

FIGURE 3.7 Low-pass to bandpass transformation.

stopband specifications ω_{p1}, ω_{p2}, ω_{s1}, ω_{s2}, A_p, A_s, the procedure to determine Ω_s for an equivalent LPP is as follows:

1. Calculate first the parameter ω_o in terms of the passband frequencies according to $\omega_o = \sqrt{\omega_{p1}\omega_{p2}}$.
2. Make the stopband frequencies geometrically symmetric with respect to ω_o determined in step 1 by redefining either ω_{s1} or ω_{s2} so that one of these frequencies becomes more constrained.* If $\omega_{s2} < \omega_o^2/\omega_{s2}$, then assign ω_{s1} the new value: $\omega_{s1} = <\omega_o^2/\omega_{s1}$. Otherwise assign ω_{s2} the new value $\omega_{s2} = \omega_o^2/\omega_{s1}$.
3. Calculate a selectivity factor of the LPP based on the redefined stopband frequency according to $\Omega_s = (\omega_{s2} - \omega_{s1})/(\omega_{p2} - \omega_{p1})$. This expression follows directly from Equations 3.19 and 3.20.
4. Calculate now the parameter ω_o in terms of the stopband frequencies, according to $\omega_o = \sqrt{\omega_{s1}\omega_{s2}}$.
5. Symmetrize the passband frequencies w.r.t. the value of ω_o determined in step 4 by constraining either ω_{p1} or ω_{p2}. If $\omega_{p1} > \omega_o^2/\omega_{p2}$, then assign ω_{p1} the new value: $\omega_{p1} > \omega_o^2/\omega_{p2}$. Otherwise assign ω_{p2} the new value $\omega_{p2} > \omega_o^2/\omega_{p1}$.
6. Calculate the selectivity factor based on the new set of passband frequencies using the same expression as in step 3.
7. Select from step 3 or step 6 the maximum selectivity factor Ω_s and determine the transformation parameters ω_o and BW from the values calculated in steps 1–3 or in 4–6, whichever sequence leads to the maximum Ω_s, which leads to the lowest order n for $T_{LPP}(s)$ and with this to the least expensive filter implementation.

Example 3.2

Consider the following nonsymmetric specifications for a bandpass filter: $\omega_{s1} = 2\pi$ 9, $\omega_{s2} = 2\pi$ 17, $\omega_{p1} = 2\pi$ 10, and $\omega_{p1} = 2\pi$ 14.4 (all frequencies specified in krad/s). Application of the above procedure leads to a new value for the upper stopband frequency $\omega_{s2} = 16$ and from this to the following parameters: $BW = 2\pi$ (14.4 −10) $= 2\pi$ 4.4, ω_o^2 $\omega_o^2 =$ 2π 9 2π 16 $= 2\pi$ 10 2π 14.4 $= (2\pi)^2$ 144, and $\Omega_s = 16 - 9/(14.4 - 10) = 1.59$.

Bandpass network transformation. Consider now the transformation of capacitors and inductors in an LPP filter. An inductor in the LPP network has an impedance $z_I(s) = sl_n$. This becomes an impedance $z_s(p) = pL_s + 1/pC_s$, where $L_s = l_n/BW$ and $C_s = BW/l_n\omega_o^2\omega_o^2$. Now consider a capacitor c_n in the LPP with admittance $Y_c(s) = sc_n$. Using the transformation (Equation 3.12), this becomes an admittance $Y_p(p) = pC_p + 1/pL_p$, where $C_p = c_n/BW$ and $L_p = BW/c_n\omega_o^2$. This indicates that to transform an LPP network into a bandpass network, inductors in the LPP network are replaced by the series connection of

* The term "constraint specifications" is used here in the sense of redefining either a stopband frequency or a passband frequency so that one of the transition bands becomes narrower, which corresponds to tighter design specifications.

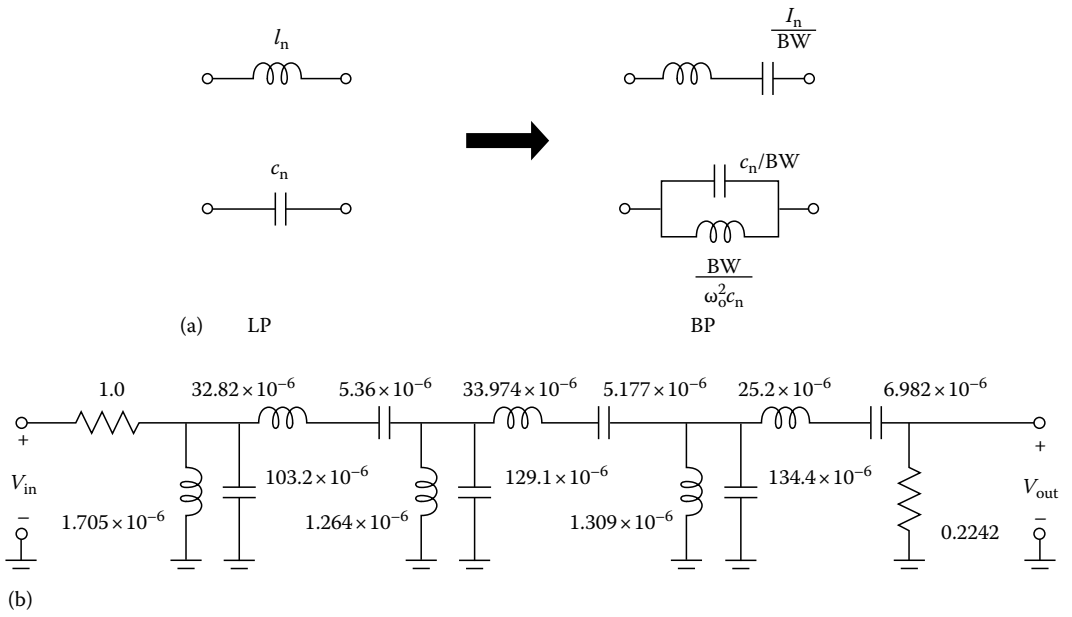

FIGURE 3.8 (a) LPP to bandpass network element transformations and (b) bandpass network derived from LPP network of Figure 3.3a.

an inductor with value L_s and a capacitor with value C_s and capacitors in the LPP are replaced by the parallel combination of a capacitor C_p and inductor L_p. This is illustrated in Figure 3.8. As with other transformations, resistors remain unchanged since they are not frequency dependent.

Example 3.3

Consider the LPP network shown in Figure 3.3a with specifications $Ap = 2$ dB, $As = 45$ dB, and $\Omega_s = 1.6$. Derive a bandpass network using the parameters calculated in Example 3.2: $\omega_o^2 = (2\pi)^2$ 144, BW = 2π 4.4 krad/s.

Solution

Straightforward application of the relations shown in Figure 3.8a leads to the network of Figure 3.8b.

3.5 Low-Pass to Band-Reject Transformation

This transformation is characterized by

$$S = \mathrm{BW}\frac{p}{p^2 + \omega_o^2} \tag{3.21}$$

and it can be best visualized as a sequence of two transformations through the intermediate complex frequency variables $s' = u' + j\Omega' \times 1$. A normalized LPP to high-pass transformations

$$s = \frac{1}{s'} \tag{3.22}$$

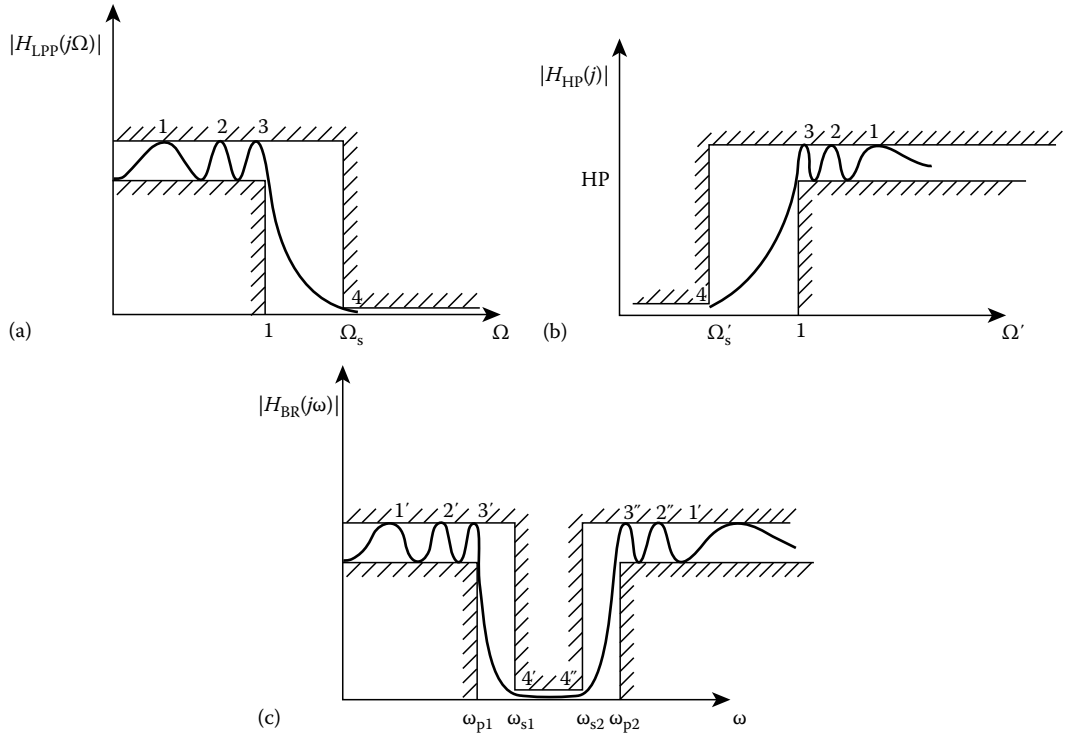

FIGURE 3.9 Low-pass to band-reject transformation: (a) Low-pass response, (b) normalized high-pass response, and (c) band-reject response derived from (a) and (b).

followed by a bandpass transformation applied to s'

$$s' = \frac{1}{\text{BW}} \frac{p^2 + \omega_o^2}{p} \tag{3.23}$$

Mapping of the imaginary ω axis to the Ω axis through this sequence of transformations leads to a band-rejection response in ω; frequency points 1, 2, 3, 4 have been singled out to better illustrate the transformation. Figure 3.9a shows the magnitude response of the LPP, Figure 3.9b shows the high-pass response obtained through Equation 3.22. This intermediate response is a normalized high-pass response with a passband extending from $\Omega'_p = 1$ to ∞ and a stopband extending from 0 to $\Omega'_s = 1/\Omega_s$. Figure 3.9c shows the magnitude response obtained by applying Equation 3.23 to the variable s'. The frequency range from $\Omega' = 0$ to ∞ in Figure 3.9b is mapped into the range from ω_o to ∞ and from $-\omega_o$ to 0. The frequency range from $-\infty$ to 0 in Ω' is mapped into the ranges from 0 to ω_o and from $-\infty$ to $-\omega_o$ in ω as indicated in Figure 3.9c. It can be seen that the bandpass transformation applied to a normalized high-pass response creates two passbands with ripple A_p from $\omega = 0$ to ω_{p1} and from ω_{p2} to ∞ and a stopband with attenuation A_s from ω_{s1} to ω_{s2}. The following conditions are satisfied:

$$\begin{aligned} \omega_{s1}\omega_{s2} &= \omega_{p1}\omega_{p2} = \omega_o^2 \\ \omega_{s2} - \omega_{s1} &= \text{BW}\Omega'_s = \text{BW}/\Omega_s \\ \omega_{p2} - \omega_{p1} &= \text{BW} \end{aligned} \tag{3.24}$$

From Equation 3.24, if ω_{s1}, ω_{s2}, ω_{p1}, ω_{p2} as well as A_p and A_s are specified for a band-rejection filter, then the selectivity factor of the equivalent LPP is calculated according to $\Omega_s = (\omega_{p2} - \omega_{p1})/(\omega_{s2} - \omega_{s1})$. Similar to the case of bandpass filters, the band-rejection specifications must be made symmetric with respect to ω_o so that an equivalent LPP can be specified. This is done following a similar procedure as for the bandpass transformation by constraining either one of the passband frequencies or one of the stopband frequencies so that the response becomes geometrically symmetric with respect to ω_o. The option leading to the largest selectivity factor (that corresponds in general to the least expensive network implementation) is then selected. In this case constraining design specifications refers to either increase ω_{p1} or ω_{s2} or to decrease ω_{p2} or ω_{s1}.

Example 3.4

Make following band-rejection filter specifications symmetric so that an equivalent LPP with the lowest Ω_s can be found: $\omega_{s1} = 2\pi$ 10, $\omega_{s2} = 2\pi$ 14.4, $\omega_{p1} = 2\pi$ 9, $\omega_{p2} = 2\pi$ 17.

Solution

Defining ω_o in terms of the passband frequencies the upper stopband frequency acquires the new value $\omega_{s2} = 2\pi$ 15.3 and the selectivity factor $\Omega_s = 1.509$ is obtained. If ω_o is defined in terms of the stopband frequencies the upper passband frequency is assigned the new value $\omega_{p2} = 2\pi$ 16 and the selectivity factor $\Omega_s = 1.59$ is obtained. Therefore, the second option with $\Omega_s = 1.59$ corresponds to the largest selectivity factor and the following transformation parameters result: $BW = \omega_{p2} - \omega_{p1} = 2\pi(16–9) = 2\pi$ 7, $\omega_o^2 = \omega_{p1}\ \omega_{p1} = (2\pi)^2$ 144 is made.

Transformation of poles and zeros of the LPP transfer function. To determine the poles and zeros of the band-rejection transfer function $H_{BR}(p)$ starting from those of $H_{LPP}(s)$, again a sequence of two transformations is required: poles and zeros of the LPP (denoted $s_{p1}, s_{p2}, \ldots, s_{pn}$ and $s_{z1}, s_{z2}, \ldots, s_{zn}$) are transformed into poles and zeros of $H_{HP}(s')$ $s'_{p1}, s'_{p2}, \ldots, s'_{z1}, s'_{z2}, \ldots, s'_{zm}$, which are reciprocal to those of the LPP. The high-pass also acquires $n - m$ zeros at the origin as explained in Sections 3.3 and 3.2. The transformations described in Section 3.4 are then applied to the high-pass poles zeros $s'_{p1}, s'_{p2}, \ldots, s'_{z1}, s'_{z2}, \ldots, s'_{zm}$.

Band-rejection network transformation. Using the transformation (Equation 3.21), an inductor in the LPP network with admittance $y_1(s) = 1/sl_n$ becomes an admittance $Y_p(p) = pC_p + 1/pL_p$, where $C_p = 1/\text{BW}\ l_n$ and $L_p = \text{BW}\ l_n/\omega_o^2$. A capacitor c_n in the LPP with impedance $z_c(s) = 1/sc_n$ becomes with Equation 3.20 an impedance $Z_s(p) = pL_s + 1/pC_s$, where $L_s = 1/c_n\text{BW}$ and $C_s = c_n\text{BW}/\omega_o^2$. To transform an LPP network into a bandpass network, capacitors in the LPP network are replaced by a series connection of an inductor with value L_s and a capacitor with value C_s, while inductors in the LPP are replaced by the parallel combination of a capacitor C_p and inductor L_p. This is illustrated in Figure 3.10a.

Example 3.5

Consider the LPP network shown in Figure 3.3a. It corresponds to the specifications: $A_p = 2$ dB, $A_s = 45$ dB, and $\Omega_s = 1.6$. Transform it into a bandpass network using the following parameters from Example 3.4: $\omega_o^2 = (2\pi)^2$ 144, $BW = 2\pi$ 7 Mrad/s (units for ω_o are microradians per second).

Solution

The circuit of Figure 3.10b is obtained applying the transformations indicated in Figure 3.10a.

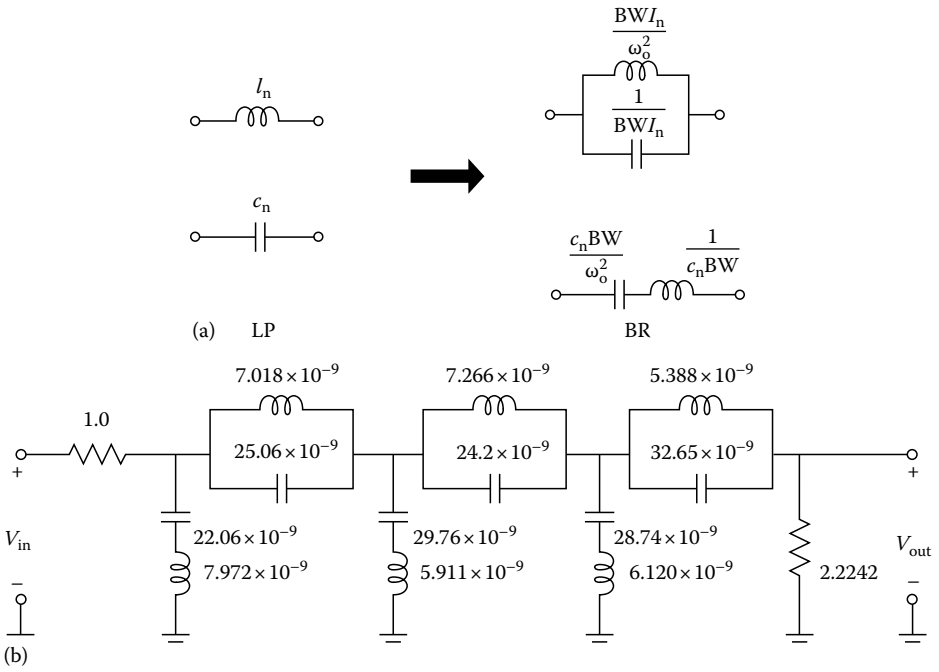

FIGURE 3.10 (a) LPP to band-reject transformations of network elements and (b) band-reject network derived from LPP of Figure 3.3a.

4.1 Introduction

Using sensitivity one can evaluate the change in a filter performance characteristic (bandpass, *Q*-factor) or in a filter function (input impedance, transfer function) resulting from a change in a nominal value of one or more of the filter components. Hence, sensitivities and based on them sensitivity measures are used to compare different realizations of electric filters that meet the same specifications. Sensitivities can also be used to estimate the spread of the performance characteristic caused by the spread of the element values. In the design of filters, one is interested both in choosing realizations that have low sensitivities and in minimizing the sensitivities. This allows use of components with wider tolerances for a given variation or a given spread of the filter characteristic or function.

4.2 Definitions of Sensitivity

Let y be the filter performance characteristic and x be the value of the parameter of a filter element that is causing the characteristic change. The *relative sensitivity* is defined as follows:

$$\mathbf{S}_x^y(y,x) = \frac{\partial y}{\partial x}\frac{x}{y} = \frac{\partial y/y}{\partial x/x} = \frac{\partial(\ln y)}{\partial(\ln x)} \tag{4.1}$$

It is usually used to establish the approximate relationship between the relative changes $\delta y = \Delta y/y$ and $\delta x = \Delta x/x$. Here, Δy and Δx are absolute changes. The interpretation of relative changes δy and δx depends on the problem at hand. If these relative changes are small, one writes that

$$\delta y \approx \mathbf{S}_x^y(y,x)\delta x \tag{4.2}$$

(This relationship assumes that $\mathbf{S}_x^y$ is different from zero. If $\mathbf{S}_x^y = 0$, the relative changes δy and δx may be independent. This happens, for example, in the passband of doubly terminated LC networks [see below], where the passband attenuation always increases independently on the sign in the variation of a reactance element.) The argument in the parentheses of Equation 4.2, when does not involve any ambiguity, will usually be omitted, i.e., we will write simply $\mathbf{S}_x^y$. Some simple properties of the sensitivity determined by Equation 4.1 can be established by differentiation only. They are summarized in Table 4.1 [1].

One can also define two *semirelative sensitivities*

$$\mathbf{S}_x(y,x) = x\frac{\partial y}{\partial x} = \frac{\partial y}{\partial x/x} = \frac{\partial y}{\partial(\ln x)} \tag{4.3}$$

which is here frequently denoted by $\mathbf{S}_x(y)$, and

$$\mathbf{S}^y(y,x) = \frac{1}{y}\frac{\partial y}{\partial x} = \frac{\partial y/y}{\partial x} = \frac{\partial(\ln y)}{\partial x} \tag{4.4}$$

which is also denoted by $\mathbf{S}^y(x)$. Both these sensitivities can be used in a way similar to Equation 4.2 to establish the approximate relationships between one relative and one absolute change. Finally, the absolute sensitivity $\mathbf{S}(y,x)$ is simply a partial derivative of y with respect to x, i.e., it can be used to establish the relationship between absolute changes. The variable x represents the value for any component of the filter. The set of values for all the components will be denoted as $\boldsymbol{x} = \{x_i\}$, where $i = 1, 2, \ldots, n$.

TABLE 4.1 Properties of the Relative Sensitivity

Property Number	Relation	Property Number	Relation
1	$\mathbf{S}_x^{ky} = \mathbf{S}_{kx}^y = \mathbf{S}_x^y$	10	$\mathbf{S}_x^{y_1/y_2} = \mathbf{S}_x^{y_1} - \mathbf{S}_x^{y_2}$
2	$\mathbf{S}_x^x = \mathbf{S}_x^{kx} = \mathbf{S}_{kx}^{kx} = 1$	11	$\mathbf{S}_{x_1}^y = \mathbf{S}_{x_2}^y \mathbf{S}_{x_1}^{x_2}$
3	$\mathbf{S}_{1/x}^y = \mathbf{S}_x^{1/y} = -\mathbf{S}_x^y$	12[a]	$\mathbf{S}_x^y = \mathbf{S}_x^{\lvert y\rvert} + j\arg y \mathbf{S}_x^{\arg y}$
4	$\mathbf{S}_x^{y_1 y_2} = \mathbf{S}_x^{y_1} + \mathbf{S}_x^{y_2}$	13[a]	$\mathbf{S}_x^{\arg y} = \frac{1}{\arg y}\operatorname{Im}\mathbf{S}_x^y$
5	$\mathbf{S}_x^{\Pi_{i=1}^n y_i} = \sum_{i=1}^n \mathbf{S}_x^{y_i}$	14[a]	$\mathbf{S}_x^{\lvert y\rvert} = \operatorname{Re}\mathbf{S}_x^y$
6	$\mathbf{S}_x^{y^n} = n\mathbf{S}_x^y$	15	$\mathbf{S}_x^{y+z} = \frac{1}{y+z}\left(y\mathbf{S}_x^y + z\mathbf{S}_x^z\right)$
7	$\mathbf{S}_x^{x^n} = n\mathbf{S}_x^{kx^n} = n$	16	$\mathbf{S}_x^{\sum_{y=1}^n y_i} = \frac{\sum_{i=1}^n y_i \mathbf{S}_x^{y_i}}{\sum_{i=1}^n y_i}$
8	$\mathbf{S}_{x^n}^y = \frac{1}{n}\mathbf{S}_x^y$	17	$\mathbf{S}_x^{\ln y} = \frac{1}{\ln y}\mathbf{S}_x^y$
9	$\mathbf{S}_{x^n}^y = \mathbf{S}_{kx^n}^x = \frac{1}{n}$		

[a] In this relation, y is a complex quantity and x is a real quantity.

4.3 Function Sensitivity to One Variable

Let the chosen quantity y be the filter function $F(s,x)$. When it does not involve any ambiguity, this function will be denoted as $F(s)$. The element x is a passive or active element in the circuit realization of the function. The function sensitivity is defined as

$$\mathbf{S}_x^{F(s,x)} = \frac{\partial F(s,x)}{\partial x}\frac{x}{F(s,x)} \tag{4.5}$$

Under condition of sinusoidal steady state, when $s = j\omega$, the function $F(j\omega,x)$ can be represented as

$$F(j\omega,x) = |F(j\omega,x)|e^{j\arg F(j\omega,x)} = e^{-\alpha(\omega,x)+j\beta(\omega,x)} \tag{4.6}$$

and using the left-hand part of Equation 4.6, one finds that

$$\mathbf{S}_x^{F(j\omega,x)} = \mathrm{Re}\,\mathbf{S}_x^{F(j\omega,x)} + j\,\mathrm{Im}\,\mathbf{S}_x^{F(j\omega,x)} = \mathbf{S}_x^{|F(j\omega,x)|} + j\frac{\partial \arg F(j\omega,x)}{\partial x/x} \tag{4.7}$$

as follows from property 12 of Table 4.1. Thus, the real part of the function sensitivity gives the relative change in the magnitude response, and the imaginary part gives the change in the phase response, both with respect to a normalized element change. If one determines $\delta F = [F(j\omega,x) - F(j\omega,x_0)]/F(j\omega,x_0)$ and $\delta x = (x - x_0)/x_0$, where x_0 is the initial value of the element and the deflection $\Delta x = x - x_0$ is small, then Equation 4.5 is used to write

$$\delta F \approx \mathbf{S}_x^{F(s,x)}\delta x \tag{4.8}$$

And if one determines $\delta|F| = [|F(j\omega,x) - F(j\omega,x_0)|]/|F(j\omega,x_0)|$, then using Equation 4.7, one obtains

$$\delta|F| \approx \mathrm{Re}\,\mathbf{S}_x^{F(s,x)}\delta x \tag{4.9}$$

These calculations assume that the sensitivity is also calculated at $x = x_0$.

A frequently used alternate form of Equation 4.7 is obtained by using the attenuation function $\alpha(\omega,x) = \ln\left(\frac{1}{|F(j\omega,x)|}\right) = -\ln|F(j\omega,x)|$ and the phase function $\beta(\omega,x) = \arg F(j\omega,x)$ defined by the right-hand part of Equation 4.6 (this interpretation is usually used when $F(s)$ is the filter transfer function $T(s)$). In terms of these, Equation 4.7 may be rewritten as

$$\mathbf{S}_x^{F(j\omega,x)} = -\frac{\partial\alpha(\omega,x)}{\partial x/x} + j\frac{\partial\beta(\omega,x)}{\partial x/x} = -\mathbf{S}_x[\alpha(\omega),x] + j\mathbf{S}_x[\beta(\omega),x] \tag{4.10}$$

From Equations 4.7 and 4.10 one concludes that $\mathbf{S}_x^{|F(j\omega,x)|} = -\mathbf{S}_x[\alpha(\omega),x]$. Besides, using Equations 4.7 and 4.10 one can write that

$$\Delta\arg F(j\omega,x) = \Delta\beta(\omega,x) \approx \mathrm{Im}\,\mathbf{S}_x^{F(j\omega,x)}\delta x = \mathbf{S}_x[\beta(\omega),x]\delta x \tag{4.11}$$

where $\Delta\arg F(j\omega,x) = \arg F(j\omega,x) - \arg F(j\omega,x_0)$.

Usually the filter function is a ratio of two polynomials $N(s)$ and $D(s)$, i.e.,

$$F(s) = \frac{N(s)}{D(s)} \tag{4.12}$$

Then, assuming that the coefficients of $N(s)$ and $D(s)$ depend on the element x, and using Equation 4.1, one derives the following form of Equation 4.5:

$$\mathbf{S}_x^{F(s)} = x\left[\frac{\partial N(s)/\partial x}{N(s)} - \frac{\partial D(s)/\partial x}{D(s)}\right] \tag{4.13}$$

which is sometimes more convenient.

4.4 Coefficient Sensitivity

In general, a network function $F(s)$ for any active or passive lumped network is a ratio of polynomials having the form

$$F(s) = \frac{N(s)}{D(s)} = \frac{a_0 + a_1 s + a_2 s^2 + \cdots + a_m s^m}{d_0 + d_1 s + d_2 s^2 + \cdots + d_n s^n} \tag{4.14}$$

Here the coefficients a_i and d_i are real and can be functions of an arbitrary filter element x. For such an element x one may define the *relative coefficient sensitivities* as follows:

$$\mathbf{S}_x^{a_i} = \frac{\partial a_i}{\partial x}\frac{x}{a_i}, \quad \mathbf{S}_x^{d_i} = \frac{\partial d_i}{\partial x}\frac{x}{d_i} \tag{4.15}$$

or the *semirelative coefficient sensitivities* (they are even more useful):

$$\mathbf{S}_x(a_i) = x\frac{\partial a_i}{\partial x}, \quad \mathbf{S}_x(d_i) = x\frac{\partial d_i}{\partial x} \tag{4.16}$$

The coefficient sensitivities defined in this way are related to the function sensitivity introduced in Section 4.3. Indeed, using Equations 4.13 and 4.16 one easily obtains that

$$\mathbf{S}_x^{F(s)} = \left[\frac{\sum_{i=0}^{m} \mathbf{s}_x(a_i)s^i}{N(s)} - \frac{\sum_{i=0}^{n} \mathbf{s}_x(d_i)s^i}{D(s)}\right] \tag{4.17}$$

or, in terms of relative sensitivities, that

$$\mathbf{S}_x^{F(s)} = \left[\frac{\sum_{i=0}^{m} \mathbf{s}_x^{a_i} a_i s^i}{N(s)} - \frac{\sum_{i=0}^{n} \mathbf{s}_x^{d_i} d_i s^i}{D(s)}\right] \tag{4.18}$$

The manner in which the filter function depends on any element x is a bilinear dependence [2]. Thus, Equation 4.14 may also be written in the form

$$F(s) = \frac{N(s)}{D(s)} = \frac{N_1(s) + xN_2(s)}{D_1(s) + xD_2(s)} \tag{4.19}$$

where $N_1(s), N_2(s), D_1(s)$, and $D_2(s)$ are polynomials with real coefficients that are not functions of the filter element x. This is true whether x is chosen to be the value of a passive resistor or capacitor, the gain of some amplifier or controlled source, etc. Only for filters with ideal transformers, ideal gyrators, and ideal negative impedance converters, the filter functions are the biquadratic functions of the ideal element parameters [2].

Because of the bilinear dependence property, there are only two ways in which a coefficient, say, a_i may depend on network element. The first of these has the form $a_i = kx$, in which case $\mathbf{S}_x^{a_i} = 1$ and $\mathbf{S}_x(a_i) = kx$; the second possible dependence for a coefficient a_i (or d_i) is $a_i = k_0 + k_1 x$, in which case $\mathbf{S}_x^{a_i} = k_1 x/(k_0 + k_1 x)$ and $\mathbf{S}_x(a_i) = k_1 x$. In this latter situation one has two cases: (1) the parities of the term are the same, and thus the magnitude of $\mathbf{S}_x^{a_i}$ is less than one and (2) the terms have opposite parities, in which case the magnitude of $\mathbf{S}_x^{a_i}$ is greater than one. In the last case the relative sensitivity $\mathbf{S}_x^{a_i}$ can have an infinite value, as a result of dividing by zero. In this case, a more meaningful measure of the change would be to use the semirelative coefficient sensitivity $\mathbf{S}_x(a_i)$.

4.5 Root Sensitivities

A filter function can also be represented as

$$F(s) = \frac{a_m \Pi_{i=0}^{m}(s - z_i)}{d_n \Pi_{i=0}^{n}(s - p_i)} \tag{4.20}$$

where z_i are zeros and p_i are poles. If $F(s)$ is also a function of the filter element x, the location of these poles and zeros will depend on this element. This dependence is described by the *semirelative root sensitivities*

$$\mathbf{S}_x(z_i) = x\frac{\partial z_i}{\partial x}, \quad \mathbf{S}_x(p_i) = x\frac{\partial p_i}{\partial x} \tag{4.21}$$

We will give calculation of the pole sensitivities only (they are used more frequently, to verify the stability) calculating the absolute change Δp_i for a given δx, the calculation of zeros follows the same pattern. Assume that p_i is a simple pole of $F(s)$, then

$$D(p_i) = D_1(p_i) + xD_2(p_i) = 0 \tag{4.22}$$

When the parameter x becomes $x + \Delta x$, the pole moves to the point $p_i + \Delta p_i$. Substituting these values in Equation 4.22 one obtains that

$$D_1(p_i + \Delta p_i) + (x + \Delta x)D_2(p_i + \Delta p_i) = 0 \tag{4.23}$$

If one uses Taylor's expansions $D_1(p_i + \Delta p_i) = D_1(p_i) + [\partial D_1(s)/\partial s]\,|_{s=p_i}\,\Delta p_i + \cdots$ and $D_2(p_i + \Delta p_i) = D_2(p_i) + [\partial D_2(s)/\partial s]\,|_{s=p_i}\,\Delta p_i + \cdots$ and substitutes them in Equation 4.23, keeping the terms of the first order of smallness, one obtains that

$$\frac{\Delta p_i}{\Delta x} = -\frac{D_2(p_i)}{D'(p_i)} \tag{4.24}$$

where $D'(p_i) = \left[\dfrac{\partial D(s)}{\partial s}\right]\Bigg|_{s=p_i}$. This result allows calculation of the pole sensitivity, which becomes

$$\mathbf{S}_x(p_i) = x\frac{\partial p_i}{\partial x} = -x\frac{D_2(p_i)}{D'(p_i)} \tag{4.25}$$

One can write that $D_1(s) = b_0 + b_1 s + b_2 s^2 + \cdots$ and $D_2(s) = c_0 + c_1 s + c_2 s^2 + \cdots$. Then, taking into consideration Equation 4.19, one can write that $D(s) = d_0 + d_1 s + d_2 s^2 + \cdots = (b_0 + xc_0) + (b_1 + xc_1)s + (b_2 + xc_2)s^2 + \cdots$. Differentiating this result, one obtains that $D_2(s) = c_0 + c_1 s + c_2 s^2 + \cdots = \partial d_0/\partial x + (\partial d_1/\partial x)s + (\partial d_2/\partial x)s^2 + \cdots = (1/x)[\mathbf{S}_x(d_0) + \mathbf{S}_x(d_1)s + \mathbf{S}_x(d_2)s^2 + \cdots]$. From

the other side, $D'(s) = \frac{\partial D(s)}{\partial s} = d_1 + 2d_2 s + 3d_3 s^2 + \cdots$. Calculating the two last expressions at $s = p_i$ and substituting them in Equation 4.25, one obtains that

$$\mathbf{S}_x(p_i) = -\frac{\sum_{j=0}^{n} p_i^j \mathbf{s}_x(d_j)}{\sum_{j=0}^{n-1} (j+1) d_{j+1} p_i^j} = -\frac{\sum_{j=0}^{n} d_j p_i^j \mathbf{s}_x^{d_j}}{\sum_{j=0}^{n-1} (j+1) d_{j+1} p_i^j} \tag{4.26}$$

The result (Equation 4.26) produces the pole sensitivity without representation of poles via coefficients of $D(s)$ (which is not possible if $n > 4$). It is convenient even for polynomials of low degree [3].

If p_i is a multiple root then the derivative $D'(p_i) = 0$ and $\mathbf{S}_x(p_i) = \infty$. But this does not mean that the variation δx causes infinitely large change of the pole location. This variation splits the multiple root into a group of simple roots. The location of these roots can be calculated in the following way. The roots are always satisfying the equation $D_1(s) + (x + \Delta x)D_2(s) = 0$, i.e., the equation $D(s) + \Delta x D_2(s) = 0$. One can rewrite the last equation as

$$1 + \delta x \left[\frac{x D_2(s)}{D(s)}\right] = 0 \tag{4.27}$$

where $\delta x = \Delta x / x$ as usual. The function $G(s) = \left[\frac{x D_2(s)}{D(s)}\right]$ can be represented as a sum of simple ratios. If the roots of $D(s)$ (i.e., the poles of $F(s)$) are simple, then

$$G(s) = \sum_{j=1}^{n} \frac{K_{ip}}{s - p_i} + K_{0p} \tag{4.28}$$

where

$K_{0p} = G(\infty)$

$K_{ip} = (s - p_i) G(s)\big|_{s=p_i}$

In the vicinity of $s = p_i$, Equation 4.27 can be substituted by

$$\lim_{s \to p_i} [1 + \delta x G(s)] = 1 + \delta x \frac{K_{ip}}{s - p_i} \tag{4.29}$$

Equating the right-hand side of Equation 4.29 to zero and substituting $s = p_i + \Delta p_i$ in this equation, one obtains that when $\Delta x \to 0$, the pole sensitivity can be calculated as

$$\mathbf{S}_x(p_i) = \frac{\partial p_i}{\partial x / x} = -K_{ip} \tag{4.30}$$

If a pole of $G(s)$ is not simple, but multiple, with multiplicity of k, then the limit form of Equation 4.28 will be

$$1 + \delta x \left[\frac{K_{ip}^{(1)}}{s - p_i} + \frac{K_{ip}^{(2)}}{(s - p_i)^2} + \cdots + \frac{K_{ip}^{(k)}}{(s - p_i)^k}\right] = 0 \tag{4.31}$$

If now $s = p_i + \Delta p_i$ is substituted in Equation 4.31 and only the largest term is kept, one finds that

$$\Delta p_i = \left[-\delta x K_{ip}^{(k)}\right]^{1/k} \tag{4.32}$$

Hence, these new simple roots of $D(s)$ are equiangularly spaced on a circle around p_i.

Similar calculations with similar results can be obtained for the zeros z_i of the function $F(s)$. They, together with the calculation for poles, allow one to establish the relationship between relative sensitivity of $F(s)$ and the sensitivities of its zeros and poles. Indeed, taking into consideration Equation 4.19, the result (Equation 4.13) can be rewritten as

$$\mathbf{S}_x^{F(s)} = \frac{xN_2(s)}{N(s)} - \frac{xD_2(s)}{D(s)} = H(s) - G(s) \tag{4.33}$$

Expanding both $H(s)$ and $G(s)$ into sums of simple ratios, one obtains

$$\mathbf{S}_x^{F(s)} = \sum_{i=1}^{n} \frac{\mathbf{S}_x(p_i)}{s - p_i} - \sum_{i=1}^{m} \frac{\mathbf{S}_x(z_i)}{s - z_i} + K_{0z} - K_{0p} \tag{4.34}$$

Here, $K_{0z} = H(\infty)$, $K_{0p} = G(\infty)$, and it is assumed that both zeros and poles of $F(s)$ are simple. Finally, a useful modification is obtained for the case when a coefficient d_k in the polynomial $D(s) = d_0 + d_1 s + d_2 s^2 + \cdots$ is considered as a variable parameter. If d_k is substituted by $d_k + \Delta d_k$, the polynomial $D(s)$ becomes $D(s) + \Delta d_k s^k$. For this case the function $G(s) = (\delta d_k s^k)/D(s)$ and one can write that

$$1 + \frac{\Delta d_k s^k}{D(s)} = 1 + \frac{\Delta d_k s^k}{(s - p_i)D'(s)} \tag{4.35}$$

Here $D'(s) = \partial D(s)/\partial s$ and it can be assumed that p_i is a simple root of $D(s)$. Hence, in the vicinity of $s = p_i + \Delta p_i$, the value of Δp_i can be obtained from the equation

$$1 + \frac{\Delta d_k p_i^k}{\Delta p_i D'(p_i)} = 0 \tag{4.36}$$

From Equation 4.36, one finds that

$$\frac{\Delta p_i}{\Delta d_k} = -\frac{p_i^k}{D'(p_i)} \tag{4.37}$$

and, if necessary, the pole-coefficient sensitivity

$$\mathbf{S}_{d_k}(p_i) = \frac{\partial p_i}{\partial d_k / d_k} = -d_k \frac{p_i^k}{D'(p_i)} \tag{4.38}$$

4.6 Statistical Model for One Variable

Assume that x is the value of a filter element. This x differs from the average value $\bar{x}$ in a way that cannot be controlled by the filter designer. This situation can be modeled by considering x as a random variable. Its statistical distribution depends on the manufacturing process. An approximate calculation is sufficient in most practical cases. If $F(s, x)$ is a filter function that depends on x, then the variation $F(s, x)$ around the average value $\bar{x}$ can be approximated by

$$F(s, x) \approx F(s, \bar{x}) + (x - \bar{x}) \frac{\partial F(s, x)}{\partial x}\Big|_{x=\bar{x}} \tag{4.39}$$

The statistical interpretation of Equation 4.29 follows. Due to its dependence on the random variable, it becomes a random variable as well. The values $\bar{x}$, $F(s,\bar{x}) = \bar{F}(s)$, and $\partial F(s,x)/\partial x$ calculated at $x = \bar{x}$ are constants. The last constant can be denoted as $\partial F(s,\bar{x})/\partial x$. Instead of x and $F(s,x)$ it is preferable to use their relative deviations from the average values, namely $\delta x = (x - \bar{x})/\bar{x}$ and $\delta F(s) = (F - \bar{F})/\bar{F}$. Then one obtains from Equation 4.39 that

$$\delta F(s) = \left[\frac{\bar{x}}{F(s,\bar{x})}\frac{\partial F(s,\bar{x})}{\partial x}\right]\delta x = \mathbf{S}_x^{F(s,\bar{x})}\delta x \tag{4.40}$$

Hence, in the first-order approximation the random variables $\delta F(s)$ and δx are proportional, and the proportionality factor is the same sensitivity of $F(s,x)$ with respect to x calculated at the average point $\bar{x}$. Thus, on the $j\omega$ axis the average and the variance of $\delta F(j\omega)$ and δx are related by

$$\mu_{\delta F} \approx \mathbf{S}_x^{F(s,\bar{x})}\mu_{\delta x} \tag{4.41}$$

and

$$\sigma_{\delta F}^2 = E\left\{\left|\frac{F(j\omega,x) - F(j\omega,\bar{x})}{F(j\omega,\bar{x})}\right|^2\right\} \approx |\mathbf{S}^{F(j\omega,\bar{x})}|^2\sigma_{\delta x}^2 \tag{4.42}$$

where $E = \{\}$ means the expected value. Here, $\mu_{\delta x}$ is the average value of δx, $\mu_{\delta F}$ is the average value of δF, and $\sigma_{\delta x}^2$ and $\sigma_{\delta F}^2$ are the dispersions of these values. If the deviation δx is bound by the modulus $M_{\delta x}$, i.e., the probability distribution is concentrated in the interval $[-M_{\delta x}, M_{\delta x}]$, then the deviation δF is bound in the first approximation by

$$|\delta F| \le M_{\delta F} \approx |\mathbf{S}_x^{F(j\omega,\bar{x})}|M_{\delta x} \tag{4.43}$$

Normally, the probability distribution of x should be centered around the average value $\bar{x}$, so that it can be assumed $\mu_{\delta x} = 0$. This implies that $\mu_{\delta F} = 0$ as well.

It is not difficult to see that Equations 4.8 and 4.40 are different by interpretation of δx and δF (since these were deflections from the nominal point, it was tacitly assumed that we were dealing with one sample of the filter, here they are random) and the point of calculation of sensitivity. The interpretation with a random variable is possible for Equation 4.9 as well. One has to determine $\delta|F| = [|F(j\omega,x)| - |F(j\omega,\bar{x})|]/|F(j\omega,\bar{x})|$, then using Equation 4.9 one can write

$$\mu_{\delta|F|} \approx \mathrm{Re}\,\mathbf{S}_x^{F(s,\bar{x})}\mu_{\delta x} \tag{4.44}$$

and

$$\sigma_{\delta|F|}^2 \approx \left(\mathrm{Re}\,\mathbf{S}_x^{F(j\omega,\bar{x})}\right)^2\sigma_{\delta x}^2 \tag{4.45}$$

The result (Equation 4.11) can also be interpreted for random variables and allows one to calculate the average and the variance of the change in the filter function argument (which is hardly ever done in filter design).

4.7 Multiparameter Sensitivities and Sensitivity Measures

The multiparameter sensitivities (sometimes [4] they are called sensitivity indices) appear as an effort to introduce generalized functions that represent the influence of all filter elements. They can be used for

comparison of different designs and should be minimized in the design process. The sensitivity measures appear as numbers (they are functionals of the parameter sensitivities) that should be minimized in the design.

First of all, the definition of function sensitivity given in Equation 4.5 is readily extended to determine the effect on the filter function of variation of more than one component. In this case $F(s, x_1, x_2, \ldots, x_n) = F(s, \mathbf{x})$ and one may write that

$$\frac{\mathrm{d}F(s,\mathbf{x})}{F(s,\mathbf{x})} = \mathrm{d}[\ln F(s,\mathbf{x})] = \sum_{i=1}^{n} \mathbf{S}_{x_i}^{F(s,\mathbf{x})} \frac{\mathrm{d}x_i}{x_i} \tag{4.46}$$

where n is the number of components being considered. Here $\mathbf{S}_{x_i}^{F(s,\mathbf{x})} = [x_i \partial F(s,\mathbf{x})]/[F(s,\mathbf{x})\partial x_i]$. From this result one directly (substituting $s = j\omega$ and separating real and imaginary parts) obtains that

$$\frac{\mathrm{d}|F(j\omega,\mathbf{x})|}{|F(j\omega,\mathbf{x})|} = \sum_{i=1}^{n} \mathrm{Re}\, \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \frac{\mathrm{d}x_i}{x_i} \tag{4.47}$$

and

$$\mathrm{d}\arg F(j,\omega) = \sum_{i=1}^{n} \mathrm{Im}\, \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \frac{\mathrm{d}x_i}{x_i} \tag{4.48}$$

The results (Equations 4.47 and 4.48) are used to evaluate the deviations of the magnitude and phase values of a given filter realization from their nominal values when the circuit elements have prescribed normalized deviations $\delta x_i = (x_i - x_{i0})/x_{i0}$ $(i = 1, 2, \cdots n)$. One can introduce a column vector of normalized deviation $[\delta x_1 \delta x_2 \cdots \delta x_n]^{\mathrm{t}}$, where t means transpose and a sensitivity row vector

$$\mathbf{S}_{\mathbf{x}}^{F(s,\mathbf{x})} = \left[\mathbf{S}_{x_1}^{F(s,\mathbf{x})} \mathbf{S}_{x_2}^{F(s,\mathbf{x})} \cdots \mathbf{S}_{x_n}^{F(s,\mathbf{x})}\right] \tag{4.49}$$

Then defining $\delta F(s,\mathbf{x}) = [F(s,\mathbf{x}) - F(s,\mathbf{x}_0)]/F(s,\mathbf{x}_0)$, one can use Equation 4.46 to write

$$\delta F(s,\mathbf{x}) \approx \mathbf{S}_{\mathbf{x}}^{F(s,\mathbf{x})} \delta\mathbf{x} \tag{4.50}$$

which is analogous to Equation 4.8. As was mentioned before, the calculation of the filter function magnitude change is traditionally considered of primary importance in filter design. Introducing $\delta|F(s,\mathbf{x})| = [|F(j\omega,\mathbf{x})| - |F(j\omega,\mathbf{x}_0)|]/|F(j\omega,\mathbf{x}_0)|$ and using Equation 4.47 one writes

$$\delta|F(j\omega,\mathbf{x})| \approx \left[\mathrm{Re}\, \mathbf{S}_{x}^{F(j\omega,\mathbf{x})}\right] \delta\mathbf{x} \tag{4.51}$$

where the row vector

$$\left[\mathrm{Re}\, \mathbf{S}_{x}^{F(j\omega,\mathbf{x})}\right] = \left[\mathrm{Re}\, \mathbf{S}_{x_1}^{F(j\omega,\mathbf{x})} \mathrm{Re}\, \mathbf{S}_{x_2}^{F(j\omega,\mathbf{x})} \cdots \mathrm{Re}\, \mathbf{S}_{x_n}^{F(j\omega,\mathbf{x})}\right] \tag{4.52}$$

is used. This vector is determined by the function $F(s,\mathbf{x})$ and its derivatives calculated at $\mathbf{x} = \mathbf{x}_0$. To characterize and compare the vectors of this type, one can introduce different vector measures that are called *sensitivity indices*. The most frequently used ones are the *average sensitivity index*

$$\psi(F) = \sum_{i=1}^{n} \mathrm{Re}\, \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \tag{4.53}$$

then the *worst-case sensitivity index*

$$\nu(F) = \sum_{i=1}^{n} \left| \operatorname{Re} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \right| \tag{4.54}$$

(sometimes it is called worst-case magnitude sensitivity), and, finally, the *quadratic sensitivity index*

$$\rho(F) = \left[\sum_{i=1}^{n} \left(\operatorname{Re} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \right)^2 \right]^{1/2} \tag{4.55}$$

These sensitivity indices can be considered as multiparameter sensitivities.

If we let the individual nominal values of n elements be given as x_{i0}, then we may define a tolerance constant ε_i (positive number) by the requirement that

$$x_{i0}(1 - \varepsilon_i) \le x_i \le x_{i0}(1 - \varepsilon_i) \tag{4.56}$$

Then we may define a worst-case measure of sensitivity

$$M_{\mathrm{W}} = \int_{\omega_1}^{\omega_2} \left(\sum_{i=1}^{n} \left| \operatorname{Re} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \right| \varepsilon_i \right) \mathrm{d}\omega \tag{4.57}$$

The goal of the filter design should be the search for the set of tolerance constants yielding the least expensive in the production filter. This is a difficult problem, and at the design stage it can be modeled by the minimization of the chosen sensitivity measure. In the design based on the worst-case measure of sensitivity, the usual approach [2] is to choose the tolerance constants in such a way that the contributions $\left| \operatorname{Re} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \right| \varepsilon_i$ are approximately equal, i.e., the elements with lower sensitivities get wider tolerance constants.

For any values of the filter elements x_i satisfying Equation 4.56, the magnitude characteristic will lie within the definite bounds that are apart from the nominal characteristic by the distance less than $\varepsilon_{i\max} \nu(F)$. If the tolerance constants are all equal to ε, then the maximum deviation from the nominal characteristic (when $\mathbf{x} = \mathbf{x}_0$) is thus given as $\varepsilon \nu(F)$. And the worst-case measure of sensitivity becomes, for this case

$$M_{\mathrm{W}} = \varepsilon \int_{\omega_1}^{\omega_2} \nu(F) \mathrm{d}\omega \tag{4.58}$$

Considering the imaginary parts of the sensitivity row vector one can introduce corresponding sensitivity indices and similar sensitivity measures for the filter function phase.

The element tolerances obtained using the worst-case sensitivity index and measures are extremely tight and this set of elements is frequently unfeasible. Besides, with given tolerances, the set of elements producing the worst-case sensitivity is never obtained in practice. A more feasible set of tolerances is obtained when one uses the sum of the squares of the individual functions. One may define a *quadratic measure of sensitivity* as

$$M_{\mathrm{Q}} = \int_{\omega_1}^{\omega_2} \left[\sum_{i=1}^{n} \left(\operatorname{Re} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \right)^2 \varepsilon_i^2 \right] \mathrm{d}\omega \tag{4.59}$$

In the design using the sensitivity measure given by Equation 4.59 one also tries to get the tolerances so that the contributions of each term $\left(\mathrm{Re}\,\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right)^2\varepsilon_i^2$ are approximately equal in the considered bandwidth. Again, if the tolerances are equal, then this expression is simplified to

$$M_Q = \varepsilon^2 \int_{\omega_1}^{\omega_2} \rho^2(F)\mathrm{d}\omega \tag{4.60}$$

which is useful for comparison of different filters.

As one can see, the multivariable sensitivities appear as a result of certain operations with the sensitivity row vector components. Additional multivariable sensitivities could be introduced, for example, the sum of magnitudes of vector components, the sum of their squares, etc. The multivariable sensitivities and the measures considered above represent the most frequently used filter design in the context of filter characteristic variations.

The case of random variables can also be generalized so that imprecisions of the values of several elements are simultaneously considered. Around the nominal value $\bar{\mathbf{x}} = [\bar{x}_i]$ $(i = 1, 2, \cdots n)$ the function $F(s, \bar{\mathbf{x}})$ can be approximated as

$$F(s, \mathbf{x}) \approx F(s, \bar{\mathbf{x}}) + \sum_{i=1}^{n} (x - \bar{x}_i) \frac{\partial F(s, \mathbf{x})}{\partial x_i} \tag{4.61}$$

And from this approximation one obtains

$$\delta F(s, \mathbf{x}) \approx \sum_{i=1}^{n} \mathbf{S}_{x_i}^{F(s,\mathbf{x})} \delta x_i \tag{4.62}$$

Here, $\delta F(s, x) = [F(s, \boldsymbol{x}) - F(s, \overline{\boldsymbol{x}})]/F(s, \overline{\boldsymbol{x}})$ and $\delta x_i = (x_i - \bar{x}_i)/\bar{x}_i$ $(i = 1, 2, \cdots n)$. This result can be rewritten as

$$\delta F(s, \mathbf{x}) \approx \mathbf{S}_{\mathbf{x}}^{F(s,\mathbf{x})} \delta \mathbf{x} \tag{4.63}$$

and is completely analogous to Equation 4.50. It is different in interpretation only. The components of the column vector $[\delta x_1 \delta x_2 \cdots \delta x_n]^{\mathrm{t}}$ are the random variables now and the components of the row vector $\mathbf{S}_{\mathbf{x}}^{F(s,\mathbf{x})} = \left[\mathbf{S}_{\mathbf{x}_1}^{F(s,\mathbf{x})} \mathbf{S}_{\mathbf{x}_2}^{F(s,\mathbf{x})} \cdots \mathbf{S}_{\mathbf{x}_n}^{F(s,\mathbf{x})}\right]$ are calculated at the point $\mathbf{x} = \bar{\mathbf{x}}$.

This interpretation allow us to obtain from Equation 4.63 that on the $j\omega$ axis

$$\mu_{\delta F} = \sum_{i=1}^{n} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \mu_i \tag{4.64}$$

Here, μ_i is the average of δx_i. If all μ_i are equal, i.e., $\mu_i = \mu_x$ $(i = 1, 2, \cdots n)$, one can introduce the average sensitivity index

$$\psi(F) = \sum_{i=1}^{n} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \tag{4.65}$$

Using Equation 4.65, the average value can be calculated as $\mu_{\delta F} = \mu_x \psi(F)$. If, in addition, the deviation of δx_i is bound by M_i, then

$$M_{\delta F} \le \sum_{i=1}^{n} \left|\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right| M_i \tag{4.66}$$

If the elements of a filter have the same precision, which means that all M_i are equal, it is reasonable to introduce the worst-case sensitivity index

$$\nu(F) = \sum_{i=1}^{n} \left|\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right| \tag{4.67}$$

so that when all M_i are equal to M_x, $M_{\delta F} = M_x \nu(F)$. Finally, one can calculate $\sigma_{\delta F}^2 = E\{[\delta F(j\omega, \mathbf{x})]^* \delta F(j\omega, \mathbf{x})\}$ (here * means complex conjugate) or

$$\sigma_{\delta F}^2 = E\left\{\left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})}\delta\mathbf{x}\right)^*\left(\mathbf{S}_{\boldsymbol{x}}^{F(j\omega,\mathbf{x})}\delta\mathbf{x}\right)\right\} \tag{4.68}$$

To take into consideration possible correlation between the components δx_i one can do the following. The value of $\left(\mathbf{S}_{\boldsymbol{x}}^{F(j\omega,\mathbf{x})}\delta\mathbf{x}\right)$ is a scalar. Then

$$\left(\mathbf{S}_{\boldsymbol{x}}^{F(j\omega,\mathbf{x})}\delta\mathbf{x}\right) = \left(\mathbf{S}_{\boldsymbol{x}}^{F(j\omega,\mathbf{x})}\delta\mathbf{x}\right)^{\mathrm{t}} = (\delta\mathbf{x})^t\left(\mathbf{S}_{\boldsymbol{x}}^{F(j\omega,\mathbf{x})}\right)^{\mathrm{t}} \tag{4.69}$$

Substituting this result into Equation 4.68 one obtains that

$$\sigma_{\delta F}^2 = E\left\{ \left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})}\right)^*(\delta\mathbf{x})^*(\delta\mathbf{x})^{\mathrm{t}}\left(\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right)^{\mathrm{t}} \right\} \tag{4.70}$$

But the components of $\delta\mathbf{x}$ are real, i.e., $(\delta\mathbf{x})^* = \delta\mathbf{x}$ and the result of multiplication in the curly brackets of Equation 4.70 is a square $n \times n$ matrix. Then $E\{(\delta\mathbf{x})^*(\delta\mathbf{x})^{\mathrm{t}}\}$ is also a square matrix

$$[\mathbf{P}] = \begin{bmatrix} \sigma_{x_1}^2 & \rho_{x_1x_2} & \cdots & \rho_{x_1x_n} \\ \rho_{x_2x_1} & \sigma_{x_2}^2 & \cdots & \rho_{x_2x_n} \\ \vdots & \vdots & \ddots & \vdots \\ \rho_{x_nx_1} & \cdots & \cdots & \sigma_{x_n}^2 \end{bmatrix} \tag{4.71}$$

the diagonal elements of which are variances of δx_i and off-diagonal terms are nonnormalized correlation coefficients. Then, Equation 4.70 can be rewritten as

$$\sigma_{\delta F}^2 = \left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})}\right)^*[\mathbf{P}]\left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})}\right)^{\mathrm{t}} \tag{4.72}$$

which is sometimes [4] called the propagation-of-variance formula. In the absence of correlation between the variations δx_i the matrix $[\mathbf{P}]$ has the diagonal terms only and Equation 4.72 becomes

$$\sigma_{\delta F}^2 = \sum_{i=1}^{n} \left|\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right|^2 \sigma_{x_i}^2 \tag{4.73}$$

If all $\sigma_{x_i}^2$ are equal to σ_x^2 one can introduce a quadratic sensitivity index

$$\rho(F) = \left[\sum_{i=1}^{n} \left|\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right|^2\right]^{1/2} \tag{4.74}$$

and in this case $\sigma^2_{\delta F} = \rho^2(F)\sigma^2_x$ (the value $\rho^2(F)$ is sometimes called Schoeffler multivariable sensitivity). One can also introduce two sensitivity measures, namely, the worst-case sensitivity measure

$$M_{\mathrm{W}} = \int_{\omega_1}^{\omega_2} \left(\sum_{i=1}^{n} \left| \mathrm{Re}\, \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \right| \mu_i \right) \mathrm{d}\omega \tag{4.75}$$

and the quadratic sensitivity measure

$$M_{\mathrm{Q}} = \int_{\omega_1}^{\omega_2} \left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})} \right)^{*} [\mathbf{P}] \left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})} \right)^{\mathrm{t}} \mathrm{d}\omega \tag{4.76}$$

which, when the correlation between the elements of $\delta\mathbf{x}$ is absent, becomes

$$M_{\mathrm{Q}} = \int_{\omega_1}^{\omega_2} \left[\sum_{i=1}^{n} \left| \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \right|^2 \sigma_i^2 \right] \mathrm{d}\omega \tag{4.77}$$

Here, for simplicity the notation $\sigma_i = \sigma_{x_i}$ is used.

The sensitivity indices and sensitivity measures introduced for the case when $\delta\mathbf{x}$ is a random vector are cumulative; they take into consideration the variation of the amplitude and phase of the filter function. For this reason some authors prefer to use the indices as they are defined in Equations 4.65, 4.67, and 4.74 and the measures as they are defined by Equations 4.75 and 4.77 for the deterministic cases as well (the deterministic case does not assume any correlation between the variations δx_i), with the corresponding substitution of μ_i by ε_i and σ_i^2 by ε_i^2. From the other side, one can take Equation 4.51 and use it for the case of random vector $\delta\mathbf{x}$ considering, for example, the variation $\delta|F(j\omega,\mathbf{x})|$ as a random variable and calculating $\mu_{\delta|F|}$ and $\sigma^2_{\delta|F|}$, which will be characteristics of this variable. In this case one can use the results (Equations 4.75, 4.77, etc.) substituting $\mathbf{S}_{x_i}^{F(s,\mathbf{x})}$ by $\mathrm{Re}\,\mathbf{S}_{x_i}^{F(s,\mathbf{x})}$. These possibilities are responsible for many formulations of multiparameter sensitivities that represent different measures of the vector $\mathbf{S}_{\boldsymbol{x}}^{F(s,\mathbf{x})}$. In the design based, for example, on Equations 4.75 and 4.77, one determines the required $\sigma^2_{\delta F}$ using the reject probability [2] depending on the ratio of $\varepsilon_{\delta F}/\sigma_{\delta F}$. Here, $\varepsilon_{\delta F}$ is the tolerance of $|\delta F(j\omega,\mathbf{x})|$ and in many cases one takes $\varepsilon_{\delta F}/\sigma_{\delta F} = 2.5$ which gives the reject probability of 0.01. Then, one determines the dispersion σ_i^2 so that the contributions of each term in Equation 4.77 are equal. Finally, using the probability function that describes the distribution of δx_i within the tolerance borders one finds these borders (if, for example, the selected element has evenly distributed values $-\varepsilon_i \le \delta x_i \le \varepsilon_i$, then $\varepsilon_i = \sqrt{3}\sigma_i$; for Gaussian distribution one frequently accepts $\varepsilon_i = 2.5\sigma_i$).

The preliminary calculation of the coefficient sensitivities is useful for finding the sensitivity measures. If, for example, one calculates a multivariable statistical measure of sensitivity then one can consider that

$$F(j\omega,\mathbf{x}) = \frac{a_0 + a_1(j\omega) + \cdots + a_m(j\omega)^m}{d_0 + d(j\omega) + \cdots + d_n(j\omega)^n} = F(j\omega,\mathbf{a},\mathbf{d},\mathbf{x}) \tag{4.78}$$

where

$$\mathbf{a} = [\, a_0 \quad a_1 \quad \cdots \quad a_m \,]^{\mathrm{t}}$$
$$\mathbf{d} = [\, d_0 \quad d_1 \quad \cdots \quad d_n \,]^{\mathrm{t}}$$

Then, the components $\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}$ defined earlier can be rewritten as

$$\begin{aligned}\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} &= \frac{x_i}{F(j\omega,\mathbf{x})}\left[\frac{\partial \mathbf{a}^t}{\partial x_i}\nabla_a F(j\omega,\mathbf{x}) + \frac{\partial \mathbf{d}^t}{\partial x_i}\nabla_d F(j\omega,\mathbf{x})\right] \\ &= \frac{1}{F(j\omega,\mathbf{x})}\left[\sum_{j=0}^{m}\frac{\partial F(j\omega,\mathbf{x})}{\partial a_j}\mathbf{S}_{x_i}(a_j) + \sum_{j=0}^{n}\frac{\partial F(j\omega,\mathbf{x})}{\partial d_j}\mathbf{S}_{x_i}(d_j)\right] \end{aligned} \tag{4.79}$$

where

$$\nabla_a F(j\omega,\mathbf{x}) = [\partial F(j\omega,\mathbf{x})/\partial a_0\ \partial F(j\omega,\mathbf{x})/\partial a_1 \cdots \partial F(j\omega,\mathbf{x})/\partial a_m]^{\mathrm{t}}$$

and

$$\nabla_d F(j\omega,\mathbf{x}) = [\partial F(j\omega,\mathbf{x})/\partial d_0\ \partial F(j\omega,\mathbf{x})/\partial d_1 \cdots \partial F(j\omega,\mathbf{x})/\partial d_n]^{\mathrm{t}}$$

For a given transfer function, the components of the vectors $\nabla_a F(j\omega,\mathbf{x})$ and $\nabla_d F(j\omega,\mathbf{x})$ are independent of the form of the realization or the values of the elements and can be calculated in advance. If we now define a matrix $k \times (m+1)$ $\mathbf{C}_1$ as

$$\mathbf{C}_1 = \begin{bmatrix} \mathbf{S}_{x_1}(a_0) & \mathbf{S}_{x_1}(a_1) & \cdots & \mathbf{S}_{x_1}(a_m) \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{S}_{x_k}(a_0) & \mathbf{S}_{x_k}(a_1) & \cdots & \mathbf{S}_{x_k}(a_m) \end{bmatrix} \tag{4.80}$$

and $k \times (n+1)$ matrix $\mathbf{C}_2$ as

$$\mathbf{C}_2 = \begin{bmatrix} \mathbf{S}_{x_1}(d_0) & \mathbf{S}_{x_1}(d_1) & \cdots & \mathbf{S}_{x_1}(d_n) \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{S}_{x_k}(d_0) & \mathbf{S}_{x_k}(d_1) & \cdots & \mathbf{S}_{x_k}(d_n) \end{bmatrix} \tag{4.81}$$

then one can rewrite

$$\left[\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})}\right]^t = \left[\mathbf{S}_{x_1}^{F(j\omega,\mathbf{x})}\mathbf{S}_{x_2}^{F(j\omega,\mathbf{x})}\cdots\mathbf{S}_{x_k}^{F(j\omega,\mathbf{x})}\right]^t = \mathbf{C}_1\frac{\nabla_a F(j\omega,\mathbf{x})}{F(j\omega,\mathbf{x})} + \mathbf{C}_2\frac{\nabla_d F(j\omega,\mathbf{x})}{F(j\omega,\mathbf{x})} \tag{4.82}$$

Then, the multiparameter sensitivity measure can be written as

$$M_{\mathrm{Q}} = \int_{\omega_1}^{\omega_2}\left[\left(\frac{\nabla_a F}{F}\right)^{*_t}\mathbf{C}_1^t\mathbf{P}\mathbf{C}_1\left(\frac{\nabla_a F}{F}\right) + \left(\frac{\nabla_d F}{F}\right)^{*_t}\mathbf{C}_2^t\mathbf{P}\mathbf{C}_2\left(\frac{\nabla_d F}{F}\right)\right]\mathrm{d}\omega + \int_{\omega_1}^{\omega_2} 2\mathrm{Re}\left[\left(\frac{\nabla_a F}{F}\right)^{*_t}\mathbf{C}_1^t\mathbf{P}\mathbf{C}_2\left(\frac{\nabla_d F}{F}\right)\right]\mathrm{d}\omega \tag{4.83}$$

and this definition of statistical multiparameter sensitivity measure may be directly applied to a given network realization. In a similar fashion, the matrices of unnormalized coefficient sensitivities can be used with other multiparameter sensitivity measures.

4.8 Sensitivity Invariants

When one is talking about sensitivity invariants [5–7], it is assumed that for a filter function $F(s, \mathbf{x})$ there exists the relationship

$$\sum_{i=1}^{n} \mathbf{S}_{x_i}^{F(s,\mathbf{x})} = k \tag{4.84}$$

where
$\mathbf{x} = [x_1 x_2 \cdots x_n]^t$, as usual,
k is a constant

These relationships are useful to check the sensitivity calculations. In the cases considered below, this constant can have one of three possible values, namely, 1, 0, and −1, and the sensitivity invariants are obtained from the homogeneity of some of the filter functions.

The function $F(s, \mathbf{x})$ is called homogeneous of order k with respect to the vector $\mathbf{x}$ if and only if it satisfies the relationship

$$F(s, \lambda\mathbf{x}) = \lambda^k F(s, \mathbf{x}) \tag{4.85}$$

where λ is an arbitrary scalar. For the homogeneous function $F(s, \mathbf{x})$ the sensitivities are related by Equation 4.84. Indeed, if one takes the logarithm of both sides of Equation 4.85, one obtains

$$\ln F(s, \lambda\mathbf{x}) = k \ln \lambda + \ln F(s, \mathbf{x}) \tag{4.86}$$

Taking the derivative of both sides of Equation 4.86 with respect to λ one obtains that

$$\frac{1}{F(s, \lambda\mathbf{x})} \left[\sum_{i=1}^{n} \frac{\partial F(s, \lambda\mathbf{x})}{\partial(\lambda x_i)} x_i \right] = \frac{K}{\lambda} \tag{4.87}$$

Substituting $\lambda = 1$ in Equation 4.87 gives Equation 4.84.

Let the filter be a passive *RLC* circuit that includes r resistors, l inductors, and c capacitors, so that $r + l + c = n$ and $\mathbf{x} = [R_1 R_2 \cdots R_r L_1 L_2 \cdots L_l D_1 D_2 \cdots D_c]$, where $D_i = 1/C_i$. One of the frequently used operations is the impedance scaling. If the scaling operation is applied to a port impedance or a transimpedance of the filter, i.e., $F(s, \mathbf{x}) = Z(s, \mathbf{x})$, then

$$Z(s, \lambda\mathbf{x}) = \lambda Z(s, \mathbf{x}) \tag{4.88}$$

Equation 4.88 is identical to Equation 4.85, with $k = 1$. Then, one can write that

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{Z(s,\mathbf{x})} + \sum_{i=1}^{l} \mathbf{S}_{L_i}^{Z(s,\mathbf{x})} + \sum_{i=1}^{c} \mathbf{S}_{D_i}^{Z(s,\mathbf{x})} = 1 \tag{4.89}$$

Considering that $D_i = 1/C_i$ and $\mathbf{S}_{C_i}^{Z(s,\mathbf{x})} = -\mathbf{S}_{D_i}^{Z(s,\mathbf{x})}$ (see Table 4.1), this result can be rewritten as

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{Z(s,\mathbf{x})} + \sum_{i=1}^{l} \mathbf{S}_{L_i}^{Z(s,\mathbf{x})} - \sum_{i=1}^{c} \mathbf{S}_{C_i}^{Z(s,\mathbf{x})} = 1 \tag{4.90}$$

If the same scaling operation is applied to a port admittance or a transadmittance of the filter, i.e., $F(s, \mathbf{x}) = Y(s, \mathbf{x})$, then,

$$Y(s, \lambda\mathbf{x}) = \lambda^{-1} Y(s, \mathbf{x}) \tag{4.91}$$

But Equation 4.91 is identical to Equation 4.85, with $k = -1$. Then,

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{Y(s,\mathbf{x})} + \sum_{i=1}^{l} \mathbf{S}_{L_i}^{Y(s,\mathbf{x})} - \sum_{i=1}^{c} \mathbf{S}_{C_i}^{Y(s,\mathbf{x})} = -1 \tag{4.92}$$

Finally, the transfer functions (voltage or current) do not depend on the scaling operation, i.e., if $F(s, \mathbf{x}) = T(s, \mathbf{x})$, hence,

$$T(s, \lambda\mathbf{x}) = T(s, \mathbf{x}) \tag{4.93}$$

which is identical to Equation 4.85, with $k = 0$. Then,

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{T(s,\mathbf{x})} + \sum_{i=1}^{l} \mathbf{S}_{L_i}^{T(s,\mathbf{x})} - \sum_{i=1}^{c} \mathbf{S}_{C_i}^{T(s,\mathbf{x})} = 0 \tag{4.94}$$

Additional sensitivity invariants can be obtained using the relation $\mathbf{S}_{x_i}^{F(s,\mathbf{x})} = -\mathbf{S}_{1/x_i}^{Z(s,\mathbf{x})}$ and using $G_i = 1/R_i$ and $\Gamma_i = 1/L_i$.

Another group of sensitivity invariants is obtained using the frequency scaling operation. The following relationship is held for a filter function:

$$F(s, R_i, \lambda L_i, \lambda C_i) = F(\lambda s, R_i, L_i, C_i) \tag{4.95}$$

Taking the logarithm of both parts, then differentiating both sides with respect to λ and substituting $\lambda = 1$ in both sides gives

$$\sum_{i=1}^{l} \mathbf{S}_{L_i}^{F(s,\mathbf{x})} + \sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(s,\mathbf{x})} = \mathbf{S}_{s}^{F(s,\mathbf{x})} \tag{4.96}$$

Substituting $s = j\omega$ in Equation 4.96 and dividing the real and imaginary parts, one obtains

$$\mathrm{Re} \sum_{i=1}^{l} \mathbf{S}_{L_i}^{F(j\omega,\mathbf{x})} + \mathrm{Re} \sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(j\omega,\mathbf{x})} = \omega \frac{\partial \ln |T(\omega)|}{\partial \omega} = -\frac{\partial \alpha(\omega)}{\partial \omega} \tag{4.97}$$

and

$$\mathrm{Im} \sum_{i=1}^{l} \mathbf{S}_{L_i}^{F(j\omega,\mathbf{x})} + \mathrm{Im} \sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(j\omega,\mathbf{x})} = \omega \frac{\partial \arg T(\omega)}{\partial \omega} \tag{4.98}$$

The results (Equations 4.97 and 4.98) show that in an *RLC* filter, when all inductors and capacitors (but not resistors) are subjected to the same relative change, then the resulting change in the magnitude

characteristic does not depend on the circuit realization and is determined by the slope of the magnitude characteristic at a chosen frequency. A similar statement is valid for the phase characteristic.

The sensitivity invariants for passive *RC* circuits can be obtained from the corresponding invariants for passive *RLC* circuits omitting the terms for sensitivities to the inductor variations. The results can be summarized the following way. For a passive *RC* circuit

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{F(s,\mathbf{x})} - \sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(s,\mathbf{x})} = k \tag{4.99}$$

where $k = 1$ if $F(s, \mathbf{x})$ is an input impedance or transimpedance function, then $k = 0$ if $F(s, \mathbf{x})$ is a voltage- or current-transfer function, and $k = -1$ if $F(s, \mathbf{x})$ is an input admittance or transconductance function. Application of the frequency scaling gives the result

$$\sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(s,\mathbf{x})} = \mathbf{S}_{s}^{F(s,\mathbf{x})} \tag{4.100}$$

and combination of Equations 4.99 and 4.100 gives

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{F(s,\mathbf{x})} = \mathbf{S}_{s}^{F(s,\mathbf{x})} + k \tag{4.101}$$

and

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{F(s,\mathbf{x})} + \sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(s,\mathbf{x})} = 2\mathbf{S}_{s}^{F(s,\mathbf{x})} + k \tag{4.102}$$

Considering real and imaginary parts of Equations 4.100 through 4.102, one can obtain the results that determine the limitations imposed on the sensitivity sums by the function $F(j\omega, \mathbf{x})$ when resistors and/or capacitors are subjected to the same relative change.

Finally, if the filter is not passive, then the vector of parameters $\mathbf{x} = \begin{bmatrix} R_1 R_2 \cdots R_r L_1 L_2 \cdots L_l C_1 C_2 \cdots C_c R_{T1} R_{T2} \cdots R_{Ta} \\ G_{T1} G_{T2} \cdots G_{Tb} A_{v1} A_{v2} \cdots A_{vp} A_{i1} A_{i2} \cdots A_{iq} \end{bmatrix}$ includes the components of transresistors R_{Tk}, transconductances G_{Tk}, voltage amplifiers A_{vk}, and current amplifiers A_{ik}. Applying the impedance scaling one can obtain the sensitivity invariant

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{F(s,\mathbf{x})} + \sum_{i=1}^{l} \mathbf{S}_{L_i}^{F(s,\mathbf{x})} - \sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(s,\mathbf{x})} + \sum_{i=1}^{a} \mathbf{S}_{R_{Ti}}^{F(s,\mathbf{x})} - \sum_{i=1}^{b} \mathbf{S}_{G_{Ti}}^{F(s,\mathbf{x})} = k \tag{4.103}$$

where

$k = 1$ if $F(s, \mathbf{x})$ is an impedance function
$k = 0$ if $F(s, \mathbf{x})$ is a transfer function
$k = -1$ if $F(s, \mathbf{x})$ is an admittance function

The frequency scaling will give the same result as Equation 4.96.

The pole (or zero) sensitivities are also related by some invariant relationships. Indeed, the impedance scaling provides the result

$$p_k\left(\lambda R_i, \lambda L_i, \frac{C_i}{\lambda}\right) = p_k(R_i, L_i, C_i) \tag{4.104}$$

Taking the derivative of both sides of Equation 4.104 with respect to λ and substituting $\lambda = 1$, one obtains that for an arbitrary *RLC* circuit

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}(p_k) + \sum_{i=1}^{l} \mathbf{S}_{L_i}(p_k) - \sum_{i=1}^{c} \mathbf{S}_{C_i}(p_k) = 0 \tag{4.105}$$

This is the relationship between semirelative sensitivities. If $p_k \neq 0$ one can divide both sides of Equation 4.105 by p_k and obtain similar invariants for relative sensitivities. The frequency scaling gives

$$p_k\left(R_i, \frac{L_i}{\lambda}, \frac{C_i}{\lambda}\right) = \lambda p_k(R_i, L_i, C_i) \tag{4.106}$$

and from Equation 4.106 one obtains, for relative sensitivities only, that

$$\sum_{i=1}^{l} \mathbf{S}_{L_i}^{p_k} + \sum_{i=1}^{c} \mathbf{S}_{C_i}^{p_k} = -1 \tag{4.107}$$

The pole sensitivity invariants for passive *RC* circuits are obtained from Equations 4.106 and 4.107, omitting the terms corresponding to the inductor sensitivities.

4.9 Sensitivity Bounds

For some classes of filters, the worst-case magnitude sensitivity index may be shown to have a lower bound [8]. Such a bound, for example, exists for filters whose passive elements are limited to resistors, capacitors, and ideal transformers, and whose active elements are limited to gyrators characterized by two gyration resistances (realized as a series connection of transresistance amplifiers and considered as different for sensitivity calculations), current-controlled current sources (CCCSs), voltage-controlled voltage sources (VCVSs), voltage-controlled current sources (VCCSs), and current-controlled voltage sources (CCVSs). Using the sensitivity invariants, it is easy to show that for such a class of networks for any dimensionless transfer function $T(s)$

$$\sum_{i=1}^{n} \mathbf{S}_{x_i}^{T(s)} = 2\mathbf{S}_s^{T(s)} \tag{4.108}$$

where the x_i are taken to include only the passive elements of resistors and capacitors and the active elements of CCVSs and gyrators (if the gyrators are realized as parallel connection of transconductance amplifiers, the corresponding terms should be taken with the negative sign). Substituting $s = j\omega$ in Equation 4.108 and equating real parts, one obtains that

$$\sum_{i=1}^{n} \mathbf{S}_{x_i}^{|T(j\omega)|} = 2\mathbf{S}_{j\omega}^{|T(j\omega)|} \tag{4.109}$$

Applying Equation 4.54 to the above equations, one obtains for the worst-case magnitude sensitivity index

$$\nu(T) - \sum_{i=1}^{n} \left|\mathbf{S}_{x_i}^{|T(j\omega)|}\right| \geq \left|\sum_{i=1}^{n} \mathbf{S}^{|T(j\omega)|}\right| - \left|2\mathbf{S}^{|T(j\omega)|}\right| \tag{4.110}$$

Taking the first and the last terms of this expression, one may define a lower bound LBν(T) of the worst-case magnitude sensitivity index as

$$\mathrm{LB}\nu(T) = \left|2\mathbf{S}_{j\omega}^{|T(j\omega)|}\right| \tag{4.111}$$

This lower bound is a function only of the transfer function $T(s)$ and is independent on the particular synthesis technique (as soon as the above-mentioned restrictions are satisfied) used to realize this transfer function. A similar lower bound may be derived (taking the imaginary parts of Equation 4.108) for worst-case phase sensitivity; but it is impossible to find the design path by which one will arrive at the circuit realizing this minimal bound.

4.10 Remarks on the Sensitivity Applications

The components of active *RC* filters have inaccuracies and parasitic components that distort the filter characteristics. The most important imperfections are the following:

1. Values of the resistors and capacitors and the values of transconductances (the gyrators can be considered usually as parallel connection of two transconductance amplifiers) are different from their nominal values. The evaluation of these effects is done using the worst-case or (more frequently) quadratic multiparameter sensitivity index, and multiparameter sensitivity measures and the tolerances are chosen so that the contributions of the passive elements' variations in the sensitivity measure are equal.
2. Operational amplifiers have finite gain and this gain is frequency dependent. The effect of finite gain is evaluated using a semirelative sensitivity of the filter function with respect to variation $1/A$, where A is the operational amplifier gain. The semirelative sensitivity is

$$-\mathbf{S}^{F(s)}\left(\frac{1}{A}\right) = -\frac{\partial F(s)}{\left[F(s)\partial\left(\frac{1}{A}\right)\right]} = \left[\frac{A^2}{F(s)}\right]\left[\frac{\partial F(s)}{\partial A}\right] = A\mathbf{S}_A^{F(s)}$$

   which is called the gain-sensitivity product. In many cases, $\mathbf{S}_A^{F(s)} \to 0$ when $A \to \infty$, whereas $\mathbf{S}_{1/A}[F(s)]$ has a limit that is different from zero. The frequency dependence is difficult to take into consideration [1]. Only in case of cascade realization, as shown below, one can evaluate the effect of this frequency dependence using the sensitivity of Q-factor.
3. Temperature dependence and aging of the passive elements and operational amplifiers can be determined. The influence of temperature, aging, and other environmental factors on the values of the elements can be determined by a dependence of the probability distributions for these parameters. For example, if θ is temperature, one has to estimate $\mu_x(\theta)$ and $\sigma_x(\theta)$ before the calculation of sensitivity measures. Normally, at the nominal temperature θ_0 the average value $\mu_x(\theta_0) = 0$ and $\sigma_x(\theta_0)$ depends on the nominal precision of the elements. When the temperature changes, $\mu_x(\theta)$ increases or decreases depending on the temperature coefficients of the elements, whereas $\sigma_x(\theta)$ usually increases for any temperature variation.

4.11 Sensitivity Computations Using the Adjoint Network

The determination of the sensitivities defined in the previous sections may pose difficult computational problems. Finding the network function with the elements expressed in literal form is usually tedious and error prone and the difficulty of such a determination increases rapidly with the number of elements. Calculating the partial derivatives, which is the most important part of the sensitivity computation, provides additional tedium and increases the possibility of error still more. Thus, in general, it is advantageous to use digital computer methods to compute sensitivities. The most obvious method for doing this is to use one of

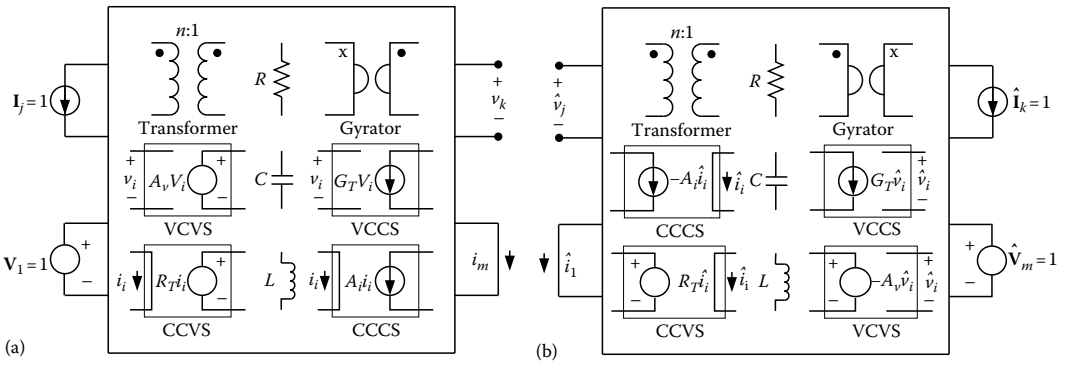

FIGURE 4.1 The components of a network (a) and its adjoint (b).

the many available computer-aided design programs (e.g., SPICE) to make an analysis of the network with nominal element values, and then repeat the analysis after having perturbed the value of one of the elements. This is not a desirable procedure, since it requires a large number of analyses. It can be justified if the network has some *a priori* known critical elements for which the analyses should be done.

The crucial part of sensitivity computation is, as was mentioned above, the calculation of network function derivatives with respect to element variations. To simplify this part of the calculation, the concept of adjoint network [9] is used. This method requires only two analyses to provide all the sensitivities of a given network immittance function.

If $\mathbf{N}$ and $\widehat{\mathbf{N}}$ are linear time invariant networks, then they are said to be adjoint (to each other) if the following hold. The two networks have the same topology and ordering of branches; thus their incidence matrices [10] are equal, namely $\mathbf{A} = \widehat{\mathbf{A}}$. If excitation with the unit current (unit voltage) at an arbitrary port j (port l) of network $\mathbf{N}$ yields a voltage (current) at an arbitrary port k (port m) of $\mathbf{N}$, excitation with the unit current (unit voltage) at port k (port m) of network $\widehat{\mathbf{N}}$ will yield the same voltage (current) as the above in port j (port l) of $\widehat{\mathbf{N}}$ (see Figure 4.1).

Figure 4.1 also shows how the adjoint network should be constructed, as follows. (a) All resistance capacitive and inductance branches and transformers in $\mathbf{N}$ are associated, respectively, with resistance, capacitive, and inductance branches and transformers in $\widehat{\mathbf{N}}$. (b) All gyrators in $\mathbf{N}$ with gyration resistance r become gyrators in $\widehat{\mathbf{N}}$ with gyration resistance $-r$. (c) All VCVSs in $\mathbf{N}$ become CCCSs in $\widehat{\mathbf{N}}$ with controlling and controlled branches reversing roles, and with the voltage amplification factor A_v becoming the current amplification factor $-A_i$. (d) All CCCSs in $\mathbf{N}$ become VCVSs in $\widehat{\mathbf{N}}$ with controlling and controlled branches reversing roles, and with the current amplification factor A_i becoming the voltage amplification factor $-A_v$. (e) All VCCCs and CCVSs have their controlling and controlled branches in $\mathbf{N}$ reversed in $\widehat{\mathbf{N}}$.

Thus, the Tellegen theorem [9] applies to the branch voltage and current variables of these two networks. If we let $\mathbf{V}$ be the vector of branch voltages and $\mathbf{I}$ be the vector of branch currents (using capital letters implies that the quantities are functions of the complex variable s), then

$$\mathbf{V}^{\mathrm{t}}\hat{\mathbf{I}} = \hat{\mathbf{I}}^{\mathrm{t}}\mathbf{V} = \widehat{\mathbf{V}}^{\mathrm{t}}\mathbf{I} = \mathbf{I}^{\mathrm{t}}\mathbf{V} = \mathbf{0} \tag{4.112}$$

If in both circuits all independent sources have been removed to form n external ports (as illustrated in Figure 4.2), then one can divide the variables in both circuits into two groups so that

$$\begin{aligned} \mathbf{I}^{\mathrm{t}} &= \left[\mathbf{I}_{\mathrm{p}}^{\mathrm{t}}\mathbf{I}_{\mathrm{b}}^{\mathrm{t}}\right] \quad \mathbf{V}^{\mathrm{t}} = \left[\mathbf{V}_{\mathrm{p}}^{\mathrm{t}}\mathbf{V}_{\mathrm{b}}^{\mathrm{t}}\right] \\ \hat{\mathbf{I}}^{\mathrm{t}} &= \left[\hat{\mathbf{I}}_{\mathrm{p}}^{\mathrm{t}}\hat{\mathbf{I}}_{\mathrm{b}}^{\mathrm{t}}\right] \quad \widehat{\mathbf{V}}^{\mathrm{t}} = \left[\widehat{\mathbf{V}}_{\mathrm{p}}^{\mathrm{t}}\widehat{\mathbf{V}}_{\mathrm{b}}^{\mathrm{t}}\right] \end{aligned} \tag{4.113}$$

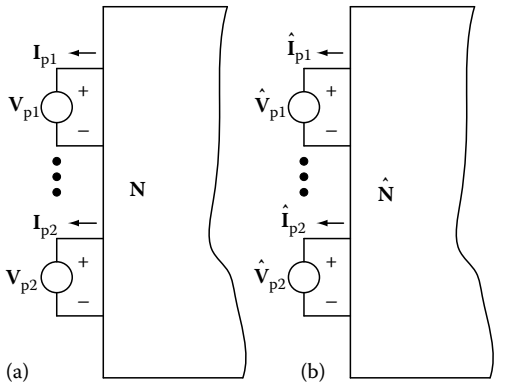

FIGURE 4.2 Separation of port variables in the network (a) and its adjoint (b).

The first are the vector of port variables $\mathbf{V}_p$ and $\mathbf{I}_p$ in $\mathbf{N}$ and $\hat{\mathbf{V}}_p$ and $\hat{\mathbf{I}}_p$, correspondingly, in $\hat{\mathbf{N}}$. These variables will define n-port open-circuit impedance matrices $\mathbf{Z}_{oc}$ and $\hat{\mathbf{Z}}_{oc}$ or n-port short-circuit admittance matrices $\mathbf{Y}_{sc}$ and $\hat{\mathbf{Y}}_{sc}$ via the relationships

$$\begin{aligned} \mathbf{V}_p &= -\mathbf{Z}_{oc}\mathbf{I}_p \quad \hat{\mathbf{V}}_p = -\hat{\mathbf{Z}}_{oc}\hat{\mathbf{I}}_p \\ \mathbf{I}_p &= -\mathbf{Y}_{sc}\mathbf{V}_p \quad \hat{\mathbf{I}}_p = -\hat{\mathbf{Y}}_{sc}\hat{\mathbf{V}}_p \end{aligned} \tag{4.114}$$

Then, the rest of the variables will be nonport variables (including the variables of dependent source branches) $\mathbf{V}_b$ and $\mathbf{I}_b$ for $\mathbf{N}$ and $\hat{\mathbf{V}}_b$ and $\hat{\mathbf{I}}_b$ for $\hat{\mathbf{N}}$. These variables may define branch impedance matrices $\mathbf{Z}_b$ and $\hat{\mathbf{Z}}_b$ and branch admittance matrices $\mathbf{Y}_b$ and $\hat{\mathbf{Y}}_b$ by the relationships

$$\begin{aligned} \mathbf{V}_b &= \mathbf{Z}_b\mathbf{I}_b \quad \hat{\mathbf{V}}_b = \hat{\mathbf{Z}}_b\hat{\mathbf{I}}_b \\ \mathbf{I}_b &= \mathbf{Y}_b\mathbf{V}_b \quad \hat{\mathbf{I}}_b = \hat{\mathbf{Y}}_b\hat{\mathbf{V}}_b \end{aligned} \tag{4.115}$$

If the branch impedance and branch admittance matrices do not exist, a hybrid matrix may be used to relate the branch variables. For $\mathbf{N}$, this may be put in the form

$$\begin{bmatrix} \mathbf{V}_{b1} \\ \mathbf{I}_{b2} \end{bmatrix} = \begin{bmatrix} \mathbf{H}_{11} & \mathbf{H}_{12} \\ \mathbf{H}_{21} & \mathbf{H}_{22} \end{bmatrix} \begin{bmatrix} \mathbf{I}_{b1} \\ \mathbf{V}_{b2} \end{bmatrix} \tag{4.116}$$

Similarly, for $\hat{\mathbf{N}}$ one may write

$$\begin{bmatrix} \hat{\mathbf{V}}_{b1} \\ \hat{\mathbf{I}}_{b2} \end{bmatrix} = \begin{bmatrix} \hat{\mathbf{H}}_{11} & \hat{\mathbf{H}}_{12} \\ \hat{\mathbf{H}}_{21} & \hat{\mathbf{H}}_{22} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{I}}_{b1} \\ \hat{\mathbf{V}}_{b2} \end{bmatrix} \tag{4.117}$$

For the adjoint networks, the branch impedance and branch admittance matrices (if they exist) are transposed, namely

$$\mathbf{Z}_b^t = \hat{\mathbf{Z}}_b \quad \mathbf{Y}_b^t = \hat{\mathbf{Y}}_b \tag{4.118}$$

and, if a hybrid representation is used, the matrices are connected by the relationship

$$\begin{bmatrix} \mathbf{H}_{11}^t & -\mathbf{H}_{21}^t \\ -\mathbf{H}_{12}^t & \mathbf{H}_{22}^t \end{bmatrix} = \begin{bmatrix} \hat{\mathbf{H}}_{11} & \hat{\mathbf{H}}_{12} \\ \hat{\mathbf{H}}_{21} & \hat{\mathbf{H}}_{22} \end{bmatrix} \tag{4.119}$$

As a result of these relationships, if no controlled sources are present in two networks, they are identical. In the general case it may be shown that

$$\mathbf{Z}_{oc}^t = \hat{\mathbf{Z}}_{oc} \quad \mathbf{Y}_{sc}^t = \hat{\mathbf{Y}}_{sc} \tag{4.120}$$

The application of adjoint circuits for sensitivity calculations requires that, first of all, using the port variables as independent ones, one finds the branch variables, and this is done for both circuits. Assume,

for example, that the branch impedance matrices exist. Then, using unity-valued excitation currents as the components of $\mathbf{I}_p$ and $\hat{\mathbf{I}}_p$ one has, first, to find $\mathbf{I}_b$ and $\hat{\mathbf{I}}_b$. Now, in the original network let the elements be perturbed. The resulting vector of currents may thus be written as $\mathbf{I} + \Delta\mathbf{I}$ and the resulting vector of voltages as $\mathbf{V} + \Delta\mathbf{V}$. From Kirchhoff's current law, we have $\mathbf{A}(\mathbf{I} + \Delta\mathbf{I}) = \mathbf{0}$, and since $\mathbf{AI} = \mathbf{0}$ one also has $\mathbf{A}\Delta\mathbf{I} = \mathbf{0}$. Thus, $\Delta\mathbf{I} = \Delta\mathbf{I}_p + \Delta\mathbf{V}_b$ may be substituted in any of the relations in Equation 4.112. By similar reasoning one can conclude that it is possible as well to substitute the perturbation vector $\Delta\mathbf{V} = \Delta\mathbf{V}_p + \Delta\mathbf{V}_b$ instead of $\mathbf{V}$ in these relations. Making these substitutions, one obtains

$$\begin{aligned} \hat{\mathbf{V}}_p^t \Delta\mathbf{I}_p + \hat{\mathbf{V}}_b^t \Delta\mathbf{I}_p &= 0 \\ \mathbf{I}_p^t \Delta\mathbf{V}_p + \hat{\mathbf{I}}_b^t \Delta\mathbf{V}_b &= 0 \end{aligned} \tag{4.121}$$

Subtracting these two equations, one has

$$\hat{\mathbf{V}}_p^t \Delta\mathbf{I}_p - \mathbf{I}_p^t \Delta\mathbf{V}_p + \hat{\mathbf{V}}_b^t \Delta\mathbf{I}_p - \hat{\mathbf{I}}_b^t \Delta\mathbf{V}_b = 0 \tag{4.122}$$

To a first-order approximation, we have

$$\begin{aligned} \Delta\mathbf{V}_p &= -\Delta(\mathbf{Z}_{oc}\mathbf{I}_p) \approx -\Delta\mathbf{Z}_{oc}\mathbf{I}_p - \mathbf{Z}_{oc}\Delta\mathbf{I}_p \\ \Delta\mathbf{V}_b &= -\Delta(\mathbf{Z}_b\mathbf{I}_b) \approx -\Delta\mathbf{Z}_b\mathbf{I}_b - \mathbf{Z}_b\Delta\mathbf{I}_b \end{aligned} \tag{4.123}$$

Substituting Equation 4.123 into Equation 4.122 and taking into consideration that $\hat{\mathbf{V}}_p^t = -\hat{\mathbf{I}}_p^t \hat{\mathbf{Z}}_{oc}^t = -\hat{\mathbf{I}}_p^t \mathbf{Z}_{oc}$ and that $\hat{\mathbf{V}}_b^t = \hat{\mathbf{I}}_b^t \mathbf{Z}_b$, one can simplify the result (Equation 4.122) to

$$\hat{\mathbf{I}}_p^t \Delta\mathbf{Z}_{oc}\mathbf{I}_p = \hat{\mathbf{I}}_b^t \Delta\mathbf{Z}_b\mathbf{I}_b \tag{4.124}$$

Equation 4.124 clearly shows that if all currents in the original network and its adjoint are known, one can easily calculate the absolute sensitivities $\mathbf{S}(\mathbf{Z}_{ij}, \mathbf{Z}_b) \approx \Delta\mathbf{Z}_{ij}/\Delta\mathbf{Z}_b$, which can be used for calculation of the corresponding relative sensitivities. Here, $\mathbf{Z}_{ij}$ is an element of the n-port open circuit impedance matrix. Then, if necessary, these sensitivities can be used for evaluation of the transfer function sensitivity or the sensitivities of other functions derived via the n-port open circuit impedance matrix.

Usually, the transfer function calculation can be easily reduced to the calculation of a particular $\mathbf{Z}_{ij}$. In this case one can choose $\hat{I}_j = 1, \hat{I}_k = 0$ (for all $k \neq j$) as an excitation in the adjoint network. Then, Equation 4.124 becomes

$$\Delta\mathbf{Z}_{ij} = \hat{\mathbf{I}}_b^t \Delta\mathbf{Z}_b\mathbf{I}_b \tag{4.125}$$

where $\mathbf{I}_b$ and $\hat{\mathbf{I}}_b$ are the branch currents in $\mathbf{N}$ and $\hat{\mathbf{N}}$ corresponding to the indicated excitation. The relations for other types of matrices are obtained in the same manner.

4.12 General Methods of Reducing Sensitivity

It is very desirable from the start of the realization procedure to concentrate on circuits that give lower sensitivity in comparison to other circuits. The practice of active filter realization allows formulation of some general suggestions ensuring that filter realizations will have low sensitivities to component variations.

It is possible to transfer the problem of lower sensitivity at the approximation stage, i.e., before any realization. It is obvious that a low-order transfer function $T(s)$ that just satisfies the specifications will require tighter tolerances in comparison to a higher order transfer function that easily satisfies the specifications. Figure 4.3 shows an example of such an approach for a low-pass filter. Hence, increasing the order of approximation and introducing a redundancy one achieves a set of wider element tolerances.

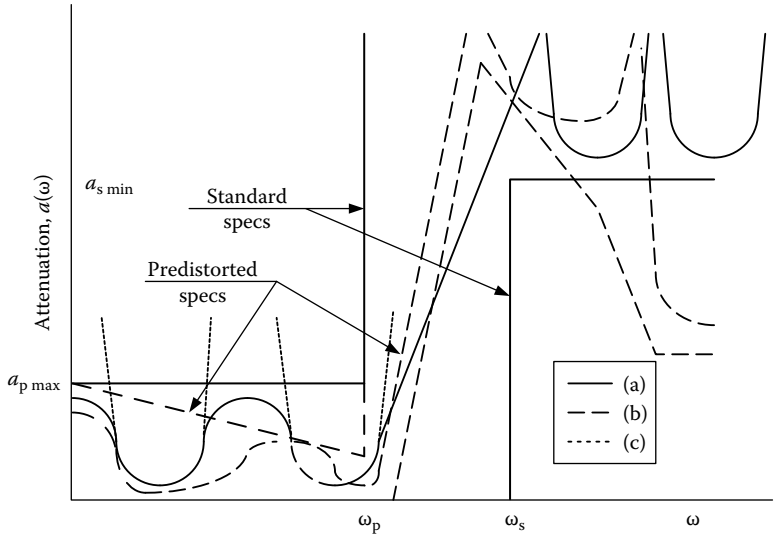

FIGURE 4.3 Attenuation requirements, their predistortion, and attenuation of different realizations: (a) attenuation of a standard circuit of a higher order; (b) attenuation of the nonstandard circuit; and (c) passband attenuation in the stages of cascade realization.

Usually the most critical region where it is difficult to satisfy the specifications is the edge of the passband. Two approaches can be used to find the function that will have less sensitivity in this frequency region. One way is to introduce predistortion in the transfer function specifications. This is also shown in Figure 4.3. The transfer function should satisfy the predistorted (tapered) specifications. It can be obtained directly if the numerical packages solving the approximation problem are available. One can also take a standard table higher order transfer function satisfying the modified specifications and then modify it to more uniformly use the tapered specifications (this allows the increase of the component tolerances even more).

Another way [11] is to preserve the initial transfer function specifications and to use transfer functions with a limited value of the maximum Q of the transfer function poles. In Ref. [11] one can find such transfer functions corresponding to the Cauer approximation. The nonstandard LC circuits corresponding to these approaches cannot be tabulated and simulated; hence, neither of them is widely used. In addition, they imply the cascaded (building-block) realization that intrinsically has worse sensitivity than the realizations using simulation of doubly terminated lossless matched filters.

4.13 Cascaded Realization of Active Filters

The cascaded (building-block) realization is based on the assumption that the transfer function will have low sensitivity if the realization provides tight control of the transfer function poles and zeros. The relationship between the element value and the transfer function poles and zeros can be established relatively easily if the transfer function is not more complicated than biquadratic (i.e., the ratio of two second-order polynomials). It is difficult (or even impossible) to establish such correspondence if, say, the denominator polynomial degree is higher than two. For a high-degree polynomial, a small variation in the polynomial coefficient can result in a large or undesirable migration of the root (it can move to the right-half plane). This justifies the cascaded approach: one hopes to have a low sensitivity of the transfer function under realization if one chooses a method allowing tight control of the poles' and zeros' locations; hence, cascade realization with $T(s) = T_1(s)T_2(s)\cdots T_i(s)\cdots T_k(s)$. Also, if one chooses for

realization of each function $T_i(s)$ the method of lowest sensitivity (discussed below), then it will be possible to obtain the largest element tolerances.

If the realization by cascade connection is chosen it is still a choice of optimum factorization of the transfer function $T(s)$ into low-order factors. This optimum depends on the filter application, the chosen method of the factor realization, and the transfer function itself. It is recommended [1] that, for realization of lower sensitivity, the poles and zeros in the partial functions $T_i(s)$ are located as far apart as possible. This statement is not always true and such a choice of poles and zeros in $T_i(s)$ is in contradiction with the requirement of high dynamic range of the stage. In general, CAD methods should be used.

The methods that are most popular for the realization of the partial transfer functions are mostly limited by the filters providing the output voltage at the output of an operational amplifier. The state–space relations satisfy this requirement and provide the direct realizations of the polynomial coefficients. It is not occasionally that such an approach is used by a series of manufacturers. This is not the best method from the sensitivity point of view; the methods of realization using gyrators usually give better results [3]. But the cascade realization of gyrator filters require buffers between the blocks, and is better to use this approach if the filter is not realized in cascade form. Other realization methods [1] are also occasionally used, mostly because of their simplicity.

If the transfer function is realized in a cascade form and $T(s) = T_1(s)T_2(s)\cdots T_i(s)\cdots T_k(s)$, the element x is located only in one stage. If this is the stage realizing $T_i(s)$, then

$$\mathbf{S}_x^{T(s)} = \mathbf{S}_x^{T_i(s)} \tag{4.126}$$

Assume that this $T_i(s)$ has the form

$$T_i(s) = K\frac{s^2 + \left(\frac{\omega_z}{Q_z}\right) + \omega_z^2}{s^2 + \left(\frac{\omega_p}{Q_p}\right) + \omega_p^2} \tag{4.127}$$

Then one can write

$$\mathbf{S}_x^{T_i(s)} = \mathbf{S}_K^{T_i(s)}\mathbf{S}_x^K + \mathbf{S}_{\omega_z}^{T_i(s)}\mathbf{S}_x^{\omega_z} + \mathbf{S}_{1/Q_z}^{T_i(s)}\mathbf{S}_x^{1/Q_z} + \mathbf{S}_{\omega_p}^{T_i(s)}\mathbf{S}_x^{\omega_p} + \mathbf{S}_{1/Q_p}^{T_i(s)}\mathbf{S}_x^{1/Q_p} \tag{4.128}$$

The second multiplier in each term of this sum depends on the stage realization method. In the first term $\mathbf{S}_K^{T_i(s)} = 1$, the first multipliers in other terms depend on Q-factors of zeros and poles. It is enough to consider the influence of the terms related to the poles. One can notice that $\mathbf{S}_{1/Q_p}^{T_i(s)}\mathbf{S}_x^{1/Q_p} = \mathbf{S}^{T_i(s)}\left[T_i(s), \frac{1}{Q_p}\right]\mathbf{S}_x\left(\frac{1}{Q_p}, x\right)$, then, calculating $\mathbf{S}^{T_i(s)}\left[T_i(s), \frac{1}{Q_p}\right]$ (the calculation of the semirelative sensitivity is done for convenience of graphic representation) and $\mathbf{S}_{\omega_p}^{T_i(s)}$, one obtains

$$\mathbf{S}^{T_i(s)}\left[T_i(s), \frac{1}{Q_p}\right] = \frac{1}{T_i(s)}\frac{\partial T_i(s)}{\partial\left(\frac{1}{Q_p}\right)} = -\frac{1}{\left(\frac{s}{\omega_p}\right) + \left(\frac{\omega_p}{s}\right) + \left(\frac{1}{Q_p}\right)} \tag{4.129}$$

and

$$\mathbf{S}_{\omega_p}^{T_i(s)} = \frac{\omega_p}{T_i(s)}\frac{\partial T_i(s)}{\partial \omega_p} = -\frac{\left(\frac{1}{Q_p}\right) + 2\left(\frac{\omega_p}{s}\right)}{\left(\frac{s}{\omega_p}\right) + \left(\frac{\omega_p}{s}\right) + \left(\frac{1}{Q_p}\right)} \tag{4.130}$$

Introducing the normalized frequency $\Omega = \left(\frac{\omega}{\omega_p} - \frac{\omega_p}{\omega}\right)$, one can find that

$$\mathrm{Re}\,\mathbf{S}^{T_i(s)}\left[T_i(s), \frac{1}{Q_\mathrm{p}}\right] = -\frac{\frac{1}{Q_\mathrm{p}}}{\Omega^2 + \left(\frac{1}{Q_\mathrm{p}}\right)^2} \tag{4.131}$$

$$\mathrm{Im}\,\mathbf{S}^{T_i(s)}\left[T_i(s), \frac{1}{Q_\mathrm{p}}\right] = -\frac{\Omega}{\Omega^2 + \left(\frac{1}{Q_\mathrm{p}}\right)^2} \tag{4.132}$$

$$\mathrm{Re}\,\mathbf{S}^{T_i(s)}_{\omega_\mathrm{p}} = \frac{\Omega\sqrt{\Omega^2+4} - \Omega^2 - \left(\frac{1}{Q_\mathrm{p}}\right)^2}{\Omega^2 + \left(\frac{1}{Q_\mathrm{p}}\right)^2} \tag{4.133}$$

$$\mathrm{Im}\,\mathbf{S}^{T_i(s)}_{\omega_\mathrm{p}} = \frac{\left(\frac{1}{Q_\mathrm{p}}\right)\sqrt{\Omega^2+4}}{\Omega^2 + \left(\frac{1}{Q_\mathrm{p}}\right)^2} \tag{4.134}$$

Figure 4.4 shows the graphs of these four functions. They allow the following conclusions [4]. The functions reach high values in the vicinity of $\Omega = 0$, i.e., when $\omega \approx \omega_\mathrm{p}$. This means that in the filter

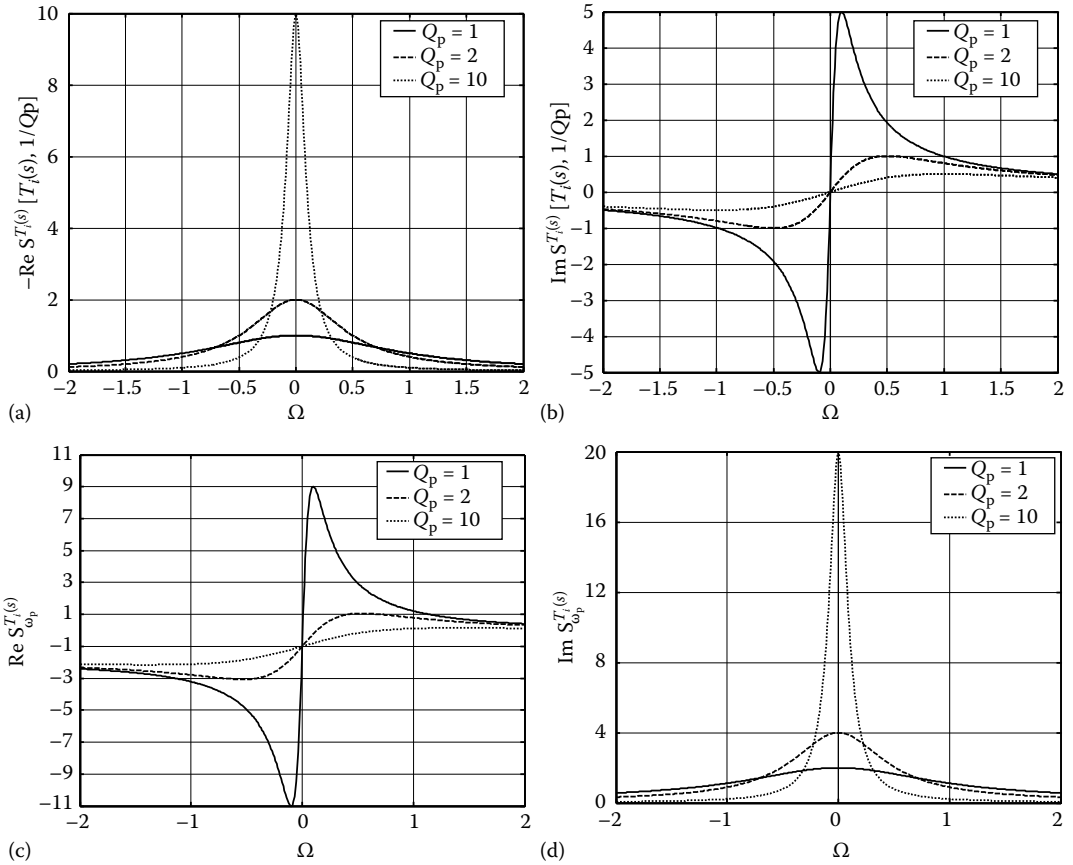

FIGURE 4.4 Stage sensitivities: (a) real and (b) imaginary parts of the *Q*-factor sensitivity; (c) real and (d) imaginary parts of the pole frequency sensitivity.

passband, especially if the poles and zeros are sufficiently divided (which is the condition of optimal cascading), one can neglect the contribution of zeros in modification of the transfer function $T_i(s)$. When Q_p becomes higher, this vicinity of $\omega \approx \omega_p$ with a rapid change of the sensitivity functions becomes relatively smaller in the case of $\mathrm{Re}\,\mathbf{S}^{T_i(s)}\left[T_i(s), \frac{1}{Q_p}\right]$ (Figure 4.4a) and $\mathrm{Im}\,\mathbf{S}^{T_i(s)}_{\omega_p}$ (Figure 4.4d) and not so small in the case of $\mathrm{Im}\,\mathbf{S}^{T_i(s)}\left[T_i(s), \frac{1}{Q_p}\right]$ (Figure 4.4b) and $\mathrm{Re}\,\mathbf{S}^{T_i(s)}_{\omega_p}$ (Figure 4.4c). Normally, the second multipliers in the terms of the sum in Equation 4.128 are all real; this means that the function $\mathrm{Re}\,\mathbf{S}^{T_i(s)}_{\omega_p}$ is the most important one in estimation of the sensitivity to variations of passive elements. In many realization methods [1,3] one obtains that $\omega_p \propto (R_1R_2C_1C_2)^{-1/2}$. This implies that $\mathbf{S}^{\omega_p}_{R_1} = \mathbf{S}^{\omega_p}_{R_2} = \mathbf{S}^{\omega_p}_{C_1} = \mathbf{S}^{\omega_p}_{C_2} = -1/2$. Thus, finally, the function $\mathrm{Re}\,\mathbf{S}^{T_i(s)}_{\omega_p}$ (which can be called the main passive sensitivity term) will determine the maximum realizable Q_p for given tolerances of passive elements (or for the elements that are simulated as passive elements).

If a stage is realized using, for example, a state–space approach, it includes operational amplifiers. The stage is usually designed assuming ideal operational amplifiers, then the realization errors are analyzed considering that the operational amplifiers can be described by a model

$$A(s) = \frac{A_0}{1 + \left(\frac{s}{\omega_0}\right)} = \frac{\mathrm{GBW}}{s + \omega_0} \tag{4.135}$$

where

A_0 is the dc gain, is the amplifier bandwidth
$\mathrm{GBW} = A_0\omega_0$ is the gain-bandwidth product

If the stage transfer function is derived anew, with amplifiers described by the model equation (Equation 4.135), then $T_i(s)$ will no longer be a biquadratic. It will be a ratio of two higher degree polynomials, and the error analysis becomes very complicated [1]. To do an approximate analysis, one can pretend that the amplifier gain is simply a real constant A. Then, the transfer function $T_i(s)$ will preserve its biquadratic appearance, and the term $1/Q_p$ will be possible to represent as

$$\frac{1}{Q_p} = \frac{1}{Q} + \frac{k}{A} \tag{4.136}$$

The first term in Equation 4.136 is determined by the ratio of passive elements, the second term (k is the design constant) can be considered as an *absolute* change $\Delta(1/Q_p)$, which on the $j\omega$ axis becomes

$$\Delta\left(\frac{1}{Q_p}\right) \approx \frac{k}{A(j\omega)} = \frac{1}{A_0} + j\frac{k\omega}{\mathrm{GBW}} \approx j\frac{k\omega}{\mathrm{GBW}} \tag{4.137}$$

Then, in calculation of $\delta|T_i| = \mathrm{Re}\,\mathbf{S}^{T_i(s)}_K$, the function $\mathrm{Im}\,\mathbf{S}^{T_i(s)}_{\omega_p}$ becomes important (it can be called the main active sensitivity term) and the product $\left[\mathrm{Im}\,\mathbf{S}^{T_i(s)}_{\omega_p}\left(\frac{k\omega}{\mathrm{GBW}}\right)\right]$ allows evaluation of the limitations on the Q-factor caused by the stage operational amplifiers.

The relationships given next are useful for any arbitrary realization, but pertain more to the cascade realization, where one can better control the pole's location when the circuit parameters are changing. If the filter transfer function is represented as

$$T(s) = \frac{a_m\Pi_{i=1}^{m}(s - z_i)}{d_n\Pi_{i=1}^{n}(s - p_i)} \tag{4.138}$$

then taking the logarithm of Equation 4.138 and its derivatives gives

$$\frac{\mathrm{d}T(s)}{T(s)} = \frac{\mathrm{d}(a_m/d_n)}{a_m/d_n} - \sum_{i=1}^{m} \frac{\mathrm{d}z_i}{s - z_i} + \sum_{i=1}^{n} \frac{\mathrm{d}p_i}{s - p_i} \tag{4.139}$$

Multiplying both sides of Equation 4.139 by x and expressing the differentials via partial derivatives one obtains

$$\mathbf{S}_x^{T(s)} = \mathbf{S}_x^{a_m/d_n} - \sum_{i=1}^{m} \frac{\mathbf{S}_x(z_i)}{s - z_i} + \sum_{i=1}^{n} \frac{\mathbf{S}_x(p_i)}{s - p_i} \tag{4.140}$$

In the vicinity of the pole $p_i = -\sigma_i + j\omega_i$, the sensitivity is determined by the term $\mathbf{S}_x(p_i)/(s - p_i)$. Besides $\mathbf{S}_x(p_i) = -\mathbf{S}_x(\sigma_i) + j\mathbf{S}_x(\omega_i)$ and on the $j\omega$ axis in this region one has

$$\frac{\mathbf{S}_x(p_i)}{j\omega - p_i} = -\frac{\mathbf{S}_x(\sigma_i)\sigma_i - \mathbf{S}_x(\omega_i)(\omega - \omega_i)}{\sigma_i^2 + (\omega - \omega_i)^2} + j\frac{\mathbf{S}_x(\omega_i)\sigma_i + \mathbf{S}_x(\sigma_i)(\omega - \omega_i)}{\sigma_i^2 + (\omega - \omega_i)^2} \tag{4.141}$$

Hence, when $\omega = \omega_i$

$$\mathbf{S}_x^{|T(j\omega)|} \approx -\frac{\mathbf{S}_x(\sigma_i)\sigma_i - \mathbf{S}_x(\omega_i)(\omega - \omega_i)}{\sigma_i^2 + (\omega - \omega_i)^2} \tag{4.142}$$

and

$$\mathbf{S}_x[\arg T(j\omega)] \approx \frac{\mathbf{S}_x(\omega_i)\sigma_i + \mathbf{S}_x(\sigma_i)(\omega - \omega_i)}{\sigma_i^2 + (\omega - \omega_i)^2} \tag{4.143}$$

Usually Equations 4.142 and 4.143 are considered at the point $\omega - \omega_i$, where $\mathbf{S}_x^{|T(j\omega)|} = -\mathbf{S}_x(\sigma_i)/\sigma_i$ and $\mathbf{S}_x[\arg T(j\omega)] = \mathbf{S}_x(\omega_i)/\sigma_i$. The frequent conclusion that follows is that the pole's movement toward the $j\omega$ axis is more dangerous (it introduces transfer function magnitude change) than the movement parallel to the $j\omega$ axis. But it is not difficult to see that in the immediate vicinity of this point, at $\omega = \omega_i \pm \sigma_i$, one has $\mathbf{S}_x^{|T(j\omega)|} = [-\mathbf{S}_x(\sigma_i) \pm \mathbf{S}_x(\omega_i)]/(2\sigma_i)$ and $\mathbf{S}_x[\arg T(j\omega)] = [\mathbf{S}_x(\omega_i) \pm j\mathbf{S}_x(\sigma_i)]/(2\sigma_i)$; i.e., one has to reduce both components of the pole movement. If care is taken to get $\mathbf{S}_x(\sigma_i) = 0$, then, indeed, $\mathbf{S}_x^{|T(j\omega)|} = 0$ at $\omega = \omega_i$, but at $\omega = \omega_i + \sigma_i$ (closer to the edge of the passband) $\mathbf{S}_x^{|T(j\omega)|} = [\mathbf{S}_x(\omega_i)/\sigma_i]$ and this can result in an essential $\delta|T(j\omega)|$.

Finally, some additional relationships between different sensitivities can be obtained from the definition of $Q_\mathrm{p} = \omega_\mathrm{p}/(2\sigma_i) = \left[\sqrt{\sigma_i^2 + \omega_i^2}\right]/(2\sigma_i) \approx \omega_i/(2\sigma_i)$. One can find that

$$\mathbf{S}_x(\omega_\mathrm{p}) = \frac{\mathbf{S}_x(\sigma_i)}{2Q_\mathrm{p}} + \sqrt{1 - \left(\frac{1}{4Q_\mathrm{p}^2}\right)}\mathbf{S}_x(\omega_i) \tag{4.144}$$

and

$$\mathbf{S}_x(Q_\mathrm{p}) = \frac{\sqrt{4Q_\mathrm{p}^2 - 1}\mathbf{S}_x(\omega_i) - (4Q_\mathrm{p}^2 - 1)\mathbf{S}_x(\sigma_i)}{\omega_\mathrm{p}} \tag{4.145}$$

for semirelative sensitivities. From this basic definition of the Q-factor, one can also derive the relationships

$$\mathbf{S}_x^{Q_p} = \frac{\mathbf{S}_x^{\sigma_i}}{4Q_p^2} + \sqrt{1 - \left(\frac{1}{4Q_p^2}\right)}\,\mathbf{S}_x^{\omega_i} \tag{4.146}$$

and

$$\mathbf{S}_x^{Q_p} \approx \mathbf{S}_x^{\omega_i} - \mathbf{S}_x^{\sigma_i} \tag{4.147}$$

involving relative sensitivities. Another group of results can be obtained considering relative sensitivity of the pole $p_i = -\sigma_i + j\omega_i$. For example, one can find that

$$\mathbf{S}_x^{Q_p} = -\sqrt{4Q_p^2 - 1}\,\mathrm{Im}\,\mathbf{S}_x^{p_i} = \frac{x}{\omega_p^2}\left(\frac{\omega_i}{\sigma_i}\right)\left(\sigma_i\frac{\partial\omega_i}{\partial x} - \omega_i\frac{\partial\sigma_i}{\partial x}\right) \tag{4.148}$$

If $\dfrac{\partial\omega_i}{\partial x} = 0$ and $\dfrac{\partial\sigma_i}{\partial x} =$ constant, then

$$\mathbf{S}_x^{Q_p} \approx kQ_p \tag{4.149}$$

which shows that in this case, $\mathbf{S}_x^{Q_p}$ increases proportionally to the Q-factor independently of the cause of this high sensitivity.

4.14 Simulation of Doubly Terminated Matched Lossless Filters

By cascading the first- and second-order sections (occasionally a third-order section is realized in odd-order filters instead of the cascade connection of a first- and a second-order section) any high-order transfer function $T(s)$ can be realized. In practice, however, the resulting circuit is difficult to fabricate for high-order and/or highly selective filters. The transfer function of such filters usually contains a pair of complex–conjugate poles very close to the $j\omega$ axis. The sensitivity of this section that realizes high-Q poles is high and the element tolerances for this section can be very tight. The section can be unacceptable for fabrication.

For filters that have such high-Q transfer function poles, other design techniques are often used. The most successful and widely used of these alternative strategies are based on simulating the low-sensitivity transfer function of a doubly-terminated lossless (reactance) two-port.

Assume that the two-port shown in Figure 4.5 is lossless and the transfer function $T(s) = V_2(s)/E(s)$ is realized. Considering power relations, one can show [12] that for steady-state sinusoidal operation the equation

$$|\rho(j\omega)|^2 + \frac{4R_1}{R_2}|T(j\omega)|^2 = 1 \tag{4.150}$$

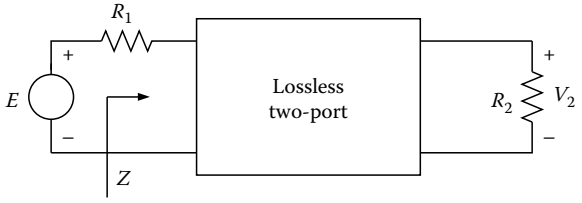

FIGURE 4.5 Lossless two-port with resistive loadings.

is valid for this circuit. Here, $\rho(j\omega) = [R_1 - Z(j\omega)]/[R_1 + Z(j\omega)]$ is the reflection coefficient and $Z(j\omega)$ is the input impedance of the loaded two-port. In many cases, the filter requirements are formulated for the transducer function:

$$H(s) = \sqrt{\frac{R_2}{4R_1}}\frac{E(s)}{V_2(s)} = \sqrt{\frac{R_2}{4R_1}}\frac{1}{T(s)} \tag{4.151}$$

For this function

$$\ln H(j\omega) = \alpha(\omega) + j\varphi(\omega) = -\ln|T(j\omega)| + \ln[\sqrt{(R_2/4R_1)}] - j\arg T(j\omega) \tag{4.152}$$

Here, $\alpha(\omega)$ is attenuation (it is different from the previously used only by the value of $\ln[\sqrt{(R_2/4R_1)}]$) and $\varphi(\omega) = -\beta(\omega) = -\arg T(j\omega)$ is phase. The impedance $Z(j\omega)$ satisfies the condition $\mathrm{Re}\, Z(j\omega) \geq 0$ (as for any passive circuit input impedance), which means that $|\rho(j\omega)|^2 < 1$. Then, as it follows from Equation 4.150 $|H(j\omega)|^2 \geq 1$ and $\alpha(\omega) \geq 0$.

When a filter is designed using $\alpha(\omega)$, the attenuation is optimized so that it is zero in one or more passband points (Figure 4.3 shows, for example, the attenuation characteristics with two zeros in the passband). Then the attenuation partial derivative with respect to the value of each of the two-port elements is equal to zero at the attenuation zeros. Indeed, let x_i be any element of the two-port and $\partial\alpha/\partial x_i$ be the partial derivative of $\alpha(\omega, x_i)$ with respect to that element. Suppose that x_i does not have its nominal value and differs from it by a small Δx_i variation. Expanding $\alpha(\omega, x_i)$ in the Taylor series one obtains that

$$\alpha(\omega, x_i + \Delta x_i) \cong \alpha(\omega, x_i) + \Delta x_i \frac{\partial\alpha(\omega, x_i)}{\partial x_i} \tag{4.153}$$

If ω_k is an attenuation zero, then $\alpha(\omega_k, x_i) = 0$; but, as was mentioned before, $\alpha(\omega) \geq 0$, and from Equation 4.153, one obtains that at the point $\omega = \omega_k$ one has

$$\Delta x_i \frac{\partial\alpha(\omega_k, x_i)}{\partial x_i} \geq 0 \tag{4.154}$$

Now, the variation Δx_i was of unspecified sign. Therefore, Equation 4.154 can only be satisfied with equality sign, which means that $\frac{\partial\alpha(\omega_k, x_i)}{\partial x_i} = 0$.

This result is called the *Fettweis-Orchard theorem* [4] and it explains why the preference is always given to the filter realized as a nondissipative two-port between resistive terminations or to the simulation of such a filter if the filter should be realized as an active circuit. First, considering the real parts of Equation 4.152, one obtains that

$$\frac{\partial\alpha(\omega, x_i)}{\partial x_i} = \mathbf{S}_{x_i}[\alpha(\omega)] = -\frac{x_i}{|T(j\omega)|}\frac{\partial|T(j\omega)|}{\partial x_i} = -\mathbf{S}_{x_i}^{|T(j\omega)|} \tag{4.155}$$

when x_i is any element inside the two-port. Hence, the points where $\alpha(\omega) = 0$ and, simultaneously, $\frac{\partial\alpha(\omega, x_i)}{\partial x_i} = 0$ are the points of zero sensitivity not only for attenuation but for transfer function magnitude as well (as a result of Equation 4.155 and this discussion, one cannot use at these points the relationships $d|T(j\omega)| \approx \mathbf{S}_{x_i}^{|T(j\omega)|}\delta x_i$; the relative change $\delta|T(j\omega)|$ is always negative and different from zero with δx_i of unspecified sign). Moreover, if α is small, $\partial\alpha/\partial x_i$ will also remain small [13], which means that the sensitivities are small in the whole passband. If $x_i = R_1$ or $x_i = R_2$, one obtains from Equation 4.152 that

$$R_1 \frac{\partial \alpha(\omega, R_1)}{\partial R_1} = -\mathbf{S}_{R_1}^{|T(j\omega)|} - \frac{1}{2} \tag{4.156}$$

and

$$R_2 \frac{\partial \alpha(\omega, R_2)}{\partial R_2} = -\mathbf{S}_{R_2}^{|T(j\omega)|} + \frac{1}{2} \tag{4.157}$$

The derivatives $\frac{\partial \alpha}{\partial R_i} (i = 1, 2)$ are also zero at the points where $\alpha = 0$ and they are small when α remains small [13]. This means that in the passband $\mathbf{S}_{R_1}^{|T(j\omega)|} \approx -1/2$ and $\mathbf{S}_{R_2}^{|T(j\omega)|} \approx 1/2$. Thus, $|T(j\omega)|$ will share the zero sensitivity of α with respect to all the elements inside the two-port, but due to the terms $\pm 1/2$ in Equations 4.156 and 4.157 a change either in R_1 or R_2 will produce a frequency-independent shift (which can usually be tolerated) in $|T(j\omega)|$ in addition to the small effects proportional to $\frac{\partial \alpha}{\partial R_i}$. This is the basis of the low sensitivity of conventional *LC*-ladder filters and of those active, switched-capacitor, or digital filters that are based on *LC* filter model. This is valid with the condition that the transfer functions of the active filter and *LC* prototype are the same and the parameters of the two filters enter their respective transfer functions the same way.

The Fettweis-Orchard theorem explains why the filtering characteristics sought are those with the maximum number of attenuation zeros (for a given order of the transfer function $T(s)$). It also helps to understand why it is difficult to design a filter that simultaneously meets the requirements of α and $\varphi(\omega)$ (or to $|T(j\omega)|$ and $\beta(\omega)$); the degrees of freedom used for optimizing $\varphi(\omega)$ will not be available to attain the maximum number of attenuation zeros. It also explains why a cascade realization is more sensitive than the realization based on *LC* lossless model. Indeed, assume that, say, one of the characteristics of Figure 4.3 is realized by two cascaded sections (with the attenuation of each section shown by the dash-and-dotted line) with each actual section realized in doubly terminated matched lossless form. Each such section of the cascaded filter will be matched at one frequency and the sensitivities to the elements that are in unmatched sections will be different from zero. In addition, the attenuation ripple in each section is usually much larger than the total ripple, and the derivative $\frac{\partial \alpha}{\partial x_i}$, which is, in the first approximation, proportional to the attenuation ripple, will not be small. Indeed, practice shows [4] that there is, in fact, a substantial increase in sensitivity in the factored realization.

4.15 Sensitivity of Active *RC* Filters

The required component tolerances are very important factors determining the cost of filters. They are especially important with integrated realizations (where the tolerances are usually higher than in discrete technology). Also, the active filter realizations commonly require tighter tolerances than *LC* realizations. Yet two classes of active *RC* filters have tolerances comparable with those of passive *LC* filters. These are analog-computer and gyrator filters that simulate doubly terminated passive *LC* filters. The tolerance comparison [4] shows the tolerance advantages (sometimes by an order of magnitude) of the doubly terminated lossless structure as compared to any cascade realization. These are the only methods that are now used [14] for high-order high-*Q* sharp cutoff filters with tight tolerances. For less demanding requirements, cascaded realizations could be used. The main advantages that are put forth in this case are the ease of design and simplicity of tuning. But even here the tolerance comparison [4] shows that the stages have better tolerances if they are realized using gyrators and computer simulation methods.

4.16 Errors in Sensitivity Comparisons

In conclusion we briefly outline some common errors in sensitivity comparison. More detailed treatment can be found in Ref. [4].

1. Calculating the wrong sensitivities. The calculated sensitivities should have as close a relation to the filter specification as possible. In general, for a filter specified in the frequency domain, the sensitivities of amplitude and phase should be calculated along the $j\omega$ axis. Sensitivities of poles, zeros, Q's, resonant frequencies, etc. should be carefully interpreted in the context of their connection with amplitude and phase sensitivities.
2. Sensitivities of optimized designs. The optimization should use a criterion as closely related as possible to filter specifications. The use of a criterion that is not closely related to the filter specifications (e.g., pole sensitivity) can lead to valid conclusions if the filters being compared differ by an order of magnitude in sensitivity [4]. A sensitivity comparison is valid only if all the circuits have been optimized using the criterion on which they will be compared. The optimized circuit should not be compared with a nonoptimized one. Another error is to optimize one part of the transfer function (usually the denominator) and forgetting about the modifying effect of the numerator.
3. Comparing the incomparable. A frequent error occurs when comparing sensitivities with respect to different types of elements. In general, different types of elements can be realized with different tolerances, and the comparison is valid only if sensitivities are weighted proportionally. Besides, there are basic differences in variability between circuit parameters with physical dimensions and those without. The latter are often determined in the circuit as the ratio of dimensional quantities (as a result, the tolerance of the ratio will be about double the tolerances of the two-dimensional quantities determining them). In integrated technologies the dimensioned quantities usually have worse tolerances but better matching and tracking ability, especially with temperature. Hence, any conclusion involving sensitivities to different types of components, in addition, is technologically dependent.
4. Correlations between component values. The correlations between components are neglected when they are essential (this is usually done for simplification of the statistical analysis). From the other side, an unwarranted correlation is introduced when it does not exist. This is a frequent case where the realization involves cancellation of terms that are equal when the elements have their nominal values (e.g., a cancellation of a pole of one section of a filter by a zero of another section, cancellation of a positive conductance by a negative conductance).
5. Incomplete analysis. Very often, only sensitivities to variations of a single component (usually an amplifier gain) are considered. This is satisfactory only if it is the most critical component, which is seldom the case. Another form of incomplete analysis is to calculate only one coordinate of a complex sensitivity measure ($\mathbf{S}_x^Q$ is calculated while $\mathbf{S}_x^{\omega_0}$ is ignored). Also, frequency-dependent sensitivities are calculated and compared at one discrete frequency instead of being calculated in frequency intervals.
6. First-order differential sensitivities are the most commonly calculated. But the fact is that $\frac{\partial y}{\partial x} = 0$ implies that the variation of y with x is quadratic at the point considered. A consequence of this is that zero sensitivities do not imply infinitely wide tolerances for the components in question. Similarly, infinite sensitivities do not imply infinitely narrow tolerances. Infinite values arise if the nominal value of y is zero, and the finite variations of x will almost always give finite variations of y.

Passive Immittances and Positive-Real Functions

Wai-Kai Chen
University of Illinois at Chicago

References **5**-8

In this chapter on passive filters, we deal with the design of one-port networks composed exclusively of passive elements such as resistors R, inductors L, capacitors C, and coupled inductors M. The one-ports are specified by their driving-point *immittances*, *impedances*, or *admittances*. Our basic problem is that given an immittance function, is it possible to find a one-port composed only of R, L, C, and M elements called the *RLCM one-port network* that realizes the given immittance function? This is known as the realizability problem, and its complete solution was first given by Brune [1].

Consider a linear RLCM one-port network of Figure 5.1 excited by a voltage source $V_1(s)$. For our purposes, we assume that there are b branches and the branch corresponding to the voltage source $V_1(s)$ is numbered branch 1 and all other branches are numbered from 2 to b. The Laplace transformed Kirchhoff current law equation can be written as

$$\mathbf{A}\mathbf{I}(s) = \mathbf{0} \tag{5.1}$$

where

A is the basis incidence matrix
I(s) is the branch-current vector of the network

If $\mathbf{V}_n(s)$ is the nodal voltage vector, then the branch-voltage vector $\mathbf{V}(s)$ can be expressed in terms of $\mathbf{V}_n(s)$ by

$$\mathbf{V}(s) = \mathbf{A}'\mathbf{V}_n(s) \tag{5.2}$$

where the prime denotes the matrix transpose. Taking the complex conjugate of Equation 5.1 in conjunction with Equation 5.2 gives

$$\mathbf{V}'(s)\bar{\mathbf{I}}(s) = \mathbf{V}_n'(s)\mathbf{A}\bar{\mathbf{I}}(s) = \mathbf{V}_n'(s)\mathbf{0} = 0 \tag{5.3}$$

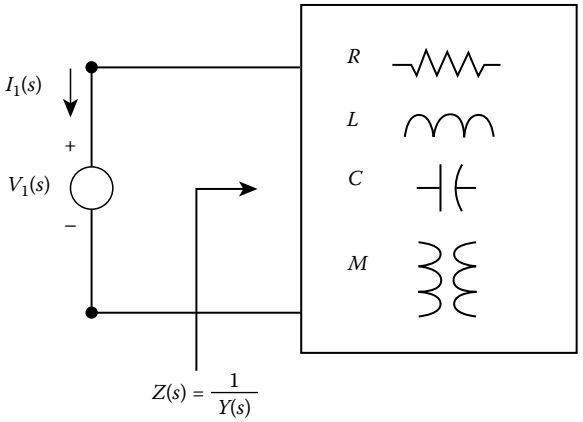

FIGURE 5.1 General linear *RLCM* one-port network.

or

$$\sum_{k=1}^{b} V_k(s)\bar{I}_k(s) = 0 \tag{5.4}$$

where $V_k(s)$ and $I_k(s)$ are the branch voltages and the branch currents, respectively.

From Figure 5.1, the driving-point impedance of the one-port is defined to be the ratio of $V_1(s)$ to $-I_1(s)$, or

$$Z(s) \equiv \frac{V_1(s)}{-I_1(s)} = \frac{V_1(s)\bar{I}_1(s)}{-I_1(s)\bar{I}_1(s)} = -\frac{V_1(s)\bar{I}_1(s)}{|I_1(s)|^2} \tag{5.5}$$

Equation 5.4 can be rewritten as

$$-V_1(s)\bar{I}_1(s) = \sum_{k=2}^{b} V_k(s)\bar{I}_k(s) \tag{5.6}$$

Substituting this in Equation 5.5 yields

$$Z(s) = \frac{1}{|I_1(s)|^2}\sum_{k=2}^{b} V_k(s)\bar{I}_k(s) \tag{5.7}$$

Likewise, the dual relation of the input admittance

$$Y(s) \equiv \frac{-I_1(s)}{V_1(s)} = \frac{1}{|V_1(s)|^2}\sum_{k=2}^{b} \overline{V}_k(s)I_k(s) \tag{5.8}$$

holds.

We know consider individual types of elements inside the one-port. For a resistive branch k of resistance R_k, we have

$$V_k(s) = R_k I_k(s) \tag{5.9}$$

For a capacitive branch of capacitance C,

$$V_k(s) = \frac{1}{sC_k} I_k(s) \tag{5.10}$$

Finally, for an inductive branch of self-inductance L_k and mutual inductances M_{kj},

$$V_k(s) = sL_kI_k(s) + \sum_{\text{all } j, j\neq k} sM_{kj}I_j(s) \tag{5.11}$$

Substituting these in Equation 5.7 and grouping the summation as sums of all resistors R, all capacitors C, and all inductors LM, we obtain

$$\begin{aligned} Z(s) &= \frac{1}{|I_1(s)|^2}\left[\sum_R R_k|I_k(s)|^2 + \sum_C \frac{1}{sC_k}|I_k(s)|^2 + \sum_{LM}\left(sL_k|I_k(s)|^2 + \sum_{\text{all } j, j\neq k} sM_{kj}I_j(s)\bar{I}_k(s)\right)\right] \\ &= \frac{1}{|I_1(s)|^2}\left[F_0(s) + \frac{1}{s}V_0(s) + sM_0(s)\right] \end{aligned} \tag{5.12}$$

where

$$F_0(s) \equiv \sum_R R_k|I_k(s)|^2 \geq 0 \tag{5.13a}$$

$$V_0(s) \equiv \sum_C \frac{1}{C_k}|I_k(s)|^2 \geq 0 \tag{5.13b}$$

$$M_0(s) \equiv \sum_{LM}\left(L_k|I_k(s)|^2 + \sum_{\text{all } j, j\neq k} M_{kj}I_j(s)\bar{I}_k(s)\right) \tag{5.13c}$$

These quantities are closely related to the average power and stored energies of the one-port under steady-state sinusoidal conditions. The average power dissipated in the resistors is

$$P_{\text{ave}} = \frac{1}{2}\sum_R R_k|I_k(j\omega)|^2 = \frac{1}{2}F_0(j\omega) \tag{5.14}$$

showing that $F_0(j\omega)$ represents twice the average power dissipated in the resistors of the one-port. The average electric energy stored in the capacitors is

$$E_C = \frac{1}{4\omega^2}\sum_C \frac{1}{C_k}|I_k(j\omega)|^2 = \frac{1}{4\omega^2}V_0(j\omega) \tag{5.15}$$

Thus, $V_0(j\omega)$ denotes $4\omega^2$ times the average electric energy stored in the capacitors. Similarly, the average magnetic energy stored in the inductors is

$$E_M = \frac{1}{4}\sum_{LM}\left[L_k|I_k(j\omega)|^2 + \sum_{\text{all } q, q\neq k} M_{kq}I_q(j\omega)\bar{I}_k(j\omega)\right] = \frac{1}{4}M_0(j\omega) \tag{5.16}$$

indicating that $M_0(j\omega)$ represents four times the average magnetic energy stored in the inductors.

Therefore, all the three quantities $F_0(j\omega)$, $V_0(j\omega)$, and $M_0(j\omega)$ are real and nonnegative, and Equation 5.12 can be rewritten as

$$Z(s) = \frac{1}{|I_1(s)|^2}\left(F_0 + \frac{1}{s}V_0 + sM_0\right) \tag{5.17}$$

Likewise, the dual result for $Y(s)$ is found to be

$$Y(s) = \frac{1}{|V_1(s)|^2}\left(F_0 + \frac{1}{\bar{s}}V_0 + \bar{s}M_0\right) \tag{5.18}$$

Now, we set $s = \sigma + j\omega$ and compute the real part and imaginary part of $Z(s)$ and obtain

$$\text{Re } Z(s) = \frac{1}{|I_1(s)|^2}\left(F_0 + \frac{\sigma}{\sigma^2+\omega^2}V_0 + \sigma M_0\right) \tag{5.19}$$

$$\text{Im } Z(s) = \frac{\omega}{|I_1(s)|^2}\left(M_0 - \frac{1}{\sigma^2+\omega^2}V_0\right) \tag{5.20}$$

where

Re stands for ''real part of''
Im for ''imaginary part of''

These equations are valid irrespective of the value of s, except at the zeros of $I_1(s)$. They are extremely important in that many analytic properties of passive impedances can be obtained from them. The following is one of such consequences:

THEOREM 5.1

If $Z(s)$ is the driving-point impedance of a linear, passive, lumped, reciprocal, and time-invariant one-port network N, then

1. *Whenever* $\sigma \geq 0$, Re $Z(s) \geq 0$.
2. *If N contains no resistors, then*
   $\sigma > 0$ *implies* Re $Z(s) > 0$
   $\sigma = 0$ *implies* Re $Z(s) = 0$
   $\sigma < 0$ *implies* Re $Z(s) < 0$
3. *If N contains no capacitors, then*
   $\omega > 0$ *implies* Im $Z(s) > 0$
   $\omega = 0$ *implies* Im $Z(s) = 0$
   $\omega < 0$ *implies* Im $Z(s) < 0$
4. *If N contains no self- and mutual-inductors, then*
   $\omega > 0$ *implies* Im $Z(s) < 0$
   $\omega = 0$ *implies* Im $Z(s) = 0$
   $\omega < 0$ *implies* Im $Z(s) > 0$

Similar results can be stated for the admittance function $Y(s)$ simply by replacing $Z(s)$, Re $Z(s)$, *and* Im $Z(s)$ *by $Y(s)$,* Re $Y(s)$, *and* Im $Y(s)$, *respectively.*

The theorem states that the driving-point impedance $Z(s)$ of a passive LMC, RLM, or RC one-port network maps different regions of the complex-frequency s-plane into various regions of the Z-plane. Now, we assert that the driving-point immittance of a passive one-port is a positive-real function, and every positive-real function can be realized as the input immittance of an RLCM one-port network.

Definition 5.1: *Positive-real function. A positive-real function $F(s)$,* abbreviated as a PR function, is an analytic function of the complex variable $s = \sigma + j\omega$ satisfying the following three conditions:

1. $F(s)$ is analytic in the open RHS (*right-half* of the s-plane), i.e., $\sigma > 0$.
2. $F(\overline{s}) = \overline{F}(s)$ for all s in the open RHS.
3. Re $F(s) \geq 0$ whenever Re $s \geq 0$.

The concept of a positive-real function, as well as many of its properties, is credited to Otto Brune [1]. Our objective is to show that positive realness is a necessary and sufficient condition for a passive one-port immittance. The above definition holds for both rational and transcendental functions. A rational function is defined as a ratio of two polynomials. Network functions associated with any linear lumped system, with which we deal exclusively in this section, are rational. In the case of rational functions, not all three conditions in the definition are independent. For example, the analyticity requirement is implied by the other two. The second condition is equivalent to stating the $F(s)$ is real when s is real, and for a rational $F(s)$ it is always satisfied if all the coefficients of the polynomial are real.

Some important properties of a positive-real function can be stated as follows:

1. If $F_1(s)$ and $F_2(s)$ are positive real, so is $F_1[F_2(s)]$.
2. If $F(s)$ is positive real, so are $1/F(s)$ and $F(1/s)$.
3. A positive-real function is devoid of poles and zeros in the open RHS.
4. If a positive-real function has any poles or zeros on the $j\omega$-axis (0 and ∞ included), such poles and zeros must be simple. At a simple pole on the $j\omega$-axis, the residue is real positive.

Property 1 states that a positive-real function of a positive-real function is itself positive real, and property 2 shows that the reciprocal of a positive-real function is positive real. The real significance of the positive-real functions is its use in the characterization of the passive one-port immittances. This characterization is one of the most penetrating results in network theory, and is stated as

THEOREM 5.2

A real rational function is the driving-point immittance of a linear, passive, lumped, reciprocal, and time-invariant one-port network if and only if it is positive real.

The necessity of the theorem follows directly from Equation 5.19. The sufficiency was first established by Brune in 1930 by showing that any given positive-real rational function can be realized as the input immittance of a passive one-port network using only the passive elements such as resistors, capacitors, and self- and mutual inductors. A formal constructive proof will be presented in the following section.

Example 5.1

Consider the passive one-port of Figure 5.2, the driving-point impedance of which is found to be

$$Z(s) = \frac{3s^2 + s + 2}{2s^2 + s + 3} \tag{5.21}$$

To verify that the function $Z(s)$ is positive real, we compute its real part by substituting $s = \sigma + j\omega$ and obtain

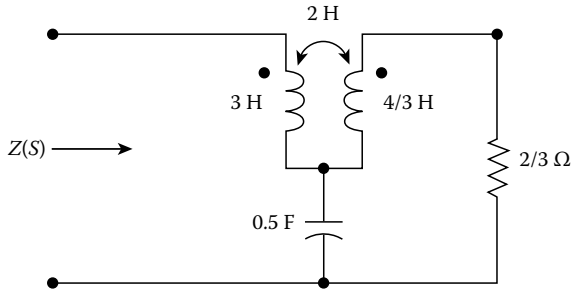

FIGURE 5.2 A passive one-port network.

$$\begin{aligned}\text{Re } Z(s) = \text{Re } Z(\sigma + j\omega) &= \text{Re}\frac{3(\sigma + j\omega)^2 + (\sigma + j\omega) + 2}{2(\sigma + j\omega)^2 + (\sigma + j\omega) + 3} \\ &= \frac{6(\omega^2 - 1)^2 + (12\omega^2\sigma + 5\omega^2 + 6\sigma^3 + 5\sigma^2 + 14\sigma + 5)\sigma}{(2\sigma^2 - 2\omega^2 + \sigma + 3)^2 + \omega^2(4\sigma + 1)^2} \geq 0, \quad \sigma \geq 0 \end{aligned} \tag{5.22}$$

This, in conjunction with the facts that $Z(s)$ is analytic in the open RHS and that all the coefficients of $Z(s)$ are real, shows that $Z(s)$ is positive real.

Observe that if the function $Z(s)$ is of high order, the task of ascertaining its positive realness is difficult if condition 3 of Definition 5.1 is employed for checking. Hence, it is desirable to have alternate but much simpler conditions for testing. For this reason, we introduce the following equivalent conditions that are relatively easy to apply:

THEOREM 5.3

A rational function $F(s)$ is positive real if and only if the following conditions are satisfied:

1. *$F(s)$ is real when s is real.*
2. *$F(s)$ has no poles in the open RHS.*
3. *Poles of $F(s)$ on the $j\omega$-axis, if they exist, are simple, and residues evaluated at these poles are real and positive.*
4. *Re $F(j\omega) \geq 0$ for all ω, except at the poles.*

PROOF: From the definition of a PR function, we see immediately that all the conditions are necessary. To prove sufficiency, we expand $F(s)$ in a partial fraction as

$$\begin{aligned} F(s) &= \left[k_\infty s + \frac{k_0}{s} + \sum_x \left(\frac{k_x}{s + j\omega_x} + \frac{k_x}{s - j\omega_x}\right)\right] + F_1(s) \\ &= \left(k_\infty s + \frac{k_0}{s} + \sum_x \frac{2k_x s}{s^2 + \omega_x^2}\right) + F_1(s) \end{aligned} \tag{5.23}$$

where k_∞, k_0, and k_x are residues evaluated at the $j\omega$-axis poles $j\infty$, 0, and $\pm j\omega_x$, respectively, and are real and positive. $F_1(s)$ is the function formed by the terms corresponding to the open LHS (left-half of the s-plane) poles of $F(s)$, and therefore is analytic in the RHS and the entire $j\omega$-axis including the point at infinity. For such a function, the minimum value of the real part throughout the region where the function is analytic lies on the boundary, namely, the $j\omega$-axis. (See, for example, Churchill [2]. This shows

that the minimum value of Re $F_1(s)$ for all Re $s \geq 0$ occurs on the $j\omega$-axis; but according to Equation 5.23, this value is nonnegative:

$$\text{Re } F_1(j\omega) = \text{Re } F(j\omega) \geq 0 \tag{5.24}$$

Thus, the real part of $F_1(s)$ is nonnegative everywhere in the closed RHS or

$$\text{Re } F_1(s) \geq 0 \quad \text{for Re } s \geq 0 \tag{5.25}$$

This, together with the fact that $F_1(s)$ is real whenever s is real, shows that $F_1(s)$ is positive real.

Since each term inside the parentheses of Equation 5.23 is positive real, and since the sum of two or more positive-real functions is positive real, $F(s)$ is positive real. This completes the proof of the theorem.

In testing for positive realness, we may eliminate some functions from consideration by inspection because they violate certain simple necessary conditions. For example, a function cannot be PR if it has a pole or zero in the open RHS. Another simple test is that the highest powers of s in numerator and denominator not differ by more than unity, because a PR function can have at most a simple pole or zero at the origin or infinity, both of which lie on the $j\omega$-axis.

A Hurwitz polynomial is a polynomial devoid of zeros in the open RHS. Thus, it may have zeros on the $j\omega$-axis. To distinguish such a polynomial from the one that has zeros neither in the open RHS nor on the $j\omega$-axis, the latter is referred to as a strictly Hurwitz polynomial. For computational purposes, Theorem 5.3 can be reformulated and put in a much more convenient form.

THEOREM 5.4

A rational function represented in the form

$$F(s) = \frac{P(s)}{Q(s)} = \frac{m_1(s) + n_1(s)}{m_2(s) + n_2(s)} \tag{5.26}$$

where $m_1(s)$, $m_2(s)$, and $n_1(s)$, $n_2(s)$ are the even and odd parts of the polynomials $P(s)$ and $Q(s)$, respectively, is positive real if and only if the following conditions are satisfied:

1. *$F(s)$ is real when s is real.*
2. *$P(s) + Q(s)$ is strictly Hurwitz.*
3. *$m_1(j\omega)m_2(j\omega) - n_1(j\omega)n_2(j\omega) \geq 0$ for all ω.*

A real polynomial is strictly Hurwitz if and only if the continued-fraction expansion of the ratio of the even part to the odd part or the odd part to the even part of the polynomial yields only real and positive coefficients, and does not terminate prematurely. For $P(s) + Q(s)$ to be strictly Hurwitz, it is necessary and sufficient that the continued-fraction expansion

$$\left[\frac{m_1(s) + m_2(s)}{n_1(s) + n_2(s)}\right]^{\pm 1} = \alpha_1 s + \cfrac{1}{\alpha_2 s + \cfrac{1}{\ddots + \cfrac{1}{\alpha_k s}}} \tag{5.27}$$

yields only real and positive α's, and does not terminate prematurely, i.e., k must equal the degree $m_1(s) + m_2(s)$ or $n_1(s) + n_2(s)$, whichever is larger. It can be shown that the third condition of the

theorem is satisfied if and only if its left-hand-side polynomial does not have real positive roots of odd multiplicity. This may be determined by factoring it or by the use of the Sturm's theorem, which can be found in most texts on elementary theory of equations. We illustrate the above procedure by the following examples.

Example 5.2

Test the following function to see if it is PR:

$$F(s) = \frac{2s^4 + 4s^3 + 5s^2 + 5s + 2}{s^3 + s^2 + s + 1} \tag{5.28}$$

For illustrative purposes, we follow the three steps outlined in the theorem, as follows:

$$F(s) = \frac{2s^4 + 4s^3 + 5s^2 + 5s + 2}{s^3 + s^2 + s + 1} = \frac{P(s)}{Q(s)} = \frac{m_1(s) + n_1(s)}{m_2(s) + n_2(s)} \tag{5.29}$$

where

$$m_1(s) = 2s^4 + 5s^2 + 2, \quad n_1(s) = 4s^3 + 5s \tag{5.30a}$$

$$m_2(s) = s^2 + 1, \quad n_2(s) = s^3 + s \tag{5.30b}$$

Condition 1 is clearly satisfied. To test condition 2, we perform the Hurwitz test, which gives

$$\frac{m_1(s) + m_2(s)}{n_1(s) + n_2(s)} = \frac{2s^4 + 6s^2 + 3}{5s^3 + 6s} = \frac{2}{5}s + \cfrac{1}{\frac{25}{18}s + \cfrac{1}{\frac{324}{165}s + \cfrac{1}{\frac{33}{54}s}}} \tag{5.31}$$

Since all the coefficients are real and positive and since the continued-fraction expansion does not terminate prematurely, the polynomial $P(s) + Q(s)$ is strictly Hurwitz. Thus, condition 2 is satisfied.

To test condition 3, we compute

$$\begin{aligned} m_1(j\omega)m_2(j\omega) - n_1(j\omega)n_2(j\omega) &= 2\omega^6 - 2\omega^4 - 2\omega^2 + 2 \\ &= 2\left(\omega^2 + 1\right)\left(\omega^2 - 1\right)^2 \geq 0 \end{aligned} \tag{5.32}$$

which is nonnegative for all ω, or, equivalently, which does not possess any real positive roots of odd multiplicity. Therefore $F(s)$ is positive real.

6.1 Introduction

In this chapter, we demonstrate that any rational positive-real function can be realized as the input immittance of a passive one-port network terminated in a resistor, thereby also proving the sufficiency of Theorem 5.2.

Consider the even part

$$\text{Ev } Z(s) = r(s) = \frac{1}{2}[Z(s) + Z(-s)] \tag{6.1}$$

of a given rational positive-real impedance $Z(s)$. As in Equation 5.26, we first separate the numerator and denominator polynomials of $Z(s)$ into even and odd parts, and write

$$Z(s) = \frac{m_1 + n_1}{m_2 + n_2} \tag{6.2}$$

Then, we have

$$r(s) = \frac{m_1 m_2 - n_1 n_2}{m_2^2 + n_2^2} \tag{6.3}$$

showing that if s_0 is a zero or pole of $r(s)$, so is $-s_0$. Thus, the zeros and poles of $r(s)$ possess quadrantal symmetry with respect to both the real and imaginary axes. They may appear in pairs on the real axis, in pairs on the $j\omega$-axis, or in the form of sets of quadruplets in the complex-frequency plane. Furthermore, for a positive-real $Z(s)$, the $j\omega$-axis zeros of $r(j\omega)$ are required to be of even multiplicity in order that Re $Z(j\omega) = r(j\omega)$ never be negative.

Suppose that we can extract from $Z(s)$ a set of open-circuit impedance parameters $z_{ij}(s)$ characterizing a component two-port network, as depicted in Figure 6.1, which produces one pair of real axis zeros, one pair of $j\omega$-axis zeros, or one set of quadruplet of zeros of $r(s)$, and leaves a rational positive-real impedance $Z_1(s)$ of lower degree, the even part of which $r_1(s)$ is devoid of these zeros but contains all

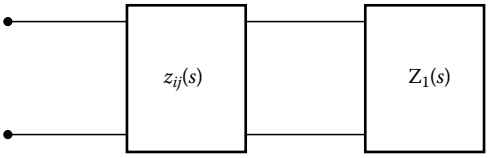

FIGURE 6.1 Two-port network terminated in $Z_1(s)$.

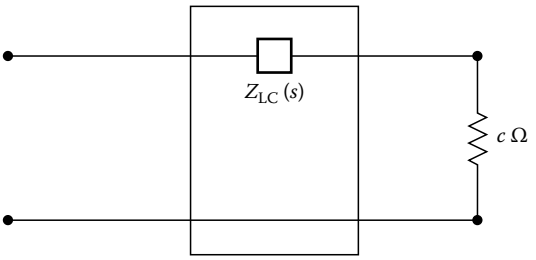

FIGURE 6.2 Two-port network terminated in a resistor.

other zeros of $r(s)$. After a finite q steps, we arrive at a rational positive-real impedance $Z_q(s)$, the even part $r_q(s)$ of which is devoid of zeros in the entire complex-frequency plane, meaning that its even part must be a nonnegative constant c:

$$r_q(s) = \frac{1}{2}\left[Z_q(s) + Z_q(-s)\right] = c \tag{6.4}$$

Therefore, $Z_q(s)$ is expressible as the sum of a reactance function* $Z_{LC}(s)$ and a resistance c:

$$Z_q(s) = Z_{LC}(s) + c \tag{6.5}$$

which can be realized as the input impedance of a lossless two-port network terminated in a c-ohm resistor, as shown in Figure 6.2.

To motivate our discussion, we first present a theorem credited to Richards [1,2], which is intimately tied up with the famous Bott–Duffin technique [3].

THEOREM 6.1

Let $Z(s)$ be a positive-real function that is neither of the form Ls nor $1/Cs$. Let k be an arbitrary positive-real constant. Then, the Richards function

$$W(s) = \frac{kZ(s) - sZ(k)}{kZ(k) - sZ(s)} \tag{6.6}$$

is also positive real.

The degree of a rational function is defined as the sum of the degrees of its relatively prime numerator and denominator polynomials. Thus, the Richards function $W(s)$ is also rational, the degree of which is

* A formal definition will be given in Chapter 7.

not greater than that of $Z(s)$. It was first pointed out by Richards that if k can be chosen so that the even part of $Z(s)$ vanishes at k, then the degree of $W(s)$ is at least two less than that of $Z(s)$. Let

$$s_0 = \sigma_0 + j\omega_0 \tag{6.7}$$

be a point in the closed RHS. Then, according to the preceding theorem, the function

$$\widehat{W}_1(s) = \frac{s_0 Z(s) - sZ(s_0)}{s_0 Z(s_0) - sZ(s)} \tag{6.8}$$

is positive real if s_0 is positive real; and the function

$$W_1(s) = Z(s_0)\widehat{W}_1(\bar{s}_0)\frac{\bar{s}_0\widehat{W}_1(s) - s\widehat{W}_1(\bar{s}_0)}{\bar{s}_0\widehat{W}_1(\bar{s}_0) - s\widehat{W}_1(s)} \tag{6.9}$$

is positive real if s_0 is a positive-real constant and $\widehat{W}_1(s)$ is a positive-real function. Substituting Equation 6.8 in Equation 6.9 yields

$$W_1(s) = \frac{D_1(s)Z(s) - B_1(s)}{-C_1(s)Z(s) + A_1(s)} \tag{6.10}$$

where

$$A_1(s) = q_4 s^2 + |s_0|^2 \tag{6.11a}$$

$$B_1(s) = q_2 s \tag{6.11b}$$

$$C_1(s) = q_3 s \tag{6.11c}$$

$$D_1(s) = q_1 s^2 + |s_0|^2 \tag{6.11d}$$

$$q_1 = \frac{R_0/\sigma_0 - X_0/\omega_0}{R_0/\sigma_0 + X_0/\omega_0} \tag{6.12a}$$

$$q_2 = \frac{2|Z_0|^2}{R_0/\sigma_0 + X_0/\omega_0} \tag{6.12b}$$

$$q_3 = \frac{2}{R_0/\sigma_0 - X_0/\omega_0} \tag{6.12c}$$

$$q_4 = \frac{R_0/\sigma_0 + X_0/\omega_0}{R_0/\sigma_0 - X_0/\omega_0} = \frac{1}{q_1} \tag{6.12d}$$

in which

$$Z(s_0) = R_0 + jX_0 \equiv Z_0 \tag{6.13}$$

In the case $\omega_0 = 0$, then X_0/ω_0 must be replaced by $Z'(\sigma_0)$:

$$\frac{X_0}{\omega_0} \to Z'(\sigma_0) = \left.\frac{dZ(s)}{ds}\right|_{s=\sigma_0} \tag{6.14a}$$

For $\sigma = 0$ and $R_0 = 0$, R_0/σ_0 is replaced by $X'(\omega_0)$:

$$\frac{R_0}{\sigma_0} \to X'(\omega_0) = \left.\frac{dZ(s)}{ds}\right|_{s=j\omega_0} \tag{6.14b}$$

Definition 6.1: *Index set*

For a given positive-real function $Z(s)$, let s_0 be any point in the open RHS or any finite nonzero point on the $j\omega$-axis where $Z(s)$ is analytic. Then, the set of four real numbers q_1, q_2, q_3, and q_4, as defined in Equations 6.12 through 6.14, is called the index set assigned to the point s_0 by the positive-real function $Z(s)$.

We illustrate this concept by the following example.

Example 6.1

Determine the index set assigned to the point $s_0 = 0.4551 + j1.099$ by the positive-real function

$$Z(s) = \frac{s^2 + s + 1}{s^2 + s + 2} \tag{6.15}$$

From definition and Equation 6.15, we have

$$s_0 = 0.4551 + j1.099 = \sigma_0 + j\omega_0 \tag{6.16a}$$

$$\begin{aligned} Z(s_0) &= Z(0.4551 + j1.099) \\ &= 0.7770 + j0.3218 = 0.8410e^{j22.5^\circ} \\ &= R_0 + jX_0 \equiv Z_0 \end{aligned} \tag{6.16b}$$

$$|Z_0|^2 = 0.7073 \tag{6.17}$$

obtaining from Equation 6.12

$$q_1 = 0.707, \quad q_2 = 0.707, \quad q_3 = 1.414, \quad q_4 = 1.414 \tag{6.18}$$

With these preliminaries, we now state the following theorem, which forms the cornerstone of the method of cascade synthesis of a rational positive-real impedance according to the Darlington theory [4].

THEOREM 6.2

Let $Z(s)$ be a positive-real function, which is neither of the form Ls nor $1/Cs$, L and C being real nonnegative constants. Let $s_0 = \sigma_0 + j\omega_0$ be a finite nonzero point in the closed RHS where $Z(s)$ is analytic, then the function

$$W_1(s) = \frac{D_1(s)Z(s) - B_1(s)}{-C_1(s)Z(s) + A_1(s)} \tag{6.19}$$

is positive real; where A_1, B_1, C_1, and D_1 are defined in Equation 6.11 and $\{q_1, q_2, q_3, q_4\}$ is the index set assigned to the point s_0 by $Z(s)$. Furthermore, $W_1(s)$ possesses the following attributes:

(1) *If $Z(s)$ is rational, $W_1(s)$ is rational, the degree of which is not greater than that of $Z(s)$, or*

$$\text{degree } W_1(s) \leq \text{degree } Z(s) \tag{6.20}$$

(2) *If $Z(s)$ rational and if s_0 is a zero of its even part $r(s)$, then*

$$\text{degree } W_1(s) \leq \text{degree } Z(s) - 4, \quad \omega_0 \neq 0 \tag{6.21a}$$

$$\text{degree } W_1(s) \leq \text{degree } Z(s) - 2, \quad \omega_0 = 0 \tag{6.21b}$$

(3) *If* $s_0 = \sigma_0 > 0$ *is a real zero of* $r(s)$ *of at least multiplicity* 2 *and if* $Z(s)$ *is rational, then*

$$\text{degree } W_1(s) \leq \text{degree } Z(s) - 4 \tag{6.22}$$

We remark that since $Z(s)$ is positive real, all the points in the open RHS are admissible. Any point on the $j\omega$-axis, exclusive of the origin and infinity, where $Z(s)$ is analytic is admissible as s_0.

We are now in a position to show that any positive-real function can be realized as the input impedance of a lossless one-port network terminated in a resistor. Our starting point is Equation 6.19, which after solving $Z(s)$ in terms of $W_1(s)$ yields

$$Z(s) = \frac{A_1(s)W_1(s) + B_1(s)}{C_1(s)W_1(s) + D_1(s)} \tag{6.23}$$

It can be shown that $Z(s)$ can be realized as the input impedance of a two-port network N_1, which is characterized by its transmission matrix

$$\mathbf{T}_1(s) = \begin{bmatrix} A_1(s) & B_1(s) \\ C_1(s) & D_1(s) \end{bmatrix} \tag{6.24}$$

terminated in $W_1(s)$, as depicted in Figure 6.3. To see this, we first compute the corresponding impedance matrix $\mathbf{Z}_1(s)$ of N_1 from $\mathbf{T}_1(s)$ and obtain

$$\mathbf{Z}_1(s) = \begin{bmatrix} z_{11}(s) & z_{12}(s) \\ z_{21}(s) & z_{22}(s) \end{bmatrix} = \frac{1}{C_1(s)} \begin{bmatrix} A_1(s) & A_1(s)D_1(s) - B_1(s)C_1(s) \\ 1 & D_1(s) \end{bmatrix} \tag{6.25}$$

The input impedance $Z_{11}(s)$ of N_1 with the output port terminating in $W_1(s)$ is found to be

$$Z_{11}(s) = z_{11}(s) - \frac{z_{12}(s)z_{21}(s)}{z_{22}(s) + W_1(s)} = \frac{A_1(s)W_1(s) + B_1(s)}{C_1(s)W_1(s) + D_1(s)} = Z(s) \tag{6.26}$$

The determinant of the transmission matrix $\mathbf{T}_1(s)$ is computed as

$$\det \mathbf{T}_1(s) = A_1(s)D_1(s) - B_1(s)C_1(s) = s^4 + 2\left(\omega_0^2 - \sigma_0^2\right)s^2 + |s_0|^4 \tag{6.27}$$

Observe that det $\mathbf{T}_1(s)$ depends only upon the point s_0 and not on $Z(s)$, and that the input impedance $Z_{11}(s)$ remains unaltered if each element of $\mathbf{T}_1(s)$ is multiplied or divided by a nonzero

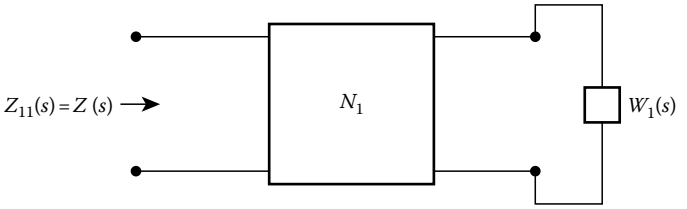

FIGURE 6.3 Two-port network N_1 terminated in the impedance $W_1(s)$.

finite quality. To complete the realization, we must now demonstrate that the two-port network N_1 is physically realizable.

6.2 Type-E Section

Consider the lossless nonreciprocal two-port network of Figure 6.4 known as the type-E section. Our objective is to show that this two-port realizes N_1. To this end, we first compute its impedance matrix $\mathbf{Z}_E(s)$ as

$$\mathbf{Z}_E(s) = \begin{bmatrix} L_1(s) + 1/Cs & Ms + 1/Cs + \zeta \\ Ms + 1/Cs - \zeta & L_2 s + 1/Cs \end{bmatrix} \tag{6.28}$$

where $M^2 = L_1 L_2$, the determinant of which is given by

$$\det\ \mathbf{Z}_E(s) = \frac{L_1 + L_2 - 2M + \zeta^2 C}{C} \tag{6.29}$$

a constant independent of s due to perfect coupling. From the impedance matrix $\mathbf{Z}_E(s)$, its corresponding transmission matrix $\mathbf{T}_E(s)$ is found to be

$$\mathbf{T}_E(s) = \frac{1}{MCs^2 - \zeta Cs + 1} \begin{bmatrix} L_1 Cs^2 + 1 & \left(L_1 + L_2 - 2M + \zeta^2 C\right)s \\ Cs & L_2 Cs^2 + 1 \end{bmatrix} \tag{6.30}$$

To show that the type-E section realizes N_1, we divide each element of $\mathbf{T}_1(s)$ of Equation 6.24 by $|s_0|^2$ $(MCs^2 - \zeta Cs + 1)$. This manipulation will not affect the input impedance $Z(s)$ but it will result in a transmission matrix having the form of $\mathbf{T}_E(s)$. Comparing this new matrix with Equation 6.30 in conjunction with Equation 6.11 yields the following identifications:

$$L_1 C = \frac{q_4}{|s_0|^2} \tag{6.31a}$$

$$L_1 + L_2 - 2M + \zeta^2 C = \frac{q_2}{|s_0|^2} \tag{6.31b}$$

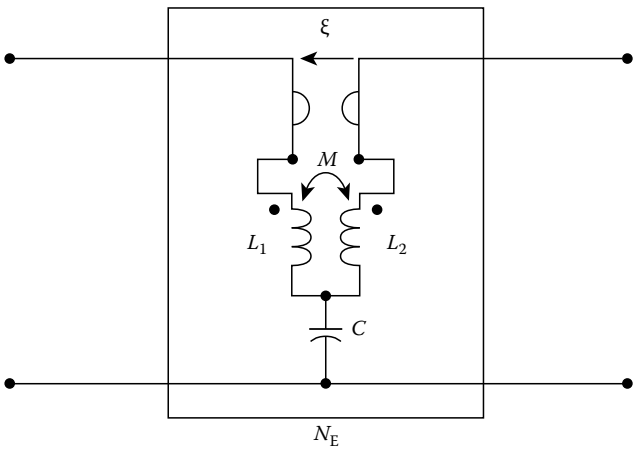

FIGURE 6.4 Type-E section.

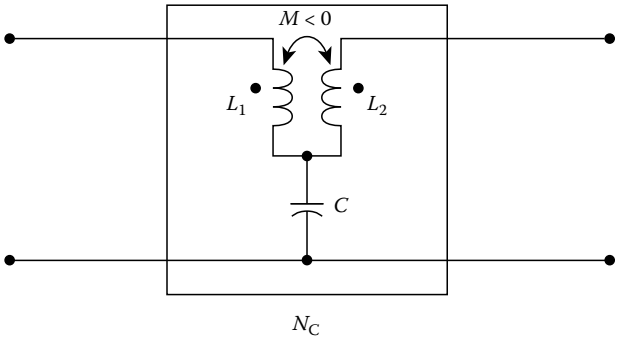

FIGURE 6.5 Darlington type-C section.

$$C = \frac{q_3}{|s_0|^2} \tag{6.31c}$$

$$L_2 C = \frac{q_1}{|s_0|^2} \tag{6.31d}$$

Solving these for the element values of the type-E section, we obtain

$$L_1 = \frac{q_4}{q_3} = \frac{1}{q_1 q_3}, \quad L_2 = \frac{q_1}{q_3} \tag{6.32a}$$

$$C = \frac{q_3}{|s_0|^2}, \quad M = \frac{1}{q_3}, \quad \zeta = \pm\frac{2\sigma_0}{q_3} \tag{6.32b}$$

Since the elements of the index set assigned to the point s_0 by $Z(s)$ are positive and finited for all admissible points s_0 in the closed RHS except at those admissible points $s_0 = j\omega_0$ on the $j\omega$-axis where $R_0 \neq 0$, all the elements in Equation 6.32 are physical. But at those admissible points $s_0 = j\omega_0$ where $R_0 \neq 0$, R_0/σ_0 becomes infinity and $q_1 = q_4 = 1$ and $q_2 = q_3 = 0$. Under this situation, $W_1(s) = Z(s)$ and the corresponding two-port network N_1 degenerates into a pair of wires.

Appealing to Theorem 6.2 shows that if s_0 is chosen to be a complex open RHS zero of the even part $r(s)$ of $Z(s)$, the type-E section is capable of extracting a set of quadrantal zeros of $r(s)$ and leads to at least a four-degree reduction. For zeros of $r(s)$ on the $j\omega$-axis or the σ-axis, the type-E section degenerates into other types of sections, as follows:

Case 1. $s_0 = \sigma_0 > 0$. Then, we have $\zeta = 0$ and

$$L_1 = \frac{q_4}{q_3} = \frac{1}{q_1 q_3}, \quad L_2 = \frac{q_1}{q_3}, \quad C = \frac{q_3}{\sigma_0^2}, \quad M = -\frac{1}{q_3} < 0 \tag{6.33}$$

The type-E section degenerates to the Darlington type-C section, as shown in Figure 6.5.

Case 2. $s_0 = j\omega_0$ and $R_0 = 0$. In this case, we replace R_0/σ_0 by $X'(\omega_0)$ and the gyrator in the type-E section can be avoided because $\zeta = 0$. The type-E section degenerates into the Brune section of Figure 6.6, the element values of which are given by

$$L_1 = \frac{q_4}{q_3} = \frac{1}{q_1 q_3} = \frac{\omega_0 X'(\omega_0) + X_0}{2\omega_0} \tag{6.34a}$$

$$L_2 = \frac{q_1}{q_3} = \frac{[\omega_0 X'(\omega_0) - X_0]^2}{2\omega_0[\omega_0 X'(\omega_0) + X_0]} \tag{6.34b}$$

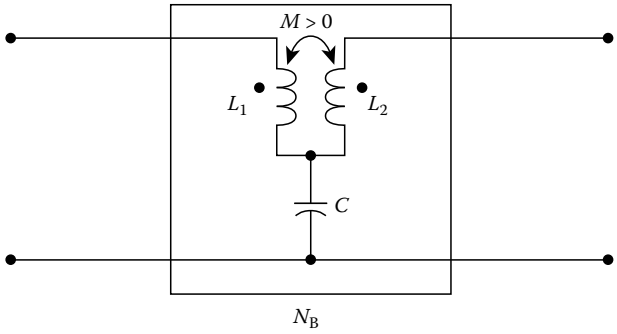

FIGURE 6.6 Brune section.

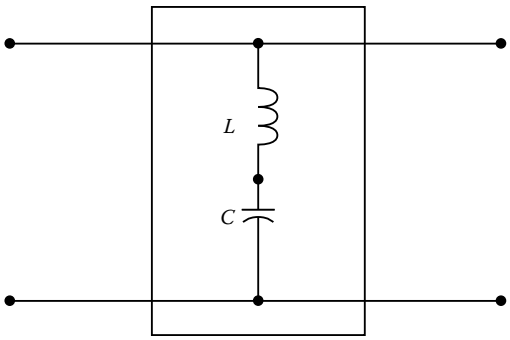

FIGURE 6.7 Degenerate Brune section.

$$C = \frac{q_3}{|s_0|^2} = \frac{2}{\omega_0[\omega_0 X'(\omega_0) - X_0]} \tag{6.34c}$$

$$M = \frac{1}{q_3} = \frac{\omega_0 X'(\omega_0) - X_0}{2\omega_0} > 0 \tag{6.34d}$$

In particular, if $X_0 = 0$ or $Z(j\omega_0) = 0$, the Brune section degenerates into the two-port network of Figure 6.7 with element values

$$L = \frac{1}{2}X'(\omega_0), \quad C = \frac{2}{\omega_0^2 X'(\omega_0)} \tag{6.35}$$

As ω_0 approaches zeros, this degenerate Brune section goes into the type-A section of Figure 6.8 with

$$L = \frac{1}{2}Z'(0) \tag{6.36}$$

When ω_0 approaches infinity, the degenerate Brune section collapses into the type-B section of Figure 6.9 with

$$\frac{2}{C} = \lim_{s\to\infty} sZ(s) \tag{6.37}$$

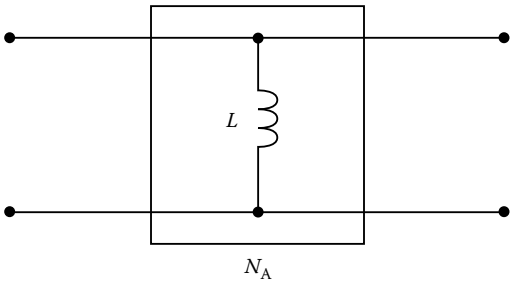

FIGURE 6.8 Type-A section.

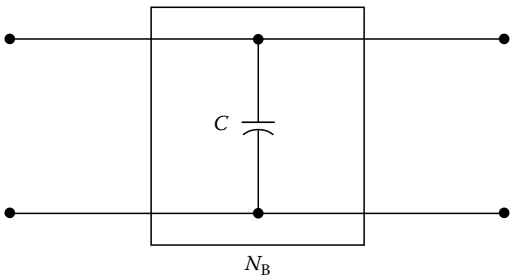

FIGURE 6.9 Type-B section.

Case 3. $s_0 = j\omega_0$ and $R_0 \neq 0$. In this case, R_0/σ_0 is infinity and

$$q_1 = q_4 = 1, \quad q_2 = q_3 = 0 \tag{6.38}$$

The type-E section degenerates into a pair of wires.

Therefore, the Brune section is capable of extracting any $j\omega$-axis zero of the even part of a positive-real impedance, and leads to at least a four-degree reduction if $j\omega_0$ is nonzero and finite, a two-degree reduction otherwise. The latter corresponds to the type-A or type-B section.

Example 6.2

Consider the positive-real impedance

$$Z(s) = \frac{8s^2 + 9s + 10}{2s^2 + 4s + 4} \tag{6.39}$$

The zeros of its even part $r(s)$ are found from the polynomial

$$m_1 m_2 - n_1 n_2 = 16\left(s^4 + s^2 + 2.5\right) \tag{6.40}$$

obtaining

$$s_0 = \sigma_0 + j\omega_0 = 0.735 + j1.020 \tag{6.41a}$$

$$Z(s_0) \equiv R_0 + jX_0 = 2.633 + j0.4279 = 2.667e^{j9.23} \equiv Z_0 \tag{6.41b}$$

The elements of the index set assigned to s_0 by $Z(s)$ are computed as

$$q_1 = 0.7904, \quad q_2 = 3.556, \quad q_3 = 0.6323, \quad q_4 = 1.265 \tag{6.42}$$

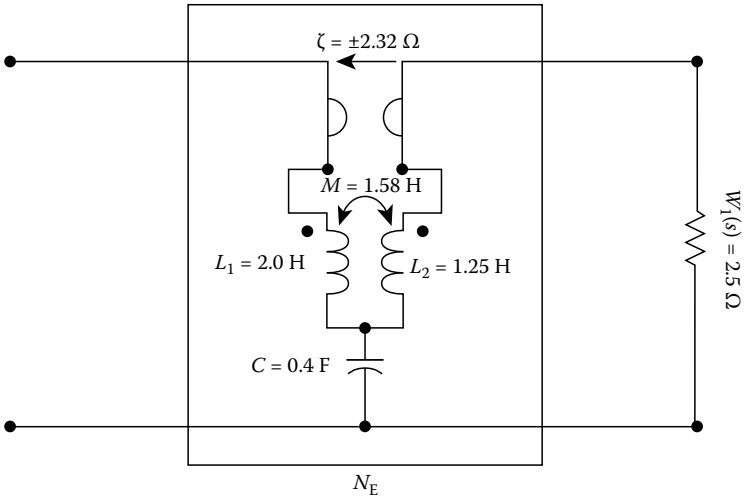

FIGURE 6.10 Realization of the impedance function of (6.39).

Substituting these in Equation 6.32 yields the element values of the type-E section as shown in Figure 6.10.

$$L_1 = 2 \text{ H}, \quad L_2 = 1.25 \text{ H}, \quad C = 0.40 \text{ F} \tag{6.43a}$$

$$M = 1.58 \text{ H}, \quad \zeta = \pm 2.32 \ \Omega \tag{6.43b}$$

The terminating impedance $W_1(s)$ is a resistance of value

$$W_1(s) = Z(0) = 2.5 \ \Omega \tag{6.44}$$

as shown in Figure 6.10.

6.3 Richards Section

In this part, we show that any positive real zero $s_0 = \sigma_0$ of the even part $r(s)$ of a positive-real impedance $Z(s)$, in addition to being realized by the reciprocal Darlington type-C section, can also be realized by a nonreciprocal section called the Richards section of Figure 6.11.

Let $Z(s)$ be a rational positive-real function. Then according to Theorem 6.1, for any positive real σ_0, the function

$$W_1(s) = Z(\sigma_0)\frac{\sigma_0 Z(s) - sZ(\sigma_0)}{\sigma_0 Z(\sigma_0) - sZ(s)} \tag{6.45}$$

is also rational and positive real, the degree of which is not greater than that of $Z(s)$. As pointed out by Richards [1], if σ_0 is a zero of $r(s)$, then

$$\text{degree } W_1(s) \leq \text{degree } Z(s) - 2 \tag{6.46}$$

Inverting Equation 6.45 for $Z(s)$ yields

$$Z(s) = \frac{\sigma_0 W_1(s) + sZ(\sigma_0)}{sW_1(s)/Z(\sigma_0) + \sigma_0} \tag{6.47}$$

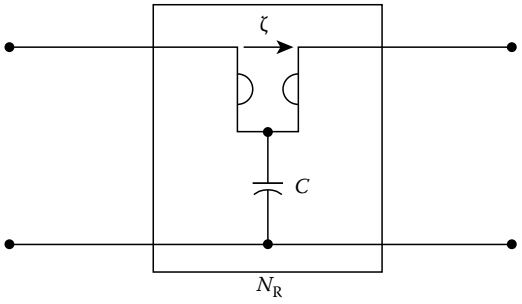

FIGURE 6.11 Richards section.

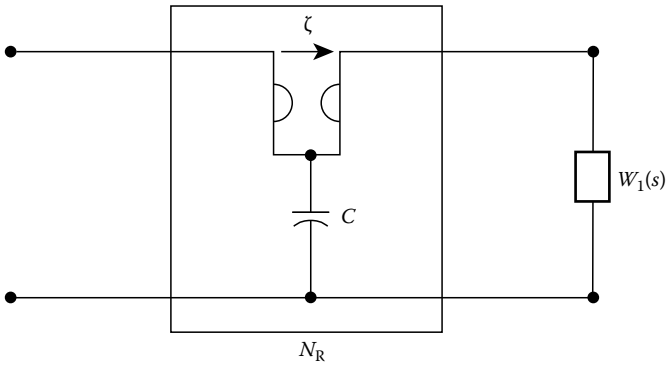

FIGURE 6.12 Realization of $Z(s)$ by Richards section.

This impedance can be realized by the Richards section terminated in the impedance $W_1(s)$ as indicated in Figure 6.12 with the element values

$$C = \frac{1}{\sigma_0 Z(\sigma_0)}, \quad \zeta = \pm Z(\sigma_0) \tag{6.48}$$

6.4 Darlington Type-D Section

In the foregoing, we have demonstrated that the lossless two-port network N_1 can be realized by the lossless nonreciprocal type-E section, which degenerates into the classical type-A, type-B, type-C, and the Brune sections when the even part zero s_0 of the positive-real impedance is restricted to the $j\omega$-axis or the positive σ-axis. In the present section, we show that N_1 can also be realized by a lossless reciprocal two-port network by the application of Theorem 6.1 twice.

Let s_0 be a zero of the even part $r(s)$ of a rational positive-real impedance $Z(s)$. By Theorem 6.2, the function $W_1(s)$ of Equation 6.19 is also rational positive real, and its degree is at least four or two less that that of $Z(s)$, depending on whether $\omega_0 \neq 0$ or $\omega_0 = 0$. Now, apply Theorem 6.2 to $W_1(s)$ at the same point s_0. Then, the function

$$W_2(s) = \frac{D_2(s)W_1(s) - B_2(S)}{-C_2(s)W_1(s) + A_2(s)} \tag{6.49}$$

is rational positive real, the degree of which cannot exceed that of $W_1(s)$, being at least two or four degrees less than that of $Z(s)$, where

$$A_2(s) = p_4 s^2 + |s_0|^2 \tag{6.50a}$$

$$B_2(s) = p_2 s \tag{6.50b}$$

$$C_2(s) = p_3 s \tag{6.50c}$$

$$D_2(s) = p_1 s^2 + |s_0|^2 \tag{6.50d}$$

and $\{p_1, p_2, p_3, p_4\}$ is the index set assigned to the point s_0 by the positive-real function $W_1(s)$. Solving for $W_1(s)$ in Equation 6.49 gives

$$W_1(s) = \frac{A_2(s)W_2(s) + B_2(s)}{C_2(s)W_2(s) + D_2(s)} \tag{6.51}$$

which can be realized as the input impedance of a two-port network N_2 characterized by the transmission matrix

$$\mathbf{T}_2(s) = \begin{bmatrix} A_2(s) & B_2(s) \\ C_2(s) & D_2(s) \end{bmatrix} \tag{6.52}$$

terminated in $W_2(s)$, as depicted in Figure 6.13.

Consider the cascade connection of the two-port N_1 of Figure 6.3 and N_2 of Figure 6.13 terminated in $W_2(s)$, as shown in Figure 6.14. The transmission matrix $\mathbf{T}(s)$ of the overall two-port network N is simply the product of the transmission matrices of the individual two-ports:

$$\mathbf{T}(s) = \mathbf{T}_1(s)\mathbf{T}_2(s) \tag{6.53}$$

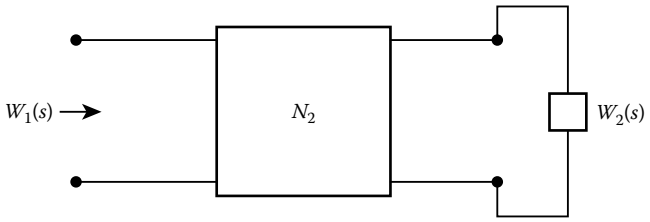

FIGURE 6.13 Realization of the impedance function $W_1(s)$.

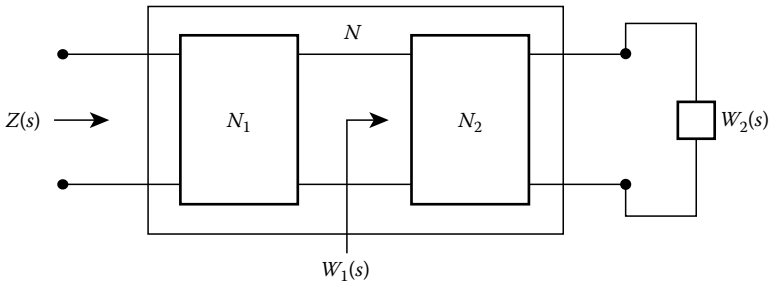

FIGURE 6.14 Cascade connection of two-port networks N_1 and N_2.

the determinant of which is found to be

$$\det\ \mathbf{T}(s) = [\det\ \mathbf{T}_1(s)][\det\ \mathbf{T}_2(s)] = \left[s^4 + 2\left(\omega_0^2 - \sigma_0^2\right)s^2 + |s_0|^4\right]^2 \tag{6.54}$$

Thus, when N is terminated in $W_2(s)$, the input impedance of Figure 6.14 is $Z(s)$. This impedance remains unaltered if each element of $\mathbf{T}_1(s)$ is divided by a nonzero finite quantity. For our purposes, we stipulate that the two-port N_1 be characterized by the transmission matrix

$$\widehat{\mathbf{T}}_1(s) = \frac{1}{\Delta(s)}\mathbf{T}_1(s) \tag{6.55}$$

where

$$\Delta(s) = s^4 + 2\left(\omega_0^2 - \sigma_0^2\right)s^2 + |s_0|^4 \tag{6.56}$$

Using this matrix $\widehat{\mathbf{T}}_1(s)$ for N_1, the transmission matrix $\widehat{\mathbf{T}}_1(s)$ of the overall two-port network N becomes

$$\begin{aligned}\widehat{\mathbf{T}}(s) &= \frac{1}{\Delta(s)}\mathbf{T}_1(s)\mathbf{T}_2(s) \equiv \frac{1}{\Delta(s)}\begin{bmatrix} A(s) & B(s) \\ C(s) & D(s)\end{bmatrix} \\ &= \frac{1}{\Delta(s)}\begin{bmatrix} p_4q_4s^4 + |s_0|^4 & (p_2q_4 + p_1q_2)s^3 \\ \quad +\left[(p_4 + q_4)|s_0|^2 + p_3q_2\right]s^2 & \quad +(p_2 + q_2)|s_0|^2 s \\ (p_4q_3 + p_3q_1)s^3 & p_1q_1s^4 + |s_0|^4 + \left[(p_1 + q_1)|s_0|^2\right. \\ \quad +(p_3 + q_3)|s_0|^2 s & \quad \left. + p_2q_3\right]s^2\end{bmatrix}\end{aligned} \tag{6.57}$$

The corresponding impedance matrix $\mathbf{Z}(s)$ of the overall two-port network is found to be

$$\mathbf{Z}(s) = \frac{1}{C(s)}\begin{bmatrix} A(s) & \Delta(s) \\ \Delta(s) & D(s)\end{bmatrix} \tag{6.58}$$

showing that N is reciprocal because $\mathbf{Z}(s)$ is symmetric.

Now consider the reciprocal lossless Darlington type-D section N_D of Figure 6.15 with two perfectly coupled transformers

$$L_1L_2 = M_1^2, \quad L_3L_4 = M_2^2 \tag{6.59}$$

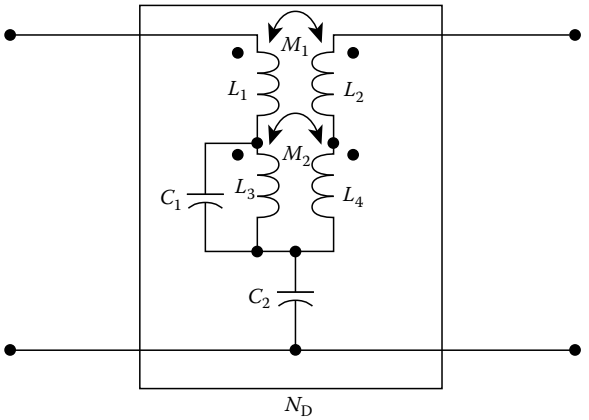

FIGURE 6.15 Darlington type-D section N_D.

The impedance matrix $\mathbf{Z}_{\mathrm{D}}(s)$ of N_{D} is found to be

$$\mathbf{Z}_{\mathrm{D}}(s) = \begin{bmatrix} L_1 s + \frac{1}{C_2 s} + \dfrac{s/C_1}{s^2+\omega_a^2} & M_1 s + \frac{1}{C_2 s} + \dfrac{\omega_a^2 M_2 s}{s^2+\omega_a^2} \\ M_1 s + \dfrac{1}{C_2 s} + \dfrac{\omega_a^2 M_2 s}{s^2+\omega_a^2} & L_2 s + \dfrac{1}{C_2 s} + \dfrac{\omega_a^2 L_4 s}{s^2+\omega_a^2} \end{bmatrix} \tag{6.60}$$

where $\omega_a^2 = 1/C_1 L_3$.

Setting $\mathbf{Z}_{\mathrm{D}}(s) = \mathbf{Z}(s)$ in conjunction with Equation 6.57 and after considerable algebraic manipulations, we can make the following identifications:

$$L_1 = \frac{p_4 q_4}{p_4 q_3 + p_3 q_1} \tag{6.61a}$$

$$L_2 = \frac{p_1 q_1}{p_4 q_3 + p_3 q_1} = \frac{M_1^2}{L_1} \tag{6.61b}$$

$$M_1 = \frac{1}{p_4 q_3 + p_3 q_1} = \sqrt{L_1 L_2} \tag{6.61c}$$

$$C_2 = \frac{p_3 + q_3}{|s_0|^2} \tag{6.61d}$$

$$\omega_a^2 = \omega_1^2 = \frac{|s_0|^2 (p_3 + q_3)}{p_4 q_3 + p_3 q_1} \tag{6.61e}$$

$$\begin{aligned} M_2 &= -\frac{\omega_1^4 - 2\left(\omega_0^2 - \sigma_0^2\right)\omega_1^2 + |s_0|^4}{\omega_1^4 (p_4 q_3 + p_3 q_1)} \\ &= -\frac{p_3^2 q_3^2 \left|\overline{W_1}(s_0) + Z(s_0) q_1\right|^2}{|s_0|^2 (p_4 q_3 + p_3 q_1)(p_3 + q_3)^2} \le 0 \end{aligned} \tag{6.61f}$$

$$L_4 = \frac{\left[(p_1 + q_1)|s_0|^2 + p_2 q_3\right]\omega_1^2 - p_1 q_1 \omega_1^4 - |s_0|^4}{\omega_1^4 (p_4 q_3 + p_3 q_1)} = -\frac{q_3 M_2}{p_3} \tag{6.61g}$$

$$L_3 = \frac{M_2^2}{L_4} = -\frac{p_3 M_2}{q_3} \tag{6.61h}$$

$$C_1 = \frac{1}{\omega_1^2 L_3} = -\frac{q_3}{\omega_1^2 p_3 M_2} \tag{6.61i}$$

Thus, all the element values except M_2 are nonnegative, and the lossless reciprocal Darlington type-D section is equivalent to the two type-E sections in cascade.

Example 6.3

Consider the positive-real impedance

$$Z(s) = \frac{6s^2 + 5s + 6}{2s^2 + 4s + 4} \tag{6.62}$$

the even part of which has a zero at

$$s_0 = \sigma_0 + j\omega_0 = 0.61139 + j1.02005 \tag{6.63}$$

The elements of the index set assigned to s_0 by $Z(s)$ are given by

$$q_1 = 0.70711, \quad q_2 = 1.76784, \quad q_3 = 0.94283, \quad q_4 = 1.41421 \tag{6.64}$$

The terminating impedance $W_1(s)$ is determined to be

$$W_1(s) = W_1(0) = Z(0) = 1.5\ \Omega \tag{6.65}$$

The elements of the index set assigned to the point s_0 by $W_1(s)$ are found to be

$$p_1 = 1, \quad p_2 = 1.83417, \quad p_3 = 0.81519, \quad p_4 = 1 \tag{6.66}$$

Substituting these in Equation 6.61 yields the desired element values of the type-D section, as follows:

$$L_1 = \frac{p_4 q_4}{p_4 q_3 + p_3 q_1} = 0.93086\ \text{H} \tag{6.67a}$$

$$L_2 = \frac{p_1 q_1}{p_4 q_3 + p_3 q_1} = 0.46543\ \text{H} \tag{6.67b}$$

$$M_1 = \frac{1}{p_3 q_3 + p_3 q_1} = 0.65822\ \text{H} \tag{6.67c}$$

$$C_2 = \frac{p_3 + q_3}{|s_0|^2} = 1.24303\ \text{F} \tag{6.67d}$$

$$\omega_1^2 = \frac{|s_0^2|(p_3 + q_3)}{p_4 q_3 + p_3 q_1} = 1.63656 \tag{6.67e}$$

$$M_2 = -\frac{\omega_1^4 - 2(\omega_0^2 - \sigma_0^2)\omega_1^2 + |s_0|^4}{\omega_1^4(p_4 q_3 + p_3 q_1)} = -0.61350\ \text{H} \tag{6.67f}$$

$$L_4 = -\frac{q_3 M_2}{p_3} = 0.70956\ \text{H} \tag{6.67g}$$

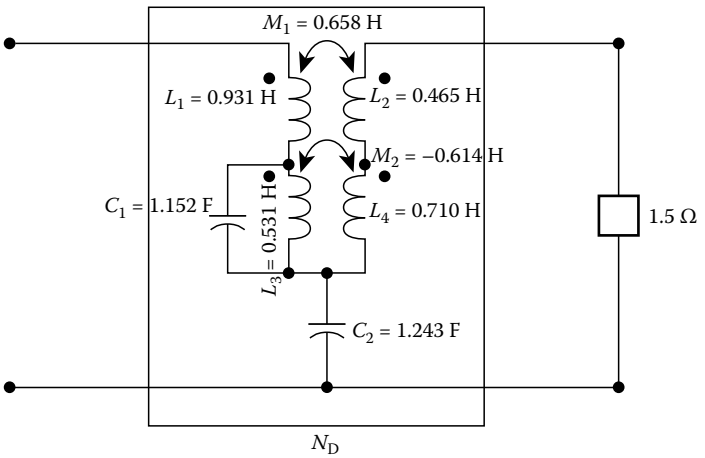

FIGURE 6.16 Darlington type-D section terminated in a resistor.

$$L_3 = \frac{M_2^2}{L_4} = -\frac{p_3 M_2}{q_3} = 0.53044 \text{ H} \tag{6.67h}$$

$$C_1 = \frac{1}{\omega_1^2 L_3} = -\frac{q_3}{\omega_1^2 p_3 M_2} = 1.15193 \text{ F} \tag{6.67i}$$

The complete network together with its termination is presented in Figure 6.16.

7.1 Introduction

In Chapter 6, we showed that any positive-real function can be realized as the input immittance of a passive one-port network, which is describable as a lossless two-port network terminated in a resistor. Therefore, insofar as the input immittance is concerned, any passive network is equivalent to one containing at most one resistor. In this section, we consider the synthesis of a one-port network composed only of self and mutual inductors and capacitors called the LCM one-port, or a one-port composed only of resistors and capacitors called the RC one-port.

7.2 LCM One-Port Networks

Consider the input impedance $Z(s)$ of an LCM one-port network written in the form

$$Z(s) = \frac{m_1 + n_1}{m_2 + n_2} \tag{7.1}$$

the even part of which is given by

$$r(s) = \frac{m_1 m_2 - n_1 n_2}{m_2^2 - n_2^2} \tag{7.2}$$

Since the one-port is lossless, we have

$$r(j\omega) = \text{Re } Z(j\omega) = 0 \quad \text{for all } \omega \tag{7.3}$$

To make Re $Z(j\omega) = 0$, there are three nontrivial ways: (1) $m_1 = 0$ and $n_2 = 0$, (2) $m_2 = 0$ and $n_1 = 0$, and (3) $m_1 m_2 - n_1 n_2 = 0$. The first possibility leads $Z(s)$ to n_1/m_2, the second to m_1/n_2. For the third possibility, we require that $m_1 m_2 = n_1 n_2$ or

$$(m_1 + n_1)m_2 = (m_2 + n_2)n_1 \tag{7.4}$$

which is equivalent to

$$Z(s) = \frac{m_1 + n_1}{m_2 + n_2} = \frac{n_1}{m_2} \tag{7.5}$$

Therefore, the driving-point immittance of a lossless network is always the quotient of even to odd or odd to even polynomials. Its zeros and poles must occur in quadrantal symmetry, being symmetric with respect to both axes. As a result, they are simple and purely imaginary from stability considerations, or $Z(s)$ can be explicitly written as

$$Z(s) = H\frac{\left(s^2 + \omega_{z1}^2\right)\left(s^2 + \omega_{z2}^2\right)\left(s^2 + \omega_{z3}^2\right)\cdots}{s\left(s^2 + \omega_{p1}^2\right)\left(s^2 + \omega_{p2}^2\right)\cdots} \tag{7.6}$$

where $\omega_{z1} \geq 0$. This equation can be expanded in partial fraction as

$$Z(s) = Hs + \frac{K_0}{s} + \sum_{i=1}^{n} \frac{2K_i s}{s^2 + \omega_i^2} \tag{7.7}$$

where $\omega_{pi} = \omega_i$, and the residues H, K_0, and K_i are all real and positive.

Substituting $s = j\omega$ and writing $Z(j\omega) = \text{Re}\, Z(j\omega) + j\,\text{Im}\, Z(j\omega)$ results in an odd function known as the reactance function $X(\omega)$:

$$X(\omega) = \text{Im}\ Z(j\omega) = H\omega - \frac{K_0}{\omega} + \sum_{i=1}^{n} \frac{2K_i\omega}{-\omega^2 + \omega_i^2} \tag{7.8}$$

Taking the derivatives on both sides yields

$$\frac{dX(\omega)}{d\omega} = H + \frac{K_0}{\omega^2} + \sum_{i=1}^{n} \frac{2K_i\left(\omega^2 + \omega_i^2\right)}{\left(-\omega^2 + \omega_i^2\right)^2} \tag{7.9}$$

Since every factor in this equation is positive for all positive and negative values of ω, we conclude that

$$\frac{dX(\omega)}{d\omega} > 0 \quad \text{for } -\infty < \omega < \infty \tag{7.10}$$

It states that the slope of the reactance function versus frequency curve is always positive, as depicted in Figure 7.1. Consequently, the poles and zeros of $Z(s)$ alternate along the $j\omega$-axis. This is known as the separation property for reactance function credited to Foster [1]. Because of this, the pole and zero frequencies of Equation 7.6 are related by

$$0 \leq \omega_{z1} < \omega_{p1} < \omega_{z2} < \omega_{p2} < \cdots \tag{7.11}$$

We now consider the realization of $Z(s)$. If each term on the right-hand side of Equation 7.7 can be identified as the input impedance of the LC one-port, the series connection of these one-ports would yield the desired realization. The first term is the impedance of an inductor of inductance H, and the second term corresponds to a capacitor of capacitance $1/K_0$. Each of the remaining term can be realized

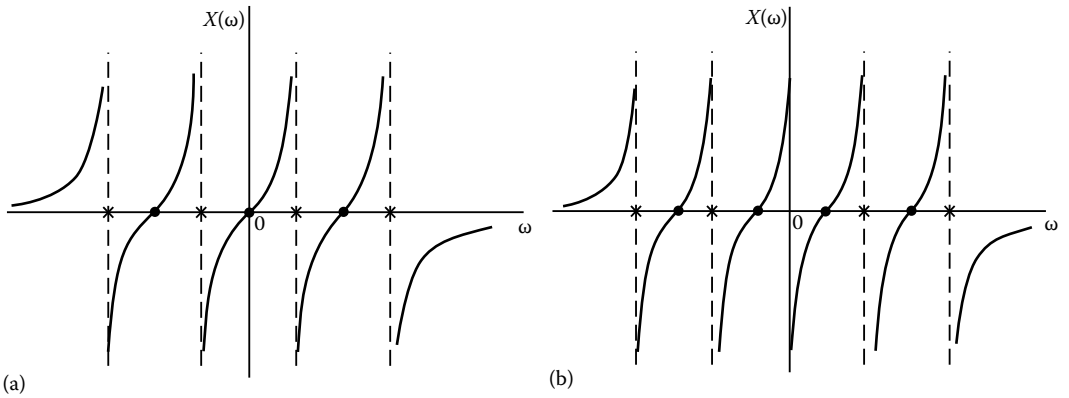

FIGURE 7.1 Plots of reactance function $X(\omega)$ versus ω. (a) The origin is a zero. (b) The origin is a pole.

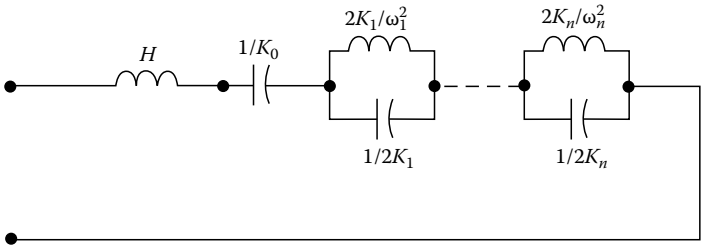

FIGURE 7.2 First Foster canonical form.

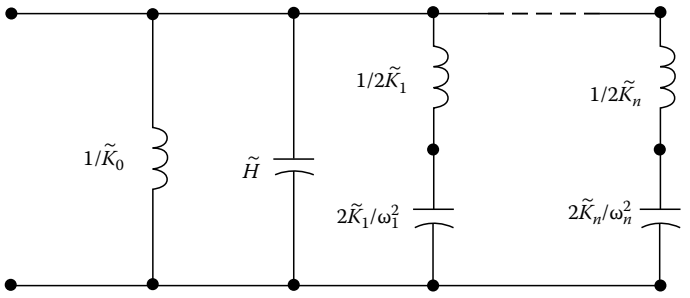

FIGURE 7.3 Second Foster canonical form.

as a parallel combination of an inductor of inductance $2K_i/\omega_i^2$ and a capacitor of capacitance $1/2K_i$. The resulting realization is shown in Figure 7.2 known as the first Foster canonical form. Likewise, if we consider the admittance function $Y(s) = 1/Z(s)$ and expanded it in partial fraction, we obtain

$$Y(s) = \tilde{H}s + \frac{\tilde{K}_0}{s} + \sum_{i=1}^{n} \frac{2\tilde{K}_i s}{s^2 + \omega_i^2} \tag{7.12}$$

which can be realized by the one-port of Figure 7.3 known as the second Foster canonical form. The term canonical form refers to a network containing the minimum number of elements to meet given specifications.

We summarize the preceding results by stating the following theorem:

THEOREM 7.1

A real rational function is the input immittance function of an LCM one-port network if and only if all of its zeros and poles are simple, lie on the jω-axis, and alternate with each other.

In addition to the two Foster canonical forms, there is another synthesis procedure, that gives rise to one-ports known as the Cauer canonical form [2]. Let us expand, $Z(s)$ in a continued fraction

$$Z(s) = \frac{m(s)}{n(s)} = L_1 s + \cfrac{1}{C_2 s + \cfrac{1}{L_3 s + \cfrac{1}{C_4 s + \cfrac{1}{\ddots}}}} \tag{7.13}$$

where $m(s)$ is assumed to be of higher degree than $n(s)$. Otherwise, we expand $Y(s) = 1/Z(s)$ instead of $Z(s)$. Equation 7.13 can be realized as the input impedance of the LC ladder network of Figure 7.4 and is known as the first Cauer canonical form.

Suppose now that we rearrange the numerator and denominator polynomials $m(s)$ and $n(s)$ in ascending order of s, and expand the resulting function in a continued fraction. Such an expansion yields

$$\begin{aligned} Z(s) = \frac{m(s)}{n(s)} &= \frac{a_0 + a_2 s^2 + \cdots + a_{k-2} s^{k-2} + a_k s^k}{b_1 s + b_3 s^3 + \cdots + b_{k-1} s^{k-1}} \\ &= \frac{1}{C_1 s} + \cfrac{1}{\cfrac{1}{L_2 s} + \cfrac{1}{\cfrac{1}{C_3 s} + \cfrac{1}{\cfrac{1}{L_4 s} + \cfrac{1}{\ddots}}}} \end{aligned} \tag{7.14}$$

which can be realized by the LC ladder of Figure 7.5 known as the second Cauer canonical form.

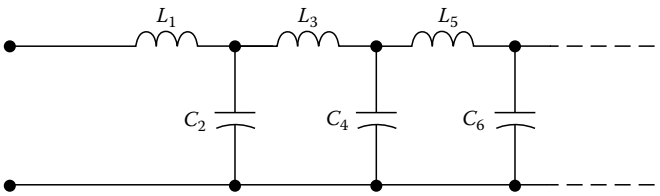

FIGURE 7.4 First Cauer canonical form.

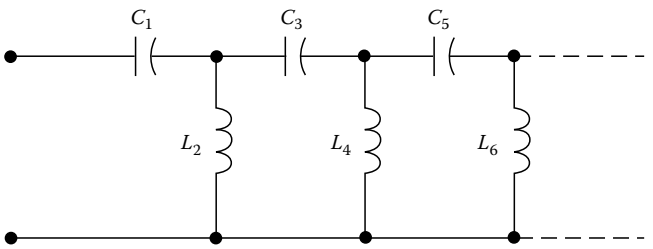

FIGURE 7.5 Second Cauer canonical form.

Example 7.1

Consider the reactance function

$$Z(s) = \frac{s(s^2+4)(s^2+36)}{(s^2+1)(s^2+25)(s^2+81)} \tag{7.15}$$

For the first Foster canonical form, we expand $Z(s)$ in a partial fraction

$$Z(s) = \frac{7s/128}{s^2+1} + \frac{11s/64}{s^2+25} + \frac{99s/128}{s^2+81} \tag{7.16}$$

and obtain the one-port network of Figure 7.6.

For the second Foster canonical form, we expand $Y(s) = 1/Z(s)$ in a partial fraction

$$Y(s) = s + \frac{225/16}{s} + \frac{4851s/128}{s^2+4} + \frac{1925s/128}{s^2+36} \tag{7.17}$$

and obtain the one-port network of Figure 7.7.

For the Cauer canonical form, we expand the function in a continued fraction

$$Z(s) = \cfrac{1}{s + \cfrac{1}{0.015s + \cfrac{1}{6.48s + \cfrac{1}{8.28 \times 10^{-3}s + \cfrac{1}{12.88s + \cfrac{1}{0.048s}}}}}} \tag{7.18}$$

and obtain the one-port network of Figure 7.8.

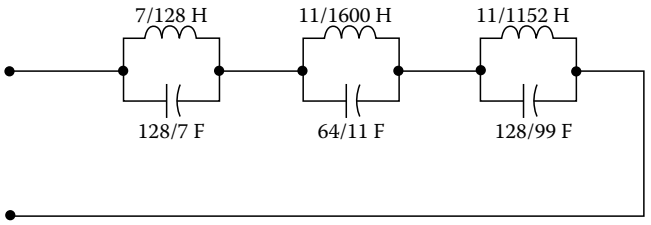

FIGURE 7.6 First Foster canonical form.

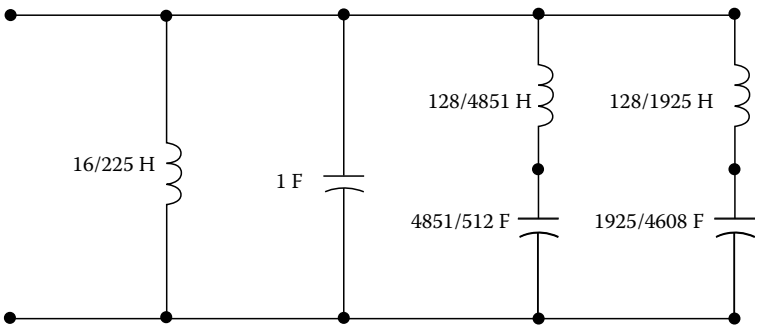

FIGURE 7.7 Second Foster canonical form.

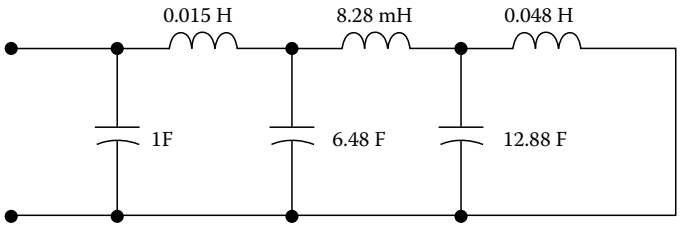

FIGURE 7.8 First Cauer canonical form.

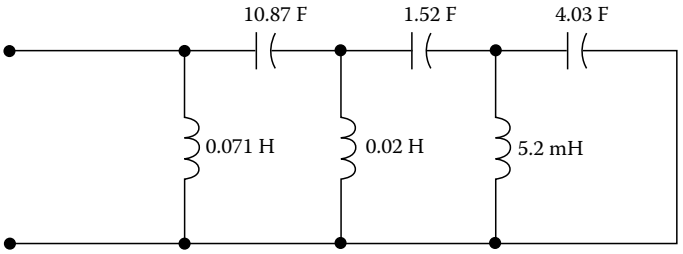

FIGURE 7.9 Second Cauer canonical form.

For the second Cauer canonical form, we rearrange the polynomials in ascending order of s, then expand the resulting function in a continued fraction, and obtain

$$Z(s) = \cfrac{1}{\cfrac{14.06}{s} + \cfrac{1}{\cfrac{0.092}{s} + \cfrac{1}{\cfrac{49.84}{s} + \cfrac{1}{\cfrac{0.66}{s} + \cfrac{1}{\cfrac{192.26}{s} + \cfrac{1}{\cfrac{0.248}{s}}}}}}} \tag{7.19}$$

The desired LC ladder is shown in Figure 7.9.

7.3 RC One-Port Networks

In this part, we exploit the properties of impedance functions of the RC one-ports from the known properties of the LCM one-ports of Section 7.2.

From a given RC one-port N_{RC}, we construct an LC one-port N_{LC} by replacing each resistor of resistance R_i by an inductor of inductance $L_i = R_i$. Suppose that we use loop analysis for both N_{RC} and N_{LC}, and choose the same set of loop currents. In addition, assume that the voltage source at the input port is traversed only by loop current ①. Then the input impedance $Z_{LC}(s)$ of N_{LC} is determined by the equation

$$Z_{LC}(s) = \frac{\tilde{\Delta}(s)}{\tilde{\Delta}_{11}(s)} \tag{7.20}$$

where

$\tilde{\Delta}$ is the loop determinant

$\tilde{\Delta}_{11}$ is the cofactor corresponding to loop current 1 in N_{LC}

Similarly, the input impedance $Z_{RC}(s)$ of N_{RC} can be written as

$$Z_{RC}(s) = \frac{\Delta(s)}{\Delta_{11}(s)} \tag{7.21}$$

where Δ is the loop determinant and Δ_{11} is the cofactor corresponding to loop current 1 in N_{RC}. It is not difficult to see that these loop determinants and cofactors are related by

$$\Delta(s) = \left.\frac{\tilde{\Delta}(p)}{p^r}\right|_{p^2=s} \tag{7.22a}$$

$$\Delta_{11}(s) = \left.\frac{\tilde{\Delta}_{11}(p)}{p^{r-1}}\right|_{p^2=s} \tag{7.22b}$$

where r is the order of the loop determinants $\tilde{\Delta}$ and Δ. Combining Equations 7.20 through 7.22 yields

$$Z_{RC}(s) = \left[\frac{1}{p} Z_{LC}(p)\right]_{p^2=s} \tag{7.23}$$

This relation allows us to deduce the properties of RC networks from those of the LC networks. Substituting Equations 7.6 and 7.7 in Equation 7.23, we obtain the general forms of the RC impedance function as

$$Z_{RC}(s) = H\frac{(s+\sigma_{z1})(s+\sigma_{z2})(s+\sigma_{z3})\cdots}{s(s+\sigma_{p1})(s+\sigma_{p2})\cdots} = H + \frac{K_0}{s} + \sum_{i=1}^{n}\frac{\hat{K}_i}{s+\sigma_i} \tag{7.24}$$

where $\sigma_{zj} = \omega_{zj}^2$, $\sigma_{pi} = \omega_{pi}^2$, $\sigma_i = \omega_i^2$ and $\hat{K}_i = 2K_i$, and from Equation 7.11

$$0 \le \sigma_{z1} < \sigma_{p1} < \sigma_{z2} < \sigma_{p2} < \cdots \tag{7.25}$$

Thus, the zeros and poles of an RC impedance alternate along the nonpositive real axis. This property turns out also to be sufficient to characterize the RC impedances.

THEOREM 7.2

A real rational function is the driving-point impedance of an RC one-port network if and only if all the poles and zeros are simple, lie on the nonpositive real axis, and alternate with each other, the first critical frequency (pole or zero) being a pole.

The slope of $Z_{RC}(\sigma)$ is found from Equation 7.24 to be

$$\frac{dZ_{RC}(\sigma)}{d\sigma} = -\frac{K_0}{\sigma^2} - \sum_{i=1}^{n}\frac{\hat{K}_i}{(\sigma+\sigma_i)^2} \tag{7.26}$$

which is negative for all values of σ, since K_0, and $\hat{k}_i$ are positive. Thus, we have

$$\frac{dZ_{RC}(\sigma)}{d\sigma} < 0 \tag{7.27}$$

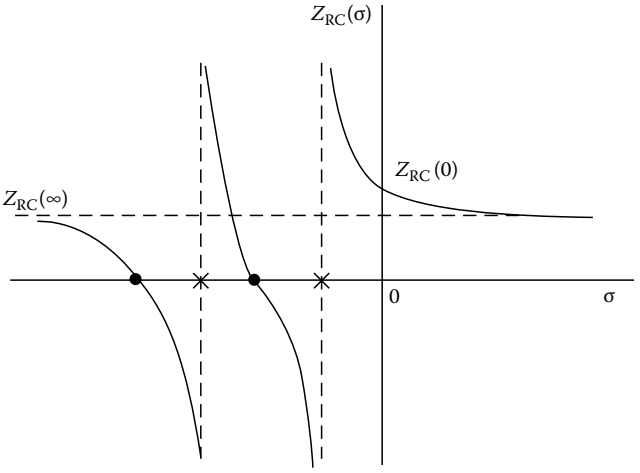

FIGURE 7.10 Plot of $Z_{RC}(\sigma)$ as a function of σ.

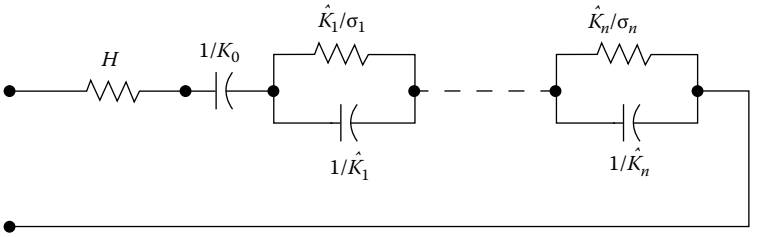

FIGURE 7.11 First Foster Canonical Form.

A plot of $Z_{RC}(\sigma)$ as a function of σ is shown in Figure 7.10. Since no poles and zeros exist along the positive real axis, we have

$$Z_{RC}(\infty) \leq Z_{RC}(0) \tag{7.28}$$

We now proceed to the realization of the RC one-port networks. Suppose that we are given $Z_{RC}(\sigma)$ as in Equation 7.24. By analogy to the LC case, this impedance can be realized by the one-port network of Figure 7.11 called the first Foster canonical form for the RC impedance.

To obtain the second Foster canonical form, we expand $Y_{RC}(s)/s$ in a partial fraction, where $Y_{RC}(s) = 1/Z_{RC}(s)$, and then multiply the resulting equation by s. The reason is that a direct partial-fraction expansion of $Y_{RC}(s)$ will result in negative residues. Proceeding in this way, we obtain

$$Y_{RC}(s) = K_0 + K_\infty s + \sum_{i=1}^{n} \frac{K_i s}{s + \sigma_i} \tag{7.29}$$

yielding the one-port network of Figure 7.12.

As before, in addition to the two Foster forms, RC ladder realizations are also possible. Following the LC case, we perform a continued-fraction expansion of $Z_{RC}(s)$ and obtain

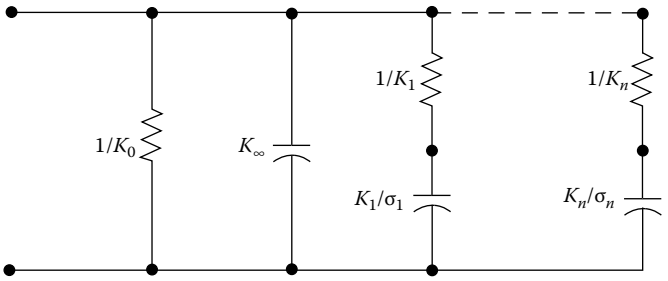

FIGURE 7.12 Second Foster canonical form.

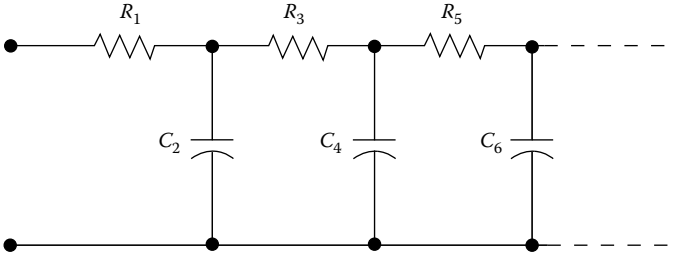

FIGURE 7.13 First Cauer canonical form.

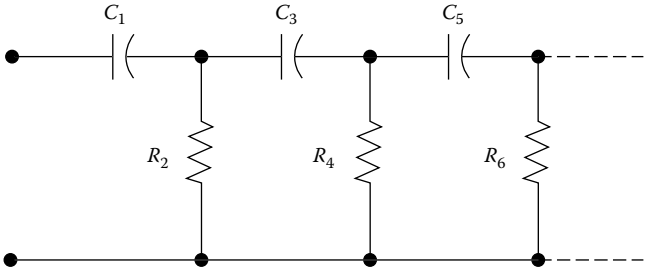

FIGURE 7.14 Second Cauer canonical form.

$$Z_{RC}(s) = R_1 + \cfrac{1}{C_2 s + \cfrac{1}{R_3 + \cfrac{1}{C_4 s + \cfrac{1}{\ddots}}}} \tag{7.30}$$

This expansion can be realized by the ladder network of Figure 7.13 known as the first Cauer canonical form for RC impedance. If we rearrange the terms of $Z_{RC}(s)$ so that the numerator and denominator polynomials appear in ascending order of s, the resulting continued-fraction expansion takes the general form

$$Z_{RC}(s) = \frac{1}{C_1 s} + \cfrac{1}{\cfrac{1}{R_2} + \cfrac{1}{\cfrac{1}{C_3 s} + \cfrac{1}{\cfrac{1}{R_4} + \cfrac{1}{\cfrac{1}{C_5 s} + \cfrac{1}{\ddots}}}}} \tag{7.31}$$

yielding the second Cauer canonical form of Figure 7.14.

Example 7.2

Consider the impedance function

$$Z(s) = \frac{s^2 + 12s + 35}{s^2 + 10s + 24} \tag{7.32}$$

To obtain the first Foster canonical form, we expand $Z(s)$ in partial fraction as

$$Z(s) = 1 + \frac{3/2}{s+4} + \frac{1/2}{s+6} \tag{7.33}$$

and obtain the one-port of Figure 7.15.

For the second Foster canonical form, the proper function to expand is $Y(s)/s$, yielding

$$Y(s) = \frac{24}{35} + \frac{s/10}{s+5} + \frac{3s/14}{s+7} \tag{7.34}$$

The corresponding realization is shown in Figure 7.16.

For the first Cauer canonical form, we expand $Z(s)$ in a continued fraction as

$$Z(s) = 1 + \cfrac{1}{\cfrac{s}{2} + \cfrac{1}{\cfrac{4}{9} + \cfrac{1}{\cfrac{27s}{2} + \cfrac{1}{\cfrac{1}{72}}}}} \tag{7.35}$$

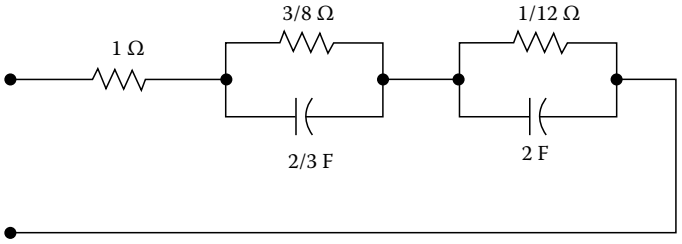

FIGURE 7.15 First Foster canonical form.

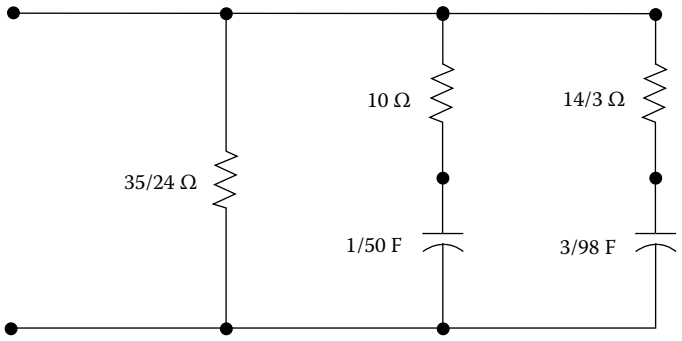

FIGURE 7.16 Second Foster canonical form.

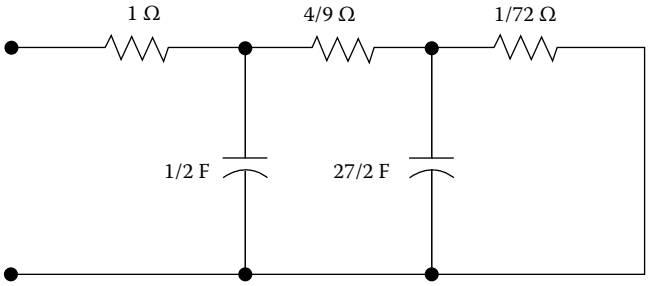

FIGURE 7.17 First Cauer canonical form.

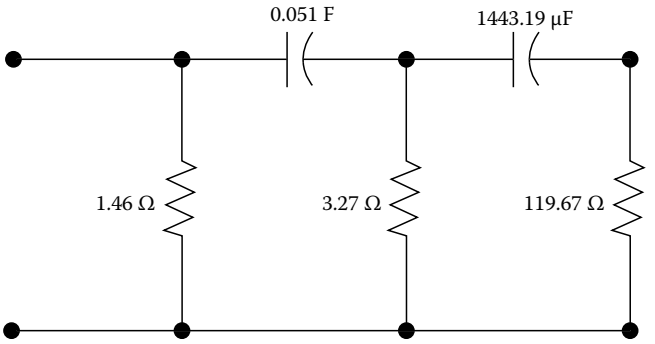

FIGURE 7.18 Second Cauer canonical form.

which can be realized by the ladder of Figure 7.17. To obtain the second Cauer canonical form, we rearrange the numerator and denominator polynomials in ascending order of s, and then expand in a continued fraction

$$Z(s) = \frac{35 + 12s + s^2}{24 + 10s + s^2} = \cfrac{1}{0.69 + \cfrac{1}{\cfrac{19.76}{s} + \cfrac{1}{0.306 + \cfrac{1}{\cfrac{692.91}{s} + \cfrac{1}{8.36 \times 10^{-3}}}}}} \tag{7.36}$$

yielding the ladder of Figure 7.18.

8.1 Introduction

In two-port synthesis, specifications are often given in terms of the transfer functions such as the transfer voltage ratio, transfer current ratio, transfer impedance, or transfer admittance. The actual realization, however, is accomplished by means of the y- or z-parameters. Figure 8.1 shows a two-port network driven by a voltage source with output terminating in an impedance $Z_2(s)$. It is straightforward to show that the transfer voltage ratio function $G_{12}(s)$ can be expressed in terms of its y-parameters $y_{ij}(s)$ or z-parameters $z_{ij}(s)$ by the equation

$$G_{12}(s) = \frac{V_2}{V_1} = \frac{-y_{21}}{y_{22} + Y_2} \tag{8.1}$$

where $Y_2(s) = 1/Z_2(s)$. When the output is open-circuited, Equation 8.1 becomes

$$G_{12}(s) = \frac{V_2}{V_1} = \frac{-y_{21}}{y_{22}} = \frac{z_{21}}{z_{11}} \tag{8.2}$$

Likewise, the transfer current ratio $\alpha_{12}(s)$ can be expressed as

$$\alpha_{12}(s) = -\frac{I_2}{I_1} = \frac{z_{21}}{z_{22} + Z_2} \tag{8.3}$$

The zeros of transmission of a two-port network are defined as the frequencies at which the two-port results in zero output for a finite input. They play an important role in ladder development. There are many ways of producing zeros of transmission. One possibility to prevent the input signal from reaching the output is by shorting together all transmission paths or by opening all transmission paths by means of a series or parallel resonance. Another possibility is that signals transmitted by different paths cancel at the output.

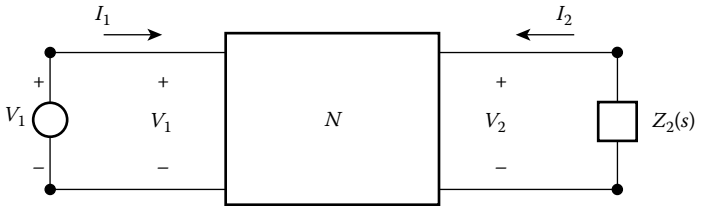

FIGURE 8.1 Terminated two-port network.

Observe from Equations 8.1 and 8.2 that zero output, $V_2 = 0$, implies a zero for each of these functions. Therefore, zeros of transmission are zeros of $-y_{21}$ or z_{21} provided y_{21} and y_{22} or z_{21} and z_{11} have the same poles. For the ladder network, the transmission can be interrupted only by the short circuit in a shunt arm or an open circuit in a series arm. The short circuit of a shunt arm corresponds to the pole frequencies of its admittances, whereas the open circuit of a series arm corresponds to the pole frequencies of its impedances. Therefore, the zeros of transmission of a ladder network can be identified directly with the zeros of the impedances of the shunt arms and the poles of the impedances of the series arms. For the LC ladder, all zeros of transmission lie on the $j\omega$-axis, and for the RC ladder they are on the nonpositive real axis of the complex-frequency s-plane.

8.2 LC Ladder

For LC ladders, the conditions imposed on $-y_{21}$ and y_{22} or z_{21} and z_{22} are that the driving-point functions y_{22} and z_{22} be positive real with poles and zeros interlaced on the $j\omega$-axis. The transfer functions $-y_{21}$ and z_{21}, assuming to have the same poles as y_{22} or z_{22}, must have all of its zeros on the $j\omega$-axis. However, these zeros need not be interlaced with the poles and they may not be simple. Our strategy in realization is that of carrying out the driving-point synthesis of y_{22} or z_{22}, using Cauer ladder development method, in such a way that the zeros of transmission are realized at the same time. The procedure consists of two steps: a zero-shifting step and a zero-producing step, as described below.

Zero shifting by partial removal. Consider an impedance of Equation 7.6, the partial-fraction expansion of which is given in Equation 7.7. The first term on the right-hand side of Equation 7.7 is due to the contribution of the pole at the infinity. If this term Hs is subtracted from $Z(s)$, the resulting function $Z(s) - Hs$ is devoid of the pole at the infinity. We say that the pole at infinity has been removed completely. Instead of complete removal of this pole, suppose that we subtract a fraction of the terms Hs from $Z(s)$ by introducing a constant k_p such that

$$Z_1(s) = Z(s) - k_p Hs, \quad k_p < 1 \tag{8.4}$$

We say that the pole at infinity has been partially removed or weakened. The function $Z_1(s)$ that results from the partial removal of the pole at infinity still possesses the pole at infinity. Since all the zeros of $Z_1(s)$ are again located on the $j\omega$-axis, these zeros are found by substituting $s = j\omega$ in Equation 8.4,

$$X_1(\omega) = X(\omega) - k_p H\omega \tag{8.5}$$

where $Z_1(j\omega) = jX_1(\omega)$. The zeros of $X_1(\omega)$ are values of ω satisfying the equation

$$X(\omega) = k_p H\omega \tag{8.6}$$

Solutions to this equation are found graphically from the intersections of the curves $X(\omega)$ and $k_p H\omega$, as depicted in Figure 8.2. Observe that all the zeros in the resulting function are shifted toward the pole

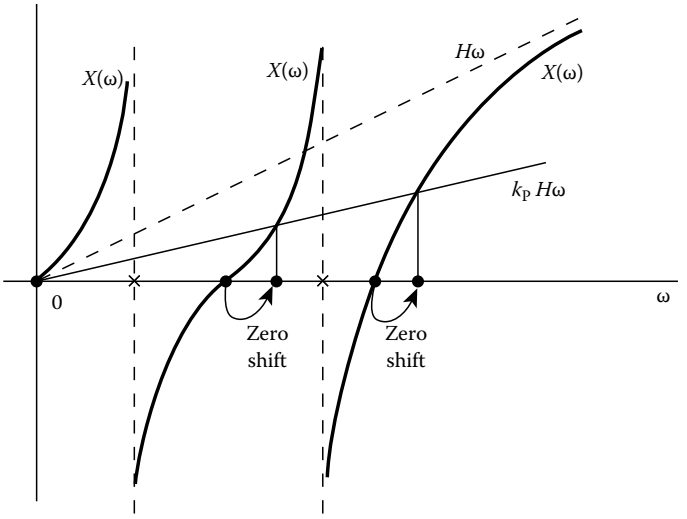

FIGURE 8.2 Zero shifting by weakening the pole at the infinity.

being weakened. The amount of shift of the zeros from their original positions depends on the value of k_p and the proximity of a zero to the pole being weakened.

We next consider the term K_0/s in Equation 7.7 due to the pole at the origin. The partial removal of this pole is equivalent to the operation

$$Z_2(s) = Z(s) - k_p \frac{K_0}{s} \tag{8.7}$$

As before, the zeros of $Z_2(s)$ are defined by the intersections of the curves $X(\omega)$ and $-k_p(K_0/\omega)$ with ω,

$$X(\omega) = -k_p \frac{K_0}{\omega} \tag{8.8}$$

as illustrated in Figure 8.3. Observe again that the zeros are shifted toward the pole being weakened, which is at the origin.

Finally, for the finite nonzero poles, the corresponding factors take the general form $2K_i s/(s^2 + \omega_i^2)$. The partial removal of this pair of complex conjugate poles results in the new function

$$Z_3(s) = Z(s) - k_p \frac{2K_i s}{s^2 + \omega_i^2}, \quad k_p < 1 \tag{8.9}$$

The zeros of this function are defined by the intersections of the plots of $X(\omega)$ and $-k_p(2K_i\omega/(\omega^2 - \omega_i^2))$ with ω,

$$X(\omega) = -k_p \frac{2K_i \omega}{\omega^2 - \omega_i^2}, \quad k_p < 1 \tag{8.10}$$

as illustrated in Figure 8.4.

Our conclusion is that the partial removal of a pole shifts the zeros toward that pole. The amount of shift depends on the value of k_p and the proximity of a zero to that pole, but in no case can a zero be shifted beyond an adjacent pole.

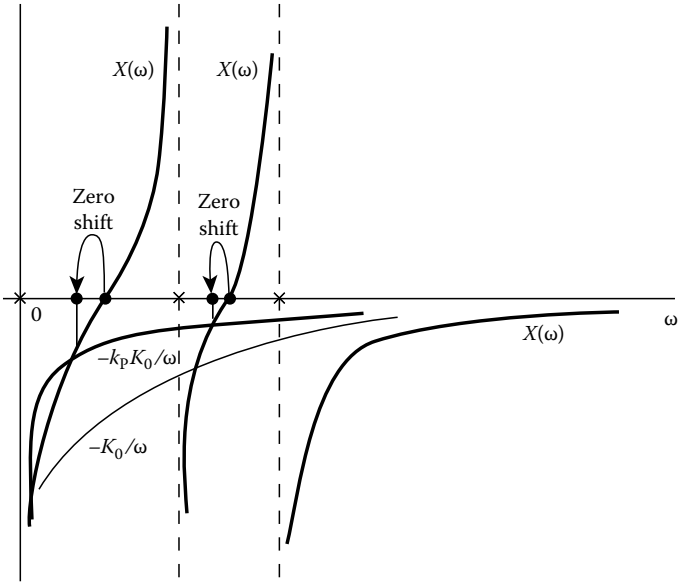

FIGURE 8.3 Zero shifting by weakening the pole at the origin.

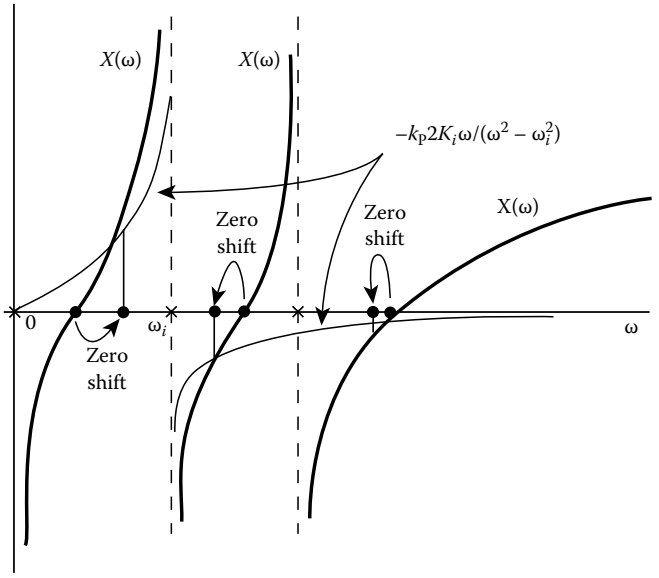

FIGURE 8.4 Zero shifting by weakening a finite nonzero pole.

Zero producing by complete pole removal. After a zero of transmission has been shifted to a desired location by the partial removal of an appropriate pole, the realization of this zero of transmission is accomplished by the complete removal of the pole of the reciprocal function corresponding to the shifted zero. For the LC ladder two-ports, a series combination of an inductor L and a capacitor C produces a zero at its resonant frequency $\omega = 1/\sqrt{LC}$ and this network is used in the shunt arm in the ladder to produce the desired zero of transmission. Likewise, the parallel connection of L and C yields

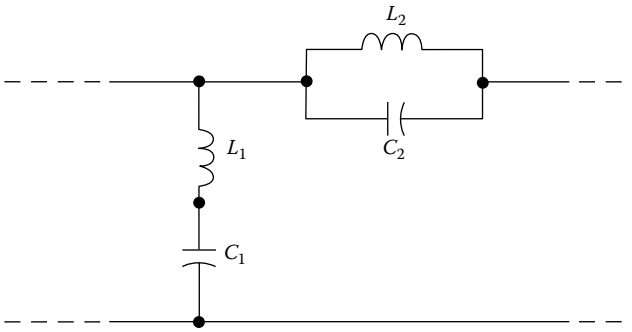

FIGURE 8.5 Zero producing sections in a ladder network.

an infinite impedance at its resonant frequency, and is used in the series arm of the ladder. They are shown in Figure 8.5.

Example 8.1

We wish to design a lossless two-port network terminated in a 100-Ω resistor to meet the specifications for the transfer voltage-ratio function

$$G_{12}(s) = \frac{V_2}{V_1} = K\frac{s^2+4}{s^3+4s^2+9s+4} \tag{8.11}$$

within a multiplicative constant.

Since magnitude scaling does not affect the voltage transfer ratio, without loss of generality, we first assume that the terminating resistor is 1 Ω. Equation 8.11 can be rewritten as

$$G_{12}(s) = K\frac{\dfrac{s^2+4}{s(s^2+9)}}{\dfrac{4(s^2+1)}{s(s^2+9)}+1} = \frac{-y_{21}}{y_{22}+Y_2} = \frac{-y_{21}}{y_{22}+1} \tag{8.12}$$

We can make the following identifications:

$$-y_{21}(s) = K\frac{s^2+4}{s(s^2+9)}, \quad y_{22}(s) = 4\frac{s^2+1}{s(s^2+9)} \tag{8.13}$$

Both functions have the same poles at $s=0$ and $s = \pm j3$ and the zeros of transmission of the ladder are located at $s=\pm j2$ and $s=\infty$. These poles and zeros are shown in Figure 8.6. To realize the zero of transmission at $s=\infty$, we remove the pole of $z_1(s) = 1/y_{22}(s)$ at $s=\infty$.

$$z_1(s) = \frac{1}{y_{22}(s)} = \frac{s(s^2+9)}{4(s^2+1)} = \frac{2s}{s^2+1} + \frac{s}{4} \tag{8.14}$$

After subtracting the term $s/4$ corresponding to an inductor of inductance 1/4 H shown in Figure 8.7 from $z_1(s)$, the remaining impedance $z_2(s)$ is found to be

$$z_2(s) = \frac{2s}{s^2+1} \tag{8.15}$$

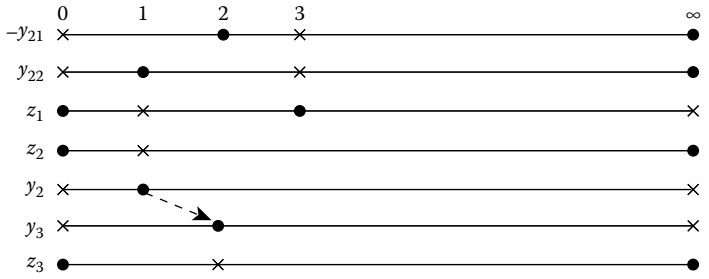

FIGURE 8.6 Poles and zeros of LC immittances.

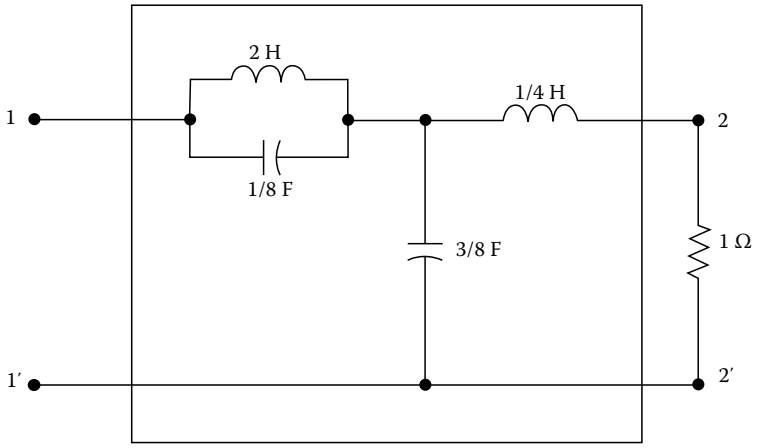

FIGURE 8.7 LC ladder realization of the transfer voltage ratio (Equation 8.11).

To realize the zero of transmission at $s = \pm j2$, we partially weaken the pole of the admittance

$$y_2(s) \equiv \frac{1}{z_2(s)} = \frac{s^2 + 1}{2s} \tag{8.16}$$

at s = ∞ in order to shift the zero at $s = \pm j$ to $s = \pm j2$, or

$$y_3(\pm j2) = y_2(s) - k_p \frac{1}{2} s \Big|_{s=\pm j2} = \frac{-4 + 1}{\pm j2 \times 2} \mp k_p \frac{1}{2} j2 = 0 \tag{8.17}$$

yielding $k_p = 3/4$. The new function becomes

$$y_3(s) = \frac{s^2 + 1}{2s} - \frac{3}{8} s = \frac{s^2 + 4}{8s} \tag{8.18}$$

after the removal of a shunt capacitor of capacitance 3/8 F, as shown in Figure 8.7. The factor $(s^2 + 4)$ in the numerator was anticipated because our objective was to produce a zero in the driving-point admittance $y_3(s)$ at $s = \pm j2$. To realize this zero, we consider the reciprocal function $z_3(s) = 1/y_3(s)$ by complete removal of its pole at $s = \pm j2$. This yields a parallel connection of $L = 2$ H and $C = 1/8$ F shown in Figure 8.7. The final realization is obtained by magnitude-scaling by a factor of 100. The realized constant K is found from the network to be $K = 1$.

8.3 RC Ladder

We now consider the realization of RC ladder with prescribed $-y_{21}(s)$ and $y_{22}(s)$ or $z_{21}(s)$ and $z_{22}(s)$. Following the LC case, the zero shifting for the RC driving-point functions is accomplished by one or any combination of the following three operations:

1. Partial removal of a constant $Z(\infty)$ from $Z(s)$
2. Partial removal of a constant $Y(0)$ from $Y(s)$
3. Partial removal of a pole from $Z(s)$ or $Y(s)$

The first operation permits a series resistance to be removed so that the resulting impedance is still positive real and possesses a desired zero of transmission:

$$Z_1(s) = Z(s) - k_p Z(\infty), \quad k_p \leq 1 \tag{8.19}$$

the zeros of which occur at those values of σ satisfying

$$Z(\sigma) = k_p Z(\infty), \quad k_p \leq 1 \tag{8.20}$$

Observe that from Figure 8.8 all zeros are shifted toward $s = \sigma = -\infty$ by the partial removal of $Z(\infty)$ because the slope is negative for the RC impedances.

The second operation corresponds to the removal of a shunt resistance, and the remaining admittance

$$Y_1(s) = Y(s) - k_p Y(0), \quad k_p \leq 1 \tag{8.21}$$

is still positive real, the zeros of which occur at those values of σ satisfying

$$Y(\sigma) = k_p Y(0), \quad k_p \leq 1 \tag{8.22}$$

Observe from Figure 8.9 that these zeros again are shifted toward $s = 0$ in relation to those of $Y(s)$.

Finally, the partial removal of a pole of $Z(s)$ results in a parallel connection of a resistor and a capacitor, and the remaining impedance becomes

$$Z_2(s) = Z(s) - k_p \frac{K_i}{s + \sigma_i}, \quad k_p < 1 \tag{8.23}$$

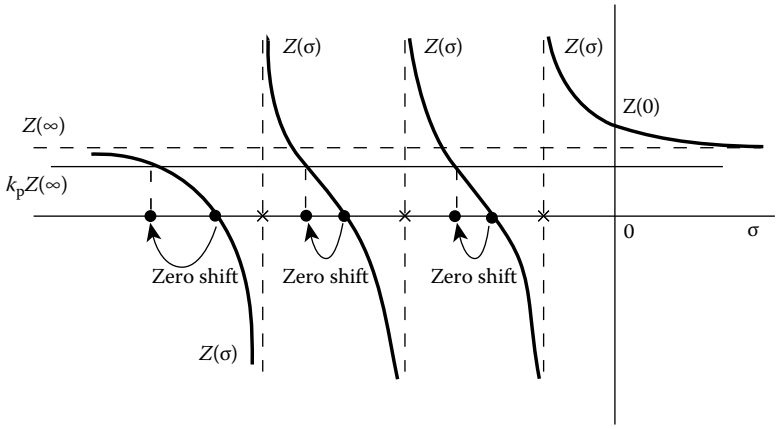

FIGURE 8.8 Zero shifting by the partial removal of $Z(\infty)$.

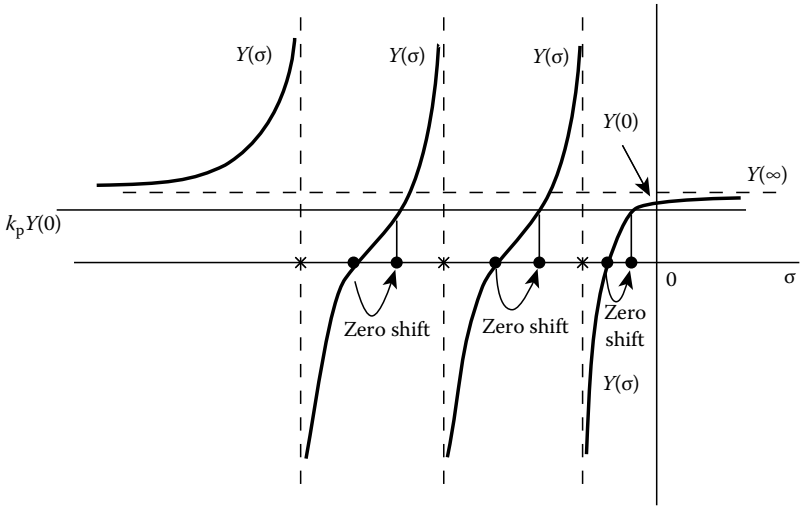

FIGURE 8.9 Zero shifting by partial removal of $Y(0)$.

the zeros of which occur at those values of σ satisfying

$$Z(\sigma) = k_p \frac{K_i}{\sigma + \sigma_i}, \quad k_p < 1 \tag{8.24}$$

As indicated in Figure 8.10, these zeros are again shifted toward the pole at $s = -\sigma_i$ being partially weakened.

Therefore, the partial removal of a constant or a pole shifts the zeros of the remaining function toward the quantity being weakened. The amount of shift depends on the value of k_p and the proximity of a zero to that quantity. Once a zero is shifted to an appropriate location, its realization is accomplished by the complete removal of the pole of the reciprocal function corresponding to the shifted zero.

Example 8.2

We wish to realize the transfer impedance

$$Z_{12}(s) = K \frac{s(s+1)}{2s^2 + 18s + 34} \tag{8.25}$$

of an RC two-port network terminated in a 1 Ω resistor.

From Equation 8.3, the transfer impedance can be written as

$$Z_{12}(s) = \frac{V_2}{I_1} = \frac{-I_2 \times 1}{I_1} = \frac{-I_2}{I_1} = \frac{z_{21}}{z_{22} + 1} = \frac{K \dfrac{s(s+1)}{(s+2)(s+5)}}{\dfrac{(s+3)(s+8)}{(s+2)(s+5)} + 1} \tag{8.26}$$

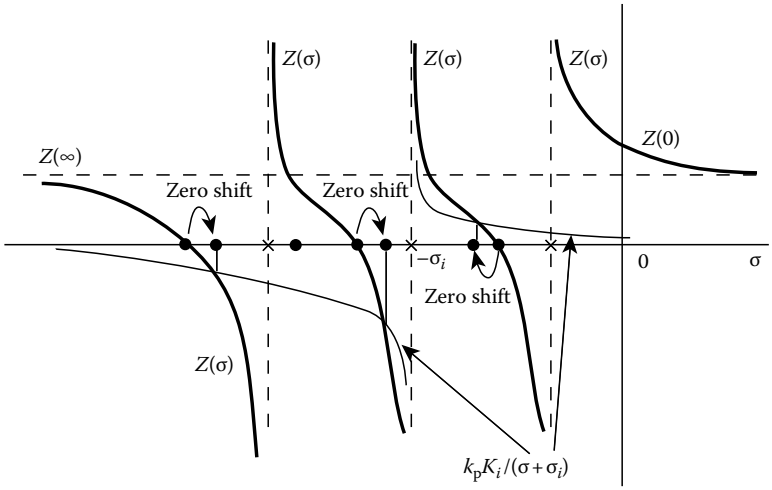

FIGURE 8.10 Zero shifting by partial removal of a pole of an RC impedance.

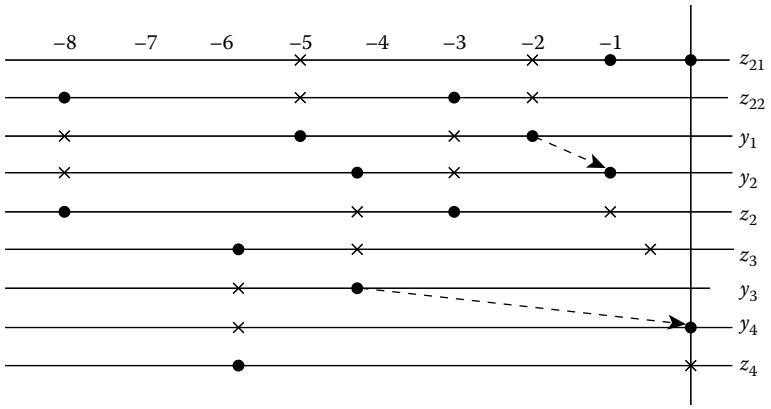

FIGURE 8.11 Zeros and poles of RC immittances.

identifying

$$z_{21}(s) = K\frac{s(s+1)}{(s+2)(s+5)}, \quad z_{22}(s) = \frac{(s+3)(s+8)}{(s+2)(s+5)} \tag{8.27}$$

The zeros of transmission are located at $s=0$ and $s=-1$. Suppose that we wish to realize these zeros in the order of -1 and 0. For this we consider the reciprocal function $y_1(s) = 1/z_{22}(s)$, the zeros. and poles of which are shown in Figure 8.11. Clearly, the zero at $s=-2$ can be shifted to $s=-1$ by partial removal of the constant $y_1(0) = 5/12$,

$$y_2(-1) = y_1(-1) - k_p y_1(0) = 0 \tag{8.28}$$

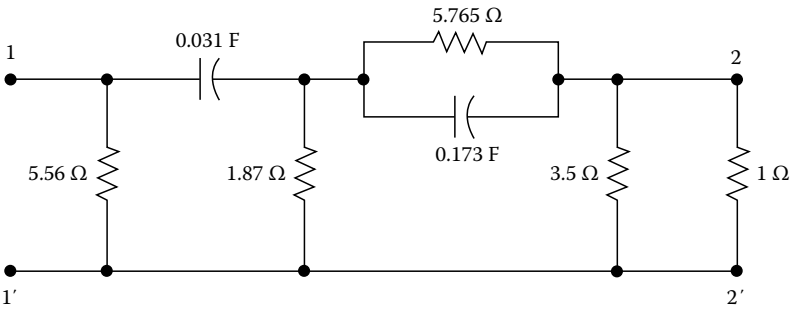

FIGURE 8.12 RC ladder realization of the transfer impedance $Z_{12}(s)$.

obtaining $k_p = 24/35$ and

$$y_2(s) = y_1(s) - \frac{24}{35}y_1(0) = \frac{(s+1)(5s+22)}{7(s^2+11s+24)} \tag{8.29}$$

This admittance has a zero at $s = -1$, as expected. The partially removed constant $k_p y_1(0)$ corresponds to a shunt resistor of resistance 3.5 Ω. To realize the zero of transmission at $s = -1$, we consider the reciprocal function $z_2(s) = 1/y_2(s)$ by the complete removal of its pole at $s = -1$. The remaining impedance $z_3(s)$ becomes

$$z_3(s) = z_2(s) - \frac{\frac{98}{17}}{s+1} = \frac{7}{5} \times \frac{s+\frac{100}{17}}{s+\frac{22}{5}} \tag{8.30}$$

The removed pole corresponds to a parallel connection of a resistor of resistance 98/17 Ω and a capacitor of capacitance 17/98 F, as illustrated in Figure 8.12.

For the zero of transmission at $s = 0$, we consider the reciprocal function $y_3(s) = 1/z_3(s)$. The zero of $y_3(s)$ at s = −22/5 can be shifted to 0 by partial removal of the constant $y_3(0) = 187/350$, or

$$y_4(0) = y_3(0) - k_p y_3(0) = 0 \tag{8.31}$$

yielding $k_p = 1$. The remaining admittance $y_4(s)$ becomes

$$y_4(s) = y_3(s) - y_3(0) = \frac{\frac{9}{50}s}{s+\frac{100}{17}} \tag{8.32}$$

showing a zero at the origin, as anticipated. This zero is realized by the complete removal of the pole at the origin of its reciprocal $z_4(s) = 1/y_4(s)$, yielding

$$z_5(s) = z_4(s) - \frac{32.68}{s} = 5.56 \tag{8.33}$$

The complete realization is presented in Figure 8.12, from which the constant K is found to be $K = 1$.

8.4 Parallel or Series Ladders

The zeros of transmission of the LC ladders are restricted to the $j\omega$-axis and those of the RC ladders to the negative real axis of the s-plane. For complex zeros of transmission such as those needed for certain phase-correction applications, they cannot be realized by a single LC or RC ladder because there is only a single transmission path from the input to the output. The use of parallel or series ladders, on the other

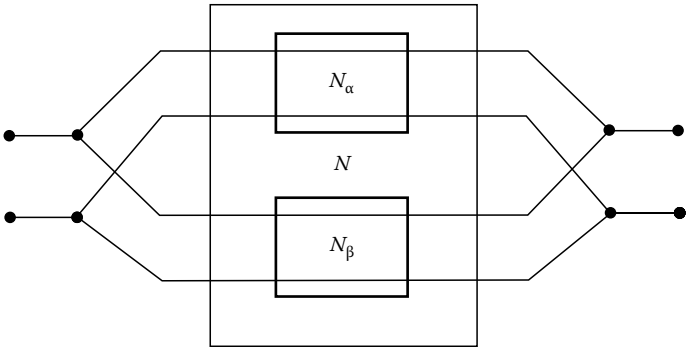

FIGURE 8.13 Parallel connection of two ladder networks.

hand, provides a conduit for multiple path signal transmission, so that the signals arriving at the output through the various paths may cancel one another, resulting in the zero output for a finite input. Therefore, they are capable of producing complex zeros of transmission. This structure was first suggested by Guillemin [1].

Figure 8.13 is the parallel connection of the ladder networks N_α and N_β. The y-parameters y_{ij} of the composite two-port N can be expressed in terms of those $y'_{ij\alpha}$ and $y'_{ij\beta}$ of the component two-ports N_α and N_β by the equation

$$y_{ij} = y'_{ij\alpha} + y'_{ij\beta}, \quad i,j = 1,2 \tag{8.34}$$

Thus, to realize $-y_{21}(s)$ and $y_{22}(s)$, we may separate them into pairs like $-y'_{21\alpha}$, $y'_{22\alpha}$ and $-y'_{21\beta}$, $y'_{22\beta}$ realize an individual pair as an LC or RC ladder. Then connect these individual ladders in parallel to realize $-y_{21}(s)$ and $y_{22}(s)$. In order for the procedure to succeed, we must resolve the following problem. Recall than in the Cauer development of LC and RC ladders, $-y_{21}(s)$ is realized only within the multiplicative constant k. Thus, the transfer admittances realized by the component two-ports actually will be $-k_\alpha y'_{21\alpha}$and $-k_\beta y'_{21\beta}$. The sum of these two functions will not result in the desired $-ky_{21}$ unless $k = k_\alpha = k_\beta$. To circumvent this difficulty, we introduce an additional degree of freedom by adjusting the admittance level of the α-ladder N_α by a factor b_α and the β-ladder N_β by b_β. Then the functions of the resulting realizations become

$$-y'_{21\alpha} = -b_\alpha k_\alpha y_{21\alpha}, \quad y'_{22\alpha} = b_\alpha y_{22\alpha} \tag{8.35a}$$

$$-y'_{21\beta} = -b_\beta k_\beta y_{21\beta}, \quad y'_{22\beta} = b_\beta y_{22\beta} \tag{8.35b}$$

where $y_{ij} = y_{ij\alpha} + y_{ij\beta}$, $i, j = 1, 2$. Substituting these in Equation 8.34 gives

$$y_{21} = b_\alpha k_\alpha y_{21\alpha} + b_\beta k_\beta y_{21\beta} \tag{8.36a}$$

$$y_{22} = b_\alpha y_{22\alpha} + b_\beta y_{22\beta} \tag{8.36b}$$

Our objective is to choose b_α and b_β to satisfy the above equations, once $k_\alpha$and k_β are known. One way to meet these requirements is to let $y'_{22\alpha}$ and $y'_{22\beta}$ have the same zeros and poles as y_{22} but different scale factors such that $y'_{22\alpha} = b_\alpha y_{22}$ and $y'_{22\beta} = b_\beta y_{22}$, obtaining from Equation 8.36b

$$b_\alpha + b_\beta = 1 \tag{8.37}$$

Since we can only realize y_{21} within a multiplicative constant, we replace y_{21} by ky_{21} in Equation 8.36a, and set

$$b_\alpha k_\alpha = b_\beta k_\beta = k \tag{8.38}$$

These two equations can be solved to yield the desired scale factors b_α and b_β.

In general, for m ladders in parallel, we require

$$b_1 + b_2 + \cdots + b_m = 1 \tag{8.39a}$$

$$b_1 k_1 = b_2 k_2 = \cdots = b_m k_m = k \tag{8.39b}$$

where

b_i is the admittance scale factor for the ith ladder

k_i is the realized multiplicative constant of the transfer admittance of the ith ladder

Once k_i are known, these m simultaneous equations can be solved for the m unknowns b_i, and the admittance level of each ladder can be scaled accordingly. The scaled ladders are connected in parallel to realize the $-y_{21}(s)$ specifications within the multiplicative constant k, and the $y_{22}(s)$ specifications exactly.

Similar results are obtained by using the z-parameters $z_{ij}(s)$ and the series connection of the component two-port networks, the details of which are omitted. However, a design example will be presented below.

Example 8.3

We wish to realize an RC two-port network to meet the following specifications:

$$-y_{21}(s) = k\frac{s^2 + 1}{(s + 5)(s + 9)} \tag{8.40a}$$

$$y_{22}(s) = \frac{(s + 3)(s + 7)}{(s + 5)(s + 9)} \tag{8.40b}$$

Since the zeros of transmission are located at $s = \pm j1$, they cannot be realized by a single RC ladder. For our purposes, we choose the y-parameters of the component two-ports as

$$-y_{21\alpha}(s) = k_\alpha \frac{s^2}{(s + 5)(s + 9)}, \quad y_{22\alpha}(s) = y_{22}(s) \tag{8.41a}$$

$$-y_{21\beta}(s) = \frac{k_\beta}{(s + 5)(s + 9)}, \quad y_{22\beta}(s) = y_{22}(s) \tag{8.41b}$$

For the α-ladder, since the zeros of transmission are all at the origin, they can be realized by the second Cauer canonical form shown in Figure 8.14 with $k_\alpha = 0.043$. For the β-ladder, since the zeros of transmission are all at the infinity, they can be realized by the first Cauer canonical form of Figure 8.15 with $k_\beta = 21$.

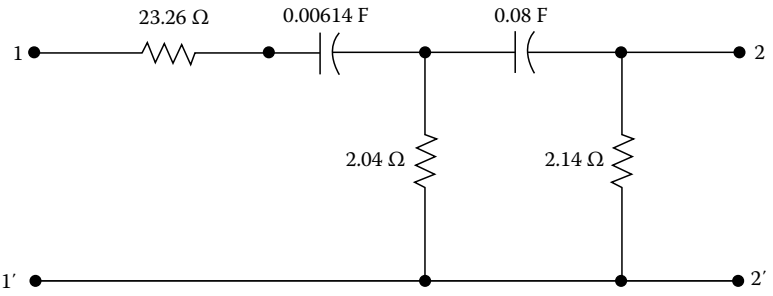

FIGURE 8.14 RC α-ladder realization.

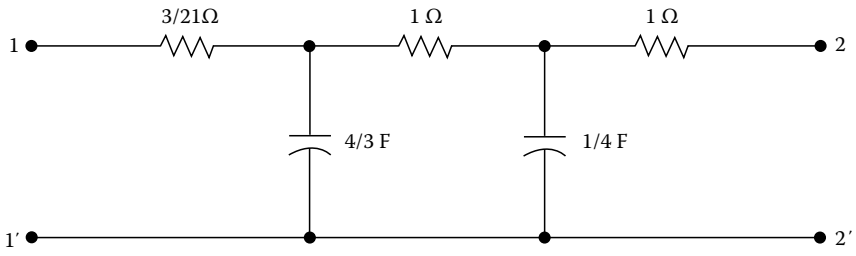

FIGURE 8.15 RC β-ladder realization.

Our next task is to adjust the admittance level of the individual ladders so that when they are connected in parallel, the $y_{22}(s)$ specifications are realized exactly, and the $-y_{21}(s)$ specifications are realized to within a multiplicative constant k. Appealing to Equations 8.37 and 8.38, we have

$$b_\alpha + b_\beta = 1 \tag{8.42a}$$

$$0.043 b_\alpha = 21 b_\beta = k \tag{8.42b}$$

yielding

$$b_\alpha = 0.998 \cong 1, \quad b_\beta = 2.043 \times 10^{-3} \tag{8.43}$$

We now adjust the admittance level of the β-ladder by a factor $b_\beta = 2.043 \times 10^{-3}$, leaving the α-ladder intact. The final realization is achieved by the parallel connection of the α-ladder and the resulting β-ladder shown in Figure 8.16. The realized multiplicative constant for the overall transfer admittance $-y_{21}(s)$ is found to be $k = 0.043$.

Example 8.4

We wish to realize the open-circuit transfer voltage ratio

$$G_{12}(s) = \frac{z_{21}(s)}{z_{11}(s)} = k\frac{s^2 - 2s + 10}{s^2 + 8s + 15} \tag{8.44}$$

by an RC two-port network.

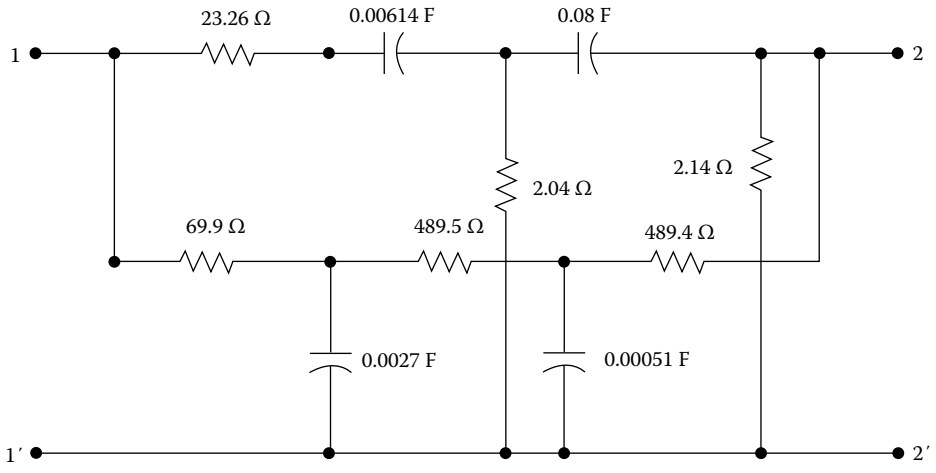

FIGURE 8.16 Parallel RC ladder realization of $-y_{21}(s)$ and $y_{22}(s)$.

First, we multiply the numerator and denominator of $G_{12}(s)$ by the factor $(s+2)$ to yield

$$G_{12}(s) = \frac{z_{21}(s)}{z_{11}(s)} = k\frac{s^3 + 6s + 20}{(s+2)(s+3)(s+5)} \tag{8.45}$$

and then divide by $(s+1)(s+2.5)(s+4)$ in order to make the following identifications:

$$z_{21}(s) = k\frac{s^3 + 6s + 20}{(s+1)(s+2.5)(s+4)} \tag{8.46a}$$

$$z_{11}(s) = \frac{(s+2)(s+3)(s+5)}{(s+1)(s+2.5)(s+4)} \tag{8.46b}$$

We next decompose the pairs into three pairs as follows:

$$z_{21\alpha}(s) = k_\alpha \frac{s^3}{(s+1)(s+2.5)(s+4)}, \quad z_{11\alpha}(s) = z_{11}(s) \tag{8.47a}$$

$$z_{21\beta}(s) = k_\beta \frac{6s}{(s+1)(s+2.5)(s+4)}, \quad z_{11\beta}(s) = z_{11}(s) \tag{8.47b}$$

$$z_{21\gamma}(s) = k_\gamma \frac{20}{(s+1)(s+2.5)(s+4)}, \quad z_{11\gamma}(s) = z_{11}(s) \tag{8.47c}$$

1. *The* α*-ladder*. Since all the zeros of transmission are located at the origin, it can be realized by the second Cauer canonical form of Figure 8.17 with $k_\alpha = 1$.
2. *The* β*-ladder*. Since one of the zeros of transmission is located at the origin, and two others at the infinity, the first half of the β-ladder can be realized as the second Cauer canonical form and the second half of the β-ladder by the first Cauer canonical forms as illustrated in Figure 8.18 with $k_\beta = 0.0117$.
3. *The* γ*-ladder*. Since all of its zeros of transmission are located at the infinity, it can be realized by the first Cauer canonical form of Figure 8.19 with $k_\gamma = 0.0145$.

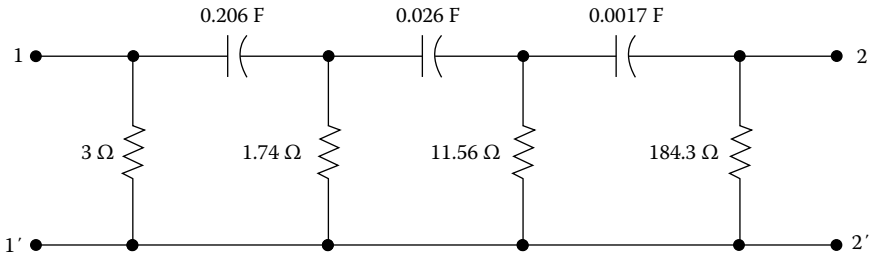

FIGURE 8.17 α-Ladder.

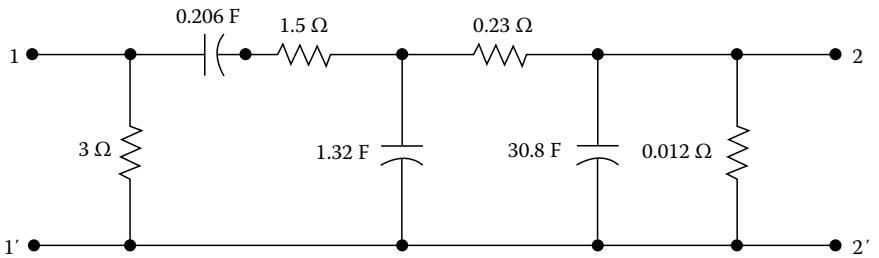

FIGURE 8.18 β-Ladder.

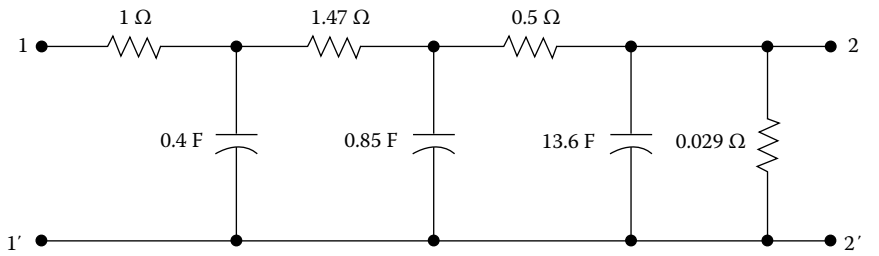

FIGURE 8.19 γ-Ladder.

We next adjust the admittance level of the ladders so that when they are connected in parallel, the desired specifications are realized. From Equation 8.39 we require that

$$b_\alpha + b_\beta + b_\gamma = 1 \tag{8.48a}$$

$$b_\alpha k_\alpha = b_\beta k_\beta = b_\gamma k_\gamma = k \tag{8.48b}$$

These equations can be solved to yield

$$b_\alpha = 0.0064, \quad b_\beta = 0.552, \quad b_\gamma = 0.4416 \tag{8.49}$$

with $k = 0.0064$. The final two-port network is shown in Figure 8.20.

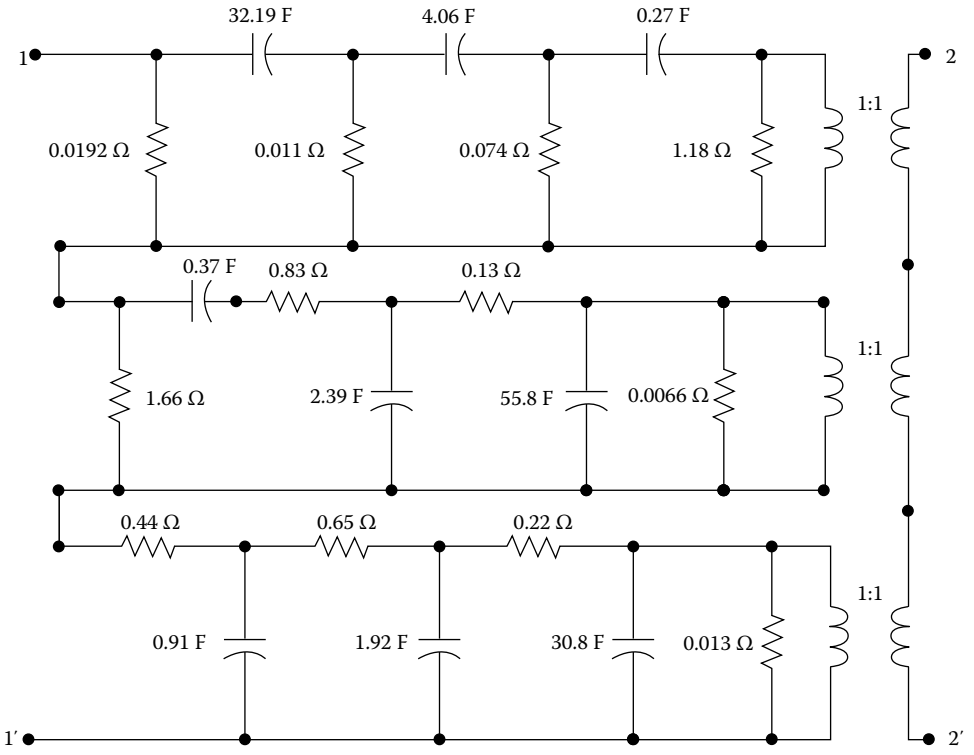

FIGURE 8.20 RC two-port realization of the open-circuit voltage ratio $G_{12}(s)$.

9.1 Introduction

In the design of communication systems, it is frequently required to synthesize a coupling network that will transform a given frequency-dependent load impedance into another specified one. We refer to this operation as impedance matching or equalization, and the resulting coupling network as a matching network or equalizer.

Refer to the network configuration of Figure 9.1 where the source is represented either by its Thévenin equivalent or by its Norton equivalent. Our objective here is to design a lossless two-port network or equalizer N, which when inserted between a resistive source and a resistive load will yield a preassigned transducer power-gain characteristic over the entire sinusoidal frequency spectrum. Explicit formulas for the design of Butterworth and Chebyshev LC ladder networks will be given. The more complicated situation where the load is frequency dependent will be discussed in Chapter 10.

In the networks of Figure 9.1, let $Z_{11}(s)$ and $Z_{22}(s)$ be the impedances looking into the input and output ports when the output and input ports are terminated in $z_2(s)$ and $z_1(s)$, respectively. The input and output reflection coefficients are defined by

$$\rho_{11}(s) = \frac{Z_{11}(s) - z_1(-s)}{Z_{11}(s) + z_1(s)} \tag{9.1a}$$

$$\rho_{22}(s) = \frac{Z_{22}(s) - z_2(-s)}{Z_{22}(s) + z_2(s)} \tag{9.1b}$$

respectively. We now demonstrate that the transducer power gain $G(\omega^2)$ defined as the ratio of average power delivered to the load to the maximum available average power at the source is given by

$$G(\omega^2) = 1 - |\rho_{11}(j\omega)|^2 \equiv |\rho_{21}(j\omega)|^2 \tag{9.2}$$

where $\rho_{21}(s)$ is known as the transmission coefficient. To prove this, we first compute

$$1 - \rho_{11}(s)\rho_{11}(-s) = \frac{4r_1(s)R_{11}(s)}{[Z_{11}(s) + z_1(s)\,][Z_{11}(-s) + z_1(-s)]} \tag{9.3}$$

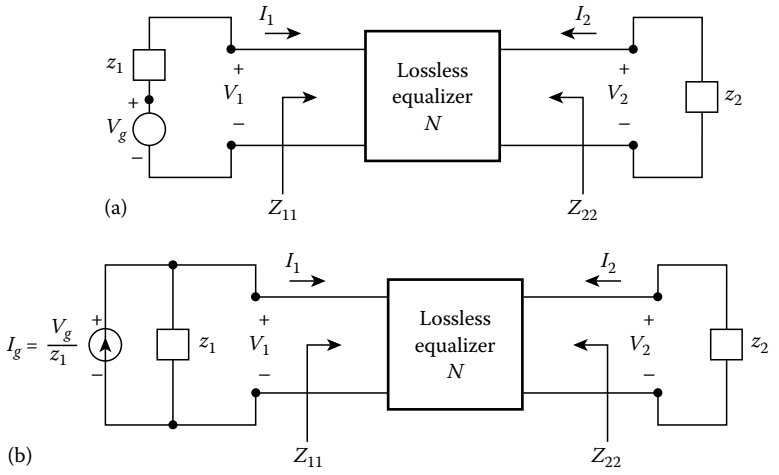

FIGURE 9.1 General broadband matching configuration. (a) The Thévenin equivalent. (b) The Norton equivalent.

where

$$r_1(s) = \text{Ev}\, z_1(s) = \frac{1}{2}[z_1(s) + z_1(-s)] \tag{9.4a}$$

$$R_{11}(s) = \text{Ev}\, Z_{11}(s) = \frac{1}{2}[Z_{11}(s) + Z_{11}(-s)] \tag{9.4b}$$

are the even parts of $z_1(s)$ and $Z_{11}(s)$, respectively. Thus, the impedance facing the voltage source V_g is given by

$$\frac{V_g(s)}{I_1(s)} = Z_{11}(s) + z_1(s) \tag{9.5}$$

On the $j\omega$-axis, Equation 9.3 reduces to

$$1 - |\rho_{11}(j\omega)|^2 = \frac{4r_1(j\omega)R_{11}(j\omega)}{|Z_{11}(j\omega) + z_1(j\omega)|^2} = \frac{|I_1(j\omega)|^2 R_{11}(j\omega)}{|V_g(j\omega)|^2/4r_1(j\omega)} \tag{9.6}$$

The power input to the network of Figure 9.1a under sinusoidal steady state is

$$P_{\text{in}} = |I_1(j\omega)|^2 R_{11}(j\omega) \tag{9.7}$$

while the power output to the load is

$$P_{\text{out}} = |I_2(j\omega)|^2 r_2(j\omega) \tag{9.8}$$

where

$$r_2(s) = \text{Ev}\, z_2(s) = \frac{1}{2}[z_2(s) + z_2(-s)] \tag{9.9}$$

is the even part of $z_2(s)$. Since the two-port N is lossless, the power input must be equal to power output or

$$|I_1(j\omega)|^2 R_{11}(j\omega) = |I_2(j\omega)|^2 r_2(j\omega) \tag{9.10}$$

The maximum average power that the source combination is capable of delivering to the network occurs when the input port is conjugately matched or $Z_{11}(j\omega) = -z_1(j\omega)$. Under this condition, the maximum available average power from the source combination is

$$P_{\text{ava}} = \frac{|V_g(j\omega)|^2}{4r_1(j\omega)} \tag{9.11}$$

Substituting Equations 9.8 and 9.11 in Equation 9.6 yields

$$1 - |\rho_{11}(j\omega)|^2 = \frac{|I_2(j\omega)|^2 r_2(j\omega)}{|V_g(j\omega)|^2/4r_1(j\omega)} = \frac{P_{\text{out}}}{P_{\text{ava}}} = G(\omega^2) \tag{9.12}$$

Using Equation 9.2 shows that

$$|\rho_{11}(j\omega)|^2 + |\rho_{21}(j\omega)|^2 = 1 \tag{9.13}$$

or

$$\begin{aligned} |\rho_{11}(j\omega)|^2 &= 1 - \frac{\text{average power to load}}{\text{average power available}} \\ &= \frac{\text{average power available} - \text{average power to load}}{\text{average power available}} \\ &= \frac{\text{“average reflected” power}}{\text{average power available}} \end{aligned} \tag{9.14}$$

$$|\rho_{21}(j\omega)|^2 = \frac{\text{average power to load}}{\text{average power available}} \tag{9.15}$$

Therefore, the magnitude squared of the reflection coefficient $|\rho_{11}(j\omega)|^2$ denotes the fraction of the maximum available average power that is reflected back to the source, and the magnitude squared of the transmission coefficient $|\rho_{21}(j\omega)|^2$ represents the fraction of the maximum available average power that is transmitted to the load from the source. In fact, their names are suggested by these interpretations. We remark that since the transducer power gain G is a function of ω^2, it is written as $G(\omega^2)$ to emphasize this.

We next express the transmission coefficient in terms of other specifications. From Equation 9.12, we have

$$|\rho_{21}[j\omega]|^2 = 4r_1(j\omega)r_2(j\omega)\left|\frac{I_2(j\omega)}{V_g(j\omega)}\right|^2 \tag{9.16}$$

Substituting $V_g(j\omega) = z_1(j\omega)I_g(j\omega)$ in Equation 9.16 gives

$$|\rho_{21}(j\omega)|^2 = \frac{4r_1(j\omega)r_2(j\omega)}{|z_1(j\omega)|^2}\left|\frac{I_2(j\omega)}{I_g(j\omega)}\right|^2 \tag{9.17}$$

In terms of the transfer voltage ratio and transfer impedance, we apply the relation $V_2(j\omega) = -I_2(j\omega)$ $z_2(j\omega)$ and obtain

$$|\rho_{21}(j\omega)|^2 = \frac{4r_1(j\omega)r_2(j\omega)}{|z_2(j\omega)|^2}\left|\frac{V_2(j\omega)}{V_g(j\omega)}\right|^2 \tag{9.18}$$

$$|\rho_{21}(j\omega)|^2 = \frac{4r_1(j\omega)r_2(j\omega)}{|z_1(j\omega)z_2(j\omega)|^2}\left|\frac{V_2(j\omega)}{I_g(j\omega)}\right|^2 \tag{9.19}$$

Similarly, we can derive a relation between the output reflection coefficient $\rho_{22}(j\omega)$ and the transmission coefficient $\rho_{12}(j\omega)$ magnitude squared as

$$|\rho_{12}(j\omega)|^2 \equiv 1 - |\rho_{22}(j\omega)|^2 \tag{9.20}$$

In fact, for the lossless reciprocal two-port network N we have

$$|\rho_{21}(j\omega)|^2 = |\rho_{12}(j\omega)|^2 = 1 - |\rho_{11}(j\omega)|^2 = 1 - |\rho_{22}(j\omega)|^2 \tag{9.21}$$

9.2 Double-Terminated Butterworth Networks

In this part, we show how to design a lossless two-port network operating between a resistive generator with internal resistance R_1 and a resistive load with resistance R_2 to yield the nth-order Butterworth transducer power-gain characteristic

$$G(\omega^2) = |\rho_{21}(j\omega)|^2 = \frac{K_n}{1 + (\omega/\omega_c)^{2n}} \tag{9.22}$$

Since for a passive network $G(\omega^2)$ is bounded between 0 and 1, the DC gain K_n is restricted by

$$0 \le K_n \le 1 \tag{9.23}$$

Substituting Equation 9.22 in Equation 9.12 yields the squared magnitude of the input reflection coefficient as

$$|\rho_{11}(j\omega)|^2 = 1 - G(\omega^2) = 1 - |\rho_{21}(j\omega)|^2 = \frac{1 - K_n + (\omega/\omega_c)^{2n}}{1 + (\omega/\omega_c)^{2n}} \tag{9.24}$$

or

$$\rho_{11}(j\omega)\rho_{11}(-j\omega) = \alpha^{2n}\frac{1 + (\omega/\alpha\omega_c)^{2n}}{1 + (\omega/\omega_c)^{2n}} \tag{9.25}$$

where

$$\alpha = (1 - K_n)^{1/2n} \tag{9.26}$$

Appealing to analytic continuation by substituting ω by $-js$ results in

$$\rho_{11}(s)\rho_{11}(-s) = \alpha^{2n}\frac{1+(-1)^n x^{2n}}{1+(-1)^n y^{2n}} \tag{9.27}$$

where

$$y = \frac{s}{\omega_c}, \quad x = \frac{y}{\alpha} \tag{9.28}$$

To obtain the input reflection coefficient $\rho_{11}(s)$ from $\rho_{11}(s)\ \rho_{11}(-s)$, we need to assign the zeros and poles of Equation 9.27. Since $\rho_{11}(s)$ is devoid of poles in the closed RHS, we must assign all the LHS poles to $\rho_{11}(s)$. The zeros of $\rho_{11}(s)$, however, may lie in the RHS, so that in general a number of different numerators are possible. For our purposes, we choose only the LHS zeros for $\rho_{11}(s)$. Define a minimum-phase reflection coefficient to be one that is devoid of zeros in the open RHS. Then, the minimum-phase solution of Equation 9.27 can be written as

$$\rho_{11}(s) = \pm\alpha^n \frac{q(x)}{q(y)} \tag{9.29}$$

where $q(x)$ is the Hurwitz polynomial with unity leading coefficient formed by the LHS roots of the equation $1+(-1)^n x^{2n} = 0$. From Equation 9.1a, the input impedance is found to be

$$Z_{11}(s) = R_1\frac{1+\rho_{11}(s)}{1-\rho_{11}(s)} \tag{9.30}$$

Combining this with Equation 9.29 yields

$$Z_{11}(s) = R_1\frac{q(y)\pm\alpha^n q(x)}{q(y)\mp\alpha^n q(x)} \tag{9.31}$$

If both R_1 and R_2 are specified, then the DC gain K_n cannot be chosen independently. In fact, by substituting $s=0$ in Equation 9.31 and assuming that $K_n \neq 0$ we obtain

$$\frac{R_2}{R_1} = \left(\frac{1+\alpha^n}{1-\alpha^n}\right)^{\pm 1} \tag{9.32}$$

where the $\pm$ signs are determined, respectively, according to $R_2 \geq R_1$ and $R_2 \leq R_1$. Therefore, if any two of the three quantities R_1, R_2, and K_n are specified, the third one is fixed.

We now show that the input impedance $Z_{11}(s)$ can be realized by an LC ladder terminated in a resistor. In fact, explicit formulas for their element values will be given, thereby reducing the design problem to simple arithmetic. Depending upon the choice of the plus and minus signs in Equation 9.32, two cases are distinguished.

Case 1. $\rho_{11}(0) \geq 0$. With the choice of the plus sign, the input impedance becomes

$$Z_{11}(s) = R_1\frac{q(y)+\alpha^n q(x)}{q(y)-\alpha^n q(x)} \tag{9.33}$$

which can be expanded in a continued fraction about infinity, as in the first Cauer canonical form, and results in an LC ladder terminated in a resistor:

$$Z_{11}(s) = L_1 s + \cfrac{1}{C_2 S + \cfrac{1}{L_3 s + \cfrac{1}{\ddots + \cfrac{1}{W}}}} \tag{9.34}$$

where W is a constant representing either a resistance or conductance. Depending upon whether n is odd or even, the LC ladder has the configuration of Figure 9.2. The element values can be computed by the following recurrence formulas:

$$L_1 = \frac{2R_1 \sin \pi/2n}{(1-\alpha)\omega_c} \tag{9.35}$$

$$L_{2m-1}C_{2m} = \frac{4 \sin \gamma_{4m-3} \sin \gamma_{4m-1}}{\omega_c^2(1 - 2\alpha \cos \gamma_{4m-2} + \alpha^2)} \tag{9.36a}$$

$$L_{2m+1}C_{2m} = \frac{4 \sin \gamma_{4m-1} \sin \gamma_{4m+1}}{\omega_c^2(1 - 2\alpha \cos \gamma_{4m} + \alpha^2)} \tag{9.36b}$$

for $m = 1, 2, \ldots, \lceil n/2 \rceil$, the largest integer not greater than $n/2$; where

$$\gamma_m = \frac{m\pi}{2n} \tag{9.37}$$

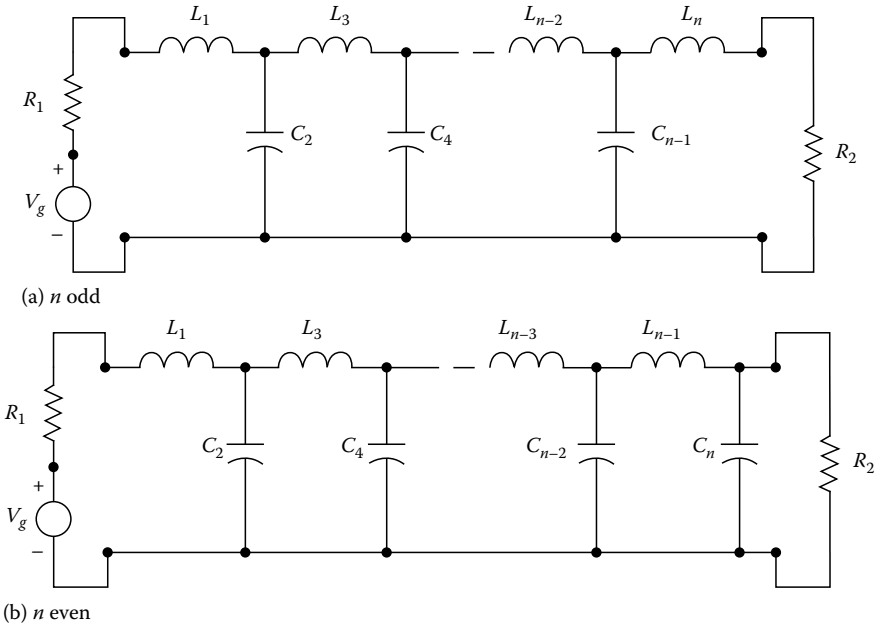

FIGURE 9.2 Butterworth LC ladder networks for $\rho_{11}(0) \geq 0$.

The values of the final elements can also be calculated directly by

$$L_n = \frac{2R_2 \sin \pi/2n}{(1+\alpha)\omega_c}, \quad n \text{ odd} \tag{9.38a}$$

$$C_n = \frac{2 \sin \pi/2n}{R_2(1+\alpha)\omega_c}, \quad n \text{ even} \tag{9.38b}$$

A complete derivation of these formulas was first given by Bossé [1]. Hence we can calculate the element values starting from either the first or the last element. When $R_1 = R_2$, formulas Equation 9.36 reduce to

$$L_{2m-1} = \frac{2R_1 \sin \gamma_{4m-3}}{\omega_c} \tag{9.39a}$$

$$C_{2m} = \frac{2 \sin \gamma_{4m-1}}{R_1 \omega_c} \tag{9.39b}$$

Example 9.1

Given

$$R_1 = 70\ \Omega, \quad R_2 = 200\ \Omega, \quad \omega_c = 10^5\ \text{rad/s}, \quad n = 4 \tag{9.40}$$

obtain a Butterworth LC ladder to meet these specifications.

Since $R_2 > R_1$, we choose the plus sign in Equation 9.32 and obtain $\rho_{11}(0) \geq 0$, $\alpha = 0.833$, and $\gamma_m = 22.5m$. Thus, from Equations 9.35 and 9.36 the element values are found to be

$$L_1 = \frac{2 \times 70 \sin 22.5^\circ}{(1-0.833) \times 10^5} = 3.2081\ \text{mH} \tag{9.41a}$$

$$C_2 = \frac{4 \sin 22.5^\circ \sin 67.5^\circ}{L_1(1.6939 - 1.666 \cos 45^\circ) \times 10^{10}} = 0.085456\ \mu\text{F} \tag{9.41b}$$

$$L_3 = \frac{4 \sin 67.5^\circ \sin 112.5^\circ}{C_2(1.6939 - 1.666 \cos 90^\circ) \times 10^{10}} = 2.3587\ \text{mH} \tag{9.41c}$$

$$C_4 = \frac{4 \sin 112.5^\circ \sin 157.5^\circ}{L_3(1.6939 - 1.666 \cos 135^\circ) \times 10^{10}} = 0.020877\ \mu\text{F} \tag{9.41d}$$

Alternatively, C_4 can be computed directly from Equation 9.39b as

$$C_4 = \frac{2 \sin 22.5^\circ}{200 \times (1+0.833) \times 10^5} = 0.020877\ \mu\text{F} \tag{9.42}$$

The ladder network together with its termination is presented in Figure 9.3. This network possesses the fourth-order Butterworth transducer power-gain response with a DC gain

$$K_4 = 1 - \alpha^8 = 0.7682 \tag{9.43}$$

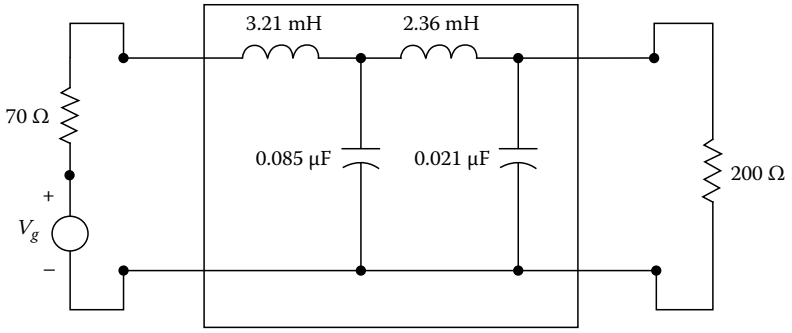

FIGURE 9.3 Fourth-order Butterworth LC ladder network.

Case 2. $\rho_{11}(0) < 0$. With the choice of the minus sign, the input impedance can be expanded in a continued fraction as

$$\frac{1}{Z_{11}(s)} = C_1 s + \cfrac{1}{L_2 s + \cfrac{1}{C_3 s + \cfrac{1}{\ddots + \cfrac{1}{W}}}} \tag{9.44}$$

which can be realized by the LC ladder networks of Figure 9.4, depending on whether W is even or odd, where W is the terminating resistance or conductance. Formulas for the element values are similar to

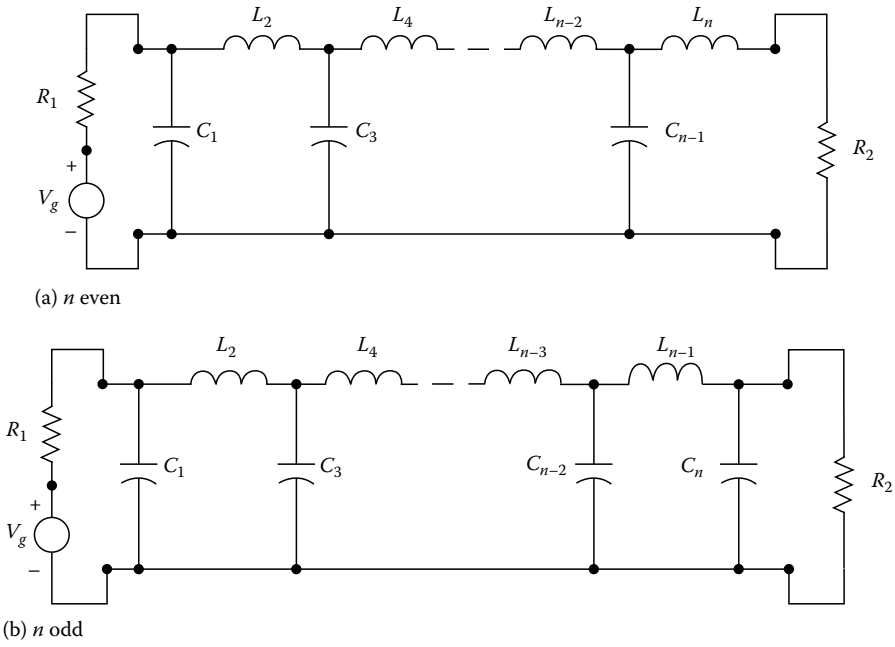

FIGURE 9.4 Butterworth LC ladder networks for $\rho_{11}(0) < 0$.

those given in Equations 9.35 through 9.39 except that the roles of C's and L's are interchanged and R_1 and R_2 are replaced by their reciprocals.

$$C_1 = \frac{2\sin\pi/2n}{R_1(1-\alpha)\omega_c} \tag{9.45a}$$

$$C_{2m-1}L_{2m} = \frac{4\sin\gamma_{4m-3}\sin\gamma_{4m-1}}{\omega_c^2(1-2\alpha\cos\gamma_{4m-2}+\alpha^2)} \tag{9.45b}$$

$$C_{2m+1}L_{2m} = \frac{4\sin\gamma_{4m-1}\sin\gamma_{4m+1}}{\omega_c^2(1-2\alpha\cos\gamma_{4m}+\alpha^2)} \tag{9.45c}$$

for $m = 1, 2, \ldots, \lceil n/2 \rceil$. The values of the final elements can also be calculated directly by

$$C_n = \frac{2\sin\pi/2n}{R_2(1+\alpha)\omega_c}, \quad n \text{ odd} \tag{9.46a}$$

$$L_n = \frac{2R_2\ \sin\pi/2n}{(1+\alpha)\omega_c}, \quad n \text{ even} \tag{9.46b}$$

9.3 Double-Terminated Chebyshev Networks

Now, we consider the problem of synthesizing an LC ladder which when connected between a resistive source of internal resistance R_1 and a resistive load of resistance R_2 will yield a preassigned Chebyshev transducer power-gain characteristic

$$G(\omega^2) = |\rho_{21}(j\omega)|^2 = \frac{K_n}{1+\varepsilon^2 C_n^2(\omega/\omega_c)} \tag{9.47}$$

with K_n bounded between 0 and 1. Following Equation 9.24, the squared magnitude of the input reflection coefficient can be written as

$$|\rho_{11}(j\omega)|^2 = 1 - G(\omega^2) = 1 - |\rho_{21}(j\omega)|^2 = \frac{1-K_n+\varepsilon^2 C_n^2(\omega/\omega_c)}{1+\varepsilon^2 C_n^2(\omega/\omega_c)} \tag{9.48}$$

Appealing to analytic continuation, we obtain

$$\rho_{11}(s)\rho_{11}(-s) = (1-K_n)\frac{1+\hat{\varepsilon}^2 C_n^2(-jy)}{1+\varepsilon^2 C_n^2(-jy)} \tag{9.49}$$

where

$$\hat{\varepsilon} = \frac{\varepsilon}{\sqrt{1-K_n}} \tag{9.50}$$

As in the Butterworth case, we assign LHS poles to $\rho_{11}(s)$ and the minimum-phase solution of Equation 9.49 becomes

$$\rho_{11}(s) = \pm\frac{\hat{p}(y)}{p(y)} \tag{9.51}$$

where $p(y)$ and $\hat{p}(y)$ are the Hurwitz polynomials with unity leading coefficient formed by the LHS roots of the equations $1 + \varepsilon^2 C_n^2(-jy) = 0$ and $1 + \hat{\varepsilon}^2 C_n^2(-jy) = 0$, respectively. From Equation 9.1a, the input impedance of the LC ladder when the output port is terminated in R_2 is found to be

$$Z_{11}(s) = R_1 \frac{p(y) \pm \hat{p}(y)}{p(y) \mp \hat{p}(y)} \tag{9.52}$$

A relationship among the quantities R_1, R_2, and K_n is given by

$$\frac{R_2}{R_1} = \left(\frac{1 + \sqrt{1 - K_n}}{1 - \sqrt{1 - K_n}}\right)^{\pm 1}, \quad n \text{ odd} \tag{9.53a}$$

$$= \left(\frac{\sqrt{1 + \varepsilon^2} + \sqrt{1 + \varepsilon^2 - K_n}}{\sqrt{1 + \varepsilon^2} - \sqrt{1 + \varepsilon^2 - K_n}}\right)^{\pm 1}, \quad n \text{ even} \tag{9.53b}$$

where the $\pm$ signs are determined, respectively, according to $R_2 \geq R_1$ and $R_2 \leq R_1$. Therefore, if n is odd and the DC gain is specified, the ratio of the terminating resistances is fixed by Equation 9.53a. On the other hand, if n is even and the peak-to-peak ripple in the passband and K_n or the DC gain is specified, the ratio of the resistances is given by Equation 9.53b.

We now show that the input impedance $Z_{11}(s)$ can be realized by an LC ladder terminated in a resistor. Again, explicit formulas for their element values will be given, thereby reducing the design problem to simple arithmetic. Depending upon the choice of the plus and minus signs in Equation 9.51, two cases are distinguished.

Case 1. $\rho_{11}(0) \geq 0$. With the choice of the plus sign, the input impedance becomes

$$Z_{11}(s) = R_1 \frac{p(y) + \hat{p}(y)}{p(y) - \hat{p}(y)} \tag{9.54}$$

which can be expanded in a continued fraction as in Equation 9.34. Depending on whether n is odd or even, the corresponding LC ladder network has the configurations of Figure 9.2. The element values can be computed by the following recurrence formulas:

$$L_1 = \frac{2R_1 \sin \pi/2n}{(\sinh a - \sinh \hat{a})\dot{\omega}_c} \tag{9.55}$$

$$L_{2m-1}C_{2m} = \frac{4 \sin \gamma_{4m-3} \sin \gamma_{4m-1}}{\omega_c^2 f_{2m-1}(\sinh a, \sinh \hat{a})} \tag{9.56a}$$

$$L_{2m+1}C_{2m} = \frac{4 \sin \gamma_{4m-1} \sin \gamma_{4m+1}}{\omega_c^2 f_{2m}(\sinh a, \sinh \hat{a})} \tag{9.56b}$$

for $m = 1, 2, \ldots, \lceil n/2 \rceil$, where

$$\gamma_m = \frac{m\pi}{2n} \tag{9.57a}$$

$$\hat{a} = \frac{1}{n} \sinh^{-1}\left(\frac{\sqrt{1 - K_n}}{\varepsilon}\right) \tag{9.57b}$$

$$f_m(u, v) = u^2 + v^2 + \sin^2 \gamma_{2m} - 2uv \cos \gamma_{2m} \tag{9.57c}$$

In addition, the values of the last elements can also be computed directly by the equations

$$L_n = \frac{2R_2 \sin \pi/2n}{(\sinh a + \sinh \hat{a})\omega_c}, \quad n \text{ odd} \tag{9.58a}$$

$$C_n = \frac{2 \sin \pi/2n}{R_2(\sinh a + \sinh \hat{a})\omega_c}, \quad n \text{ even} \tag{9.58b}$$

A formal proof of these formulas was first given by Takahasi [2]. Hence, we can calculate the element values starting from either the first or the last element.

Example 9.2

Given

$$R_1 = 150\ \Omega, \quad R_2 = 470\ \Omega, \quad \omega_c = 10^8\pi \text{ rad/s}, \quad n = 4 \tag{9.59}$$

find a Chebyshev LC ladder network to meet these specifications with peak-to-peak ripple in the passband not exceeding 1.5 dB.

Since R_1 and R_2 are both specified, the minimum passband gain $G_{\min}$ is fixed by Equation 9.53b as

$$G_{\min} \equiv \frac{K_n}{1+\varepsilon^2} = 1 - \left(\frac{\dfrac{470}{150} - 1}{\dfrac{470}{150} + 1}\right)^2 = 0.7336 \tag{9.60}$$

For the 1.5 dB ripple in the passband, the corresponding ripple factor is given by

$$\varepsilon = \sqrt{10^{0.15} - 1} = 0.64229 \tag{9.61}$$

obtaining $K_4 = 1.036$, which is too large for the network to be physically realizable. Thus, let $K_4 = 1$, the maximum permissible value, and the corresponding ripple factor becomes

$$\varepsilon = \sqrt{\frac{1}{G_{\min}} - 1} = \sqrt{\frac{1}{0.7336} - 1} = 0.6026 \quad \text{or} \quad 1.345 \text{ dB} \leq 1.5 \text{ dB} \tag{9.62}$$

We next compute the quantities

$$\gamma_m = \frac{m\pi}{2n} = 22.5m \tag{9.63a}$$

$$a = \frac{1}{4} \sinh^{-1} \frac{1}{0.6026} = 0.32, \quad \hat{a} = 0 \tag{9.63b}$$

$$f_m(\sinh\ 0.32,\ 0) = \sinh^2 0.32 + \sin^2 \gamma_{2m} = 0.1059 + \sin^2 \gamma_{2m} \tag{9.63c}$$

Appealing to formulas Equations 9.55 and 9.56, the element values are calculated as follows:

$$L_1 = \frac{2 \times 150\ \sin 22.5^\circ}{(\sinh\ 0.32 - \sinh\ 0) \times 10^8\pi} = 1.123\ \mu\text{H} \tag{9.64a}$$

$$C_2 = \frac{4 \sin 22.5^\circ \sin 67.5^\circ}{L_1 10^{16} \pi^2 \left(\sinh^2 0.32 + \sin^2 45^\circ\right)} = 21.062 \text{ pF} \tag{9.64b}$$

$$L_3 = \frac{4 \sin 67.5^\circ \sin 112.5^\circ}{C_2 10^{16} \pi^2 \left(\sinh^2 0.32 + \sin^2 90^\circ\right)} = 1.485 \ \mu\text{H} \tag{9.64c}$$

$$C_4 = \frac{4 \sin 112.5^\circ \sin 157.5^\circ}{L_3 10^{16} \pi^2 \left(\sinh^2 0.32 + \sin^2 135^\circ\right)} = 15.924 \text{ pF} \tag{9.64d}$$

Alternatively, the last capacitance can also be computed directly from Equation 9.58b as

$$C_4 = \frac{2 \sin \ 22.5^\circ}{470 \times (\sinh 0.32 + \sinh 0) \times 10^8 \pi} = 15.925 \text{ pF} \tag{9.65}$$

The LC ladder together with its terminations is presented in Figure 9.5.

Case 2. $\rho_{11}(0) < 0$. With the choice of the minus sign in Equation 9.51, the input impedance, aside from the constant R_1, becomes the reciprocal of Equation 9.54

$$Z_{11}(s) = R_1 \frac{p(y) - \hat{p}(y)}{p(y) + \hat{p}(y)} \tag{9.66}$$

and can be expanded in a continued fraction as that shown in Equation 9.44. Depending on whether n is even or odd, the LC ladder network has the configurations of Figure 9.4. Formulas for the element values are similar to those given in Equations 9.55 through 9.58 except that the roles of C's and L's are interchanged and R_1 and R_2 are replaced by their reciprocals:

$$C_1 = \frac{2 \sin \pi/2n}{R_1 (\sinh a - \sinh \hat{a}) \omega_c} \tag{9.67a}$$

$$C_{2m-1} L_{2m} = \frac{4 \sin \gamma_{4m-3} \sin \gamma_{4m-1}}{\omega_c^2 f_{2m-1}(\sinh a, \ \sinh \hat{a})} \tag{9.67b}$$

$$C_{2m+1} L_{2m} = \frac{4 \sin \gamma_{4m-1} \sin \gamma_{4m+1}}{\omega_c^2 f_{2m}(\sinh a, \ \sinh \hat{a})} \tag{9.67c}$$

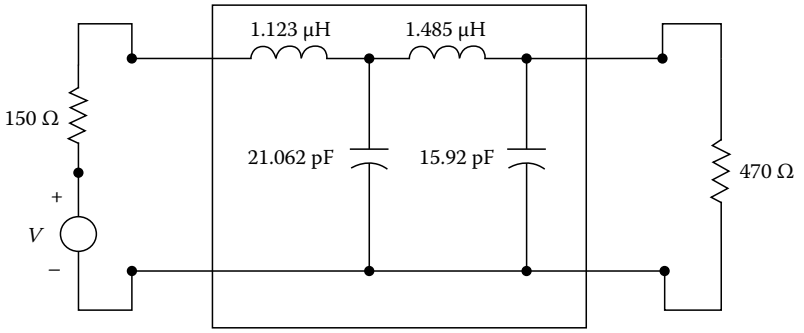

FIGURE 9.5 Fourth-order Chebyshev LC ladder network for $\rho_{11}(0) \geq 0$.

for $m = 1, 2, \ldots, \lceil n/2 \rceil$, where γ_m and $f_m(\sinh a, \sinh \hat{a})$ are defined in Equation 9.57. In addition, the values of the last elements can also be computed directly by the formulas

$$C_n = \frac{2 \sin \pi/2n}{R_2(\sinh a + \sinh \hat{a})\omega_c}, \quad n \text{ odd} \tag{9.68a}$$

$$L_n = \frac{2R_2 \sin \pi/2n}{(\sinh a + \sinh \hat{a})\omega_c}, \quad n \text{ even} \tag{9.68b}$$

10.1 Introduction

Refer to the network configuration of Figure 10.1 where the source is represented either by its Thévenin equivalent or by its Norton equivalent. The load impedance $z_2(s)$ is assumed to be strictly passive over a frequency band of interest, because the matching problem cannot be meaningfully defined if the load is purely reactive. Our objective is to design an "optimum" lossless two-port network or equalizer N to match out the load impedance $z_2(s)$ to the resistive source impedance $z_1(s) = R_1$, and to achieve a preassigned transducer power-gain characteristic $G(\omega^2)$ over the entire sinusoidal frequency spectrum.

As stated in Chapter 9, the output reflection coefficient is given by

$$\rho_{22}(s) = \frac{Z_{22}(s) - z_2(-s)}{Z_{22}(s) + z_2(s)} \tag{10.1}$$

where $Z_{22}(s)$ is the impedance looking into the output port when the input port is terminated in the source resistance R_1. As shown in Chapter 9, the transducer power gain $G(\omega^2)$ is related to the transmission and reflection coefficients by the equation

$$G(\omega^2) = |\rho_{21}(j\omega)|^2 = |\rho_{12}(j\omega)|^2 = 1 - |\rho_{11}(j\omega)|^2 = 1 - |\rho_{22}(j\omega)|^2 \tag{10.2}$$

Recall that in computing $\rho_{11}(s)$ from $\rho_{11}(s)\rho_{11}(-s)$ we assign all of the LHS poles of $\rho_{11}(s)\rho_{11}(-s)$ to $\rho_{11}(s)$ because with resistive load $z_2(s) = R_2$, $\rho_{11}(s)$ is devoid of poles in the RHS. For the complex load, the poles of $\rho_{22}(s)$ include those of $z_2(-s)$, which may lie in the open RHS. As a result, the assignment of poles of $\rho_{22}(s)\rho_{22}(-s)$ is not unique. Furthermore, the nonanalyticity of $\rho_{22}(s)$ leaves much to be desired in terms of our ability to manipulate. For these reasons, we consider the normalized reflection coefficient defined by

$$\rho(s) = A(s)\rho_{22}(s) = A(s)\frac{Z_{22}(s) - z_2(-s)}{Z_{22}(s) + z_2(s)} \tag{10.3}$$

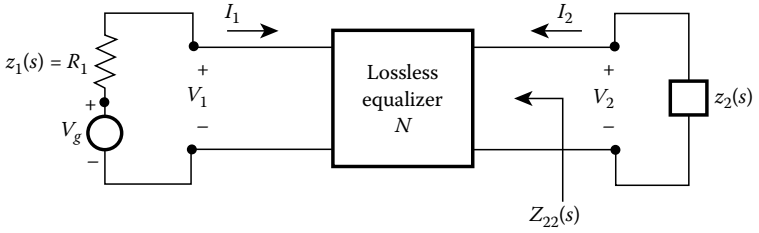

FIGURE 10.1 Schematic of broadband matching.

where

$$A(s) = \prod_{i=1}^{q} \frac{s - s_i}{s + s_i}, \quad \text{Re } s_i > 0 \tag{10.4}$$

is the real all-pass function defined by the open RHS poles s_i ($i = 1, 2, \ldots, q$) of $z_2(-s)$. An all-pass function is a function whose zeros are all located in the open RHS and whose poles are located at the LHS mirror image of the zeros. Therefore, it is analytic in the closed RHS and such that

$$A(s)A(-s) = 1 \tag{10.5}$$

On the $j\omega$-axis, the magnitude of $A(j\omega)$ is unity, being flat for all sinusoidal frequencies, and we have

$$|\rho(j\omega)| = |A(j\omega)\rho_{22}(j\omega)| = |\rho_{22}(j\omega)| \tag{10.6}$$

and Equation 10.2 becomes

$$G(\omega^2) = 1 - |\rho(j\omega)|^2 \tag{10.7}$$

This equation together with the normalized reflection coefficient $\rho(s)$ of Equation 10.3 forms the cornerstone of Youla's theory of broadband matching [1].

10.2 Basic Coefficient Constraints

In Chapter 8, we define the zeros of transmission for a terminate two-port network as the frequencies at which a zero output results for a finite input. We extend this concept by defining the zeros of transmission for a one-port impedance.

Definition 10.1: Zero of transmission. For a given impedance $z_2(s)$, a closed RHS zero of multiplicity k of the function

$$w(s) \equiv \frac{r_2(s)}{z_2(s)} \tag{10.8}$$

where $r_2(s)$ is the even part of $z_2(s)$, is called a zero of transmission of order k of $z_2(s)$.

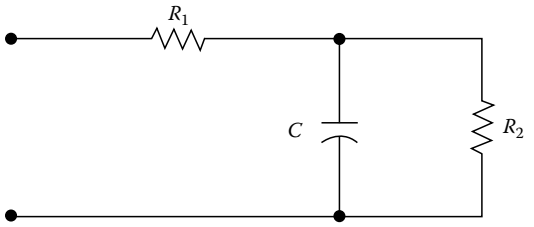

FIGURE 10.2 RC one-port network.

The reason for this name is that if we realize the impedance $z_2(s)$ as the input impedance of a lossless two-port network terminated in a $1-\Omega$ resistor, the magnitude squared of the transfer impedance function $Z_{12}(j\omega)$ between the $1-\Omega$ resistor and the input equals the real part of the input impedance,

$$|Z_{12}(j\omega)|^2 = \mathrm{Re}\, z_2(j\omega) = r_2(j\omega) \tag{10.9}$$

After appealing to analytic continuation by substituting ω by $-js$, the zeros of $r_2(s)$ are seen to be the zeros of transmission of the lossless two-port.

Consider, for example, the RC impedance $z_2(s)$ of Figure 10.2,

$$z_2(s) = R_1 + \frac{R_2}{R_2Cs+1} \tag{10.10}$$

the even part of which is given by

$$r_2(s) = \frac{1}{2}[z_2(s) + z_2(-s)] = \frac{R_1 + R_2 - R_1R_2^2C^2s^2}{1 - R_2^2C^2s^2} \tag{10.11}$$

obtaining

$$w(s) = \frac{r_2(s)}{z_2(s)} = \frac{R_2Cs^2 - (R_1+R_2)/R_1R_2C}{(R_2Cs-1)[s+(R_1+R_2)/R_1R_2C]} \tag{10.12}$$

Thus, the impedance $z_2(s)$ has a zero of transmission of order 1 located at

$$s = \sigma_0 = \frac{1}{R_2C}\sqrt{1+\frac{R_2}{R_1}} \tag{10.13}$$

For our purposes, the zeros of transmission are divided into four mutually exclusive classes.

Definition 10.2: *Classification of zeros of transmission*. Let $s_0 = \sigma_0 + j\omega_0$ be a zero of transmission of an impedance $z_2(s)$. Then s_0 belongs to one of the following four mutually exclusive classes depending on σ_0 and $z_2(s_0)$, as follows:

Class I: $\sigma_0 > 0$, which includes all the open RHS zeros of transmission.
Class II: $\sigma_0 = 0$ and $z_2(\omega_0) = 0$.

Class III: $\sigma_0 = 0$ and $0 < |z_2(j\omega 0)| < \infty$.
Class IV: $\sigma_0 = 0$ and $|z_2(j\omega 0)| = \infty$.

For the impedance $z_2(s)$ of Equation 10.10, its zero of transmission given in Equation 10.13 belongs to Class I of order 1. If $z_2(s)$ is the load of the network of Figure 10.1, it imposes the basic constraints on the normalized reflection coefficient $\rho(s)$. These constraints are important in that they are necessary and sufficient for $\rho(s)$ to be physically realizable, and are most conveniently formulated in terms of the coefficients of the Laurent series expansions of the following quantities about a zero of transmission $s_0 = \sigma_0 + j\omega_0$ of order k of $z_2(s)$:

$$\rho(s) = \rho_0 + \rho_1(s - s_0) + \rho_2(s - s_0)^2 + \cdots = \sum_{m=0}^{\infty} \rho_m (s - s_0)^m \tag{10.14a}$$

$$A(s) = A_0 + A_1(s - s_0) + A_2(s - s_0)^2 + \cdots = \sum_{m=0}^{\infty} A_m (s - s_0)^m \tag{10.14b}$$

$$F(s) \equiv 2r_2(s)A(s) = F_0 + F_1(s - s_0) + F_2(s - s_0)^2 + \cdots = \sum_{m=0}^{\infty} F_m (s - s_0)^m \tag{10.14c}$$

We remark that the expansions of the Laurent type can be found by any method because it is unique, and the resulting expansion is *the* Laurent series expansion. For the zero of transmission at infinity, the expansions take the form

$$\rho(s) = \rho_0 + \frac{\rho_1}{s} + \frac{\rho_2}{s^2} + \frac{\rho_3}{s^3} + \cdots = \sum_{m=0}^{\infty} \frac{\rho_m}{s^m} \tag{10.15a}$$

$$A(s) = A_0 + \frac{A_1}{s} + \frac{A_2}{s^2} + \frac{A_3}{s^3} + \cdots = \sum_{m=0}^{\infty} \frac{A_m}{s^m} \tag{10.15b}$$

$$F(s) = F_0 + \frac{F_1}{s} + \frac{F_2}{s^2} + \frac{F_3}{s^3} + \cdots = \sum_{m=0}^{\infty} \frac{F_m}{s^m} \tag{10.15c}$$

In fact, they can be obtained by means of the binomial expansion formula

$$(s + c)^n = s^n + ns^{n-1}c + \frac{n(n-1)}{2!}s^{n-2}c^2 + \cdots \tag{10.16}$$

which is valid for all values of n if $|s| > |c|$, and is valid only for nonnegative integers n if $|s| \leq |c|$.

Example 10.1

Assume that the network of Figure 10.1 is terminated in the passive impedance

$$z_2(s) = \frac{s}{s^2 + 2s + 1} \tag{10.17}$$

and possesses the transducer power-gain characteristic

$$G(\omega^2) = \frac{K\omega^2}{\omega^4 - \omega^2 + 1}, \quad 0 \leq K \leq 1 \tag{10.18}$$

We first compute the even part

$$r_2(s) = \frac{1}{2}[z_2(s) + z_2(-s)] = \frac{-2s^2}{(s^2 + 2s + 1)(s^2 - 2s + 1)} \tag{10.19}$$

of $z_2(s)$, and obtain the function

$$w(s) = \frac{r_2(s)}{z_2(s)} = \frac{-2s}{s^2 - 2s + 1} \tag{10.20}$$

showing that $z_2(s)$ possesses two Class II zeros of transmission at $s = 0$ and ∞. Since the pole of $z_2(-s)$ is located at $s = 1$ of order 2, the all-pass function $A(s)$ takes the form

$$A(s) = \frac{s^2 - 2s + 1}{s^2 + 2s + 1} \tag{10.21}$$

The other required functions are found to be

$$F(s) = 2A(s)r_2(s) = -\frac{4s^2}{(s^2 + 2s + 1)^2} \tag{10.22}$$

$$\boldsymbol{\rho}(s)\boldsymbol{\rho}(-s) = 1 - G(-s^2) = \frac{s^4 + (1 + K)s^2 + 1}{s^4 + s^2 + 1} \tag{10.23}$$

The minimum-phase solution of Equation 10.23 is determined as

$$\pm\hat{\boldsymbol{\rho}}(s) = \frac{s^2 + \sqrt{1 - K}s + 1}{s^2 + s + 1} \tag{10.24}$$

Now, we expand the functions $A(s)$, $F(s)$, and $\hat{\boldsymbol{\rho}}(s)$ in Laurent series about the zeros of transmission at the origin and at infinity, and obtain

$$A(s) = 1 - 4s + \cdots = 1 - \frac{4}{s} + \cdots \tag{10.25}$$

$$F(s) = 0 + 0 - 4s^2 + \cdots = 0 + 0 - \frac{4}{s^2} + \cdots \tag{10.26}$$

$$\pm\hat{\boldsymbol{\rho}}(s) = 1 + (\sqrt{1 - K} - 1)s + \cdots = 1 + \frac{\sqrt{1 - K} - 1}{s} + \cdots \tag{10.27}$$

In both expansions, we can make the following identifications:

$$A_0 = 1, \quad F_0 = 0, \quad \boldsymbol{\rho}_0 = 1 \tag{10.28a}$$

$$A_1 = -4, \quad F_1 = 0, \quad \boldsymbol{\rho}_1 = \sqrt{1 - K} - 1 \tag{10.28b}$$

$$F_2 = -4 \tag{10.28c}$$

10.2.1 Basic Coefficient Constraints on $\boldsymbol{\rho}(S)$

The basic constraints imposed on the normalized reflection coefficient $\boldsymbol{\rho}(s)$ by a load impedance $z_2(s)$ are most succinctly expressed in terms of the coefficients of the Laurent series expansions (Equation 10.14) of

the functions $\rho(s)$, $A(s)$, and $F(s)$ about each zero of transmission $s_0 = \sigma_0 + j\omega_0$. Depending on the classification of the zero of transmission, one of the following four sets of coefficient conditions must be satisfied:

Class I: For $x = 0, 1, 2, \ldots, k-1$

$$A_x = \rho_x \tag{10.29a}$$

Class II: $A_x = \rho_x$ for $x = 0, 1, 2, \ldots, k-1$, and

$$\frac{A_k - \rho_k}{F_{k+1}} \geq 0 \tag{10.29b}$$

Class III: $A_x = \rho_x$ for $x = 0, 1, 2, \ldots, k-2$, $k \geq 2$, and

$$\frac{A_{k-1} - \rho_{k-1}}{F_k} \geq 0 \tag{10.29c}$$

Class IV: $A_x = \rho_x$ for $x = 0, 1, 2, \ldots, k-1$, and

$$\frac{F_{k-1}}{A_k - \rho_k} \geq a_{-1}, \text{ the residue of } z_2(s) \text{ evaluated at the pole } s = j\omega_0 \tag{10.29d}$$

To determine the normalized reflection coefficient $\rho(s)$ from a preassigned transducer power-gain characteristic $G(\omega^2)$, we appeal to Equation 10.7 and analytic continuation by replacing ω by $-js$ and obtain

$$\rho(s)\rho(-s) = 1 - G(-s^2) \tag{10.30}$$

Since the zeros and poles of $\rho(s)\rho(-s)$ must appear in quadrantal symmetry, being symmetric with respect to both the real and imaginary axes of the s-plane, and since $\rho(s)$ is analytic in the closed RHS, the open LHS poles of $\rho(s)\rho(-s)$ belong to $\rho(s)$ whereas those in the open RHS belong to $\rho(-s)$. For a lumped system, $\rho(s)$ is devoid of poles on the $j\omega$-axis. For the zeros, no unique ways are available to assign them. The only requirement is that the complex–conjugate pair of zeros must be assigned together. However, if we specify that $\rho(s)$ be made a minimum-phase function, then all the open LHS zeros of $\rho(s)\rho(-s)$ are assigned to $\rho(s)$. The $j\omega$-axis zeros of $\rho(s)\rho(-s)$ are of even multiplicity, and thus they are divided equally between $\rho(s)$ and $\rho(-s)$. Therefore, $\rho(s)$ is uniquely determined by the zeros and poles of $\rho(s)\rho(-s)$ only if $\rho(s)$ is required to be minimum-phase.

Let $\hat{\rho}(s)$ be the minimum-phase solution of Equation 10.30. Then, any solution of the form

$$\rho(s) = \pm\eta(s)\hat{\rho}(s) \tag{10.31}$$

is admissible, where $\acute{\eta}(s)$ is an arbitrary real all-pass function possessing the property that

$$\eta(s)\eta(-s) = 1 \tag{10.32}$$

The significance of these coefficient constraints is that they are both necessary and sufficient for the physical realizability of $\rho(s)$, and is summarized in the following theorem. The proof of this result can be found in Ref. [2].

THEOREM 10.1

Given a strictly passive impedance $z_2(s)$, the function defined by the equation

$$Z_{22}(s) \equiv \frac{F(s)}{A(s) - \rho(s)} - z_2(s) \tag{10.33}$$

is positive real if and only if $|\rho(j\omega)| \leq 1$ for all ω and the coefficient conditions Equation 10.29 are satisfied.

The function $Z_{22}(s)$ defined in Equation 10.33 is actually the back-end impedance of a desired equalizer. To see this, we solve for $Z_{22}(s)$ in Equation 10.3 and obtain

$$Z_{22}(s) = \frac{A(s)[z_2(s) + z_2(-s)]}{A(s) - \rho(s)} - z_2(s) = \frac{F(s)}{A(s) - \rho(s)} - z_2(s) \tag{10.34}$$

which is guaranteed to be positive real by Theorem 10.1. This impedance can be realized as the input impedance of a lossless two-port network terminated in a resistor. The removal of this resistor gives the desired matching network. An ideal transformer may be needed at the input port to compensate for the actual level of the generator resistance R_1.

Example 10.2

Design a lossless matching network to equalize the load impedance

$$z_2(s) = \frac{s}{s^2 + 2s + 1} \tag{10.35}$$

to a resistive generator of internal resistance of 0.5 Ω and to achieve the transducer power-gain characteristic

$$G(\omega^2) = \frac{K\omega^2}{\omega^4 - \omega^2 + 1}, \quad 0 \leq K \leq 1 \tag{10.36}$$

From Example 10.1, the load possesses two Class II zeros of transmission of order 1 at $s = 0$ and $s = \infty$. The coefficients of the Laurent series expansions of the functions $A(s)$, $F(s)$, and $\rho(s)$ about the zeros of transmission at $s = 0$ and $s = \infty$ were computed in Example 10.1 as

$$A_0 = 1, \quad F_0 = 0, \quad \rho_0 = 1 \tag{10.37a}$$

$$A_1 = -4, \quad F_1 = 0, \quad \rho_1 = \sqrt{1 - K} - 1 \tag{10.37b}$$

$$F_2 = -4 \tag{10.37c}$$

The coefficient constraints (Equation 10.29b) for the Class II zeros of transmission of order 1 become

$$A_0 = \rho_0, \quad \frac{A_1 - \rho_1}{F_2} \geq 0 \tag{10.38}$$

Clearly, the first condition is always satisfied. To meet the second requirement, we set

$$\frac{-4 - \left(\sqrt{1 - K} - 1\right)}{-4} \geq 0 \tag{10.39}$$

or $0 \leq K \leq 1$, showing that the maximum realizable K is 1. For our purposes, set $K = 1$ and choose the plus sign in Equation 10.24. From Equation 10.34, the equalizer back-end impedance is computed as

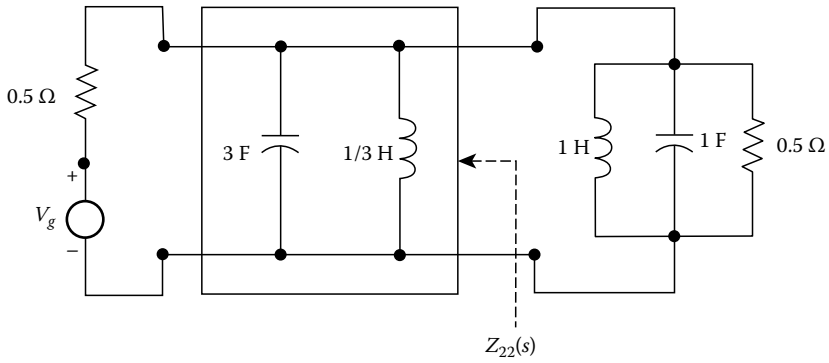

FIGURE 10.3 Equalizer having transducer power-gain characteristics Equation 10.36.

$$Z_{22}(s) = \frac{F(s)}{A(s) - \hat{\rho}(s)} - z_2(s) = \frac{\frac{-4s^2}{(s^2+2s+1)^2}}{\frac{s^2-2s+1}{s^2+2s+1} - \frac{s^2+1}{s^2+s+1}} - \frac{s}{s^2+2s+1}$$
$$= \frac{s}{3s^2+2s+3} \tag{10.40}$$

This impedance can be realized as the input impedance of the parallel connection of an inductor $L = 1/3$ H, a capacitor $C = 3$F, and a resistor $R = 0.5\ \Omega$. The resulting equalizer together with the load is presented in Figure 10.3.

10.3 Design Procedure

We now outline an eight-step procedure for the design of an optimum lossless matching network that equalizes a frequency-dependent load impedance $z_2(s)$ to a resistive generator of internal resistance R_1 and achieves a preassigned transducer power-gain characteristic $G(\omega^2)$ over the entire sinusoidal frequency spectrum.

Step 1. From a preassigned transducer power-gain characteristic $G(\omega^2)$, verify that $G(\omega^2)$ is an even rational real function and satisfies the inequality

$$0 \le G(\omega^2) \le 1 \quad \text{for all } \omega \tag{10.41}$$

The gain level is usually not specified to allow some flexibility.

Step 2. From a prescribed strictly passive load impedance $z_2(s)$, compute

$$r_2(s) \equiv \text{Ev}\, z_2(s) = \frac{1}{2}[z_2(s) + z_2(-s)] \tag{10.42}$$

$$A(s) = \prod_{i=1}^{q} \frac{s - s_i}{s + s_i}, \quad \text{Re}\, s_i > 0 \tag{10.43}$$

where s_i $(i = 1, 2, \ldots, q)$ are the open RHS poles of $z_2(-s)$, and

$$F(s) = 2A(s)r_2(s) \tag{10.44}$$

Step 3. Determine the locations and the orders of the zeros of transmission of $z_2(s)$, which are defined as the closed RHS zeros of the function

$$w(s) = \frac{r_2(s)}{z_2(s)} \tag{10.45}$$

and divide them into respective classes according to Definition 10.2.

Step 4. Perform the unique factorization of the function

$$\hat{\rho}(s)\hat{\rho}(-s) = 1 - G\left(-s^2\right) \tag{10.46}$$

in which the numerator of the minimum-phase solution $\hat{\rho}(s)$ is a Hurwitz polynomial and the denominator $\hat{\rho}(s)$ is a strictly Hurwitz polynomial.

Step 5. Obtain the Laurent series expansions of the functions $A(s)$, $F(s)$, and $\hat{\rho}(s)$ about each zero of transmission s_0 of $z_2(s)$, as follows:

$$A(s) = \sum_{m=0}^{\infty} A_m (s - s_0)^m \tag{10.47a}$$

$$F(s) = \sum_{m=0}^{\infty} F_m (s - s_0)^m \tag{10.47b}$$

$$\hat{\rho}(s) = \sum_{m=0}^{\infty} \rho_m (s - s_0)^m \tag{10.47c}$$

They may be obtained by any available methods.

Step 6. According to the classes of zeros of transmission, list the basic constraints (Equation 10.29) imposed on the coefficients of Equation 10.47. The gain level is ascertained from these constraints. If not all the constraints are satisfied, consider the more general solution

$$\rho(s) = \pm\eta(s)\hat{\rho}(s) \tag{10.48}$$

where $\acute{\eta}(s)$ is an arbitrary real all-pass function. Then repeat Step 5 for $\rho(s)$, starting with lower-order $\acute{\eta}(s)$. If the constraints still cannot be satisfied, modify the preassigned transducer power-gain characteristics $G(\omega^2)$. Otherwise, no match exists.

Step 7. Having successfully carried out Step 6, the equalizer back-end impedance is determined by the equation

$$Z_{22}(s) \equiv \frac{F(s)}{A(s) - \rho(s)} - z_2(s) \tag{10.49}$$

where $\rho(s)$ may be $\hat{\rho}(s)$ and $Z_{22}(s)$ is guaranteed to be positive real.

Step 8. Realize $Z_{22}(s)$ as the input impedance of a lossless two-port network terminated in a resistor. An ideal transformer may be required at the input port to compensate for the actual level of the generator resistance R_1. This completes the design of an equalizer.

Example 10.3

Design a lossless matching network to equalize the RLC load as shown in Figure 10.4 to a resistive generator and to achieve the fifth-order Butterworth transducer power-gain characteristic with a maximal DC gain. The cutoff frequency is 10^8 rad/s.

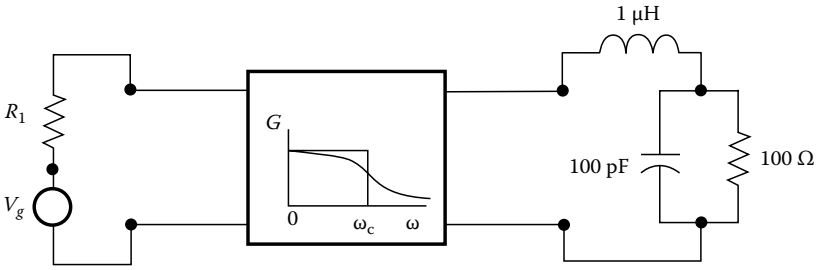

FIGURE 10.4 Broadband matching of an RLC load to a resistive generator.

To simplify the computation, we magnitude-scale the network by a factor of 10^{-2} and frequency-scale it by a factor of 10^{-8}. Thus, s denotes the normalized complex frequency and $\boldsymbol{\omega}$ the normalized real frequency. The load impedance becomes

$$z_2(s) = \frac{s^2 + s + 1}{s + 1} \tag{10.50}$$

We now follow the eight steps outlined below to design a lossless equalizer to meet the desired specifications.

Step 1. The fifth-order Butterworth transducer power-gain characteristic is given by

$$G(\boldsymbol{\omega}^2) = \frac{K_5}{1 + \boldsymbol{\omega}^{10}}, \quad 0 \le K_5 \le 1 \tag{10.51}$$

Our objective is to maximize the DC gain K_5.

Step 2. From the load impedance $z_2(s)$, we compute the functions

$$r_2(s) = \frac{1}{2}[z_2(s) + z_2(-s)] = \frac{1}{1 - s^2} \tag{10.52}$$

$$A(s) = \frac{s - 1}{s + 1} \tag{10.53}$$

where $s = 1$ is the open RHS pole of $z_2(-s)$, and

$$F(s) = 2A(s)r_2(s) = \frac{-2}{(s + 1)^2} \tag{10.54}$$

Step 3. The zeros of transmission $z_2(s)$ are defined by the closed RHS zero of the function.

$$w(s) = \frac{r_2(s)}{z_2(s)} = \frac{1}{(s^2 + s + 1)(1 - s)} \tag{10.55}$$

indicating that $s = \infty$ is a Class IV zero of transmission of order 3.

Step 4. Substituting Equation 10.51 in Equation 10.46 with $-js$ replacing $\boldsymbol{\omega}$ gives

$$\boldsymbol{\rho}(s)\boldsymbol{\rho}(-s) = 1 - G(-s^2) = 1 - \frac{K_5}{1 - s^{10}} = \boldsymbol{\alpha}^{10}\frac{1 - x^{10}}{1 - s^{10}} \tag{10.56}$$

where

$$\alpha = (1 - K_5)^{1/10}, \quad x = \frac{s}{\alpha} \tag{10.57}$$

The minimum-phase solution of Equation 10.56 is found to be

$$\hat{\rho}(s) = \frac{s^5 + 3.23607\alpha s^4 + 5.23607\alpha^2 s^3 + 5.23607\alpha^3 s^2 + 3.23607\alpha^4 s + \alpha^5}{s^5 + 3.23607s^4 + 5.23607s^3 + 5.23607s^2 + 3.23607s + 1} \tag{10.58}$$

The maximum attainable DC gain will be ascertained later from the coefficient conditions.

Step 5. The Laurent series expansions of the functions $A(s)$, $F(s)$, and $\hat{\rho}(s)$ about the zero of transmission $s_0 = \infty$ of $z_2(s)$ are obtained as follows:

$$A(s) = \frac{s-1}{s+1} = 1 - \frac{2}{s} + \frac{2}{s^2} - \frac{2}{s^3} + \cdots \tag{10.59a}$$

$$F(s) = \frac{-2}{(s+1)^2} = 0 + 0 - \frac{2}{s^2} + \frac{4}{s^3} + \cdots \tag{10.59b}$$

$$\hat{\rho}(s) = 1 + \frac{3.23607(\alpha - 1)}{s} + \frac{5.23607(\alpha - 1)^2}{s^2} + \frac{5.23607(\alpha^3 - 3.23607\alpha^2 + 3.23607\alpha - 1)}{s^3} + \cdots \tag{10.59c}$$

Step 6. For a Class IV zero of transmission of order 3, the coefficient conditions are, from Equation 10.29d with $k = 3$,

$$A_m = \rho_m, \quad m = 0, 1, 2 \tag{10.60a}$$

$$\frac{F_2}{A_3 - \rho_3} \geq a_{-1}(\infty) = 1 \tag{10.60b}$$

where $a_{-1}(\infty)$ is the residue of $z_2(s)$ evaluated at the pole $s = \infty$, which is also the zero of transmission of $z_2(s)$. Substituting the coefficients of Equation 10.59 in Equation 10.60 yields the constraints imposed on K_5 as

$$A_0 = 1 = \rho_0 \tag{10.61a}$$

$$A_1 = -2 = \rho_1 = 3.23607(\alpha - 1) \tag{10.61b}$$

$$A_2 = 2 = \rho_2 = 5.23607(\alpha - 1)^2 \tag{10.61c}$$

yielding $\alpha = 0.3819664$, and

$$\frac{F_2}{A_3 - p_3} = \frac{-2}{-2 - 5.23607(\alpha^3 - 3.23607\alpha^2 + 3.23607\alpha - 1)} \geq a_{-1}(\infty) = 1 \tag{10.62}$$

This inequality is satisfied for $\alpha = 0.3819664$. Hence, we choose $\alpha = 0.3819664$ and obtain from Equation 10.57 the maximum realizable DC gain K_5 as

$$K_5 = 1 - \alpha^{10} = 0.99993 \tag{10.63}$$

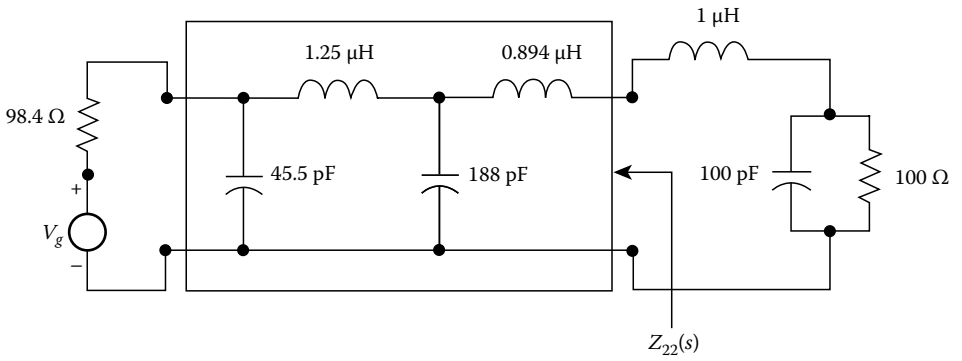

FIGURE 10.5 Fifth-order Butterworth broadband matching equalizer.

With this value of K_5, the minimum-phase reflection coefficient becomes

$$\hat{p}(s) = \frac{s^5 + 1.23607s^4 + 0.76393s^3 + 0.2918s^2 + 0.068884s + 0.0081307}{s^5 + 3.23607s^4 + 5.23607s^3 + 5.23607s^2 + 3.23607s + 1} \tag{10.64}$$

Step 7. The equalizer back-end impedance is determined by

$$\begin{aligned} Z_{22}(s) &\equiv \frac{F(s)}{A(s) - \hat{\rho}(s)} - z_2(s) = \frac{\frac{-2}{(s+1)^2}}{\frac{s-1}{s+1} - \hat{\rho}(s)} - \frac{s^2 + s + 1}{s + 1} \\ &= \frac{0.94427s^4 + 2.1115s^3 + 2.6312s^2 + 2.1591s + 0.9919}{1.0557s^3 + 2.3607s^2 + 2.3131s + 1.0081} \end{aligned} \tag{10.65}$$

Step 8. Expanding $Z_{22}(s)$ in a continued fraction results in

$$Z_{22}(s) = 0.894s + \cfrac{1}{1.88s + \cfrac{1}{1.25s + \cfrac{1}{0.455s + \cfrac{1}{0.984}}}} \tag{10.66}$$

which can be identified as an LC ladder network terminated in a resistor. Denormalizing the element values with regard to magnitude-scaling by a factor of 100 and frequency-scaling by a factor 10^8 gives the final design of the equalizer of Figure 10.5.

Example 10.4

Design a lossless equalizer to match the load

$$z_2(s) = \frac{s^2 + 9s + 8}{s^2 + 2s + 2} \tag{10.67}$$

to a resistive generator and to achieve the largest flat transducer power gain over the entire sinusoidal frequency spectrum.

Step 1. For truly-flat transducer power gain, let

$$G(\omega^2) = K, \quad 0 \le K \le 1 \tag{10.68}$$

Step 2. The following functions are computed from $z_2(s)$:

$$r_2(s)\frac{(s^2-4)^2}{(s^2+2s+2)(s^2-2s+2)} \tag{10.69a}$$

$$A(s)=\frac{s^2-2s+2}{s^2+2s+2} \tag{10.69b}$$

$$F(s)=\frac{2(s^4-8s^2+16)}{(s^2+2s+2)^2} \tag{10.69c}$$

Step 3. Since

$$w(s)=\frac{r_2(s)}{z_2(s)}=\frac{(s^2-4)^2}{(s^2-2s+2)(s^2+9s+8)} \tag{10.70}$$

the load impedance $z_2(s)$ possesses a Class I zero of transmission of order 2 at $s=2$.

Step 4. Substituting Equation 10.68 in Equation 10.46 yields

$$\boldsymbol{\rho}(s)\boldsymbol{\rho}(-s)=1-K \tag{10.71a}$$

the minimum-phase solution of which is found to be

$$\hat{\boldsymbol{\rho}}(s)=\pm\sqrt{1-K} \tag{10.71b}$$

Step 5. For a Class I zero of transmission of order 2, the coefficient conditions (Equation 10.29a) become

$$A(2)=\hat{\boldsymbol{\rho}}(2) \tag{10.72a}$$

$$A_1=\left.\frac{\mathrm{d}A(s)}{\mathrm{d}s}\right|_{s=2}=\boldsymbol{\rho}_1=\left.\frac{\mathrm{d}\boldsymbol{\rho}(s)}{\mathrm{d}s}\right|_{s=2} \tag{10.72b}$$

The Laurent series expansions of the functions $A(s)$, $F(s)$, and $\hat{\boldsymbol{\rho}}(s)$ about the zero of transmission at $s=2$ are not needed.

Step 6. Substituting Equations 10.69b and 10.71b in Equation 10.72 gives

$$A_0=A(2)=0.2=\boldsymbol{\rho}_0=\pm\sqrt{1-K} \tag{10.73a}$$

$$A_1=\left.\frac{\mathrm{d}A(s)}{\mathrm{d}s}\right|_{s=2}=0.08\neq\boldsymbol{\rho}_1=0 \tag{10.73b}$$

Since the coefficient conditions cannot all be satisfied without the insertion of a real all-pass function, let

$$\boldsymbol{\rho}(s)=\boldsymbol{\eta}(s)\hat{\boldsymbol{\rho}}(s)=\frac{s-\boldsymbol{\sigma}_1}{s+\boldsymbol{\sigma}_1}\hat{\boldsymbol{\rho}}(s) \tag{10.74}$$

Using this $\boldsymbol{\rho}$(s) in Equation 10.72 results in the new constraints.

$$A_0=0.2=\boldsymbol{\rho}_0=\pm\frac{2-\boldsymbol{\sigma}_1}{2+\boldsymbol{\sigma}_1}\sqrt{1-K} \tag{10.75a}$$

$$A_1=0.08=\boldsymbol{\rho}_1=\pm\frac{2\boldsymbol{\sigma}_1\sqrt{1-K}}{(2+\boldsymbol{\sigma}_1)^2} \tag{10.75b}$$

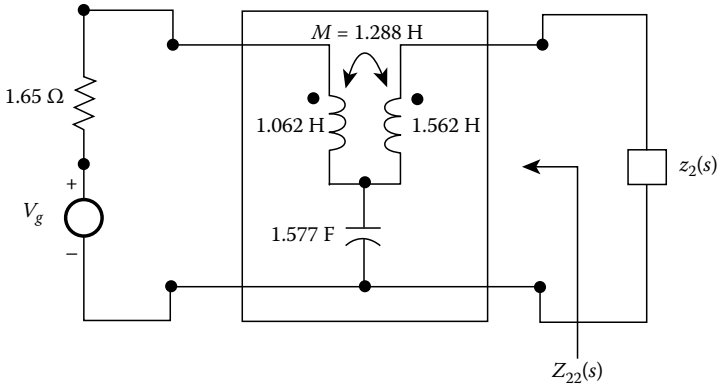

FIGURE 10.6 Lossless equalizer having a truly flat transducer power gain.

which can be combined to yield

$$\sigma_1^2 + 5\sigma_1 - 4 = 0 \tag{10.76}$$

obtaining $\sigma_1 = 0.70156$ or -5.7016. Choosing $\sigma_1 = 0.70156$ and the plus sign for $\rho(s)$, the maximum permissible flat transducer power gain is found to be

$$K_{\max} = 0.82684 \tag{10.77}$$

Step 7. The equalizer back-end impedance is determined as

$$Z_{22}(s) \equiv \frac{F(s)}{A(s) - \rho(s)} - z_2(s) = \frac{1.4161s + 0.8192}{0.58388s + 0.49675} \tag{10.78}$$

Step 8. The positive-real impedance $Z_{22}(s)$ can be realized as the input impedance of a lossless two-port network terminated in a resistor. The overall network is presented in Figure 10.6.

10.4 Explicit Formulas for the RLC Load

In many practical cases, the source can usually be represented by an ideal voltage source in series with a pure resistor, which may be the Thévenin equivalent of some other network, and the load is composed of the parallel combination of a resistor and a capacitor and then in series with an inductor, as shown in Figure 10.7, which may include the parasitic effects of a physical device. The problem is to match out this load and source over a preassigned frequency band to within a given tolerance, and to achieve a prescribed transducer power-gain characteristic $G(\omega^2)$. In the case that $G(\omega^2)$ is of Butterworth or Chebyshev type of response, explicit formulas for the design of such optimum matching networks for any RLC load of the type shown in Figure 10.7 are available, thereby avoiding the necessity of applying the coefficient constraints and solving the nonlinear equations for selecting the optimum design parameters. As a result, we reduce the design of these equalizers to simple arithmetic.

10.4.1 Butterworth Networks

Refer to Figure 10.7. We wish to match out the load impedance

$$z_2(s) = Ls + \frac{R}{RCs + 1} \tag{10.79}$$

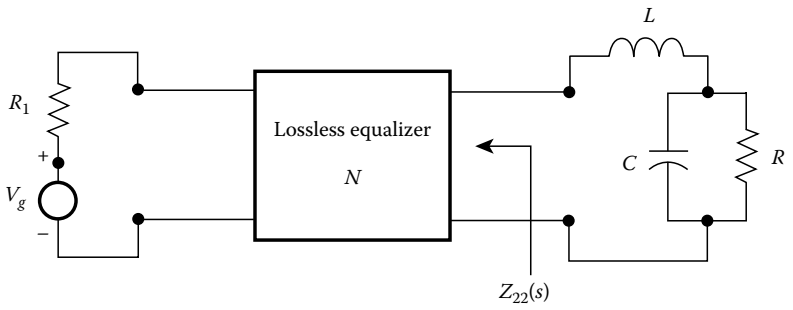

FIGURE 10.7 Broadband matching of an RLC load to a resistive source.

to a resistive generator and to achieve the *n*th-order Butterworth transducer power-gain characteristic

$$G(\omega^2) = \frac{K_n}{1 + (\omega/\omega_c)^{2n}}, \quad 0 \le K_n \le 1 \tag{10.80}$$

with maximum attainable DC gain K_n, where ω_c is the 3 dB bandwidth or the radian cutoff frequency.

The even part $r_2(s)$ of $z_2(s)$ is found to be

$$r_2(s) = \frac{-R}{R^2C^2s^2 - 1} \tag{10.81}$$

Since $z_2(-s)$ has an open RHS pole at $s = 1/RC$, the all-pass real function defined by this pole is given by

$$A(s) = \frac{s - 1/RC}{s + 1/RC} = \frac{RCs - 1}{RCs + 1} \tag{10.82}$$

yielding

$$F(s) = 2A(s)r_2(s) = \frac{-2R}{(RCs + 1)^2} \tag{10.83}$$

We next replace ω by $-js$ in Equation 10.80 and substitute the resulting equation in Equation 10.46 to obtain

$$\rho(s)\rho(-s) = \alpha^{2n}\frac{1 + (-1)^n x^{2n}}{1 + (-1)^n y^{2n}} \tag{10.84}$$

where

$$y = \frac{s}{\omega_c}, \quad x = \frac{y}{\alpha} \tag{10.85a}$$

$$\alpha = (1 - K_n)^{1/2n} \tag{10.85b}$$

As previously shown in Equation 9.29, the minimum-phase solution $\hat{\rho}(s)$ of Equation 10.84 is found to be

$$\hat{\rho}(s) = \alpha^n \frac{q(x)}{q(y)} \tag{10.86}$$

For our purposes, we consider the more general solution

$$\rho(s) = \pm\eta(s)\hat{\rho}(s) \tag{10.87}$$

where $\hat{\eta}(s)$ is an arbitrary first-order real all-pass function of the form

$$\eta(s) = \frac{s - \sigma_1}{s + \sigma_1}, \quad \sigma_1 \geq 0 \tag{10.88}$$

Since the load impedance $z_2(s)$ possesses a Class IV zero of transmission at infinity of order 3, the coefficient constraints become

$$A_m = \rho_m, \quad m = 0, 1, 2 \tag{10.89a}$$

$$L_a \equiv \frac{F_2}{A_3 - \rho_3} \geq L \tag{10.89b}$$

After substituting the coefficients F_2, A_3, and ρ_3 from the Laurent series expansions of $F(s)$, $A(s)$, and $\rho(s)$ in Equation 10.89b, Equation 10.89a can all be satisfied by requiring that the DC gain be

$$K_n = 1 - \left[1 - \frac{2(1 - RC\sigma_1)\sin\gamma_1}{RC\omega_c}\right]^{2n} \tag{10.90}$$

where γ_m is defined in Equation 9.37, and after considerable mathematical manipulations the constraint (Equation 10.89b) becomes

$$L_a = \frac{4R\sin\gamma_1\sin\gamma_3}{(1 - RC\sigma_1)\left[RC\omega_c^2(\alpha^2 - 2\alpha\cos\gamma_2 + 1) + 4\sigma_1\sin\gamma_1\sin\gamma_3\right]} \geq L \tag{10.91}$$

The details of these derivations can be found in Ref. [3]. Thus, with K_n as specified in Equation 10.90, a match is possible if and only if the series inductance L does not exceed a critical inductance L_a. To show that any RLC load can be matched, we must demonstrate that there exists a nonnegative real σ_1 such that L_a can be made at least as large as the given inductance L and satisfies the constraint (Equation 10.90) with $0 \leq K_n \leq 1$. To this end, four cases are distinguished. Let

$$L_{a1} = \frac{R^2C\omega_c\sin\gamma_3}{\left[(RC\omega_c - \sin\gamma_1)^2 + \cos^2\gamma_1\right]\omega_c\sin\gamma_1} > 0 \tag{10.92}$$

$$L_{a2} = \frac{8R\sin^2\gamma_1\sin\gamma_3}{\left[(RC\omega_c - \sin\gamma_3)^2 + (1 + 4\sin^2\gamma_1)\sin\gamma_1\sin\gamma_3\right]\omega_c} > 0 \tag{10.93}$$

Case 1. $RC\omega_c \geq 2\sin\gamma_1$ and $L_{a1} \geq L$. Under this situation, $\sigma_1 = 0$ and the maximum attainable K_n is given by Equation 10.90. The equalizer back-end impedance $Z_{22}(s)$ can be expanded in a continued fraction as

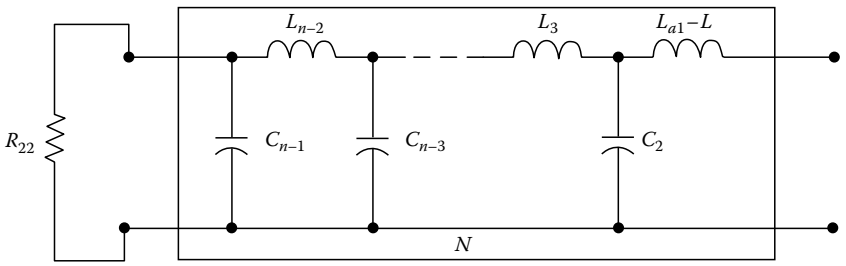
$$Z_{22}(s) = (L_{a1} - L)s + \cfrac{1}{C_2 s + \cfrac{1}{L_3 s + \cfrac{1}{\ddots + \frac{1}{W}}}} \tag{10.94}$$

where
W is a constant representing either a resistance or a conductance, and

$$L_1 = L_{a1} \tag{10.95a}$$

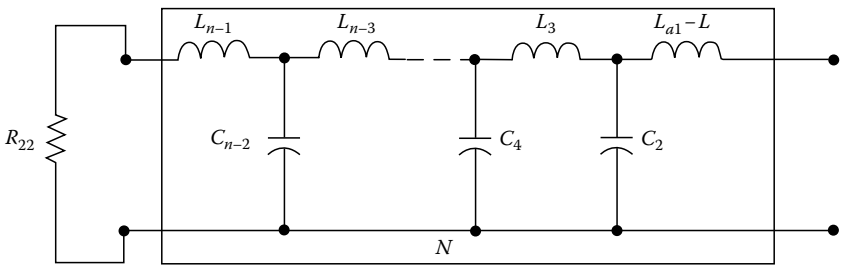
$$C_{2m}L_{2m-1} = \frac{4\sin\gamma_{4m-1}\sin\gamma_{4m+1}}{\omega_c^2(1-2\alpha\cos\gamma_{4m}+\alpha^2)}, \quad m \le \frac{1}{2}(n-1) \tag{10.95b}$$

$$C_{2m}L_{2m+1} = \frac{4\sin\gamma_{4m+1}\sin\gamma_{4m+3}}{\omega_c^2(1-2\alpha\cos\gamma_{4m+2}+\alpha^2)}, \quad m < \frac{1}{2}(n-1) \tag{10.95c}$$



where $m = 1, 2, \ldots, \lceil \frac{1}{2}(n-1) \rceil, n > 1$. In addition, the final reactive element can also be computed directly by the formulas

$$C_{n-1} = \frac{2(1+\alpha^n)\sin\gamma_1}{R(1-\alpha^n)(1+\alpha)\omega_c}, \quad n \text{ odd} \tag{10.96a}$$



$$L_{n-1} = \frac{2R(1-\alpha^n)\sin\gamma_1}{(1+\alpha^n)(1+\alpha)\omega_c}, \quad n \text{ even} \tag{10.96b}$$

Equation 10.94 can be identified as an LC ladder terminated in a resistor, as depicted in Figure 10.8. The terminating resistance is determined by

$$R_{22} = R\frac{1-\alpha^n}{1+\alpha^n} \tag{10.97}$$

(a) n odd

(b) n even

FIGURE 10.8 nth-order Butterworth ladder network N.

Case 2. $RC\omega_c \geq 2\sin\gamma_1$ and $L_{a1} < L$. Under this situation, σ_1 is nonzero and can be determined by the formula

$$\sigma_1 = \frac{1}{RC}\left(1 + 2\sqrt{p}\sinh\frac{\varphi}{3} - \frac{2RC\omega_c\sin^2\gamma_1 + \sin\gamma_3}{3\sin\gamma_1}\right) \tag{10.98}$$

where

$$\mathrm{p} = \frac{(RC\omega_c - 2\sin\gamma_1)^2\sin\gamma_3}{9\sin\gamma_1} > 0 \tag{10.99a}$$

$$w = \frac{(2RC\omega_c\sin^2\gamma_1 + \sin\gamma_3)}{54\sin^3\gamma_1}\left[3(RC\omega_c - 2\sin\gamma_1)^2\sin\gamma_1\sin\gamma_3 + \left(2RC\omega_c\sin^2\gamma_1 + \sin\gamma_3\right)^2\right] - \frac{R^2C\sin\gamma_3}{2L\sin\gamma_1} \tag{10.99b}$$

$$\varphi = \sinh^{-1}\frac{w}{(\sqrt{p})^3} \tag{10.99c}$$

Using this value of σ_1, the DC gain K_n is computed by Equation 10.90.

Case 3. $RC\omega_c < 2\sin\gamma_1$ and $L_{a2} \geq L$. Then, we have

$$K_n = 1 \tag{10.100a}$$

$$\sigma_1 = \frac{1}{RC}\left(1 - \frac{RC\omega_c}{2\sin\gamma_1}\right) > 0 \tag{10.100b}$$

Case 4. $RC\omega_c < 2\sin\gamma_1$ and $L_{a2} < L$. Then the desired value of σ_1 can be computed by Equation 10.98. Using this value of σ_1, the DC gain K_n is computed by Equation 10.90.

Example 10.5

Let

$$R = 100\,\Omega, \quad C = 100\,\mathrm{pF}, \quad L = 0.5\,\mu\mathrm{F} \tag{10.101a}$$

$$n = 6, \quad \omega_c = 10^8\,\mathrm{rad/s} \tag{10.101b}$$

From Equation 10.92, we first compute

$$L_{a1} = \frac{100\sin 45^\circ}{[(1 - \sin 15^\circ)^2 + \cos^2 15^\circ] \times 10^8\sin 15^\circ} = 1.84304\,\mu\mathrm{H} \tag{10.102}$$

Since $L_{a1} > L$ and

$$RC\omega_c = 1 > 2\sin 15^\circ = 0.517638 \tag{10.103}$$

Case 1 applies and the matching network can be realized as an LC ladder terminating in a resistor as shown in Figure 10.8b. With $\sigma_1 = 0$, the maximum attainable DC gain K_6 is from Equation 10.90

$$K_6 = 1 - \left(1 - \frac{2\sin 15^\circ}{RC\omega_c}\right)^{12} = 0.999841 \tag{10.104}$$

giving from Equation 10.85b

$$\alpha = (1 - K_6)^{1/12} = 0.482362 \tag{10.105}$$

Applying Equation 10.95 yields the element values of the LC ladder network, as follows:

$$L_1 = L_{a1} = 1.84304\,\mu\text{H} \tag{10.106a}$$

$$C_2 = \frac{4\sin 45^\circ \sin 75^\circ}{1.84304 \times 10^{-6} \times 10^{16}(1 - 2 \times 0.482362\cos 60^\circ + 0.482362^2)} = 197.566\,\text{pF} \tag{10.106b}$$

$$L_3 = \frac{4\sin 75^\circ \sin 105^\circ}{197.566 \times 10^{-12} \times 10^{16}(1 - 2 \times 0.482362\cos 90^\circ + 0.482362^2)} = 1.53245\,\mu\text{H} \tag{10.106c}$$

$$C_4 = \frac{4\sin 105^\circ \sin 135^\circ}{1.53245 \times 10^{-6} \times 10^{16}(1 - 2 \times 0.482362\cos 120^\circ + 0.482362^2)} = 103.951\,\text{pF} \tag{10.106d}$$

$$L_5 = \frac{4\sin 135^\circ \sin 165^\circ}{103.951 \times 10^{-12} \times 10^{16}(1 - 2 \times 0.482362\cos 150^\circ + 0.482362^2)} = 0.34051\,\mu\text{H} \tag{10.106e}$$

The last reactive elements L_5 can also be calculated directly from Equation 10.96b as

$$L_5 = \frac{2 \times 100(1 - 0.482362^6)\sin 15^\circ}{(1 + 0.482362^6)(1 + 0.482362)10^8} = 0.34051\,\mu\text{H} \tag{10.107}$$

Finally, the terminating resistance is determined from Equation 10.97 as

$$R_{22} = 100\frac{1 - 0.482362^6}{1 + 0.482362^6} = 97.512\,\Omega \tag{10.108}$$

The matching network together with its terminations is presented in Figure 10.9. We remark that for computational accuracy we retain five significant figures in all the calculations. In practice, one or two significant digits are sufficient, as indicated in the figure.

Example 10.6

Let

$$R = 100\,\Omega, \quad C = 50\,\text{pF}, \quad L = 0.5\,\mu\text{F} \tag{10.109a}$$

$$n = 5, \quad \omega_c = 10^8\,\text{rad/s} \tag{10.109b}$$

Since

$$RC\omega_c = 0.5 < 2\sin 18^\circ = 0.618 \tag{10.110}$$

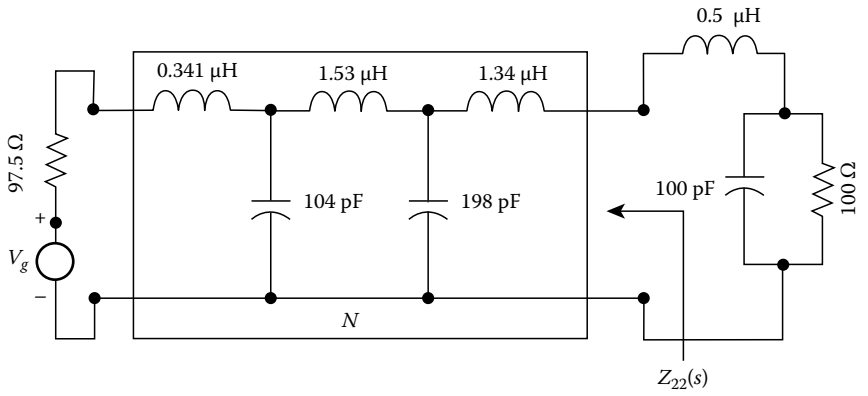


FIGURE 10.9 Sixth-order Butterworth matching network.

and from Equation 10.93,

$$L_{a2} = 1.401\ \mu\text{H} > L = 0.5\ \mu\text{H} \tag{10.111}$$

Case 3 applies, and we have $K_5 = 1$ and from Equation 10.100b

$$\sigma_1 = 0.381966 \times 10^8 \tag{10.112}$$

The normalized reflection coefficient is found to be

$$\rho(y) = \frac{(y - 0.381966)y^5}{(y + 0.381966)(y^5 + 3.23607y^4 + 5.23607y^3 + 5.23607y^2 + 3.23607y + 1)} \tag{10.113}$$

where $y = s/10^8$. Finally, we compute the equalizer back-end impedance as

$$\begin{aligned}
\frac{Z_{22}(s)}{100} &= \frac{F(y)}{A(y) - \rho(y)} - z_2(y) \\
&= \frac{\frac{-2}{(0.5y+1)^2}}{\frac{0.5y-1}{0.5y+1} - \rho(s)} - 0.5y - \frac{1}{0.5y + 1} \\
&= \frac{2.573y^5 + 4.1631y^4 + 5.177y^3 + 4.2136y^2 + 2.045y + 0.38197}{2.8541y^4 + 4.618y^3 + 4.118y^2 + 2.045y + 0.38197} \\
&= 0.9015y + \cfrac{1}{1.949y + \cfrac{1}{1.821y + \cfrac{1}{0.8002y + \cfrac{1}{\cfrac{1.005y + 0.3822}{0.9944y + 0.3822}}}}}
\end{aligned} \tag{10.114}$$

The final matching network together with its terminations is presented in Figure 10.10.

Example 10.7

Let

$$R = 100\ \Omega, \quad C = 50\ \text{pF}, \quad \text{L} = 3\ \mu\text{F} \tag{10.115a}$$

$$n = 4, \quad \omega_c = 10^8\ \text{rad/s} \tag{10.115b}$$

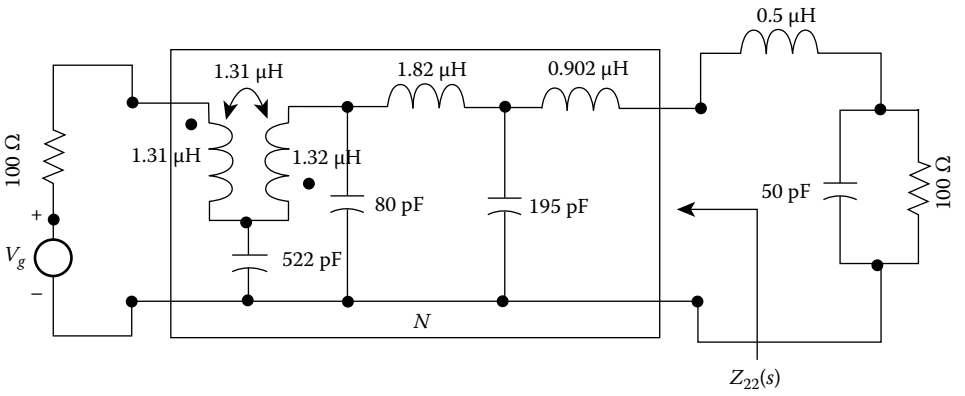

FIGURE 10.10 Fifth-order Butterworth matching network.

Since

$$RC\omega_c = 0.5 < 2\sin 22.5^\circ = 0.76537 \tag{10.116}$$

and from Equation 10.93

$$L_{a2} = 1.462\ \mu\text{H} < L = 3\ \mu\text{H} \tag{10.117}$$

Case 4 applies, and from Equation 10.98

$$\sigma_1 = 1.63129 \times 10^8 \tag{10.118}$$

where Equation 10.99

$$p = 0.0188898, \quad w = 0.2304, \quad \varphi = 5.17894 \tag{10.119}$$

From Equation 10.90, the maximum attainable DC gain is obtained as

$$K_4 = 1 - \left[1 - \frac{2(1 - 100 \times 50 \times 10^{-12} \times 1.63129 \times 10^8)\sin 22.5^\circ}{100 \times 50 \times 10^{-12} \times 10^8}\right]^8 = 0.929525 \tag{10.120}$$

giving from Equation 10.85b

$$\alpha = (1 - K_4)^{1/8} = 0.717802 \tag{10.121}$$

Finally, the normalized reflection coefficient $\rho(s)$ is obtained as

$$\rho(s) = \frac{(y - 1.63129)(y^4 + 1.87571\,y^3 + 1.75913\,y^2 + 0.966439\,y + 0.265471)}{(y + 1.63129)(y^4 + 2.61313\,y^3 + 3.41421\,y^2 + 2.61313\,y + 1)} \tag{10.122}$$

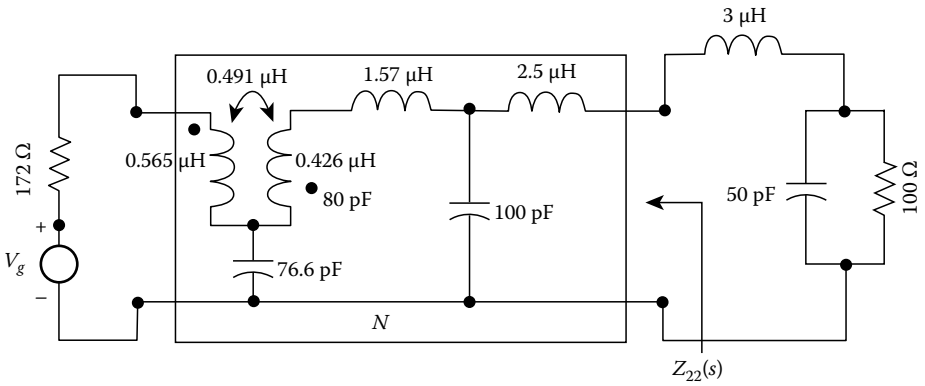

FIGURE 10.11 Fourth-order Butterworth matching network.

where $y = s/10^8$. Finally, we compute the equalizer back-end impedance as

$$\begin{aligned}\frac{Z_{22}(s)}{100} &= \frac{F(y)}{A(y)-\rho(y)} - z_2(y) = \frac{\frac{-2}{(0.5y+1)^2}}{\frac{0.5y-1}{0.5y+1}-\rho(s)} - 0.5y - \frac{1}{0.5y+1} \\ &= \frac{3.3333y^4 + 7.4814y^3 + 8.6261y^2 + 5.9748y + 2.0642}{1.3333y^3 + 2.9926y^2 + 2.9195y + 1.1982} \\ &= 2.5y + \cfrac{1}{1.0046y + \cfrac{1}{1.5691y + \cfrac{1}{\cfrac{1.0991y + 2.0642}{0.84591y + 1.1982}}}}\end{aligned} \tag{10.123}$$

The final matching network together with its terminations is presented in Figure 10.11.

10.4.2 Chebyshev Networks

Refer again to Figure 10.7. We wish to match out the load impedance

$$z_2(s) = Ls + \frac{R}{RCs+1} \tag{10.124}$$

to a resistive generator and to achieve the nth-order Chebyshev transducer power-gain characteristic

$$G(\omega^2) = \frac{K_n}{1+\varepsilon^2 C_n^2(\omega/\omega_c)}, \quad 0 \le K_n \le 1 \tag{10.125}$$

with maximum attainable constant K_n. Following Equation 10.84, we obtain

$$\rho(s)\rho(-s) = (1-K_n)\frac{1+\hat{\varepsilon}^2 C_n^2(-jy)}{1+\varepsilon^2 C_n^2(-jy)} \tag{10.126}$$

where $y = s/\omega_c$ and

$$\hat{\varepsilon} = \frac{\varepsilon}{\sqrt{1-K_n}} \tag{10.127}$$

As in Equation 10.86, let $\hat{\rho}(s)$ be the minimum-phase solution of Equation 10.126. For our purposes, we consider the more general solution

$$\rho(s) = \pm\eta(s)\hat{\rho}(s) \tag{10.128}$$

where $\acute{\eta}(s)$ is an arbitrary first-order real all-pass function of the form

$$\eta(s) = \frac{s - \sigma_1}{s + \sigma_1}, \quad \sigma_1 \geq 0 \tag{10.129}$$

Since the load impedance $z_2(s)$ possesses a Class IV zero of transmission at infinity of order 3, the coefficient constraints become

$$A_m = \rho_m, \quad m = 0, 1, 2 \tag{10.130a}$$

$$\frac{F_2}{A_3 - \rho_3} \geq L \tag{10.130b}$$

After substituting the coefficients F_2, A_3, and ρ_3 from the Laurent series expansions of $F(s)$, $A(s)$, and $\rho(s)$ in Equation 10.130a, they lead to the constraints on the constant K_n as

$$K_n = 1 - \varepsilon^2 \sinh^2 \left\{ n \sinh^{-1} \left[\sinh a - \frac{2(1 - RC\sigma_1)\sin\gamma_1}{RC\omega_c} \right] \right\} \tag{10.131}$$

where γ_m is defined in Equation 9.37, and

$$a = \frac{1}{n} \sinh^{-1} \frac{1}{\varepsilon} \tag{10.132}$$

To apply the constraint (Equation 10.130b), we rewrite it as

$$L_b \equiv \frac{F_2}{A_3 - \rho_3} \geq L \tag{10.133}$$

After substituting the coefficients F_2, A_3, and ρ_3 from the Laurent series expansions of $F(s)$, $A(s)$, and $\rho(s)$ in Equation 10.133 and after considerable mathematical manipulations, we obtain

$$L_b = \frac{4R \sin\gamma_1 \sin\gamma_3}{(1 - RC\sigma_1)\left[RC\omega_c^2 f_1(\sin a, \sinh\hat{a}) + 4\sigma_1 \sin\gamma_1 \sin\gamma_3\right]} \geq L \tag{10.134}$$

where

$$\hat{a} = \frac{1}{n} \sinh^{-1} \frac{1}{\hat{\varepsilon}} = \frac{1}{n} \sinh^{-1} \frac{\sqrt{1 - K_n}}{\varepsilon} \tag{10.135}$$

$$f_m(x,y) = x^2 + y^2 - 2xy\cos\gamma_{2m} + \sin^2\gamma_{2m}, \quad m = 1, 2, \ldots, \left\lceil \frac{1}{2} n \right\rceil \tag{10.136}$$

The details of these derivations can be found in Ref. [3]. Thus, with K_n as specified in Equation 10.131, a match is possible if and only if the series inductance L does not exceed a critical inductance L_b. To show that any RLC load can be matched, we must demonstrate that there exists a nonnegative real σ_1 such that L_b can be made at least as large as the given inductance L and satisfies the constraint (Equation 10.131) with $0 \le K_n \le 1$. To this end, four cases are distinguished. Let

$$L_{b1} = \frac{R^2 C\omega_c \sin\gamma_3}{\left[(1 - RC\omega_c \sinh a \sin\gamma_1)^2 + R^2C^2\omega_c^2 \cosh^2 a \cos^2\gamma_1\right]\omega_c \sin\gamma_1} > 0 \tag{10.137}$$

$$L_{b2} = \frac{8R \sin^2\gamma_1 \sin\gamma_3}{\left[(RC\omega_c \sinh a - \sin\gamma_3)^2 + (1 + 4\sin^2\gamma_1)\sin\gamma_1 \sin\gamma_3 + R^2C^2\omega_c^2 \sin^2\gamma_2\right]\omega_c \sinh a} > 0 \tag{10.138}$$

Observe that both L_{b1} and L_{b2} are positive.

Case 1. $RC\omega_c \sinh a \ge 2\sin\gamma_1$ and $L_{b1} \ge L$. Under this situation, $\sigma_1 = 0$ and the maximum attainable K_n is given by

$$K_n = 1 - \varepsilon^2 \sinh^2\left[n \sinh^{-1}\left(\sinh a - \frac{2\sin\gamma_1}{RC\omega_c}\right)\right] \tag{10.139}$$

The equalizer back-end impedance $Z_{22}(s)$ can be expanded in a continued fraction as in Equation 10.94 with L_{b1} replacing L_{a1} and realized by the LC ladders Figure 10.8 with

$$L_1 = L_{b1} \tag{10.140a}$$

$$C_{2m}L_{2m-1} = \frac{4\sin\gamma_{4m-1}\sin\gamma_{4m+1}}{\omega_c^2 f_{2m}(\sinh a, \sinh\hat{a})}, \quad m < \frac{1}{2}(n-1) \tag{10.140b}$$

$$C_{2m}L_{2m+1} = \frac{4\sin\gamma_{4m+1}\sin\gamma_{4m+3}}{\omega_c^2 f_{2m+1}(\sinh a, \sinh\hat{a})}, \quad m < \frac{1}{2}(n-1) \tag{10.140c}$$

where $m = 1, 2, \ldots, \left\lceil \frac{1}{2}(n-1)\right\rceil, n > 1$. In addition, the final reactive element can also be computed directly by the formulas

$$C_{n-1} = \frac{2(\sinh na + \sinh n\hat{a})\sin\gamma_1}{R\omega_c(\sinh a + \sinh\hat{a})(\sinh na - \sinh n\hat{a})}, \quad n \text{ odd} \tag{10.141a}$$

$$L_{n-1} = \frac{2R(\cosh na - \cosh n\hat{a})\sin\gamma_1}{\omega_c(\sinh a + \sinh\hat{a})(\cosh na + \cosh n\hat{a})}, \quad n \text{ even} \tag{10.141b}$$

The terminating resistance is determined by

$$R_{22} = R\frac{\sinh na - \sinh n\hat{a}}{\sinh na + \sinh n\hat{a}}, \quad n \text{ odd} \tag{10.142a}$$

$$R_{22} = R\frac{\cosh na - \cosh n\hat{a}}{\cosh na + \cosh n\hat{a}}, \quad n \text{ even} \tag{10.142b}$$

Case 2. $RC\omega_c \sinh a \ge 2\sin\gamma_1$ and $L_{b1} < L$. Under this situation, σ_1 is nonzero and can be determined by the formula

$$\sigma_1 = \frac{1}{RC}\left(1 + 2\sqrt{q}\sinh\frac{\varphi}{3} - \frac{2RC\omega_c \sin^2\gamma_1 \sinh a + \sin\gamma_3}{3\sin\gamma_1}\right) \tag{10.143}$$

where

$$q = \frac{(RC\omega_c \sinh a - 2\sin\gamma_1)^2 \sin\gamma_3 + 3R^2C^2\omega_c^2 \sin\gamma_1 \cos^2\gamma_1}{9\sin\gamma_1} > 0 \tag{10.144a}$$

$$\begin{aligned}\zeta = {} & \frac{(2RC\omega_c \sin^2\gamma_1 \sinh a + \sin\gamma_3)}{54\sin^3\gamma_1} \\ & \times \left[3(RC\omega_c \sinh a - 2\sin\gamma_1)^2 \sin\gamma_1 \sin\gamma_3 \right. \\ & \left. + \; 2.25R^2C^2\omega_c^2 \sin^2\gamma_2 + \left(2RC\omega_c \sin^2\gamma_1 \sinh a + \sin\gamma_3\right)^2\right] \\ & - \frac{R^2C\sin\gamma_3}{2L\sin\gamma_1}\end{aligned} \tag{10.144b}$$

$$\varphi = \sinh^{-1}\frac{\zeta}{\left(\sqrt{q}\right)^3} \tag{10.144c}$$

Using this value of σ_1, the constant K_n is computed by Equation 10.131.

Case 3. $RC\omega_c \sinh a < 2\sin\gamma_1$ and $L_{b2} \geq L$. Then, we have

$$K_n = 1 \tag{10.145a}$$

$$\sigma_1 = \frac{1}{RC}\left(1 - \frac{RC\omega_c \sinh a}{2\sin\gamma_1}\right) > 0 \tag{10.145b}$$

Case 4. $RC\omega_c \sinh a < 2\sin\gamma_1$ and $L_{b2} < L$. Then the desired value of σ_1 can be computed by formula given by Equation 10.143. Using this value of σ_1, the constant K_n is computed by Equation 10.131.

Example 10.8

Let

$$R = 100\,\Omega, \quad C = 500\,\text{pF}, \quad L = 0.5\,\mu\text{F} \tag{10.146a}$$

$$n = 6, \quad \varepsilon = 0.50885(1\text{ dB ripple}), \quad \omega_c = 10^8\text{ rad/s} \tag{10.146b}$$

From Equation 10.137, we first compute

$$\begin{aligned}L_{b1} &= \frac{500\sin 45^\circ}{\left[(1 - 5\sinh 0.237996\sin 15^\circ)^2 + 25\cosh^2 0.237996\cos^2 15^\circ\right]10^8\sin 15^\circ} \\ &= 0.54323\,\mu\text{H}\end{aligned} \tag{10.147}$$

Since $L_{b1} > L$ and

$$RC\omega_c \sinh a = 5\sinh 0.237996 = 1.20125 > 2\sin 15^\circ = 0.517638 \tag{10.148}$$

Case 1 applies and the matching network can be realized as an LC ladder terminating in a resistor as shown in Figure 10.8. With $\sigma_1 = 0$, the maximum attainable DC gain K_6 is from Equation 10.131

$$K_6 = 1 - 0.50885^2 \sinh^2\left[6\sinh^{-1}\left(\sinh 0.237996 - \frac{2\sin 15^\circ}{5}\right)\right] = 0.78462 \tag{10.149}$$

giving from Equations 10.127 and 10.135

$$\hat{\varepsilon} = \frac{0.50885}{\sqrt{1 - 0.78462}} = 1.0964 \tag{10.150a}$$

$$\hat{\alpha} = \frac{1}{6}\sinh^{-1}\frac{1}{1.0964} = 0.13630 \tag{10.150b}$$

Applying formulas given by Equation 10.140 yields the element values of the LC ladder network, as follows:

$$L_1 = L_{b1} = 0.54323\,\mu\text{H}, \quad C_2 = 634\,\text{pF}, \quad L_3 = 0.547\,\mu\text{H} \tag{10.151a}$$

$$C_4 = 581\,\text{pF}, \quad L_5 = 0.329\,\mu\text{H} \tag{10.151b}$$

The last reactive element L_5 can be calculated directly from Equation 10.141b as

$$L_5 = \frac{2 \times 100[\cosh(6 \times 0.237996) - \cosh(6 \times 0.13630)]\sin 15^\circ}{10^8(\sinh 0.237996 + \sinh 0.13630)[\cosh(6 \times 0.237996) + \cosh(6 \times 0.13630)]} = 0.328603\,\mu\text{H} \tag{10.152}$$

Finally, the terminating resistance is determined from Equation 10.142b as

$$R_{22} = 100\frac{\cosh(6 \times 0.237996) - \cosh(6 \times 0.13630)}{\cosh(6 \times 0.237996) + \cosh(6 \times 0.13630)} = 23.93062\,\Omega \tag{10.153}$$

The matching network together with its terminations is presented in Figure 10.12. We remark that for computational accuracy we retain five significant figures in all the calculations. In practice, one or two significant digits are sufficient, as indicated in the figure.

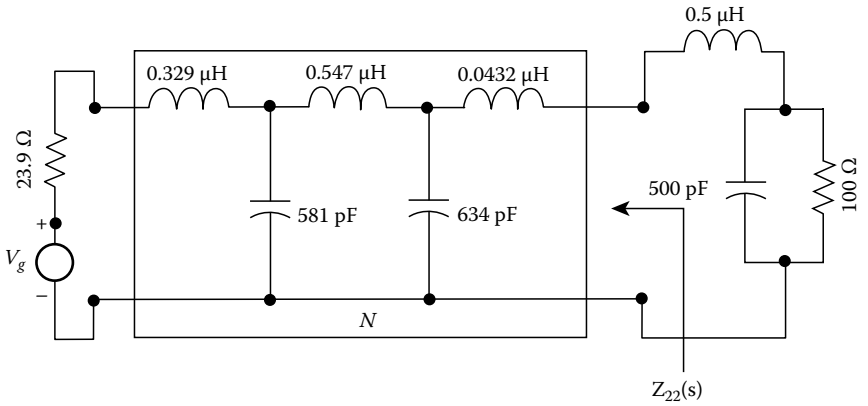

FIGURE 10.12 Sixth-order Chebyshev matching network.

Example 10.9

Let

$$R = 100\,\Omega, \quad C = 500\,\text{pF}, \quad L = 1\,\mu\text{H} \tag{10.154a}$$

$$n = 5, \quad \varepsilon = 0.50885\,(1\text{ dB ripple}), \quad \omega_c = 10^8\text{ rad/s} \tag{10.154b}$$

From Equation 10.137, we first compute

$$L_{b1} = 0.52755\,\mu\text{H} \tag{10.155}$$

Since $L_{b1} < L$ and

$$RC\omega_c \sinh a = 5 \sinh 0.28560 = 1.44747 > 2 \sin 18^\circ = 0.61803 \tag{10.156}$$

Case 2 applies. From Equation 10.144, we obtain

$$q = 7.73769, \quad \zeta = 7.84729, \quad \varphi = 0.356959 \tag{10.157}$$

Substituting these in Equation 10.143 gives

$$\sigma_1 = 0.0985305 \times 10^8 \tag{10.158}$$

From Equation 10.131, the maximum attainable constant K_5 is found to be

$$K_5 = 0.509206 \tag{10.159}$$

The rest of the calculations proceed exactly as in the previous example, and the details are omitted.

Example 10.10

Let

$$R = 100\,\Omega, \quad C = 100\,\text{pF}, \quad L = 0.5\,\mu\text{F} \tag{10.160a}$$

$$n = 5, \quad \varepsilon = 0.76478\,(2\text{ dB ripple}), \quad \omega_c = 10^8\text{ rad/s} \tag{10.160b}$$

We first compute

$$a = \frac{1}{5} \sinh^{-1} \frac{1}{\varepsilon} = 0.2166104 \tag{10.161}$$

and from Equation 10.138

$$L_{b2} = 2.72234\,\mu\text{H} \tag{10.162}$$

Since $L_{b2} \geq L$ and

$$RC\omega_c \sinh a = \sinh 0.2166104 = 0.218308 < 2 \sin 18^\circ = 0.618034 \tag{10.163}$$

Case 3 applies. Then $K_5 = 1$ and from Equation 10.145b

$$\sigma_1 = \frac{1}{10^{-8}}\left(1 - \frac{\sinh 0.2166104}{2\sin 18^\circ}\right) = 0.64677 \times 10^8 \tag{10.164}$$

For $K_5 = 1$, Equation 10.126 degenerates into

$$\rho(y)\rho(-y) = \frac{\varepsilon^2 C_5^2(-jy)}{1 + \varepsilon^2 C_5^2(-jy)} \tag{10.165}$$

where $y = s/10^8$, the minimum-phase solution of which is found to be

$$\hat{\rho}(y) = \frac{y^5 + 1.25y^3 + 0.3125y}{y^5 + 0.706461y^4 + 1.49954y^3 + 0.693477y^2 + 0.459349y + 0.0817225} \tag{10.166}$$

A more general solution is given by

$$\rho(y) = \frac{y - 0.64677 \times 10^8}{y + 0.64677 \times 10^8}\hat{\rho}(y) \tag{10.167}$$

Finally, we compute the equalizer back-end impedance as

$$\begin{aligned}
\frac{Z_{22}(y)}{100} &= \frac{F(y)}{A(y) - \rho(y)} - z_2(y) \\
&= \frac{\frac{-2}{(y+1)^2}}{\frac{y-1}{y+1} - \rho(x)} - 0.5y - \frac{1}{y+1} \\
&= \frac{1.63267y^5 + 0.576709y^4 + 2.15208y^3 + 0.533447y^2 + 0.554503y + 0.0528557}{0.734663y^4 + 0.259505y^3 + 0.639438y^2 + 0.123844y + 0.0528557} \\
&= 2.222y + \cfrac{1}{1.005y + \cfrac{1}{3.651y + \cfrac{1}{0.8204y + \cfrac{1}{\cfrac{0.2441y + 0.05286}{0.02736y + 0.05286}}}}}
\end{aligned} \tag{10.168}$$

The final matching network together with its terminations is presented in Figure 10.13.

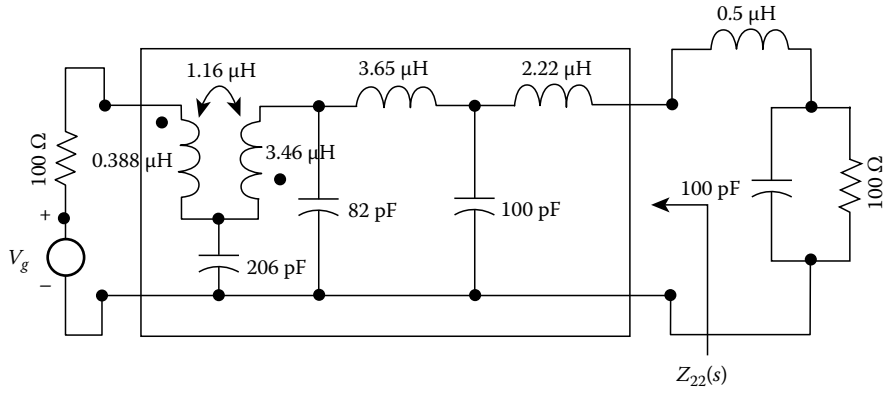

FIGURE 10.13 Fifth-order Chebyshev matching network.

Example 10.11

Let

$$R = 100\,\Omega, \quad C = 100\,\text{pF}, \quad L = 3\,\mu\text{F} \tag{10.169a}$$

$$n = 4, \quad \varepsilon = 0.76478\,(2\text{ dB ripple}), \quad \omega_c = 10^8\text{ rad/s} \tag{10.169b}$$

We first compute

$$a = \frac{1}{4}\sinh^{-1}\frac{1}{0.76478} = 0.27076 \tag{10.170}$$

and from Equation 10.138

$$L_{b2} = 2.66312\,\mu\text{H} \tag{10.171}$$

Since $L_{b2} < L$ and

$$RC\omega_c \sinh a = \sinh 0.27076 = 0.27408 < 2\sin 22.5^\circ = 0.765367 \tag{10.172}$$

Case 4 applies. From Equation 10.144, we obtain

$$q = 0.349261, \quad \zeta = 0.390434, \quad \varphi = 1.39406 \tag{10.173}$$

Substituting these in Equation 10.143 gives

$$\sigma_1 = 0.694564 \times 10^8 \tag{10.174}$$

obtaining from Equations 10.127 and 10.131

$$K_4 = 0.984668, \quad \hat{\varepsilon} = 6.17635 \tag{10.175}$$

From Equation 10.126,

$$\rho(y)\rho(-y) = (1 - K_4)\frac{1 + \hat{\varepsilon}^2 C_4^2(-jy)}{1 + \varepsilon^2 C_4^2(-jy)} \tag{10.176}$$

where $y = s/10^8$, the minimum-phase solution of which is found to be

$$\hat{\rho}(y) = \frac{y^4 + 0.105343\,y^3 + 1.00555\,y^2 + 0.0682693\,y + 0.126628}{y^4 + 0.716215\,y^3 + 1.25648\,y^2 + 0.516798\,y + 0.205765} \tag{10.177}$$

A more general solution is given by

$$\rho(y) = \frac{y - 0.694564 \times 10^8}{y + 0.694564 \times 10^8}\hat{\rho}(s) \tag{10.178}$$

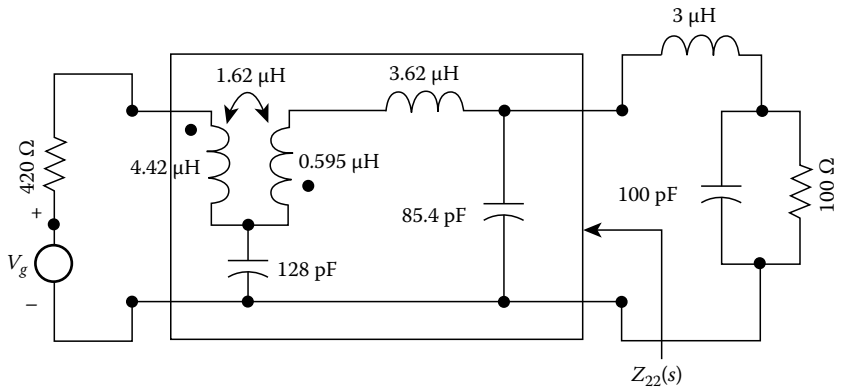

FIGURE 10.14 A fourth-order Chebyshev matching network.

Finally, we compute the equalizer back-end impedance as

$$\begin{aligned}\frac{Z_{22}(y)}{100} &= \frac{F(y)}{A(y)-\rho(y)} - z_2(y) = \frac{\frac{-2}{(y+1)^2}}{\frac{y-1}{y+1}-\rho(s)} - \frac{3y^2+3y+1}{y+1} \\ &= \frac{0.780486\,y^2+0.320604\,y+0.23087}{0.666665\,y^3+0.273851\,y^2+0.413057\,y+0.0549659} \\ &= \cfrac{1}{0.8542\,y+\cfrac{1}{3.616\,y+\cfrac{1}{\cfrac{0.1219\,y+0.2309}{0.2159\,y+0.05497}}}}\end{aligned} \tag{10.179}$$

The final matching network together with its terminations is presented in Figure 10.14.

11.1 Introduction

Active filters consist of only amplifiers, resistors, and capacitors. Complex roots are achieved by the use of feedback eliminating the need for inductors. The gain of the amplifier can be finite or infinite (an op-amp). This section describes active filters using low-gain or finite-gain amplifiers. Filter design equations and examples will be given along with the performance limits of low-gain amplifier filters.

11.2 First- and Second-Order Transfer Functions

Before discussing the characteristics and the synthesis of filters, it is important to understand the transfer functions of first- and second-order filters. Later we will explain the implementations of these filters and show how to construct higher order filters from first- and second-order sections. The transfer functions of most first- and second-order filters are examined in the following.

11.2.1 First-Order Transfer Functions

A standard form of the transfer function of a first-order low-pass filter is

$$T_{LP}(s) = \frac{T_{LP}(j0)\omega_o}{s + \omega_o} \tag{11.1}$$

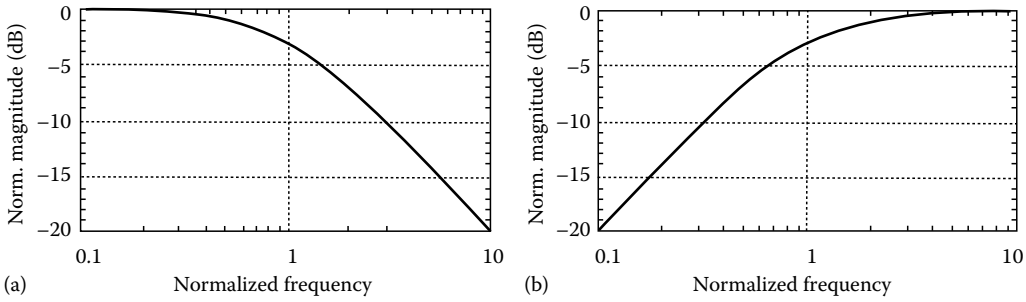

FIGURE 11.1 Normalized magnitude response of (a) first-order low-pass and (b) first-order high-pass filters.

where

$T_{LP}(j0)$ is the value of $T_{LP}(s)$ at dc
ω_o is the pole frequency

It is common practice to normalize both the magnitude and frequency. Normalizing Equation 11.1 yields

$$T_{LPn}(s_n) = \frac{T_{LP}(s_n\omega_o)}{|T_{LP}(j0)|} = \frac{1}{s_n + 1} \tag{11.2}$$

where $s_n = s/\omega_o$ and amplitude has been normalized as

$$T_{LPn}(s) = \frac{T_{LP}(s)}{|T_{LP}(j0)|} \tag{11.3}$$

The equivalent normalized forms of a first-order high-pass filter are

$$T_{HP}(s) = \frac{T_{HP}(j\infty)s}{s + \omega_o} \tag{11.4}$$

and

$$T_{HPn}(s_n) = \frac{T_{HP}(s_n\omega_o)}{|T_{HP}(j\infty)|} = \frac{s_n}{s_n + 1} \tag{11.5}$$

where $T_{HP}(j\infty) = T_{HP}(s)\,|$ at $\omega = \infty$. The normalized magnitude responses of these functions are shown in Figure 11.1.

11.2.2 Second-Order Transfer Functions

The standard form of a second-order low-pass filter is given as

$$T_{LP}(s) = \frac{T_{LP}(j0)\omega_o^2}{s^2 + \left(\frac{\omega_o}{Q}\right)s + \omega_o^2} \tag{11.6}$$

where

$T_{LP}(j0)$ is the value of $T_{LP}(s)$ at dc
ω_o is the pole frequency
Q is the pole Q or the pole quality factor

The damping factor ζ, which may be better known to the reader, is given as

$$\zeta = \frac{1}{2Q} \tag{11.7}$$

The poles of the transfer function of Equation 11.7 are

$$p_1, p_2 = \frac{-\omega_o}{2Q} \pm j\left(\frac{\omega_o}{2Q}\right)\sqrt{4Q^2 - 1} \tag{11.8}$$

Normalization of Equation 11.6 in both amplitude and frequency gives

$$T_{LPn}(s_n) = \frac{T_{LP}(s_n\omega_o)}{|T_{LP}(j0)|} = \frac{1}{s_n^2 + \frac{s_n}{Q} + 1} \tag{11.9}$$

where $s_n = s/\omega_o$. The standard second-order, high-pass and bandpass transfer functions are

$$T_{HP}(s) = \frac{T_{HP}(j\infty)s^2}{s^2 + \left(\frac{\omega_o}{Q}\right)s + \omega_o^2} \tag{11.10}$$

and

$$T_{BP}(s) = \frac{T_{BP}(j\omega_o)\left(\frac{\omega_o}{Q}\right)s}{s^2 + \left(\frac{\omega_o}{Q}\right)s + \omega_o^2} \tag{11.11}$$

where $T_{BP}(j\omega_o) = T_{BP}(s)$ at $s = j\omega = j\omega_o$. The poles of the second-order high-pass and bandpass transfer functions are given by Equation 11.8.

We can normalize these equations as we did for $T_{LP}(s)$ to get

$$T_{HPn}(s_n) = \frac{T_{HP}(s_n\omega_o)}{|T_{HP}(j\infty)|} = \frac{s_n^2}{s_n^2 + \frac{s_n}{Q} + 1} \tag{11.12}$$

$$T_{BPn}(s_n) = \frac{T_{BP}(s_n\omega_o)}{|T_{BP}(j\omega_o)|} = \frac{\frac{s_n}{Q}}{s_n^2 + \frac{s_n}{Q} + 1} \tag{11.13}$$

where

$$T_{HPn}(s) = \frac{T_{HP}(s)}{|T_{HP}(j\infty)|} \tag{11.14}$$

and

$$T_{BPn}(s) = \frac{T_{BP}(s)}{|T_{BP}(j\omega_o)|} \tag{11.15}$$

Two other types of second-order transfer function filters that we have not covered here are the bandstop and the all-pass. These transfer functions have the same poles as the previous ones. However, the zeros of the bandstop transfer function are on the $j\omega$ axis while the zeros of the all-pass transfer function are quadratically symmetric to the poles (they are mirror images of the poles in the right-half plane). Both of these transfer functions can be implemented by a second-order biquadratic transfer function whose transfer function is given as

$$T_{BQ}(s) = \frac{K\left[s^2 \pm \left(\frac{\omega_z}{Q_z}\right)s + \omega_z^2\right]}{s^2 + \left(\frac{\omega_p}{Q_p}\right)s + \omega_p^2} \tag{11.16}$$

where

K is a constant
ω_z is the zero frequency
Q_z the zero Q
ω_p is the pole frequency
Q_p the pole Q

11.2.3 Frequency Response (Magnitude and Phase)

The magnitude and phase response of the normalized second-order low-pass transfer function is shown in Figure 11.2, where Q is a parameter. In this figure we see that Q influences the frequency response near ω_o. If Q is greater than 0.707, then the normalized magnitude response has a peak value of

$$|T_n[\omega_n(\max)]| = \frac{Q}{\sqrt{1-(1/4Q^2)}} \tag{11.17}$$

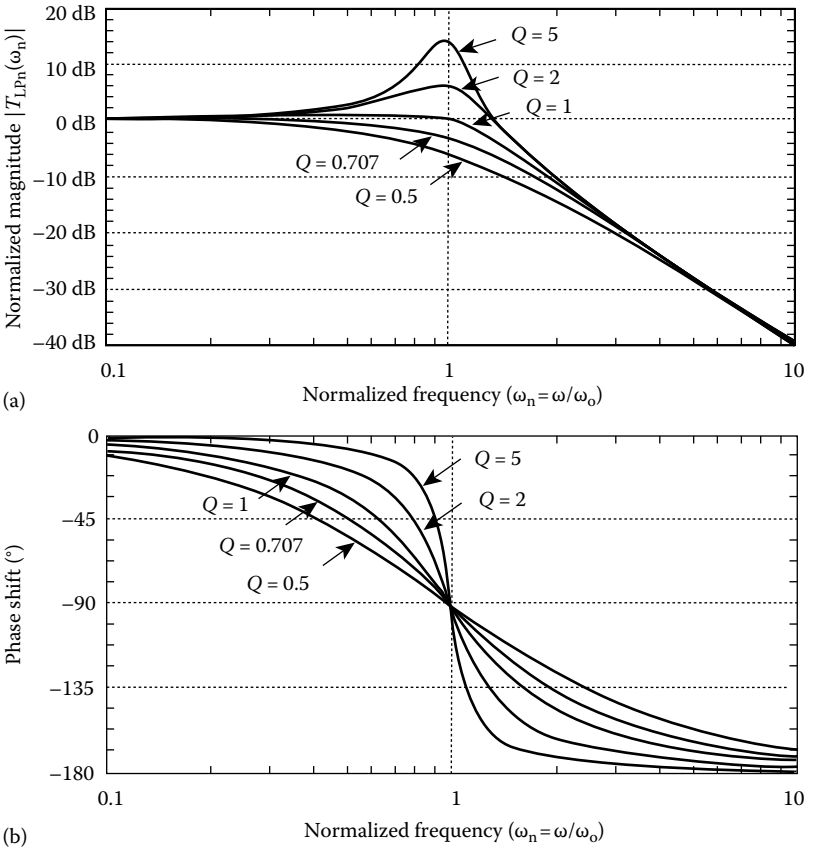

FIGURE 11.2 (a) Normalized magnitude and (b) phase response of the standard second-order low-pass transfer function with Q as a parameter.

at a frequency of

$$\omega_n(\max) = \sqrt{1 - \frac{1}{2Q^2}} \tag{11.18}$$

If the transfer function is multiplied by -1, the phase shift is shifted vertically by $\pm 180°$.

The magnitude and phase response of the normalized second-order high-pass transfer function is shown in Figure 11.3. For Q greater than 0.707 the peak value of the normalized magnitude response is as

$$\omega_n(\max) = \frac{1}{\sqrt{1 - \frac{1}{2Q^2}}} \tag{11.19}$$

The normalized frequency response of the standard second-order bandpass transfer function is shown in Figure 11.4. The slopes of the normalized magnitude curves at frequencies much greater or much less than ω_o are ± 20 dB/decade rather than ± 40 dB/decade of the second-order high and low-pass transfer functions. This difference is because one pole is causing the high-frequency roll-off while the other pole is causing the low-frequency roll-off. The peak of the magnitude occurs at $\omega = \omega_o$ or $\omega_n = 1$.

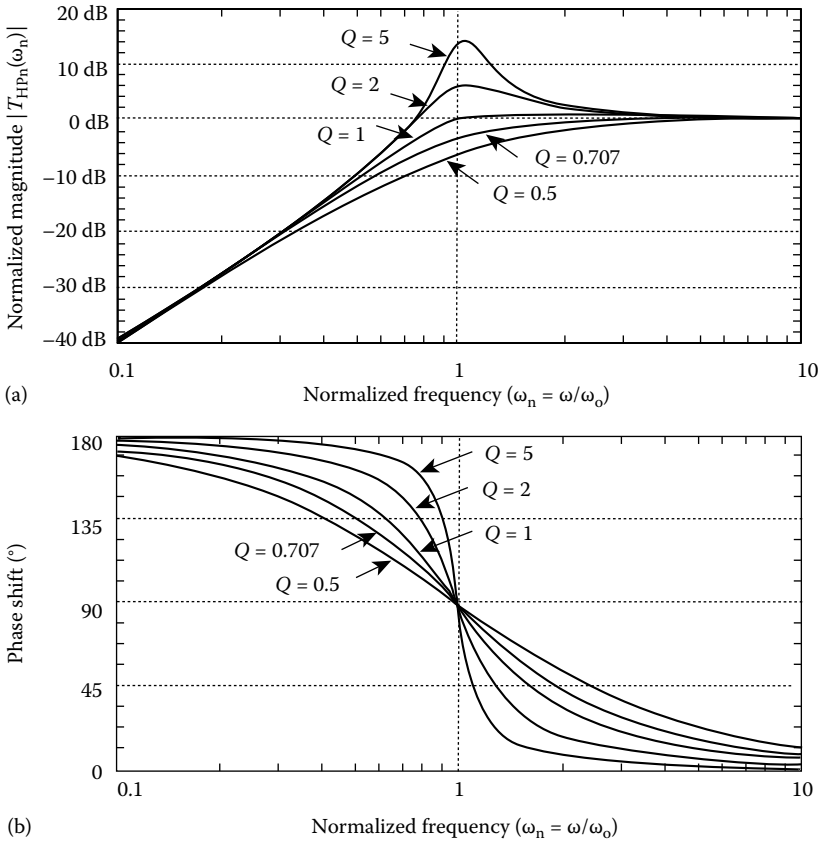

FIGURE 11.3 (a) Normalized magnitude and (b) phase response of the standard second-order high-pass transfer function with Q as a parameter.

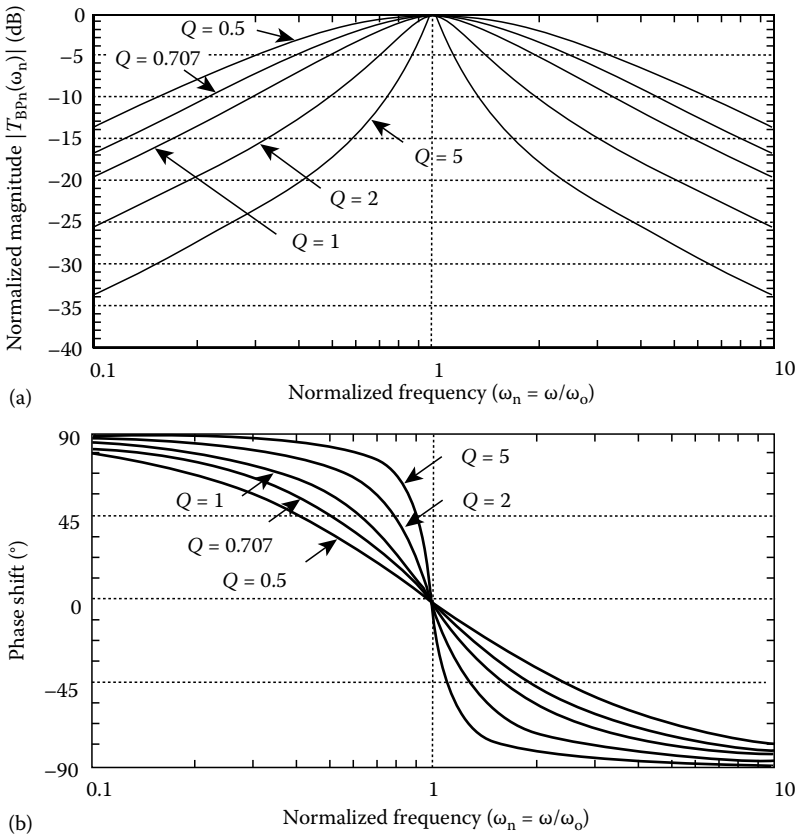

FIGURE 11.4 (a) Normalized magnitude and (b) phase response of the standard second-order bandpass transfer function with Q as a parameter.

11.2.4 Tuning Active Filters

A general tuning procedure for most second-order active filters is outlined below. This method is illustrated for adjusting the magnitude of the frequency response of a low-pass filter. The filter parameters are assumed to be the pole frequency f_o, the pole Q, and the gain $T(j0)$.

1. The component(s) which set(s) the parameter f_o is (are) tuned by adjusting the magnitude of the filter response to be $T(j0)/10$ or $T(j0)$ (dB) -20 dB at $10f_o$.
2. The component(s) that set(s) the parameter $T(j0)$ is (are) tuned by adjusting the magnitude to $T(j0)$ at $f_o/10$.
3. The component(s) that set(s) the parameter Q is (are) tuned by adjusting the magnitude of the peak (if there is one) to the value given by Figure 11.2. If there is no peaking, then adjust so that the magnitude at f_o is correct (i.e., -3 dB for $Q = 0.707$).

The tuning procedure should follow in the order of steps 1 through 3 and may be repeated if necessary. One could also use the phase shift to help in the tuning of the filter. The concept of the above tuning procedure is easily adaptable to other types of second-order filters.

11.3 First-Order Filter Realizations

A first-order filter has only one pole and zero. For stability, the pole must be on the negative real axis but the zero may be on the negative or positive real axis. A single-amplifier low-gain realization of a first-order low-pass filter is shown in Figure 11.5a. The transfer function for this filter is

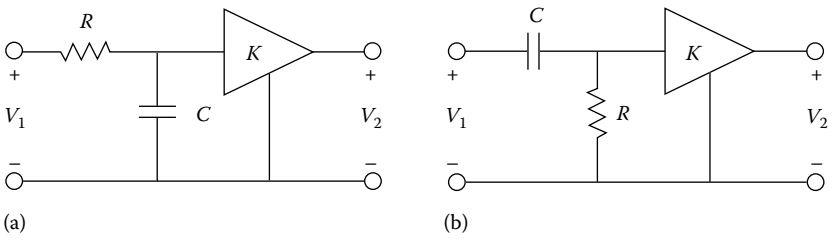

FIGURE 11.5 (a) Low-pass and (b) high-pass first-order filters.

$$T(s) = \frac{V_2(s)}{V_1(s)} = \frac{K/RC}{s + 1/RC} = \frac{K\omega_o}{s + \omega_o} = \frac{T_{LP}(0)\omega_o}{s + \omega_o} \tag{11.20}$$

The low-frequency ($\omega \ll \omega_o$) gain magnitude and polarity are set by K.

First-order high-pass filters can also be realized in a single-amplifier low-gain circuit (see Figure 11.5b). The transfer function for this filter is given in Equation 11.4, and in this case $T_{HP}(j\infty) = K$. Both low-pass and high-pass magnitude responses are shown in Figure 11.1. Note that the first-order filters exhibit no peaking and the frequency-dependent part of the magnitude response approaches ± 20 dB/decade.

11.4 Second-Order Positive-Gain Filters

Practical realizations for second-order filters using positive gain amplifiers are presented here. These filters are easy to design and have been extensively used in many applications. The first realization is a low-pass Sallen and Key filter and is shown in Figure 11.6 [8].

The transfer function of Figure 11.6 is

$$\frac{V_2(s)}{V_1(s)} = \frac{\frac{K}{R_1R_3C_2C_4}}{s^2 + s\left(\frac{1}{R_3C_4} + \frac{1}{R_1C_2} + \frac{1}{R_3C_2} - \frac{K}{R_3C_4}\right) + \frac{1}{R_1R_3C_2C_4}} \tag{11.21}$$

Equating this transfer function with the standard form of a second-order low-pass filter given in Equation 11.6 gives

$$\omega_o = \frac{1}{\sqrt{R_1R_3C_2C_4}} \tag{11.22}$$

$$\frac{1}{Q} = \sqrt{\frac{R_3C_4}{R_1C_2}} + \sqrt{\frac{R_1C_4}{R_3C_2}} + (1 - K)\sqrt{\frac{R_1C_2}{R_3C_4}} \tag{11.23}$$

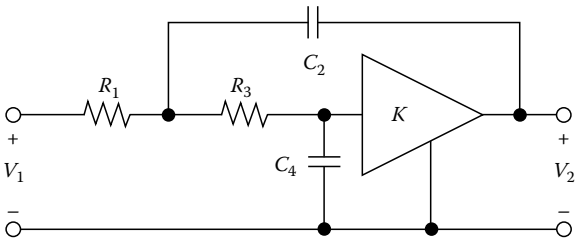

FIGURE 11.6 Low-pass Sallen and Key filter.

and

$$T_{LP}(j0) = K \tag{11.24}$$

These three equations have five unknowns, giving the designer some freedom in selecting component values. Two examples showing different techniques for defining these values of the circuit in Figure 11.6 are given below.

Example 11.1

An equal-resistance equal-capacitance low-pass filter. For this example, $R = R_1 = R_3$ and $C = C_2 = C_4$. A Butterworth low-pass filter characteristic is needed with $\omega_o = 6283$ rad/s (1 kHz) and $Q = 0.7071$. With these constraints,

$$\omega_o = \frac{1}{RC} \quad \frac{1}{Q} = 3 - K \tag{11.25}$$

and $RC = 159$ μs, $T_{LP}(j0) = K = 1.586$. Selecting $C = 0.1$ μF yields $R = 1.59$ kΩ.

Example 11.2

A unity-gain low-pass filter. For this example let $K = 1$. Therefore, Equation 11.23 becomes

$$\frac{1}{Q} = \sqrt{\frac{R_3 C_4}{R_1 C_2}} + \sqrt{\frac{R_1 C_4}{R_3 C_2}} = \sqrt{\frac{C_4}{C_2}}\left(\sqrt{\frac{R_3}{R_1}} + \sqrt{\frac{R_1}{R_3}}\right) \tag{11.26}$$

The desired transfer function, with the complex frequency normalized by a factor of 10^4 rad/s, is

$$\frac{V_2(s)}{V_1(s)} = \frac{0.988}{s^2 + 0.179s + 0.988} = \frac{T_{LP}(j0)\omega_o^2}{s^2 + \frac{\omega_o}{Q}s + \omega_o^2} \tag{11.27}$$

and $\omega_o = 0.994$ rad/s, $Q = 5.553$. To obtain a real-valued resistor ratio, pick

$$\frac{C_4}{C_2} \le \frac{1}{4Q^2} = 0.00811 \tag{11.28}$$

or $C_4/C_2 = 0.001$ in this case. Equation 11.26 yields two solutions for the ratio R_3/R_1, 30.3977 and 0.0329. From Equation 11.22 with $\omega_o = 9.94$ krad/s, $R_1C_2 = 577$ μs. If C_2 is selected as 0.1 μF, then $C_4 = 100$ pF, $R_1 = 5.77$ kΩ, and $R_3 = 175.4$ kΩ.

A Sallen and Key bandpass circuit is shown in Figure 11.7, and its voltage transfer function is

$$\frac{V_2(s)}{V_1(s)} = \frac{\frac{sK}{R_1C_5}}{s^2 + s\left(\frac{1}{R_1C_5} + \frac{1}{R_2C_5} + \frac{1}{R_4C_5} + \frac{1}{R_4C_3} - \frac{K}{R_2C_5}\right) + \frac{1}{R_4C_3C_5}\left(\frac{1}{R_1} + \frac{1}{R_2}\right)} \tag{11.29}$$

Equating this transfer function to that of Equation 11.11 results in

$$\omega_o = \sqrt{\frac{1 + \frac{R_1}{R_2}}{R_1R_4C_3C_5}} \tag{11.30}$$

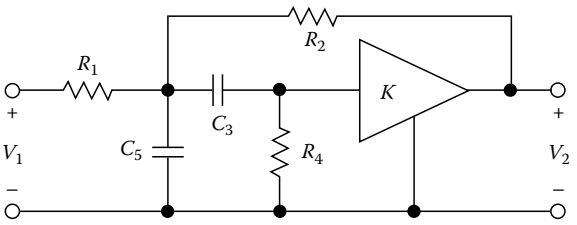

FIGURE 11.7 Bandpass Sallen and Key filter.

$$\frac{1}{Q} = \frac{\left[1 + \frac{R_1}{R_2}(1-K)\right]\sqrt{\frac{R_4 C_3}{R_1 C_5}} + \sqrt{\frac{R_1 C_3}{R_4 C_5}} + \sqrt{\frac{R_1 C_5}{R_4 C_3}}}{\sqrt{1 + \sqrt{\frac{R_1}{R_2}}}} \tag{11.31}$$

and

$$T_{BP}(j0) = \frac{\frac{K}{R_1 C_5}}{\frac{1}{R_1 C_5} + \frac{1}{R_2 C_5} + \frac{1}{R_4 C_5} + \frac{1}{R_4 C_3} + \frac{K}{R_2 C_5}} \tag{11.32}$$

These three equations contain six unknowns. A common constraint is to set $K = 2$, requiring the gain block to have two equal-valued resistors connected around an op-amp.

Example 11.3

An equal-capacitance gain-of-2 bandpass filter. Design a bandpass filter with $\omega_n = 1$ and $Q = 2$. Arbitrarily select $C_3 = C_5 = 1$ F and $K = 2$. If R_1 is selected to be 1 Ω, then Equations 11.11, 11.29, and 11.30 give

$$\omega_o^2 = \left(1 + \frac{R_1}{R_2}\right)\frac{1}{R_4} = 1 \tag{11.33}$$

and

$$\frac{\omega_o}{Q} = 1 - \frac{1}{R_2} + \frac{2}{R_4} = \frac{1}{2} \tag{11.34}$$

Solving these equations gives $R_2 = 0.7403$ Ω and $R_4 = 2.3508$ Ω. Practical values are achieved after frequency and impedance denormalizations are made.

The high-pass filter, the third type of filter to be discussed, is shown in Figure 11.8. Its transfer function is

$$\frac{V_2(s)}{V_1(s)} = \frac{s^2 K}{s^2 + s\left(\frac{1}{R_2 C_1} + \frac{1}{R_4 C_3} + \frac{1}{R_4 C_1} - \frac{K}{R_2 C_1}\right) + \frac{1}{R_2 R_4 C_1 C_3}} \tag{11.35}$$

Equating Equation 11.35 to Equation 11.10 results in

$$\omega_o = \frac{1}{\sqrt{R_2 R_4 C_1 C_3}} \tag{11.36}$$

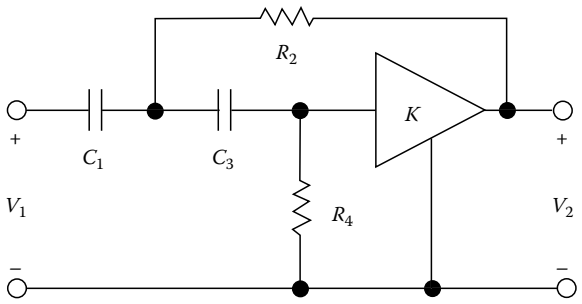

FIGURE 11.8 High-pass Sallen and Key filter.

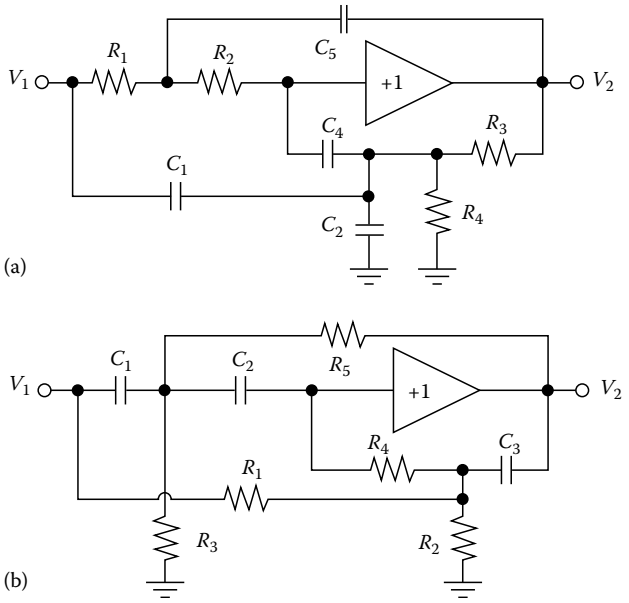

FIGURE 11.9 Notch filters derived from center-loaded twin-*T* networks: (a) $\omega_z \leq \omega_p$ and (b) $\omega_z < \omega_p$. (From Sedra, A. S. and Brackett, P. O., *Filter Theory and Design: Active and Passive*, Matrix, Portland, OR, 1978. With permission.)

$$\frac{1}{Q} = \sqrt{\frac{R_4 C_3}{R_2 C_1}} + \sqrt{\frac{R_2 C_1}{R_4 C_3}} + \sqrt{\frac{R_2 C_3}{R_4 C_1}} - K\sqrt{\frac{R_4 C_3}{R_2 C_1}} \tag{11.37}$$

and

$$T_{HP}(j\infty) = K \tag{11.38}$$

The design procedure using these equations is similar to that for the low-pass and bandpass filters.

The last type of second-order filter in this section is the notch filter, shown in Figure 11.9. The general transfer function for the notch filter is

$$\frac{V_2(s)}{V_1(s)} = T_N(j0)\frac{s^2 + \omega_z^2}{s^2 + \frac{\omega_p}{Q_p}s + \omega_p^2} \tag{11.39}$$

where

ω_p and ω_z are the pole and zero frequencies (ω_o), respectively
Q_p is the pole Q

For the circuit of Figure 11.9a,

$$T_N(j0) = \frac{\omega_z^2}{\omega_p^2}, \quad R_2C_4 = \frac{\sqrt{1+a}}{\omega_p} \tag{11.40}$$

and

$$R_2 = (1+a)R_1 = 2R_3 = aR_4, \quad C_4 = \frac{\omega_z^2}{\omega_p^2}C_1 = C_2 + C_1 = \frac{C_5}{2} \tag{11.41}$$

For the circuit of Figure 11.9b.

$$T_N(j0) = 1, \quad R_2C_4 = \frac{\sqrt{1+a}}{\omega_p} \tag{11.42}$$

and

$$R_4 = (1+a)\frac{\omega_z^2}{\omega_p^2}R_1 = (1+a)(R_1+R_2) = aR_3 = 2R_5, \quad C_1 = C_2 = \frac{C_3}{2} \tag{11.43}$$

The Q for both notch circuits is

$$Q = \frac{\sqrt{1+a}}{a} \tag{11.44}$$

so a is a helpful design parameter for these circuits. For typical values of Q, say 0.5, 1, and 5, the corresponding values of a are 4.828, 1.618, and 0.2210, respectively.

11.5 Second-Order Biquadratic Filters

Next, second-order biquadratic functions will be described. These functions are general realizations of the second-order transfer function. Filters implementing biquadratic functions, often referred to as biquads, are found in many signal processing applications.

11.5.1 Biquadratic Transfer Function

The general form of the second-order biquadratic transfer function is

$$T(s) = H\frac{s^2 + b_1 s + b_0}{s^2 + a_1 s + a_0} = H\frac{s^2 + \frac{\omega_z}{Q_z}s + \omega_z^2}{s^2 + \frac{\omega_p}{Q_p}s + \omega_p^2} \tag{11.45}$$

with the pole locations given by Equation 11.8 and the zero locations by

$$z_1, z_2 = -\frac{\omega_z}{2Q_z} \pm j\omega_z\sqrt{1 - \frac{1}{4Q_z^2}} \tag{11.46}$$

where Q_p and Q_z are the pole and zero Q, respectively. Filters capable of implementing this voltage transfer function are called biquads since both the numerator and denominator of their transfer functions contain biquadratic expressions. The zeros described by the numerator of Equation 11.45 strongly influence the magnitude response of the biquadratic transfer function and determine the filter type (low-pass, high-pass, etc.).

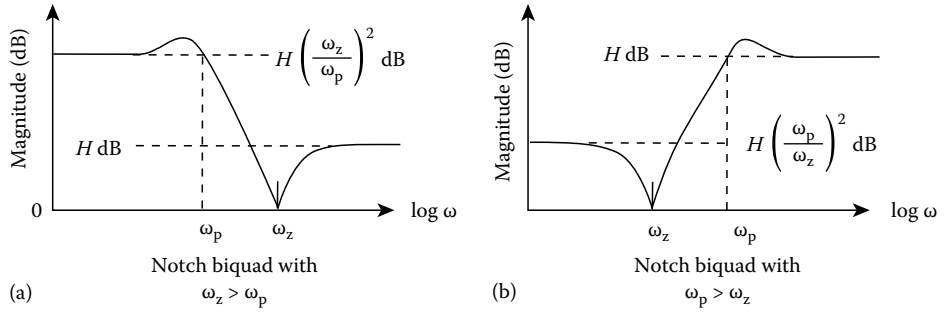

FIGURE 11.10 Frequency response of second-order notch filters. (a) $\omega_z > \omega_p$ and (b) $\omega_p > \omega_z$.

The notch filter form of the biquadratic transfer function is

$$T_{NF}(s) = H\frac{s^2 + \omega_z^2}{s^2 + \frac{\omega_p}{Q_p}s + \omega_p^2} \tag{11.47}$$

with zeros located at $s = \pm j\omega_z$. Attenuation of high or low frequencies is determined by selection of ω_z relative to ω_p. The low-pass notch filter (LPN) requires $\omega_z > \omega_p$, shown in Figure 11.10a and the high-pass notch filter (HPN) requires $\omega_p > \omega_z$, shown in Figure 11.10b.

An all-pass filter implemented using the biquadratic transfer function has the general form

$$T_{AP}(s) = H\frac{s^2 - \frac{\omega_z}{Q_z}s + \omega_z^2}{s^2 + \frac{\omega_p}{Q_p}s + \omega_p^2} \tag{11.48}$$

The all-pass magnitude response is independent of frequency; i.e., its magnitude is constant. The all-pass filter finds use in shaping the phase response of a system. To accomplish this, the all-pass has right-half plane zeros that are mirror images around the imaginary axis of left-half plane poles.

11.5.2 Biquad Implementations

A single-amplifier low-gain realization [4] of the biquadratic transfer function with transmission zeros on the $j\omega$ axis is shown in Figure 11.11. Zeros are generated by the circuit's input "twin-*T*" *RC* network. This filter is well suited for implementing elliptic functions. Its transfer function has the form

$$T(s) = H\frac{s^2 + \omega_z^2}{s^2 + \frac{\omega_p}{Q_p}s + \omega_p^2} = H\frac{s^2 + b_o^2}{s^2 + a_1 s + a_o^2} \tag{11.49}$$

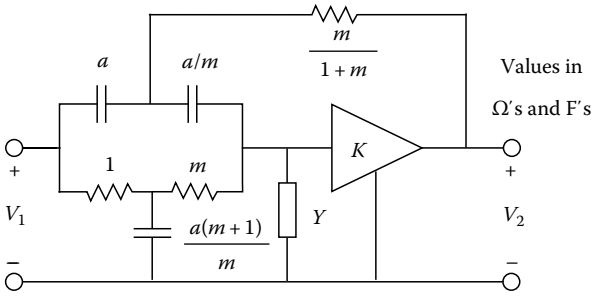

FIGURE 11.11 Low-gain realization for biquadratic network functions. (From Huelsman, L. P. and Allen, P. E., *Introduction to the Theory and Design of Active Filters*, McGraw-Hill, New York, 1980. With permission.)

The selection of element $Y(s)$ in the filter circuit can be a resistor or capacitor. If the condition $\omega_p > \omega_z$ is desired, $Y = 1/R$ is chosen. For this choice the resulting transfer function has the form

$$T(s) = \frac{V_2(s)}{V_1(s)} = \frac{K(s^2 + 1/a^2)}{s^2 + (m+1/a)[1/R + (2-K)/m]s + [1 + (m+1)/R]/a^2} \tag{11.50}$$

where, K, m, and a are defined in Figure 11.11. The design parameter m is used to control the spread of circuit element values. The design equations for this filter resulting from equating Equation 11.49 and 11.50 are

$$a = \frac{1}{\sqrt{b_o}} \tag{11.51}$$

$$R = \frac{m+1}{a_o/b_o - 1} \tag{11.52}$$

$$K = 2 + \frac{m}{m+1}\left(\frac{a_o}{b_o} - 1 - \frac{a_1}{\sqrt{b_o}}\right) \tag{11.53}$$

and

$$H = K \tag{11.54}$$

If the condition $\omega_z > \omega_p$ is desired, then $Y = s(aC)$ is chosen. This choice has the following transfer function:

$$\frac{V_2(s)}{V_1(s)} = \frac{\dfrac{K(s^2 + 1/a^2)}{(m+1)C + 1}}{s^2 + \left\{\dfrac{(m+1)[C + (2-K)/m]}{a[(m+1)C + 1]}\right\}s + \dfrac{1}{a^2[(m+1)C + 1]}} \tag{11.55}$$

The design equations follow from equating Equations 11.49 and 11.55 to get

$$a = \frac{1}{\sqrt{b_o}} \tag{11.56}$$

$$C = \frac{b_o/a_o - 1}{m+1} \tag{11.57}$$

$$K = 2 + \frac{m}{m+1}\left(\frac{b_o}{a_o} - 1 - \frac{a_1\sqrt{b_o}}{a_o}\right) \tag{11.58}$$

and

$$H = \frac{a_o}{b_o}K \tag{11.59}$$

As before, the factor m is chosen arbitrarily to control the spread of element values.

Example 11.4

A low-pass elliptic filter. It is desired to realize the elliptic voltage transfer function given as

$$\frac{V_2(s)}{V_1(s)} = \frac{H(s^2 + 2.235990)}{s^2 + 0.641131s + 1.235820}$$

This transfer function will have a 1 dB ripple in the passband, and at least 6 dB of attenuation for all frequencies greater than 1.2 rad/s [12]. Obviously, the second choice described above applies. From Equations 11.56 through 11.59, with $m = 0.2$, we find that $a = 0.66875$, $C = 0.67443$, $K = 2.0056$, and $H = 1.1085$.

Biquadratic transfer functions can also be implemented using the two-amplifier low-gain configuration in Figure 11.12 [5]. When zeros located off the $j\omega$ axis are desired, the design equations for the two-amplifier low-gain configuration are simpler than those required by the single-amplifier low-gain configuration. Also note that the required gain blocks of -1 and $+2$ are readily implemented using operational amplifiers. The transfer function for this configuration is

$$\frac{V_2(s)}{V_1(s)} = \frac{2(Y_1 - Y_2)}{Y_3 - Y_4} \tag{11.60}$$

The values of the admittances are determined by separately dividing the numerator and denominator by $s + c$, where c is a convenient value greater than zero. Partial fraction expansion results in expressions that can be implemented using *RC* networks. From the partial fraction expansion of the numerator divided by $s + c$, the pole residue at $s = -c$ is

$$k_b = \frac{H(c^2 - cb_1 + b_o)}{-c} \tag{11.61}$$

Depending on c, b_1, and b_o, the quality k_b can be positive or negative. If positive, Y_1 is

$$Y_1 = \frac{Hs}{2} + \frac{Hb_o}{2c} + \frac{1}{2/k_b + 2c/k_b s} \tag{11.62}$$

with $Y_2 = 0$, removing the inverting gain amplifier from the circuit. The *RC* network used to realize Y_1 when k_b is positive is shown in Figure 11.13a. If k_b is negative, Y_1 and Y_2 become

$$Y_1 = \frac{Hs}{2} + \frac{Hb_o}{2c} \quad \text{and} \quad Y_2 = \frac{1}{2/|k_b| + 2c/|k_b|s} \tag{11.63}$$

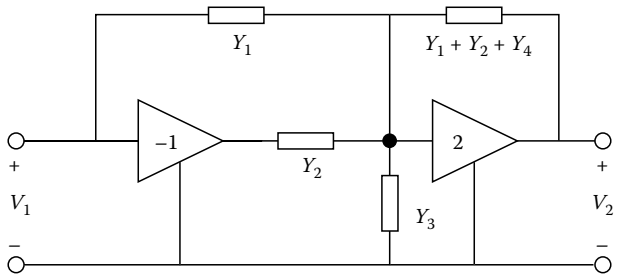

FIGURE 11.12 Two-amplifier low-gain biquad configuration.

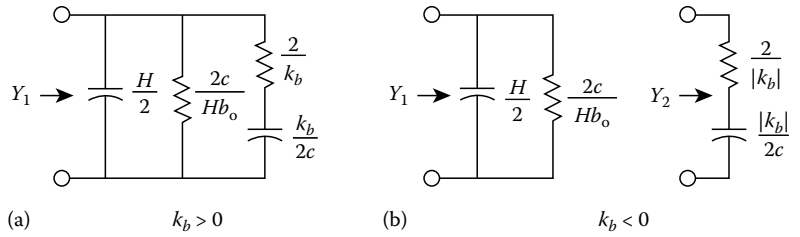

FIGURE 11.13 Realizations for (a) $Y_1(s)$ and (b) $Y_2(s)$ in Figure 11.12.

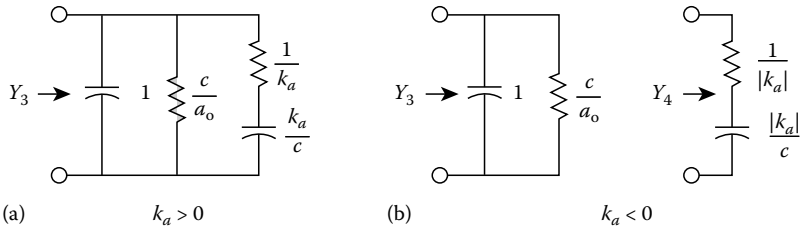

FIGURE 11.14 Realizations for (a) $Y_3(s)$ and (b) $Y_4(s)$ in Figure 11.12.

Realizations for Y_1 and Y_2 for this case are shown in Figure 11.13b. In determining Y_3 and Y_4, the partial fraction expansion of the denominator divided by $s+c$ yields a pole residue at $s=-c$,

$$k_a = \frac{c_2 - ca_1 + a_o}{-c} \tag{11.64}$$

If k_a is positive, then $Y_4 = 0$ and Y_3 is

$$Y_3 = s + \frac{a_o}{c} + \frac{1}{1/k_a + c/k_a s} \tag{11.65}$$

The realization of Y_3 is shown in Figure 11.14a. For a negative k_a, Y_3 and Y_4 become

$$Y_3 = s + \frac{a_o}{c} \tag{11.66}$$

and

$$Y_4 = \frac{1}{1/|k_a| + c/|k_a|s} \tag{11.67}$$

RC network realizations for Y_3 and Y_4 are shown in Figure 11.14b.

Example 11.5

An all-pass function [5]. It is desired to use the configuration of Figure 11.12 to realize the following all-pass function:

$$\frac{V_2(s)}{V_1(s)} = \frac{s^2 - 4s + 4}{s^2 + 4s + 4}$$

The choice of $c = +2$ will simplify the network. For this choice the numerator partial-fraction expansion is

$$\frac{s^2 = 4s + 4}{s + 2} = s + 2 - \frac{8s}{s + 2}$$

Hence $Y_1(s) = (s + 2)/2$ and $Y_2(s) = 4s/(s + 2)$. The denominator partial-fraction expansion is

$$\frac{s^2 + 4s + 4}{s + 2} = s + 2$$

Thus, $Y_3(s) = (s + 2) + [4s/(s + 2)]$ and $Y_4(s) = 0$.

11.6 Higher Order Filters

Many applications require filters of order greater than two. One way to realize these filters is simply to cascade second-order filters to implement the higher order filter. If the order is odd, then one first-order (or third-order) section will be required. The advantage of the cascade approach is that it builds on the precious techniques described in this section. The desired high-order transfer function of the filter $T(s)$ will be broken into second-order functions $T_k(s)$ so that

$$T(s) = T_1(s)T_2(s)T_3(s)\cdots T_{n/2}(s) \tag{11.68}$$

Since the output impedance of the second-order sections is low, the sections can be cascaded without significant interaction.

If $T(s)$ is an odd-order function then a first-order passive network (like those shown in Figure 11.15) can be added to the cascade of second-order functions. Both of the sections shown have nonzero output impedances, so it is advisable to use them only in the last stage of a cascade filter. Alternatively, Figure 11.5 could be used.

Several considerations should be taken into account when cascading second-order sections together. Dynamic range is one of these considerations. To maximize the dynamic range of the filter, the peak gain of each of the individual transfer functions should be equal to the maximum gain of the overall transfer function [10].

To maximize the signal-to-noise of the cascade filter, the magnitude curve in the passband of each of the individual transfer functions should be flat when possible. Otherwise, signals with frequencies in a minimum gain region of an individual transfer function will have a lower signal-to-noise ratio than other signals [10]. Another consideration is minimum noise which is achieved by placing high gain stages first.

Designing a higher order filter as a cascade of second-order sections allows the designer many options. For instance, a fourth-order bandpass filter could result from the cascade of two second-order bandpass sections or one second-order low-pass and a second-order high-pass. Since the bandpass section is the easiest of the three types to tune [10] it might be selected instead of the low-pass–high-pass combination.

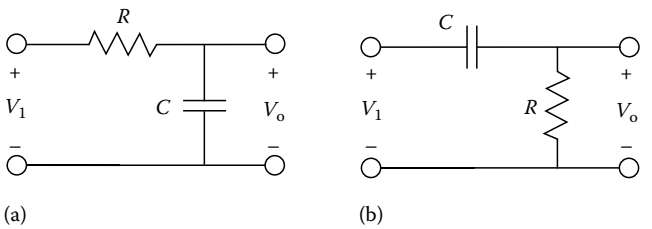

FIGURE 11.15 First-order filter sections: (a) low-pass and (b) high-pass.

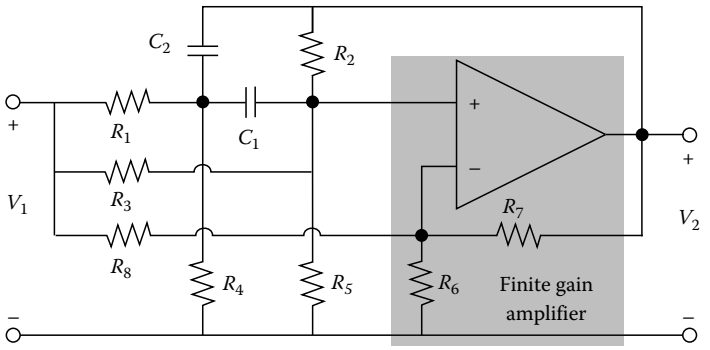

FIGURE 11.16 Biquad multiloop feedback stage.

Other guidelines for the cascade of second-order sections include putting the low-pass or bandpass sections at the input of the cascade in order to decrease the high-frequency content of the signal, which could avoid slewing in following sections. Using a bandpass or high-pass section at the output of the cascade can reduce dc offsets or low-frequency ripple.

One option that is now available is to use CAD tools in the design of filters. When high-order filters are needed, CAD tools can save the designer time. The examples that are worked later in this section require the use of filter tables interspersed with calculations. A CAD tool such as MicroSim Filter Designer [6] can hasten this process since it eliminates the need to refer to tables. The designer can also compare filters of different orders and different approximation methods (Butterworth, Chebyshev, etc.) to determine which one is the most practical for a specific application. The Filter Designer is able to design using the cascade method as discussed in this section, and after proposing a circuit it can generate a netlist so that a program such as SPICE can simulate the filter along with additional circuitry, if necessary.

The Filter Designer allows the user to specify a filter with either a passband/stopband description, center frequency/bandwidth description, or a combination of filter order and type (low-pass, high-pass, etc.). Then an approximation type is chosen, with Butterworth, Chebyshev, inverse Chebyshev, Bessel, and elliptic types available. A Bode plot, pole-zero plot, step or impulse response plot of the transfer function can be inspected. The designer can then select a specific circuit that will be used to realize the filter. The Sallen and Key low-pass and high-pass stages and the biquad multiloop feedback (Figure 11.16) stages are included. The *s*-coefficients of the filter can also be displayed.

The Filter Designer allows modifications to the specifications, *s*-coefficients, or actual components of the circuit in order to examine their effect on the transfer function. There is also a rounding function that will round components to 1%, 5%, or 10% values for resistors and 5% for capacitors and then recompute the transfer function based on these new component values. Finally, the package offers a resize function that will rescale components without changing the transfer function.

Example 11.6

A fifth-order low-pass filter. Design a low-pass filter using the Chebyshev approximation with a 1 dB equiripple passband, a 500 Hz passband, 45 dB attenuation at 1 kHz, and a gain of 10. Using a nomograph for Chebyshev magnitude functions, the order of this function is found to be five [5]. Using this information and a chart of quadratic factors of 1.0 dB equal-ripple magnitude low-pass functions, the transfer function is found to be

$$T(s_n) = \frac{0.9883K_1}{s_n^2 + 0.1789s_n + 0.9883} \cdot \frac{0.4293K_2}{s_n^2 + 0.4684s_n + 0.4293} \cdot \frac{0.2895K_3}{s_n + 0.2895}$$

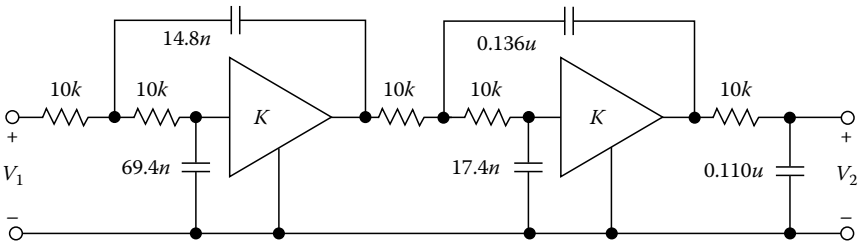

FIGURE 11.17 Fifth-order low-pass filter.

Denormalizing the frequency with $s_n = s/500(2\pi)$ gives

$$T_1(s) = \frac{9,751,000K_1}{(s^2 + 562s + 9,751,000)}$$
$$T_2(s) = \frac{4,240,000K_2}{(s^2 + 1470s + 4,240,000)}$$

and

$$T_3(s) = \frac{909K_3}{s + 909}$$

Stages 1 and 2 will be Sallen and Key low-pass filters with $R = 10$ kΩ. Following the guidelines given above, stage 1 will have the gain of 10 and successive stages will have unity gain. Using Equation 11.23 for stage 1 ($R_2 = R_4 = R$),

$$\frac{1}{Q} = 2\sqrt{\frac{C_4}{C_2}} + (1 - K)\sqrt{\frac{C_2}{C_4}} = 0.1800$$

So $C_4 = 4.696C_2$. Substituting this into Equation 11.22,

$$\omega_n = \frac{1}{2.167RC_2} = 3123\,\text{rad/s}$$

Thus, $C_2 = 14.8$ nF and $C_4 = 69.4$ μF. Analysis for stage 2 with $K_2 = 1$ yields $C_2 = 0.135$ μF and $C_4 = 17.4$ nF. Stage 3 is simply an *RC* low-pass section with $R = 10$ kΩ and $C = 0.110$ μF. The schematic for this filter is shown in Figure 11.17.

Example 11.7

A fourth-order bandpass filter. Design a bandpass filter centered at 4 kHz with a 1 kHz bandwidth. The time delay of the filter should be 0.5 ms (with less than 5% error at the center frequency).

The group of filters with constant time delays are called Thomson filters. For this design, begin with a low-pass filter with the normalized bandwidth of 1/4 kHz, or 0.25. Consulting a table for delay error in Thomson filter [5] shows that a fourth-order filter is needed. From tables for Thomson filters, the quadratic factors for the fourth-order low-pass filter give the overall transfer function

$$T_{LP}(s_n) = \frac{1}{(s_n^2 + 4.208s_n + 11.488)(s_n^2 + 5.792s_n + 9.140)}$$

To convert $T_{LP}(s_n)$ to a bandpass function $T_{BP}(s_n)$, the transformation

$$s_n = \frac{\omega_R}{BW}\frac{s_{bn}^2 + 1}{s_{bn}} = 4\frac{s_{bn}^2 + 1}{s_{bn}}$$

is used, giving

$$T_{BPn}(s) = \frac{s^4/256}{(s^4 + 1.05s^3 + 2.72s^2 + 1.05s + 1)(s^4 + 1.45s^3 + 2.57s^2 + 1.45s + 1)}$$

ω_R and BW are the geometric center frequency and bandwidth of the bandpass filter. The polynomials in the denominator of the expression are difficult to factor, so an alternate method can be used to find the poles of the normalized bandpass function. Each pole p_{In} of the normalized low-pass transfer function generates two poles in the normalized bandpass transfer function [5–10] given by

$$p_{bn} = \frac{BW\ p_{1n}}{2\omega_R} \pm \sqrt{\left(\frac{BW\ p_{1n}}{2\omega_R}\right)^2 - 1} \tag{11.69}$$

Using Equation 11.69 with each of the poles of $T_{LP}(s_n)$ gives the following pairs of poles (which are also given in tables for Thomson filters):

$$p_{b1n} = -0.1777 \pm j0.6919 \quad p_{b2n} = -0.3483 \pm j1.356$$
$$p_{b3n} = -0.3202 \pm j0.8310 \quad p_{b4n} = -0.4038 \pm j1.0478$$

Note that each low-pass pole does not generate a conjugate pair, but when taken together, the bandpass poles generated by the low-pass poles will be conjugates. The unnormalized transfer functions generated by the normalized bandpass poles are

$$T_{BP1}(s) = \frac{6283s}{(s^2 + 8932s + 322.3 \times 10^6)}$$
$$T_{BP2}(s) = \frac{6283s}{(s^2 + 1751s + 1238 \times 10^6)}$$
$$T_{BP3}(s) = \frac{6283s}{(s^2 + 16100s + 501.0 \times 10^6)}$$

and

$$T_{BP4}(s) = \frac{6283s}{(s^2 + 20300s + 796.5 \times 10^6)}$$

The overall transfer function realized by these four intermediate transfer functions could also be grouped into two low-pass stages followed by two high-pass stages, however, this example will use four bandpass filters. Using the equal-capacitance gain of two-design strategy for the Sallen and Key bandpass stage,

$$\omega_n^2 = \left(1 + \frac{R_1}{R_2}\right)\frac{1}{R_1 R_4 C^2} \tag{11.70}$$

$$\frac{1}{Q} = \left[\left(1 - \frac{R_1}{R_2}\right)\sqrt{\frac{R_4}{R_1}} + 2\sqrt{\frac{R_1}{R_4}}\right]\sqrt{\frac{R_2}{R_1 + R_2}} \tag{11.71}$$

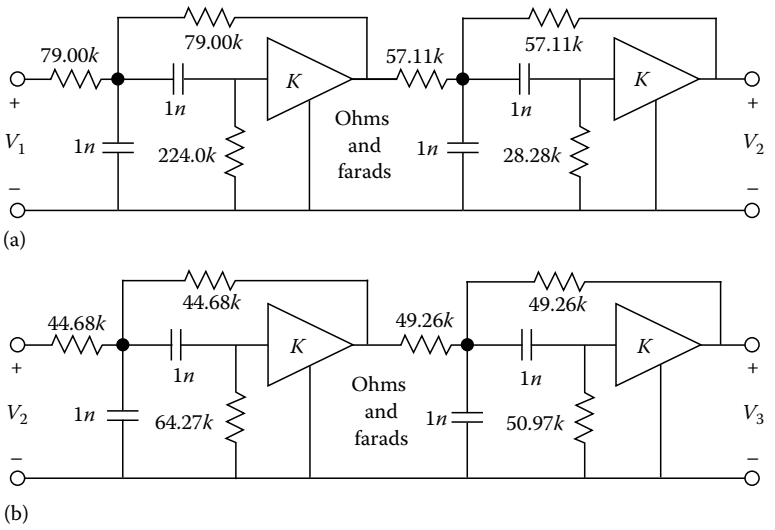

FIGURE 11.18 Fourth-order bandpass filter. (a) Stages 1 and 2 and (b) stages 3 and 4.

and

$$H_o = \left(\frac{\dfrac{K}{R_1}}{\dfrac{1}{R_1} + \dfrac{1}{R_2} + \dfrac{2}{R_4} - \dfrac{K}{R_2}} \right) \tag{11.72}$$

Making the further assignment $R_2 = R_1$ simplifies the equations to

$$\omega_n^2 = \frac{2}{R_1 R_4 C^2}, \quad \frac{1}{Q} = 2\sqrt{\frac{R_1}{R_4}}, \quad \text{and} \quad H_o = 2Q^2$$

Selecting $C = 1$ nF gives the component values shown in Figure 11.18, the schematic diagram for the fourth-order bandpass filter. While the gain of the filter is greater than unity, the output can be attenuated if unity gain is desired.

Example 11.8

A sixth-order high-pass filter. Design a Butterworth high-pass filter with a −3 dB frequency of 100 kHz and a stopband attenuation of 30 dB at 55 kHz. A nomograph for Butterworth (maximally flat) functions indicates that this filter must have an order of at least six. A table for quadratic factors of Butterworth functions [5] gives

$$T(s_n) = \frac{K_1}{\left(s_n^2 + 0.518 s_n + 1\right)} \quad \frac{K_2}{\left(s_n^2 + 1.414 s_n + 1\right)} \quad \frac{K_3}{\left(s_n^2 + 1.932 s_n + 1\right)}$$

Using $s_{nH} = 1/s_n$ for low-pass to high-pass transformation and $s_n = s/2\pi \times 10^5$ to denormalize the frequency,

$$T_1(s) = \frac{s^2 K_1}{s^2 + 325,500 s + 394.8 \times 10^9}$$

$$T_2(s) = \frac{s^2 K_2}{s^2 + 888,600 s + 394.8 \times s10^9}$$

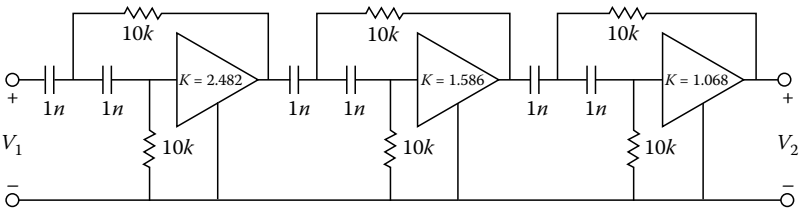

FIGURE 11.19 A sixth-order high-pass filter (all component values are Ω or F).

and

$$T_3(s) = \frac{s^2 K_3}{s^2 + 1,214,000s + 394.8 \times 10^9}$$

The Sallen and Key high-pass filter can be used to implement all three of these stages. Picking a constant R, constant C design style with $\omega_n = 10^5$ rad/s gives $R = 10$ kΩ and $C = 1$ nF for each stage. Equation 11.23 then simplifies to

$$\frac{1}{Q} = 3 - K$$

for each stage. Thus $K_1 = 2.482$, $K_2 = 1.586$, and $K_3 = 1.068$, and the resulting high-pass filter is shown in Figure 11.19.

Example 11.9

A fifth-order low-pass filter. Design a low-pass filter with an elliptic characteristic such that it has a 1 dB ripple in the passband (which is 500 Hz) and 65 dB attenuation at 1 kHz. From a nomograph for elliptic magnitude functions, the required order of this filter is five. A chart for a fifth-order elliptic filter with 1 dB passband ripple gives

$$T(s_n) = \frac{H\left(s_n^2 + 4.365\right)\left(s_n^2 + 10.568\right)}{\left(s_n + 0.3126\right)\left(s_n^2 + 0.4647s_n + 0.4719\right)\left(s_n^2 + 0.1552s_n + 0.9919\right)}$$

This transfer function can be realized with two notch filters like Figure 11.9a and a first-order low-pass section. Denormalizing the frequency with $s_n = s/1000\pi$ gives

$$T_1(s) = \frac{H_1(s^2 + 43,080,000)}{s^2 + 1,460s + 4,657,000}$$

$$T_2(s) = \frac{H_2(s^2 + 104,300,000)}{s^2 + 487.6s + 9,790,000}$$

and

$$T_3(s) = \frac{982.1}{s + 982.1}$$

For the first stage, use Equations 11.40 and 11.44, $H_1 = 0.1081$, and $a = 0.9429$. Setting $C_1 = 1$ nF and applying Equations 11.40 and 11.41,

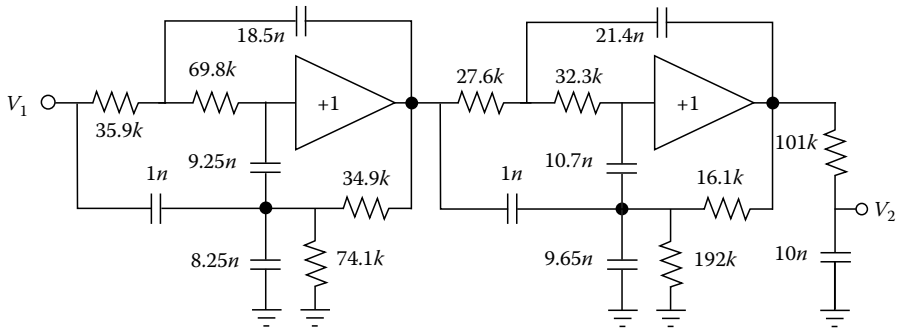

FIGURE 11.20 Fifth-order low-pass filter (all component values are Ω or F).

$$C_1 = 1\,\text{nF}, \quad C_4 = 9.25\,\text{nF}, \quad C_2 = 8.25\,\text{nF}, \quad C_5 = 18.5\,\text{nF}$$
$$R_2 = 69.8\,\text{k}\Omega, \quad R_1 = 35.9\,\text{k}\Omega, \quad R_3 = 34.9\,\text{k}\Omega, \quad R_1 = 74.1\,\text{k}\Omega$$

Similarly, in the second stage $H_2 = 0.0939$, $a = 0.1684$, and

$$C_1 = 1\,\text{nF}, \quad C_4 = 10.7\,\text{nF}, \quad C_2 = 9.65\,\text{nF}, \quad C_5 = 21.4\,\text{nF}$$
$$R_2 = 32.3\,\text{k}\Omega, \quad R_1 = 27.6\,\text{k}\Omega, \quad R_3 = 16.1\,\text{k}\Omega, \quad R_4 = 192\,\text{k}\Omega$$

The third stage can be a simple *RC* low-pass with $C = 10$ nF and $R = 101$ kΩ. The resulting cascade filter is shown in Figure 11.20.

These examples illustrate both the use of the Filter Designer and the method of cascading first- and second-order stages to achieve higher order filters.

11.7 Influence of Nonidealities

Effective filter design requires an understanding of how circuit nonidealities influence performance. Important nonidealities to consider include passive component tolerance (i.e., resistor and capacitor accuracy), amplifier gain accuracy, finite amplifier gain-bandwidth, amplifier slew rate, and noise.

11.7.1 Sensitivity Analysis

Classical sensitivity functions [5] are valuable tools for analyzing the influence of nonidealities on filter performance. The sensitivity function, s_x^Y [2], by definition, describes the change in a performance characteristic of interest, say y, due to the change in nominal value of some element x,

$$S_x^y = \left(\frac{\partial y}{\partial x}\right)\frac{x}{y} = \frac{\partial y/y}{\partial y/x} = \frac{\partial(l_n\, y)}{\partial(l_n\, x)} \tag{11.73}$$

The mathematical properties of the sensitivity function are given in Table 11.1 [5] for convenient reference.

A valuable result of the sensitivity function is that it enables us to estimate the percentage change in a performance characteristic due to variation in passive circuit elements from their nominal values. Consider, for example, a low-pass filter's cutoff frequency ω_o, which is a function of R_1, R_2, C_1, and C_2. Using sensitivity functions, the percentage change in ω_o is estimated as [3]

$$\frac{\Delta\omega_o}{\omega_o} \approx S_{R_1}^{\omega_o}\left(\frac{\Delta R_1}{R_1}\right) + S_{R_2}^{\omega_o}\left(\frac{\Delta R_2}{R_2}\right) + S_{C_1}^{\omega_o}\left(\frac{\Delta C_1}{C_1}\right) + S_{C_2}^{\omega_o}\left(\frac{\Delta C_2}{C_2}\right) \tag{11.74}$$

TABLE 11.1 Properties of Sensitivity Function

$S_x^{ky} = S_{kx}^y = S_x^y$	$S_x^{y_1/y_2} = S_x^{y_1} - S_x^{y_2}$
$S_x^x = S_x^{kx} = S_{kx}^{kx} = 1$	$S_{x_1}^y = S_{x_2}^y S_{x_1}^{y_2}$
$S_{1/x}^y = S_x^{1/y} = -S_x^y$	$S_x^y = S_x^{\lvert y\rvert} + j \arg y S_x^{\arg y}$
$S_x^{y_1 y_2} = S_x^{y_1} + S_x^{y_2}$	$S_x^{\arg y} = \frac{1}{\arg y} \operatorname{Im} S_x^y(\star)$
$S_x^{\prod_{i=1}^n y_i} = \sum_{i=1}^n S_x^{y_i}$	$S_x^{\lvert y\rvert} = \operatorname{Re} S_x^y(\star)$
$S_x^{y^n} = n S_x^y$	$S_x^{y+x} = \frac{1}{y+z}\left(y S_x^y + z S_x^z\right)$
$S_x^{x^n} = S_x^{kx^n} = n$	$S_x^{\sum_{i=1}^n y_i} = \frac{\sum_{i=1}^n y_i S_x^{y_i}}{\sum_{i=1}^n y_i}$
$S_{x^n}^y = \frac{1}{n} S_x^y$	$S_x^{\ln y} = \frac{1}{\ln y} S_x^y$
$S_{x^n}^x = S_{kx^n}^x = \frac{1}{n}$

Note: Relations denoted by "(⋆)" use y to indicate a complex quantity and x to indicate a real quantity.

Not that the quantity $\Delta\omega_o/\omega_o$ represents a small differential change in the cutoff frequency ω_o. When considering the root locus of a filter design, the change in pole location due to a change in gain K, for example, could be described by [3]

$$S_K^{p_1} = \left(\frac{\partial \sigma_o}{\partial K}\right) + j\frac{\partial \omega_o}{\partial K}\left(\frac{K}{\omega_o}\right) \tag{11.75}$$

where the pole $p_1 = \sigma_o + j\omega_o$. Furthermore, the filter transfer function's magnitude and phase sensitivity is defined by [3]

$$S_x^{T(j\omega)} = S_x^{|T(j\omega)|} + S_x^{\theta(j\omega)} = \operatorname{Re} S_x^{T(j\omega)} + \frac{1}{\theta(\omega)} \operatorname{Im} S_x^{T(j\omega)} \tag{11.76}$$

and

$$S_x^{T(j\omega)} = \frac{x}{|T(j\omega)|}\frac{\partial}{\partial x}|T(j\omega)| + jx\frac{\partial \theta(\omega)}{\partial x} \tag{11.77}$$

where $T(j\omega) = |T(j\omega)|\exp[j\theta(\omega)]$. The interested reader is directed to Ref. [5, Chapter 3] for a detailed discussion of sensitivity.

11.7.2 Gain-Bandwidth

Now let us consider some of the amplifier nonidealities that influence the performance of our low-gain amplifier filter realizations. There are two amplifier implementations of interest each using an operational amplifier. They are the noninverting configuration and the inverting configuration shown in Figure 11.21.

The noninverting amplifier is described by

$$K = \frac{V_2}{V_1} = \frac{A_d(s)}{1 + A_d(s)/K_o} \tag{11.78}$$

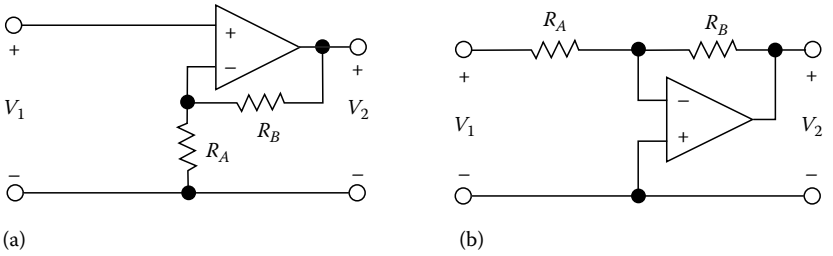

FIGURE 11.21 (a) Noninverting amplifier and (b) inverting amplifier.

where

$K_o = 1 + R_B/R_A$ is the ideal gain

$A_d(s)$ is the operational amplifier's differential gain

Using the dominant-pole model for the op-amp,

$$A_d(s) = \frac{GB}{s + \omega_a} = \frac{A_o \omega_a}{s + \omega_a} \tag{11.79}$$

where

A_o is the dc gain

ω_a is the dominant pole

GB is the gain-bandwidth product of the op-amp

Inserting Equation 11.79 into Equation 11.78 gives

$$K = \frac{GB}{s + \omega_a(1 + A_o/K_o)} \approx \frac{GB}{s + GB/K_o} \tag{11.80}$$

The approximation of the K expression is valid provided $A_o \gg K_o$. The magnitude and phase of Equation 11.80 are

$$|K(j\omega)| = \frac{GB}{\sqrt{\omega^2 + (GB/K_o)^2}} \tag{11.81}$$

and

$$\arg[K(j\omega)] = -\tan^{-1}\left(\frac{\omega}{GB} K_o\right) \tag{11.82}$$

Note that for $\omega > GB/K_o$, Equations 11.81 and 11.82 may be approximated by

$$|K(j\omega)| \approx K_o \tag{11.83}$$

and

$$\arg[K(j\omega)] \approx -\frac{\omega}{GB} K_o \tag{11.84}$$

The phase expression (Equation 11.84) describes the phase lag introduced to an active filter realization by the op-amp's finite gain-bandwidth product. To illustrate the importance of taking this into account, consider a positive-gain filter with $K_o = 3$ and operation frequency $\omega = \text{GB}/30$ [5]. According to Equation 11.84, a phase lag of 5.73° is introduced to the filter by the op-amp. Such phase lag might significantly impair the performance of some filter realizations.

The inverting amplifier of Figure 11.21b is described by

$$K = \frac{V_2}{V_1} = \frac{-A_d(s)[R_B/(R_A + R_B)]}{1 + A_d(s)[R_A/(R_A + R_B)]} \tag{11.85}$$

Inserting Equation 11.79 into Equation 11.85 gives

$$K = \frac{-[R_B/(R_A + R_B)]\text{GB}}{s + \omega_a[1 + A_o R_A/(R_A + R_B)]} \approx \frac{-[R_B/(R_A + R_B)]\text{GB}}{s + \text{GB}[R_A/(R_A + R_B)]} \tag{11.86}$$

where as before the approximation is valid if $A_o \gg (R_A + R_B)/R_A$. The magnitude and phase expressions for Equation 11.86 are

$$|K(j\omega)| = \frac{\text{GB}R_B/(R_A + R_B)}{\sqrt{\omega^2 + [\text{GB}R_A/(R_A + R_B)]^2}} \tag{11.87}$$

and

$$\arg[K(j\omega)] = \pi - \tan^{-1}\left[\frac{\omega}{\text{GB}}\left(1 + \frac{R_B}{R_A}\right)\right] \tag{11.88}$$

If $\omega < \text{GB}\ R_A/(R_A + R_B)$, then Equations 11.87 and 11.88 are approximated by

$$|K(j\omega)| \approx \frac{R_B}{R_A} \tag{11.89}$$

and

$$\arg[K(j\omega)] \approx \pi - \left[\frac{\omega}{\text{GB}}\left(1 + \frac{R_B}{R_A}\right)\right] \tag{11.90}$$

An important limitation of the inverting configuration is its bandwidth [5], compared to that of the noninverting configuration, when small values of gain K are desired. Take, for example, the case where a unity-gain amplifier is needed. Using the amplifier of Figure 11.21a, the resistor values would be $R_B = 0$ and $R_A = \infty$. From Equation 11.80 we see that this places a pole at $s = -\text{GB}$. Using the amplifier of Figure 11.21b, the resistors would be selected such that $R_B = R_A$. From Equation 11.86 we see that a pole located at $s = -\text{GB}/2$ results. Hence, for unity-gain realizations, the inverting configuration has half the bandwidth of the noninverting case. However, for higher gains, as the ratio R_B/R_A becomes large, both configurations yield a pole location that approaches $s = -(\text{GB})R_A/R_B$.

When using the inverting configuration described above to implement a negative-gain realization, the input impedance to the amplifier is approximately R_A. R_A must then be carefully selected to avoid loading the *RC* network. Another problem is related to maintaining low phase lag when a high Q is desired [5]. A Q of 10 requires that the ratio R_B/R_A be approximately 900. However, to avoid a phase lag of 6°, Equation 11.90 indicates that for $Q = 10$ the maximum filter design frequency cannot exceed

approximately GB/8500. If GB = 1 MHz, say if the 741 op-amp is being used, then the filter cannot function properly above a frequency of about 100 Hz.

We have seen that a practical amplifier implementation contributes a pole to the gain K of a filter due to the op-amp's finite gain-bandwidth product GB. This means that an active filter's transfer function will have an additional pole that is attributed to the amplifier. The poles then of an active filter will be influenced by this additional pole. Consider the positive-gain amplifier used in the Sallen–Key low-pass filter (Figure 11.6). The filter's ideal transfer function is expressed in Equation 11.21. For the equal R, equal C case ($R_1 = R_3$, $C_2 = C_4$) we have $R_B = R_A[2 - (1/Q)]$. By inserting Equation 11.80 into Equation 11.21, the transfer function becomes [3]

$$T(s_n) = \frac{V_2}{V_1} = \frac{\mathrm{GB_n}}{s_\mathrm{n}^3 + s_\mathrm{n}^2\left(3 + \frac{\mathrm{GB_n}}{1-\frac{1}{Q}}\right) + s_\mathrm{n}\left(1 + \frac{\mathrm{GB_n}}{3Q-1}\right) + \frac{\mathrm{GB_n}}{3-\frac{1}{Q}}} \tag{11.91}$$

where the normalized terms are defined by $s_\mathrm{n} = s/\omega_\mathrm{o}$ and $\mathrm{GB_n}/\omega_\mathrm{o}$. The manner in which the poles of Equation 11.91 are influenced by the amplifier's finite gain-bandwidth product is illustrated in Figure 11.22a. This plot is the upper left-half s_n plane. The solid lines correspond to constant values of Q and the circles correspond to discrete values of $\mathrm{GB_n}$, which were the same for each Q. For $Q = 0.5$ the $\mathrm{GB_n}$ values are labeled. Note that the $\mathrm{GB_n} = \infty$ case shown is the ideal case where amplifier GB is infinite. The poles shift toward the origin as ω_o approaches a value near GB. Furthermore, for large design values of Q, i.e., greater than 3, the actual Q value will decrease as ω_o approaches GB.

As another example, consider the Sallen–Key low-pass again but for the case where positive unity-gain and equal resistance ($R_1 = R_3$) are desired. When the amplifier's gain-bandwidth product is taken into account, the filter's transfer function becomes [3]

$$T(s) = \frac{V_2}{V_1} = \frac{\mathrm{GB_n}}{s_\mathrm{n}^3 + s_\mathrm{n}^2\left(2Q + \frac{1}{Q} + \mathrm{GB_n}\right) + s_\mathrm{n}\left(1 + \frac{\mathrm{GB_n}}{Q}\right) + \mathrm{GB_n}} \tag{11.92}$$

where again $s_\mathrm{n} = s/\omega_\mathrm{o}$ and $\mathrm{GB_n} = \mathrm{GB}/\omega_\mathrm{o}$. The poles of Equation 11.92 are shown in Figure 11.22b. The plots are similar but the Figure 11.22b) plot constant $\mathrm{GB_n}$ values for the range of Q shown are closer

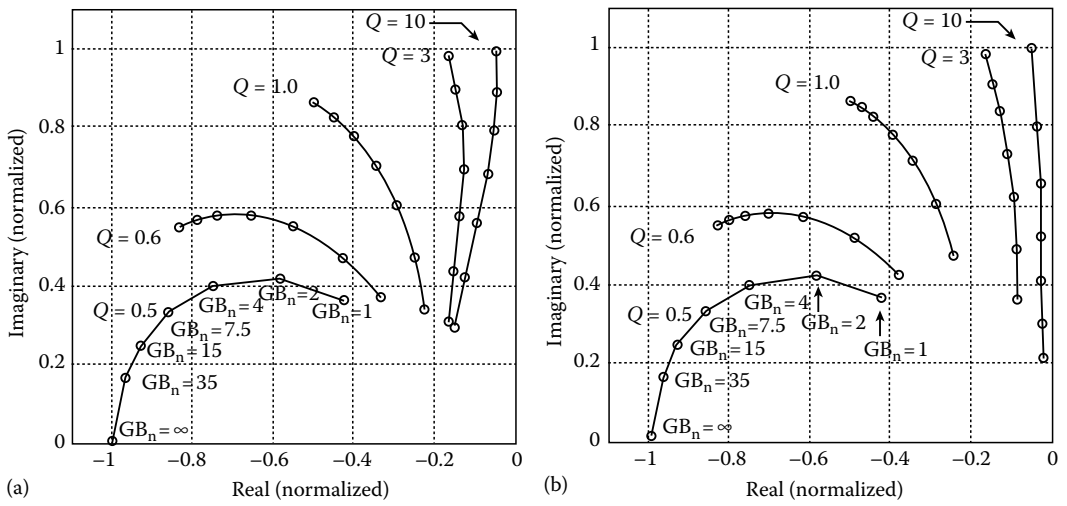

FIGURE 11.22 Effect of GB on the poles of the Sallen–Key second-order low-pass case. (a) Equal R, equal C case and (b) unity gain, equal R case.

TABLE 11.2 Summary of Finite GB on Filter Parameters

Sallen–Key Low-Pass Realizations	
Equal R, equal C	$\omega_0(\text{actual}) \approx \omega_o(\text{design})\left[1-\frac{1}{2}\left(3-\frac{1}{Q}\right)^2\frac{\omega_o}{GB}\right]$
	$Q(\text{actual}) \approx Q(\text{design})\left[1-\frac{1}{2}\left(3-\frac{1}{Q}\right)^2\frac{\omega_o}{GB}\right]$
	$GB \geq 45\left(1-\frac{1}{3Q}\right)^2\omega_0^*$
Unity-gain, equal R	$\omega_0(\text{actual}) \approx \omega_o(\text{design})\left(1-\frac{\omega_o Q}{GB}\right)$
	$Q(\text{actual}) \approx Q(\text{design})\left(1+\frac{\omega_o Q}{GB}\right)$
	$GB \geq 10\omega_0^*$

"*" denotes the condition for $\Delta\omega_o/\omega_o = \Delta Q/Q \leq 10\%$, i.e., for ω_o and Q to change less than 10% [3].

together than the Figure 11.22a plot. This means that the poles of the unity-gain, equal R design are less sensitive to amplifier gain-bandwidth product than the equal R, equal C case. The influence GB has on Sallen–Key low-pass filter parameters is summarized in Table 11.2.

11.7.3 Slew Rate

Slew rate is another operational amplifier parameter that warrants consideration in active filter design. When a filter signal level is large and/or the frequency is high, op-amp slew rate (SR) limitations can affect the small-signal behavior of amplifiers used in low-gain filter realizations. The amplifier's amplitude and phase response can be distorted by large-signal amplitudes. An analysis of slew rate induced distortion is presented in Ref. [1]. For the inverting amplifier (Figure 11.21b), slewing increases the small-signal phase lag. This distortion is described by Ref. [5]

$$\arg[K(j\omega)] = \pi - \tan^{-1}\left(\frac{(\omega/\text{GB}(1+R_B/R_A))}{N(A)}\right) \tag{11.93}$$

where

$N(A)$ is a describing function

A is the peak amplitude of the sinusoidal voltage input to the amplifier

$N(A) = 1$ while the op-amp is not slewing, yielding the same phase lag described by Equation 11.88. However, for conditions where slewing is present, $N(A)$ becomes less than 1. Under such conditions the filter may become unstable. Refer to Ref. [1] and Ref. [5, Chapter 4, Section 6] for a detailed discussion of slew rate distortion.

Selecting an operational amplifier with higher slew rate can reduce large-signal distortion. Given the choice of FET input or BJT input op-amps, FET input op-amps tend to have higher slew rates and higher input signal thresholds before slewing occurs. When selecting an amplifier for a filter it is important to remember that slewing occurs when the magnitude of the output signal slope exceeds SR and when the input level exceeds a given voltage threshold. Often the slew rate of a filter's amplifier sets the final limit of performance that can be attained in a given active filter realization at high frequencies.

11.7.4 Noise

The noise performance of a given filter design will ultimately determine the circuit's signal-to-noise ratio and dynamic range [7]. For these reasons, a strong understanding of noise analysis is required for effective filter design. In this section noise analysis of the noninverting and inverting op-amp

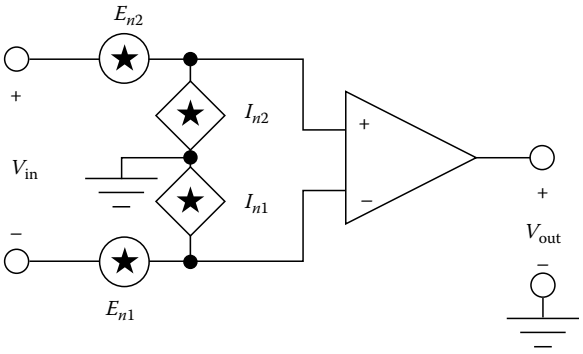

FIGURE 11.23 Operational amplifier noise model with four noise sources.

configurations are discussed for the implementation of the gain block *K*. An example noise analysis is illustrated for a simple filter design.

Proceeding with noise analysis, consider the four noise sources associated with operational amplifier. Shown in Figure 11.23, E_{n1} and E_{n2} represent the op-amp's voltage noise referred to the negative and positive inputs, respectively, and I_{n1} and I_{n2} represent the op-amp's current noise referred to the negative and positive inputs, respectively. E_{n1} and E_{n2} are related to E_n, from an op-amp manufacture's data sheet, through the relationship

$$E_n = \sqrt{E_{n1}^2 + E_{n2}^2} \left[\text{V}/\sqrt{\text{Hz}}\right] \tag{11.94}$$

I_n is also usually reported in an op-amp manufacturer's data sheet. The value given for I_n is used for I_{n1} and I_{n2}.

$$I_n = I_{n1} = I_{n2} \left[\text{A}/\sqrt{\text{Hz}}\right] \tag{11.95}$$

The analysis of the filter noise performance begins with the identification of all noise sources, which include the op-amp noise sources and all resistor thermal noise ($E_t = \sqrt{4\,\text{kt}\,R\Delta f}$ where 4kT is approximately 1.65×10^{-20} V^2/Ω; Hz at room temperature and Δf is the noise bandwidth). To begin the analysis, uncorrelated independent signal generators can be substituted for each noise source, voltage sources for noise voltage sources, and current sources for current noise sources. By applying superposition and using the rms value of the result, the noise contribution of each element to the total output noise E_{no} can be determined. Only squared rms values can be summed to determine E_{no}^2. The resultant expression then for E_{no}^2 should never involve subtraction of noise sources, only addition. Sources of noise in a circuit always add to the total noise at the circuit's output. The total noise referred to the input E_{ni} is simply E_{no} divided by the circuit's transfer function gain. Capacitors ideally only influence noise performance through their effect on the circuit's transfer function. That is, the transfer gain seen by a noise source to the circuit's output can be influenced by capacitors depending on the circuit. As a result, of course, a circuit's noise performance can be a strong function of frequency.

Consider again the noninverting op-amp configuration, which can be used to implement positive *K*. The circuit is shown in Figure 11.24a with appropriate noise sources included. Resistor R_s has been included to represent the driving source's (V_1) output resistance. The simplified circuit lumps together the amplifier's noise sources into E_{na}, shown in Figure 11.24b. E_{na} is described by Equation 11.96. The circuit in Figure 11.24b can be used in place of the positive gain block *K* to simplify the noise analysis of a larger circuit. R_s obviously will be determined by the circuit seen looking back from the amplifier's input:

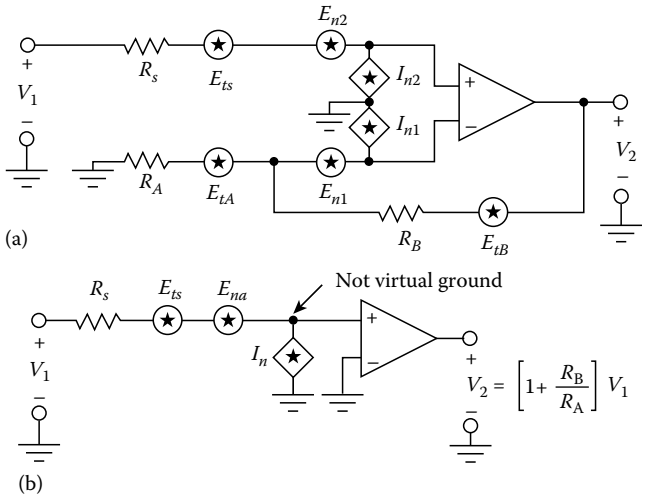

FIGURE 11.24 (a) Noninverting op-amp configuration with noise sources and (b) simplified noninverting amplifier circuit with noise sources.

$$E_{na}^2 = E_n^2 + \left(\frac{R_A}{R_A + R_B}\right)^2 \left(E_{tB}^2\right) + \left(\frac{R_B}{R_A + R_B}\right)^2 \left(E_{tA}^2\right) + I_{n1}^2 (R_A \| R_B)^2 \tag{11.96}$$

The inverting op-amp configuration for implementing a negative gain is shown in Figure 11.25a with noise sources included. Here again, the op-amp's noise sources can be lumped together and referred to the input as noise source E_{nb} shown in Figure 11.25b. For simplicity, R_s has been lumped together with R_A.

E_{nb} is described by Equation 11.97. The simplified circuit in Figure 11.25b is convenient for simplifying the noise analysis of larger circuit that uses a negative gain block.

$$E_{nb}^2 = \left(1 + \frac{R_A}{R_B}\right)^2 \left(E_n^2\right) + \left(\frac{R_A}{R_B}\right)^2 \left(E_{tB}^2\right) \tag{11.97}$$

Example 11.10

First-order low-pass filter noise analysis. Noise analysis of a low-pass filter with noninverting midband gain of 6 dB and −20 dB/decade gain roll-off after a 20 kHz cutoff frequency is desired. Recall from Section 11.3 that $\omega_o = RC$. Let us designate R_1 for R and C_2 for C. To obtain $\omega_o = 2\pi$(20 kHz), commercially available component values $R_1 = 16.9$ kΩ and $C_2 = 470$ pF (such as a 1% metal-film resistor for R_1 and a ceramic capacitor for C_2) can be used. Implement K with the noninverting op-amp configuration and use Figure 11.24b as a starting point of the noise analysis. The midband gain of 6 dB can be achieved by selecting $R_A = R_B$. For this example let $R_A = R_B = 10.0$ kΩ, also available in 1% metal film. Including the thermal noise source for R_1, the circuit shown in Figure 11.26 results.

From this circuit we can easily derive the output noise of the low-pass filter.

$$E_{\text{no}}^2 = K^2 \left[E_{na}^2 + \left| \frac{Z_2}{R_1 + Z_2} \right|^2 \left(E_{t1}^2\right) + |R_1 \| Z_2|^2 \left(I_n^2\right) \right] \tag{11.98}$$

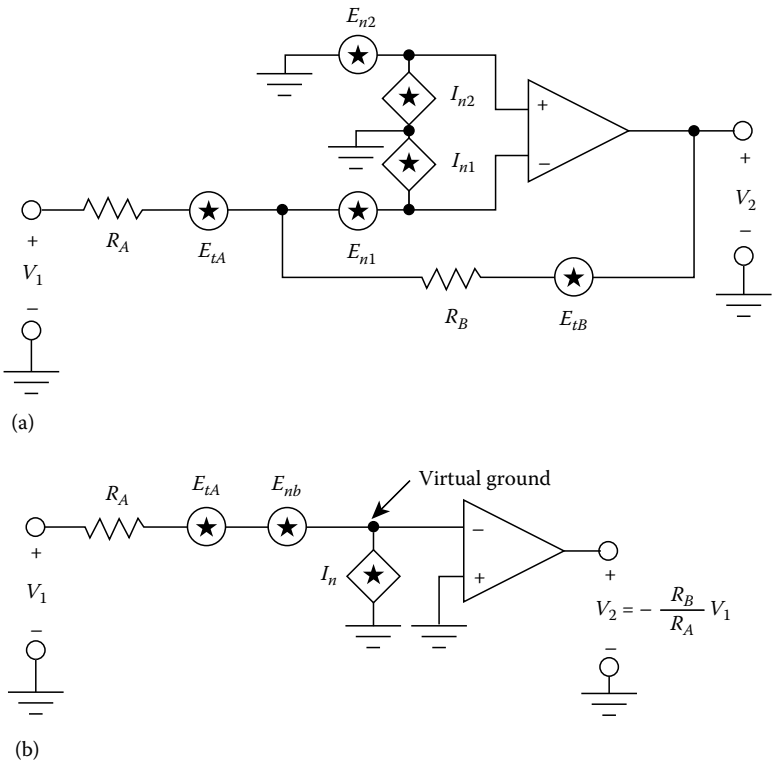

FIGURE 11.25 (a) Inverting op-amp configuration with noise sources and (b) simplified inverting amplifier circuit with noise sources.

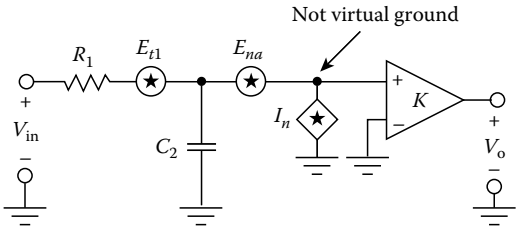

FIGURE 11.26 Positive gain first-order low-pass filter with noise sources.

where

$Z_2 = 1/sC_2$, the impedance of the capacitor

E_{na} is defined by Equation 11.96

The commercial op-amp OP-27 can be used to implement K and thus determines the values of E_n and I_n. For OP-27, $E_n = 3\,\text{nV}/\sqrt{\text{Hz}}$ and $I_n = 0.4\,\text{pA}/\sqrt{\text{Hz}}$. A comparison of the hand analysis to a PSpice simulation of this low-pass filter is shown in Figure 11.27. The frequency dependence of K was not included in the hand analysis since the filter required a low midband gain of two and low cutoff frequency relative to the OP-27's 8 MHz gain-bandwidth product. The simulated frequency response is shown in Figure 11.28. The computer simulation did include a complete model for the OP-27.

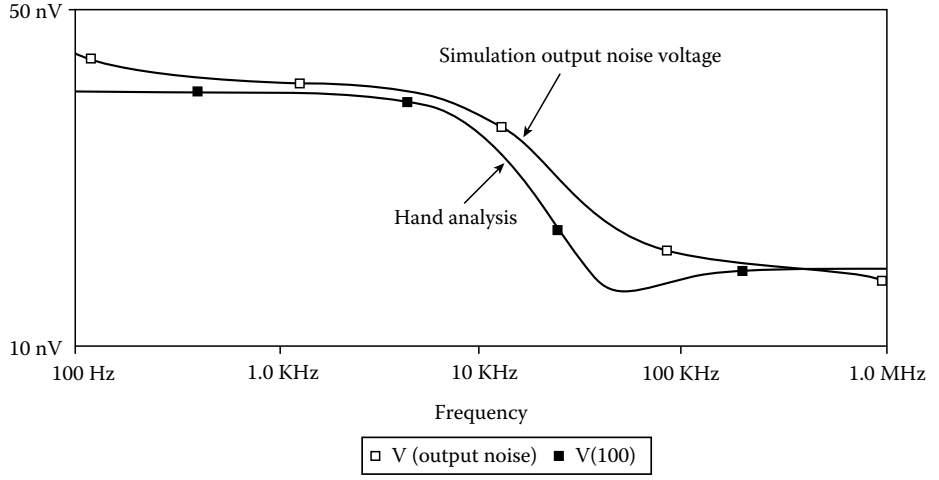

FIGURE 11.27 Comparison of calculated output noise with simulation.

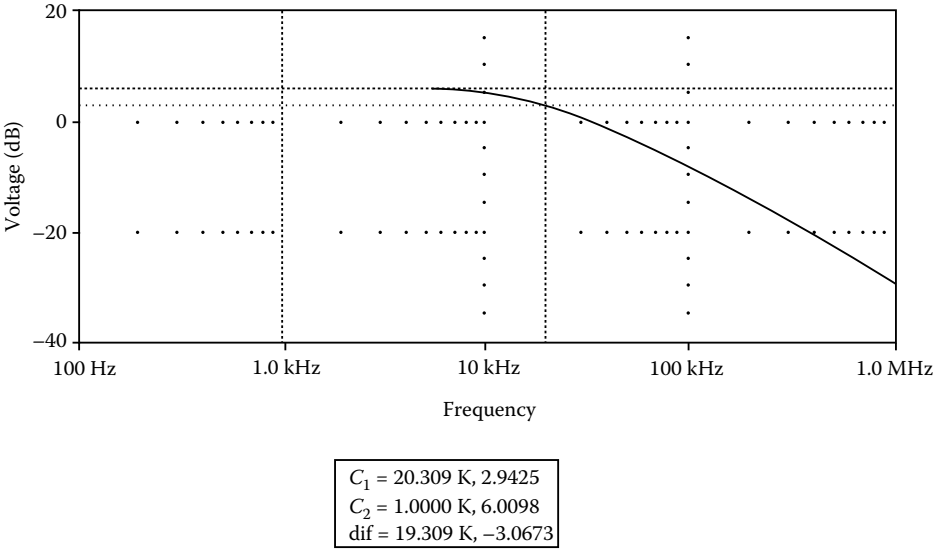

FIGURE 11.28 Simulated low-pass filter frequency response. The cursors indicate a −3 dB frequency of 20 kHz.

As indicated by Figure 11.27, the output noise predicted by Equation 11.98 agrees well with the simulation. Analyzing the noise contribution of each circuit element to the filter's total output noise can provide insight for improving the design. To this end, Table 11.3 was generated for this filter.

Note that at 1 kHz R_1 is the dominant source of noise. A smaller value of R_1 could be chosen at the expense of increasing C_2. Care must be taken in doing so because changing C_2 also changes the gain multiplier for I_n and R_1's noise source, as described in Equation 11.98. The noise bandwidth, using a single-pole response approximation, is 20 kHz $(\pi/2) = 31.4$ kHz. Hence, $E_{ni} = \left(20.2\,\text{nV}/\sqrt{\text{Hz}}\right)$. $(31.4\ \text{kHz})^{1/2} = 3.58\ \mu\text{V}$. To achieve then a signal-to-noise ratio of 10, the input signal level must be 35.8 μV. This would be more difficult to attain if 741 op-amp has been used, with its $E_n = 20.2\,\text{nV}/\sqrt{\text{Hz}}$, rather than the OP-27.

TABLE 11.3 Noise Contributions of Each Circuit Element at 1 kHz

Noise Source	Noise Value	Gain Multiplier	Output Noise Contribution	Input Noise Contribution
E_n	$3\,nV/\sqrt{Hz}$	2	$6\,nV/\sqrt{Hz}$	$3\,nV/\sqrt{Hz}$
I_n	$0.4\,pA/\sqrt{Hz}$	35.2 k	$14.1\,nV/\sqrt{Hz}$	$7.04\,nV/\sqrt{Hz}$
R_A	$12.65\,nV/\sqrt{Hz}$	1	$12.65\,nV/\sqrt{Hz}$	$6.325\,nV/\sqrt{Hz}$
R_B	$12.65\,nV/\sqrt{Hz}$	1	$12.65\,nV/\sqrt{Hz}$	$6.325\,nV/\sqrt{Hz}$
R_1	$16.4\,nV/\sqrt{Hz}$	1.998	$32.8\,nV/\sqrt{Hz}$	$16.4\,nV/\sqrt{Hz}$
Total noise contributions			$40.4\,nV/\sqrt{Hz}$	$20.2\,nV/\sqrt{Hz}$

Often in signal processing circuits several stages are cascaded to shape the response of the system. In doing so, the noise contributed by each stage is an important consideration. Placement of each stage within the cascade ultimately determines the E_{ni} of the entire cascade. The minimum E_{ni} is achieved by placing the highest gain first. By doing so the noise of all the following stages is divided by the single largest gain stage of the entire cascade. This comes, however, at the sacrifice of dynamic range. With the highest gain first in the cascade, each following stage has a larger input signal than in the case where the highest gain stage is last or somewhere between first and last in the cascade. Dynamic range is lost since there is a finite limit in the input signal level to any circuit before distortion results.

11.8 Summary

This chapter has examined active filters using low-gain amplifiers. These filters are capable of realizing any second-order transfer function. Higher order transfer functions are realized using cascaded first- and second-order stages. The nonideal behavior of finite gain-bandwidth, slew rate, and noise was examined. More information on this category of filters can be found in the references.

12.1 Introduction

In this section we will consider the design of second-order sections that incorporate a single operational amplifier. Such designs are based upon one of the earliest approaches to *RC* active filter synthesis, which has proven to be a fundamentally sound technique for over 30 years. Furthermore, this basic topology has formed the basis for designs as technology has evolved from discrete component assemblies to monolithic realizations. Hence, the circuits presented here truly represent reliable well-tested building blocks for sections of modest selectivity.

12.2 General Structure for Single-Amplifier Filters

The general structure of Figure 12.1 forms the basis for the development of infinite-gain single-amplifier configurations. Simple circuit analysis may be invoked to obtain the open-circuit voltage transfer function. For the passive network

$$I_1 = y_{11}V_1 + y_{12}V_2 + y_{13}V_3 \tag{12.1}$$

$$I_2 = y_{21}V_1 + y_{22}V_2 + y_{23}V_3 \tag{12.2}$$

$$I_3 = y_{31}V_1 + y_{32}V_2 + y_{33}V_3 \tag{12.3}$$

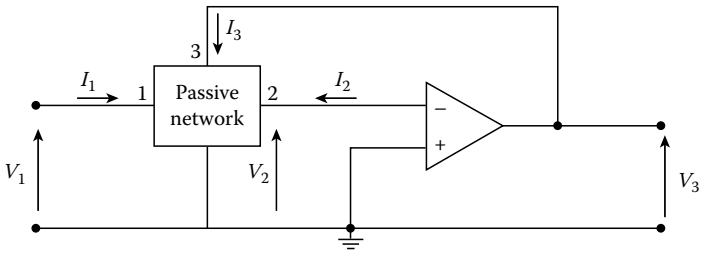

FIGURE 12.1 General infinite-gain single-amplifier structure.

For the amplifier, ideal except for finite gain A

$$V_3 = -AV_2 \tag{12.4}$$

Noting that $I_2 = 0$, the above equations reduce to the following expression for the voltage transfer function:

$$\frac{V_3}{V_1} = \frac{-y_{31}}{y_{32} + \frac{y_{33}}{A}} \tag{12.5}$$

As $A \to \infty$, which we can expect at low frequencies, the above expression reduces to the more familiar

$$\frac{V_3}{V_1} = -\frac{y_{31}}{y_{32}} \tag{12.6}$$

Theoretically, a wide range of transfer characteristics can be realized by appropriate synthesis of the passive network [1]. However, it is not advisable to extend synthesis beyond second-order functions for structures containing only one operational amplifier due to the ensuing problems of sensitivity and tuning. Furthermore, notch functions require double-element replacements [2] or parallel ladder arrangements [3], which are nontrivial to design, and whose performance is inferior to that resulting from other topologies such as those discussed in Chapters 13 and 14.

While formal synthesis techniques could be used to meet particular requirements, the most common approach is to use a double-ladder realization of the passive network, as shown in Figure 12.2. This arrangement, commonly referred to as the multiple-loop feedback (MFB) structure, is described by the following voltage transfer ratio:

$$\frac{V_3}{V_1} = \frac{-Y_1 Y_3}{Y_5(Y_1 + Y_2 + Y_3 + Y_4) + Y_3 Y_4} \tag{12.7}$$

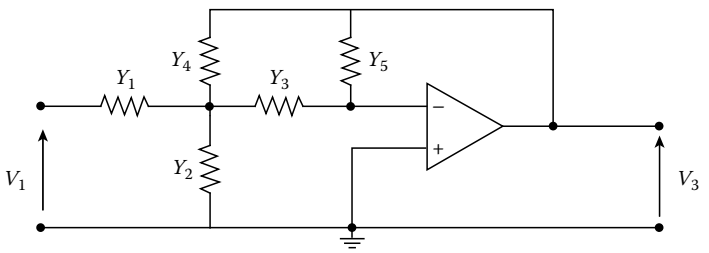

FIGURE 12.2 General double ladder multiple-feedback network.

This negative feedback arrangement yields highly stable realizations. The basic all-pole (low-pass, bandpass, high-pass) functions can be realized by single-element replacements for the admittances $Y_1, \ldots, Y_5$, as described in the following section.

12.3 All-Pole Realizations of the MFB Structure

12.3.1 Low-Pass Structure

The general form of the second-order all-pole low-pass structure is described by the following transfer ratio:

$$\frac{V_3}{V_1} = \frac{H}{s^2 + \frac{\omega_p s}{Q_p} + \omega_p^2} \tag{12.8}$$

By comparing the above requirement with Equation 12.7 it is clear that both Y_1 and Y_3 must represent conductances. Furthermore, by reviewing the requirements for the denominator, Y_5 and Y_2 must be capacitors, while Y_4 is a conductance.

12.3.2 High-Pass Structure

The general form of the second-order all-pole high-pass transfer function is

$$\frac{V_3}{V_1} = \frac{Hs^2}{s^2 + \frac{\omega_p s}{Q_p} + \omega_p^2} \tag{12.9}$$

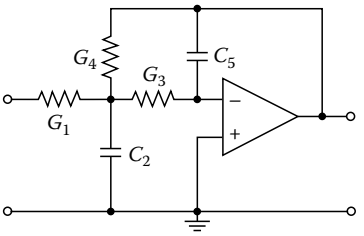
With reference to Equation 12.7, it is seen that both Y_1 and Y_3 must represent capacitors. There is a need for a third capacitor ($Y_4 = sC_4$) to yield the s^2 term in the denominator function. The remaining two elements, Y_2 and Y_5, represent conductances.

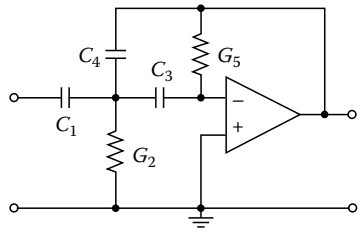
12.3.3 Bandpass Structure

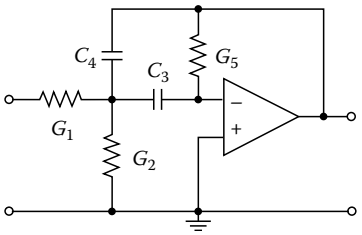
The general form of the second-order all-pole bandpass transfer function is

$$\frac{V_3}{V_1} = \frac{Hs}{s^2 + \frac{\omega_p s}{Q_p} + \omega_p^2} \tag{12.10}$$

Two solutions exist since Y_1 and Y_3 can be either capacitive or conductive. Choosing $Y_1 = G_1$ and $Y_3 = sC_3$ yields $Y_4 = sC_4$ and Y_2, Y_5 are both conductances.







The general forms of the above realizations are summarized in Table 12.1 [4].

12.4 MFB All-Pole Designs

MFB designs are typically reserved for sections having a pole-Q of 10 or less. One of the reasons for this constraint is the reliance upon component ratios for achieving Q. This can be illustrated by consideration of the low-pass structure for which

$$\frac{V_3}{V_1} = \frac{-G_1 G_3}{s^2 C_2 C_5 + sC_5(G_1 + G_3 + G_4) + G_3 G_4} \tag{12.11}$$

TABLE 12.1 MFB All-Pole Realizations

Filter Type	Network	Voltage Transfer Function
Low-pass		$\frac{-G_1G_3}{s^2C_2C_5 + sC_5(G_1 + G_3 + G_4) + G_3G_4}$
High-pass		$\frac{-s^2C_1C_3}{s^2C_3C_4 + sG_5(C_1 + C_3 + C_4) + G_2G_5}$
Bandpass		$\frac{-sG_1C_3}{s^2C_3C_4 + sG_5(C_3 + C_4) + G_5(G_1 + G_2)}$

By comparison with Equation 12.8,

$$Q_p = \frac{\sqrt{C_2C_5G_3G_4}}{C_5(G_1 + G_3 + G_4)}$$

or, in terms of component ratios:

$$Q_p = \frac{\sqrt{C_2}}{\sqrt{C_5}}\left(\frac{1}{\frac{G_1}{\sqrt{G_3G_4}} + \sqrt{\frac{G_3}{G_4}} + \sqrt{\frac{G_4}{G_3}}}\right) \tag{12.12}$$

Hence, high Q_p can only be achieved by means of high component spreads. In general terms, a Q_p of value n requires a component spread proportional to n^2.

Filter design is effected by means of coefficient matching. Thus, for the low-pass case, comparison of like coefficients in Equation 12.8 and the transfer ratio in Table 12.1 yields

$$G_1G_3 = H \tag{12.13}$$

TABLE 12.2 Element Values for the MFB All-Pole Realizations

Element (Table 12.1)	Low-pass	Bandpass	High-Pass
Y_1	$G_1 = \frac{H}{\omega_p}$	$G_1 = H$	$C_1 = H$
Y_2	$C_2 = \dfrac{Q_p\left(2\omega_p^2 + H\right)}{\omega_p^2}$	$G_2 = 2\omega_p Q_p - H$	$G_2 = \omega_p(2+H)Q_p$
Y_3	$G_3 = \omega_p$	$C_3 = 1$	$C_3 = 1$
Y_4	$G_4 = G_3$	$C_4 = C_3$	$C_4 = C_3$
Y_5	$C_5 = \dfrac{\omega_p^2}{Q_p\left(2\omega_p^2 + H\right)}$	$G_5 = \dfrac{\omega_p}{2Q_p}$	$G_5 = \dfrac{\omega_p}{Q_p(2+H)}$

$$C_2 C_5 = 1 \tag{12.14}$$

$$C_5(G_1 + G_3 + G_4) = \frac{\omega_p}{Q_p} \tag{12.15}$$

$$G_3 G_4 = \omega_p^2 \tag{12.16}$$

These equations do not yield an equal-capacitor solution but can be solved for equal-resistor pairs. Hence, if $G_1 = G_3$,

$$G_1 = G_3 = \sqrt{H} \quad \text{(From Equation 12.13)}$$

$$G_4 = \frac{\omega_p^2}{\sqrt{H}} \quad \text{(From Equation 12.16)}$$

Then,

$$C_5 = \frac{\omega_p \sqrt{H}}{Q_p\left(2H + \omega_p^2\right)} = \frac{1}{C_2}$$

An alternative solution for which $G_3 = G_4$ is shown in Table 12.2, together with equal-capacitor designs for the bandpass and high-pass cases.

The conditions [4] for maximum Q_p in the bandpass realization require $C_3 = C_4$ and $G_1 = G_2 = nG_5$, where n is a real number. This yields a maximum Q_p of $\sqrt{n/2}$, and requires that $H = \omega_p Q_p$.

Example 12.1

Using the cascade approach, design a four-pole Butterworth bandpass filter having a Q of 5, a center frequency of 1.5 kHz, and midband gain of 20 dB. Assume that only 6800 pF capacitors are available.

Solution

The low-pass prototype is the second-order Butterworth characteristic having a dc gain of 10 (i.e., 20 dB). Thus,

$$T(s) = \frac{10}{s^2 + \sqrt{2}s + 1} \tag{i}$$

The low-pass-to-bandpass frequency transformation for a Q of 5 entails replacing s in (i) by $5(s + 1/s)$. This yields the following bandpass function for realization:

$$\frac{V_o}{V_i} = \frac{0.4s^2}{s^4 + 0.28284s^3 + 2.04s^2 + 0.28284s + 1}$$
$$= \underbrace{\frac{-sH_1}{(s^2 + 0.15142s + 1.15218)}}_{\text{(section 1)}} \cdot \underbrace{\frac{-sH_2}{(s^2 + 0.13142s + 0.86792)}}_{\text{(section 2)}} \qquad \text{(ii)}$$

$$Q_1 = Q_2 = 7.089$$
$$\omega_{p1} = 1.0734; \quad \omega_{p2} = 0.9316$$

As expected, the Q-factors of the cascaded sections are equal in the transformed bandpass characteristic. However, the order of cascade is still important. So as to reduce the noise output of the filter, it is necessary to apportion most of the gain to section 1 of the cascade. Section 2 then filters out the noise without introducing excessive passband gain. In the calculation that follows, it is important to note that the peak gain of a bandpass section is given by HQ/ω_p.

Since the overall peak gain of the cascade is to be 10, let this also be the peak gain of section 1. Hence,

$$\frac{H_1 Q_1}{\omega_{p1}} = 6.6041 H_1 = 10$$

giving $H_1 = 1.514$.

Furthermore, from (ii)

$$H_1 H_2 = 0.4$$

so that $H_2 = 0.264$.

The design of each bandpass section proceeds by coefficient matching, conveniently simplified by Table 12.2. Setting $C_3 = C_4 = 1$ F, the normalized resistor values for section 1 may be determined as

$$R_1 = 0.661\ \Omega; \quad R_2 = 0.073\ \Omega; \quad R_5 = 13.208\,\Omega$$

The impedance denormalization factor is determined as

$$z_n = \frac{10^{12}}{2\pi \times 1500 \times 6800} = 15{,}603$$

Thus, the final component values for section 1 are

$$\left.\begin{aligned} C_1 &= C_2 = 6800\ \text{pF} \\ R_1 &= 10.2\ \text{k}\Omega \\ R_2 &= 1.13\ \text{k}\Omega \\ R_5 &= 205\ \text{k}\Omega \end{aligned}\right\} \text{Standard 1\% values}$$

Note the large spread in resistance values ($R_5/R_2 \simeq 4Q^2$) and the fact that this circuit is only suitable for low-Q realizations. It should also be noted that the amplifier open-loop gain at ω_p must be much greater than $4Q^2$ if it is not to cause significant differences between the design and measured values of Q.

The component values for section 2 are determined in an identical fashion.

Example 12.2

Design the MFB bandpass filter characterized in Example 12.1 as a high-pass/low-pass cascade of second-order sections. Use the design equations of Table 12.2 and, where possible, set capacitors equal to 5600 pF. It is suggested that you use the same impedance denormalization factor in each stage. Select the nearest preferred 1% resistor values.

Solution

Since the peak gain of the overall cascade is to be 10, let this also be the gain of stage 1 (this solution yields the best noise performance). The peak gain of the low-pass section is given by

$$\frac{H_1 Q}{\sqrt{1 - 1/2Q^2}} = 7.16H_1 = 10 \quad \therefore H_1 = 1.397$$

The overall transfer function (from Example 12.1) is

$$\frac{V_o}{V_i} = \frac{0.4s^2}{s^4 + 0.2824s^3 + 2.04s^2 + 0.2824s + 1}$$
$$\therefore H_1 H_2 = 0.4 \quad \text{so that } H_2 = 0.286$$

Thus, assuming a low-pass/high-pass cascade, we have

$$\frac{V_o}{V_i} = \underbrace{\frac{1.397}{s^2 + 0.15145 + 1.1522}}_{\text{section 1}} \cdot \underbrace{\frac{0.286s^2}{s^2 + 0.1314s + 0.8679}}_{\text{section 2}}$$

Design the low-pass section (section 1) using Table 12.2 to yield

$$G_1 = \frac{H_1}{\sqrt{1.15218}} = 1.301, \quad \text{so that } R_1 = 0.7684\,\Omega$$
$$C_2 = \frac{\left(2\omega_p^2 + H_1\right)}{\omega_p^2} Q_p = 22.77\,\text{F}$$
$$G_3 = \omega_p = 1.0733, \quad \text{so that } R_3 = 0.9316\,\Omega = R_4$$
$$C_5 = 1/C_2 = 0.0439\,\text{F}$$

Now, design the high-pass section (section 2) to yield

$$C_1' = 0.286\,\text{F}$$
$$G_2' = \omega_p(2 + H_2)Q = 15.099, \quad \text{so that } R_2' = 0.0662\,\Omega$$
$$C_3' = C_4' = 1\ \text{F}$$
$$G_5' = \frac{\omega_p}{Q_p(2 + H)} = 0.0574, \quad \text{so that } R_5' = 17.397\,\Omega$$

To obtain as many 5600 pF capacitors as possible, the two sections should be denormalized separately. However, in this example, a single impedance denormalization will be used. Setting $C_3' = C_4' = 5600$ pF yields $z_n = 18{,}947$.

This leads to the following component values:

Low-Pass Stage	High-Pass Stage
$R_1 = 2.204\ \text{k}\Omega\ (2.21\ \text{k}\Omega)$	$C_1' = 1602\ \text{pF}$
$C_2 = 0.128\ \mu\text{F}$	$R_2' = 1.254\ \text{k}\Omega\ (1.24\ \text{k}\Omega)$
$R_3 = 17.651\ \text{k}\Omega\ (17.8\ \text{k}\Omega) = R_4$	$C_3' = C_4' = 5600\ \text{pF}$
$C_5 = 246\ \text{pF}$	$R_5' = 329.62\ \text{k}\Omega\ (332\ \text{k}\Omega)$

Note: 1% values in parentheses.

12.5 Practical Considerations in the Design of MFB Filters

Sensitivity, the effects of finite amplifier gain, and tuning are all of importance in practical designs. The following discussion is based upon the bandpass case.

12.5.1 Sensitivity

Taking account of finite amplifier gain A, but assuming $R_{\text{in}} = \infty$ and $R_{\text{o}} = 0$ for the amplifier, the bandpass transfer function becomes

$$\frac{V_3}{V_1} = \frac{-sG_1/C_4\left(1+\frac{1}{A}\right)}{s^2 + s\left\{\frac{G_5(C_3+C_4)}{C_3C_4} + \frac{G_1+G_2}{C_4(1+A)}\right\} + \left\{\frac{G_5(G_1+G_2)}{C_3C_4}\right\}} \tag{12.17}$$

which is identical to the expression in Table 12.1 if $A = \infty$.

Assuming a maximum Q design,

$$Q = \frac{Q_{\text{p}}}{1 + \frac{2Q_{\text{p}}^2}{(1+A)}} \tag{12.18}$$

where

Q_{p} is the desired selectively

Q is the actual Q-factor in the presence of finite amplifier gain

If $A \gg 2Q - 1$, the classical Q-sensitivity may be derived as

$$S_A^Q = \frac{2Q^2}{A} \tag{12.19}$$

which is uncomfortably high. By contrast, the passive sensitivities are relatively low:

$$S_{C_3,C_4}^Q = 0; \quad S_{G_5}^Q = -0.5; \quad S_{G_1,G_2}^Q = 0.25$$

while the ω_{p} sensitivities are all ± 0.5.

12.5.2 Effect of Finite Amplifier Gain

The effect of finite amplifier gain can be further illustrated by plotting Equation 12.18 for various Q-factors, and for two commercial operational amplifiers. Assuming a single-pole roll-off model, the frequency dependence of open-loop gain for μ *A*741 and *LF*351 amplifiers is as follows:

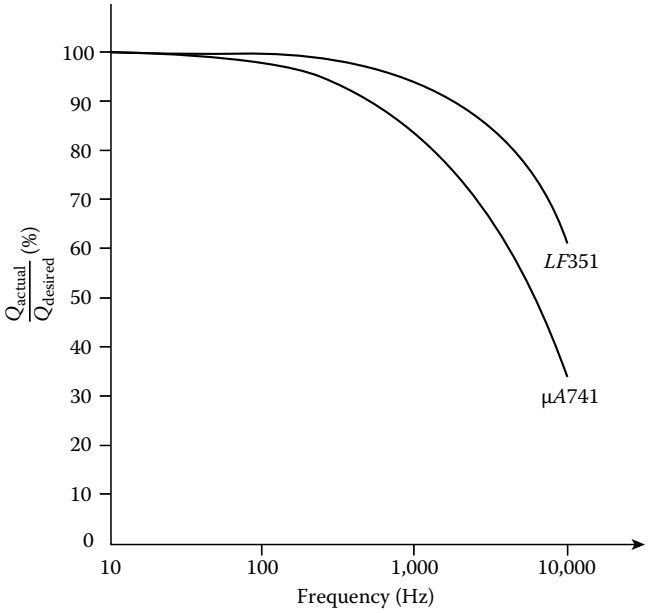


FIGURE 12.3 Effect of finite amplifier gain on the design Q for MFB bandpass realizations using two commercial operational amplifiers.

	Gain	
Frequency (Hz)	μ*A*741	*LF*351
10	1.3×10^5	3.16×10^5
100	10^4	3.16×10^4
1,000	10^3	3.16×10^3
10,000	10^2	3.16×10^2

Figure 12.3 shows the rather dramatic fall-off in actual Q as frequency increases (and hence gain decreases). Thus, for designs of modest Q (note that $A \gg 2Q - 1$), a very high quality amplifier is needed if the center frequency is more than a few kilohertz. For example, the *LF*351 with a unity gain frequency of 4 MHz will yield 6% error in Q at a frequency of only 1 kHz.

12.5.3 Tuning

Limited functional tuning of the bandpass section is possible. For example, the midband (peak) gain

$$K_o = \frac{G_1 C_3}{G_5(C_3 + G_4)} \tag{12.20}$$

may be adjusted by means of either G_1 or G_5.

Subsequent adjustment of either Q_p or ω_p is possible via G_2. In view of the discussion above, it is most likely that adjustment of Q_p will be desired. However, since the expressions for Q_p and ω_p are so similar, any adjustment of Q_p is likely to require an iterative procedure to ensure that ω_p does not change undesirably.

A more desirable functional tuning result is obtained in circumstances where it is necessary to preserve a constant bandwidth, i.e., in a spectrum analyzer. Since

$$\omega_p = \sqrt{G_5(G_1 + G_2)/C_3C_4} \tag{12.21}$$

and bandwidth, B, is

$$B = \frac{\omega_p}{Q_p} = G_5(C_3 + C_4) \tag{12.22}$$

adjustment of G_2 will allow for a frequency sweep without affecting K_o or B.

An alternative to functional tuning may be found by adopting deterministic [5] or automatic [6] tuning procedures. These are particularly applicable to hybrid microelectronic or monolithic realizations.

12.6 Modified Multiple-Loop Feedback Structure

In negative feedback topologies such as the MFB, "high" values of Q_p are obtained at the expense of large spreads in element values. By contrast, in positive feedback topologies such as those attributed to Sallen and Key, Q_p is enhanced by subtracting a term from the s^1 (damping) coefficient in the denominator. The two techniques are combined in the MMFB (Deliyannis) arrangement [7] of Figure 12.4.

Analysis of the circuit yields the bandpass transfer function as

$$\frac{V_o}{V_i} = \frac{-sC_3G_1(1+k)}{s^2C_3C_4 + s\{G_5(C_3 + C_4) - kC_3G_1\} + G_1G_5} \tag{12.23}$$

where $k = G_b/G_a$, and the Q-enhancement term "$-kC_3G_1$" signifies the presence of positive feedback. This latter term is also evident in the expression for Q_p:

$$Q_p = \frac{\sqrt{G_1/G_5}}{\left\{\sqrt{\frac{C_4}{C_3}} + \sqrt{\frac{C_3}{C_4}} - k\frac{G_1}{G_5}\sqrt{\frac{C_1}{C_2}}\right\}} \tag{12.24}$$

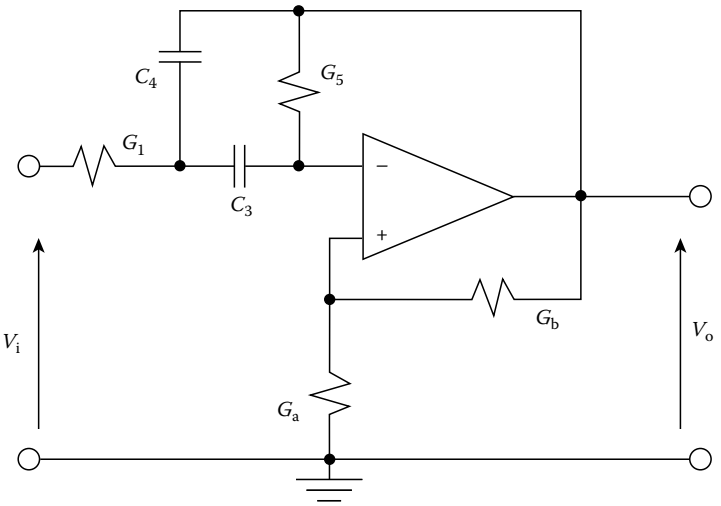

FIGURE 12.4 MMFB structure.

The design process consists of matching coefficients in Equation 12.23 with those of the standard bandpass expression of Equation 12.10. The design steps have been conveniently summarized by Huelsman [8] for the equal-capacitor solution and the following procedure is essentially the same as that described by him.

Example 12.3

Design a second-order bandpass filter with a center frequency of 1 kHz, a pole-Q of 8, and a maximum resistance spread of 50. Assume that the only available capacitors are of value 6800 pF.

1. The above constraint suggests an equal-valued capacitor solution. Thus, set $C_3 = C_4 = C$.
2. Determine the resistance ratio parameter n_o that would be required if there were no positive feedback. From Section 12.4, $n_o = 4Q_p^2 = 256$.
3. Select the desired ratio n (where n is greater than 1 but less than 256) and use it to determine the amount of positive feedback k. From Equation 12.24,

$$Q_p = \frac{\sqrt{n}}{2 - kn}$$

so that

$$k = \frac{1}{\sqrt{n}}\left\{\frac{2}{\sqrt{n}} - \frac{1}{Q_p}\right\}$$

Since $n = 50$ and $Q_p = 8$, $k = 0.0316$.

4. A convenient value may now be selected for R_B. If $R_B = 110\,\text{k}\boldsymbol{\Omega}$, then $R_A = R_B\,(0.0316) = 3.48\,\text{k}\boldsymbol{\Omega}$.
5. Since, from Equation 12.23,

$$\boldsymbol{\omega}_p = \sqrt{\frac{G_1 G_5}{C_3 C_4}}$$

and $G_1/G_5 = n$, we may determine G_5 as

$$G_5 = \frac{\boldsymbol{\omega}_p C}{\sqrt{n}}$$

Since $C = 6800$ pF, $n = 50$, and $G_5 = 1/R_5$:

$$R_5 = \frac{\sqrt{50}}{2\boldsymbol{\pi}10^3 \times 6.8 \times 10^{-9}} = 165.5\,\text{k}\boldsymbol{\Omega}$$

Hence $R_1 = R_5/n = 3.31\,\text{k}\boldsymbol{\Omega}$.

6. Using 1% preferred resistor values we have

$$R_B = 110\,\text{k}\boldsymbol{\Omega}; \quad R_A = 3.16\,\text{k}\boldsymbol{\Omega}$$
$$R_5 = 165\,\text{k}\boldsymbol{\Omega}; \quad R_1 = 3.48\,\text{k}\boldsymbol{\Omega}$$

Judicious use of positive feedback in the Deliyannis circuit can yield bandpass filters with Q values as high as 15–20 at modest center frequencies. A more detailed discussion of the optimization of this structure may be found elsewhere [9].

12.7 Biquadratic MMFB Structure

A generalization of the MMFB arrangement, yielding a fully biquadratic transfer ratio is shown in Figure 12.5. If the gain functions K_1, K_2, K_3 are realized by resistive potential dividers, the circuit reduces to the more familiar Friend biquad of Figure 12.6, for which

$$\frac{V_o}{V_i} = \frac{cs^2 + ds + e}{s^2 + as + b} \tag{12.25}$$

where

$$\begin{aligned} K_1 &= \frac{R_5}{R_4 + R_5}; \quad K_2 = \frac{R_D}{R_c + R_D}; \quad K_3 = \frac{R_7}{R_6 + R_7} \\ R_1 &= \frac{R_4 R_5}{R_4 + R_5}; \quad R_A = \frac{R_c R_D}{R_c + R_D}; \quad R_3 = \frac{R_6 R_7}{R_6 + R_7} \end{aligned} \tag{12.26}$$

This structure is capable of yielding a full range of biquads of modest pole Q, including notch functions derived as elliptic characteristics of low modular angle. It was used extensively in the Bell System, where the benefits of large-scale manufacture were possible. Using the standard tantalum thin film process, and deterministic tuning by means of laser trimming, quite exacting realizations were possible [10].

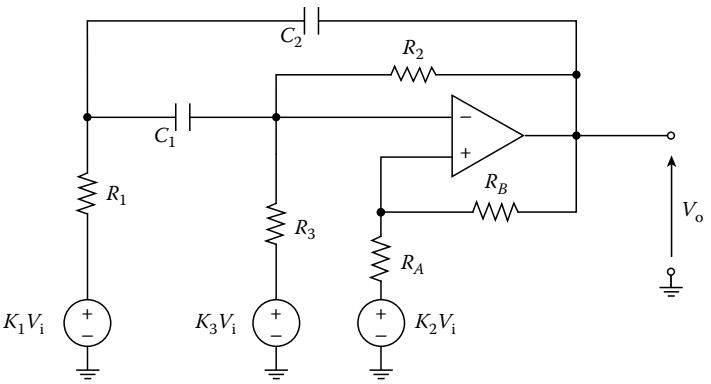

FIGURE 12.5 Generalization of the MMFB circuit.

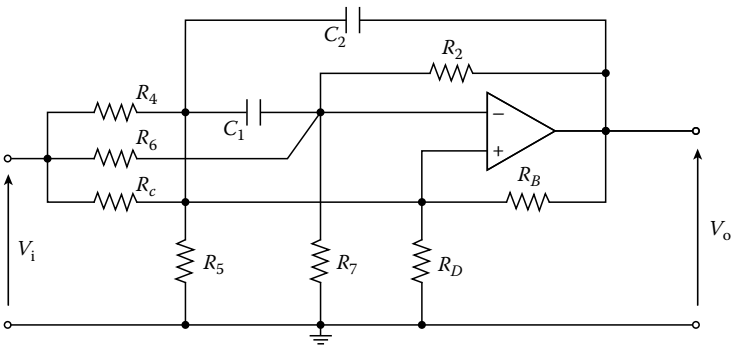

FIGURE 12.6 Friend biquad.

The structure is less suited to discrete component realizations. However, design is possible by coefficient matching. The reader is referred to an excellent step-by-step procedure developed by Huelsman [11].

12.8 Conclusions

The multiple-feedback structure is one of the most basic active filter building blocks. It is extremely reliable when used to realize low-Q (<10), low frequency (up to 15 kHz) second-order sections of the low-pass, bandpass, and high-pass forms. Stability is ensured by the negative feedback topology, though component spreads are proportional to Q^2.

The disadvantage of larger component spread may be reduced by the judicious use of positive feedback. This approach may be extended to yield the widely used Friend biquad, which allows the realization of notch and other approximations requiring a pair of imaginary zeros.

All networks described in this section readily lend themselves to the cascade method for realizing higher-order filters.

13.1 Introduction

The step from single-amplifier to multiple-amplifier biquadratic filter sections provides several benefits. The most important benefits are as follows:

- Reduced passive element spread, i.e., the ratio between the largest and the smallest values of resistors and/or capacitors can be reduced compared to the single-amplifier case.
- The required amplifier gains in some circuits grow linearly or less with the *Q*-factor of the complex pole pairs.
- Multiple-amplifier biquads often provide lower sensitivities to both passive and active components.
- Most of the multiple-amplifier biquads are more universal filter structures realizing the general biquadratic transfer function.
- Most of the filter parameters such as pole and zero *Q*-factors, pole and zero frequencies, and the gain factor of the transfer function can be tuned independently.
- Designing multiple-amplifier filters, often the values of the capacitors can be chosen freely. The filter parameters are then determined by resistors, which is less costly than by capacitors.

On the other hand, these benefits must be paid for by increased space requirements and increased power dissipation. However, today there are low-cost and low-power integrated-circuit op-amps available with up to four op-amps on one chip. Therefore, size and power dissipation are often no longer the main problem.

In the following, we will first consider biquadratic filter sections and dual-amplifier twin-*T* biquads. Both circuit families are directly derived from single-amplifier circuits. Next we will derive filter circuits having a quite different origin: filters that are derived from the generalized impedance converter (GIC) and filters derived from state-variable representation of linear systems on the analog computer. Finally, we will briefly consider filter circuits based on first-order all-pass sections.

13.2 Biquads with Decoupled Time Constants

One of the simplest methods for improving the performance of a biquad is demonstrated in Figure 13.1.

Figure 13.1a shows a well-known Sallen and Key bandpass circuit [1], which offers moderate pole sensitivities with respect to the passive elements. It can easily be shown that this circuit has the following transfer voltage ratio:

$$H(s) = \frac{V_o}{V_i} = \frac{-K \cdot sT_2}{s^2 T_1 T_2 (1 + K) + s(T_{12} + T_1 + T_2) + 1} \tag{13.1}$$

with the amplifier gain K and the time constants $T_1 = R_1C_1$, $T_2 = R_2C_2$, and $T_{12} = R_1C_2$. The gain requirement is more than $4Q_p^2 - 1$ with Q_p being the Q-factor of the pole pair. This relationship limits the circuit to low or medium-Q applications.

If we insert another amplifier between the two RC networks R_1C_1 and R_2C_2, we obtain the biquad in Figure 13.1b [2,3], which possesses a transfer voltage ratio

$$H(s) = \frac{V_o}{V_i} = \frac{K_1K_2 \cdot sT_2}{s^2 T_1 T_2 (1 - K_1K_2) + s(T_1 + T_2) + 1} \tag{13.2}$$

Here the product K_1K_2 of the gain factors plays the role of the gain $-K$ in Figure 13.1a. One of the gain factors must be positive, the other negative. A comparison of Equations 13.1 and 13.2 shows that after isolating both RC networks the "cross time constant" T_{12} disappears. The two time constants T_1 and T_2 are decoupled. From this change we can derive two benefits. Both factors K_1 and K_2 require only a gain of approximately $2Q_p$ and, as will be shown later, this circuit can be designed with zero Q-sensitivity.

Next, we generalize the structure in Figure 13.1b by replacing the passive elements by general admittances; see Figure 13.2. In this circuit, the two subnetworks Y_{1a}, Y_{1b} and Y_{2a}, Y_{2b} are decoupled.

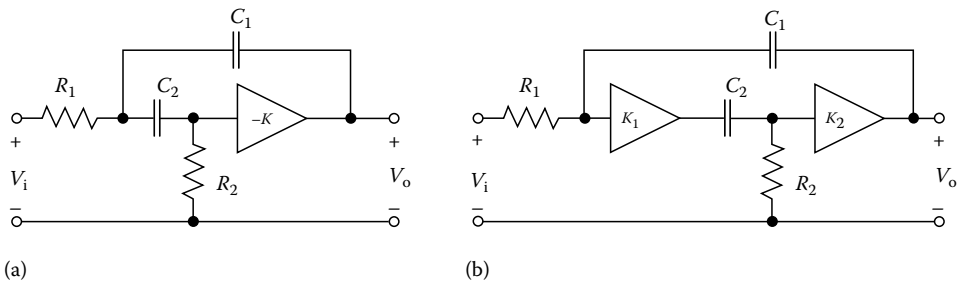

FIGURE 13.1 (a) Sallen and Key bandpass filter and (b) dual-amplifier bandpass filter with decoupled time constants.

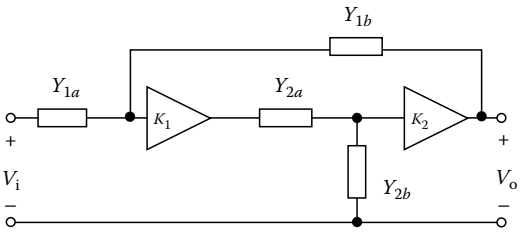

FIGURE 13.2 General biquad with decoupled networks.

By a simple analysis we obtain the transfer voltage ratio of the general circuit in Figure 13.2:

$$H(s) = \frac{V_o}{V_i} = \frac{K_1 K_2 Y_{1a} Y_{2a}}{(Y_{2a} + Y_{2b})(Y_{1a} + Y_{1b}) - K_1 K_2 Y_{1b} Y_{2a}} \tag{13.3}$$

By prespecifying the types of passive elements in Figure 13.2 and Equation 13.3, respectively, we next will derive a low-pass, a bandpass, and high-pass filter section.

With the prespecified elements $Y_{1a} = G_1$, $Y_{1b} = sC_1$, $Y_{2a} = G_2$, and $Y_{2b} = sC_2$ we obtain from Equation 13.3 the low-pass transfer function:

$$\begin{aligned} H_{LP}(s) = \frac{V_o}{V_i} &= \frac{K_1 K_2 G_1 G_2}{s^2 C_1 C_2 + s[G_1 C_2 + G_2 C_1 (1 - K_1 K_2)] + G_1 G_2} \\ &= \frac{K_1 K_2}{s^2 T_1 T_2 + s[T_2 + T_1 (1 - K_1 K_2)] + 1} \end{aligned} \tag{13.4}$$

If we predefine $K_1 = K_2 = 1$ we simply get voltage followers in the filter circuit and additionally a simple design procedure resulting in a low-sensitivity filter section. Figure 13.3 shows the low-pass filter section with two op-amps and four passive elements.

For $K_1 = K_2 = 1$ we will have dc gain $H_0 = 1$, a pole frequency

$$\omega_p = 1/\sqrt{T_1 T_2} \tag{13.5}$$

and a Q-factor

$$Q_p = \sqrt{T_2/T_1} \tag{13.6}$$

Thus, designing the filter section, from the predefined parameters ω_p and Q_p we determine the time constants

$$T_2 = \frac{Q_p}{\omega_p}, \quad T_1 = \frac{1}{Q_p \omega_p} \tag{13.7}$$

Finally, we choose the values of the capacitors and calculate the resistors from the time constants.

From Equations 13.5 and 13.6, we can immediately read the pole sensitivities:

$$S_{R_1}^{\omega_p} = S_{C_1}^{\omega_p} = S_{R_2}^{\omega_p} = S_{C_2}^{\omega_p} = -\frac{1}{2} \tag{13.8}$$

$$S_{R_1}^{Q_p} = S_{C_1}^{Q_p} = -S_{R_2}^{Q_p} = -S_{C_2}^{Q_p} = -\frac{1}{2} \tag{13.9}$$

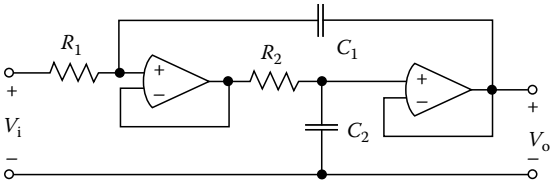

FIGURE 13.3 Dual op-amp low-pass filter section.

This result is comparable with the pole sensitivities of passive second-order *RLC* networks.

Next we will develop a high-pass filter section by prespecifying $Y_{1a} = sC_1$, $Y_{1b} = G_1$, $Y_{2a} = sC_2$, and $Y_{2b} = G_2$ resulting in a transfer voltage ratio:

$$H_{\mathrm{HP}}(s) = \frac{V_\mathrm{o}}{V_\mathrm{i}} = \frac{s^2 K_1 K_2 C_1 C_2}{s^2 C_1 C_2 + s[G_2 C_1 + G_1 C_2(1 - K_1 K_2)] + G_1 G_2}$$
$$= \frac{s^2 K_1 K_2 T_1 T_2}{s^2 T_1 T_2 + s[T_1 + T_2(1 - K_1 K_2)] + 1} \tag{13.10}$$

The only difference of this transfer function compared with the low-pass transfer function in Equation 13.4 is the high-pass term (with s^2) in the numerator and the fact that the time constants T_1 and T_2 are interchanged in the denominator polynomial. Thus we can transfer the results in Equation 13.5 through 13.9 to the high-pass filter by only replacing the index 1 by 2 and vice versa. Figure 13.4 shows the high-pass filter section.

The bandpass filter circuit mentioned at the beginning of this section is defined by the following types of elements: $Y_{1a} = G_1$, $Y_{1b} = sC_1$, $Y_{2a} = sC_2$, and $Y_{2b} = G_2$. Its transfer function is written in Equation 13.2. The bandpass design is somewhat different from that of the low-pass and the high-pass filters described above. If we set the design values

$$G_1 = G_2 = 1, \quad C_1 = C_2 = \frac{1}{2Q_\mathrm{p}} \tag{13.11}$$

and

$$-K_1 K_2 = 4Q_\mathrm{p}^2 - 1 \tag{13.12}$$

we obtain a special design where all passive Q-sensitivities are zero and all other sensitivities are very low [2,3]:

$$S_{R_1}^{Q_\mathrm{p}} = S_{C_1}^{Q_\mathrm{p}} = S_{R_2}^{Q_\mathrm{p}} = S_{C_2}^{Q_\mathrm{p}} = 0 \tag{13.13}$$

$$S_{R_1}^{\omega_\mathrm{p}} = S_{C_1}^{\omega_\mathrm{p}} = S_{R_2}^{\omega_\mathrm{p}} = S_{C_2}^{\omega_\mathrm{p}} = -\frac{1}{2} \tag{13.14}$$

$$S_{K_1}^{Q_\mathrm{p}} = S_{K_2}^{Q_\mathrm{p}} = \frac{-K_1 K_2}{2(1 - K_1 K_2)} < \frac{1}{2} \tag{13.15}$$

$$S_{K_1}^{\omega_\mathrm{p}} = S_{K_2}^{\omega_\mathrm{p}} = -\frac{1}{2}\left(1 - \frac{1}{4Q_\mathrm{p}^2}\right) \tag{13.16}$$

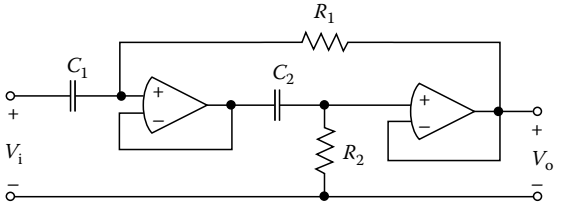

FIGURE 13.4 Dual op-amp high-pass filter section.

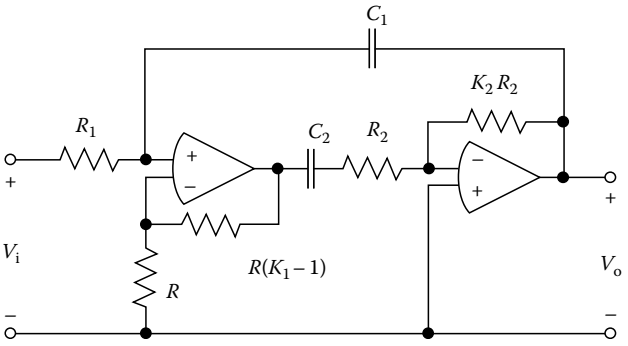

FIGURE 13.5 Dual op-amp bandpass filter section.

Figure 13.5 shows the bandpass filter section realized with two op-amps. In this circuit K_1 is a noninverting and K_2 an inverting amplifier. The resistor R_2 of the passive network R_2, C_2 is realized by the input resistor of the inverting amplifier.

13.3 Dual-Amplifier Twin-*T* Biquads

Twin-*T* feedback networks are easily tunable and provide relatively favorable sensitivity properties. In active filters, a twin-*T* network is connected between the input and the output of an inverting amplifier. It has been shown [4] that the sensitivity to the active element can be substantially reduced when a symmetrical feedback network is used, i.e., when the dc gain of the feedback network is equal to the high-frequency gain.

In a single-amplifier twin-*T* biquad, the output port of the feedback network is loaded by the input resistance of the inverting amplifier. As a consequence, the feedback network is no longer symmetrical. Here again we can significantly improve the behavior of the twin-*T* biquad by introducing a second amplifier: inserting a voltage follower between the twin-*T* network and the inverting amplifier maintains the symmetry of the feedback network. Figure 13.6 shows the corresponding dual-amp twin-*T* resonator* with the usually chosen passive element relations.

From the resonator in Figure 31.6 several filter circuits can be derived by inserting the input voltage source in one of the grounded branches and by taking one of the two amplifier outputs as output terminal

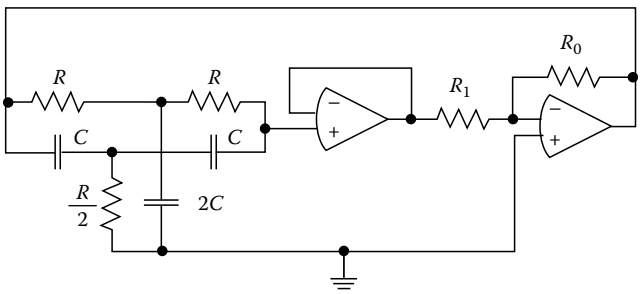

FIGURE 13.6 Dual-amp twin-*T* resonator.

* A resonator is a circuit without input and output terminals that only serves to show the feedback mechanism.

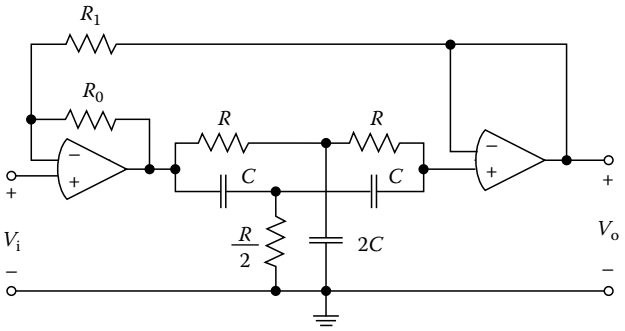

FIGURE 13.7 Dual-amp twin-T band-rejection filter.

of the filter section. The voltage transfer ratios of all these circuits will have different numerator polynomials but the same denominator polynomial. As an example, Figure 31.7 shows a band-rejection filter derived from the dual-amp twin-T resonator in Figure 13.6.

The voltage transfer ratio of the band-rejection filter in Figure 13.7 can be calculated to be

$$H_{BR}(s) = \frac{V_o}{V_i} = \frac{s^2T^2 + 1}{s^2T^2 + s4T/K + 1} \tag{13.17}$$

with the time constant $T = RC$ and the gain $K = (R_0 + R_1)/R_1$ of the series connection of the two op-amp circuits. Designing this filter, we determine the time constant T from the notch frequency ω_z or pole frequency ω_p, respectively,

$$T = \frac{1}{\omega_z} = \frac{1}{\omega_p} \tag{13.18}$$

and the amplifier gain from the Q-factor:

$$K = 4 \cdot Q_p \tag{13.19}$$

In Ref. [4], it is shown that the filter has favorably low gain-sensitivity products.

In order to obtain further filter variants, in Ref. [4] a complementary circuit is derived from the resonator in Figure 13.6; see Figure 13.8.

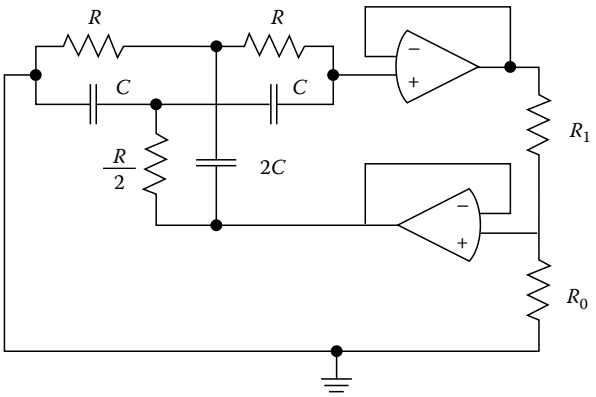

FIGURE 13.8 Complementary circuit of the resonator in Figure 13.6.

This resonator is especially useful for deriving filter sections with frequently applied transfer functions. In Figures 13.9 through 13.13 some of these filter sections are depicted. Their voltage transfer ratios are given by

$$H(s) = \frac{V_o}{V_i} = \frac{N(s)}{s^2T^2 + s4T/K + 1} \tag{13.20}$$

The band-rejection filter in Figure 13.9 has a numerator polynomial $N(S) = s^2T^2 + 1$. The filter section in Figure 13.10 is low-pass with a numerator $N(s) = 1$, the filter section in Figure 13.11 is high-pass

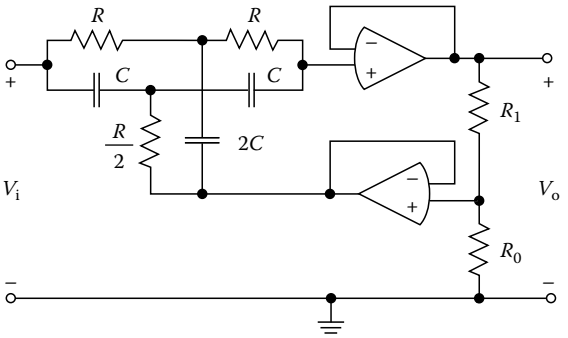

FIGURE 13.9 Twin-*T* band-rejection filter.

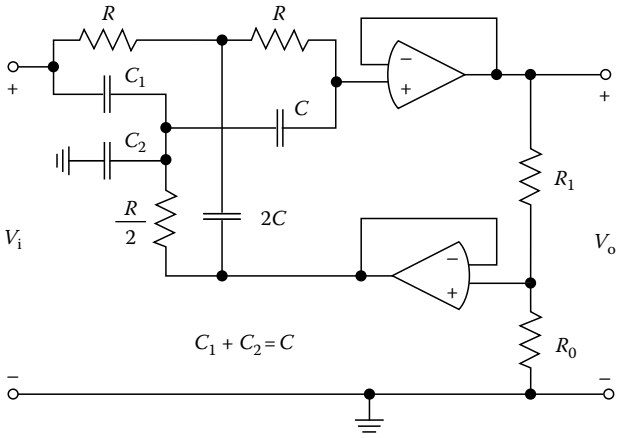

FIGURE 13.12 Twin-*T* Cauer low-pass filter section.

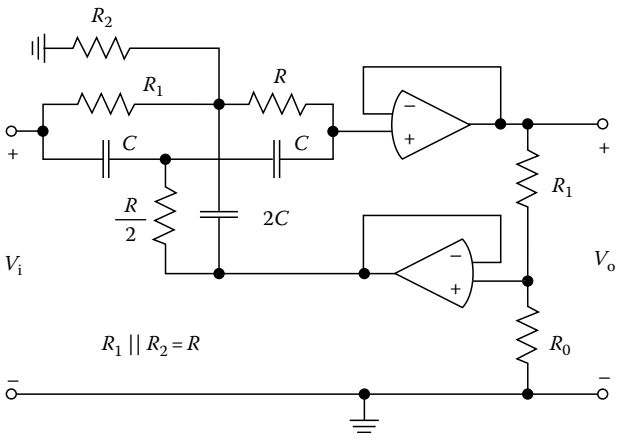

FIGURE 13.13 Twin-*T* Cauer high-pass filter section.

with $N(s) = s^2T^2$. The design of these sections is exactly the same as that of the filter in Figure 13.7. It also provides the same pole sensitivities.

The two structures in Figure 13.12 and 13.13 are particularly suitable for realizing elliptical filter sections (also called Cauer filters). The Cauer low-pass filter section in Figure 13.12 has a numerator polynomial:

$$N(s) = s^2R^2CC_1 + 1, \quad C_1 + C_2 = C \tag{13.21}$$

In this circuit, the first capacitor C is split into a parallel connection of two capacitors C_1 and C_2, where C_2 is grounded. The zeros are on the $j\omega$ axis at positions $\pm j\omega_z$ with $\omega_z = 1/\sqrt{R^2CC_1}$. The notch frequency ω_z is greater than the pole frequency ω_p. Designing the filter section, we determine the parameters T and K as described above. The splitting ratio of the input capacitor is determined by the poles and zeros:

$$\frac{C_2}{C_1} = \frac{\omega_z^2}{\omega_p^2} - 1 \tag{13.22}$$

Finally, in Figure 13.13 we have a Cauer high-pass filter section with a numerator polynomial:

$$N(s) = s^2 RR_1C^2 + 1, \quad R_1 \| R_2 = R \tag{13.23}$$

Here the zero frequency ω_z is less than the pole frequency ω_p. As in the low-pass case, the splitting ratio of the input resistors is determined by these two frequencies:

$$\frac{R_1}{R_2} = \frac{\omega_p^2}{\omega_z^2} - 1 \tag{13.24}$$

The circuit in Figure 13.6 is actually of third order. By matching the passive components, as shown in Figure 13.6, we obtain a second-order transfer function. The question may arise as to what happens if we have a small mismatch due to the tolerances of practical components. In this case, a third pole and a third zero appear on the negative real axis of the s-plane. They do not cancel each other exactly, but approximately. In general, the existence of the third pole and the third zero does not affect the frequency response of the filter significantly. However, there is a second effect due to a small mismatch of passive components that is more severe: the position of the pole pair desired by design is changed. This change can be estimated by the pole sensitivities with respect to the passive elements [4].

13.4 GIC-Derived Dual-Amplifier Biquads

In this section, we consider a class of biquadratic building blocks with two op-amps that are derived from the generalized impedance converter (GIC). A catalog of such building blocks realizing a wide variety of network functions, including elliptic and all-pass ones, was published by Fliege [5].

Figure 13.14b shows the general filter structure, which is based on the resonator with two nullors in Figure 13.14a. Each nullor consists of one nullator and one norator and constitutes a model for the ideal op-amp. Combining the norator between the node between the admittances Y_2 and Y_3 and ground and the nullator across Y_4 and Y_6 yields the op-amp μ_1 in Figure 13.14b. It can readily be verified that the voltage transfer ratio of the circuit in Figure 13.14b with $\mu_i = \infty$, $i = 1, 2$ is given by

$$H(s) = \frac{V_o}{V_i} = \frac{Y_{6b}(Y_2Y_4 + Y_{1a}Y_4) + Y_{1b}(Y_3Y_5 - Y_{6a}Y_4)}{Y_1Y_3Y_5 + Y_2Y_4Y_6} \tag{13.25}$$

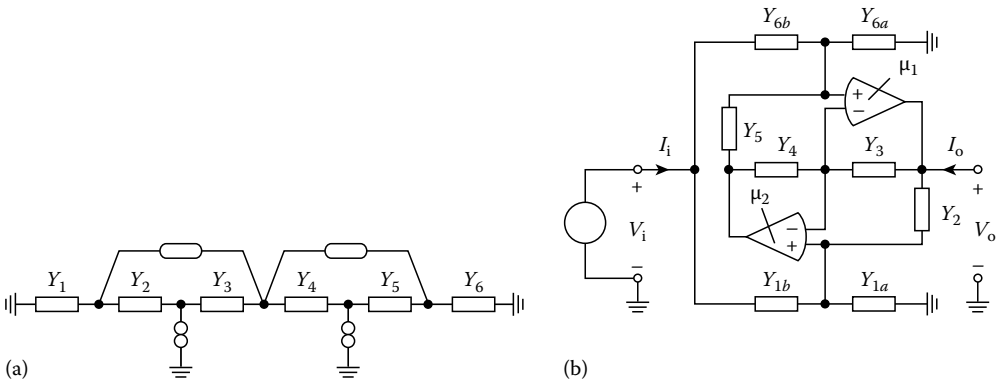

FIGURE 13.14 Resonator with (a) two nullors and (b) the corresponding general dual-amplifier filter structure.

with

$$Y_1 = Y_{1a} + Y_{1b}, \quad Y_6 = Y_{6a} + Y_{6b} \tag{13.26}$$

If we choose the node between Y_4 and Y_5 as the output of the building block we will obtain a similar transfer function. We only have to interchange the admittances Y_1 by Y_6, Y_2 by Y_5, and Y_3 by Y_4.

First, we will derive a second-order low-pass building block from the general structure and we will take this low-pass filter as a prototype for the whole circuit family to explain their advantageous characteristics. If we choose the passive elements of the building block as $Y_{1a} = G_1$, $Y_{1b} = 0$, $Y_2 = G_2$, $Y_3 = sC_3$, $Y_4 = G_4$, $Y_5 = G_5 + sC_5$, $Y_{6a} = 0$, and $Y_{6b} = G_6$ we obtain the low-pass building block in Figure 13.15. Its voltage transfer ratio reads

$$\begin{aligned} H_{\mathrm{LP}}(s) = \frac{V_\mathrm{o}}{V_\mathrm{i}} &= \frac{G_6 G_4 (G_2 + G_1)}{s^2 C_3 C_5 G_1 + s C_3 G_5 G_1 + G_2 G_4 G_6} \\ &= H_0 \cdot \frac{\omega_\mathrm{p}^2}{s^2 + s\omega_\mathrm{p}/Q_\mathrm{p} + \omega_\mathrm{p}^2} \end{aligned} \tag{13.27}$$

with dc gain

$$H_0 = \frac{1 + \alpha_{21}}{\alpha_{21}} \tag{13.28}$$

pole frequency

$$\omega_\mathrm{p} = \sqrt{\frac{\alpha_{21}}{T_{34} T_{56}}} \tag{13.29}$$

and Q-factor

$$Q_\mathrm{p} = \omega_\mathrm{p} \cdot T_{55} \tag{13.30}$$

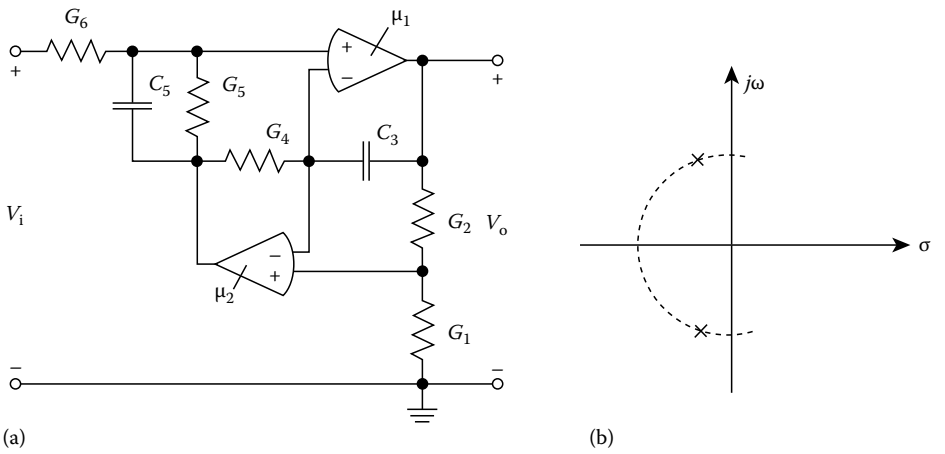

FIGURE 13.15 Second-order low-pass building block. (a) The circuitry. (b) The pole locations.

Here, the time constants are defined as

$$T_{\mu\nu} = \frac{C_\mu}{G_\nu} \tag{13.31}$$

and the conductance ratios as

$$\alpha_{\mu\nu} = \frac{G_\mu}{G_\nu} \tag{13.32}$$

Figure 13.15b shows the location of the finite poles and zeros in the *s*-plane.

In the following, we predefine $G_1 = G_2$, i.e., $\alpha_{21} = 1$, and $T_{34} = T_{56} = T$. This provides optimum pole sensitivities with respect to the passive elements and with respect to the gain-bandwidth products of the operational amplifiers. Hence, the gain factor H_0 always has the value 2.

Based on these parameter restrictions, we can establish an easy design procedure. First, we can choose the capacitors $C_3 = C_5 = C$. Then, given the pole parameters ω_p and Q_p, we determine the two resistors

$$R_4 = R_6 = R = \frac{1}{\omega_p \cdot C} \tag{13.33}$$

and from Equation 13.30 the resistor

$$R_5 = Q_p \cdot R \tag{13.34}$$

There are three key features that make these dual-amplifier biquads particularly favorable for practical applications.

- Biquad building blocks have a low spread of elements. The resistors $R_1 = R_2$ can be chosen freely. The same holds for the two capacitors $C_3 = C_5$. The frequency-determining resistors $R_4 = R_6$ have equal values, too. There is only the *Q*-determining resistor R_5, which differs by a factor of Q_p.
- Relative sensitivities of the gain and the pole parameters with respect to the passive elements are of the same order of magnitude as in case of a second-order passive *RLC* network; see Equation 13.35.
- Impact of the op-amp gain and gain-bandwidth product on the pole parameter is extremely low.

A sensitivity analysis of the biquad circuit in Figure 13.15 gives the following results:

$$\begin{aligned}
&S_{R_1}^{H_0} = -S_{R_2}^{H_0} = -\frac{1}{2}s \\
&S_{R_1}^{\omega_p} = -S_{R_2}^{\omega_p} = -S_{C_3}^{\omega_p} = -S_{R_4}^{\omega_p} = -S_{C_5}^{\omega_p} = -S_{R_6}^{\omega_p} = \frac{1}{2} \\
&S_{R_1}^{Q_p} = -S_{R_2}^{Q_p} = -S_{C_3}^{Q_p} = -S_{R_4}^{Q_p} = +S_{C_5}^{Q_p} = -S_{R_6}^{Q_p} = \frac{1}{2} \\
&S_{R_5}^{Q_p} = 1.
\end{aligned} \tag{13.35}$$

In most practical applications, we can describe the op-amp dynamics by a one-pole model:

$$\mu(s) = \frac{\mu_0}{1 + (s/\omega_c)} = \frac{1}{(1/\mu_0) + (s/\omega_T)} \tag{13.36}$$

with the dc gain μ_0, the 3-dB cutoff frequency ω_c, and the gain-bandwidth product $\omega_T = \mu_0\omega_c = 1/T_T$.

If the circuit elements are chosen properly, e.g., choosing network parameters $\alpha_{21} = 1$ and $T_{34} = T_{56} = T = 1/\omega_p$, an analysis of the impact of the parameters μ_{0i} and $T_{Ti} = 1/\omega_{Ti}$ of the two op-amps μ_i, $i = 1, 2$, on the pole parameters of the transfer function yields

$$\frac{\Delta\omega_p}{\omega_p} \approx \frac{1}{\mu_{01}} - \frac{1}{\mu_{02}} - \frac{T_{T1} + T_{T2}}{T} \tag{13.37}$$

$$\frac{\Delta Q_p}{Q_p} \approx -2Q_p\left(\frac{1}{\mu_{01}} + \frac{1}{\mu_{02}} + \frac{T_{T1} - T_{T2}}{T}\right) \tag{13.38}$$

In case of high pole frequencies the impact of the dc gains μ_{01} and μ_{02} can be neglected against that of the gain-bandwidth products. From Equation 13.37, after some intermediate steps, we obtain

$$\omega_p + \Delta\omega_p \approx \frac{1}{T + T_{T1} + T_{T2}} \tag{13.39}$$

In case of an ideal op-amp we have $\omega_P = 1/T$. The nonideal op-amp causes a pole frequency change $\Delta\omega_p$ due to the time constants T_{Ti}. The frequency determining time constant T of the passive network is increased by the two time constants T_{Ti} of the op-amps, which are reciprocals of the gain-bandwidth products ω_{Ti}.

The most interesting result is the Q-factor change in Equation 13.38. If the frequency responses of the two op-amps are matched, as is usually the case with dual packages, the impact of the two gain-bandwidth products cancels out. Thus, we have nearly no Q enhancement at higher pole frequencies.

To make the GIC-derived biquad almost independent of op-amp parameters, the above-mentioned conditions ($\alpha_{21} = 1$, $T_{34} = T_{56}$) must be met by the passive elements. In a more general view, this result holds for the whole family of GIC-derived building blocks. Each of these building blocks has two frequency-determining time constants and one resistive voltage divider (G_1 and G_2 or G_3 and G_4). In any case, to obtain independence of op-amp parameters we have to choose equal time constants and a voltage divider with equal resistors. If the time constants or the resistors, respectively, do not match exactly, the independence of op-amp parameters remains nearly unchanged.

Next we will derive a bandpass building block from the general biquad in Figure 13.14b. If we choose the passive elements as $Y_{1a} = G_1$, $Y_{1b} = 0$, $Y_2 = G_2$, $Y_3 = G_3$, $Y_4 = sC_4$, $Y_5 = G_5$, $Y_{6a} = sC_6$, and $Y_{6b} = G_6$, we obtain the bandpass building block in Figure 13.16, which has a voltage transfer ratio:

$$\begin{aligned} H_{BP}(s) = \frac{V_o}{V_i} &= \frac{G_6(sC_4G_2 + sC_4G_1)}{s^2C_4C_6G_2 + sC_4G_2G_6 + G_1G_3G_5} \\ &= H_0 \cdot \frac{s}{s^2 + s\omega_p/Q_p + \omega_p^2} \end{aligned} \tag{13.40}$$

with pole frequency

$$\omega_p = \sqrt{\alpha_{12}/(T_{43}T_{65})} \tag{13.41}$$

Q-factor

$$Q_p = \omega_p \cdot T_{66} \tag{13.42}$$

and midband gain

$$H_0Q_p = (1 + \alpha_{12}) \tag{13.43}$$

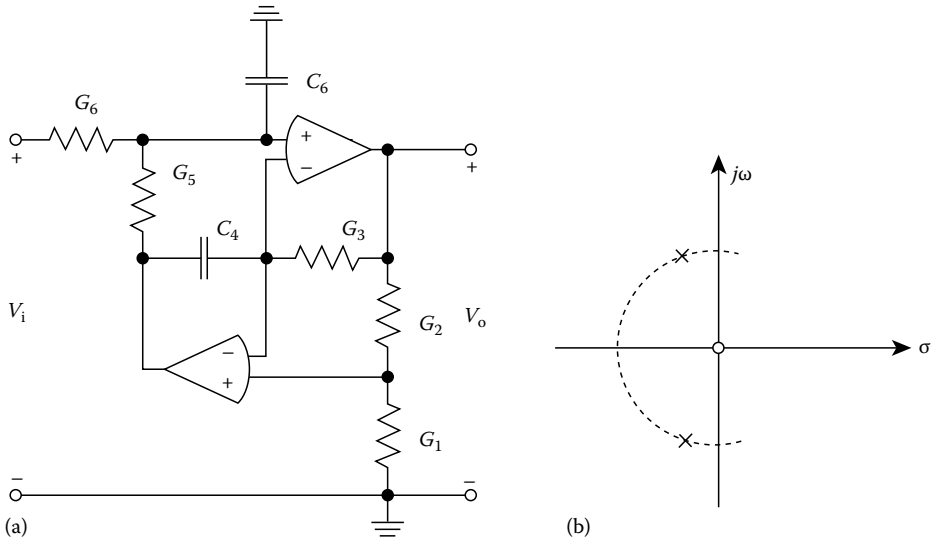

FIGURE 13.16 Second-order bandpass building block. (a) The circuitry. (b) The pole and zero locations.

The filter design is similar to that of the low-pass building block. First we choose the two resistors $R_1 = R_2$ and the two capacitors $C_4 = C_6 = C$. Then, from the pole frequency ω_p we determine the two resistors:

$$R_3 = R_5 = R = \frac{1}{\omega_p \cdot C} \tag{13.44}$$

and from the Q-factor Q_p the resistor

$$R_6 = Q_p \cdot R \tag{13.45}$$

The pole sensitivities with respect to the passive elements and the relationship between the gain and the gain-bandwidth product of the op-amps are the same as in case of the low-pass filters. It should be mentioned that the maximum of the magnitude response $|H(j\omega)|$ occurs at $\omega = \omega_p$ and has exactly the value 2, independent of the Q-factor and the time constants of the circuit*; see Equation 13.43.

We can derive a high-pass building block by choosing the following elements: $Y_{1a} = G_1$, $Y_{1b} = 0$, $Y_2 = G_2$, $Y_3 = G_3$, $Y_4 = sC_4$, $Y_5 = G_5$, $Y_{6a} = G_6$, and $Y_{6b} = sC_6$; see Figure 13.17.

This filter circuit has a voltage transfer ratio

$$\begin{aligned} H_{HP}(s) = \frac{V_o}{V_i} &= \frac{sC_6(sC_4G_2 + sC_4G_1)}{s^2C_4C_6G_2 + sC_4G_2G_6 + G_1G_3G_5} \\ &= (1 + \alpha_{12}) \cdot \frac{s^2}{s^2 + s\omega_p/Q_p + \omega_p^2} \end{aligned} \tag{13.46}$$

with ω_p as in Equation 13.41 and Q_p as in Equation 13.42.

The design of the high-pass building block in Figure 13.17 is identical to that of the bandpass described above. Both building blocks also have the same pole sensitivities and the same impact of the op-amps on the pole parameters.

* Only assuming $\alpha_{12} = 1$.

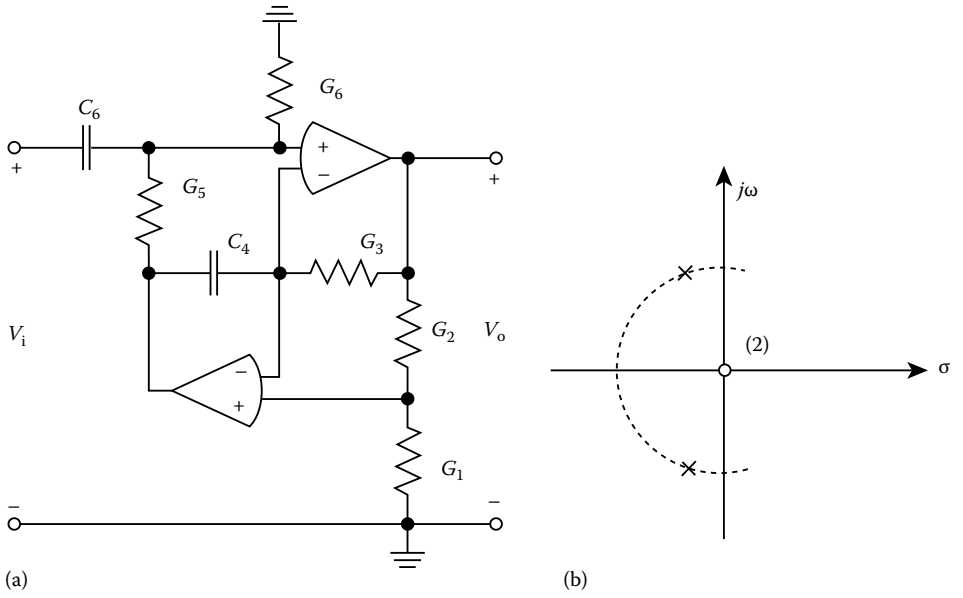

FIGURE 13.17 Second-order high-pass building block. (a) The circuitry. (b) The pole and zero locations.

If we feed the input signal not only through the capacitor C_6, but additionally through the element G_1, and if we set again $\alpha_{12} = 1$ we obtain the all-pass building block in Figure 13.18.

Its voltage transfer ratio reads

$$H_{AP}(s) = \frac{V_o}{V_i} = \frac{s^2 C_6 C_4 G_2 - sC_4 G_1 G_6 + G_1 G_3 G_5}{s^2 C_4 C_6 G_2 + sC_4 G_2 G_6 + G_1 G_3 G_5} = \frac{s^2 - \dfrac{s}{T_{66}} + \dfrac{1}{T_{43} T_{65}}}{s^2 + \dfrac{s}{T_{66}} + \dfrac{1}{T_{43} T_{65}}} \tag{13.47}$$

The all-pass building block is designed exactly as the high-pass or bandpass circuit.

From the all-pass building block, we can derive a second-order notch filter by adding a conductor G_{6b} in parallel with the capacitor G_6; see Figure 13.19.

The circuit in Figure 13.19 has the general voltage transfer ratio

$$H(s) = \frac{V_o}{V_i} = \frac{sC_6 C_4 G_2 + sC_4 (G_2 G_{6b} - G_1 G_{6a}) + G_1 G_3 G_5}{s^2 C_4 C_6 G_2 + sC_4 G_2 G_6 + G_1 G_3 G_5} \tag{13.48}$$

with $G_6 = G_{6a} + G_{6b}$. By setting $G_2 G_{6b} = G_1 G_{6a}$ (normally $G_1 = G_2$ and $G_{6a} = G_{6b}$) we obtain a second-order notch filter with a voltage transfer ratio:

$$H(s) = \frac{s^2 + \dfrac{\alpha_{12}}{T_{43} T_{65}}}{s^2 + \dfrac{s}{T_{66}} + \dfrac{\alpha_{12}}{T_{43} T_{65}}} \tag{13.49}$$

where $\alpha_{12} = 1$ if $G_1 = G_2$.

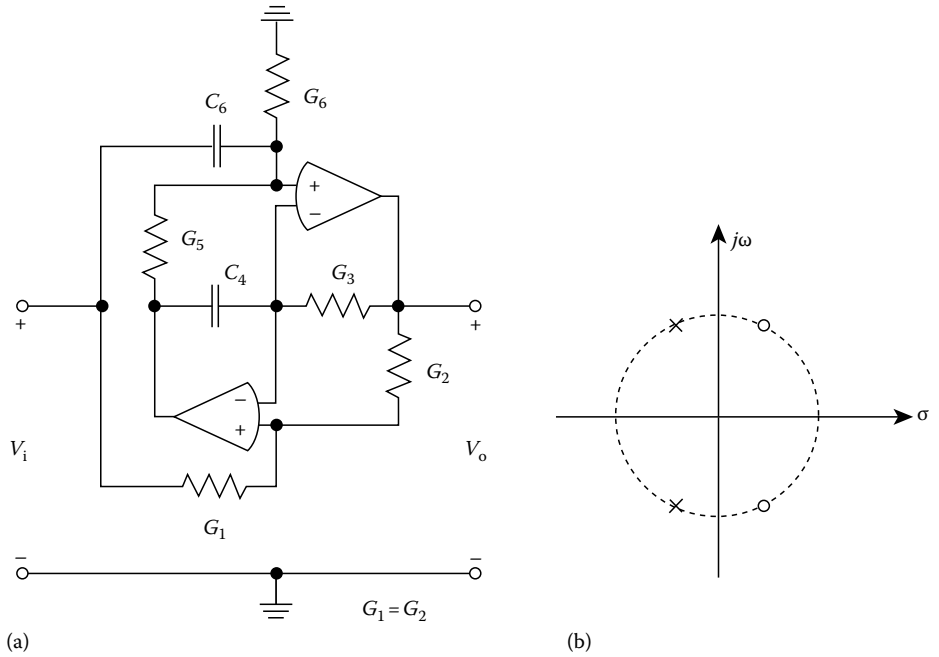

FIGURE 13.18 Second-order all-pass building block. (a) The circuitry. (b) The pole and zero locations.

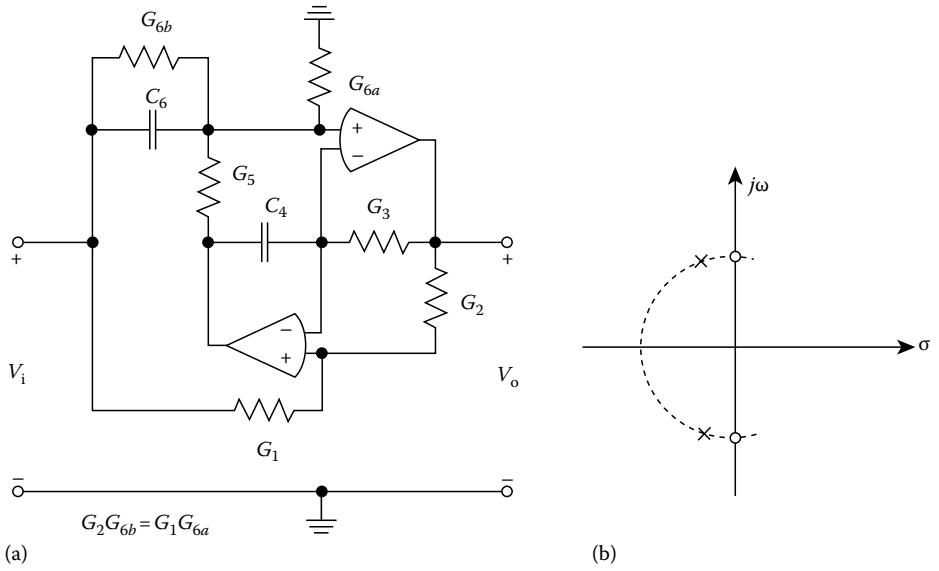

FIGURE 13.19 Notch filter building block. (a) The circuitry. (b) The pole and zero locations.

Finally we will derive two second-order elliptic or Cauer-type building blocks from the general dual-amplifier structure in Figure 13.14b. To get a Cauer low-pass building block we take $Y_{1a} = G_1$, $Y_{1b} = C_1$, $Y_2 = G_2$, $Y_3 = G_3$, $Y_4 = G_4$, $Y_5 = sC_5$, $Y_{6a} = 0$, and $Y_{6b} = G_6$; see Figure 13.20.

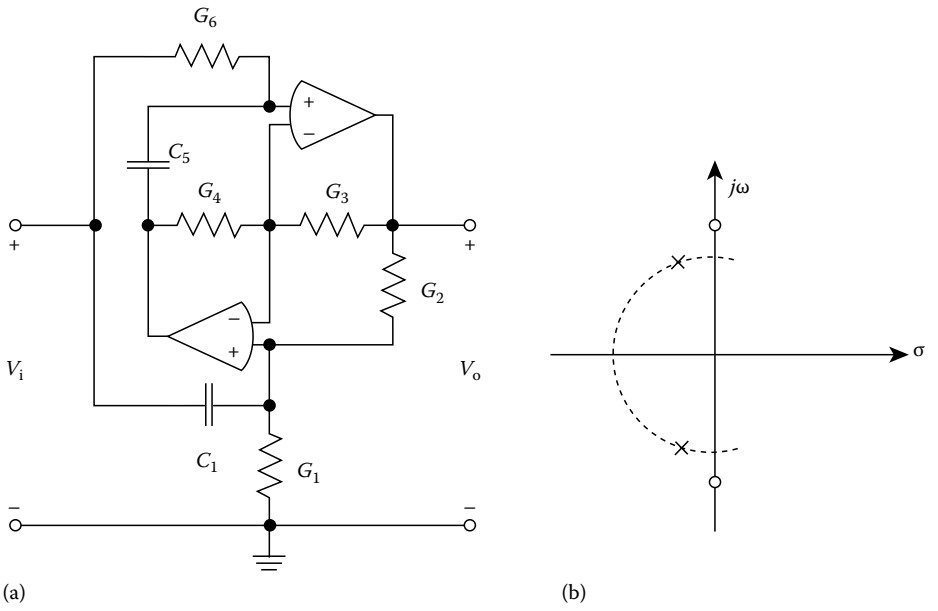

FIGURE 13.20 Second-order Cauer low-pass building block. (a) The circuitry. (b) The pole and zero locations.

This filter circuit has a voltage transfer ratio

$$\begin{aligned} H(s) = \frac{V_o}{V_i} &= \frac{s^2 C_1 G_3 C_5 + G_6(G_2 G_4 + G_1 G_4)}{s^2 C_1 G_3 C_5 + s G_1 G_3 C_5 + G_2 G_4 G_6} \\ &= \frac{s^2 + \dfrac{\alpha_{43}(1+\alpha_{12})}{T_{12} T_{56}}}{s^2 + \dfrac{s}{T_{11}} + \dfrac{\alpha_{43}}{T_{12} T_{56}}} \\ &= \frac{s^2 + \omega_z^2}{s^2 + s\omega_p / Q_p + \omega_p^2} \end{aligned} \tag{13.50}$$

The magnitude ω_z of the zeros is always greater than the magnitude ω_p of the poles. Additionally, without any matching of elements, the real part of the zeros is always zero.

The design can proceed in the following steps. First we predefine $\alpha_{43} = 1$ and choose due to practical considerations the values of the resistors $R_3 = R_4$. We also select the two capacitors C_1 and C_5. Then, comparing the first coefficient in the denominator of $H(s)$ in Equation 13.50, namely, $T_{11} = Q_p/\omega_p$ with $T_{11} = C_1 R_1$, we determine the resistor

$$R_1 = \frac{Q_p}{\omega_p C_1} \tag{13.51}$$

Further, comparing the last coefficients in the numerator and denominator yields

$$\frac{\omega_z^2}{\omega_p^2} = 1 + \alpha_{12} \tag{13.52}$$

With $\alpha_{12} = R_2/R_1$ we can solve Equation 13.52 for

$$R_2 = R_1 \cdot \left(\frac{\omega_z^2}{\omega_p^2} - 1 \right) \tag{13.53}$$

Finally, from $\omega_p^2 = 1/(T_{12}T_{56})$ we can determine the resistor

$$R_6 = \frac{1}{\omega_p^2 C_1 C_5 R_2} \tag{13.54}$$

In order to get the three resistors R_1, R_2, and R_6 in the same order of magnitude it might be advisable to predefine different values for the capacitors C_1 and C_5.

A Cauer high-pass building block is depicted in Figure 13.21. Its voltage transfer ratio reads

$$\begin{aligned} H(s) = \frac{V_o}{V_i} &= \frac{s^2 C_2 G_4 C_6 + G_1(G_3 G_5 - G_6 G_4)}{s^2 C_2 G_4 C_6 + s G_6 G_4 C_2 + G_1 G_3 G_5} \\ &= \frac{s^2 + \dfrac{\alpha_{34} - \alpha_{65}}{T_{21} T_{65}}}{s^2 + s\dfrac{1}{T_{11}} + \dfrac{\alpha_{43}}{T_{12} T_{56}}} \\ &= \frac{s^2 + \omega_z^2}{s^2 + s\omega_p/Q_p + \omega_p^2} \end{aligned} \tag{13.55}$$

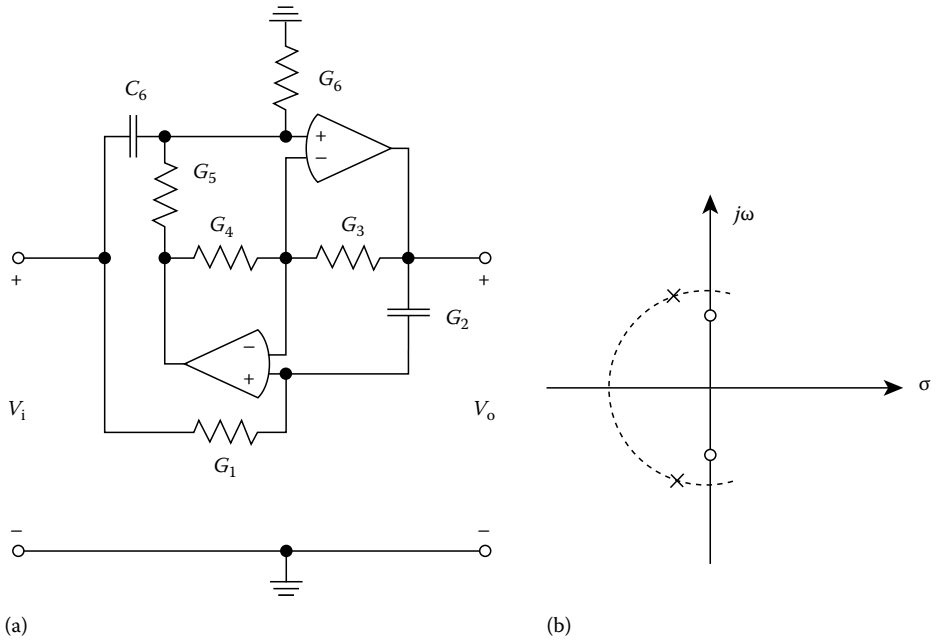

FIGURE 13.21 Second-order Cauer high-pass building block. (a) The circuitry. (b) The pole and zero locations.

The design of this building block is similar to that of the low-pass circuit. First we choose the resistors $R_3 = R_4$ and the capacitors C_2 and C_6 and then, with predefined parameters Q_p, ω_p, and ω_z, we determine the remaining three resistors:

$$R_6 = \frac{Q_p}{\omega_p C_6} \tag{13.56}$$

$$R_5 = R_6 \cdot \left(1 - \frac{\omega_z^2}{\omega_p^2}\right) \tag{13.57}$$

$$R_1 = \frac{1}{\omega_p^2 C_6 C_2 R_5} \tag{13.58}$$

13.5 GIC-Derived Three-Amplifier Biquads

In order to get more flexibility for realizing arbitrary second-order transfer functions and to obtain less resistor spread for realizing a given pole-Q, we can extend the resonator in Figure 13.14a to a resonator with three nullors; see Figure 13.22.

There are two different biquads known from the literature that are based on the resonator in Figure 13.22. The first one is proposed by Mikhael and Bhattacharyya [6] and is shown in Figure 13.23.

This filter circuit requires a small resistor spread to realize high pole-Q. The zeros of the transfer function are formed with a resistive feed-forward network providing a flexible design with arbitrary numerator coefficients. The voltage transfer ratio V_3/V_i is

$$H_3(s) = \frac{V_3}{V_i} = \frac{N_3(s)}{D(s)} \tag{13.59}$$

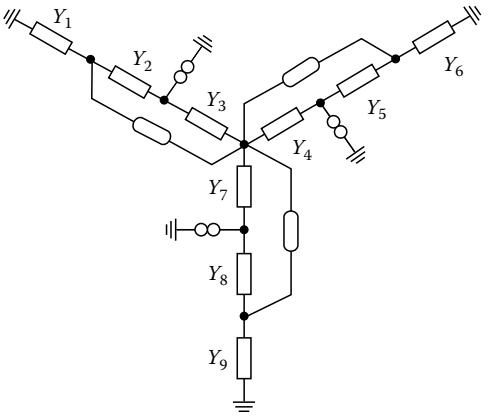

FIGURE 13.22 Resonator with three nullors.

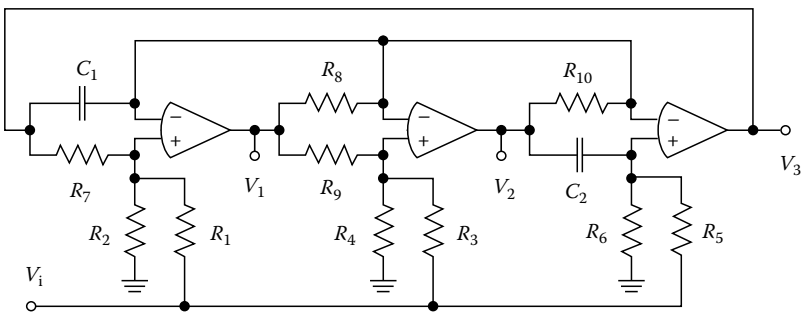

FIGURE 13.23 Mikhael–Bhattacharyya biquad.

with

$$N_3(s) = s^2C_1C_2G_1G_9 + sC_2(G_7G_8G_3 + G_8G_2G_3 - G_8G_1G_4) + (G_9G_7G_{10}G_5 + G_9G_{10}G_2G_5 - G_9G_{10}G_4G_6) \tag{13.60}$$

and

$$D(s) = s^2C_1C_2(G_1G_9 + G_2G_9) + sC_2(G_7G_8G_3 + G_7G_8G_4) + (G_9G_7G_{10}G_5 + G_9G_{10}G_7G_6) \tag{13.61}$$

The two other output nodes lead to similar transfer expressions.

The second biquad, which is based on the resonator in Figure 13.22, was proposed by Padukone et al. [7] and is depicted in Figure 13.24. Assuming ideal op-amps and choosing V_3 as output voltage, we obtain the following transfer function:

$$H_3(s) = \frac{V_3}{V_i} = \frac{N_3(s)}{D(s)} \tag{13.62}$$

with

$$N_3(s) = s^2[C_2C_3(G_2G_6 - G_1G_3) + C_1C_2G_1G_8] + s[C_1G_2G_5G_9 - C_3G_2G_5G_7 + C_2G_1G_4G_8] + (G_2G_4G_5G_9) \tag{13.63}$$

and

$$D(s) = s^2(C_1 + C_3)C_2G_2G_6 + sC_2G_1G_4(G_3 + G_8) + G_2G_4G_5(G_7 + G_9) \tag{13.64}$$

It has been shown [7] that the pole sensitivities to all passive components are not greater than unity. The filter section has the main advantage of being particularly insensitive to gain-bandwidth variations even when the op-amps are mismatched.

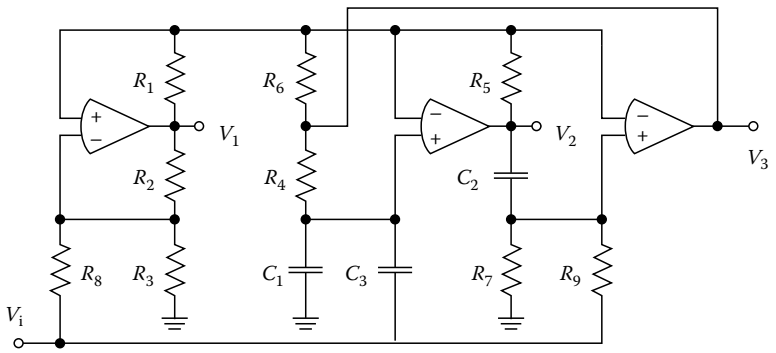

FIGURE 13.24 Padukone–Mulawka–Ghausi biquad.

13.6 State-Variable-Based Biquads

A frequently-used multiple-amplifier biquad is the circuit proposed by Kerwin et al. [8]. This filter circuit has extreme flexibility, good performance, and low sensitivities to the passive components. The filter is based on analog computer structures [9], which are derived from the state-variable representation of linear continuous systems. Therefore, these filters are also referred to as *state-variable filters*.

Figure 13.25a shows the basic analog computer structure consisting of one summing amplifier and two integrators. We assume both integrators to have the same transfer function $-1/(sT)$, where T is called the integrator time constant. Analyzing this structure yields

$$V_1 = -K_1 \cdot V_3 + K_2 \cdot V_i + K_3 \cdot V_2 \tag{13.65}$$

$$V_2 = -\frac{1}{sT} \cdot V_1 \tag{13.66}$$

$$V_3 = -\frac{1}{sT} \cdot V_2 \tag{13.67}$$

which results in

$$H_{HP}(s) = \frac{V_1}{V_i} = \frac{s^2T^2K_2}{s^2T^2 + sTK_3 + K_1} \tag{13.68}$$

Using Equation 13.66, we can immediately derive the voltage transfer ratio V_2/V_i from Equation 13.68:

$$H_{BP}(s) = \frac{V_2}{V_i} = \frac{-sTK_2}{s^2T^2 + sTK_3 + K_1} \tag{13.69}$$

Finally, with Equation 13.67 we obtain from Equation 13.69

$$H_{LP}(s) = \frac{V_3}{V_i} = \frac{K_2}{s^2T^2 + sTK_3 + K_1} \tag{13.70}$$

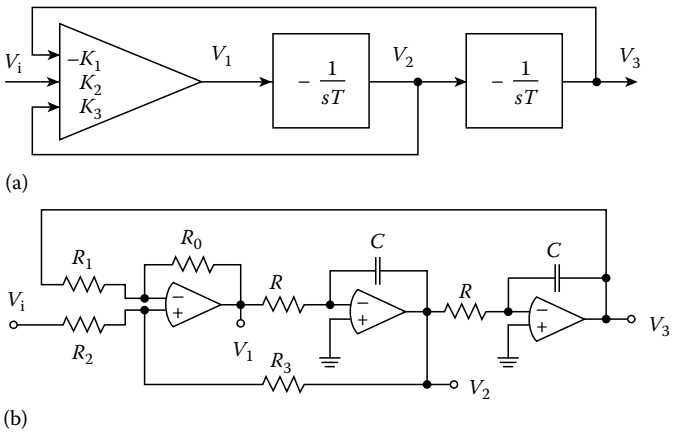

FIGURE 13.25 (a) Second-order analog computer structure and (b) state-variable filter section proposed by Kerwin, Huelsman, and Newcomb.

Thus, the structure in Figure 13.25a simultaneously realizes a high-pass filter, a bandpass filter, and a low-pass filter. The corresponding filter circuit proposed by Kerwin, Huelsman, and Newcomb is depicted in Figure 13.25b. The integrators consist of one op-amp, one resistor R, and one capacitor C. The time constant is given by $T = RC$. The three gain factors of the summing amplifier are determined by the four resistors $R_0 - R_3$:

$$K_1 = \frac{R_0}{R_1} \tag{13.71}$$

$$K_2 = \frac{R_3}{R_2 + R_3}\left(1 + \frac{R_0}{R_1}\right) \tag{13.72}$$

$$K_3 = \frac{R_2}{R_2 + R_3}\left(1 + \frac{R_0}{R_1}\right) \tag{13.73}$$

Obviously, the integrator time constant T plays the role of a reciprocal normalization frequency. Thus, if we refer the frequency variable s to $1/T$, we obtain from Equation 13.70 the normalized low-pass transfer function:

$$H_{\mathrm{LP}}(s) = \frac{V_3}{V_\mathrm{i}} = \frac{K_2}{s^2 + sK_3 + K_1} \tag{13.74}$$

Given the normalized pole frequency ω_p and the pole Q-factor Q_p, we can design the filter section by equating

$$K_1 = \omega_\mathrm{p}^2 \tag{13.75}$$

and

$$K_3 = \frac{\omega_\mathrm{p}}{Q_\mathrm{p}} \tag{13.76}$$

Then K_2 is fixed by the dc gain of the transfer function:

$$K_2 = H_0 \tag{13.77}$$

The state-variable filter circuit can be extended to a general biquad by adding an output amplifier that sums the three voltages V_1, V_2, and V_3. Figure 13.26a shows a state-variable filter with an output amplifier summing the voltages V_1, V_2, and V_3 of the circuit in Figure 13.25b. This biquad has been proposed also by Kerwin et al. [8]. As alternative circuits, the amplifiers in Figure 13.26b and c can be used. Figure 13.26b shows an output amplifier that realizes the following sum:

$$V_\mathrm{o} = \alpha_1 V_1 + \alpha_2 V_2 + \alpha_3 V_3 \tag{13.78}$$

with

$$\alpha_1 = -\frac{R_{10}}{R_{11}}, \quad \alpha_2 = \frac{R_{14}}{R_{12} + R_{14}}\left(1 + \frac{R_{10}}{R_{11} \| R_{13}}\right), \quad \alpha_3 = -\frac{R_{10}}{R_{13}} \tag{13.79}$$

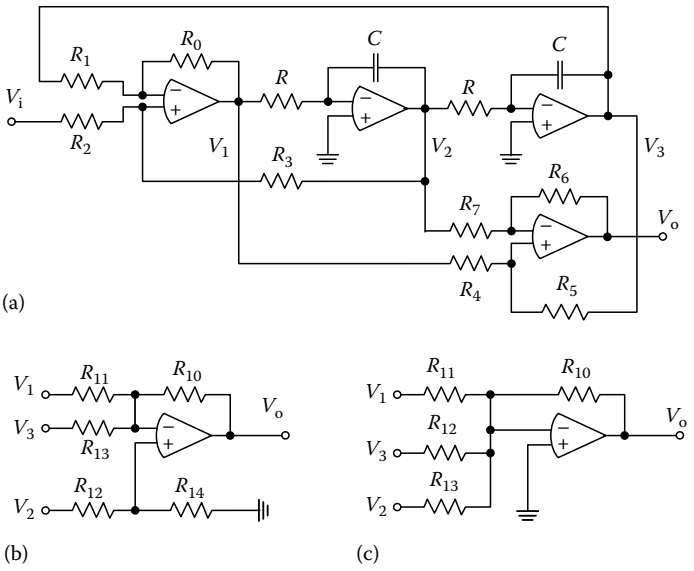

FIGURE 13.26 (a) State-variable filter with output amplifier, (b) output amplifier with inverting and noninverting inputs, and (c) output amplifier with three inverting inputs.

If we solve Equations 13.68 through 13.70 for the three output voltages and substitute them in Equation 13.79 with normalized variables s we obtain

$$H(s) = \frac{V_o}{V_i} = -K_2 \frac{|\alpha_1|s^2 + |\alpha_2|s + |\alpha_3|}{D(s)} \tag{13.80}$$

All numerator coefficients have the same sign. Therefore, the zeros of the transfer function are in the left-s-half plane. If we set $\alpha_2 = 0$, i.e., if we delete the voltage divider R_{12}, R_{14} and ground the noninverting input terminal of the op-amp, we obtain zeros on the $j\omega$ axis.

When designing the biquad, R_{14} and R_{10} may be used to scale the impedance level of the two resistive subnetworks. Then from the three numerator coefficients or from the overall gain constant of the transfer function, the zero frequency ω_z, and the zero Q-factor Q_z we can easily determine the remaining resistors R_{11}, R_{12}, and R_{13}.

The output amplifier in Figure 13.26c has three inverting inputs. Summing the voltages V_1, V_2, and V_3 leads to a numerator polynomial where the sign of the middle coefficient is different from the sign of the other two. Thus, the zeros are in the right-s-half plane. Again, we can delete the resistor R_{12} to realize zero on the $j\omega$ axis.

A second state-variable biquad circuit proposed by Tow and Thomas [10–12] yields similar performance to that of the Kerwin–Huelsman–Newcomb circuit. It uses a feedback loop with one damped integrator, one integrator, and one inverting amplifier; see Figure 13.27a. Figure 13.27b shows the Tow–Thomas circuit with three op-amps.

The damped integrator has a transfer function

$$\frac{V_1}{V_3} = \left.\frac{-1}{sT + \alpha}\right|_{V_i=0} \tag{13.81}$$

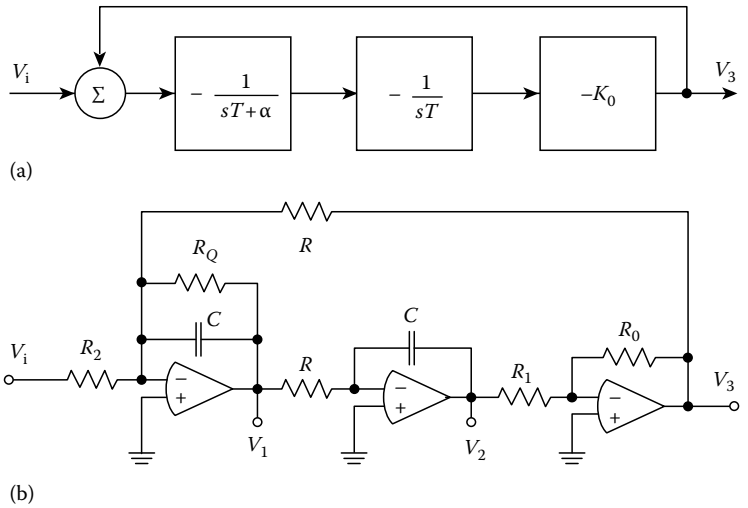

FIGURE 13.27 (a) Principle and (b) three op-amp realization of Tow–Thomas filter.

with $T = RC$ and $\alpha = R/R_Q$. The inverting amplifier has a gain

$$\frac{V_3}{V_2} = -\frac{R_0}{R_1} = -K_0 \tag{13.82}$$

An analysis of the circuit in Figure 13.27b with V_i being the input voltage and V_3 the output voltage yields a transfer function

$$H_{LP}(s) = \frac{V_3}{V_i} = \frac{-K_0\alpha_2}{s^2T^2 + sTK_Q + K_0} \tag{13.83}$$

with

$$K_0 = \frac{R_0}{R_1}, \quad \alpha_2 = \frac{R}{R_2}, \quad K_Q = \frac{R}{R_Q} \tag{13.84}$$

For the design of the filter, the integrator time constant T serves as a reciprocal normalization frequency. Then, from the predefined normalized pole frequency we can determine the resistor ratio K_0, from the pole Q-factor the ratio K_Q, and from the dc gain of the filter section the ratio α_2. Choosing convenient values for C and R_0, we finally determine the resistors R, R_1, R_Q, and R_2 from the parameters T, K_0, K_Q, and α_2, respectively.

The filter circuit in Figure 13.26 requires an additional op-amp to realize a transfer function with a general second-degree numerator polynomial. An alternative method is to feed fractions of the input signal forward into the input of each op-amp. This is realized in the multiple-input Tow–Thomas biquad [10]; see Figure 13.28. The transfer function of this circuit can be calculated to be

$$H(s) = \frac{V_o}{V_i} = -\frac{s^2T^2\alpha_4 + sT(K_Q\alpha_4 - K_0\alpha_3) + [K_0(\alpha_2 - K_Q\alpha_3)]}{s^2T^2 + sTK_Q + K_0} \tag{13.85}$$

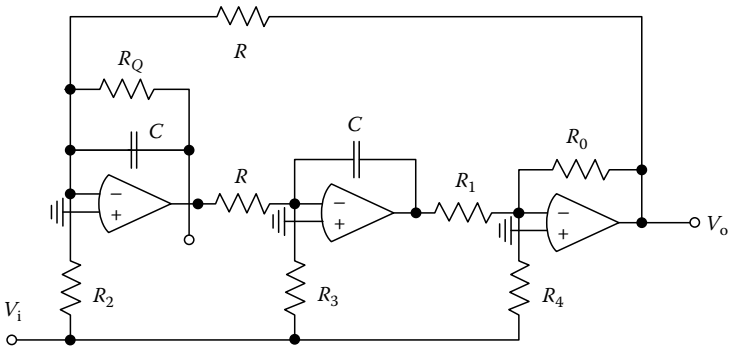

FIGURE 13.28 Generalized Tow–Thomas biquad.

with K_0, α_2, and K_Q as defined in Equation 13.84 and

$$\alpha_3 = \frac{R}{R_3}, \quad \alpha_4 = \frac{R_0}{R_4} \tag{13.86}$$

Thus, arbitrary numerator coefficients can be predescribed. In particular, if we choose $\alpha_3 = \alpha_4 = 0$ we obtain the low-pass filter circuit in Figure 13.27b and the transfer function in Equation 13.83.

When the state-variable filters described above are used to realize high-Q filter functions, the Q practically obtained is usually higher than that desired in the design. This effect is called Q enhancement and is caused by the phase lag introduced by the nonideal op-amps. One way to solve this problem is to use integrators with phase compensation.

Figure 13.29 shows a noninverting integrator with an additional op-amp for phase lag compensation. A detailed description of this circuit can be found in Ref. [13]. Putting this noninverting integrator together with an inverting integrator in a feedback loop results in a resonator with a Q-factor that is almost independent of the gain-bandwidth product of the op-amps. Thus, nearly no Q enhancement occurs.

Exactly this feedback loop is used in the Åkerberg–Mossberg biquad [14]; see Figure 13.30. In this circuit, a noninverting integrator with phase lag compensation together with an inverting damped integrator is connected as a feedback loop. More details about this filter section can be found in Refs. [4,13,14].

Finally, let us consider the general biquad proposed by Berka and Herpy [15]; see Figure 13.31. This biquad is also based on a state-variable representation and requires a second-order differentiator and a damped integrator. One of the main advantages of this circuit is extremely low sensitivities. A detailed description of the filter circuit and its design can be found in Ref. [4].

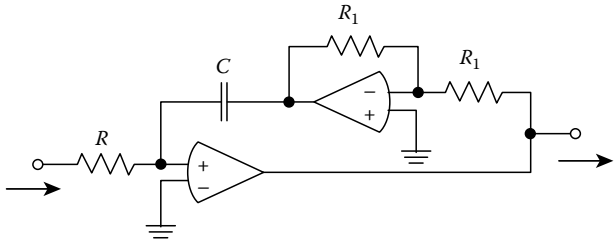

FIGURE 13.29 Noninverting integrator using an additional op-amp to compensate for phase lag.

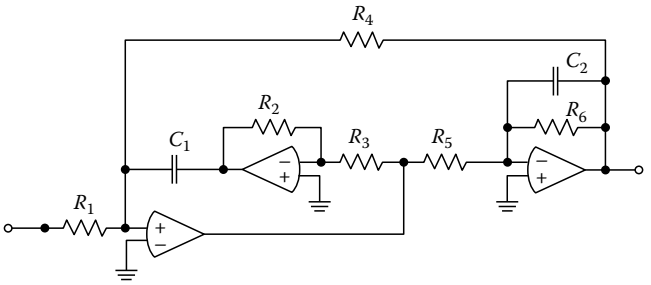

FIGURE 13.30 Åkerberg–Mossberg biquad.

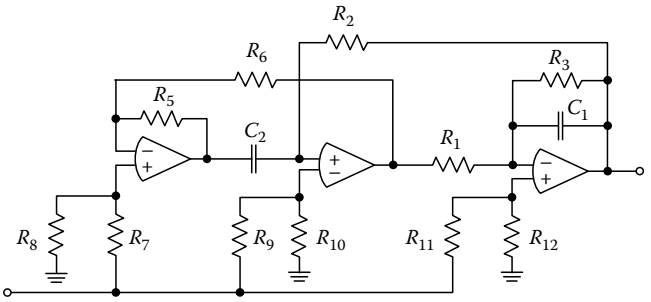

FIGURE 13.31 Berka–Herpy biquad.

13.7 All-Pass-Based Biquads

Finally, we will briefly consider two circuits that are based on first-order all-pass sections. Figure 13.32 shows the classical filter circuit introduced by Tarmy and Ghausi [16].

In this circuit, amplifiers with differential inputs and differential outputs are used. In the feedback loop, two all-pass sections with voltage transfer ratios

$$H_i(s) = \frac{sT_i - 1}{sT_i + 1} \tag{13.87}$$

$T_i = R_iC_i$, $i = 1, 2$, and one inverting amplifier are cascaded. The overall transfer function is

$$H(s) = \frac{V_o}{V_i} = \alpha_1 \frac{s^2T_1T_2 - s(T_1 + T_2) + 1}{s^2T_1T_2 + s\alpha_2(T_1 + T_2) + 1} \tag{13.88}$$

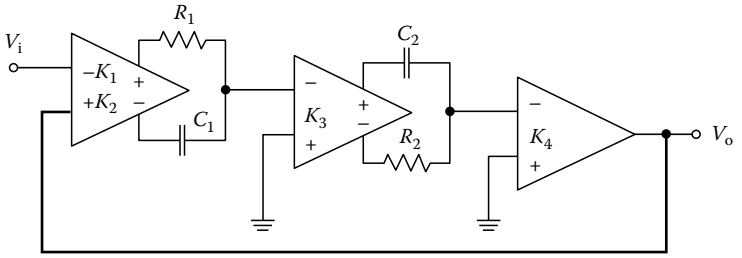

FIGURE 13.32 Tarmy–Ghausi circuit.

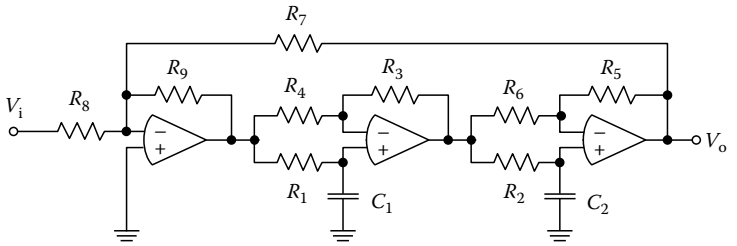

FIGURE 13.33 Tarmy–Ghausi circuit modified by Moschytz.

with

$$\alpha_1 = \frac{K_1K_3K_4}{1 + K_2K_3K_4}, \quad \alpha_2 = \frac{1 - K_2K_3K_4}{1 + K_2K_3K_4} \tag{13.89}$$

The main advantages of the Tarmy–Ghausi circuit are its low sensitivities to the gain-bandwidth products of the op-amps and thus its favorable performance at high pole frequencies and high pole Q-factors.

Most of the popular low-cost op-amps are not configured for differential output operations. This problem is bypassed by a circuit proposed by Moschytz [17]; see Figure 13.33.

The circuit in Figure 13.33 is also based on first-order all-pass sections. But the all-pass circuits are realized by means of only single-ended op-amps. Therefore, this circuit is more convenient for practical realizations.

13.8 Summary

In this chapter, we have shown that a lot of different multiple-amplifier biquads are known from the literature. Hence, a design engineer who aims to realize a high-performance active filter is in the favorable situation to find a rich variety of alternative circuits and design methods. On the other hand, this variety is also confusing and the design engineer may need assistance in deciding among all these circuits and methods. Unfortunately, the multiple-amplifier biquads mentioned in this chapter cannot be classified in a simple way. Therefore, only a rough guidance can be given. In a practical case, it is advisable to compare two or three solutions next to the predefined demands by a thorough analysis and then to find the final solution.

The biquads with decoupled time constants offer some of the benefits mentioned at the beginning of this section at low costs, namely, small passive element spread and low sensitivities. The dual-amplifier twin-T biquads and the GIC-derived dual-amplifier biquads offer a trade-off between costs and performance. The twin-T biquads are particularly suitable for the design of elliptic filters. The special merits of the GIC-derived biquads are the small number of passive components and the independence of the op-amp parameters. Thus, this biquad represents a robust filter solution for many different applications. Additionally, these filters can be easily designed.

The GIC-derived three-amplifier biquads and the state-variable-based filters offer additional flexibility with respect to an independent choice and an independent tuning of the filter parameters. Typically, these circuits are used in applications with switched parameters, e.g., filters with switched cutoff frequencies. This flexibility is paid for by a higher number of op-amps and passive components. It should be mentioned that the original state-variable circuits, i.e., two integrators in a loop, are rather sensitive to the phase lag introduced by the nonideal op-amps. This is always a problem when simultaneously high-frequency and high-Q performance shall be achieved. In such applications, biquads with compensated phase lag should be applied, e.g., the biquads proposed by Åkerberg and Mossberg, Berka and Herpy, or Tarmy and Ghausi.

14.1 Introduction

Current generalized immittance convertors (CGICs) have been used to realize high-performance active biquads with 2 OAs, 3 OAs, or n OAs per sections [1,5].

In this chapter two- and three-amplifier biquads are presented that are based on CGICs. Although several biquads have been reported, the ones presented here have proved to be clearly superior

* Wasfy B. Mikhael, "Chapter 9: Biquad II," in *RC Active Filter Design Handbook*, Stephenson, New York: Wiley, 1985.

to single-amplifier biquads. This is because the design carried out [1] was constrained by stringent performance criteria satisfying important properties and features such as stability, versatility, insensitivity to component tolerances and drift, low dependence on the op-amp (OA) frequency limitations, finite gain, tunability, small spread in component values, and minimum total capacitance.

In addition, the performance of the CGIC-based biquads presented here are comparable to multiple OA biquads. On the other hand, the 3-OA CGIC biquad is shown to yield additional performance improvements over the 2-OA CGIC biquad. Also, the CGIC biquads use the OAs in the differential mode.

In the following discussion the generalized structure of the 2-OA and 3-OA CGIC biquads are presented. Illustrative examples of the element identification to realize the most commonly used biquads are tabulated. Stability and sensitivity properties are discussed. A design procedure for each biquad is described that minimizes the active sensitivities while maintaining the filter's stability. Several second-order design examples are given. A sixth-order Chebyshev LPF and a sixth-order elliptic BPF are designed using the design values and tuning procedure suggested. The excellent performance of the resulting realizations is experimentally verified. A universal 2-OA GIC hybrid implementation using thick film is also described. 2-OA CGIC biquadratic active filter realizations for extended high-frequency applications employing the composite operational amplifiers technique [2,3] are given.

14.2 Biquadratic Structure Using the Antoniou CGIC (2-OA CGIC Biquad)

Consider the network of Figure 14.1, which is simply Antoniou's CGIC [4], with two new ports created across 3-G and 4-G. This is represented symbolically in Figure 14.2.

A new configuration is now obtained, as shown in Figure 14.3. A synthesis procedure is now described that uses this configuration. The transfer functions between the input and output terminals 2, 3, and 4, assuming ideal OAs are readily obtained as

$$\frac{V_3}{V_1} = T_1 = \{Y_5 + h(s)[Y_7(1 + Y_6/Y_2) - Y_5Y_8/Y_2]\}/D(s) \tag{14.1a}$$

$$\frac{V_4}{V_i} = T_2 = [Y_5(1 + Y_8/Y_4) - Y_6Y_7/Y_4 + h(s)Y_7]/D(s) \tag{14.1b}$$

$$\frac{V_2}{V_i} = T_3 = [Y_5 + h(s)Y_7]/D(s) \tag{14.1c}$$

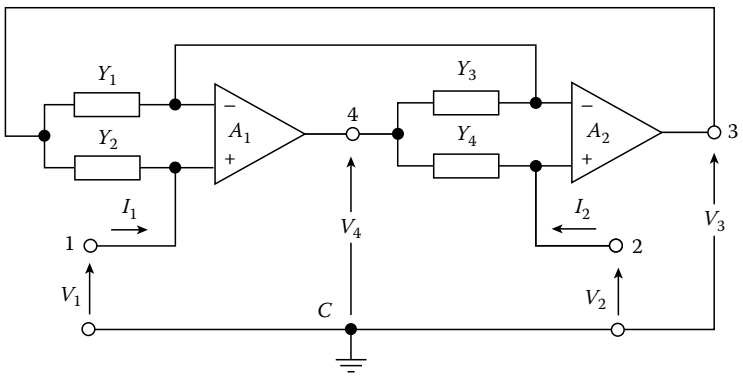

FIGURE 14.1 Antoniou's CGIC with additional ports 3*G* and 4*G*.

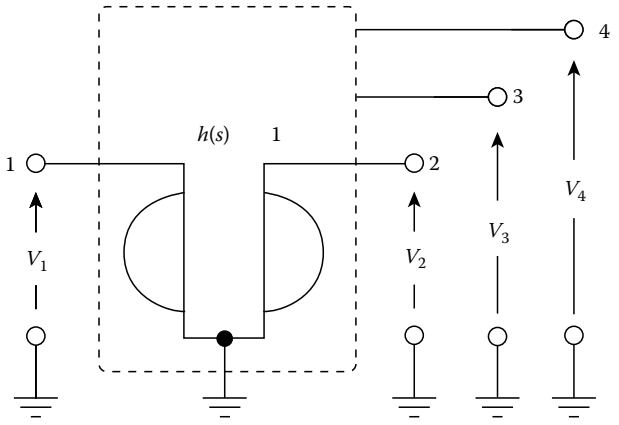

FIGURE 14.2 Symbolic representation of the CGIC in Figure 14.1.

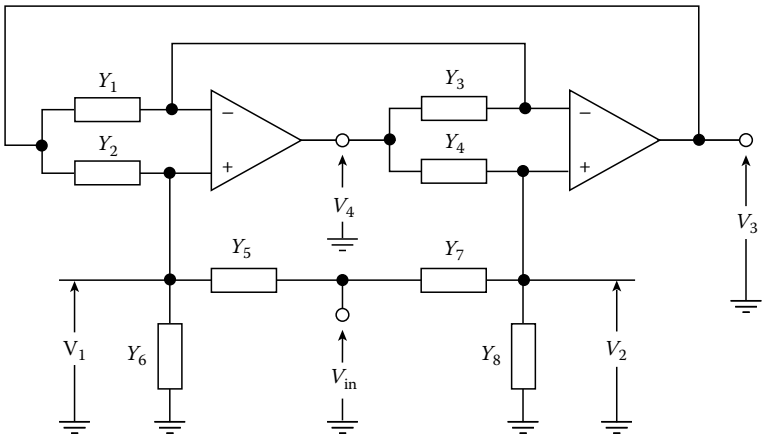

FIGURE 14.3 Basic configuration.

where

$$\begin{aligned} h(s) &= Y_2Y_3/Y_1Y_4 \\ D(s) &= (Y_5 + Y_6) + h(s)(Y_7 + Y_8) \end{aligned} \tag{14.1d}$$

The conversion function $h(s)$ and the admittances Y_5–Y_8 can be selected in many different ways, and it is clear that any stable second-order transfer function with any desired zero and pole locations can be realized.

Letting

$$Y_i = sC_i + G_i \tag{14.2}$$

where $i = 1$–4, we have from Equation 14.1

$$h(s) = \frac{(sC_2 + G_2)(sC_3 + G_3)}{(sC_1 + G_1)(sC_4 + G_4)} \tag{14.3}$$

Clearly, by omitting one or more conductances and/or capacitances, a number of specific conversion functions can be generated.

14.3 Realization of the Most Commonly Used Biquad Functions Using the 2-OA CGIC

The most frequently used second-order transfer functions have already been described in Chapter 11. Realizations of these functions are given in Table 14.1. The LP, HP, BP, and BS sections are produced by choosing $h(s)$ in a simple manner such as $K_1 s$, $K_2 s^2$, $K_3 s + K_4 s^2$ or their reciprocals. Circuits 3, 4, and 7 can be regarded as realizations of simple RLC networks [4,5]. Second-order AP sections can be obtained from circuits 11 and 12 of Table 14.1.

Figures 14.1 and 14.2 and Table 14.1 show that, with the exception of circuit 10, the response is obtained from the output of an OA. Owing to the low output resistance of the amplifier, any number of sections can be cascaded without using isolation amplifiers.

14.4 Stability during Activation and Sensitivity Using the 2-OA CGIC Biquad

14.4.1 Stability Properties

It has been shown [6] that some networks using CGICs can be conditionally stable, that is, a circuit can lock in an unstable mode during activation (just after switching on the power supply). For amplifiers with a finite open loop gain A, the circuit of Figure 14.3 gives

$$\frac{V_k}{V_i} = \frac{N_k(s)}{D(s)}$$

where $k = 2, 3, 4$ and

$$\begin{aligned} D(s) &= M_1 Y_1 + M_2 Y_3 \\ &\quad + (1 + M_1)(1 + M_2)[Y_1/A_1 + Y_3/A_2 + Y_1/A_1A_2 + Y_3/A_1A_2] \end{aligned} \tag{14.4}$$

$$M_1 = \frac{Y_5 + Y_6}{Y_2}$$

$$M_2 = \frac{Y_7 + Y_8}{Y_4}$$

It can be easily shown that for the circuit in Figure 14.3 low-frequency unstable modes cannot arise during activation. This is due to the absence of differences and changes of sign in the denominator coefficients. Thus any combination of OA gains that occur during transients and power supply switching does not result in saturation or low-frequency instability before reaching the steady state [7].

14.4.2 Sensitivity Analysis

The pole Q-factor Q_p, the undamped frequency of oscillation ω_p, the notch frequency ω_n, and the multiplier constants H_{BS}, H_{LP}, H_{HP}, and H_{BP}, as well as Q_z, ω_z, and H_{AP}, have been previously defined in

12[b]	$\frac{sG_2G_3}{G_1G_4}$	G_1	G_2	sC_3	G_4	G_5	G_6	sC_7	G_8	$T_1=\frac{s^2C_3C_7(G_2+G_6)-sC_3G_5G_8+G_1G_4G_5}{s^2C_3C_7G_2+sC_3G_2G_8+(G_5+G_6)G_1G_4}$	Nonminimum phase For all pass: $G_6=0$, $G_2=G_5$

[a] These elements can be set equal to zero.

[b] A special case of Circuit 12—namely, the all-pass case—has also been independently proposed by J. T. Lim, Bell Northern Research, Canada, as communicated privately by him to Dr. A. Antoniou.

Chapter 7. The sensitivity of a quantity x with respect to variations in an element e is denoted by S_e^x. For ideal amplifiers, the use of Table 14.1 leads to

$$0 \leq S_e^x \leq 1 \tag{14.5}$$

where

x represents any one of these H, ω, or Q qualities
e represents any capacitance or conductance

14.5 Design and Tuning Procedure of the 2-OA CGIC Biquad

A design procedure is now described. Table 14.1 shows that there are several degrees of freedom in the choice of element values. These may be used to minimize $S_A^{Q_p}$ or the spread of element values. By using minimum sensitivity (to the OA parameters) constraints in circuits 1, 3, 7, 10, and 12, possible sets of element values for LP, HP, BP, BS, and AP sections have been obtained, as shown in Table 14.2. In addition, this choice of elements guarantees stable operation with real OA's. It is seen that the notch frequency ω_n, the undamped frequency of oscillation ω_p, and Q-factor Q_p can be easily adjusted by sequentially trimming three distinct resistors. A tuning sequence is also given in Table 14.2.

It is to be noted from Table 14.2 for the design of the BS sections, that

$$\omega_n^2 = \frac{\omega_p G_s}{C_s} \tag{14.6}$$

where

$$G_5 + G_6 = G_1, \quad C_7 + C_8 + C, \quad \text{and} \quad \omega_p = \frac{G}{C}$$

TABLE 14.2 Design Values and Tuning Procedure

Circuit Number (from Table 14.1)	Design Values	Transfer Function Realized	Tuning Sequence		
			ω_o	ω_p	Q_p
1	$G_1 = G_4 = G_5 = G_8 = G$, $G_3 = G/Q_p$, $C_2 = C_3 = C$, where $C = \frac{G}{\omega_p}$	$T_2 = \frac{2\omega_p^2}{D(s)}$	—	G_8	G_3
3	$G_1 = G_2 = G_4 = G_6 = G$, $G_8 = G/Q_p$, $C_8 = 0$, $C_3 = C_7 = C$, where $C = \frac{G}{\omega_p}$	$T_1 = \frac{2s^2}{D(s)}$	—	G_4	G_8
7	$G_1 = G_2 = G_4 = G_6 = G$, $G_7 = G/Q_p$, $G_8 = 0$, $C_3 = C_8 = C$, where $C = \frac{G}{\omega_p}$	$T_1 = \frac{\left(\frac{2\omega_p}{Q_p}\right)s}{D(s)}$	—	G_2	G_7
10	$G_1 = G_2 = G_4 = G_5 + G_6 = G$, $G_8 = G/Q_p$, $C_3 = C_7 + C_8 = C$, where $\omega_p = \frac{G}{C}$ and $\omega_n^2 = \omega_p \frac{G_5}{C_7}$	$T_3 = \frac{C_7}{C} \frac{\left(s^2 + \omega_n^2\right)}{D(s)}$	G_2	G_6	G_8
12	$G_1 = G_2 = G_4 = G_5 = G$, $G_6 = 0$, $C_3 = C_7 = C$, $C_8 = G/Q_p$, where $\omega_p = \frac{G}{C}$	$T_1 = \frac{D(-s)}{D(s)}$	G_4		G_8

Note: $D(s) = s^2 + (\omega_p/Q_p)s + \omega_p^2$.

Hence

$$\frac{w_n^2}{w_p^2} = \frac{G_5}{G} \cdot \frac{C}{C_7} \tag{14.7}$$

where

$$\frac{G_5}{G} \text{ is always} \leq 1 \quad \text{and} \quad \frac{C}{C_7} \text{ is always} \geq 1$$

It is seen from Equation 14.7 that for $\omega_n \leq \omega_p$, C_8 can be set to zero ($C_7 = C$), and only two capacitors per section are used. For $\omega_n > \omega_p$, three capacitors are required. In all cases, regardless of the choice of C_7 and C_8, the total capacitance per section is equal to $2C$.

In most applications where notch sections are used, ω_n/ω_p is close to unity and care should be taken when choosing G_5 and C_7 in Equation 14.7. A suitable choice of G_5, G_6, G_7, and C_8 values may be obtained by letting

$$\frac{G_5}{G} = \frac{1}{K} \quad \text{and} \quad \frac{C}{C_7} = 2$$

Thus K is approximately equal to 2 ($K < 2$ for $\omega_n > \omega_p$ and $K > 2$ for $\omega_n \leq \omega_p$). The suggested choice yields a capacitor spread of 2 and both R_5 and R_6 are approximately equal to $2R$.

14.6 Design Examples Using the 2-OA CGIC Biquad

Example 14.1

Design a second-order Butterworth ($Q_p = 0.707$) LP filter having a cutoff frequency $f_p = 20{,}000/2\pi$ Hz.

Procedure

1. Circuit 1 in Table 14.2 realizes an LPF. The design equations are also given in Table 14.2.
2. First we choose an appropriate value for C, say 10 nF. Thus $C = C_2 = C_3 = 10$ nF.
3. Now, $R = \frac{1}{C\omega_p} = \frac{1}{20{,}000 \times 10^{-8}}$
   Therefore, $R = 5$ kΩ
4. Consequently, $R = R_1 = R_4 = R_5 = R_8 = 5$ kΩ and $R_3 = RQ_p = 3.535$ kΩ.
5. The circuit is shown in Figure 14.4a. It is noted that the low-frequency gain of the LP filter H_{LP} is 2.

A simple procedure can be followed to scale H_{LP} by a factor x less than unity, that is, effectively multiplying the transfer function realized by x. This is done by replacing the resistance R_5 by two resistors R_A, and R_B (in series with the input V_{in}) in the manner shown in Figure 14.4b, where

$$\begin{aligned} R_5 &= R = 5 \text{ k}\Omega \\ &= R_A \parallel R_B \end{aligned}$$

The desired gain and scale factor $x = R_B/(R_A + R_B)$. Thus for $x = \frac{1}{2}$, resulting in a dc gain of the LP filter of unity, the choice of resistors R_A and R_B is $R_A = R_B = 10$ kΩ.

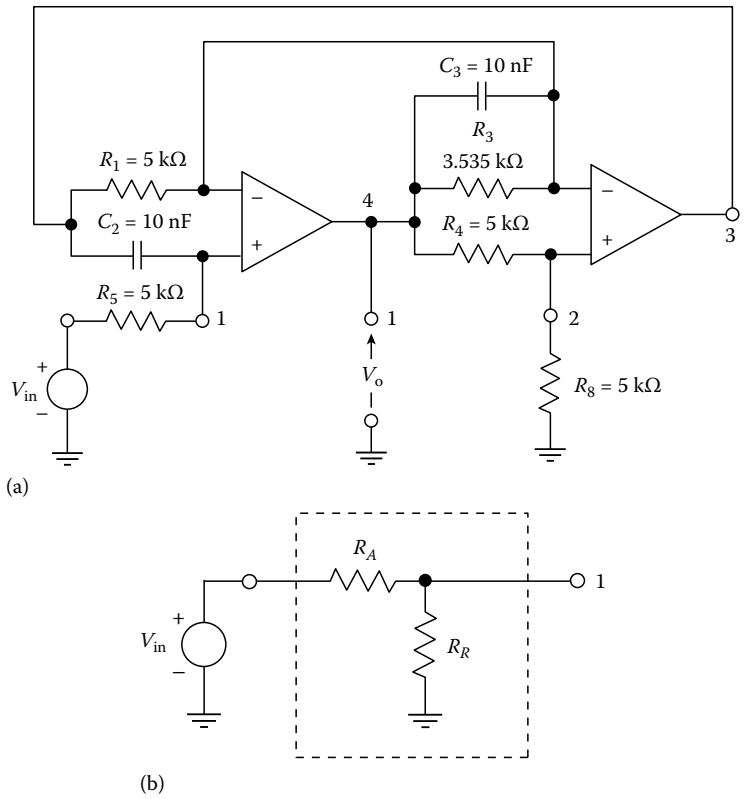

FIGURE 14.4 (a) Second-order Butterworth LPF design example and (b) controlling the gain factor of the LPF.

If functional tuning of the filter is desired, the tuning sequence of circuit 1 in Table 14.2 can be followed. First, ω_p is adjusted by applying a sinusoidal input at the desired ω_p frequency. Then R_B is tuned until ω_p realized equals the desired value. This can be detected by monitoring the phase angle of the output relative to the input. When the proper ω_p is reached, the output lags the input by 90°. Next, to adjust the Q_p, the filter gain H_{dc} of the LPF at a frequency much lower than ω_p is determined. Then an input at ω_p is applied. R_3 is adjusted until the gain of the LPF at ω_P is Q_P desired H_{dc}.

Example 14.2

Design a second-order BP filter with $Q_p = 10$ and $f_p = 10{,}000/2\pi$ Hz.

Procedure

1. Circuit 7 in Table 14.2 realizes a BP filter. The design equations are also given in Table 14.2.
2. First we choose a suitable value for C, say 10 nF.
3. Thus $C_3 = C_8 = C = 10$ nF.
4. Hence $R = (1/C\omega_p) = 10\,\text{k}\Omega$. Consequently, $R = R_1 = R_2 = R_4$, $R_6 = 10\,\text{k}\Omega$, and $R_7 = RQ_p = 100\,\text{k}\Omega$.
5. The circuit is shown in Figure 14.5. The gain at resonance, that is, at $\omega = \omega_p$, is equal to 2. To scale the gain by a factor x less than 2, the resistor R_7 is split into two resistors in a manner similar to that in Figure 14.4b and explained in Example 14.1.

Again, if functional tuning is desired, the sequence in Table 14.2 can be followed.

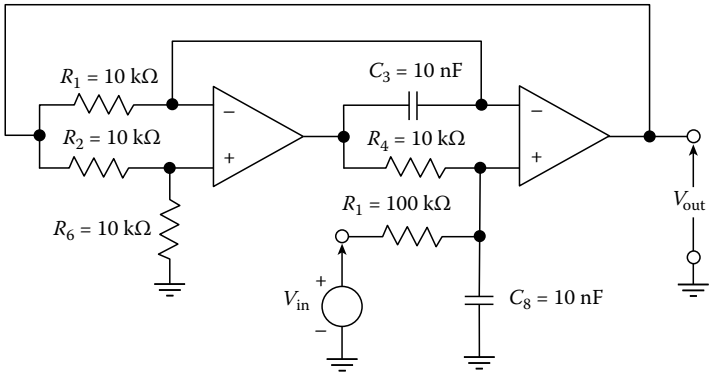

FIGURE 14.5 Design of a second-order BPF.

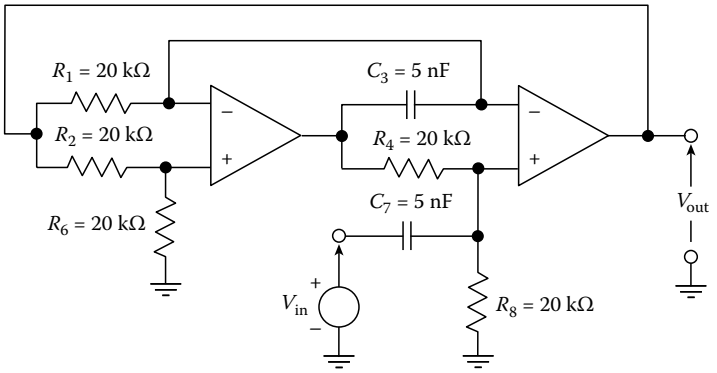

FIGURE 14.6 Design of a second-order HPF.

Example 14.3

Design a second-order HP filter with $Q_p = 1$ and $f_p = 10{,}000/2\pi$ Hz.

Procedure

1. Circuit 3 in Table 14.2 realizes an HP filter.
2. Let us choose $C_3 = C_7 = C = 5$ nF. Hence R can be computed as $R = \frac{1}{\omega_p C} = \frac{1}{10{,}000 \times 50 \times 10^{-9}}$ Therefore, $R = 20$ kΩ.
3. Consequently, $R_1 = R_2 = R_4 = R_6 = R = 20$ kΩ and $R_8 = RQ = 20$ kΩ.
4. The realization is shown in Figure 14.6. The gain at high-frequency H_{HP} is equal to 2.

14.7 Practical High-Order Design Examples Using the 2-OA CGIC Biquad

Using Table 14.2, 1% metal-film resistors, 2% polystyrene capacitors and μ A741 OA's, a sixth-order Chebyshev LP filter, and a sixth-order elliptic BP filter were designed and constructed. The LP filter has a

maximum passband attenuation of 1.0 dB; bandwidth = 3979 Hz. The BP filter has the following specifications:

Center frequency = 1500 Hz
Passband = 60 Hz
Maximum passband attenuation = 0.3 dB
Minimum stopband attenuation outside the frequency range 1408 → 1595 Hz = 38 dB

14.7.1 Low-Pass Filter

The realization uses cascaded section of type 1, in Table 14.2, as shown in Figure 14.7a. The measured frequency response (input level = 50 mV), shown in Figure 14.7b and c, agrees with the theoretical response. The effect of dc-supply variations is illustrated in Figure 14.7d. The deviation in the passband ripple is about 0.1 dB for supply voltage in the range 5–15 V. The effect of temperature variations is illustrated in Figure 14.7e, which shows the frequency response at −10°C (right-hand curve), 20°C, and 70°C (left-hand curve). The last peak has been displaced horizontally by 42 Hz, which corresponds to a

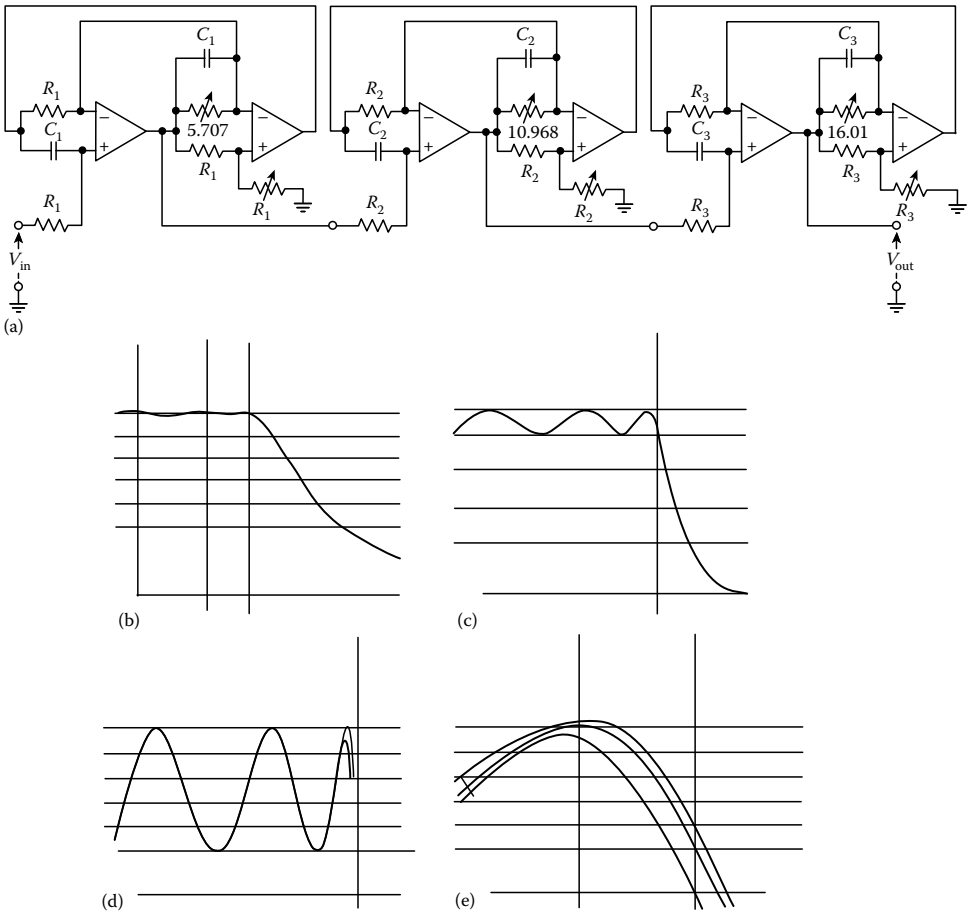

FIGURE 14.7 (a) Realization of the sixth-order Chebyshev low-pass filter. Frequency responses: (b) logarithmic gain scale and linear frequency scale; (c) linear gain and frequency scales; (d) for supply voltages ±5 V (lower curve) and ±15 V, input level = 0.05 V; (e) at temperatures −10°C (right-hand curve), 20°C, and 70°C (left-hand curve).

change of 133 ppm/°C. The frequency displacement is due to passive element variations and is within the predicted value.

14.7.2 Bandpass Filter

The realization uses cascaded sections of the types 7 and 10, in Table 14.2, and is shown in Figure 14.8a. The measured frequency response is shown in Figure 14.8b and c, and it is in agreement with the theoretical response. Figure 14.8d shows the frequency response for supply voltages of 7.5 V (lower curve) and 15 V; the input is 0.3 V. The passband ripple remains less than 0.39 dB and the deviation in the stopband is negligible. Figure 14.8e and f illustrate the effect of temperature variations. The passband ripple remains less than 0.35 dB in the temperature range −10°C to 70°C. A center frequency displacement of 15 Hz has been measured that corresponds to a change of 125 ppm/°C.

14.8 Universal 2-OA CGIC Biquad

Study of Table 14.2 suggests that several circuits may be combined to form a universal biquad. This can be achieved on a single substrate using thick-film technology.

Upon examining the element identification and design values in Table 14.2 it is easy to see that one common thick-film substrate can be made to realize circuits 1, 3, 7, and 10 in Table 14.2 (other circuits from Table 14.1 can be included if desired) with no duplication in OAs and chip capacitors and minimal duplication in resistors. The superposition of circuits 1, 3, 7, and 10 is shown in Figure 14.9. The following items should be noted.

1. Each resistor having the same subscript represents one resistor only and needs to appear once in a given biquad realization and thus once on the substrate. As an example, for $R_J = RQ_p$, only one R_J is needed with connection to several nodes. The unwanted connections may be opened during the trimming process according to the type of circuit required.
2. Three capacitor pads are needed; they are marked 1, 2, and 3 in Figure 14.9. To obtain capacitor 4, either capacitor 2 or 3 connections are made common with capacitor 4 terminals. The capacitor pad terminals are available on the external terminals of the substrate.* The chip capacitors are reflow-soldered in the appropriate locations based on the circuit realized.

A dual CGIC universal biquad implemented using thick-film resistors, chip NPO capacitors, and one quad OA is shown in Figure 14.10. Note that this hybrid array is capable of realizing gyrators and simulating inductors and super capacitors. Sample results are given in Figure 14.11 for realizing different biquadratic functions using this implementation.

14.9 3-OA CGIC Biquadratic Structure

Consider the circuit shown in Figure 14.12 where the output can be taken to be V_1, V_2, or V_3. Assuming ideal OAs, the transfer functions between the input and output terminals 1, 2, and 3 can be readily obtained as

$$\begin{aligned} V_1/V_i &= T_1 \\ &= \{Y_{11}Y_{12}[Y_1(1 + Y_4/Y_9) - Y_2Y_3/Y_9] \\ &\quad + (Y_{12}Y_3Y_7Y_8)/Y_9 + [(1 + Y_4/Y_9)Y_5 - Y_3Y_6/Y_9]Y_7Y_{10}\}/D(s) \end{aligned} \tag{14.8a}$$

* This can readily be understood by examining the different realizations to be obtained from this layout.

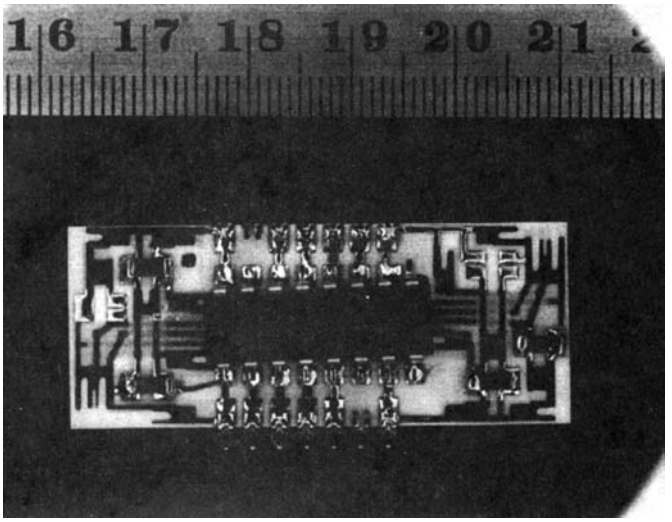

FIGURE 14.10 Dual CGIC universal biquad implemented using thick-film resistors; chip NPO capacitors and one quad OA.

$$V_2/V_i = T_2$$
$$= \{Y_{11}Y_{12}Y_1 + Y_{12}[Y_1Y_6 + (Y_3Y_7Y_8)/Y_9 - Y_5Y_6] + [Y_3Y_6 - Y_4Y_5](Y_7Y_8Y_{12})/Y_9Y_{11} + Y_5Y_7Y_{10}\}/D(s) \quad (14.8b)$$

$$V_3/V_i = T_3$$
$$= \{Y_1Y_{11}Y_{12} + Y_{12}[(1 + Y_2/Y_7)Y_3 - Y_1Y_4/Y_7]Y_8/Y_9 + [(1 + Y_2/Y_7)Y_5 - Y_1Y_6/Y_7]Y_7Y_{10}\}D(s) \quad (14.8c)$$

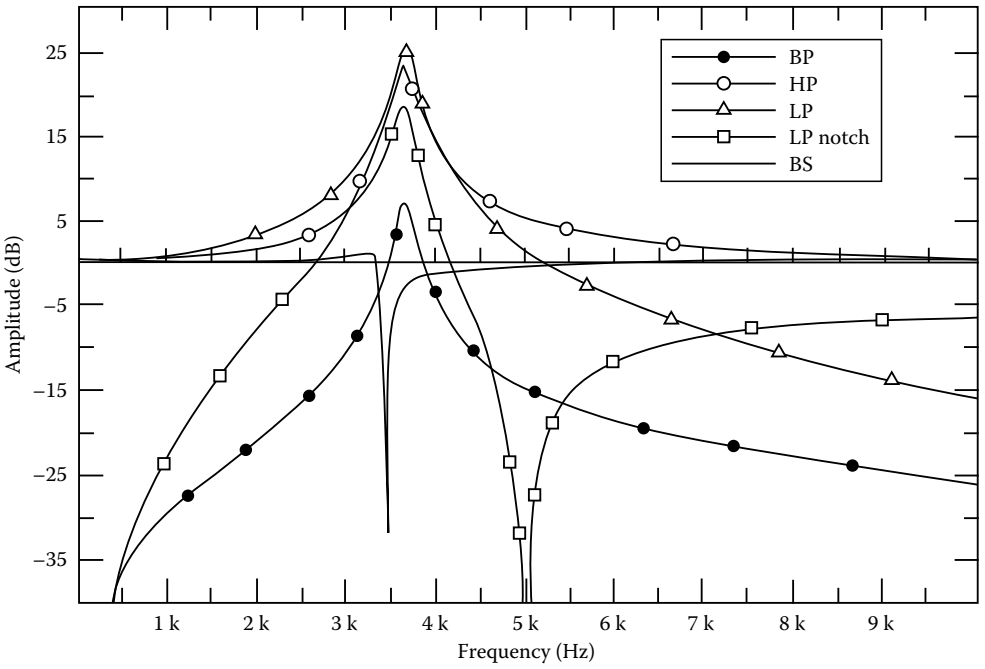

FIGURE 14.11 Different second-order realizations obtained from the universal CGIC biquad.

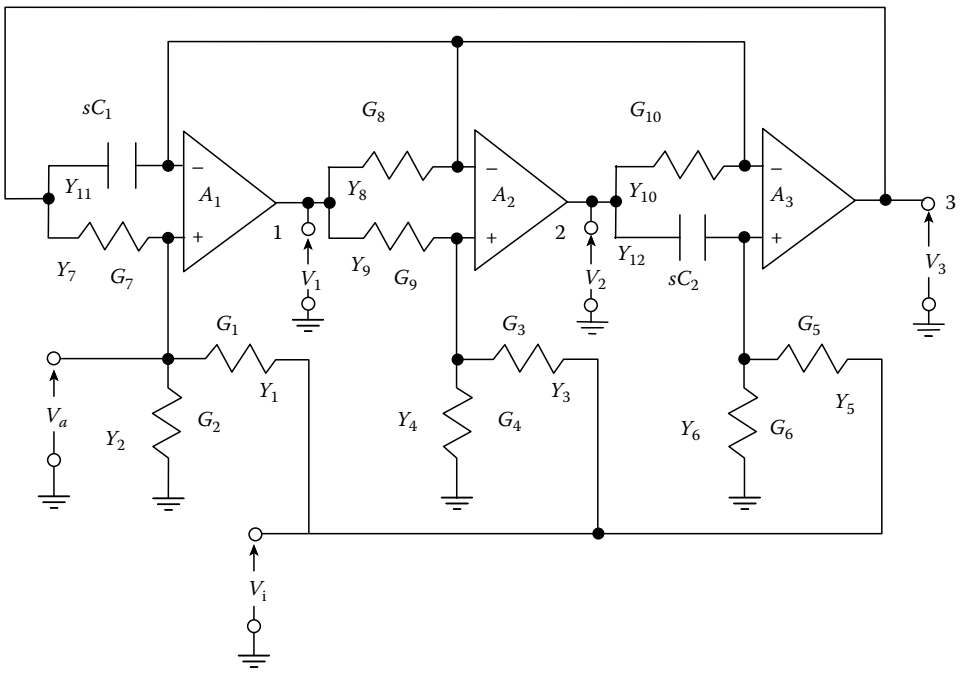

FIGURE 14.12 3-OA CGIC biquad.

where

$$D(s) = Y_{11}Y_{12}(Y_1 + Y_2) + Y_{12}(Y_3 + Y_4)Y_7Y_8/Y_9 + (Y_5 + Y_6)Y_7Y_{10} \tag{14.9}$$

The admittances Y_1–Y_{12} can be selected in many ways and any stable second-order transfer function can be realized. For the purposes of this chapter, Y_1–Y_{10} are taken to be purely conductive, while Y_{11} and Y_{12} are purely capacitive, that is,

$$\begin{aligned} Y_1 - Y_{10} &= G_1 - G_{10} \\ Y_{11} &= sC_1, \quad Y_{12} = sC_2 \end{aligned} \tag{14.10}$$

Any rational and stable transfer function can be expressed as a product of second-order transfer functions of the form

$$T(s) = \frac{a_2s^2 + a_1s + a_0}{b_2s^2 + b_1s + b_0} \tag{14.11}$$

where $a_1 = a_2 = 0$, $a_0 = a_1 = 0$, $a_0 = a_2 = 0$, or $a_1 = 0$, for an LP, HP, BP, or N section, respectively. These section can be realized by choosing the G_i's ($i = 1$–10) properly in Equation 14.8. By comparing Equations 14.8 through 14.11, circuits 1–4 in Table 14.3 can be obtained.

All-pass transfer functions can be realized by setting $a_2 = b_2$, $a_1 = -b_1$, $a_0 = b_0$; these can be obtained from circuit 5 of Table 14.3.

It can be easily shown that this biquad possesses similar excellent low sensitivity properties and stability during activation as those of the 2-OA CGIC biquad, given in Section 14.4.

14.10 Design and Tuning Procedure of the 3-OA CGIC Biquad

Several degrees of freedom exist in choosing element values, as shown in Table 14.3. These are used to satisfy the constraints of the given design, namely, those of low sensitivity, reduced dependence on the

TABLE 14.3 Element Identification for Realizing the Most Commonly Used Transfer Functions

Circuits Number	G_1	G_2	G_3	G_4	G_5	G_6	Transfer Function	Remarks
1	0		0			[a]	$T_3 = \dfrac{\left(1 + \frac{G_2}{G_7}\right)\frac{G_5G_7G_{10}}{C_1C_2}}{s^2G_2 + s\frac{G_4G_7G_8}{C_1G_9} + \frac{(G_5 + G_6)G_7G_{10}}{C_1C_2}}$	LP

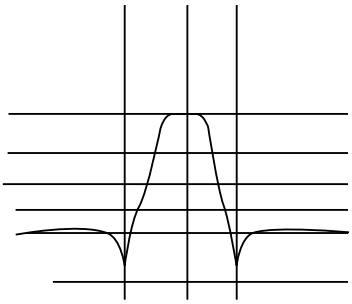
$C_1 = C_2 = C = 1/(\omega_p R)$, $R_{10} = \alpha R$, $R_8 = RQ_p^{1/2}$, $R_7 = R_8 = R$.

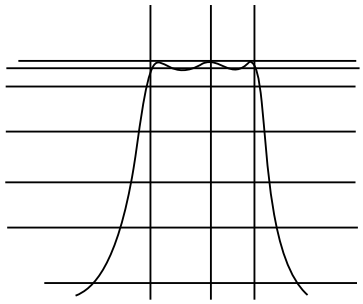
OA finite gain and bandwidth, and low element-spread design, in circuits 1–5 in Table 14.3. Using these constraints, a possible design for LP, HP, BP, AP, and N sections is obtained, as indicated in Table 14.4. It is seen that Q_p, ω_p, ω_n, Q_z, and ω_z, can be independently adjusted by trimming at most three resistors. A trimming sequence is also given in Table 14.4.

14.11 Practical Sixth-Order Elliptic BP Filter Design Using the 3-OA CGIC Biquad



The sixth-order elliptic bandpass filter specified in Section 14.7 was designed using the 3-OA CGIC biquad and similar components to those in Section 14.7.

The realization shown in Figure 14.13a uses cascaded sections of the types 3 and 4 in Table 14.4. The element design values are also given in Figure 14.13a. The measured frequency response is shown in Figure 14.13b and c; it is in agreement with the theoretical response. Figure 14.13d shows the frequency response for supply voltages of ±7.5 V (lower curve), and ±15 V (upper curve); the input voltage is 0.3 V. The passband ripple remains less than 0.34 dB and the deviation in the stopband is negligible. Figure 14.13e and f illustrate the effect of temperature variations. The passband ripple remains less than 0.5 dB in the temperature range from −10°C (right-hand curve) to 70°C (left-hand curve). A center frequency displacement of 9 Hz has been measured, which corresponds to a change of 75 ppm/°C.



These results illustrate the additional performance improvements compared with the results in Section 14.7 using the 2-OA CGIC biquad.

14.12 Composite GIC Biquad: 2 C 2-OA CGIC

To obtain the composite CGIC biquad [3], each single OA in the original 2-OA CGIC biquad is replaced by a composite amplifier each constructed using two regular OAs [2] and denoted C2OA. All possible combinations of the four C2OA structures in Ref. [3] were used to replace the two OAs in the CIC network. Although several useful combinations were obtained, it was found that the best combination is shown in Figure 14.14, where A_1 is replaced by C2OA-4 and A_2 is replaced by C2OA-3 in the CGIC of Figure 14.1.

Computer simulation plots and experimental results of Figure 14.15 show clearly the considerable improvements of the new CGIC filter responses over those of a 2-OA CGIC implemented using regular OAs.

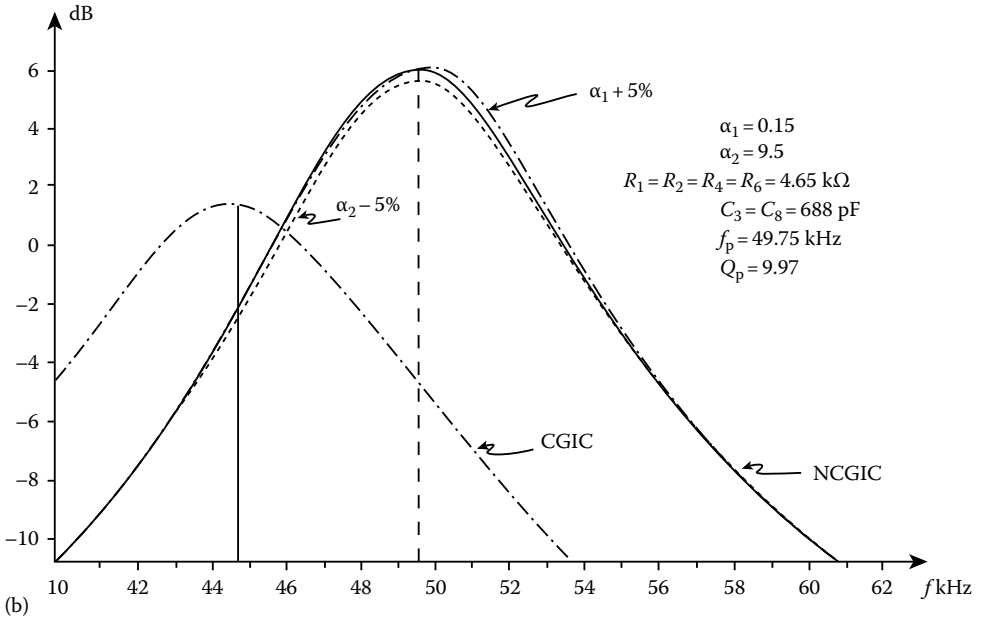

FIGURE 14.15 (continued) (b) Experimental results of single and composite GIC BP filters of Figure 6.3, and the response sensitivity for a_1 and a_2 variations ($f_0 = 50$ kHz, $Q_p = 10$).

Similar improvements in inductance simulation applications, employing the 2C2-OA CGIC, have been reported.

14.13 Summary

Two configurations have been presented for the synthesis of *RC*-active networks. These have been used to design a number of universal second-order sections such as low-pass, high-pass, bandpass, and bandstop sections. By using these sections, most of the practical filter specifications can be realized. Each section employs a CGIC, which can be implemented by using 2 OAs in the 2-OA CGIC biquad and 3 OAs in the 3-OA CGIC design. The sensitivities of Q_p, ω_p, Q_z, ω_z, and also the multiplier constant of the realization, have been found to be low with respect to the passive- and active-element variations. A simple functional tuning sequence in which only resistors are adjusted has been described. With the exception of one of the notch sections using the 2-OA CGIC, of all the circuits considered, the output can be located at an OA output. Consequently, these sections can be cascaded without the need for isolating amplifiers. Although exact matching of the gain bandwidth products of the OAs in the CGIC biquad is not essential, optimum results are obtained when they are matched within practical ranges. This is achieved easily by using dual or quad OAs. Also, the choice of the element values for optimum performance is also given. The additional performance improvements using the 3-OA CGICiquads are illustrated experimentally. Useful operating frequencies extension employing the composite operational amplifier technique in the 2-OA CGIC biquad is also given.

15.1 Introduction

With the realization of second-order filters discussed in the previous chapters of this section, we will now treat methods for practical filter implementations of order higher than two. Specifically, we will investigate how to realize efficiently, with low sensitivities to component tolerances, the input-to-output voltage transfer function

$$H(s) = \frac{V_{\text{out}}}{V_{\text{in}}} = \frac{N(s)}{D(s)} = \frac{a_m s^m + a_{m-1}s^{m-1} + \cdots + a_1 s + a_0}{s^n + b_{n-1}s^{n-1} + \cdots + b_1 s + b_0} \tag{15.1}$$

where $n \geq m$ and $n > 2$. The sensitivity behavior of high-order filter realizations shows that, in general, it is not advisable to realize the transfer function $H(s)$ in the so-called direct form [5, Chapter 3] (see also Chapter 5). By direct form we mean an implementation of Equation 15.1 that uses only one or maybe two active devices, such as operational amplifiers (op-amps) or operational transconductance amplifiers (OTAs), embedded in a high-order passive *RC* network. Although it is possible in principle to realize Equation 15.1 in direct form, the resulting circuits are normally so sensitive to component tolerances as to be impractical. Since the direct form for the realization of high-order functions is ruled out, in this section we present those methods that result in designs of practical manufacturable active filters with acceptably low sensitivity, the *cascade* approach, the *multiple-loop feedback topology,* and *ladder simulations*. Both cascade and multiple-loop feedback techniques are modular, with active biquads used as the fundamental building blocks. The ladder simulation method seeks active realizations that inherit the low passband sensitivity properties of passive doubly terminated *LC* ladder filters (see Chapter 9).

In the cascade approach, a high-order function $H(s)$ is factored into low (first or second) order subnetworks, which are realized as discussed in the previous chapters of this section and connected in cascade such that their product implements the prescribed function $H(s)$. The method is widely

employed in industry; it is well understood, very easy to design, and efficient in its use of active devices. It uses a modular approach and results in filters that, for the most part, show satisfactory performance in practice. The main advantage of cascade filters is their generality, i.e., any arbitrary stable transfer function can be realized as a cascade circuit, and tuning is very easy because each biquad is responsible for the realization of only one pole pair (and zero pair): the realizations of the individual critical frequencies of the filter are decoupled from each other. The disadvantage of this decoupling is that for filters of high order, say $n > 8$, with stringent requirements and tight tolerances, the passband sensitivity of cascade designs to component variations is often found to remain still too sensitive. In these cases, the following approaches lead to more reliable circuits.

The multiple-loop feedback or coupled-biquad methods also split the high-order transfer function into second-order subnetworks. These are interconnected in some type of feedback configuration that introduces coupling chosen to reduce the transfer function sensitivities. The multiple-loop feedback approach retains the modularity of cascade designs but at the same time yields high-order filter realizations with noticeably better passband sensitivities. Of the numerous topologies that have been proposed in the literature, see, e.g., Ref. [5, Chapter 6], we discuss only the follow-the-leader feedback (FLF) and the LF (leapfrog) methods. Both are particularly well suited for all-pole characteristics but can be extended to realizations of general high-order transfer functions. Although based on coupling of biquads in a feedback configuration, the LF procedure is actually derived from an *LC* ladder simulation and will, therefore, be treated as part of that method.

As the name implies, the ladder simulation approach uses an active circuit to simulate the behavior of doubly terminated *LC* ladders in an attempt to inherit their excellent low passband-sensitivity properties. The methods fall into two groups. One is based on element replacement or substitution, where the inductors are simulated via electronic circuits whose input impedance is inductive over the necessary frequency range; the resulting active ''components'' are then inserted into the *LC* filter topology. The second group may be labeled operational simulation of the *LC* ladder, where the active circuit is configured to realize the internal operation, i.e., the equations, of the *LC* prototype. Active filters simulating the structure or the behavior of *LC* ladders have been found to have the lowest passband sensitivities among active filters and, consequently, to be the most appropriate if filter requirements are stringent. They can draw on the wealth of information available for lossless filters, e.g., Refs. [5, Chapter 2], [9, Chapter 13], [7] that can be used directly in the design of active ladder simulations. A disadvantage of this design method is that a passive *LC* prototype must, of course, exist* before an active simulation can be attempted.

15.2 Cascade Realizations

Without loss of generality we may assume in our discussion of active filters that the polynomials $N(s)$ and $D(s)$ of Equation 15.1 are even, i.e., both n and m are even. An odd function can always be factored into the product of an even function and a first-order function, where the latter can easily be realized by a passive *RC* network and can be appended to the high-order active filter as an additional section. Thus, we can factor Equation 15.1 into the product of second-order pole-zero pairs, so that the high-order transfer function $H(s)$ is factored into the product of the second-order functions

$$T_i(s) = k_i \frac{\alpha_{2i}s^2 + \alpha_{1i}s + \alpha_{0i}}{s^2 + s\omega_{0i}/Q_i + \omega_{0i}^2} = k_i t_i(s) \tag{15.2}$$

* The realizability conditions for passive *LC* filters are more restrictive than those for active *RC* filters; specifically, the numerator $N(s)$ of Equation 16.1 must be strictly even or odd so that only $j\omega$-axis transmission zeros can be realized.

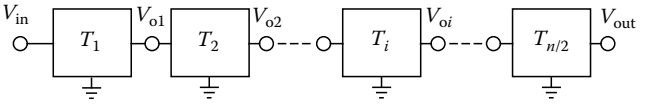

FIGURE 15.1 Cascade realization of an *n*th-order transfer function; *n* is assumed even.

such that

$$H(s) = \prod_{i=1}^{n/2} T_i(s) = \prod_{i=1}^{n/2} k_i \frac{\alpha_{2i}s^2 + \alpha_{1i}s + \alpha_{0i}}{s^2 + s\omega_{0i}/Q_i + \omega_{0i}^2} = \prod_{i=1}^{n/2} k_i t_i(s) \tag{15.3}$$

In Equation 15.2, ω_{0i} is the pole frequency and Q_i the pole quality factor; the coefficients α_{2i}, α_{1i}, and α_{0i} determine the type of second-order function $T_i(s)$ that can be realized by an appropriate choice of biquad from the literature, e.g., Refs. [5, Chapter 5], [9, Chapters 4 and 5] (see also Chapters 12 through 14). The transfer functions $T_i(s)$ of the individual biquads are scaled by a suitably defined gain constant k_i, e.g., such that the leading coefficient in the numerator of the gain-scaled transfer function $t_i(s)$ is unity or such that $|t_i(j\omega)| = 1$ at some desired frequency. If we assume now that the output impedances of the biquads are small compared to their input impedances, all second-order blocks can be connected in cascade as in Figure 15.1 without causing mutual interactions due to loading. The product of the biquadratic functions is then realized as required by Equation 15.3.

The process is straightforward and leads to many possibilities for cascading the identified circuit blocks, but several questions must still be answered:

1. Which pair of zeros of Equation 15.1 should be assigned to which pole-pair when the biquadratic functions $T_i(s)$ are formed? Since we have $n/2$ pole pairs and $n/2$ zero pairs (counting zeros at 0 and at ∞) we can select from $(n/2)!$ possible pole-zero pairings.
2. In which order should the biquads be cascaded? For $n/2$ biquads, we have $(n/2)!$ possible ways of section ordering.
3. How should the gain constants k_i in Equation 15.2 be chosen to determine the signal level for each biquad? In other words, what is the optimum gain assignment?

Because the total prescribed transfer function $H(s)$ is simply the product of $T_i(s)$, the choices in 1, 2, and 3 are quite arbitrary as far as $H(s)$ is concerned. However, they determine significantly the dynamic range,* i.e., the distance between the maximum possible undistorted signal (limited by the active devices) and the noise floor, because the maximum and minimum signal levels throughout the cascade filter depend on the pole-zero pairings, cascading sequence, and gain assignment.

There exist well-developed techniques and algorithms for answering the questions of pole-zero pairing, section ordering, and gain assignment exactly [3, Chapter 1], [5, Chapter 6]; they rely heavily on computer routines and are too lengthy to be treated in this chapter. We will only give a few rules-of-thumb, which are based on the intuitive observation that in the passband the magnitude of each biquad should vary as little as possible. This keeps signal levels as equal as possible versus frequency and avoids in-band attenuation and the need for subsequent amplification that will at the same time raise the noise floor and thereby further limit the dynamic range. Note also that in-band signal amplification may overdrive the amplifier stages and cause distortion. The simple rules below provide generally adequate designs.

* Pole-zero pairing also affects to some extent the sensitivity performance, but the effect usually is not very strong and will not be discussed in this chapter. For a detailed treatment see Ref. [3].

1. Assign each zero or zero-pair to the closest pole-pair.
2. Sequence the sections in the order of increasing values of Q_i, i.e., $Q_1 < Q_2 < \cdots < Q_{n/2}$, so that the section with the flattest transfer function magnitude comes first, the next flattest one follows, and so on. If the position of any section is predetermined,* use the sequencing rule for the remaining sections.

After performing steps (1) and (2), assign the gain-scaling constants k_i such that the maximum output signals of all sections in the cascade are the same, i.e.,

$$\max|V_{oi}(j\omega)| = \max\left|V_{o,n/2}(j\omega)\right| = \max|V_{out}(j\omega)| \quad i = 1, \ldots, n/2 - 1 \tag{15.4}$$

This can be done readily with the help of a network analysis routine or simulator, such as SPICE, by computing the output signals at each biquad: using the notation, from Equation 15.3,

$$H(s) = \prod_{i=1}^{n/2} T_i(s) = \prod_{i=1}^{n/2} k_i t_i(s) = \prod_{i=1}^{n/2} k_i \prod_{i=1}^{n/2} t_i(s) \tag{15.5}$$

and

$$H_i(s) = \prod_{j=1}^{i} T_j(s) = \prod_{j=1}^{i} k_j t_j(s) = \prod_{j=1}^{i} k_j \prod_{j=1}^{i} t_j(s) \tag{15.6}$$

we label the total prescribed gain constant

$$K = \prod_{i=1}^{n/2} k_i \tag{15.7}$$

such that

$$\max\left|\prod_{i=1}^{n/2} t_i(j\omega)\right| = M_{n/2} \tag{15.8a}$$

is some given value. Further, let us denote the maxima of the intermediate gain-scaled transfer functions by M_i, i.e.,

$$\max\left|\prod_{k=1}^{i} t_k(j\omega)\right| = M_i \quad i = 1, \ldots, n/2 - 1 \tag{15.8b}$$

then we obtain [5, Chapter 6]

$$k_1 = K\frac{M_{n/2}}{M_1} \quad \text{and} \quad k_j = \frac{M_{j-1}}{M_j} \quad j = 2, \ldots, n/2 \tag{15.9}$$

* Such as, e.g., placing a lowpass at the input may be preferred to avoid unnecessary high-frequency signals from entering the filter.

Choosing the gain constants as in Equation 15.9 guarantees that the same maximum voltage appears at all biquad outputs to assure that the largest possible signal can be processed without distortion.

To illustrate the process, let us realize the sixth-order transfer function

$$H(s) = \frac{0.7560s^3}{(s^2 + 0.5704s + 1)(s^2 + 0.4216s + 2.9224)(s^2 + 0.1443s + 0.3422)} \tag{15.10}$$

where the frequency parameter s is normalized with respect to $\omega_n = 130{,}590\ \text{s}^{-1}$. It defines a sixth-order bandpass filter with a 1 dB equiripple passband in 12 kHz $\leq f \leq$ 36 kHz and at least 25 dB attenuation in $f \leq 4.8$ kHz and $f \geq 72$ kHz [5, Chapter 1]. $H(s)$ can be factored into the product of

$$T_1(s) = k_1 t_1(s) = \frac{k_1 s}{s^2 + 0.5704s + 1} \quad \text{with}$$

$$Q_1 = \frac{\sqrt{1}}{0.5704} \approx 1.75 \tag{15.11a}$$

$$T_2(s) = k_2 t_2(s) = \frac{k_2 s}{s^2 + 0.4216s + 2.9224} \quad \text{with}$$

$$Q_2 = \frac{\sqrt{2.9224}}{0.4216} \approx 4.06 \tag{15.11b}$$

$$T_3(s) = k_3 t_3(s) = \frac{k_3 s}{s^2 + 0.1443s + 0.3422} \quad \text{with}$$

$$Q_3 = \frac{\sqrt{0.3422}}{0.1443} \approx 4.06 \tag{15.11c}$$

which are cascaded in the order of increasing values of Q, i.e., $T_1T_2T_3$. We can compute readily the maximum values at the output of the sections in the cascade as $M_1 = |t_1|_{\max} \approx 1.75$, $M_2 = |t_1t_2|_{\max} \approx 1.92$, and $M_3 = |t_1t_2t_3|_{\max} \approx 1.32$ to yield by Equation 15.9

$$k_1 = 0.7560\frac{1.32}{1.75} \approx 0.57 \quad k_2 = \frac{1.75}{1.92} \approx 0.91 \quad k_3 = \frac{1.92}{1.32} \approx 1.45 \tag{15.12}$$

Let us build the sections with the Åckerberg–Mossberg circuit [9, Chapter 4.4] shown in Figure 15.2. It realizes

$$\frac{V_o}{V_i} = -\frac{k\omega_0^2}{s^2 + s\omega_0/Q + \omega_0^2} \quad \text{with } \omega_0 = \frac{1}{RC} \tag{15.13}$$

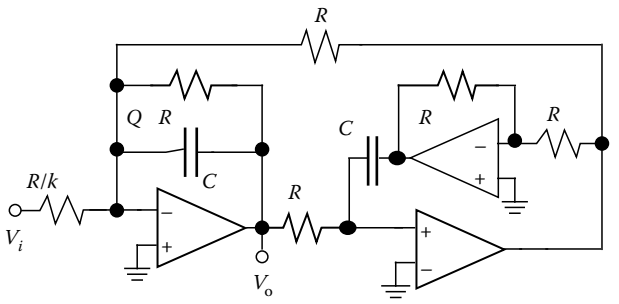

FIGURE 15.2 Åckerberg–Mossberg bandpass circuit.

We obtain readily from Equations 15.11 through 15.13 the following (rounded) component values:

$$\text{for } T_1\text{: } R = 1.5\ \text{k}\Omega \quad QR = 2.7\ \text{k}\Omega \quad R/k = 2.7\ \text{k}\Omega$$

$$\text{for } T_2\text{: } R = 0.9\ \text{k}\Omega \quad QR = 3.6\ \text{k}\Omega \quad R/k = 1.7\ \text{k}\Omega$$

$$\text{for } T_3\text{: } R = 2.6\ \text{k}\Omega \quad QR = 10\ \text{k}\Omega \quad R/k = 1\ \text{k}\Omega$$

The three sections are then interconnected in cascade in the order $T_1T_2T_3$.

15.3 Multiple-Loop Feedback Realizations

These topologies are also based on biquad building blocks, which are then embedded, as the name implies, into multiple-loop resistive feedback configurations. The resulting coupling between sections is selected such that transfer function sensitivities are reduced below those of cascade circuits. It has been shown that the sensitivity behavior of the different available configurations is comparable. We shall, therefore, concentrate our discussion only on the FLF and, as part of the ladder simulation techniques, on the leapfrog (LF) topologies, which have the advantage of being relatively easy to derive without any sacrifice in performance. Our derivation will reflect the fact that both configurations* are particularly convenient for geometrically symmetrical bandpass functions and that the LF topology is obtained from a direct simulation of an *LC* lowpass ladder.

15.3.1 Follow-the-Leader Feedback Topology

The FLF topology consists of a cascade of biquads whose outputs are fed back into a summer at the filter's input. At the same time, the biquad outputs may be fed forward into a second summer at the filter's output to permit an easy realization of arbitrary transmission zeros. The actual implementation of the summers and the feedback factors is shown in Figure 15.3; if there are n noninteracting biquads, the order of the realized transfer function $H(s)$ is $2n$. Assuming that the two summer op-amps are ideal, routine analysis yields

$$-V_0 = \frac{R_{F0}}{R_{\text{in}}} V_{\text{in}} + \sum_{i=1}^{n} \frac{R_{F0}}{R_{Fi}} V_i = \alpha V_{\text{in}} + \sum_{i=1}^{n} F_i V_i \tag{15.14}$$

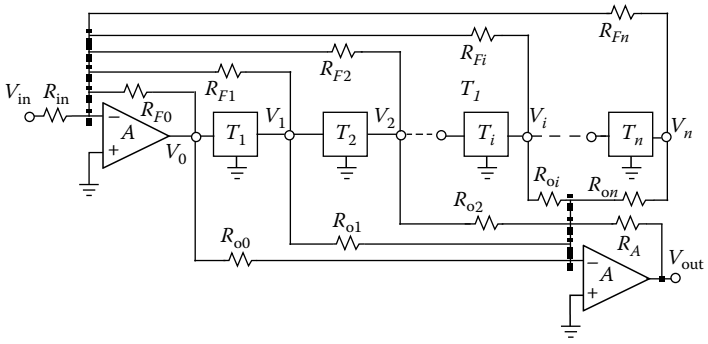

FIGURE 15.3 FLF circuit built from second-order sections $T_i(s)$ and a feedback network consisting of an op-amp summer with resistors R_{Fi}. Also shown is an output summer with resistors R_{oi} to facilitate the realization of arbitrary transmission zeros.

* As are all other multiple-loop feedback circuits.

where we defined $\alpha = R_{F0}/R_{\text{in}}$ and the feedback factors $F_i = R_{F0}/R_{Fi}$. Similarly, we find for the output summer

$$V_{\text{out}} = -\sum_{i=0}^{n} K_i V_i = -\sum_{i=0}^{n} \frac{R_A}{R_{\text{o}i}} V_i \tag{15.15}$$

from which the definition of the resistor ratios K_i is apparent. Any of the parameters F_i and K_i may, of course, be reduced to zero by replacing the corresponding resistor, R_{Fi} or $R_{\text{o}i}$, respectively, by an open circuit. Finally, the internal voltages V_i can be computed from

$$V_i = V_0 \prod_{j=1}^{i} T_j(s) \quad i = 1, \ldots, n \tag{15.16}$$

so that with Equation 15.14

$$H_0(s) = \frac{V_0}{V_{\text{in}}} = -\frac{\alpha}{1 + \sum_{k=1}^{n} \left[F_k \prod_{j=1}^{k} T_j(s) \right]} \tag{15.17}$$

which with Equation 15.16 yields

$$H_i(s) = \frac{V_i}{V_{\text{in}}} = -\frac{N_i(s)}{D(s)} = -\frac{\alpha \prod_{j=1}^{i} T_j(s)}{1 + \sum_{k=1}^{n} \left[F_k \prod_{j=1}^{k} T_j(s) \right]} \quad i = 1, \ldots, n \tag{15.18}$$

Note that

$$H_n(s) = \frac{V_n}{V_{\text{in}}} = -\frac{N_n(s)}{D(s)} = -\frac{\alpha \prod_{j=1}^{n} T_j(s)}{1 + \sum_{k=1}^{n} \left[F_k \prod_{j=1}^{k} T_j(s) \right]} \tag{15.19}$$

is the transfer function of the FLF network without the output summer, i.e., with $R_{\text{o}i} = \infty$ for all i.

By Equation 15.19, the transmission zeros of $H_n(s)$ are set by the zeros of $T_j(s)$, i.e., by the feedforward path, whereas the poles of $H_n(s)$ are determined by the feedback network and involve both the poles and zeros of the biquads $T_j(s)$ and the feedback factors F_k. Typically, an FLF network is designed with second-order bandpass biquads

$$T_i(s) = A_i \frac{s/Q_i}{s^2 + s/Q_i + 1} = A_i t_i(s) \tag{15.20}$$

so that $H_n(s)$ has all transmission zeros at the origin, i.e., it is an all-pole bandpass function. Note that in Equation 15.20 the frequency parameter s is normalized to the pole frequency ω_0 ($\omega_{0i} = \omega_0$ for all i is assumed), and Q_i and A_i are the section's pole quality factor and midband gain, respectively. Designing an FLF network with arbitrary zeros requires second-order sections with finite transmission zeros, which leads to quite difficult design procedures. It is much simpler to use Equation 15.15 with Equation 15.18 to yield

$$H(s) = \frac{V_{\text{out}}}{V_{\text{in}}} = \frac{N_{2n}(s)}{D_{2n}(s)} = \alpha \frac{K_0 + \sum_{k=1}^{n} \left[K_k \prod_{j=1}^{k} T_j(s) \right]}{1 + \sum_{k=1}^{n} \left[F_k \prod_{j=1}^{k} T_j(s) \right]} \tag{15.21}$$

which realizes the transfer function of the complete circuit in Figure 15.3 with an arbitrary numerator polynomial $N_{2n}(s)$, even for second-order bandpass functions $T_i(s)$ as in Equation 15.20. It is a ratio of two polynomials whose roots can be set by an appropriate choice of the functions $T_i(s)$, the parameters K_i for the transmission zeros, and the feedback factors F_i for the poles.

We illustrate the design procedure by considering a specific case. For $n = 3$, Equation 15.21 becomes

$$H(s) = \alpha \frac{K_0 + K_1 T_1 + K_2 T_1 T_2 + K_3 T_1 T_2 T_3}{1 + F_1 T_1 + F_2 T_1 T_2 + F_3 T_1 T_2 T_3} \tag{15.22}$$

Next we transform the bandpass functions $T_i(s)$ in Equation 15.20 into lowpass functions by the lowpass-to-bandpass transformation (see Chapter 3)

$$p = Q \frac{s^2 + 1}{s} \tag{15.23}$$

where

$Q = \omega_0 / B$ is the "quality factor" of the high-order bandpass with bandcenter ω_0 and bandwidth B
p is the normalized lowpass frequency

This step transforms the bandpass functions (Equation 15.20) with all identical pole frequencies ω_0 into the first-order lowpass functions

$$T_{i\text{LP}}(p) = \frac{A_i Q / Q_i}{p + Q/Q_i} = \frac{q_i}{p + q_i} \tag{15.24}$$

where

$q_i = Q/Q_i$
A_i is the dc gain of the lowpass section

Applying Equation 15.23 to the prescribed function $H(s)$ of order $2n$ in Equation 15.22 converts it into a prototype lowpass function $H_{\text{LP}}(p)$ of order n. Substituting Equation 15.24 into the numerator and denominator expressions of that function, of order $n = 3$ in our case, shows that the zeros and poles, respectively, are determined by

$$N_3(p) = \alpha K_0 \prod_{j=1}^{3} (p + q_j) + \sum_{j=1}^{2} \left[k_j \prod_{i=j+1}^{3} (p + q_i) \right] + k_3 \tag{15.25a}$$

and

$$D_3(p) = \prod_{j=1}^{3} (p + q_j) + \sum_{k=1}^{2} \left[f_k \prod_{i=k+1}^{3} (p + q_i) \right] + f_3 \tag{15.25b}$$

where we introduced the abbreviations

$$f_i = F_i \prod_{j=1}^{i} A_j q_j \quad \text{and} \quad k_i = \alpha K_i \prod_{j=1}^{i} A_j q_j \tag{15.26}$$

To realize the prescribed third-order function

$$H_{\mathrm{LP}}(p) = \frac{V_o}{V_i} = \frac{a_3 p^3 + a_2 p^2 + a_1 p + a_0}{p^3 + b_2 p^2 + b_1 p + b_0} \tag{15.27}$$

we compare coefficients between Equations 15.25 and 15.27. For the denominator terms we obtain

$$\begin{aligned} b_2 &= q_1 + q_2 + q_3 + f_1 \\ b_1 &= q_1 q_2 + q_1 q_3 + q_2 q_3 + f_1(q_2 + q_3) + f_2 \\ b_0 &= q_1 q_2 q_3 + f_1 q_2 q_3 + f_2 q_3 + f_3 \end{aligned}$$

These are three equations in six unknowns, f_i and q_i, $i = 1, \ldots, 3$, which can be written more conveniently in matrix form:

$$\begin{pmatrix} 1 & 0 & 0 \\ q_2 + q_3 & 1 & 0 \\ q_2 q_3 & q_3 & 1 \end{pmatrix} \begin{pmatrix} f_1 \\ f_2 \\ f_3 \end{pmatrix} = \begin{pmatrix} b_2 - (q_1 + q_2 + q_3) \\ b_1 - (q_1 q_2 + q_1 q_3 + q_2 q_3) \\ b_0 - q_1 q_2 q_3 \end{pmatrix} \tag{15.28}$$

The transmission zeros are found via an identical process: the unknown parameters k_i are computed from an equation of the form (Equation 15.28) with f_i replaced by $k_i/(\alpha K_0)$ and b_i replaced by a_i/a_3, $i = 1, \ldots, 3$. Also, $K_0 = a_3/\alpha$.

The unknown parameters f_i can be solved from the matrix expression (Equation 15.28). It is a set of linear equations whose coefficients are functions of the prescribed coefficients b_i and of the numbers q_i which for given Q are determined by the quality factors Q_i of the second-order sections $T_i(s)$. Thus, the Q_i are free parameters that may be selected to satisfy any criteria that may lead to a better-working circuit. The free design parameters may be chosen, for example, to reduce a circuit's sensitivity to element variations. This leads to a multiparameter (i.e., the n Q_i-values) optimization problem whose solution requires the availability of the appropriate computer algorithms. If such software is not available, specific values of Q_i can be chosen. The design becomes particularly simple if all the Q_i-factors are equal, a choice that has the additional practical advantage of resulting in all identical second-order building blocks, $T_i(s) = T(s)$. For this reason, this approach has been referred to as the "Primary Resonator Block" (PRB) technique. The passband sensitivity performance of PRB circuits is almost as good as that of fully optimized FLF structures. The relevant equations are derived in the following:

With $q_i = q$ for all i we find from Equation 15.28

$$\begin{pmatrix} 1 & 0 & 0 \\ 2q & 1 & 0 \\ q^2 & q & 1 \end{pmatrix} \begin{pmatrix} f_1 \\ f_2 \\ f_3 \end{pmatrix} = \begin{pmatrix} b_2 - 3q \\ b_1 - 3q^2 \\ b_0 - q^3 \end{pmatrix} \tag{15.29}$$

It shows that

$$\begin{aligned} F_1 A_1 q &= f_1 = b_2 - 3q \\ F_2 A_1 A_2 q^2 &= f_2 = b_1 - 3q^2 - 2q f_1 \\ F_3 A_1 A_2 A_3 q^3 &= f_3 = b_0 - q^3 - q^2 f_1 - q f_2 \end{aligned} \tag{15.30}$$

The system (Equation 15.30) represents three equations for the four unknowns, q, f_i, $i = 1, \ldots, 3$, (in general, one obtains n equations for $n+1$ unknowns) so that one parameter, q, can still be used for optimization purposes. This single degree of freedom is often eliminated by choosing

$$q = \frac{b_{n-1}}{nb_n} \tag{15.31a}$$

i.e., $q = b_2/3$ in our example, which means $f_1 = 0$. The remaining feedback factors can then be computed recursively from Equation 15.30. The systematic nature of the equations makes it apparent how to proceed for $n > 3$. As a matter of fact, it is not difficult to show that, with $f_1 = 0$, in general

$$f_2 = b_{n-2} - \frac{n(n-1)}{2!} q^2 b_n \tag{15.31b}$$

$$f_i = b_{n-i} - \frac{q^i}{(n-i)!}\left[\frac{n!}{i!} b_n + \sum_{j=1}^{i-1} \frac{f_j}{q^j} \frac{(n-j)!}{(i-j)!}\right] \quad i = 3, \ldots, n \tag{15.31c}$$

Note that b_n usually equals unity. As mentioned earlier, equations of identical form, with f_i replaced by $k_i/(\alpha K_0)$ and b_i by a_i/a_n with $K_0 = a_n/\alpha$, are used to determine the summing coefficients K_i of the output summer, which establishes the transmission zeros. Thus, given a geometrically symmetrical bandpass function with center frequency ω_0, quality factor Q, and bandwidth B, Equation 15.31 can be used to calculate the parameter q and all feedback and summing coefficients required for a PRB design. All second-order bandpass sections, Equation 15.20, are tuned to the same pole-frequency, $\omega = \omega_0$, and have the same pole quality factor, $Q_p = Q/q$, where $Q = \omega_0/B$.

As discussed, the design procedure computes only the *products* f_i and k_i; the actual values of F_i, K_i, and A_i are not uniquely determined. As a matter of fact, the gain constants A_i are *free* parameters that are selected to maximize the circuit's dynamic range in much the same way as for cascade designs.* With a few simple approximations, it can be shown [5, Chapter 6] that the appropriate choice of gain constants in the FLF circuit is

$$A_i \approx \sqrt{1 + (Q_i/Q)^2} = \sqrt{1 + q_i^{-2}} \quad i = 1, \ldots, n \tag{15.32a}$$

The same equation holds for the PRB case where $Q_i = Q_p$ for all i so that

$$A_i = A \approx \sqrt{1 + (Q_p/Q)^2} = \sqrt{1 + q^{-2}} \tag{15.32b}$$

The following example demonstrates the complete FLF (PRB) design process.

Let us illustrate the multiple-loop feedback procedure by realizing again the bandpass function (Equation 15.10), but now as an FLF (PRB) circuit. The previous data specify that the bandpass function should be converted into a prototype lowpass function with bandcenter $\omega_0/(2\pi) = \sqrt{12 \cdot 36}$ kHz and bandwidth $B/(2\pi) = (36 - 12)$ kHz by the transformation Equation 15.23,

$$p = Q\frac{s^2 + 1}{s} = \frac{\omega_0}{B}\frac{s^2 + 1}{s} = \frac{\sqrt{12.36}}{36 - 12}\frac{s^2 + 1}{s} = 0.866\frac{s^2 + 1}{s} \tag{15.33}$$

* For practical FLF (PRB) designs, this step of scaling the signal levels is very important because an inadvertently poor choice of gain constants can result in very large internal signals and, consequently, very poor dynamic range.

where s is normalized by ω_0 as before. Substituting Equation 15.33 into Equation 15.10 results in

$$H_{\mathrm{LP}}(s) = \frac{0.491}{p^3 + 0.984p^2 + 1.236p + 0.491} \tag{15.34}$$

which corresponds to Equation 15.27 with $a_i = 0$, $i = 1, 2, 3$. To realize this function, we need three first-order lowpass sections of the form (Equation 15.24), i.e.,

$$T_{\mathrm{LP}}(p) = A\frac{q}{p+q} \tag{15.35}$$

where $A = \sqrt{1 + 1/q^2}$ from Equation 15.32b. We proceed with Equation 15.31a to choose $q = 0.984/3 = 0.328$, so that $A = 3.209$. With these numbers, we can apply Equation 15.33 to Equation 15.35 to obtain the second-order bandpass that must be realized:

$$T_{\mathrm{BP}}(p) = 3.209\frac{0.328}{0.866\frac{s^2+1}{s} + 0.328} = \frac{1.2153s}{s^2 + 0.379s + 1} \tag{15.36}$$

The feedback resistors we obtain by Equation 15.30:

$$\begin{aligned} 1.052F_1 &= f_1 = 0 \rightarrow F_1 = 0 \\ 1.108F_2 &= f_2 = b_1 - 3q^2 = 0.913 \rightarrow F_2 = 0.777 \\ 1.166F_3 &= f_3 = b_0 - q^3 - qf_2 = 0.371 \rightarrow F_3 = 0.318 \end{aligned} \tag{15.37}$$

Choosing, e.g., $R_{F0} = 10\ \mathrm{k}\Omega$ results in $R_{Fi} = R_{F0}/F_i$, that is, $R_{F1} = \infty$, $R_{F2} = 12.9\ \mathrm{k}\Omega$, and $R_{F3} = 31.5\ \mathrm{k}\Omega$. Also, $R_{F0}/R_{\mathrm{in}} = \alpha = 0.491$ $(Aq)^{-3} = 0.421 \rightarrow R_{\mathrm{in}} = 23.7\ \mathrm{k}\Omega$.

There remains the choice of second-order bandpass sections. Notice from Equation 15.19 that the sections must have positive, i.e., noninverting, gain to keep the feedback loops stable. We choose GIC (general impedance converter) sections [5, Chapter 4], [9, Chapter 4.5], one of which is shown explicitly in Figure 15.4. They realize

$$T(s) = \frac{V_{\mathrm{o}}}{V_i} = \frac{\left(1 + \frac{G_3}{G_2}\right)\frac{G_1}{C}s}{s^2 + \frac{G_1}{C}s + \left(\frac{G}{C}\right)^2\frac{G_3}{G_2}} = \frac{K\frac{\omega_0}{Q}s}{s^2 + \frac{\omega_0}{Q}s + \omega_0^2} \tag{15.38}$$

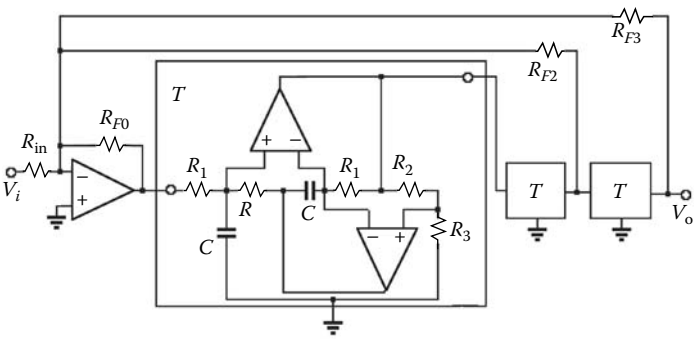

FIGURE 15.4 PRB topology with three identical GIC bandpass sections. The circuit for one section is shown explicitly, as is the input summer with the feedback resistors.

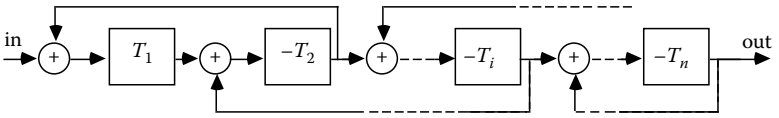

FIGURE 15.5 Leapfrog topology.

Comparing Equation 15.38 with Equation 15.36, choosing $R_3 = 5$ kΩ, $C = 2$ nF, and remembering that s is normalized with respect to $\omega_0 = 130{,}590$ s^{-1} results in the rounded values

$$R = 5.5 \text{ k}\Omega \quad R_1 = 10 \text{ k}\Omega \quad R_2 = 10 \text{ k}\Omega$$

15.3.2 Leapfrog Topology

The LF configuration is pictured in Figure 15.5. Each of the boxes labeled T_i realizes a second-order transfer function. The feedback loops always comprise two sections; thus, inverting and noninverting sections must alternate to keep the loop gains negative and the loops stable. If the circuit is derived from a resistively terminated lossless ladder filter as is normally the case, T_1 and T_n are lossy and all the internal sections are lossless. A lossless block implies a function T_i with infinite Q, which may not be stable by itself, but the overall feedback connection guarantees stability.

An LF circuit can be derived from the configuration in Figure 15.5 by direct analysis with, e.g., bandpass transfer functions as in Equation 15.20 assumed for the blocks T_i. Comparing the resulting equation with that of a prescribed filter yields expressions that permit determining all circuit parameters in a similar way as for FLF filters [1]. Because the topology is identical to that derived from a signal-flow graph representation of an *LC* ladder filter, we do not consider the details of the LF approach here, but instead proceed directly to the ladder simulation techniques.

15.4 Ladder Simulations

Although transfer functions of *LC* ladders are more restrictive than those realizable by cascade circuits (see footnote in Section 15.2), lossless ladder filters designed for maximum power transfer have received considerable attention in the active filter literature because of their significant advantage of having the lowest possible sensitivities to component tolerances in the passband. Indeed, the majority of high-order active filters with demanding specifications are being designed as simulated *LC* ladders. Many active circuit structures have been developed, which simulate the performance of passive *LC* ladders and inherit their good sensitivity performance. The ladder simulations can be classified into two main groups: *operational simulation* and *element substitution*. Starting from an existing *LC* prototype ladder, the operational simulation models the internal operation of the ladder by simulating the circuit equations, i.e., Kirchhoff's voltage and current laws and the *I–V* relationships of the ladder arms. Fundamentally, this procedure simulates the *signal-flow graph* (SFG) of the ladder where all voltages and all currents are considered signals, which are integrated on the inductors and capacitors, respectively. The SFG method is developed in Section 15.4.1. The element substitution procedure replaces all inductors or inductive branches by active networks whose input impedance is inductive over the frequency range of interest. A practical approach to this method is presented in Section 15.4.3. For more detailed discussions of these important and practical procedures, we refer the reader to a modern text on active filters, such as Refs. [5,6,9] and, for approaches using operational transconductance amplifiers, to Section 16.3.

15.4.1 Signal-Flow Graph Methods

To derive the SFG method, consider the ladder structure in Figure 15.6, whose branches may contain arbitrary combinations of capacitors and inductors. In general, resistors are permitted to allow for lossy components. Labeling the combination of elements in the series arms as admittances Y_i, $i = 2, 4$, and those in the shunt branches as impedances Z_j, $j = 1, 3, 5$, we can readily analyze the ladder by writing Kirchhoff's laws and the I–V relationships for the ladder arms as follows:

$$\begin{aligned} I_i &= G_i(V_i - V_1) \quad V_1 = Z_1 I_1 = Z_1(I_i - I_2) \\ I_2 &= Y_2 V_2 = Y_2(V_1 - V_3) \quad V_3 = Z_3 I_3 = Z_3(I_2 - I_4) \\ I_4 &= Y_4 V_4 = Y_4(V_3 - V_5) \quad V_5 = V_o = Z_5 I_5 = Z_5(I_4 - I_6) \quad I_6 = G_o V_o \end{aligned} \tag{15.39}$$

In the active simulation of this circuit, all currents and voltages are to be represented as *voltage* signals. To reflect this in the expressions, we use a resistive scaling factor R as shown in one of these equations as an example:

$$V_3 = \frac{Z_3}{R} I_3 R = \frac{Z_3}{R}(I_2 R - I_4 R) \tag{15.40}$$

and introduce the notation

$$I_k R = i_k \quad V_k = v_k \quad G_i R = g_i \quad Z_k/R = z_k \quad Y_k R = y_k \tag{15.41}$$

The lower-case symbols are used to represent the *scaled* quantities; notice that z_k and y_k are dimensionless voltage transfer functions, also called *transmittances*, and that both i_k and v_k are voltages. We shall retain the symbol i_k to remind ourselves of the origin of that signal as a current in the original ladder. Equation 15.39 then takes on the form

$$\begin{aligned} i_i &= g_i[v_i + (-v_1)] \quad -v_1 = -z_1\ i_1 = -z_1\ [i_i + (-i_2)] \\ -i_2 &= y_2(-v_2) = y_2[(-v_1) + v_3] \quad v_3 = -z_3(-i_3) = -z_3[(-i_2) + i_4] \\ i_4 &= y_4\ v_4 = y_4[v_3 + (-v_5)] \quad -v_5 = -v_o = -z_5 i_5 = -z_5[i_4 + (-i_6)] \quad -i_6 = g_o(-v_o) \end{aligned} \tag{15.42}$$

where we have made all the transmittances z_i inverting and assigned signs to the signals in a consistent fashion, such that only *signal addition* is required in the circuit to be derived from these equations. We made this choice because addition can be performed at op-amp summing nodes with no additional circuitry (see below), whereas subtraction would require either differential amplifiers or inverters. The price to be paid for this convenience is that in some cases the overall transfer function suffers a sign inversion (a 180° phase shift), which is of no consequence in most cases. The signal-flow block diagram

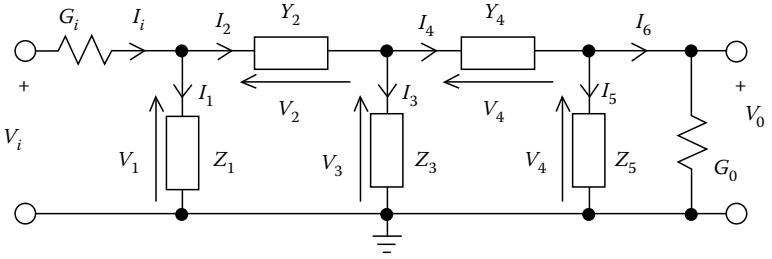

FIGURE 15.6 Ladder network.

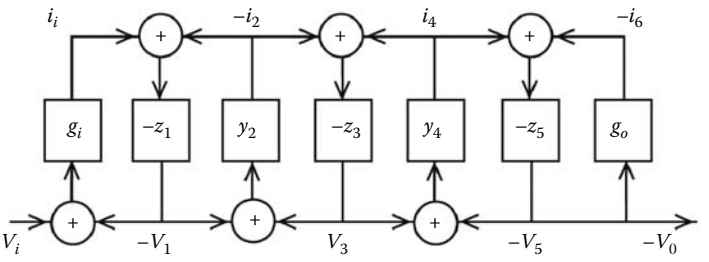

FIGURE 15.7 Signal-flow graph block diagram realizing Equation 15.42.

implementing Equation 15.42 is shown in Figure 15.7. As is customary, all voltage signals are drawn at the bottom of the diagram, and those derived from currents at the top. We observe that the circuit consists of a number of interconnected loops of two transmittances each and that all loop-gains are negative as required for stability. Notice that redrawing this figure in the form of Figure 15.5 results in an identical configuration, i.e., as mentioned earlier, the leapfrog method is derived from a ladder simulation technique.

To determine how the transmittances are to be implemented, we need to know which elements are in the ladder arms. Consider first the simple case of an all-pole lowpass ladder where $Z_i = 1/(sC_i)$ and $Y_j = 1/(sL_j)$, i.e., $z_i = 1/(sC_iR)$ and $y_i = 1/(sL_i/R)$ (see Figure 15.11). Evidently then, for this case all transmittances are integrators. Suitable circuits are shown in Figure 15.8 where for each integrator we have used two inputs in anticipation of the final realization, which has to sum two signals as indicated in Figure 15.7. The circuits realize

$$V_o = \pm \frac{G_1 V_1 + G_2 V_2}{sC + G_3} \tag{15.43}$$

where the plus sign is valid for the series transmittances $y_i(s)$ in Figure 15.8b and the minus sign for the shunt transmittances $z_i(s)$* in Figure 15.8a. G_3 is zero if the integration is lossless as required in an internal branch of the ladder; in the two end branches, G_3 is used to implement the source and load resistors of the ladder.

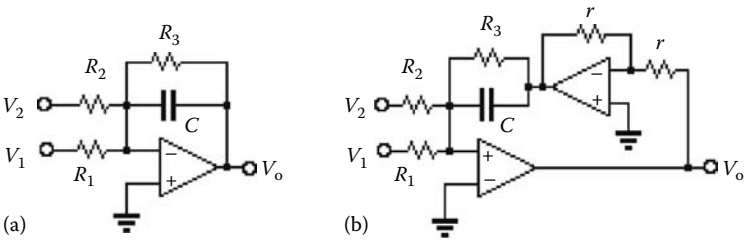

FIGURE 15.8 (a) Inverting lossy Miller integrator; (b) noninverting lossy phase-lead integrator.

* These two circuits are good candidates for building two-integrator loops as required in Figure 15.7 because the op-amp in the Miller integrator causes a phase lag, whereas the op-amps in the noninverting integrator cause a phase lead of the same magnitude. In the loop, these two phase shifts just cancel and cause no errors in circuit performance. Notice that the Åckerberg–Mossberg biquad in Figure 15.2 is also constructed as a loop of these two integrators.

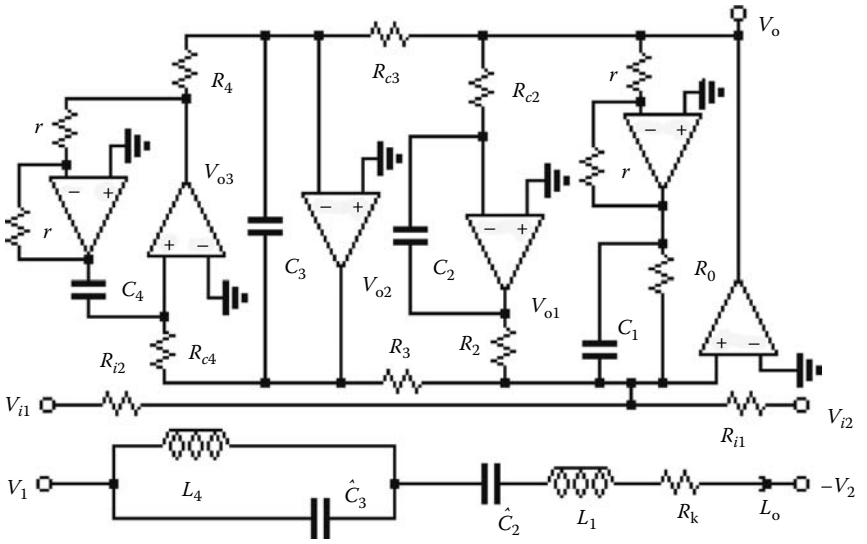

FIGURE 15.9 Active realization of a series ladder branch (plus sign in Equation 15.46).

The next question to be answered is what circuitry will realize more general ladder arms which may contain both series and parallel *LC* elements, and resistors to handle the source or load terminations (or losses if required). Such general series and shunt branches are shown at the bottom of Figures 15.9 and 15.10, respectively, where we have labeled the capacitors in the *passive* network as "$\hat{C}$" to be able to distinguish them from the capacitors in the active circuit (labeled *C* without circumflex). We have chosen the signs of the relevant voltages and currents in Figures 15.9 and 15.10 appropriately to obtain

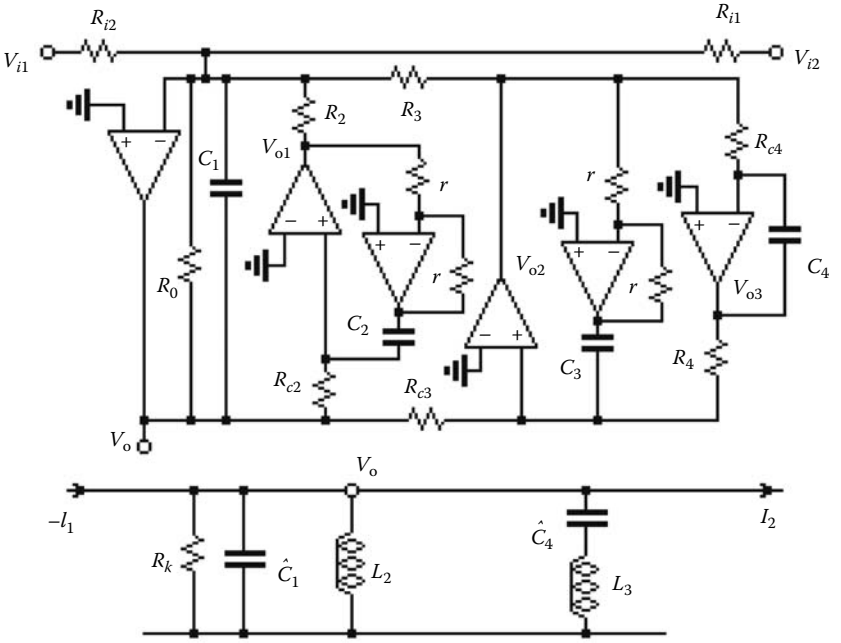

FIGURE 15.10 Active realization of a shunt ladder branch minus sign in Equation 15.46.

noninverting transmittances $y(s)$ for the series arms and *inverting transmittances* $z(s)$ for the shunt arms as requested in Figure 15.7. Recall that this choice permits the flowgraph to be realized with only *summing* functions. For easy reference, the active *RC* circuits realizing these branches are shown directly above the passive *LC* arms [5, Chapter 6], [9, Chapter 15].

The passive series branch in Figure 15.9 realizes the current I_o

$$\begin{aligned} I_o R_\mathrm{p} &= +Y(s)R_\mathrm{p}(aV_1 + bV_2) \\ &= +\frac{1}{R_k/R_\mathrm{p} + sL_1/R_\mathrm{p} + \frac{1}{s\hat{C}_2 R_\mathrm{p}} + \frac{1}{s\hat{C}_3 R_\mathrm{p} + \frac{1}{sL_4/R_\mathrm{p}}}}(aV_1 + bV_2) \end{aligned} \tag{15.44a}$$

which was converted into a voltage through multiplication with a scaling resistor R_p (p stands for *passive*; R_p is the resistor used to scale the *passive* circuit). Also, we have multiplied the input signals by two constants, a and b, in anticipation of future scaling possibilities in the *active* circuit. Using, as before, *lower-case* symbols for the *normalized* variables, we obtain for the series branch

$$i_o = +y(s)(av_1 + bv_2) = +\frac{1}{r_k + sl_1 + \frac{1}{sc_2} + \frac{1}{sc_3 + \frac{1}{sl_4}}}(av_1 + bv_2) \tag{15.44b}$$

In an analogous fashion we find for the voltage V_o in the passive shunt branch in Figure 15.10, after impedance-level scaling with R_p and signal-level scaling with a and b, the expression

$$\begin{aligned} V_\mathrm{o} &= -\frac{Z(s)}{R_\mathrm{p}}(aI_1 R_\mathrm{p} + bI_2 R_\mathrm{p}) \\ &= -\frac{1}{G_k R_\mathrm{p} + s\hat{C}_1 R_\mathrm{p} + \frac{1}{sL_2/R_\mathrm{p}} + \frac{1}{sL_3/R_\mathrm{p} + \frac{1}{sC_4 R_\mathrm{p}}}}(aI_1 R_\mathrm{p} + bI_2 R_\mathrm{p}) \end{aligned} \tag{15.45a}$$

which with lower-case notation gives

$$v_o = -z(s)(ai_1 + bi_2) = -\frac{1}{g_k + sc_1 + \frac{1}{sl_2} + \frac{1}{sl_3 + \frac{1}{sc_4}}}(ai_1 + bi_2) \tag{15.45b}$$

Turning now to the active *RC* branches in Figures 15.9 and 15.10, elementary analysis of the two circuits, assuming ideal op-amps,* results in

$$V_\mathrm{o} = \pm\frac{R_\mathrm{a}G_{i1}V_{i1} + R_\mathrm{a}G_{i2}V_{i2}}{R_\mathrm{a}G_0 + sC_1R_\mathrm{a} + \frac{R_\mathrm{a}G_2}{sC_2R_{c2}} + \frac{R_\mathrm{a}G_3}{sC_3R_{c3} + \frac{G_4R_{c3}}{sC_4R_{c4}}}} \tag{15.46}$$

where we used a normalizing resistor R_a (a stands for *active*; R_a is the resistor used to scale the *active* circuit). In Equation 15.46 the plus sign is valid for the series arm, Figure 15.9, and the minus sign for the shunt arm, Figure 15.10.

---

* Using a more realistic op-amp model, $A(s) \approx \omega_t/s$, one can show [5, Chapter 6] that Equation 16.46 to a first-order approximation is multiplied by $(1 + j\omega/\omega_t) \approx \exp(j\omega/\omega_t)$ for the series arm (plus sign in Equation 16.46) and by $(1 - j\omega/\omega_t) \approx \exp(-j\omega/\omega_t)$ for the shunt arm [minus sign in Equation 16.46]. Thus, in the loop gains determined by the product of an inverting and a noninverting branch, op-amp effects cancel to a first order, justifying the assumption of ideal op-amps. See footnote in Section 15.4.1.

Notice that Equation 15.46 is of the same form as Equations 15.44 and 15.45 so that we can compare the expressions term-by-term to obtain the component values required for the active circuit (s) to realize the prescribed passive ladder arms. Thus, we find for the *series* branch, Figure 15.9, by comparing coefficients between Equations 15.46 and 15.44a, and assuming all equal capacitors C in the active circuit:

$$\begin{gathered} R_{i1} = \frac{R_\mathrm{a}}{a} \quad R_{i2} = \frac{R_\mathrm{a}}{b} \quad R_0 = \frac{R_\mathrm{a}R_\mathrm{p}}{R_k} \quad C = \frac{L_1}{R_\mathrm{a}R_\mathrm{p}} \\ R_{c2}R_2 = \frac{\hat{C}_2}{C}R_\mathrm{a}R_\mathrm{p} \quad R_{c3}R_3 = \frac{\hat{C}_3}{C}R_\mathrm{a}R_\mathrm{p} \quad R_{c4}R_4 = \frac{L_4\hat{C}_3}{C^2} \end{gathered} \tag{15.47a}$$

In an identical fashion we obtain from Equations 15.46 and 15.45a for the components of the *shunt* arm

$$\begin{gathered} R_{i1} = \frac{R_\mathrm{a}}{a} \quad R_{i2} = \frac{R_\mathrm{a}}{b} \quad R_0 = R_k\frac{R_\mathrm{a}}{R_\mathrm{p}} \quad C = \hat{C}_1\frac{R_\mathrm{p}}{R_\mathrm{a}} \\ R_{c2}R_2 = \frac{L_2}{C}\frac{R_\mathrm{a}}{R_\mathrm{p}} \quad R_{c3}R_3 = \frac{L_3}{C}\frac{R_\mathrm{a}}{R_\mathrm{p}} \quad R_{c4}R_4 = \frac{L_3\hat{C}_4}{C^2} \end{gathered} \tag{15.47b}$$

The scaling resistors R_a and R_p are chosen to obtain convenient element values. Note that each of the last three equations for both circuits determines only the *product* of two resistors. This leaves three degrees of freedom that are normally chosen to maximize dynamic range by equalizing the maximum signal levels at all op-amp outputs. We provide some discussion of these matters in Section 15.4.2.

We have displayed the active and passive branches in Figures 15.9 and 15.10 together to illustrate the one-to-one correspondence of the circuits. For example, if we wish to design an all-pole lowpass filter, such as the one in Figure 15.11, where the internal series arms consist of a single inductor and each internal shunt arm of a single capacitor, the corresponding active realizations reduce to those of Figure 15.8b and a, respectively, with $R_3 = \infty$. For the end branches, R_s in series with L_1 and R_l in parallel with $\hat{C}_4$, we obtain the circuits in Figure 15.8b and a, respectively, with R_3 *finite* to account for the source and load resistors. The remaining branches in the active circuits are absent. Assembling the resulting circuits as prescribed in Figure 15.7 leads to the active SFG filter in Figure 15.12, where we have for convenience chosen all identical capacitors, C, and have multiplied the input by an arbitrary constant K because the active circuit may realize a gain scaling factor. The component values are computed from a set of equations similar to Equation 15.47. To show in some detail how they are arrived at, we derive the equations for each integrator in Figure 15.12 and compare them with the corresponding arm in the passive ladder. Recalling that signals with lower-case symbols in the active circuit are voltages, we obtain

$$\frac{G_1R_\mathrm{a}V_\mathrm{in} + G_2R_\mathrm{a}(-v_2)}{sCR_\mathrm{a} + G_3R_\mathrm{a}} \rightarrow \frac{KV_\mathrm{in} - V_2}{sL_1/R_\mathrm{p} + R_\mathrm{s}/R_\mathrm{p}} \tag{15.48a}$$

$$\frac{G_4R_\mathrm{a}i_1 + G_5R_\mathrm{a}(-i_3)}{sCR_\mathrm{a}} \rightarrow \frac{I_1 - I_3}{s\hat{C}_2R_\mathrm{p}} \tag{15.48b}$$

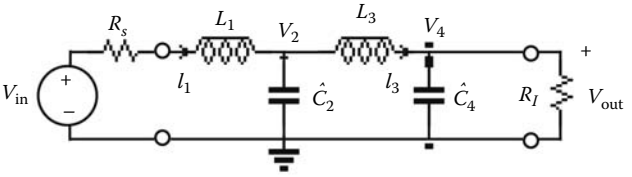

FIGURE 15.11 Fourth-order all-pole lowpass ladder.

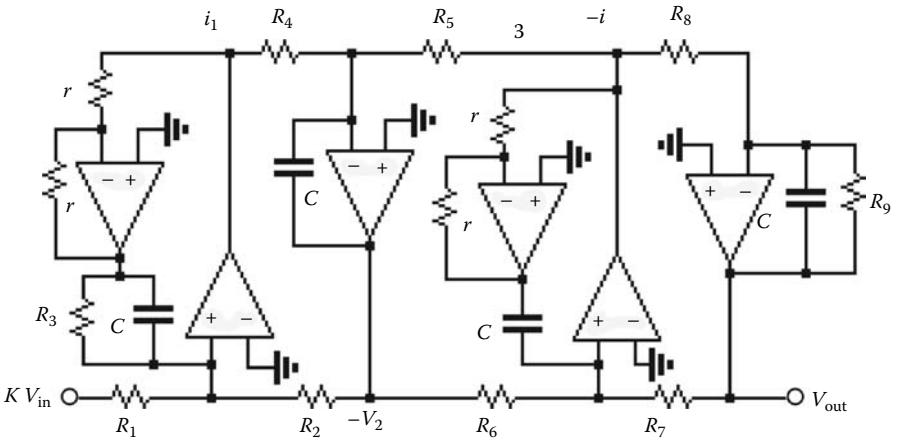

FIGURE 15.12 Active realization of the ladder in Figure 15.11.

$$\frac{G_6R_a(-v_2) + G_7R_aV_{out}}{sCR_a} \rightarrow \frac{-V_2 + V_4}{sL_3/R_p} \tag{15.48c}$$

$$\frac{G_8R_a(-i_3)}{sCR_a + G_9R_a} \rightarrow \frac{-i_3}{s\hat{C}_4R_p + R_p/R_l} \tag{15.48d}$$

where we used scaling resistors for the active (R_a) and the passive (R_p) circuits as before. Choosing a convenient value for C in the active circuit and equating the time constants and the dc gains in Equation 15.48a results in the following expressions:

$$R_3 = \frac{L_1}{C}\frac{1}{R_s} \quad R_1 = R_3\frac{R_s}{KR_p} \quad R_2 = R_3\frac{R_s}{R_p} \tag{15.49a}$$

Similarly,

$$R_4 = R_5 = \frac{\hat{C}_2}{C} \quad R_6 = R_7 = \frac{L_3}{C}\frac{1}{R_p} \quad R_8 = \frac{\hat{C}_4}{C} \quad R_9 = \frac{\hat{C}_4}{C}\ R_l = \frac{R_l}{R_p}R_8 \tag{15.49b}$$

15.4.2 Maximization of the Dynamic Range

The remaining task in a signal-flow graph simulation of an *LC* ladder is that of voltage-level scaling for dynamic range maximization. As in cascade design, we need to achieve that all op-amps in $0 \leq \omega \leq \infty$ see the same maximum signal level so that no op-amp becomes overdriven sooner than any other one. It may be accomplished by noting that a scale factor can be inserted into any signal line in a signal-flow graph *as long as the loop gains are not changed*. Such signal-level scaling will not affect the transfer function except for an overall gain factor. The procedure can be illustrated in the flow diagram in Figure 15.7. If we simplify the circuit by combining the self-loops at input and output and employ the scale factors α, β, γ, δ and their inverses to the loops in Figure 15.7, we obtain the modified flow diagram in Figure 15.13. Simple analysis shows that the transfer function has not changed except for a multiplication by the factor $\alpha\beta\gamma\delta$, which is canceled by the multiplier $(\alpha\beta\gamma\delta)^{-1}$ at the input. To understand how the scale factors are

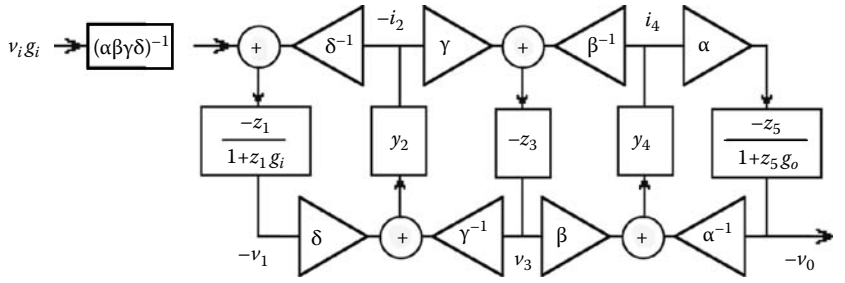

FIGURE 15.13 Using scale factor for signal-level equalization.

computed, assume that in Figure 15.7, i.e., before scaling, the maximum of $|i_4(j\omega)|$ is α times as large as the maximum of $|v_o(j\omega)|$, where α may be less than or larger than unity. Since

$$-v_o = \frac{-z_5}{1 + z_5 g_o} i_4$$

the maxima can be equalized, i.e., the level of v_o can be increased by α, if we apply a gain scale factor α as indicated in Figure 15.13. To keep the loop gain unchanged, a second scale factor α^{-1} is inserted as shown. Continuing, if in Figure 15.7 max $|v_3(j\omega)|$ is β times as large as max $|i_4(j\omega)|$, we raise the level of $|i_4|$ by a gain factor β and correct the loop gain by a second factor β^{-1} as shown in Figure 15.13. In a similar fashion we obtain the maxima of the remaining voltages and apply the appropriate scale factors γ, δ, γ^{-1}, and δ^{-1} in Figure 15.13.

It is easy to determine the relevant maxima needed for calculating the gain factors. Recall that the node voltages v_i, v_1, i_2, v_3, i_4, and $v_5 = v_o$ in the signal-flow graph of Figure 15.13 correspond directly to the actual currents and voltages in the original ladder, Figure 15.6, and that their maxima in $0 \le \omega \le \infty$ can be evaluated readily with any network analysis program. For the circuit in Figure 15.13, the scale factors that ensure that the currents (normalized by R_p) in all series ladder arms and the voltages in all shunt ladder arms have the same maxima are then obtained as

$$\alpha = \frac{\max|i_4|}{\max|v_o|} \quad \beta = \frac{\max|v_3|}{\max|i_4|} \quad \gamma = \frac{\max|i_2|}{\max|v_3|} \quad \delta = \frac{\max|v_1|}{\max|i_2|} \tag{15.50}$$

The procedure thus far takes care of ladders with only one element in each branch, such as all-pole lowpass filters (Figure 15.11). In the more general case, we must also equalize the maxima of the magnitudes of V_{o1}, V_{o2}, and V_{o3} at the *internal* op-amp outputs in Figures 15.9 and 15.10. This is achieved easily if we remember that the "external" voltage maxima of $|V_{i1}|$, $|V_{i2}|$, and $|V_o|$ are already equalized by the previous steps leading to Equation 15.50, and that in the passive *series* branch V_{o1} represents the voltage on $\hat{C}_2$, V_{o2} stands for the voltage on $\hat{C}_3$, and V_{o3} corresponds to the current (times R_p) through the inductor L_4. After finding the maxima of these signals with the help of a network analysis program and computing the scale factors

$$m_1 = \frac{\max|V_{o1}|}{\max|V_o|} \quad m_2 = \frac{\max|V_{o2}|}{\max|V_o|} \quad m_3 = \frac{\max|V_{o3}|}{\max|V_o|} \tag{15.51}$$

we can equalize all internal branch voltages of the *series* arm (Figure 15.9) by modifying the design Equations 15.47a as follows [5, Chapter 6]:

$$R_{i1} = \frac{R_a}{a} \quad R_{i2} = \frac{R_a}{b} \quad R_0 = \frac{R_a R_p}{R_k} \quad C = \frac{L_1}{R_a R_p}$$
$$m_1 R_{c2} \frac{R_2}{m_1} = \frac{\hat{C}_2}{C} R_a R_p \quad m_2 R_{c3} \frac{R_3}{m_2} = \frac{\hat{C}_3}{C} R_a R_p \quad \frac{m_3}{m_2} R_{c4} \frac{R_4}{m_3/m_2} = \frac{L_4 \hat{C}_3}{C^2} \tag{15.52}$$

A possible choice for the element values given by products is

$$m_1 R_{c2} = \frac{R_2}{m_1} = \sqrt{\frac{\hat{C}_2}{C} R_a R_p} \quad m_2 R_{c3} = \frac{R_3}{m_2} = \sqrt{\frac{\hat{C}_3}{C} R_a R_p}$$
$$\frac{m_3}{m_2} R_{c4} = \frac{m_2}{m_3} R_4 = \frac{\sqrt{L_4 \hat{C}_3}}{C} \tag{15.53a}$$

In the passive *shunt* branch, V_{o1} and V_{o2} represent the currents (times R_p) through the inductors L_2 and L_3, respectively, and V_{o3} stands for the voltage across $\hat{C}_4$. In an identical fashion we obtain then with Equation 15.50 from Equation 15.47b for the components of the *shunt* arm

$$R_{i1} = \frac{R_a}{a} \quad R_{i2} = \frac{R_a}{b} \quad R_0 = R_k \frac{R_a}{R_p} \quad C = \hat{C}_1 \frac{R_p}{R_a}$$
$$m_1 R_{c2} = \frac{R_2}{m_1} = \sqrt{\frac{L_2}{C} \frac{R_a}{R_p}} \quad m_2 R_{c3} = \frac{R_3}{m_2} = \sqrt{\frac{L_3}{C} \frac{R_a}{R_p}}$$
$$\frac{m_3}{m_2} R_{c4} = \frac{m_2}{m_3} R_4 = \sqrt{\frac{L_3 \hat{C}_4}{C}} \tag{15.53b}$$

Next we present an example [2], [5, Chapter 6] in which the reader may follow the different steps discussed.

To simulate the fourth-order elliptic lowpass ladder filter in Figure 15.14a by the signal-flow graph technique, we first reduce the loop count by a source transformation. The resulting circuit, after

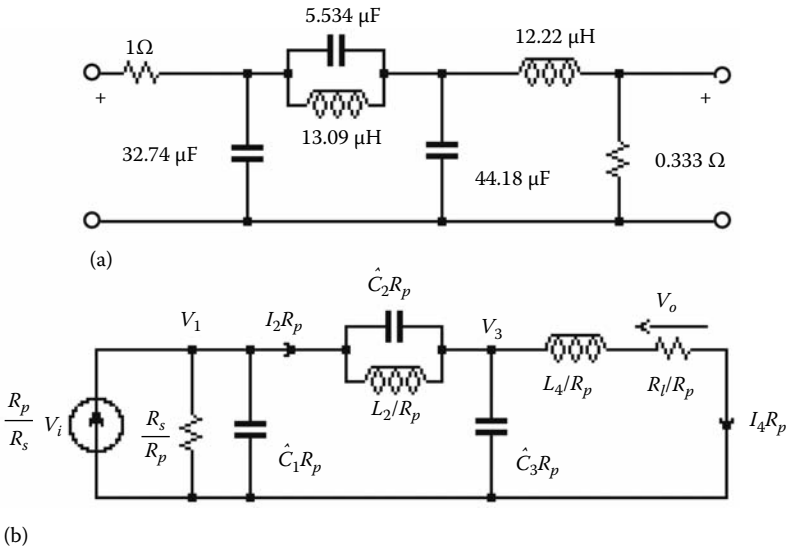

FIGURE 15.14 (a) Fourth-order elliptic *LC* lowpass ladder; (b) the circuit after source transformation and impedance scaling.

TABLE 15.1 Voltage and Current Maxima for Figure 15.14a

Voltage or Current	Maximum of Voltage or Current
Voltage across $\hat{C}_1$	0.699 V
Current through L_2	1.550 A
Voltage across $\hat{C}_2$	1.262 V
Current through $L_1 \| \hat{C}_2$	1.125 A
Voltage across $\hat{C}_2$	0.690 V
Current through L_4	0.866 A

impedance scaling, is shown in Figure 15.14b. To use signal-level scaling for optimizing the dynamic range, the relevant maxima of the *LC* ladder currents and voltages are needed. Table 15.1 lists the relevant data obtained with the help of network analysis software. From these numbers we find

$$\alpha = \frac{\max|v_3|}{\max|i_4 R_p|} = \frac{0.69}{0.866} = 0.797 \quad \beta = \frac{\max|i_2 R_p|}{\max|v_3|} = \frac{1.125}{0.690} = 1.630$$
$$\gamma = \frac{\max|v_1|}{\max|i_2 R_p|} = \frac{0.699}{1.125} = 0.621 \tag{15.54}$$

For ease of reference, the signal-flow graph with scaling factors is shown in Figure 15.15. Let $R_p = 1\ \Omega$. Note that the input signal voltage $i_{in} = R_p V_i / R_s$ has been multiplied by a factor K to permit realizing an arbitrary signal gain. If the desired gain is unity, and since the *dc* gain in the passive *LC* ladder equals

$$\frac{V_o}{V_i} = \frac{R_l}{R_s + R_l} = \frac{0.333}{1.333} = 0.25$$

we need to choose $K = 1/0.25 = 4$. Thus, the input signal i_i is multiplied by

$$\frac{K}{\alpha\beta\gamma} = \frac{4}{0.797 \cdot 1.630 \cdot 0.621} = 4.958 \tag{15.55}$$

The transmittances are defined as

$$z_1 = \frac{1}{s\hat{C}_1 R_p + G_s R_p} \quad y_2 = \frac{1}{\frac{1}{s\hat{C}_2 R_p + R_p/(sL_p)}}$$
$$z_3 = \frac{1}{s\hat{C}_3} \quad y_4 = \frac{1}{sL_4/R_p + R_l/R_p} \tag{15.56}$$

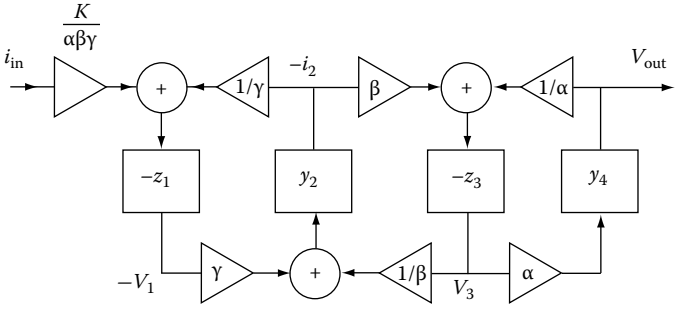

FIGURE 15.15 Signal-flow graph for the filter in Figure 15.14.

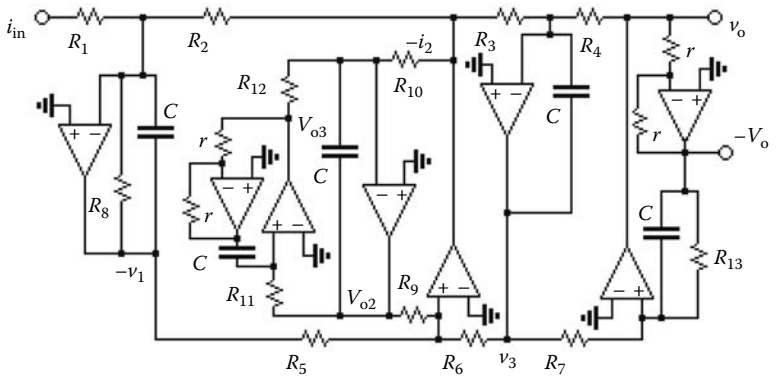

FIGURE 15.16 Active realization of the circuit in Figure 15.14.

With the numbers in Equations 15.54 and 15.55 we obtain from the signal-flow graph

$$\begin{aligned} -v_1 &= -z_1\left(4.958 i_{\text{in}} - \frac{1}{0.621} i_2\right) \quad -i_2 = y_2\left(-0.621 v_1 + \frac{1}{1.630} v_3\right) \\ v_3 &= -z_3\left(-1.630 i_2 + \frac{1}{0.797} v_{\text{out}}\right) \quad v_{\text{out}} = y_4 0.792 v_3 \end{aligned} \tag{15.57}$$

The reader is encouraged to verify from Equations 15.56 and 15.57 and Figures 15.9 and 15.10 that the active SFG realization of the ladder is as shown in Figure 15.16. For instance, the circuitry between the nodes v_1, v_3, and i_2 implements the parallel LC series branch to realize the finite transmission zero, obtained from Figure 15.9 by setting the components G_0, C_1, G_2, G_{c2}, and C_2 to zero. The element values in the active circuit are now determined readily by comparing the circuit equations for the active circuit,

$$\begin{aligned} -v_1 &= -\frac{G_1 R_{a1} i_{\text{in}} + G_2 R_{a1}(-i_2)}{sCR_{a1} + G_8 R_{a1}} \quad -i_2 = \frac{G_5 R_{a2}(-v_1) + G_6 R_{a2} v_3}{\frac{G_9 R_{a2}}{sCR_{10} + \frac{G_{12} R_{10}}{sCR_{11}}}} \\ v_3 &= -\frac{G_3 R_{a3}(-i_2) + G_4 R_{a3} v_o}{sCR_{a3}} \quad v_o = \frac{G_7 R_{a4} v_3}{sCR_{a4} + G_{13} R_{a4}} \end{aligned} \tag{15.58}$$

to Equation 15.57 and using Equation 15.56.* Comparing the coefficients results in

$$\begin{aligned} G_1 R_{a1} &= 4.958 \quad G_2 R_{a1} = \frac{1}{0.621} \quad G_5 R_{a2} = 0.621 \quad G_6 R_{a2} = \frac{1}{1.630} \\ G_3 R_{a3} &= 1.630 \quad G_4 R_{a3} = \frac{1}{0.797} \quad G_7 R_{a4} = 0.797 \end{aligned}$$

Further,

$$\hat{C}_1 R_p = CR_{a1} \quad \hat{C}_2 R_p = C\frac{R_9 R_{10}}{R_{a2}} \quad \hat{C}_3 R_p = CR_{a3} \quad \frac{L_4}{R_p} = CR_{a4}$$

Thus, with $R_p = 1\ \Omega$ and choosing $C = 5$ nF,

* Observe that for greater flexibility we permitted a different scaling resistor R_{ai}, $i = 1, \ldots, 4$, in each branch.

$$R_{a1} = \frac{\hat{C}_1}{C} R_p = 6.55\ \text{k}\Omega \quad R_{a3} = \frac{\hat{C}_3}{C} R_p = 8.84\ \text{k}\Omega \quad R_{a4} = \frac{L_4}{CR_p} = 2.44\ \text{k}\Omega$$

R_{a2} is undetermined; choosing $R_{a2} = 5\ \text{k}\Omega$ leads to the feed-in resistors for each branch

$$R_1 = \frac{R_{a1}}{4.958} = 0.800\ \text{k}\Omega \quad R_2 = 0.621 R_{a1} = 4.07\ \text{k}\Omega \quad R_3 = \frac{R_{a3}}{1.630} = 5.42\ \text{k}\Omega$$
$$R_4 = 0.797\ R_{a3} = 7.05\ \text{k}\Omega \quad R_5 = \frac{R_{a2}}{0.621} = 8.05\ \text{k}\Omega$$
$$R_6 = 1.630\ R_{a3} = 8.15\ \text{k}\Omega \quad R_7 = \frac{R_{a4}}{0.797} = 3.06\ \text{k}\Omega$$

The remaining components are determined from the equations

$$R_8 = R_s \frac{R_{a1}}{R_p} = 6.55\ \text{k}\Omega \quad R_{13} = \frac{R_{a4} R_p}{R_l} = 7.33\ \text{k}\Omega$$

and

$$R_9 R_{10} = R_p R_{a2} \frac{\hat{C}_2}{C} = (2.35\ \text{k}\Omega)^2 \quad R_{11} R_{12} = \frac{L_2}{C} \frac{R_9 R_{10}}{R_{a2} R_p} = (1.70\ \text{k}\Omega)^2$$

Since only the products of these resistors are given, we select their values uniquely for dynamic range maximization. According to Equation 15.51 we compute from Table 15.1

$$m_2 = \frac{\max|v_{c2}|}{\max|i_2|} = \frac{1.262}{1.125} = 1.12 \quad \text{and} \quad m_3 = \frac{\max|i_{L2}|}{\max|i_2|} = \frac{1.550}{1.125} = 1.38$$

to yield from Equation 15.53a:

$$R_9 = m_2\ 2.35\ \text{k}\Omega = 2.64\ \text{k}\Omega \quad R_{10} = \frac{2.35\ \text{k}\Omega}{m_2} = 2.10\ \text{k}\Omega$$
$$R_{11} = \frac{m_2}{m_3} 1.70\ \text{k}\Omega = 1.38\ \text{k}\Omega \quad R_{12} = \frac{m_3}{m_2} 1.70\ \text{k}\Omega = 2.09\ \text{k}\Omega$$

15.4.3 Element Substitution

LC ladders are known to yield low-sensitivity filters with excellent performance, but high-quality inductors cannot be implemented in microelectronic form. An appealing solution to the filter design problem is, therefore, to retain the ladder structure and to simulate the behavior of the inductors by circuits consisting of resistors, capacitors, and op-amps. A proven technique uses *impedance converters*, electronic circuits whose input impedance is proportional to frequency when loaded by the appropriate element at the output. The best-known impedance converter is the gyrator, a two-port circuit whose input impedance is inversely proportional to the load impedance, i.e.,

$$Z_{in}(s) = \frac{r^2}{Z_L(s)} \tag{15.59}$$

The parameter r is called the *gyration resistance*. Clearly, when the load is a capacitor, $Z_L(s) = 1/(sC)$, $Z_{in}(s) = sr^2C$ is the impedance of an inductor of value $L = r^2C$. Gyrators are very easy to realize with

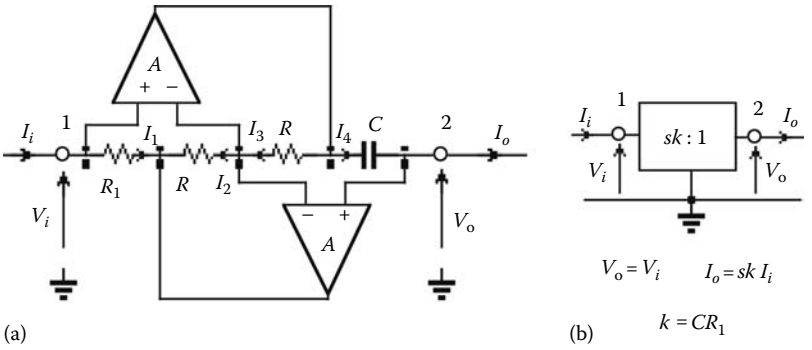

FIGURE 15.17 General impedance converter: (a) circuit; (b) symbolic representation.

transconductors (voltage-to-current converters) and are widely used in transconductance-*C* filters; see Section 16.3. However, no high-quality gyrators with good performance beyond the audio range have been designed to date with op-amps. If op-amps are to be used, a different kind of impedance converter is employed, one that converts a load resistor R_L into an inductive impedance, such that

$$Z_{in}(s) = (sk)R_L \tag{15.60}$$

A good circuit that performs this function is Antoniou's general impedance converter (GIC) shown in Figure 15.17a. The circuit, with elements slightly rearranged, was encountered in Figure 15.4, where we used the GIC to realize a second-order bandpass function. The circuit is readily analyzed if we recall that the voltage measured between the op-amp input terminals and the currents flowing into the op-amp input terminals are zero. Thus, we obtain from Figure 15.17a the set of equations

$$V_o = V_i \quad \frac{I_4}{sC} = I_3 R \quad I_2 R = I_1 R_1 \quad I_2 = I_3 \quad I_i = I_1 \quad I_4 = I_o \tag{15.61}$$

These equations indicate that the terminal behavior of the general impedance converter is described by

$$V_o = V_i \quad I_o = sCR_1 I_i = skI_i \tag{15.62}$$

that is

$$\frac{V_i}{I_i} = Z_{in}(s) = sk\frac{V_o}{I_o} = sk\, Z_L(s) \tag{15.63}$$

Notice that the input impedance is inductive as prescribed by Equation 15.60 if the load is a resistor.* Figure 15.17b also shows the circuit symbol we will use for the GIC in the following to keep the circuit diagrams simple. This impedance converter and its function of converting a resistive load into an inductive input impedance is the basis for Gorski-Popiel's embedding technique [5, Chapter 6], [9, Chapter 14.4], which permits replacing the inductors in an *LC* filter by resistors.

* To optimize the performance of the GIC, i.e., to make it optimally independent of the finite gain-bandwidth product of the op-amps, the GIC elements should be chosen as follows: For an arbitrary load $Z_L(s)$ one chooses $\omega_c C = 1/{}^*Z_L(j\omega_c)^*$. ω_c is some critical frequency, normally chosen at the upper passband corner. If the load is resistive, $Z_L = R_L$, select $C = 1/(\omega_c R_L)$ [6].

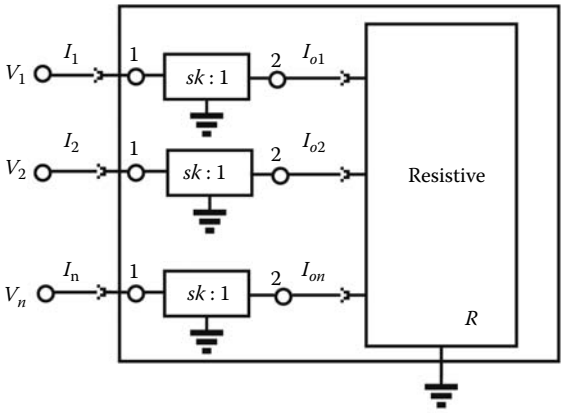

FIGURE 15.18 Simulation of an inductance network.

15.4.3.1 Inductor Replacement: Gorski-Popiel's Method

To understand the behavior of the circuit in Figure 15.18, recall from Equation 15.62 that the voltages at terminals 1 and 2 of the GICs are the same. Then, by superposition the typical input current I_{oi} into the resistive network $\boldsymbol{R}$ can be written as

$$I_{oi} = \frac{1}{R_{i1}} V_1 + \frac{1}{R_{i2}} V_2 + \cdots + \frac{1}{R_{in}} V_n = \sum_{j=1}^{n} \frac{1}{R_{ij}} V_j \quad i = 1, \ldots, n \tag{15.64}$$

where the parameters R_{ij} are given by the resistors and the configuration of $\boldsymbol{R}$. Using the current relationship $I_{oi} = skI_i$ of the impedance converters in Equation 15.64 results in

$$I_i = \sum_{j=1}^{n} \frac{1}{skR_{ij}} V_j \quad i = 1, \ldots, n \tag{15.65}$$

which makes the combined network consisting of the n GICs and the network $\boldsymbol{R}$ look purely inductive, i.e., each resistor R_r in the network $\boldsymbol{R}$ appears replaced by an inductor of value

$$L_r = skR_r = sCR_1R_r \tag{15.66}$$

Examples of this process are contained in Figure 15.19. Figure 15.19a and b illustrate the conventional realizations of a grounded and a floating inductor requiring one and two converters, respectively. This is

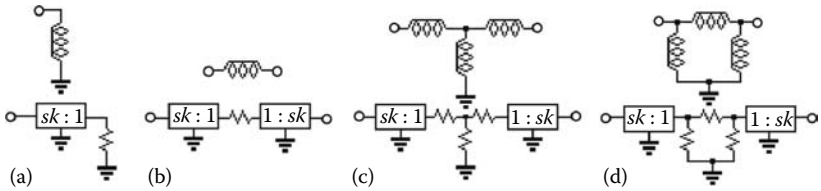

FIGURE 15.19 Elementary inductance networks and their GIC-*R* equivalents: (a) grounded inductor (b) floating inductor (c) inductive T (d) inductive Π.

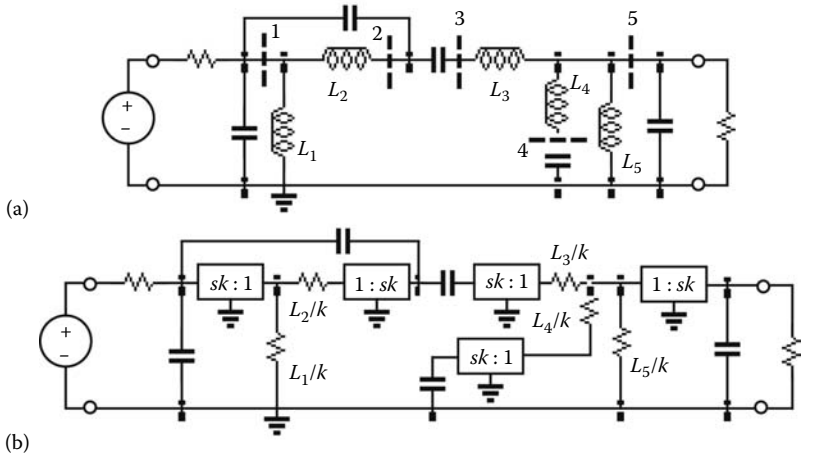

FIGURE 15.20 *LC* ladder realization with GICs: (a) a choice of cuts; (b) the cuts replaced by GICs.

completely analogous to the use of gyrators, where a grounded inductor requires one gyrator, but a floating inductor is realized with two gyrators connected back-to-back. Figure 15.19c and d show how the process is extended to complete inductive subnetworks: the GICs are used to isolate the subnetworks from the remainder of the circuit; there is no need to convert each inductor separately. The method is further illustrated with the filter in Figure 15.20. The *LC* ladder is designed to specifications by use of the appropriate design tables [4,7] or filter design software [8]. In the resulting ladder, the inductive subnetworks are separated as shown in Figure 15.20a by the five dashed cuts. The cuts are repaired by inserting GICs with conversion factor k and the correct orientation (output, terminal 2 in Figure 15.17, toward the inductors). Note that all GICs must have the same conversion factor k. Finally, the inductors L_i are replaced by resistors of value L_i/k as shown in Figure 15.20b. A numerical example will illustrate the design steps:

Assume we wish to implement a sixth-order bandpass filter with the following specifications:
Maximally flat passband with $\leq$3 dB attenuation in 900 Hz $\leq f \leq$ 1200 Hz
Transmission zero at $f_z = 1582.5$ Hz; source and load resistors $R = 3$ kΩ

Using the appropriate software or tables, the *LC* filter in Figure 15.21a is found with element values in kiloohm, megahertz, and nanofarad. Figure 15.21b shows the circuit redrawn to help identify the inductive subnetwork and the locations of the cuts. Note that only three impedance converters are used rather than six (two each for the two floating inductors and one each for the grounded ones), if a direct conversion of the individual inductors had been attempted.

For the final active realization, we assumed a conversion parameter $k = CR_1 = 30$ μs. Finally, to design the GICs we compute the impedances seen into the nodes where the GICs see the (now) resistive subnetworks. Using analysis software to compute $|V_i/I_i|$ at these nodes, we find

$$\text{for GIC}_a,\ |Z_a| \approx 18\ \text{k}\Omega,\ \text{and for GIC}_b \text{ and GIC}_c, |Z_b| \approx |Z_c| \approx 4.7\ \text{k}\Omega$$

so that with $\omega_c = 2\pi \cdot 1.2$ kHz and $k = 30$ μs the design elements are

$$C_a = \frac{1}{\omega_c |z_a|} \approx 7.4\ \text{nF} \quad R_{1a} = \frac{k}{C_a} \approx 4\ \text{k}\Omega \quad C_b = C_c \approx 28\ \text{nF} \quad R_b = R_c \approx 1\ \text{k}\Omega$$

To complete the design, we choose the resistors R in Figure 15.17a as $R = 1$ kΩ.

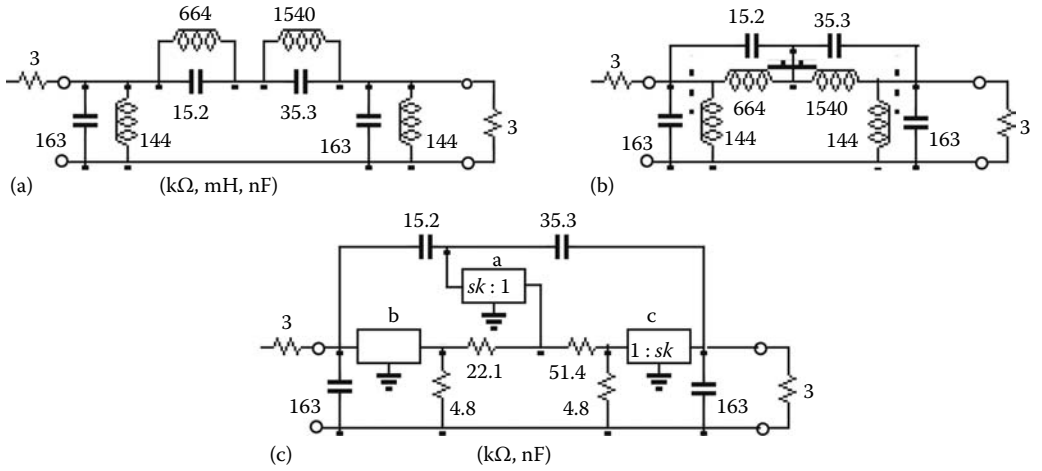

FIGURE 15.21 Sixth-order *LC* bandpass filter and active realization using impedance converters. (a) The LC filter with element values in kiloohm, megahertz, and nanoforad. (b) The circuit redrawn to help identify the inductive subnetwork and the locations of the cuts. (c) The final active realization using a conversion parameter $k = CR_i = 30\mu s$.

15.5 Summary

In this chapter, we discussed the more practical techniques for the design of active filters of order higher than two: *cascade* design, *multiple-loop feedback* approaches, and methods that *simulate the behavior of LC ladder* filters. We pointed out that direct realization methods are impractical because they result in high sensitivities to component values. In many applications, a cascade design leads to satisfactory results. The practical advantages of cascade circuits are modularity, ease of design, flexibility, very simple tuning procedures, and economical use of op-amps with as few as one op-amp per pole pair. Also, we pointed out again that an arbitrary transfer function can be realized with the cascade design method, i.e., no restrictions are placed on the permitted locations of poles and zeros.

For challenging filter requirements, the cascade topologies may still be too sensitive to parameter changes. In those cases the designer can use the FLF configuration or, for best performance, a ladder simulation, provided that a passive prototype ladder exists. FLF circuits retain the advantage of modularity, but if optimal performance is desired, computer-aided optimization routines must generally be used to adjust the available free design parameters. However, excellent performance with very simple design procedures, no optimization, and high modularity can be obtained by use of the *primary-resonator-block* (PRB) method, where all biquad building blocks are identical.

From the point of view of minimum passband sensitivity to component tolerances, the best active filters are obtained by simulating *LC ladders*. If the prescribed transfer characteristic can at all be realized as a passive *LC* ladder, the designer can make use of the wealth of available information about the design of such circuits, and simple procedures are available for ''translating'' the passive *LC* circuit into its active counterpart. We may either take the passive circuit and replace the inductors by active networks, or we imitate the mathematical behavior of the whole *LC* circuit by realizing the integrating action of inductors and capacitors via active *RC* integrators. Both approaches result in active circuits of high quality; a disadvantage is that more op-amps may be required than in cascade or FLF methods. This drawback is offset, however, by the fact that the sensitivities to component tolerances are very nearly as low as those of the originating ladder.

An alternative method for the active realization of a passive *LC* ladder is obtained by scaling each impedance of the passive circuit by $1/(ks)$ (Bruton's transformation) [5, Chapter 6], [9, Chapter 14.5].

This impedance transformation converts resistors into capacitors, inductors into resistors, and capacitors into "*frequency-dependent negative resistors* (FDNRs)," which can readily be realized with Antoniou's GIC circuit. The procedure is especially useful for passive prototype circuits that have only *grounded* capacitors because capacitors are converted to FDNRs and floating FDNRs are very difficult to implement in practice. The method results in biasing difficulties for active elements, and because the *entire* ladder must be transformed, the active circuit no longer contains source and load resistors. If these two components are prescribed and must be maintained as in the original passive circuit, additional buffers are required. The method was not discussed in this text because it shows no advantages over the Gorski-Popiel procedure.

An important practical aspect is the *limited dynamic range* of active filters, restricted by noise and by the finite linear signal swing of op-amps. Dynamic range maximization should be addressed whenever possible. Apart from designing low-noise circuits, the procedures always proceed to equalize the op-amp output voltages by exploiting available free gain constants or impedance scaling factors. It is a disadvantage of the element substitution method that no general dynamic range scaling method appears to be available.

The methods discussed in this chapter dealt with the design of filters in *discrete* form, that is, separate passive components and operational or transconductance amplifiers are assembled on, e.g., a printed circuit board to make up the desired filter. Chapter 16 addresses modifications in the design approach that lead to filters realizable in fully integrated form.

16.1 Introduction

All modern signal-processing systems include various types of electrical filters that the designer has to realize in an appropriate technology. The literature contains many well-defined filter design techniques [1–3], and computer programs are available, which help the designer find the appropriate transfer function that describes the required filter characteristics mathematically. The reader may also refer to Section I in this book and the other chapters of this section (Section II).

Once the filter's transfer function is obtained, implementation methods must be found that are compatible with the technology selected for the design of the total system. In some situations, considerations of power consumption, frequency range, signal level, or production numbers may dictate *discrete* (*passive* or *active*) filter realizations. Often, however, as much as possible of the total system must be *fully integrated* in microelectronic form, so that the filters can be implemented in the same technology.

Often, digital (Section III) or sampled-data (Chapter 18) implementations are suitable for realizing the filter requirements. However, in modern communications applications, the required frequency range is so high that digital or sampled-data circuitry is inappropriate or too expensive so that *continuous-time* (*c-t*) filters are necessary. In addition, filters in many signal-processing situations must interface with the ''real world,'' where the input and output signals take on continuous values as functions of the continuous variable time, i.e., they are *c-t* signals. In these situations *c-t* antialiasing and reconstruction filters are often required. Because the performance of the total filter system is of relevance and not just the performance of the intrinsic filter, the designer may have to consider if it might not be preferable to implement the entire system in the *c-t* domain rather than as a digital or sampled-data system. At least at low frequencies the latter methods have the advantages of very high accuracy, better signal-to-noise ratio, and little or no parameter drifts, but they entail a number of problems connected with

analog-to-digital (A/D) and digital-to-analog (D/A) conversion (see Chapter 10 of *Analog and VLSI Circuits*), sample-and-hold, switching, antialiasing, and reconstruction circuitry.

Traditionally, *c-t* filters were implemented as discrete designs. Well-understood procedures exist for deriving passive *LC* filters (Section I) from a given transfer function with prescribed complex natural frequencies, e.g., [1, Chapter 2], [2], [3, Chapter 13]. To date no practical methods exist for building high-quality, i.e., low-loss, inductors on an integrated circuit (IC) chip.* The required complex natural frequencies must, therefore, be realized by using *gain*, i.e., as we saw earlier in this section, by embedding an operational amplifier (op-amp; see Chapter 16 of *Fundamentals of Circuits and Filters*) in an *RC* feedback network [1,3]. Since op-amps, resistors, and capacitors can be implemented on an integrated circuit, it appears that with active *RC* networks the problem of monolithic filter design is solved in principle: all active devices and any necessary capacitors and resistors can be integrated together on one silicon chip. Although this conclusion is correct, the designer needs to consider four other factors that are important in integrated *c-t* filter design and perhaps are not immediately obvious.

The first item concerns the most important design task for achieving commercially practical designs: integrated filters must be *electronically tunable*, preferably by an *automatic* tuning scheme. Because of its importance, we shall devote a separate section, Section 16.4, to this topic. The second item deals with the economics of practical implementations of active filters: in *discrete* designs, the cost of components and stocking them usually necessitate designing the filter with a minimum number of active devices. One, two, or possibly three op-amps per pole pair are used and the smallest number of different (if possible, all identical) capacitors. In *integrated* realizations, capacitors are determined by processing mask dimensions and the number of different capacitor values is unimportant, as long as the *element spread* is not excessive. Further, active devices frequently occupy less chip area than passive elements so that it is often preferable to use active elements instead of passive ones.† Also, the designer should remember that in IC technology it is not easy to generate accurate absolute component values, but that *ratios* of like components, such as capacitor ratios, can be realized very precisely. The third observation pertains to the fact that filters usually have to share an integrated circuit with other, possibly switched or digital, systems so that the ac ground lines (power supply and ground wires) are likely to contain switching transients and generally are noisy. Measuring the analog signals relative to ac ground, therefore, may result in designs with poor signal-to-noise ratio and low power-supply rejection. The situation is remedied in practice by building continuous-time filters in fully differential, balanced form, where the signals are referred to each other as $V = V^+ - V^-$ as shown in Figure 16.4b through d. An additional advantage of this arrangement is that the signal range is doubled (for an added 6 dB of signal-to-noise ratio) and that the even-order harmonics in the nonlinear operation of the active devices cancel. All filters in this chapter are understood, therefore, to be designed in fully differential form. Finally, we point out that communication circuitry is often required to operate at hundreds of megahertz or higher, where op-amp–based active *RC* filters will not function because of the op-amps' limited bandwidth.

Today, *c-t* filters integrated in bipolar, CMOS, or BiCMOS technology are no longer academic curiosities but a commercial reality (see Ref. [5] for some recent advances in the field). In the following we discuss the main methods that have proven to be reliable. First, we present *MOSFET-C filters*, whose design methods resemble most closely the standard active *RC* procedures discussed in Chapters 11–14; they can, therefore, be most readily understood by the reader without requiring further background. Next, we introduce the *transconductance-C* (also referred to as g_m-*C*) technique, which is currently the predominant method for

* Spiral inductors of a few nanohenry or microhenry in size, however, can be used at gigahertz frequencies. Typically, they are extremely lossy, with quality factors of the order of only 10. Since such low values of Q are unacceptable for the design of high-quality selective filters, the inductor losses must be reduced. This is accomplished by placing a simulated negative resistor (Figure 16.17c) in series or parallel with the inductor. Similarly, since the spiral inductor itself cannot be tuned, variable current-shunting circuitry is employed to change the effective inductor value; see Ref. [4].

† However, keeping the number of active devices small remains important because active devices consume power and generate noise.

c-t integrated filters. Designs based on transconductors lead to filters for the higher operating frequencies that are important for modern communication systems.

16.2 MOSFET-*C* Filters

As mentioned in the introduction, the MOSFET-*C* method follows standard op-amp–based active filter techniques [6], which, as we saw in previous chapters, rely heavily on the availability of integrators and summers. The only difference is that the method replaces the resistors used in the conventional active *RC* integrating and summing circuitry by MOSFET devices (Figure 16.1) based in the triode (ohmic) region ($V_C - V_T > V_D$, see Section 1.2 of *Analog and VLSI Circuits*). Defining the source (V_S), drain (V_D), gate (V_C), and substrate (V_B) voltages as shown in Figure 16.1, the resulting nonlinear drain current I becomes

$$\begin{aligned} I &= \frac{W}{L}\mu C_{ox}\left[(V_C - V_T)(V_D - V_S) + a_2\left(V_D^2 - V_S^2\right) + a_3\left(V_D^3 - V_S^3\right) + \cdots\right] \\ &= \left[\frac{W}{L}\mu C_{ox}(V_C - V_T)\right](V_D - V_S) + b_2\left(V_D^2 - V_S^2\right) + b_3\left(V_D^3 - V_S^3\right) + \cdots \end{aligned} \tag{16.1}$$

where

W and L are the channel width and length, respectively
μ is the effective mobility
C_{ox} is the gate capacitance per unit area
V_T is the threshold voltage of the device

The term in brackets is a tunable conductor,

$$G(V_C) = \frac{W}{L}\mu C_{ox}(V_C - V_t) \tag{16.2}$$

where the gate voltage V_C is used for control or *tuning*. Thus, the drain current of a MOSFET in the triode region is proportional to the drain-to-source voltage, but contains nonlinear second- and higher order terms. Third- and higher order terms can be shown to be small and will be neglected in the following. Now consider placing two of these MOS conductances in parallel as shown in Figure 16.2a. Note that the two devices are driven in balanced form by $+V_1$ and $-V_1$ at one pair of terminals and that the other terminals are at the same voltage V. Applying these conditions to Equation 16.1 results in

$$I_1 = G(V_C)(+V_1 - V) + b_2\left[(+V_1)^2 - V^2\right] \tag{16.3a}$$

$$I_2 = G(V_C)(-V_1 - V) + b_2\left[(-V_1)^2 - V^2\right] \tag{16.3b}$$

Consequently, apart from the neglected high-order odd terms, the difference current $I_1 - I_2$ is perfectly linear in the applied signal voltage V_1:

$$I_1 - I_2 = 2G(V_C)V_1 \tag{16.4}$$

Thus, in the MOSFET-*C* method, the even-order nonlinearities can be shown to be eliminated by carefully balanced circuit design, where all signals are measured

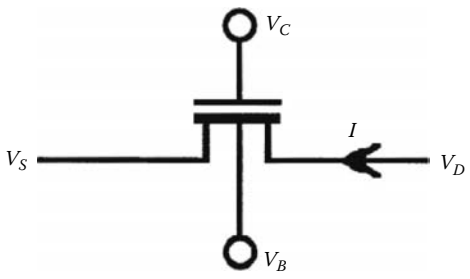

FIGURE 16.1 MOS transistor biased in the triode region.

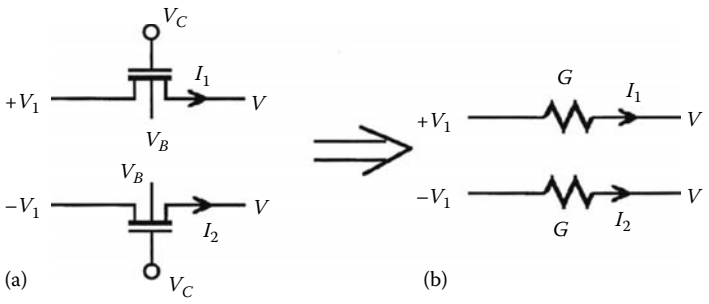

FIGURE 16.2 (a) Balanced linear MOSFET conductance; (b) equivalent resistor circuit.

strictly differentially [6]. Note that the expression for $I_1 - I_2$ in Equation 16.4 is the same as that for the linear resistive equivalent circuit in Figure 16.2b. This means that the MOSFET circuit in Figure 16.2a can be substituted for a pair of resistors in any *appropriate* active *RC* circuit; appropriate means that the resistor pair is driven by balanced signals at one end and that the voltages at the other two terminals are the same (in practice, usually virtual ground). In addition to these conditions, the substitution is valid if the MOSFETs are operated in the triode region and if $v_1(t)$ and $v(t)$ are safely within the range $|V_C - V_B^\star|$. Of course, in practice there remains some small distortion due to mismatches and the neglected odd-order terms. Odd-order nonlinearities are usually small enough to be negligible. Typically, the remaining nonlinearities, arising from odd harmonics, device mismatch, and body effects, are found to be of the order of 0.1% for 1 V signals.

In Section 16.2.1, we discuss the MOSFET-*C* integrator that is the fundamental building block used in *all* MOSFET-*C* active filter designs. The integrator will initially be used to construct first- and second-order MOSFET-*C* sections from which higher order filters can be assembled by the cascade method (Section 16.2.2). In Section 16.2.3, we show how simulated *LC* ladder filters are designed by use of integrators.

16.2.1 Basic Building Blocks

Substituting MOSFETs for resistors in an active *RC* prototype works correctly if the active *RC* circuit is of a form where all resistors come in balanced pairs, with one end of the resistor pair voltage-driven and the two other terminals seeing the same voltage (see Figure 16.2a). Active *RC* circuits do not normally satisfy these conditions, but many can readily be converted into that form if a balanced symmetrical op-amp as pictured in Figure 16.3 is available. It is important to note that this structure is not simply a differential op-amp, but that the input and output voltages are symmetrical with respect to a ground reference. Using a balanced op-amp, the conversion of many active *RC* prototypes into balanced form proceeds simply by taking the single-ended circuits and mirroring them at ground as shown below.

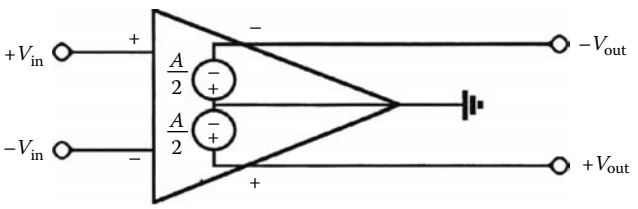

FIGURE 16.3 Balanced operational amplifier configuration realizing $V_{out} = -AV_{in}$.

16.2.1.1 Integrators

Mirroring the active *RC* integrator structure in Figure 16.4a at ground and using the balanced op-amp in Figure 16.3 leads to the balanced integrator in Figure 16.4b. Note that the two resistors are connected in the configuration prescribed in Figure 16.2 with $V = 0$ (virtual ground) so that they may be replaced by the MOSFET equivalent in Figure 16.4c. Analysis of the circuit in the time domain results in

$$-v_{\text{out}} = v^+ - \frac{1}{C}\int_{-\infty}^{t} i_2(t)\mathrm{d}t; \quad +v_{\text{out}} = v^- - \frac{1}{C}\int_{-\infty}^{t} i_1(t)\mathrm{d}t \tag{16.5a}$$

$$v_{\text{out}} - (-v_{\text{out}}) = v^- - v^+ - \frac{1}{C}\int_{-\infty}^{t} [i_1(t) - i_2(t)]\mathrm{d}t \tag{16.5b}$$

$$2v_{\text{out}} = 0 - \frac{1}{C}\int_{-\infty}^{t} 2G(V_C)v_1(t)\mathrm{d}t = -\frac{1}{C}\int_{-\infty}^{t} \frac{2v_1(t)}{R(V_C)}\mathrm{d}t \tag{16.5c}$$

or, after simplifying and using the Laplace transform, in the frequency domain,

$$v_{\text{out}} = -\frac{1}{CR(V_C)}\int_{-\infty}^{t} v_1(t)\mathrm{d}t \rightarrow V_{\text{out}}(s) = -\frac{1}{sCR(V_C)}V_1(s) \tag{16.5d}$$

We see that the MOSFET-*C* integrator realizes exactly the same transfer function as the active *RC* prototype and that the integration time constant $CR(V_C)$ is tunable by the control voltage V_C that is applied to all gates. Note that the circuit in Figure 16.4c is not a differential integrator. To build a

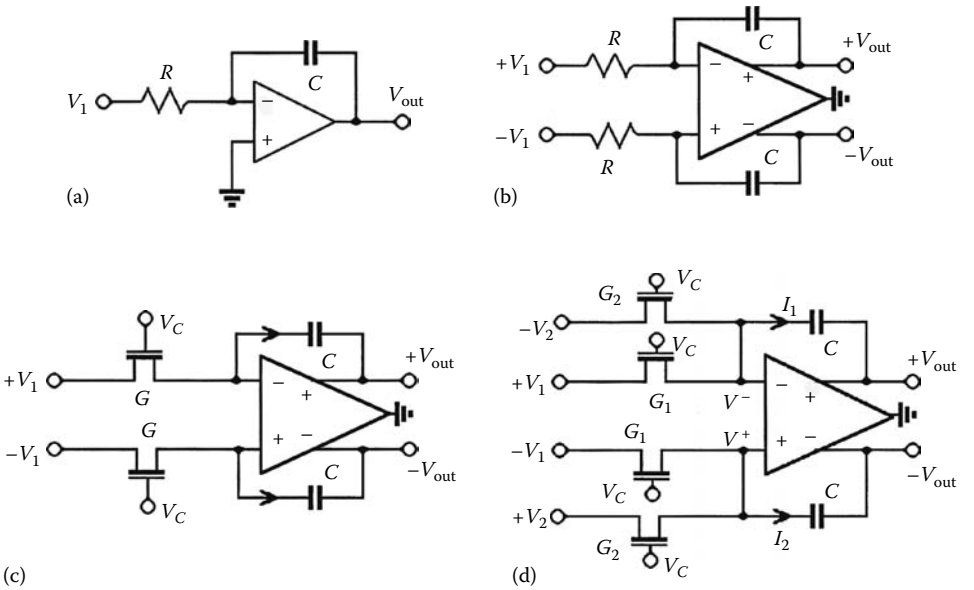

FIGURE 16.4 (a) Active *RC* integrator; (b) fully balanced equivalent; (c) MOSFET-*C* equivalent; and (d) differential MOSFET-*C* integrator.

differential integrator, one must connect a second pair of balanced resistors (MOSFETs) with inputs $-V_2$ and $+V_2$ as in Figure 16.4d to yield

$$v_{\text{out}} = -\frac{1}{C}\int_{-\infty}^{t}\left[\frac{v_1(t)}{R_1} - \frac{v_2(t)}{R_2}\right]\mathrm{d}t \rightarrow V_{\text{out}}(s) = -\frac{1}{sC}\left[\frac{V_1(s)}{R_1} - \frac{V_2(s)}{R_2}\right] \tag{16.6}$$

The same principle can also be used to build *programmable* integrators and, therefore, programmable filters: consider in Figure 16.4d the terminals for V_1 and $-V_2$ connected, i.e., $V_1 = -V_2$. The two resistors are then connected in parallel to give a resistive path $G_1 + G_2$, and the two resistor values can be controlled by different gate voltages V_{C1} and V_{C2}. Similarly, additional *balanced* MOSFET-resistor paths may be connected from V_1 or other signals to the integrator inputs (summing nodes). These paths can be turned on or off by an appropriate choice of gate voltages, so that transfer functions with different parameters (such as gains, quality factors, or pole-frequencies) or even transfer functions of different types (such as bandpass, low-pass, etc.) are obtainable.

If better linearity is required than is obtainable with the two-transistor MOSFET circuit in Figure 16.4c that replaces each resistor in the balanced active *RC* structure by one MOSFET, a four-MOSFET cross-coupled modification for each resistor pair can be used instead [7, paper 2-B.7]. The configuration is illustrated in Figure 16.5. The current difference can be shown to equal

$$\Delta I = I_1 - I_2 = K(V_{C1} - V_{C2})[V_1 - (-V_1)] \tag{16.7}$$

that is, ΔI is proportional to the product of the difference of the input signals and the difference of the applied gate voltages V_{Ci}, $i = 1, 2$. This indicates that one may interchange the input and gate-control voltages and reduce the drive requirements of the previous op-amp stage because no resistive current flows, only the small gate-capacitor current flows with the input applied at the control gates (now at $\pm V_1$). The price paid for this advantage is that the requirements on the control voltage source become more difficult and may necessitate an appropriate common-mode voltage on the signal lines.

Additional resistive or capacitive inputs may, of course, be used to design more general lossy integrators as illustrated in Figure 16.6. By writing the node equation at the summing node, this circuit may be analyzed to realize

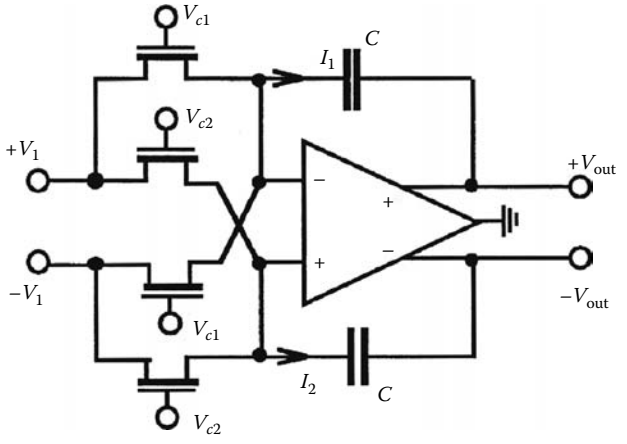

FIGURE 16.5 Integrator using a four-MOSFET configuration for greater linearity.

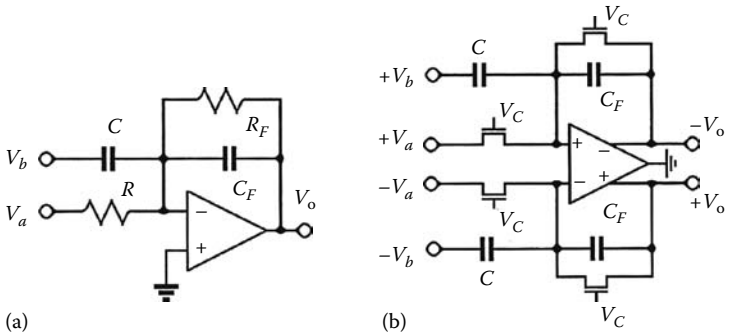

FIGURE 16.6 (a) Lossy integrator with capacitive feed-in branch; (b) MOSFET-*C* equivalent.

$$V_o = -\frac{1}{sC_F + G_F}(GV_a + sCV_b) \tag{16.8}$$

where the conductors are implemented in Figure 16.6b as

$$R(V_C) = \frac{1}{\mu C_{ox}(W/L)(V_C - V_T)}; \quad R_F(V_C) = \frac{1}{\mu C_{ox}(W_F/L_F)(V_C - V_T)} \tag{16.9}$$

as was derived in Equation 16.2. The controlling gate voltages V_C for the two resistors R and R_F may, in general, be different so that the resistor values may be tuned (or turned on or off) independently.

With lossy and lossless MOSFET-*C* integrators available, we can obtain not only first- and second-order filters as shown in Section 16.2.1.2, but also simulations of *LC* ladders in much the same way as was done in Chapter 15 for active *RC* circuits. We discuss this procedure in some detail in Section 16.2.3.

16.2.1.2 First- and Second-Order Sections

Based on the principle of balancing a single-ended structure, appropriate* standard classical active *RC* filters from the literature can be converted into balanced form and resistors can be replaced by MOSFETs. As an illustration, consider the single-ended prototype (Tow–Thomas) biquad in Figure 16.7a. As is typical for second-order active *RC* filter sections (see Chapter 13), the circuit is a two-integrator loop consisting of inverting lossy and lossless integrators (in addition to an inverter to keep the loop gain negative for stability reasons). The realized transfer function is not important to our discussion, but we point out that all resistors are voltage-driven (by the signal source or by an op-amp) and at their other ends all resistors are connected to an op-amp input, i.e., they are at virtual ground. Thus, this circuit satisfies our earlier condition for conversion to a MOSFET-*C* structure. Figure 16.7b shows the balanced active *RC* equivalent that is necessary to eliminate the nonlinear performance. Replacing the resistors by MOSFETs biased in the triode region leads to the final MOSFET-*C* version in Figure 16.7c. The W/L ratios are chosen appropriately to realize the prescribed resistor values

$$G_i = \frac{W_i}{L_i}\mu C_{ox}(V_C - V_T) \tag{16.10}$$

with excellent resistor matching given by aspect ratios

* All resistors must be voltage-driven from one side and see the same voltage, usually virtual ground, on the other.

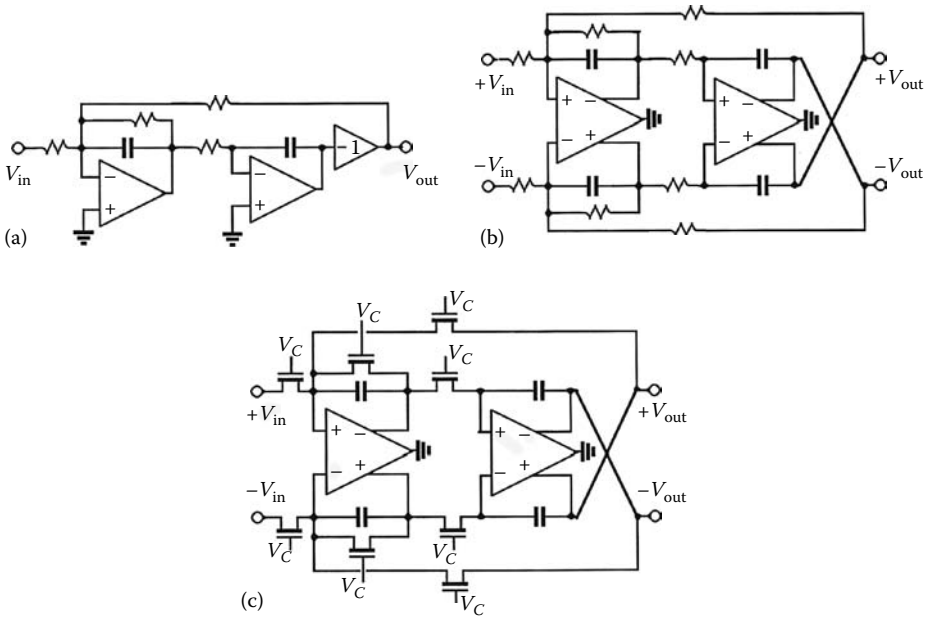

FIGURE 16.7 (a) Active *RC* prototype (Tow–Thomas biquad) for conversion into a MOSFET-*C* structure; (b) fully balanced version of the biquad with resistors; and (c) fully balanced version of the biquad with MOSFETs.

$$\frac{G_i}{G_k} = \frac{(W/L)_i}{(W/L)_k} \tag{16.11}$$

The voltage-variable resistors given by Equation 16.10 permit loss and time constants to be electronically tuned. Note that the inverter in the original circuit is not needed in Figure 16.7b and c because inversion in the differential topology is obtained by crossing wires.

The circuit may be made *programmable* by connecting additional MOSFET resistors with appropriate W/L ratios in parallel with the fundamental ones shown in Figure 16.7c and then switching them on or off as required by the desired values of the filter coefficients.

The above method indicates how first- or second-order sections can be obtained by choosing any suitable configuration from the active *RC* filter literature [1, Chapter 5], [3, Chapters 4 and 5] and converting it to balanced MOSFET-*C* form. Next we show a couple of entirely general first- and second-order sections that can be developed from the integrator in Figure 16.6b. The resulting circuits are shown in Figure 16.8 [7, paper 2-A.2]. If we combine the inputs $V_a = V_b = V_i$ of the integrator in Figure 16.6b and add two further cross-coupled feed-in capacitors, we obtain the first-order circuit in Figure 16.8a. Writing the node equation at the (inverting or noninverting)* op-amp input results in the transfer function

$$T_1(s) = \frac{V_o}{V_i} = \frac{s(C_1 - C_2) + G_1}{sC_F + G_2} \tag{16.12}$$

Note that this first-order circuit can realize zeros anywhere on the real axis. Similarly, if we combine two such integrators in a loop, with the individual signal paths and signs selected to assure negative feedback,

* Because the circuit is completely symmetrical, it is only necessary to derive the equations for one side, e.g., for V_o; the expressions for the other side, i.e., $-V_o$, are the same.

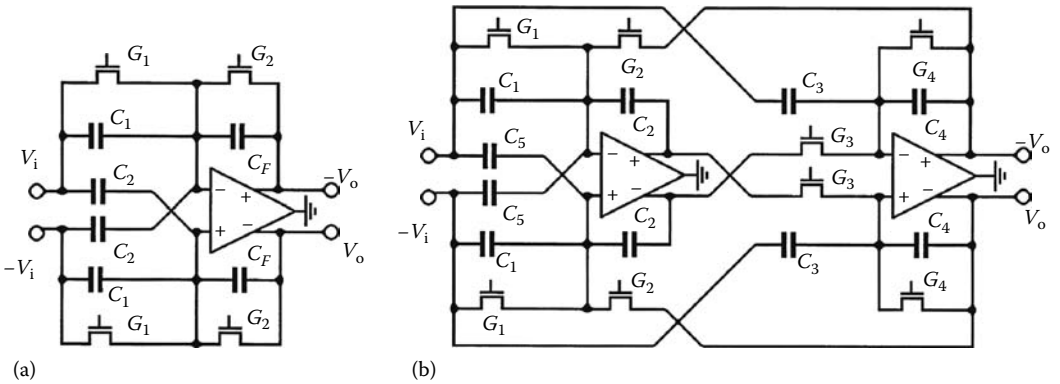

FIGURE 16.8 General (a) first- and (b) second-order MOSFET-*C* sections. The MOSFETs are labeled by the conductance values they are to implement.

TABLE 16.1 Functions Realizable with Figure 16.8b

Function	Choice of Elements
Bandpass	$G_1 = C_3 = 0$; $C_5 = 0$ if noninverting, $C_1 = 0$ if inverting
Low-pass	$C_1 = C_3 = C_5 = 0$
High-pass	$C_1 = C_5 = G_1 = 0$
Notch	$C_1 = C_5$
All-pass	$(C_1 - C_5)G_3 = -C_2G_4$

we obtain the general second-order section in Figure 16.8b. Writing again the node equations at the op-amp input nodes leads to the transfer function

$$T_2(s) = \frac{V_o}{V_i} = \frac{s^2C_2C_3 + s(C_1 - C_5)G_3 + G_1G_3}{s^2C_2C_4 + sC_2G_4 + G_2G_3} \tag{16.13}$$

Observe that this circuit can realize zeros anywhere in the *s*-plane, depending on the choice of element values. Consequently, the sections in Figure 16.8 can be used to implement arbitrary high-order transfer functions in a cascade topology. Specifically, for the indicated choice of elements the general biquad function in Equation 16.13 realizes the different transfer functions in Table 16.1.

16.2.2 Cascade Realizations

The realization of high-order transfer functions as a connection of low-order sections, including the *cascade*, *multiple-loop feedback*, and *coupled-biquad* approaches, is identical to that discussed for discrete active *RC* filters. The difference lies only in the implementation of the sections in fully integrated form. We do not repeat the process here but only discuss the most prevalent method, cascade design, in terms of an example and encourage the reader to refer to the earlier discussion in Chapter 15 for details. To repeat briefly, if a high-order function

$$H(s) = \frac{V_{out}}{V_{in}} = \frac{N(s)}{D(s)} = \frac{a_ms^m + a_{m-1}s^{m-1} + \cdots + a_1s + a_0}{s^n + b_{n-1}s^{n-1} + \cdots + b_1s + b_0} \tag{16.14}$$

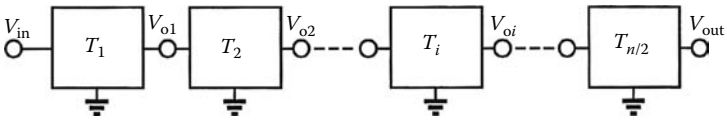

FIGURE 16.9 Cascade realization of an *n*th-order transfer function.

with $m \leq n$ and $n > 2$ is given, it is factored into second-order sections (and one first-order section if n is odd),

$$H(s) = \prod_{i=1}^{n/2} T_i(s) = \prod_{i=1}^{n/2} k_i \frac{a_{2i}s^2 + a_{1i}s + a_{0i}}{s^2 + s\omega_{0i}/Q_i + \omega_{0i}^2} = \prod_{i=1}^{n/2} k_i t_i(s) \tag{16.15}$$

where each of the second-order functions

$$T_i(s) = \frac{V_{oi}}{V_{oi-1}} = k_i \frac{a_{2i}s^2 + a_{1i}s + a_{0i}}{s^2 + s\omega_{0i}/Q_i + \omega_{0i}^2} = k_i t_i(s) \tag{16.16}$$

is implemented as a suitable biquad with specified pole quality factor Q_i and pole frequency ω_{0i}, such as the one in Figure 16.8b realizing Equation 16.13. As was explained in Chapter 15, k_i is a suitable gain constant, chosen to equalize the signal levels in order to optimize the dynamic range, and $t_i(s)$ is a gain-scaled transfer function. Note that in writing Equation 16.15 we assumed that n is even. Figure 16.9 shows the general (single-ended) structure of the filter.

To provide an example, assume we wish to realize a delay of $\tau_D = 0.187$ μs via a fifth-order Bessel approximation, but with a transmission zero at $f/f_n = 4.67$ to improve the attenuation in the stopband.* The transfer function is found to be

$$H_5(s) = \frac{43.3315(s^2 + 21.809)}{(s + 3.6467)(s^2 + 6.7040s + 14.2729)(s^2 + 4.6494s + 18.1563)} \tag{16.17}$$

The normalizing frequency is $f_n = 1/(2\pi\tau_D) = 850$ kHz [1, Chapter 1], [3, Chapter 10]. Let us choose a cascade implementation with the circuits in Figure 16.8. Factoring Equation 16.17 leads to the first-order and the two second-order functions on the left-hand side of Equation 16.18 to be realized by the functions on the right, which are obtained from Equations 16.12 and 16.13:

$$T_1(s) = \frac{3.6467}{s + 3.6467} \rightarrow T_1(s) = \frac{V_{o1}}{V_{in}} = \frac{G_1}{sC_F + G_2} \tag{16.18a}$$

$$T_2(s) = \frac{14.2729}{s^2 + 6.7040s + 14.2729} \rightarrow T_2(s) = \frac{V_{o2}}{V_{o1}} = \frac{G_1G_3}{s^2C_2C_4 + sC_2G_4 + G_2G_3} \tag{16.18b}$$

$$T_3(s) = \frac{0.8325(s^2 + 21.809)}{s^2 + 4.6494s + 18.1563} \rightarrow T_3(s) = \frac{V_{o3}}{V_{o2}} = \frac{s^2C_2C_3 + G_1G_3}{s^2C_2C_4 + sC_2G_4 + G_2G_3} \tag{16.18c}$$

The components of the first- and second-order filters in Figure 16.8 are to be determined from these equations. The gain constants in the function were chosen to result in unity gain at dc. Comparing coefficients, we find with $\omega_n = 1/\tau_D \approx 2\pi$. 850 krad $s^{-1} \approx 5.341$ Mrad s^{-1}:

* Note that transmission zeros on the $j\omega$-axis can be added [3, Chapter 10.8] to a linear-phase network, such as a Bessel filter, without changing the phase because a zero factor, $(\omega_z^2 - \omega^2)$, is a purely real number on the $j\omega$-axis.

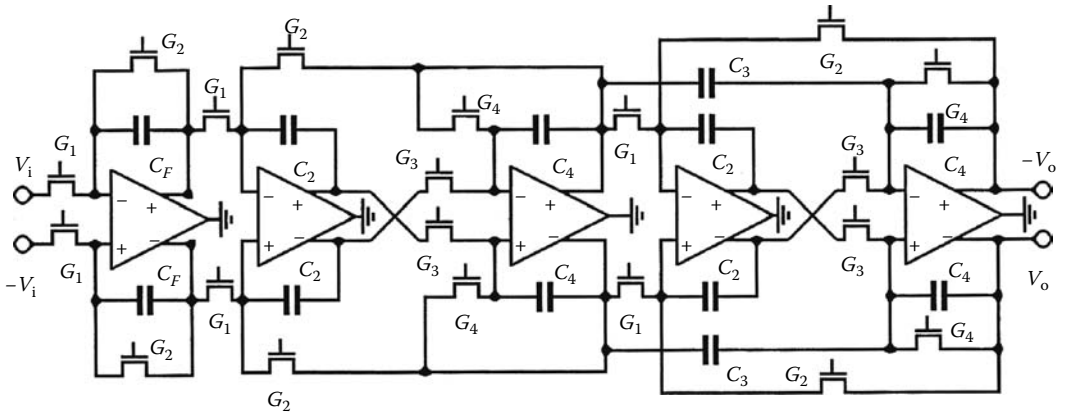

FIGURE 16.10 Circuit to realize the filter described by Equation 16.17. Note that for easy reference we have kept the subscripts on the elements in each section the same as in Figure 16.8.

From Equation 16.18a

$$G_1 = G_2 = 3.6467\omega_n C_F \tag{16.19a}$$

Choosing $C_F = 2$ pF gives $G_1 = G_2 = 38.952$ μS; also $C_1 = C_2 = 0$.

From Equation 16.18b

$$G_1 G_3 = G_2 G_3 = 14.2729\omega_n^2 C_2 C_4; \quad G_4 = 6.7040\omega_n C_4 \tag{16.19b}$$

Choosing $C_2 = C_4 = 2$ pF results in $G_1 = G_2 = G_3 = 40.354$ μS and $G_4 = 71.6$ μS; also, $C_1 = C_3 = C_5 = 0$.

From Equation 16.18c, $G_1 G_3 = 0.8325 \times 21.809\omega_n^2 C_2 C_4 = 18.1563\omega_n^2 C_2 C_4$;

$$G_2 G_3 = 18.1563\omega_n^2 C_2 C_4; \quad G_4 = 4.6494\omega_n C_4; \quad C_3 = 0.8325 C_4 \tag{16.19c}$$

Choosing $C_2 = 2$ pF and $C_4 = 10$ pF yields $C_3 = 8.325$ pF, $G_1 = G_2 = G_3 = 101.77$ μS and $G_4 = 248.32$ μS; also, $C_1 = C_5 = 0$. The remaining task is to convert the resistors into MOSFET devices. Assume the process provides transistors with $\mu C_{ox} = 120$ μA/V^2 and $V_T = 0.9$ V. For the choice of $V_C = 2$ V, the aspect ratios are then calculated from the above conductance values and from Equation 16.10 via

$$\frac{W_i}{L_i} = \frac{G_i(V_C)}{\mu C_{ox}(V_C - V_T)} = \frac{G_i(V_C)}{120\ \mu\text{A/V}^2 \times 1.1V} = \frac{G_i/\mu\text{S}}{132} \tag{16.20}$$

For instance, in the first-order section we find $W_1/L_1 = W_2/L_2 = 38.952/132 = 1/3.389$. The resulting circuit is shown in Figure 16.10.

16.2.3 Ladder Simulations

Using MOSFET-*C* integrators, the ladder simulation method for the MOSFET-*C* approach is entirely analogous to the active *RC* procedures discussed earlier in this book (see Chapter 15). The process is illustrated by a step-by-step generic example, which should guide the reader when implementing a specific design.

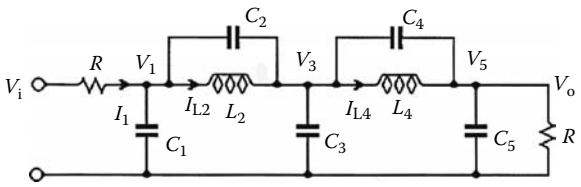

FIGURE 16.11 Fifth-order elliptic *LC* low-pass filter.

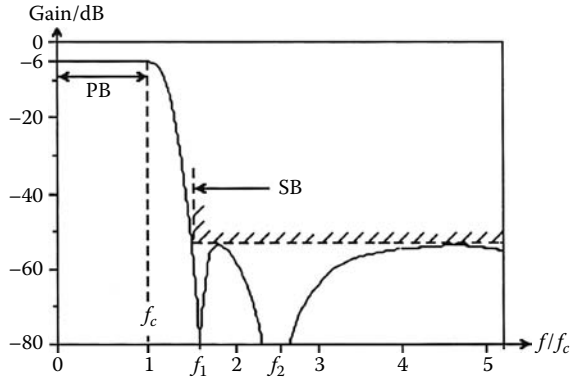

FIGURE 16.12 Transfer function magnitude of a fifth-order elliptic low-pass function.

Assume a fifth-order elliptic low-pass filter with the transfer function

$$H_{\text{ell}}(s) = \frac{\left(s^2 + \omega_1^2\right)\left(s^2 + \omega_2^2\right)}{(s + a)(s^2 + bs + c)(s^2 + ds + e)} \tag{16.21}$$

is prescribed, which with the help of readily available ladder synthesis software is realized by the *LC* ladder structure in Figure 16.11 with known component values. A plot of such a function is shown in Figure 16.12. The two transmission zeros f_1 and f_2 in the figure are obtained when L_2, C_2, and L_4, C_4, respectively, resonate. The *LC* active simulation proceeds by deriving the signal-flow graph equations [1, Chapter 6], [3, Chapter 15] or by writing the loop and node equations of the ladder along with the *V*–*I* relationships describing the functions of the elements:

$$I_1 = \frac{V_i - V_1}{R}, \quad I_{L2} = \frac{V_1 - V_3}{sL_2}, \quad I_{L4} = \frac{V_3 - V_5}{sL_4} \tag{16.22a}$$

$$V_1 = \frac{I_1 - [I_{L2} + sC_2(V_1 - V_3)]}{sC_1} \tag{16.22b}$$

$$V_3 = \frac{I_{L2} - I_{L4} + sC_2(V_1 - V_3) - sC_4(V_3 - V_5)}{sC_1} \tag{16.22c}$$

$$V_5 = V_o = \frac{I_{L4} + sC_4(V_3 - V_5)}{sC_5 + G} \tag{16.22d}$$

We recognize that these equations represent *integrations* of voltages into currents and currents into voltages. We also note that the currents through the capacitors C_2 and C_4 can be taken care of efficiently without resorting to integration: by connecting C_2 and C_4 directly to the voltage nodes V_1, V_3, and V_3, V_5, respectively, they conduct the currents as prescribed in Equation 16.22b through d. Next we reformat Equation 16.22a through d by eliminating I_1 from Equation 16.22a and b and rewriting Equation 16.22b through d such that V_1, V_3, and V_5, respectively, appear only on the left-hand side. The result is the new set of equations

$$I_{L2} = \frac{V_1 - V_3}{sL_2}; \quad I_{L4} = \frac{V_3 - V_5}{sL_4} \tag{16.23a}$$

$$V_1 = \frac{V_i G - I_{L2} + sC_2 V_3}{s(C_1 + C_2) + G} \tag{16.23b}$$

$$V_3 = \frac{I_{L2} - I_{L4} + sC_2 V_1 + sC_4 V_5}{s(C_2 + C_3 + C_4)} \tag{16.23c}$$

$$V_5 = V_o = \frac{I_{L4} + sC_4 V_3}{s(C_4 + C_5) + G} \tag{16.23d}$$

Recall that all signals in the MOSFET-*C* circuit are voltages, which in turn produce currents summed at the op-amp inputs, and that the integration constant must be *time* rather than *capacitance*. This is achieved by scaling the equations by a resistor R. We illustrate the process on Equation 16.23a and b:

$$I_{L4} = \frac{V_3 - V_5}{sL_4} \rightarrow \frac{I_{L4}}{G} = \frac{GV_3 - GV_5}{s(L_4 G)G} \tag{16.24a}$$

$$V_1 = \frac{V_i G - I_{L2} + sC_2 V_3}{s(C_1 + C_2) + G} \rightarrow V_1 = \frac{V_i G - (I_{L2}/G)G + sC_2 V_3}{s(C_1 + C_2) + G} \tag{16.24b}$$

Notice that $L_4 G^2$ has the unit of *farad*, i.e., it is a capacitor that, however, in Figures 16.13 and 16.14 will be labeled L_4 (and L_2, respectively) to help keep track of its origin. Similarly, I_{L2}/G and I_{L4}/G will be labeled V_{I2} and V_{I4}, respectively. The integrators can now be realized as in Figure 16.6b and then interconnected as the equations prescribe. Figure 16.13 illustrates the process for Equation 16.24. The MOSFET-*C* implementation of all appropriately scaled equations (Equation 16.23) leads to the

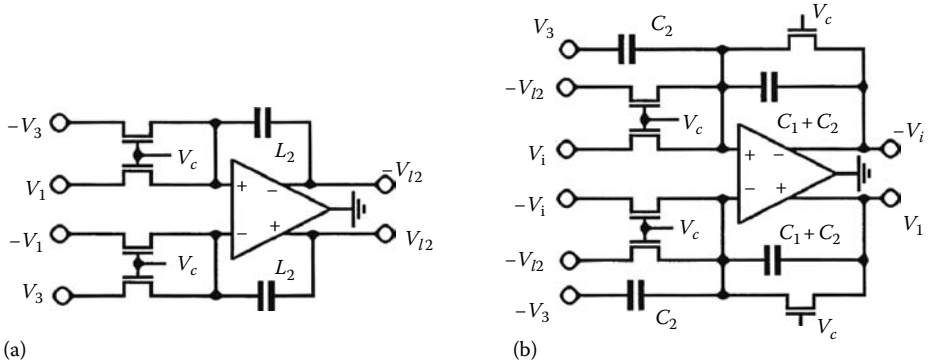

FIGURE 16.13 MOSFET-*C* implementation of (a) Equation 16.24a and (b) Equation 16.24b. All MOSFETs realize the value G.

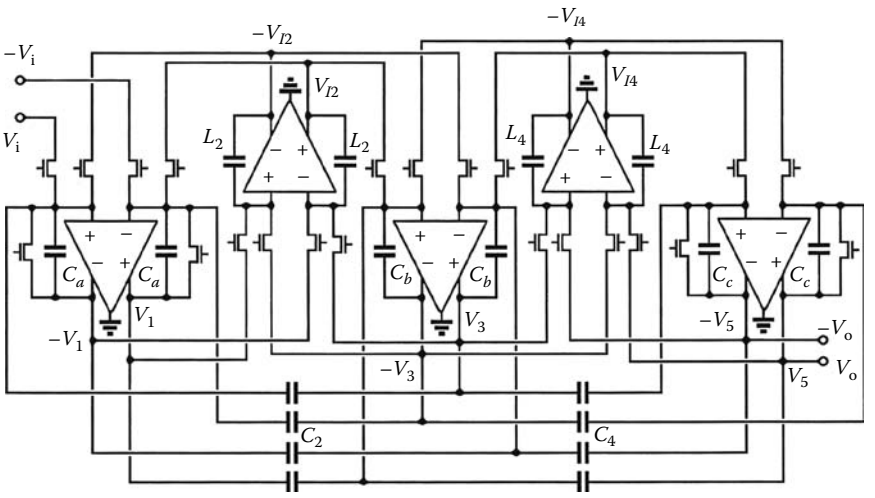

FIGURE 16.14 Operational simulation of the *LC* ladder of Figure 16.11 with MOSFET-*C* integrators; $C_a = C_1 + C_2$, $C_b = C_2 + C_3 + C_4$, $C_c = C_4 + C_5$.

fifth-order elliptic filter shown in Figure 16.14. As given in Equation 16.10, the aspect ratio of each MOSFET and the control voltage V_C are adjusted to realize the corresponding resistor values of the standard active *RC* implementation and all MOSFET gates are controlled by the same V_C for tuning purposes. Arrays of MOSFETs controlled by different values of V_C can be used to achieve programmable filter coefficients.

An often cited advantage of the MOSFET-*C* technique is the reduced sensitivity to parasitic capacitors, whereas the g_m-*C* approach discussed next must carefully account for parasitics by predistortion. Note from Figures 16.6b, 16.8, 16.10, and 16.14 that all capacitors and the MOSFET resistors are connected to voltage-driven nodes or to virtual ground so that parasitic capacitors to ground are of no consequence as long as amplifiers with sufficiently high gain and wide bandwidth are used. Fortunately, such amplifiers are being developed [7, paper 2-B.5] so that MOSFET-*C* circuits promise to become increasingly attractive in the future.

16.3 g_m-*C* Filters

At the time of this writing, the dominant active device used in the design of integrated continuous-time filters is the *transconductor* (g_m) or the *operational transconductance amplifier* (OTA) [8, Chapter 5], [3, Chapter 16]. Both names, g_m-*C* filters and OTA-*C* filters, are used in the literature; we will use the term g_m-*C* filter in this text. The main reasons for this prevalence appear to be the simple systematic design methods for g_m-*C* filters and, especially, the higher range of frequencies over which g_m-based filters can operate. Also, OTAs often have simpler circuitry (fewer elements) than op-amps. A transconductor is a voltage-to-current converter described by

$$I_{\text{out}} = g_m(s)V_{\text{in}} \tag{16.25}$$

where $g_m(s)$ is the frequency-dependent transconductance parameter with units of ampere/volt or siemens, abbreviated S. Typical values for g_m are tens to hundreds of microsiemens in CMOS and up to millisiemens in bipolar technology. A simplified small-signal equivalent circuit is shown in Figure 16.15. The dashed components in Figure 16.15 are parasitics that in an ideal OTA should be

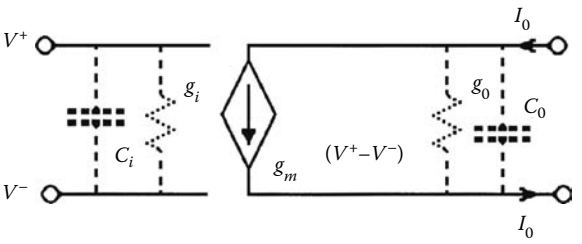

FIGURE 16.15 Small-signal equivalent circuit.

zero but that in practice must be accounted for. For common designs in CMOS technology, the input conductance g_i is zero; the input and output capacitances, c_i and c_o, are typically of the order of 0.05 pF or less and the output resistance $r_o = 1/g_o$ is in the range of 50 kΩ to 1 MΩ. The bandwidth of well-designed transconductors is so large that g_m in many cases can be regarded as constant, $g_m(s) = g_{m0}$, but for critical applications in high-frequency designs the transconductance pole and the resulting phase errors must be considered. A good model for these situations is

$$g_m(s) \approx g_{m0}e^{-s\tau} \approx \frac{g_{m0}}{1+s\tau} \approx g_{m0}(1-s\tau) \tag{16.26}$$

where $f = 1/(2\pi\tau)$ is the pole location (typically at several 100 MHz to 10 GHz) and the phase error $\Delta\phi = -\omega\tau$ is considered small, i.e., $\omega\tau \ll 1$. The three different approximations in Equation 16.26 for representing the frequency dependence are equivalent; the pole is used most often, the zero frequently results in simpler equations and algebra, and the phase may give better insight into the behavior of feedback loops.

The most commonly used circuit symbols are shown in Figure 16.16. Note that OTA designs with multiple differential inputs as in Figure 16.16c are readily available. They often lead to simpler filter designs with less silicon area and power consumption because only the OTA input stages must be duplicated, whereas the remaining parts of the OTA, such as output and common-mode feedback circuitry, can be shared. Essentially, if two OTAs with the same g_m value in a filter have a common output node (a frequent situation), the two OTAs can be merged into the circuit of Figure 16.16c, thus saving circuitry and power.

Filter design methods discussed in this section use only OTAs and capacitors: OTAs to provide gain and capacitors to provide integration. To establish time constants, resistors may also be required, but their function can be obtained from OTAs: ''resistors'' of value $1/g_m$ can be simulated by connecting the OTA output to its input with the polarities shown in Figure 16.17a and b. Inverting one pair of

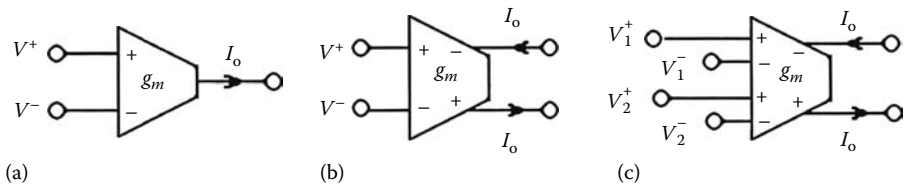

FIGURE 16.16 OTA symbols (a) differential input–single-ended output: $I_o = g_m(V^+ - V^-)$; (b) fully differential; and (c) with multiple inputs: $I_o = g_m\,[(V_1^+ - V_1^-) + (V_2^+ - V_2^-)]$.

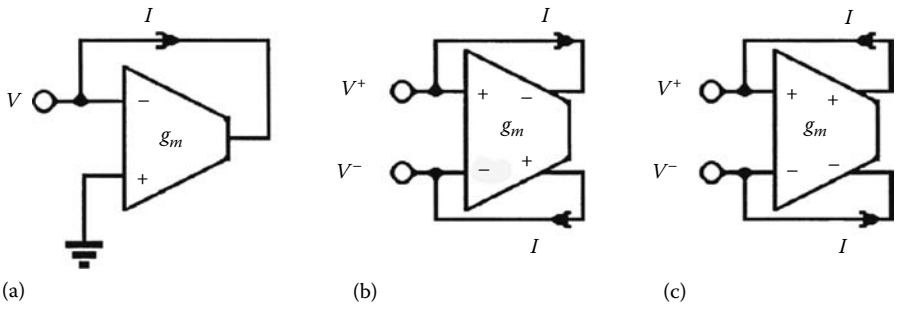

FIGURE 16.17 Simulated resistors: (a) positive single-ended of value $V/I = 1/g_m$; (b) positive differential resistor of value $(V^+ - V^-)/I = 1/g_m$; and (c) negative differential resistor $-1/g_m$.

terminals results in a negative resistor as in Figure 16.17c.* Since transconductors and capacitors can be used to build all components necessary for designing the filters, they are called transconductance-C or g_m-C filters. We discuss the remaining "composite" building blocks, integrators and gyrators† subsequently in Section 16.3.1.

In this section we will not go into the electronic circuit design methods for OTAs, but refer the reader to the literature, which contains a great number of useful transconductance designs in all current technologies. References [5,7] contain numerous papers that discuss practical transconductance circuits. The most popular designs currently use CMOS, but bipolar and BiCMOS are also widely employed, and GaAs has been proposed for applications at the highest frequencies or under unusually severe environmental conditions. Since transconductors are almost always used in open loop without local feedback, their input stages must handle the full amplitude of the signal to be processed. Typically, the OTA input stage is a differential pair with quite limited signal swing before nonlinearities become unacceptable. Thus, much design expertise has gone into developing linearization schemes for transconductance circuits. They have resulted in designs that can handle signals of the order of volts with nonlinearities of a fraction of 1%. Apart from simple source-degeneration techniques, the most commonly employed approaches use variations of the principle of taking the difference between the drain currents of two MOS devices in the saturation region but driven differentially, so that the difference current is linear in V_{gs}:

$$\begin{aligned} I_d^+ &= k(V_{gs} - V_T)^2 = k\left(V_{gs}^2 + V_T^2 - 2V_{gs}V_T\right) \\ I_d^- &= k(-V_{gs} - V_T)^2 = k\left(V_{gs}^2 + V_T^2 + 2V_{gs}V_T\right) \\ \Delta I_d &= I_d^+ - I_d^- = -4V_{gs}V_T \end{aligned} \tag{16.27}$$

Another approach reasons that the most linear (trans)conductance behavior should be obtainable from the current through a resistor. Thus, operating an MOS device in the resistive (triode) region,

$$I_d = k\left[(V_{gs} - V_T)V_{ds} - 0.5V_{ds}^2\right]$$

and taking the derivative with respect to V_{gs} for constant $V_{ds} = V_{DS}$ results in a perfectly linear transconductance,

* Such "negative resistors" are often used to cancel losses, for example to increase the dc gain of transconductors or the quality factors of filter stages. Specifically, a negative resistor can be employed to increase the quality factor of the inductor in Figures 16.21 and 16.22.

† A gyrator is a two-port circuit whose input impedance is inversely proportional to the load impedance: $Z_{in}(s) = r^2/Z_{load}(s)$. If $Z_{load} = 1/(sC)$, the input is inductive, $Z_{in}(s) = sr^2C = sL$. r is called the gyration resistance (see the discussion to follow).

$$g_m = \frac{dI_d}{dV_{gs}} = kV_{DS} \tag{16.28}$$

that furthermore can be adjusted (tuned) by varying a dc bias voltage (V_{DS}) as long as V_{DS} stays small enough for the transistor to remain in the triode region. The circuitry surrounding the triode-region MOS device must assure that V_{DS} remains constant and independent of the signal.

As mentioned, the literature contains numerous practical CMOS, bipolar, or biCMOS transconductance designs that require low power supply voltages (±1.5 V, or 0 to 3 V, or even less for low-power applications), and have acceptable signal swing (of the order of volts), with low nonlinearities (as low as a small fraction of 1%) and wide bandwidth (up to several hundred megahertz and even into the gigahertz range). Two further aspects of OTA design should be stressed at this point. First, since g_m-C filters often contain many transconductors, the designer ought to strive for simple OTA circuitry. It saves silicon real estate and at the same time often results in better frequency performance because of reduced parasitics at internal nodes. We point out though that there exists a trade-off between simple circuitry and large voltage swing: a wide linear signal range always requires special linearizing circuit techniques and, therefore, additional components. The second issue pertains to tuning. We mentioned earlier that continuous-time filters always require tuning steps to eliminate the effects of fabrication tolerances and component drifts. In IC technologies this implies that the circuit components must be electronically adjustable. Since (MOS) capacitors are generally fixed,* all tuning must be handled via the transconductance cells by changing one or more bias points. Usually two adjustments are needed: the magnitude of g_m must be varied to permit tuning the frequency parameters set by g_m/C-ratios and, as explained later, the phase $\Delta\phi$ must be varied to permit tuning the filters' quality factors. We discuss tuning methods in some detail in Section 16.4.

In the Section 16.3.1 we introduce the central building blocks from which g_m-C filters are constructed, the integrator and the gyrator. Just as we saw in the discussion of MOSFET-C circuits and in the earlier treatment of active RC filters, integrators are fundamental to the development of active filter structures, both for second-order sections and cascade designs, as well as for higher order LC ladder simulations. Gyrators along with capacitors are used to replace inductors in passive RLC filters so that many passive filter structures, such as LC ladders, can be directly translated into g_m-C form.

16.3.1 Basic Building Blocks

16.3.1.1 Integrators

Integrators are obtained readily by loading an OTA with a floating or a grounded capacitor as shown in Figure 16.18. Observe that the simpler technology of grounded capacitors requires four times the capacitor value and silicon area. Ideally, the integrator realizes the transfer function

$$\frac{V_o}{V_i} = -\frac{g_m}{sC} \tag{16.29a}$$

but notice that the function is sensitive to unavoidable parasitic capacitors as well as to the OTA output conductance g_o. Observe from Figure 16.19 that the output conductance is in parallel with the integrating capacitor C, and that the output capacitances C_o from the positive and negative output nodes of the OTA circuitry to ground add to the value of C. Furthermore, the designer should bear in mind that in IC technology floating capacitors have a substantial parasitic capacitance C_s (about 10% of the value of C) from the bottom plate to the substrate, i.e., to ac ground. To maintain symmetry, the designer may wish

* To implement small values of variable capacitor, MOS transistors connected as varactors can be used. The capacitor can be varied, e.g., via substrate bias.

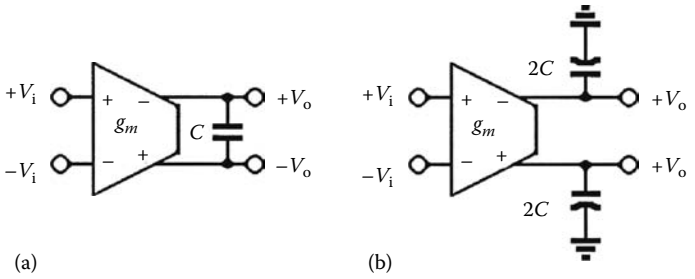

FIGURE 16.18 Integrator. The integrator capacitor may be floating (a) or grounded (b). Note that the grounded-capacitor realization requires four times the area.

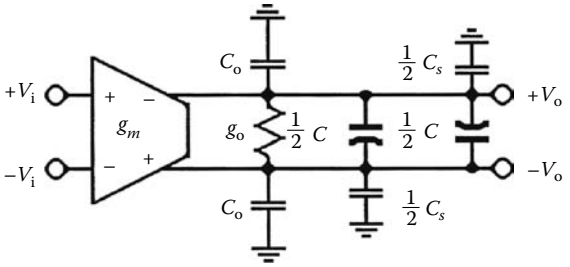

FIGURE 16.19 Parasitic capacitors associated with a g_m-C integrator.

to split the integrating capacitor into two halves connected such that the parasitic bottom plate capacitors $0.5C_s$ appear at the two OTA outputs. The situation is illustrated in Figure 16.19. Taking the parasitics into consideration, evidently, the integrator realizes

$$\frac{V_o}{V_i} = -\frac{g_m}{sC_{int} + g_o}\bigg|_{s=j\omega} = -\frac{g_m}{j\omega C_{int}(1 - j/Q_{int})} \tag{16.29b}$$

that is, it becomes lossy with a finite integrator quality factor

$$Q_{int} = \frac{\omega C_{int}}{g_o} \tag{16.30a}$$

and an effective integrating capacitor equal to

$$C_{int} = C + \frac{1}{2}\left(\frac{C_s}{2} + C_o\right) \tag{16.30b}$$

To maintain the correct integration constant as nominally designed, the circuit capacitor C should be predistorted to reflect the parasitics appearing at the integration nodes. The parasitics should be estimated as best as possible, for example, from a layout process file, and their values subtracted from the nominal value of C in the final layout. If grounded capacitors are used as in Figure 16.18b, the bottom plate should, of course, be connected to ground so that the substrate capacitances are connected between ground and the power supply. Thus, they are shorted out for the signals and play no role. Observe that the presence of parasitic capacitors tends to limit the high-frequency performance of these

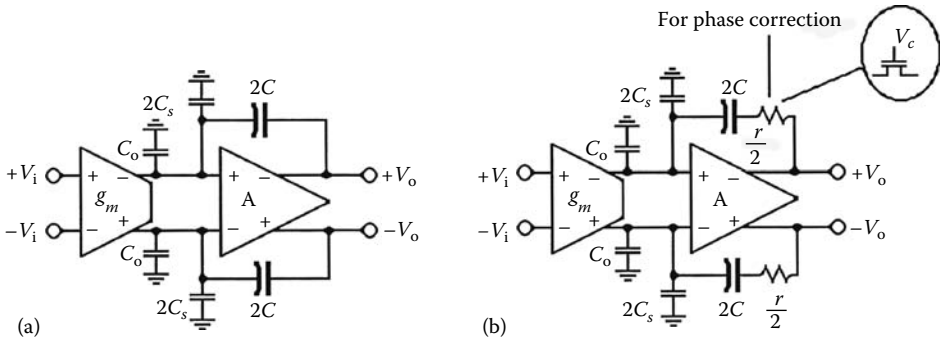

FIGURE 16.20 (a) g_m-C–op-amp integrator; (b) nominal correction for phase errors.

filters because high-frequency filters require large time constants, g_m/C, i.e., small capacitors.* The smallest capacitor C, however, must obviously be larger than the sum of all parasitics connected at the integrator output nodes to be able to absorb these parasitics.† Because the values of the parasitic capacitors can generally only be estimated, one typically chooses C to be three to five times larger than the expected parasitics to maintain some predictability in the design. The reader will notice that integrators with grounded capacitors, Figure 16.18b, have a small advantage in high-frequency circuits where parasitic capacitors become large relative to C. Because of the problem with parasitic capacitors, an alternative "g_m-C–op-amp" integrator is also used. It employs an op-amp to minimize their effects for the price of a second active device, increased noise, silicon area, and power consumption. Figure 16.20a shows the configuration. Notice that now the parasitic capacitors play no role because they are connected between ground and virtual ground (the op-amp inputs) so that they are never charged. A more careful analysis shows that the integrator realizes

$$\frac{V_o}{V_i} = \frac{g_m}{sC}\frac{1}{1+\frac{1}{A(s)}\left(1+\frac{C_p}{C}\right)} \approx \frac{g_m}{sC}\frac{1}{1+\frac{s}{\omega_t}\left(1+\frac{C_p}{C}\right)} \tag{16.31}$$

where $C_p = 0.5(C_o + 2C_s)$ represents the total parasitic capacitance at each of the op-amp input terminals. Evidently, the integrator has acquired a parasitic pole at

$$s = -\omega_t \frac{C}{C + C_p} \tag{16.32}$$

where we have modeled the amplifier gain as $A(s) \approx \omega_t/s$. The high-frequency performance is now limited by the op-amp behavior. It has been shown, though, that a low-gain wideband amplifier, essentially a second OTA with dc gain g_m/g_o, can be used for this application. Nevertheless, the second active device introduces parasitic poles (and zeros) whose effects must be carefully evaluated in practice. The dominant pole introduced by the op-amp may be canceled *nominally* by an rC phase lead as shown in Figure 16.20b. The circuit realizes

* Increasing g_m is generally not a satisfactory solution because it also increases the parasitics.

† Obviously, the highest operating frequencies are obtained for $C = 0$, that is, when a parasitic capacitor C_p is used as the integrating capacitor C. In that case, operating frequencies in the gigahertz range can be realized: $g_m/C \approx 2\pi \times 1$ GHz for $g_m = 100$ μS and $C_p \approx 15$ fF. Naturally, because of the uncertainty in the design values, an automatic tuning scheme is unavoidable.

$$\frac{V_o}{V_i} = \frac{g_m}{sC} \frac{1 + sCr}{1 - \frac{\omega}{\omega_t}\omega C_p r + \frac{s}{\omega_t}\left(1 + \frac{C_p}{C}\right)} \approx \frac{g_m}{sC} \frac{1 + sCr}{1 + \frac{s}{\omega_t}\left(1 + \frac{C_p}{C}\right)} \tag{16.33}$$

so that r should be chosen as

$$r = \frac{1}{\omega_t C}\left(1 + \frac{C_p}{C}\right) \tag{16.34}$$

to cancel the pole. The small resistor r may be a MOSFET in the triode region as indicated in Figure 16.20b so that $r(V_C)$ becomes variable for any necessary fine adjustments. Notice that the cancellation is only *nominal* because Equation 16.34 can never be satisfied exactly because of the uncertain values of ω_t and C_p.

16.3.1.2 Gyrators

A gyrator is defined by the equations

$$I_i = \frac{1}{r} V_o; \quad I_o = -\frac{1}{r} V_i \tag{16.35a}$$

where r is the so-called gyration resistance and the currents are defined as positive when flowing into the gyrator. Thus, the input impedance $Z_{in}(s)$ is inversely proportional to the load impedance $Z_{load}(s)$:

$$Z_{in}(s) = \frac{V_i}{I_i} = r^2 \frac{-I_o}{V_o} = r^2 \frac{1}{Z_{load}(s)} \tag{16.35b}$$

If a gyrator is loaded by a capacitor, $Z_{load}(s) = 1/(sC)$, the input impedance is proportional to frequency, i.e., it behaves like an inductor of value r^2C:

$$Z_{in}(s) = sr^2C = sL \tag{16.36}$$

Equation 16.35a indicates that a gyrator can be interpreted as a connection of an inverting and a noninverting transconductor of value $g_m = 1/r$ as shown in Figure 16.21a. This fact makes it very easy to build excellent gyrators with OTAs (see Figure 16.21b and c), whereas it has been found quite difficult to obtain good gyrators with op-amps. An exception is Antoniou's general impedance converter (GIC) [1, Chapter 5], [3, Chapter 14.1]. However, it is useful only at relatively moderate frequencies (up to about 5%–10% of the op-amp's gain-bandwidth product);* also, the circuit contains resistors that are not voltage-driven and, therefore, cannot readily be translated into a MOSFET-C equivalent as was discussed previously. The availability of good gyrators provides us with a convenient method for building high-frequency integrated g_m-C ladder filters, which is based on inductor-replacement to be discussed in Section 16.3.3.1.

Notice that the comments made earlier about the effects of parasitic capacitors also apply to inductor simulation: the parasitic input and output capacitors of the OTAs and the bottom-plate-to-substrate capacitances (Figure 16.19) add to the capacitor used to set the value of the simulated inductor. For instance, using the same notation as in Figure 16.19, the effective capacitor in Figure 16.21b equals

* As stated, Antoniou's GIC is really an *impedance converter*, not a gyrator (see Equation 15.63 and Figure 15.17). The GIC converts a load resistor into an inductive input impedance, rather than inverting a capacitor as described in Equation 16.35b.

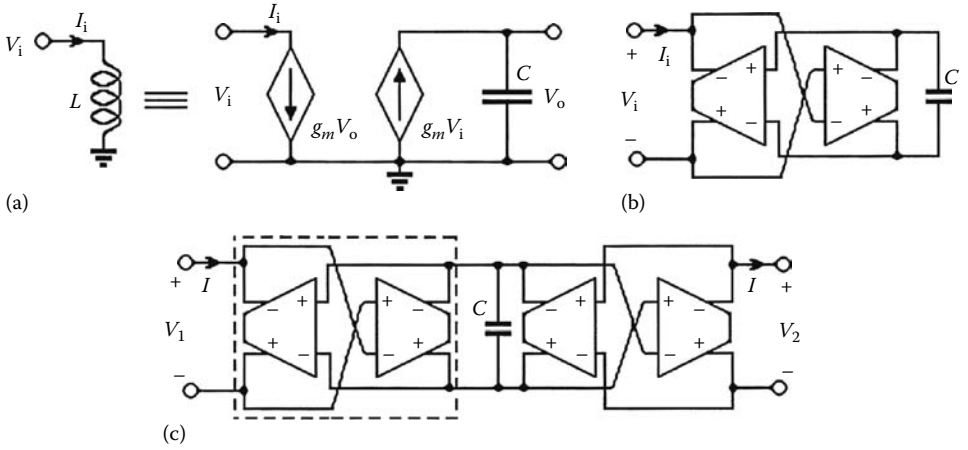

FIGURE 16.21 (a) Controlled-source realization of capacitively loaded gyrator to realize a grounded inductor; (b) differential g_m-C implementation; and (c) a floating inductor requires two gyrators.

$$C_{\text{eff}} = C + \frac{1}{2}\left(\frac{C_s}{2} + C_{\text{i}} + C_{\text{o}}\right) \tag{16.37}$$

where C_{i} is the parasitic capacitance at the input terminals of the OTA, see Figure 16.15, and C is assumed to be split as in Figure 16.19. Note also that a parasitic capacitor of value $C_{\text{in}} = C_{\text{i}} + C_{\text{o}}$ is measured across the inductor of Figure 16.21b so that the inductor

$$L_{\text{eff}} = \frac{C_{\text{eff}}}{g_m^2} \tag{16.38}$$

has a self-resonance frequency*

$$\omega_0 = \frac{1}{\sqrt{L_{\text{eff}} C_{\text{in}}}} \tag{16.39}$$

Finally, to complete the inductor model, recall that the OTAs have finite differential output conductances,† g_{o} (see Figure 16.15), which appear across the input and load terminals of the gyrator in Figure 16.21b. Consequently, the full inductive admittance realized by Figure 16.21b equals

$$Y_L(s) = g_{\text{o}} + sC_{\text{in}} + \frac{g_m^2}{sC_{\text{eff}} + g_{\text{o}}} \tag{16.40}$$

to yield the equivalent circuit in Figure 16.22 for the inductor L. The designer should keep this circuit in mind when using this method to develop a filter.

Evidently, the realized quality factor of the inductor equals $Q_L = \omega C_{\text{eff}}/g_{\text{o}}$. This means OTAs with large output resistance $r_{\text{o}} = 1/g_{\text{o}}$ are needed for high-quality inductor simulations.

* With modern submicron CMOS processes, the self-resonance frequency of electronic inductors can be as high as a few gigahertz with quality factors in the range of a few 100. See Ref. [9].

† As was mentioned, the input conductances can normally be neglected.

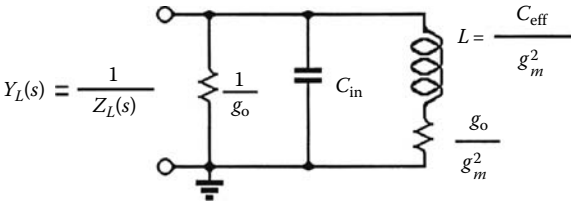

FIGURE 16.22 Passive equivalent circuit for the grounded inductor simulated in Figure 16.21b.

Next we discuss first- and second-order g_m-C sections used as building blocks for the cascade approach to high-order filter design. As was the case for the MOSFET-C method, we will see that g_m-C sections are constructed by interconnecting integrators.

16.3.1.3 First- and Second-Order Sections

Consider the integrator in Figure 16.18a; we make it lossy by loading it with the resistor in Figure 16.17b. Let the input signals also be fed through capacitors into the integrator output nodes as shown in Figure 16.23. The circuit is readily analyzed by writing Kirchhoff's current law at the output node to yield

$$\frac{V_o}{V_i} = -\frac{sC_1 + g_{m1}}{s(C_1 + C) + g_{m2}} \tag{16.41}$$

The circuit may realize any desired first-order function by choosing the appropriate values for the transconductances and the capacitors. For example, a low-pass can be obtained by setting $C_1 = 0$; a high-pass results from $g_{m1} = 0$ and possibly $C = 0$; and $C = 0$ and $g_{m1} = -g_{m2}$ results in an all-pass function.

A second-order block can be designed by interconnecting two integrators in a variety of feedback configurations. To keep the method more transparent, we show one such possibility in Figure 16.24 with single-ended outputs. A differential structure is obtained by mirroring the circuit at ground and duplicating the appropriate components as was demonstrated in connection with Figure 16.4. Let us disregard for now the dashed OTA with inputs V_a and V_b and apply an input signal V_i; writing the node equations for Figure 16.24 we obtain

$$g_{m3}(V_i - V_2) + g_{m4}(V_1 - V_3) = 0; \quad sC_1V_1 = -g_{m1}V_3; \quad sC_2V_2 = -g_{m2}V_1 \tag{16.42}$$

By eliminating two of the three voltages V_1, V_2, or V_3 from these equations, we obtain the bandpass, low-pass, and high-pass functions, respectively,

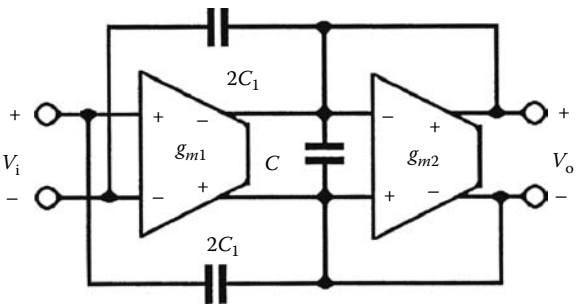

FIGURE 16.23 First-order g_m-C section.

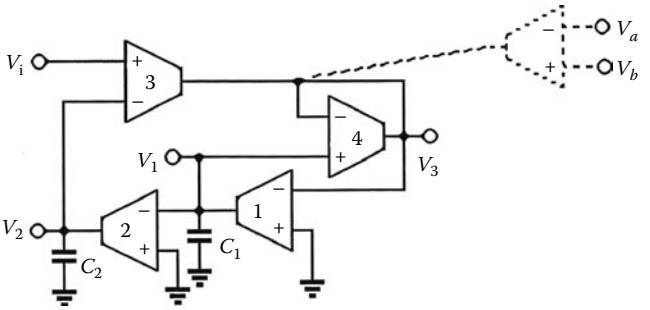

FIGURE 16.24 General biquadratic g_m-C section.

$$\frac{V_1}{V_i} = H_{BP}(s) = \frac{-sC_2g_{m1}g_{m3}}{s^2C_1C_2g_{m4} + sC_2g_{m1}g_{m4} + g_{m1}g_{m2}g_{m3}} \tag{16.43a}$$

$$\frac{V_2}{V_i} = H_{LP}(s) = \frac{g_{m1}g_{m2}g_{m3}}{s^2C_1C_2g_{m4} + sC_2g_{m1}g_{m4} + g_{m1}g_{m2}g_{m3}} \tag{16.43b}$$

$$\frac{V_3}{V_i} = H_{HP}(s) = \frac{s^2C_1C_2g_{m3}}{s^2C_1C_2g_{m4} + sC_2g_{m1}g_{m4} + g_{m1}g_{m2}g_{m3}} \tag{16.43c}$$

In *any* electrical network, one can generate different numerator polynomials, i.e., different transmission zeros, without disturbing the poles, i.e., the system polynomial, by applying an input *voltage* to any node that is lifted off *ground*, or by sending an input *current* into any *floating* node. The second of these possibilities is illustrated in Figure 16.24 in dashed form where a current $g_m(V_b - V_a)$ is sent into Node 3. We leave the analysis to the reader. We demonstrate the first possibility by applying V_i to the noninverting terminals of OTA_1 and OTA_2, which are grounded in Figure 16.24. The reader may show by routine analysis that lifting these two nodes off ground and then applying V_i to both of them (in addition to the original input) results in the complete biquadratic transfer function

$$\frac{V_3}{V_i} = \frac{s^2C_1C_2g_{m3} + sg_{m1}(C_2g_{m4} - C_1g_{m3}) + g_{m1}g_{m2}g_{m3}}{s^2C_1C_2g_{m4} + sC_2g_{m1}g_{m4} + g_{m1}g_{m2}g_{m3}} \tag{16.44}$$

with which, for example, a notch filter may be realized by setting $C_2g_{m4} = C_1g_{m3}$.

A great variety of second-order sections can be found in the literature, e.g., [3, Chapter 16.3]. Many are designed for specific transfer functions rather than the general circuit in Figure 16.24, and are often simpler and contain fewer OTAs. Readers are well advised to scan the available literature for the best circuit for their applications.

16.3.2 Cascade Realizations

Apart from modularity and simple design methods, the main advantage of the cascade approach is its generality: a cascade structure can realize a transfer function with arbitrary zero locations, whereas simulations of lossless *LC ladders* discussed below are restricted to $j\omega$-axis transmission zeros. Implementing a prescribed transfer function by the cascade method with g_m-C integrated filters follows the same principles that were discussed in Chapter 15 for discrete active *RC* filters and leads to the filter structure in Figure 16.9. The difference lies only in the final realization of the sections in monolithic form. We demonstrate the principle with the example of a high-frequency filter for the read/write channel of a

TABLE 16.2 Filter Parameters for Equation 16.45

	Pole Frequency (Normalized to 10^7 s^{-1})	Pole Quality Factor (Normalized to 10^7 s^{-1})	Zero
Biquad 1	$\omega_1 = 1.14762$	$Q_1 = 0.68110$	$\sigma_z = 0.95$
Biquad 2	$\omega_2 = 1.71796$	$Q_2 = 1.11409$	
Biquad 3	$\omega_3 = 2.31740$	$Q_3 = 2.02290$	
Section 4	$\sigma = 0.86133$	—	

magnetic disk storage system,* where the most critical specification is constant delay, i.e., linear phase. To this end, let us discuss the design of a seventh-order cascade low-pass with a constant delay approximated in the Chebyshev (equiripple) sense. The specifications call for a delay variation of maximally 1 ns over the passband and a bandwidth $f_c = 10$ MHz. The transfer function to be implemented is

$$H_7(s) = \frac{K_0\left(s^2 - \sigma_z^2\right)}{(s+\sigma)(s^2 + s\omega_1/Q_1 + \omega_1^2)(s^2 + s\omega_2/Q_2 + \omega_2^2)(s^2 + s\omega_3/Q_3 + \omega_3^2)} \tag{16.45}$$

with the required parameters given in Table 16.2. The purpose of the symmetrical pair of zeros at $\pm\sigma_z$ is magnitude equalization to effect a gain boost for pulse slimming. Note that these zeros do not affect the phase or the delay because the factor $(\omega^2 + \sigma_z^2)$ is real on the $j\omega$-axis. The fully differential second-order circuit chosen for the low-pass sections is shown in Figure 16.25a. Simple analysis shows that it realizes the function

$$H_{\mathrm{LP}}(s) = \frac{V_{\mathrm{LP}}}{V_{\mathrm{i}}} = \frac{g_{m1}g_{m2}}{s^2C_1C_2 + sC_1g_{m2} + g_{m1}g_{m2}} = \frac{\omega_0^2}{s^2 + s\omega_0/Q_0 + \omega_0^2} \tag{16.46}$$

where

$$\omega_0 = \sqrt{\frac{g_{m1}g_{m2}}{C_1C_2}} \tag{16.47a}$$

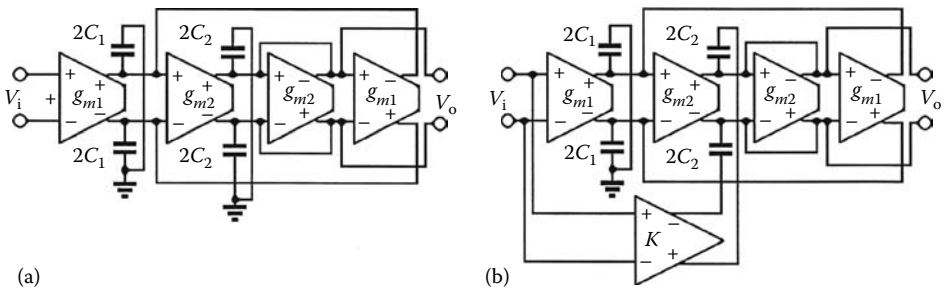

FIGURE 16.25 (a) Second-order low-pass g_m-C section; (b) an equalizer section.

* A similar commercially successful design in bipolar technology is discussed in Ref. [12].

and

$$Q_0 = \sqrt{\frac{g_{m1}C_2}{g_{m2}C_1}} \tag{16.47b}$$

are the pole frequency and pole quality factor, respectively. There remains the question of how to obtain the two real transmission zeros at $\pm\sigma_z$. For this purpose we recall that the zeros of a transfer function can be changed without destroying the poles by feeding the input signal or a fraction thereof into any of the ground nodes lifted off ground. For the situation at hand this can be accomplished by lifting the capacitors $2C_2$ in the low-pass off ground and feeding KV_i with the appropriate polarity into the terminals so generated. Figure 16.25b shows the resulting circuit, which may be analyzed to yield the transfer function

$$\frac{V_\mathrm{o}}{V_\mathrm{i}} = \frac{-Ks^2C_1C_2 + g_{m1}g_{m2}}{s^2C_1C_2 + sC_1g_{m2} + g_{m1}g_{m2}} \tag{16.48}$$

with the zero at $\sigma_\mathrm{z} = \pm\omega_0 K^{-1/2}$. Observe that the two transconductors labeled g_{m1} and g_{m2}, respectively, have common output terminals; they can, therefore, be merged into one double-input transconductor each as discussed in connection with Figure 16.16c. Further, we need the circuit in Figure 16.23 with $C_1 = 0$ to realize a first-order section, a lossy integrator with the function

$$\frac{V_\mathrm{o}}{V_\mathrm{i}} = -\frac{g_{m1}}{sC + g_{m2}} \tag{16.49}$$

Finally, we must determine the component values. To this end we compute from Equations 16.47 and 16.49 the relationships

$$\begin{gathered} C_1 = \frac{g_m}{\omega_i Q_i} = \frac{12.5}{\omega_i Q_i}\ \text{pF}; \quad C_2 = g_m\frac{Q_i}{\omega_i} = 12.5\frac{Q_i}{\omega_i}\ \text{pF}; \\ C = \frac{g_m}{\sigma} = \frac{12.5}{\sigma}\ \text{pF}; \quad K = \left(\frac{\omega_1}{\sigma_z}\right)^2 \end{gathered} \tag{16.50}$$

where we used that ω_i in Table 16.2 was normalized by a factor $10^7\ \mathrm{s}^{-1}$ and we assumed for simplicity that all OTAs have the same transconductance values,* $g_{m1} = g_{m2} = g_m = 125\ \mu\text{S}$. Lastly, to illustrate the need to account for parasitics, we observe that in Figure 16.25 the capacitor C_1 is paralleled by $2C_\mathrm{o}$ and $1C_\mathrm{i}$, and the capacitor C_2 by $2C_\mathrm{o}$ and $3C_\mathrm{i}$. The third input capacitor in parallel with C_2 is arrived at by the fact that each biquad must drive the next biquad in the cascade connection and there sees an OTA input. The capacitor C in Figure 16.23 is in parallel with $2C_\mathrm{o}$ and $1C_\mathrm{i}$. To arrive at numerical values we will assume $C_\mathrm{o} = 0.09$ pF and $C_\mathrm{i} = 0.04$ pF. Consequently, the capacitor values are obtained from Equation 16.50 as

$$C_1 = \frac{12.5}{\omega_i Q_i}\ \text{pF} - 0.22\ \text{pF}; \quad C_2 = 12.5\frac{Q_i}{\omega_i}\ \text{pF} - 0.3\ \text{pF}; \quad C = \frac{12.5}{\sigma}\ \text{pF} - 0.22\ \text{pF} \tag{16.51}$$

Table 16.3 contains the computed capacitor values and Figure 16.26 shows the final cascade block diagram with the equalizer section leading and the first-order low-pass at the end. The two control

* This assumption is for convenience of design and layout because it permits a given transconductance cell to be used throughout the circuit. However, using different transconductance values in different sections has the advantage that capacitor values may be equalized, since by Equation 17.50 the capacitors are proportional to g_m.

blocks are necessary to be able to tune the filter electronically: the gain K is varied via the *Equalizer control* block to set the position of the zeros and thereby the amount of gain boost, i.e., pulse slimming. Electronic tuning of the frequency parameter g_m/C is accomplished via adjusting the bias currents of the OTAs by the block labeled *Bias f_c control*. Thereby uncontrollable changes in the value g_m/C due to process variations or temperature can be accounted for. Details of such a control scheme are discussed in Section 16.4.

16.3.3 Ladder Simulations

As mentioned earlier, the main reason for using the popular *LC* ladder simulation method for filter design is the generally lower passband sensitivity of this topology to component tolerances [1, Chapter 3], [3, Chapter 13], see also Chapter 7. As before, the procedures are, in principle, identical to those discussed in connection with discrete circuits and are best illustrated with the help of a generic example. Let us consider again the classical ladder structure in Figure 16.11, which realizes the fifth-order elliptic low-pass characteristic Equation 16.21 and is described by Equation 16.22. Two methods are available to simulate the ladder. The first and most intuitive method replaces the inductors L_2 and L_4 by capacitively loaded gyrators (Figure 16.21). The second method recognizes that the inductors and the grounded capacitors in Figure 16.11 perform the function of integration. This signal-flow graph method is completely analogous to the process discussed earlier in Chapter 15 and for MOSFET-*C* filters, and will be presented in Section 16.3.3.2. We point out here that the element replacement and the signal-flow graph methods lead to the same circuitry [3, Chapter 16.4] so that either method can be used at the designer's convenience.

16.3.3.1 Element Replacement Methods

Replacing the inductors L_2 and L_4 in Figure 16.11 by capacitively loaded gyrators and using differential balanced circuitry leads to the circuit in Figure 16.27a. It is obtained by first converting the voltage source to a current source (Norton transformation), which also converts the series source resistor R into a shunt resistor. The first OTA in Figure 16.27a performs the source transformation, the second OTA is the grounded resistor. Since the two inductors are floating, the implementation of each requires two gyrators, i.e., four OTAs (see Figure 16.21c). Note that all OTAs are identical, and that all

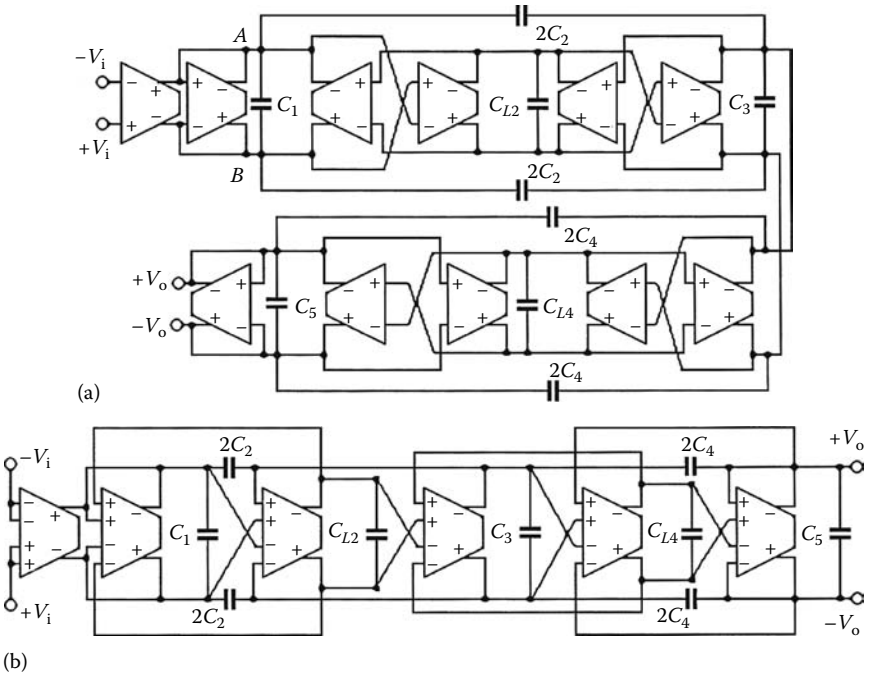

FIGURE 16.27 (a) Transconductor-*C* simulation by the element replacement method of the fifth-order elliptic low-pass ladder in Figure 16.11, including source and load resistors. All g_m-cells are identical. Note that the floating inductors require two gyrators for implementation. (b) The circuit with dual-input OTAs.

capacitors except C_2 and C_4 could be grounded; for example, instead of connecting C_1 *between* nodes *A* and *B* in Figure 16.27a, capacitors of value $2C_1$ could be connected from *both* nodes *A* and *B* to ground. Comparing the active circuit with the *LC* prototype readily identifies both structure* and components. The element values are obtained directly from the prototype *LC* ladder, e.g., from published tables, such as Ref. [2], or from appropriate synthesis software. Labeling for the moment the normalized components in the prototype *LC* ladder by the subscript *n*, i.e., R_n, $C_{i,n}$, and $L_{i,n}$, the transformation into the real component values with units of [F] and [H] is achieved by the following equations:

$$R = \frac{R_n}{g_m}; \quad C_i = C_{i,n}\frac{g_m}{\omega_c}; \quad L_i = L_{i,n}\frac{1}{g_m\omega_c} = \frac{C_{Li}}{g_m^2} \rightarrow C_{Li} = L_{i,n}\frac{g_m}{\omega_c} \tag{16.52}$$

where

g_m is the transconductance value chosen by the designer
ω_c is the normalizing frequency (usually the specified passband corner frequency)
R_n is in most prototype designs normalized to $R_n = 1$

Naturally, as discussed earlier, all capacitor values must be predistorted to account for the parasitic capacitors appearing at the capacitor nodes. For example, note that C_{L2} is paralleled by two OTA input and two OTA output capacitors, and for symmetrical layout (Figure 16.19), by $0.25C_s$. We see that the

* The number of floating capacitors is of course doubled because of the balanced differential structure of the active implementation.

element replacement method is a very straightforward design process; it has been found to work very well in practice.

Figure 16.27b shows the same circuit but realized with dual-input OTAs (Figure 16.16c). As was pointed out earlier, this merging of OTAs can always be used when two (or more) OTAs share a common output node. It results in simplified circuitry, and possibly reduced power consumption and chip area. In such cases, only the linearized input stages of the OTA must be duplicated, but bias, output, and common-mode rejection circuitry can be shared. Observe also that the input voltage is applied to both inputs of the first dual-input OTA in Figure 16.27b, thereby doubling its value of g_m. This multiplies the transfer function by a factor of two and eliminates the 6 dB loss inherent in the *LC* ladder (see Figure 16.12).

A small example will show the design process. For an antialiasing application we need to realize a third-order elliptic low-pass filter with $f_c = 10$ MHz bandwidth, 0.5 dB passband ripple, 17.5 MHz stopband edge, and 23 dB stopband attenuation. It leads to the transfer function [2]

$$H(s) = \frac{0.28163(s^2 + 3.2236)}{(s + 0.7732)(s^2 + 0.5016s + 1.1742)} \tag{16.53}$$

and the normalized element values $R_n = 1$, $C_{1n} = C_{3n} = 1.293$, $C_{2n} = 0.3705$, and $L_{2n} = 0.8373$. The topology is as in Figure 16.11 with $C_{4n} = L_{4n} = C_{5n} = 0$. Figure 16.28 shows the active circuit. Observe that we have realized each of the floating capacitors C_j as $0.5C_j + 0.5C_j$, $j = 1, 2, 3, L2$, with inverted bottom-plate connections. This design choice preserves symmetry in the balanced differential layout by placing the unavoidable substrate capacitors of value $\approx 0.1 \times (0.5C_{L2})$ *at each* of the upper and lower nodes of C_{L2} and $\approx 0.1 \times (0.5C_k + 0.5C_2)$ at the upper and lower nodes of C_k, $k = 1, 3$. Choosing the value of transconductance as $g_m \approx 180$ μS, using Equation 16.51, $\omega_c = 2\pi \times 10 \times 10^6$ s^{-1}, and observing the necessary predistortion for the *differential* parasitic OTA input and output capacitors, $C_i = 0.03$ pF and $C_o = 0.08$ pF, respectively, and for the bottom-plate capacitors C_s assumed to be 10% of the corresponding circuit capacitor value, results in

$$\begin{aligned}
C_1 &= C_{1n}\frac{g_m}{\omega_c} - 3C_o - 2C_i - 0.1\frac{1}{2}\left(C_2 + \frac{C_1}{2}\right) = 3.191 \text{ pF} \\
C_2 &= C_{2n}\frac{g_m}{\omega_c} = 1.061 \text{ pF} \\
C_3 &= C_{3n}\frac{g_m}{\omega_c} - 2(C_o + C_i) - 0.1\left(\frac{C_2}{2} + \frac{C_3}{4}\right) = 3.268 \text{ pF} \\
C_{L2} &= L_{2n}\frac{g_m}{\omega_c} - 2(C_o + C_i) - 0.1\frac{C_L}{4} = 2.120 \text{ pF}
\end{aligned} \tag{16.54}$$

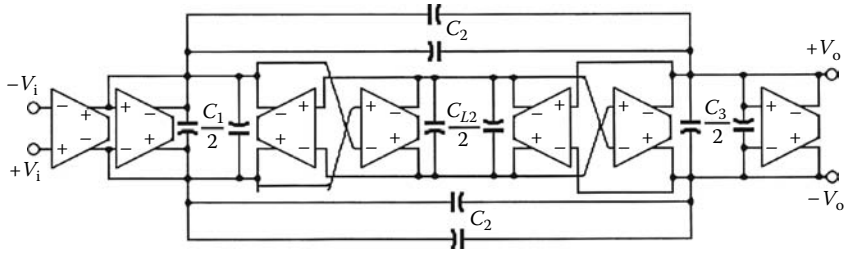

FIGURE 16.28 Realization of the third-order elliptic low-pass ladder of Equation 16.53. The capacitor values indicated refer to *each* of the pair of capacitors.

Notice that in a ladder structure all parasitic capacitors can be absorbed in the circuit capacitors. Consequently, no new parasitic poles or zeros are created that might destroy the transfer function shape. This is a further important advantage of the ladder-simulation method for g_m-C filters.

16.3.3.2 Signal-Flow Graph Methods

As we have seen earlier, the signal-flow graph (SFG) or operational-simulation method takes the circuit equations describing the ladder (Kirchhoff's laws and the I–V relationships for the elements) and realizes them directly via summers (for Kirchhoff's laws) and integrators (for inductors and grounded capacitors). The procedure was detailed in connection with Equations 16.22 through 16.24. Recall that Equation 16.23 represents *integrations* of voltages into currents and currents into voltages. As was the case for the op-amp–based active RC filters in Chapter 15 and the MOSFET-C design, all signals in the SFG g_m-C circuit are voltages. They are summed at the OTA inputs, then are multiplied by g_m to produce an output current that is integrated by a capacitor to produce a voltage as input for the OTA of the next stage. To reflect these facts in the relevant equations, we scale Equation 16.23 analogously to Equation 16.24 to obtain

$$\frac{I_{L2}}{g_m} = \frac{g_m(V_1 - V_3)}{s(L_{2n}g_m)g_m}; \quad \frac{I_{L4}}{g_m} = \frac{g_m(V_3 - V_5)}{s(L_{4n}g_m)g_m} \tag{16.55a}$$

$$V_1 = \frac{g_m V_\mathrm{i} - (I_{l2}/g_m)g_m + sC_{2n}V_3}{s(C_{1n} + C_{2n}) + g_m} \tag{16.55b}$$

$$V_3 = \frac{(I_{L2}/g_m)g_m - (I_{L4}/g_m)g_m + sC_{2n}V_1 + sC_{4n}V_5}{s(C_{2n} + C_{3n} + C_{4n})} \tag{16.55c}$$

$$V_5 = V_\mathrm{o} = \frac{(I_{L4}/g_m)g_m + sC_{4n}V_3}{s(C_{4n} + C_{5n}) + g_m} \tag{16.55d}$$

The scaling factor in this case is the design transconductance g_m. Note that $L_\mathrm{i}\, g_m^2$ in Equation 16.55a has units of capacitance and that source and load resistors in Equations 16.55b and d have the value $1/g_m$. Implementing these equations with lossless or lossy, as appropriate, integrators in fully differential form results in the circuit in Figure 16.29, where we used a signal notation similar to that in Figure 16.14 and chose all integrating capacitors grounded. Starting from a normalized LC prototype, the actual component values are obtained again via Equation 16.52. Note that the OTA at the input performs the voltage-to-current conversion (V_i to I_1) and that the last OTA both here and in Figure 16.27 implements the load resistor. The second OTA in Figure 16.27, realizing the source resistor, is saved in Figure 16.29 by sending the current I_1 directly into the integrating node (the capacitor C_1), as suggested by Equation 16.55b.* Also observe that circuit complexity in Figure 16.29 was kept low by resorting to OTAs with dual inputs. We note again that all transconductors in Figures 16.27through 16.29 are identical† so that a single optimized g_m-cell (an *analog gate*) can be used throughout the filter chip for an especially simple IC design process, analogous to that of a gate array. The inherent 6 dB loss of the LC ladder can also be eliminated, if desired, by lifting the two grounded inputs of the second OTA in Figure 16.29 off ground and connecting them to the input voltage $\pm V_\mathrm{i}/2$ as indicated by the dashed connections.

---

* Had we used this "resistor," the current into the integration node would have been realized as $g_m V_\mathrm{i} = g_m V_\mathrm{i} \times (1/g_m) \times g_m$, clearly a redundant method.

† This can generally be achieved in g_m-C ladder simulations; the only exception occurs for those LC ladders that require unequal terminating resistors, such as even-order Chebyshev filters; in that case, one of the transconductors will also be different.

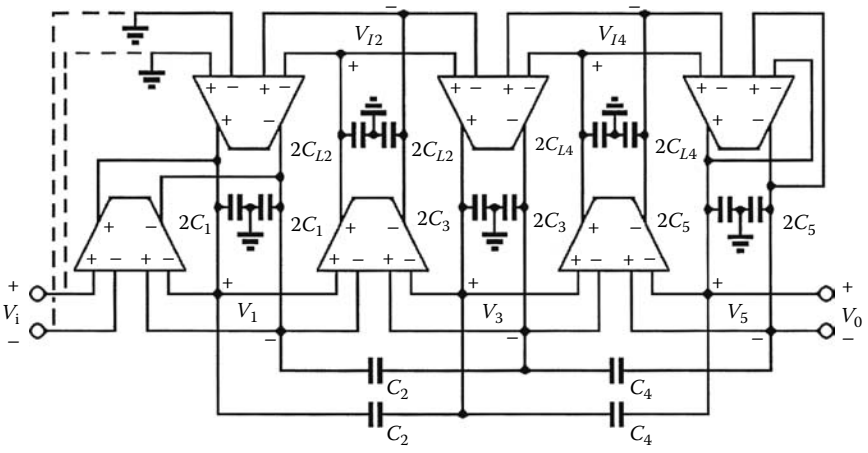

FIGURE 16.29 Signal-flow graph g_m-C realization of a fifth-order elliptic low-pass function. The circuit is an active simulation of the LC-ladder in Figure 16.11, including source and load resistors. All g_m-cells are identical.

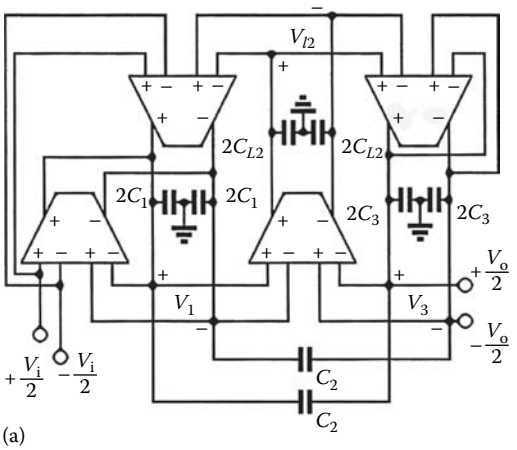
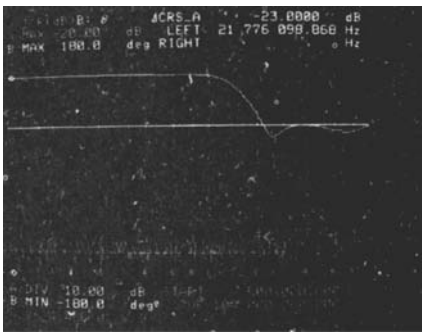


As a simple design example, consider again the realization of the third-order elliptic low-pass filter described by Equation 16.53. The nominal LC elements were given earlier; the circuit is described by Equation 16.55 with $C_{4n} = C_{5n} = L_{4n} = 0$, i.e.,

$$\frac{I_{L2}}{g_m} = \frac{g_m(V_1 - V_3)}{s(L_{2n}g_m)g_m} \tag{16.56a}$$



$$V_1 = \frac{2g_mV_i - (I_{L2}/g_m)g_m + sC_{2n}V_3}{s(C_{1n} + C_{2n}) + g_m} \tag{16.56b}$$

$$V_3 = V_o = \frac{(I_{L2}/g_m)g_m + sC_{2n}V_1}{s(C_{2n} + C_{3n}) + g_m} \tag{16.56c}$$

which leads to the circuit in Figure 16.30a, as the reader may readily verify. Note the connection of the input, which realizes the term $2g_mV_i$ in Equation 16.56b and eliminates the 6 dB loss as mentioned

(a)

(b)

FIGURE 16.30 (a) SFG g_m-C third-order elliptic low-pass filter; (b) experimental performance in 2-μm CMOS technology.

earlier. We observe again that the capacitors must be predistorted to account for parasitics as was discussed in connection with Equation 16.54; specifically, labeling as before the *differential* OTA input and output capacitors as C_i and C_o, respectively, we find

$$C_1 \approx C_{1,\text{nominal}} - 2C_o - 2C_i; \quad C_{L2} \approx C_{L2,\text{nominal}} - C_o - 2C_i; \quad C_3 \approx C_{3,\text{nominal}} - C_o - 2C_i$$

Figure 16.30b shows the experimental performance of the circuit fabricated in 2-μm CMOS technology with design-automation software that uses the OTAs from a design library as "analog gates," and *automatically* lays out the chip and predistorts the capacitors according to the process file. The transconductance value used is $g_m \approx 180$ μS, and the capacitors are approximately the same as the ones for the example in Figure 16.28. We will see in Section 16.5 that apart from differences due to layout parasitics, it is no coincidence that the element values are essentially the same as before. Notice that the filter meets all design specifications. The lower trace is the thermal noise at ≈70 dB below the signal; the measured total harmonic distortion was THD < 1% for a 2-$V_{p\text{-}p}$ input signal at 3 MHz.

16.4 Tuning

To obtain accurate filter performance with frequency-parameters set by *RC* products or C/g_m ratios, accurate *absolute* values of components are required. These must be realized by the IC process *and maintained during operation*. Although IC processing is very reliable in realizing accurate *ratios* of like components on a chip, the processing tolerances of *absolute values* must be expected to be of the order of 20%–50% or more. Component tolerances of this magnitude are generally far too large for an untuned filter to perform within specifications. Consequently, filters *must be tuned* to their desired performance by adjusting element values. Clearly, in fully integrated filters, where all components are on a silicon chip, tuning must be performed electronically by some suitably designed automatic control circuitry that is part of the total continuous-time filter system. Tuning implies *measuring* filter performance, *comparing* it with a known standard, *calculating* the errors, and *applying a correction* to the system to reduce the errors. An accurate *reference frequency*, e.g., a system clock (V_{REF} in Figure 16.31), is usually used as a convenient standard. From the filter's response to the signal at this known frequency, errors are detected and the appropriate correction signals, typically dc bias voltages, are applied via the control circuitry [1, Chapter 7], [3, Chapter 16.5]. Reference [7, pt. 6] contains many papers showing practical approaches to specific tuning problems.

Figure 16.31 shows a block diagram of this so-called Master–Slave architecture that is followed by most currently proposed designs. The Master–Slave system is used because the reference signal, V_{REF}, cannot be applied to the Main Filter simultaneously with the main signal, V_{in}, because of undesirable interactions (intermodulation) between V_{in} and V_{REF}. The approach is based on the premise that the filter must operate continuously, i.e., that V_{in} cannot be switched off occasionally to permit tuning in a signal-free

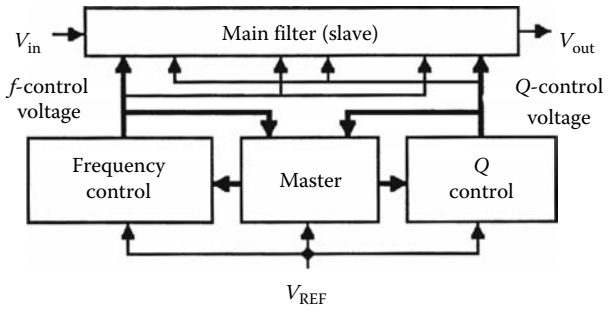


FIGURE 16.31 Block diagram of Master–Slave control system for integrated *c-t* filters.

environment. Therefore, V_{REF} is applied to a circuit, the "Master" filter, that is carefully designed to model the relevant behavior of the "Slave." Master–Slave design and layout require great care to avoid serious matching, noise, and crosstalk problems.

Figure 16.31 should help the reader understand the principle of the operation without having to consider the actual circuitry that is very implementation-specific, see Ref. [7, pt. 6] for design examples. The Main Filter (the "Slave") performs the required signal processing. Since the Master is designed to model the Slave, the behaviors of Master and Slave are assumed to match and track. Tuning is then accomplished by applying the generated correction or control signal simultaneously to both Master and Slave. The system contains a *Frequency-Control* block that detects frequency-parameter errors in the Master's response to the reference signal and generates a frequency-control voltage that is applied to the Master in a closed-loop control scheme such that any detected errors are minimized.* Since the Master is designed to be an accurate model of the Slave, their errors, too, can be assumed to match and track. Consequently, when the frequency-control voltage is applied at the appropriate locations to the Slave, it can be expected to correct any frequency errors in the main filter.

The purpose of the additional block in Figure 16.31, labeled *Q-Control*, is to tune the *shape* of the transfer characteristic. Once the frequency parameters are correct as tuned by the *f*-control loop, the transfer function shape is determined only by the quality factors Q_i of the poles and zeros. *Q*, as a ratio of two frequencies, is a *dimensionless* number and as such is determined by a *ratio* of like components (resistor, capacitor, and/or g_m-ratio; see e.g., Equation 16.47b). *At fairly low frequencies and moderate values of Q,* the quality factor is realizable quite accurately in an IC design. For high-frequency, high-*Q* designs, however, *Q* is found to be a very sensitive function of parasitic elements and phase shifts so that it is unreasonable to expect *Q* to turn out correctly without tuning. Therefore, including for generality a *Q*-Control block† permits automatic tuning of the transfer function shape by a scheme that is completely analogous to the *f*-control method, as illustrated in Figure 16.31.

With few exceptions, all currently proposed automatic tuning schemes follow the Master–Slave approach. A different concept proposed in Ref. [11] uses adaptive techniques to tune all poles *and* zeros of a filter function for improved tuning accuracy. Although the Master–Slave and the adaptive techniques work well, generally, the necessary circuitry has been found to be too large, noisy, and power hungry for many practical applications. Thus, alternative choices use a simple post-fabrication trim step‡ to eliminate the large fabrication tolerances, possibly together with careful design to make the electronic devices (OTAs) independent of temperature variations [12,13].

We also point out that at the highest frequencies, higher than, say, 100 MHz, circuit capacitors to realize the prescribed frequency parameters, g_m/C, become very small ($C \approx 0.15$ pF at 100 MHz and $g_m = 100$ μS). Filter behavior is then essentially determined by parasitics, and matching required between Master and Slave circuitry is unreliable. In that case, a form of direct tuning [7, paper 6.4] must be used, where the main filter is tuned during time periods when the signal is absent. The system is essentially as depicted in Figure 16.31, except that the Master is absent and V_{REF} is applied to the main filter. When tuning is complete (taking a few milliseconds), V_{REF} is turned off, V_{in} is again applied to the filter, and the generated dc control signals are held on a capacitor until the next tuning update.

---

* In the designs reported to date, frequency-control blocks built around some type of phase-locked loop scheme, using a multiplier or an EXOR gate as phase detector, have been found most successful, but magnitude-locking approaches similar to those employed for *Q* control have also been used. A largely digital approach to frequency and *Q* tuning is discussed in Ref. [10].

† Because magnitude errors can be shown in many cases to be proportional to errors in quality factor, the *Q*Control block is normally implemented around an amplitude-locking scheme, where the filter's magnitude response at a given frequency is locked to a known reference level.

‡ For example, an on-chip laser-trimmed resistor or an external resistor set to determine the bias for OTAs. It works for applications with very low quality factors or where no component drifts are expected during operation.

16.5 Discussion and Conclusions

In this chapter we discussed one of the fastest growing research and development areas in the topic of continuous-time filters, the field of fully integrated filters. Growing pressures to reduce costs and size, and improve reliability lead to increasingly larger parts of electronic systems being placed onto integrated circuits, a trend that *c-t* filters need to follow. As might have been expected, in most respects the methods for IC *c-t* filter design are identical to well-known active *RC* techniques, and follow directly the well-understood and proven standard active *RC* biquad-cascade or ladder-simulation methodologies. The difference lies in the final implementation, which the designer may adapt to any IC process and power supply level appropriate for the implementation of the system. Signal-to-noise ratios of the order of 65–80 dB and better, and distortion levels of less than 0.5% at signal levels of 1 V are obtainable. The two most prominent design approaches are the MOSFET-*C* and the g_m-*C* methods, both of which lead to easy and systematic designs and result in filters that have proven themselves in practice. At the time of this writing, g_m-*C* filters appear to have the edge in high-frequency performance: with OTA bandwidths reaching gigahertz frequencies even for CMOS technology, *c-t* filters can be designed readily for applications in the range of several hundred megahertz, i.e., to about 40%–60% of the active-device bandwidth. A second important difference that requires the designer's attention is that the IC filter must be automatically tunable. This implies electronically variable components, OTAs or MOSFET ''resistors,'' in the filter and some automatic control scheme for detecting errors and providing adjustments. Only area- and power-efficient designs, and simple low-noise circuitry for such tuning schemes will be acceptable and guarantee the ultimate commercial success of integrated filters. At the present time, many approaches have been proposed that the reader may modify or adapt to his/her system [7].

We point out again that the cascade design is the more general procedure because it permits the realization of arbitrary transmission zeros anywhere in the complex *s*-plane, as required, for example, in gain or phase equalizers. Lossless ladders, on the other hand, are more restrictive because their transmission zeros are constrained to lie on the $j\omega$ axis, but they have lower passband sensitivities to component tolerances than cascade filters. Since good gyrators are readily available for g_m-*C* filters—in contrast to MOSFET-*C* designs—two competing implementation methods appear to suggest themselves in the g_mC approach: the signal-flow graph and the element-substitution methods. As mentioned, there is in fact no discernible difference between the two methods; indeed, they lead to the same structures. For instance, the reader may readily verify that apart from a minor wiring change at the inputs, the circuits in Figures 16.27b and 16.29 are identical, as are the ones in Figures 16.28 (after redrawing it for dual-input OTAs) and 16.30. The wiring change is illustrated in Figure 16.32. Figure 16.32a shows

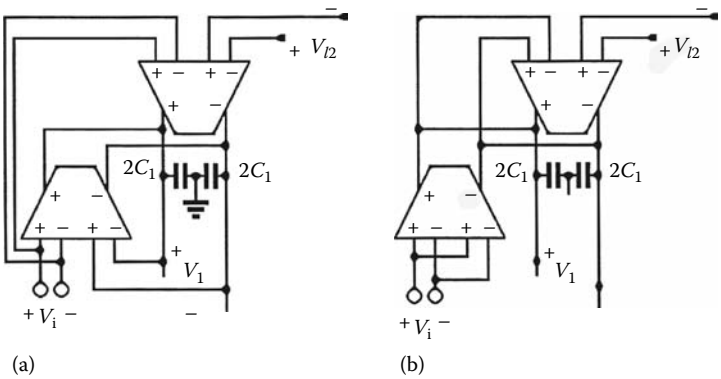

FIGURE 16.32 Excerpt from Figure 16.28 (a) to illustrate alternative wiring and (b) at the filter input 0.

the input section of Figure 16.29 (wired for 0-dB dc gain) and the wiring in Figure 16.32b is that of Figure 16.27b. Notice that both circuits realize

$$(sC_1 + g_m)V_1 = 2g_m V_i - g_m V_{I2} \tag{16.57}$$

The designer, therefore, may choose a ladder method based on his/her familiarity with the procedure, available tables, or prototype designs; the final circuits are the same.

A further item merits reemphasizing at this point: As the reader may verify from the examples presented, g_m-C ladder structures generally have at all circuit nodes a design capacitor that can be used to absorb parasitics by predistortion as was discussed earlier. It may be preferable, therefore, to avoid the g_m-C–op-amp integrator of Figure 16.20 with its increased noise level, power consumption, and with its associated parasitic poles (and zeros) and use parasitics-absorption as we have done in our examples. This method will *not* introduce any new parasitic critical frequencies into the filter and result in lower distortion of the transfer function shape and easier tuning. As we mentioned earlier, this feature is a substantial advantage of g_m-C ladder filters.

17.1 Introduction

The need to have monolithic high-performance analog filters motivated circuit designers in the late 1970s to investigate alternatives to conventional active-RC filters. A practical alternative appeared in the form of switched-capacitor (SC) filters [1–3]. The original idea was to replace a resistor by an SC simulating the resistor. Thus, this equivalent resistor could be implemented with a capacitor and two switches operating with two-clock phases. SC filters consist of switches, capacitors, and op-amps. They are characterized by difference equations in contrast to differential equations for continuous-time filters. Simultaneously, the mathematical operator to handle sample-data systems such as SC circuits is the z-transform, while the Laplace transform is used for continuous-time circuits. Several key properties of SC circuits have made them very popular in industrial environments:

1. Time constants (RC products) from active-RC filters become capacitor ratios multiplied by the clock period T. That is

$$\mathrm{RC} \Rightarrow \frac{C}{C_\mathrm{R}} T = \frac{C}{C_\mathrm{R} f_\mathrm{c}}$$

   where f_c is the clock frequency used to drive the SC equivalent resistor.
2. Reduced silicon area, since the equivalent of large resistors can be simulated using small-size capacitors. Furthermore, positive and/or negative equivalent resistors can be easily implemented with SC techniques.
3. Above expression can be realized in real applications with a good accuracy of nearly 0.1%.
4. Typically, the load of an SC circuit is mainly capacitive; therefore the required op-amps do not require a low-impedance output stage. This allows the use of unbuffered cascode operational transconductance amplifiers, which is especially useful in high-speed applications.
5. SC filters can be implemented in digital circuit process technologies; metal–metal capacitors are quite often used in deep submicron technologies. Thus, useful mixed-mode signal circuits can be economically realized.
6. SC design technique has matured. In the audio range, SC design techniques have become the dominant design approach. Many circuits in communication applications and data converters use SC implementations.

In what follows, we will discuss basic building blocks involved in low- and high-order filters. Limitations and practical design considerations will be presented. Furthermore, due to the industrial push for lower power supply voltages, a brief discussion on low-voltage circuit design is included.

17.2 Basic Building Blocks

The basic building blocks involved in SC circuits are voltage gain amplifiers, integrators, second-order filters, and nonoverlapping clock generators. A key building block is the integrator. By means of a two-integrator loop a second-order (biquadratic) filter can be realized. Furthermore, a cascade connection of biquadratic filters yields higher order filters.

17.2.1 Voltage Gain Amplifiers

The gain amplifier is a basic building block in SC circuits. Both the peak gain of a second-order filter and the link between the resonators in a ladder filter are controlled by voltage amplifier stages rather than by integrators. Many other applications such as pipeline data converters require voltage gain stages as well. A voltage amplifier can be implemented by using two capacitors and an operational amplifier, as shown in Figure 17.1a. Ideally, the gain of this amplifier is given by $-C_\mathrm{S}/C_\mathrm{i}$. This topology is compact, versatile, and time continuous. Although this gain amplifier is quite simple, several second-order effects present in the op-amp make its design more complex. A major drawback of this topology is the lack of dc feedback.

For dc, the capacitors behave as open circuits; hence the operating point of the operational amplifier is not stabilized by the integrating capacitor C_i. In addition, the leakage current present at the input of the op-amp is integrated by the integrating capacitor, whose voltage eventually saturates the circuit. The leakage current I_leak in SCs circuits is a result of the diodes associated with the bottom plate of the capacitors and the switches (drain and source junctions). The leakage current is typically about 1 nA/cm^2. Analysis of Figure 17.1a considering the leakage current I_leak present at the inverting terminal of the amplifier yields

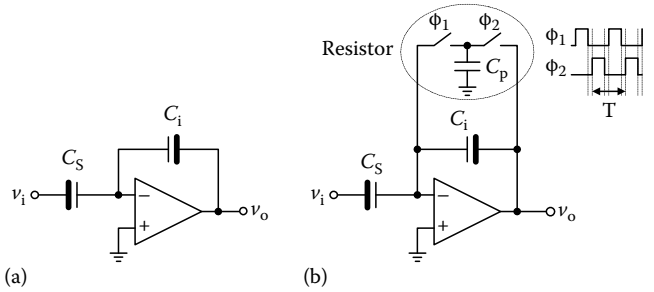

FIGURE 17.1 Voltage amplifiers. (a) Without dc feedback and (b) with dc feedback.

$$v_o(t) = v_o(t_o) - \frac{C_S}{C_i} V_i(t) - \frac{I_{leak}}{C_i}(t - t_o) \tag{17.1}$$

Note that the dc output voltage is defined by the input signal and the initial conditions at $t - t_o$. The leakage current present at the input of the op-amp is integrated by C_i and eventually saturates the circuit. To overcome this drawback, an SC resistor can be added as shown in Figure 17.1b. ϕ_1 and ϕ_2 are two nonoverlapping clock phases with nearly 50% duty cycle. The SC resistor gives a dc path for the leakage current but reduces further the low-frequency gain. A detailed analysis of this topology shows that the dc output voltage is equal to $-I_{leak}T/C_p$, with C_p the parasitic capacitor associated with the feedback path. Employing charge conservation analysis method for SC networks, it can also be shown that the z-domain transfer function of this topology is

$$H(z) = \frac{V_o(z)}{V_i(z)} = -\frac{C_S}{C_i} \frac{1 - z^{-1}}{1 - \left(1 - \frac{C_p}{C_i}\right) z^{-1}} \tag{17.2}$$

with $z = e^{j2\pi fT}$. For low frequencies, $z \approx 1$, the magnitude of the transfer function is very small, and only for high frequencies, $z \approx -1$, the circuit behaves as an inverting voltage amplifier.

An offset free voltage amplifier is shown in Figure 17.2. During the clock phase ϕ_2, the output voltage is equal to the op-amp offset voltage and it is sampled by both the integrating and sampling capacitors. Because of the sampling of the offset voltage during the previous clock phase, during the integrating clock phase the charge injected by the sampling capacitor is equal to $C_S V_i$, and the charge extracted from the integrating capacitor becomes equal to $C_i V_o$ if the offset voltage of the amplifier is the same in both clock phases. In this case, the offset voltage does not affect the charge recombination, and the z-domain transfer function during the clock phase ϕ_1 becomes

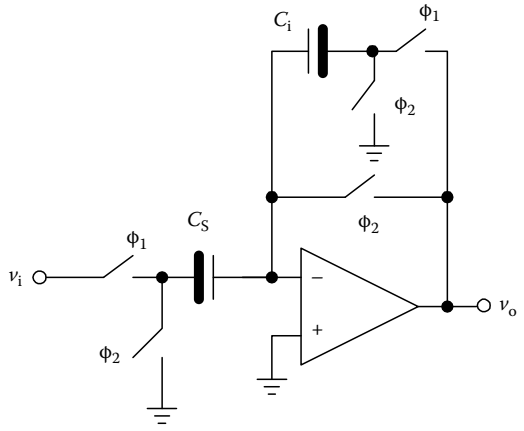

FIGURE 17.2 Voltage amplifier available during the ϕ_1 clock phase.

$$H(z) = -\frac{C_S}{C_i} \tag{17.3}$$

Equation 17.3 shows that ideally this topology is insensitive to the op-amp offset voltage, and does

not have any low-frequency limitation. The topology behaves as an inverting amplifier if the clock phases shown in Figure 17.2 are used. A noninverting amplifier is obtained if the clock phases associated with the sampling capacitor are interchanged.

Because during ϕ_2 the op-amp output is short circuited with the inverting input, this topology presents two drawbacks. First, the amplifier output is only available during the clock phase ϕ_1. This limitation could be important in complex applications wherein the output of the amplifier is required during both clock phases. The second disadvantage of this topology is the large excursion of the op-amp output voltage. During the first clock phase, the op-amp output voltage is equal to the offset voltage and in the next clock phase this voltage is equal to $-(C_S/C_i)V_i$. Hence an op-amp with large slew rate may be required; this may demand significant amount of power since the load capacitor is driving during this phase too.

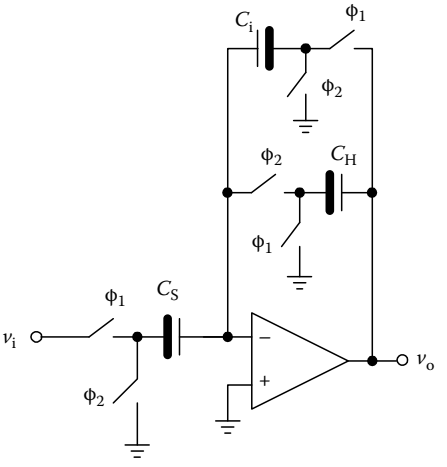

FIGURE 17.3 Voltage amplifier available during both clock phases.

Another interesting topology is shown in Figure 17.3. During ϕ_2, the op-amp output voltage is equal to the previous voltage plus the op-amp offset voltage plus V_o/A_V, where A_V is the open-loop dc gain of the op-amp. In this clock phase, both capacitors C_i and C_S are charged to the voltage at the inverting terminal of the op-amp. This voltage is approximately equal to the op-amp offset voltage plus V_o/A_V. During the next clock phase, the sampling capacitor is charged to $C_S(V_i - V_-)$, but because it was precharged to $-C_S V_-$, the injected charge to C_i is equal to $C_S V_i$. As a result of this charge cancellation, the op-amp output voltage is equal to $-(C_S/C_i)V_i$. Therefore, this topology has low sensitivity to the op-amp offset voltage and to the op-amp dc gain. A minor drawback of this topology is that the op-amp stays in open loop during the nonoverlapping clock phase transition times. This fact produces spikes during these time intervals. A solution for this is to connect a small capacitor between the op-amp output and the left-hand plate of C_S.

17.2.2 First-Order Blocks

The standard stray-insensitive integrators are shown in Figure 17.4. Note that in sampled data systems both input and output signals can be sampled at different clock periods. This yields different transfer functions; this property increases the flexibility of the architecture when used in complex systems. We will assume a two-phase nonoverlapping clock: an odd clock phase ϕ_1 and an even clock phase ϕ_2.

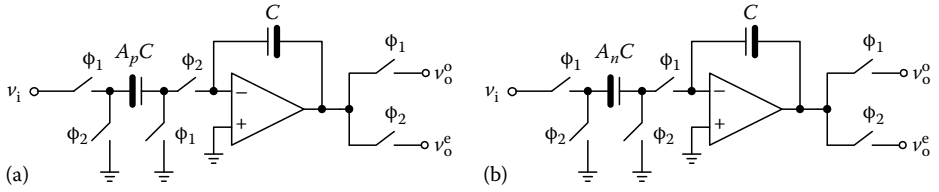

FIGURE 17.4 Conventional stray-insensitive SC integrators. (a) Noninverting and (b) inverting.

For the noninverting integrator the following transfer functions are often used

$$H^{oo}(z) = \frac{V_o^o(z)}{V_{in}^o(z)} = \frac{A_p z^{-1}}{1 - z^{-1}} = \frac{A_p}{z - 1} \tag{17.4a}$$

$$H^{oe}(z) = \frac{V_o^e(z)}{V_{in}^o(z)} = \frac{A_p z^{-1/2}}{1 - z^{-1}} = \frac{A_p z^{1/2}}{z - 1} \tag{17.4b}$$

where H^{xy} stands for the output defined at phase x while the input is sampled during phase y. For the inverting integrator

$$H^{oe}(z) = \frac{V_o^o(z)}{V_{in}^o(z)} = -\frac{A_n}{1 - z^{-1}} = -\frac{A_n z}{z - 1} \tag{17.5a}$$

$$H^{oe}(z) = \frac{V_o^e(z)}{V_{in}^o(z)} = -\frac{A_n z^{-1/2}}{1 - z^{-1}} = -\frac{A_n z^{1/2}}{z - 1} \tag{17.5b}$$

where z^{-1} represents a unit delay. A crude demonstration showing the integration nature of these SC integrators [1,8] in the s-domain is to consider high-sampling rate, that is, a clock frequency ($f_c = 1/T$) much higher than the operating signal frequencies. Let us consider Equation 17.4a, and assuming high-sampling rate ($\omega T \ll 1$) we can write a mapping from the z- to the s-domain:

$$z = e^{j2\pi fT} = e^{sT} \cong 1 + sT \tag{17.6}$$

$$H(s) = \frac{A_p}{z - 1}\bigg|_{z \cong 1 + sT} \cong \frac{1}{(T/A_p)s} \tag{17.7}$$

where s ($=j2\pi f$) is the complex frequency variable. This last expression corresponds to a continuous-time noninverting integrator with a time constant of $T/A_p = 1/f_c A_p$, that is, a capacitance ratio times the clock period.

In many applications the capacitor ratios associated with the integrators are very large, thus the total capacitance becomes excessive. This is particularly critical for biquadratic filters with high Q, where the ratio between the largest and smallest capacitance is proportional to the quality factor Q. A suitable inverting SC integrator for high-Q applications [11,13] is shown in Figure 17.5; the corresponding transfer function during ϕ_2 is

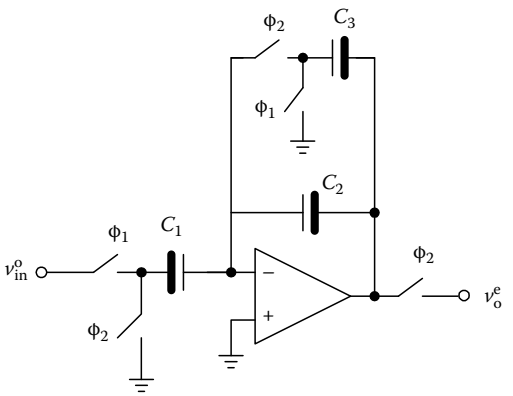

FIGURE 17.5 A SC integrator with reduced capacitance spread.

$$H^{oe}(z) = \frac{V_o^e(z)}{V_{in}^o(z)} = -\frac{C_1 C_3}{C_2(C_2 + C_3)}\left(\frac{z^{-1/2}}{1 - z^{-1}}\right) \tag{17.8}$$

This integrator is comparable in performance to the conventional of Figure 17.3, in terms of stray sensitivity and finite gain error. Note from Equation 17.8 that the transfer function is only defined during ϕ_2. During ϕ_1, the circuit behaves as a voltage amplifier plus the initial conditions of the previous clock phase, and in the following clock phase the same

amount of charge is extracted but the integrating capacitor is reduced due to the switches connected to C_1, thus relatively high-slew-rate op-amps could be required. A serious drawback could be the increased offset in comparison with the standard SC integrators. However, in typical two integrator loop filters, the other integrator can be chosen to be offset and low dc gain compensated as shown in Figure 17.6.

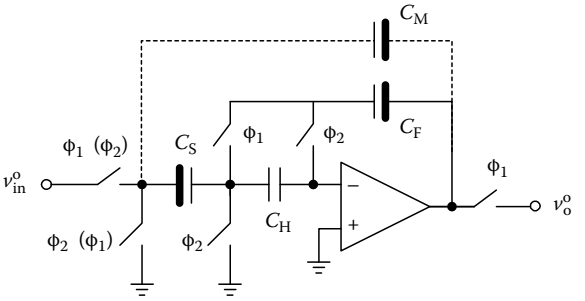

FIGURE 17.6 Offset and gain compensated integrator.

The SC integrator performs the integration during ϕ_1 by means of C_S and C_F and the hold capacitor C_H stores the offset voltage. The voltage across C_H compensates the offset voltage and the dc gain error of the op-amp. Note that the SC integrator of Figure 17.6 can operate as a noninverting integrator if the clocking in parenthesis is employed. C_M provides a time-continuous feedback around the op-amp. The transfer function for infinite op-amp gain is

$$H^{oo}(z) = \frac{V_o^o(z)}{V_{in}^o(z)} = -\frac{C_S}{C_F}\left(\frac{1}{1-z^{-1}}\right) \tag{17.9}$$

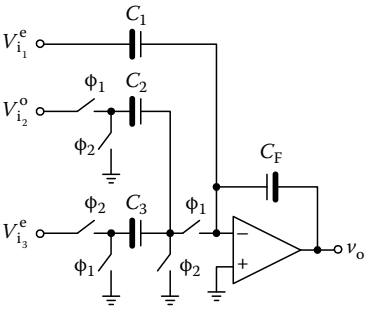

FIGURE 17.7 General form of a first-order building block.

Next we discuss a general form of a first-order building block (see Figure 17.7). Observe that some switches can be shared. The output voltage during ϕ_1 can be expressed as

$$V_o^o = -\frac{C_1}{C_F}V_{i_1}^e - \frac{C_2}{C_F}\left(\frac{1}{1-z^{-1}}\right)V_{i_2}^o + \frac{C_3}{C_F}\left(\frac{z^{-1/2}}{1-z^{-1}}\right)V_{i_3}^e \tag{17.10}$$

Observe that the capacitor C_3 and switches can be considered as the implementation of a negative resistor leading to a noninverting amplifier. Also note that $V_{i_2}^o$ could be V_o^e, this connection would make the integrator a lossy one. In that case Equation 17.10 can be written as

$$V_o^o\frac{\left(1+\frac{C_2}{C_F}\right)z-1}{z-1} = -\frac{C_1}{C_F}V_{i_1}^e + \frac{C_3}{C_F}\frac{z^{1/2}}{z-1}V_{i_3}^e, \quad \text{for } V_{i_2}^o = V_o^o \tag{17.11}$$

The building block of Figure 17.7 is the basis of higher order filters.

17.2.3 Switched-Capacitor Biquadratic Sections

The circuit shown in Figure 17.8 can implement any pair of poles and zeros in the z-domain. For $C_A = C_B = 1$ we can write

$$H^{ee}(z) = \frac{V_o^e(z)}{V_{in}^e(z)} = -\frac{(C_5+C_6)z^2 + (C_1C_2 - C_5 - 2C_6)z + C_6}{z^2 + (C_2C_3 + C_2C_4 - 2)z + (1 - C_2C_4)} \tag{17.12}$$

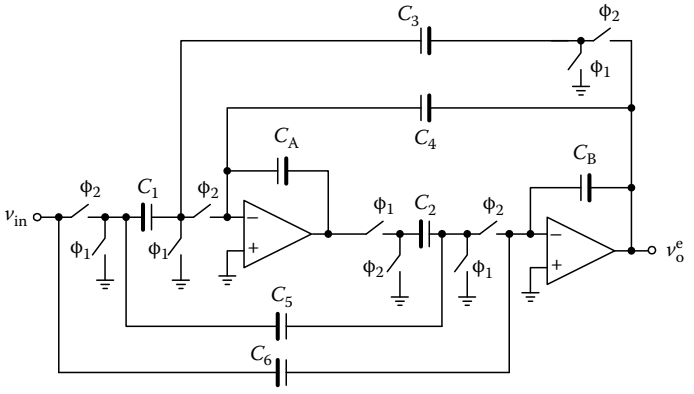

FIGURE 17.8 A SC biquadratic section [Martin-Sedra].

Simple design equations for a particular type of filter follows:

$$\text{Low-pass case: } C_5 = C_6 = 0 \tag{17.13a}$$

$$\text{High-pass case: } C_1 = C_5 = 0 \tag{17.13b}$$

$$\text{Bandpass case: } C_1 = C_6 = 0 \tag{17.13c}$$

Comparing the coefficients of the denominator of Equation 17.12 with the general z-domain expression $z^2 - (2r\cos\theta)z + r^2$ of a second-order system, we can obtain the following expressions:

$$C_2C_4 = 1 - r^2 \tag{17.14a}$$

$$C_2C_3 = 1 - 2r\cos\theta + r^2 \tag{17.14b}$$

Note that in this expression it has been assumed that the filter poles are complex conjugate located at $z = re^{\pm j\omega_{od}T}$. ω_{od} and Q are the poles frequency and the filter's quality factor, respectively. For equal voltage levels at the two integrator outputs, and assuming Q greater than 3, and high-sampling rate ($\theta = \omega_{od}T \ll 1$) we can write

$$C_2 = C_3 = \sqrt{1 + r^2 - 2r\cos\theta} \cong \sqrt{(1-r)^2 + r\theta^2} \cong \theta = \omega_{od}T \tag{17.14c}$$

$$C_4 = \frac{1 - r^2}{C_2} \cong \frac{1}{Q} \tag{17.14d}$$

where $\cos(\theta) \cong 1 - \theta^2/2$ and $r \cong 1$. The capacitance spread for high-sampling rate and high-Q unity DC gain low-pass filter can be expressed as

$$\frac{C_{max}}{C_{min}} = \max\left\{\frac{1}{C_2}, \frac{1}{C_4}\right\} = \max\left\{\frac{1}{\omega_{od}T}, Q\right\} \tag{17.15}$$

In some particular cases this capacitance spread becomes prohibited large. For such cases the SC integrators shown in Figures 17.5 and 17.6 can be used to replace the conventional building blocks.

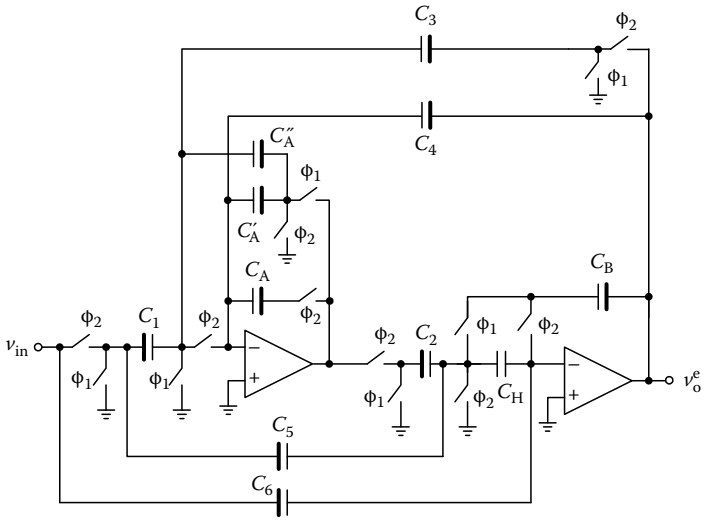

FIGURE 17.9 An improved capacitance area SC biquadratic section.

This combination yields the SC biquadratic section shown in Figure 17.9. This structure, besides offering a reduction of the total capacitance, also yields a reduction of the offset voltage of the op-amps. Note that the capacitors C_H does not play an important role in the design, and can be chosen to have a small value. The design equations for the zeros are similar to Equation 17.13a through c. For the poles, comparing with $z^2 - (2r\cos\theta)z + r^2$ and the analysis of Figure 17.9, we can write

$$\frac{C_2 C_3}{C_A + C_B} = 1 + r^2 - 2r\cos\theta \tag{17.16a}$$

$$\frac{C'_A C_2 C_4}{C_{A_1} C_A C_B} = 1 - r^2 \tag{17.16b}$$

where $C_{A1} = C'_A + C''_A$. Simple design equations can be obtained assuming high-sampling rate, large Q, and $C_2 = C_3 = C_4 = C'_A = C_h = 1$; then

$$C_A + C_B \cong \frac{1}{\omega_{od} T} \tag{17.17a}$$

$$C''_A \cong Q\omega_{od} T - 1 \tag{17.17b}$$

Another common situation is the use of SC filters at high frequencies; in such cases a structure with minimum gain-bandwidth product ($GB = \omega_u$) requirements is desirable. This structure is shown in Figure 17.10 and is often referred to as a decoupled structure. It is worthwhile to mention that two SC architectures can have ideally the same transfer function; however, with real op-amps their frequency (and time) response differs significantly. A rule of thumb to reduce the GB effects in SC filters is to minimize the direct connections between the output of one op-amp to the input of another op-amp. It is desirable to transfer the output of an op-amp to a grounded capacitor, and in the next clock phase, transfer the capacitor charge into the op-amp input. If required, the connection to the next op-amp has to be done during the hold phase of the previous op-amp. If the connection is done during the charge

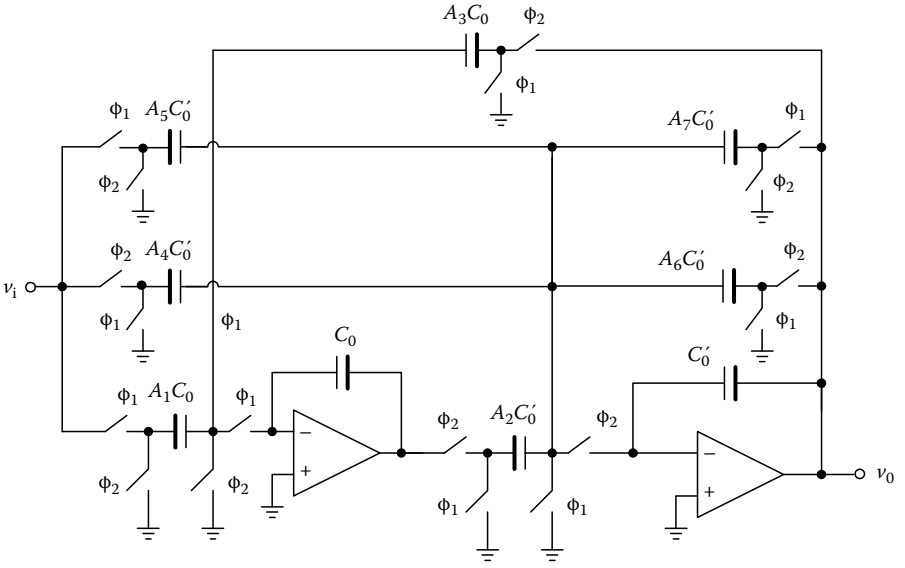

FIGURE 17.10 A decoupled SC biquadratic section.

injection phase, the output of the first integrator is a ramp (step response of the integrator), and the settling time for the next integrator increases further. More discussion on ω_u effects is given in Section 17.3.

If the input signal is sampled during ϕ_2 and held during ϕ_1, the ideal transfer function is given by

$$H^{ee}(z) = \frac{V_o^e(z)}{V_i^e(z)} = -\left(\frac{A_4}{1+A_6}\right)\left(\frac{z^2 - z\left(\frac{A_4+A_5-A_1A_2}{A_4}\right) + \frac{A_5}{A_4}}{z^2 - z\left(\frac{2+A_6+A_7-A_2A_3}{1+A_6}\right) + \frac{1+A_7}{1+A_6}}\right) \tag{17.18}$$

Analysis of this equation yields the following expressions:

$$r^2 = \frac{1+A_7}{1+A_6} \tag{17.19a}$$

$$2r\cos\theta = \frac{2+A_6+A_7-A_2A_3}{1+A_6} \tag{17.19b}$$

The capacitor A_7C_0' can be used as a design trade-off parameter to optimize the biquad performance. A simple set of design equations follows:

$$A_6 = \frac{(1+A_7)-r^2}{r^2} \tag{17.20a}$$

$$A_2 = A_3 = (1+A_7)\sqrt{\frac{1+r^2-2r\cos\theta}{r^2}} \tag{17.20b}$$

Under high-sampling rate and high-Q conditions, the following expressions can be obtained:

$$\omega_o \cong f_c\sqrt{\frac{A_2A_3}{1+A_6}} \tag{17.21a}$$

and

$$Q \cong \sqrt{\frac{A_2 A_3 (1 + A_6)}{A_6 - A_7}} \tag{17.21b}$$

A trade-off between Q-sensitivity and total capacitance is given by A_6 and A_7.

17.3 Effects of the Op-Amp Finite Parameters

17.3.1 Finite Op-Amp DC Gain Effects

The effect of finite op-amp dc voltage gain A_o in a lossless SC integrator is to transform a lossless integrator into a lossy one. This brings degradation in the transfer function both in magnitude and phase. Typically, the magnitude deviation due to the integrator amplitude variation is not critical. By contrast, the phase deviation from the ideal integrator has a very important influence on the overall performance. When the real SC integrators are used to build a two-integrator biquadratic filter, it can be proved that the actual quality factor becomes

$$Q_A = \frac{1}{\frac{1}{Q} + \frac{2}{A_o}} \cong \left(1 - \frac{2Q}{A_o}\right) Q \tag{17.22}$$

where Q and A_0 are the desired filter's quality factor and op-amp dc gain, respectively. The actual frequency of the poles suffers small deviations as well

$$\omega_{o_A} = \frac{A_o}{1 + A_o} \omega_o \tag{17.23}$$

From this equation we can conclude that the ω_o deviations are negligible if $A_o > 100$. However, the Q deviations can be significant depending on the Q and A_o values, e.g., Q_{error} is given by $-2Q/A_o$, which is more critical for high-Q applications.

17.3.2 Finite Op-Amp Gain-Bandwidth Product Effects

The op-amp bandwidth is very critical for high-frequency applications. The analysis is carried out when the op-amp voltage gain is modeled with one dominant pole, i.e.,

$$A_v(s) = \frac{A_o}{1 + s/\omega_p} = \frac{A_o \omega_p}{s + \omega_p} = \frac{\omega_u}{s + \omega_p} \cong \frac{\omega_u}{s} \tag{17.24}$$

where

A_o is the dc gain
ω_u is approximately the unity-gain bandwidth (GB)
ω_p is the op-amp bandwidth

The analysis taking into account $A_v(s)$ is rather cumbersome since the op-amp input–output characterization is a continuous-time system modeled by a first-order differential equation, and the rest of the SC circuit is characterized by discrete-time systems modeled by difference equations. It can be shown that the step response of a single SC circuit with an op-amp gain modeled by Equation 17.24 due to step inputs applied at $t = t_1$ is

$$V_o(t - t_1) = V_o(t_1) e^{-(t-t_1)\alpha\omega_u} + V_{od}\{1 - e^{-(t-t_1)\alpha\omega_u}\} \tag{17.25}$$

where

$V_o(t_1)$ and V_{od} are the initial and the final output voltages, respectively

α is a topology dependent voltage divider, $0 < \alpha \leq 1$, given by the following expression:

$$\alpha = \frac{\sum C_f}{\sum_i C_i} \tag{17.26}$$

where

C_f sum consists of all feedback capacitors connected directly between the op-amp output and the inverting input terminal

C_i sum comprises the capacitors connected to the negative op-amp terminal

Note that $\alpha\omega_u$ should be maximized for fast settling time. For the common case the SC circuit is driven by 50% duty cycle clock phases, the integrating time is close to $T/2$, hence the figure of merit to be maximized is $\alpha T\omega_u/2$. The output voltage will settle to its final value within an error of 0.67% after five equivalent time constants, hence a rule of thumb yielding reduced GB product effects requires

$$\frac{\alpha T\omega_u}{2} > 5 \tag{17.27a}$$

or

$$f_u > \frac{1.6}{\alpha} f_s \tag{17.27b}$$

For the multiple op-amp case the basic concept prevails. For a two-clock phase SC filters the system can be described by an $\mathbf{M} \times \mathbf{M}$ matrix $\mathbf{A}$ for each clock-phase, where $\mathbf{M}$ is the number of op-amps in the filter architecture. For a fixed clock frequency, $f_c = 1/T$, there are two components to be optimized: α and ω_u. effects biquadratic SC filter presented in the previous section (Figure 17.10) has the property that matrix $\mathbf{A}$ has been optimized. For illustration on how to determine the $\mathbf{A}$ matrix of an SC filter, let us consider the filter depicted in Figure 17.10; for each clock phases matrix $\mathbf{A}$ is given by

$$\mathbf{A}|_{\varphi_1} = \begin{bmatrix} \frac{1}{1+A_1+A_3} & 0 \\ 0 & 1 \end{bmatrix} \tag{17.28}$$

$$\mathbf{A}|_{\varphi_2} = \begin{bmatrix} 1 & \frac{A_2}{1+A_2+A_4+A_5+A_6+A_7} \\ 0 & \frac{1+A_8}{1+A_2+A_4+A_5+A_6+A_7} \end{bmatrix} \tag{17.29}$$

Thus, the designer should use the extra degrees of freedom to maximize the diagonal entries of $\mathbf{A}$ during all phases. Thus, the worst case for any entry of $\mathbf{A}$ determines the minimum value of ω. Another design consideration could be to maximize ω_u. This last consideration should be carefully addressed since very large ω_u values besides extra power consumption can cause excessive phase margin degradation or excessive noise if the capacitors are reduced. Therefore, a judiciously trade-off must be used in choosing the ω_u of each op-amp in the filter topology.

17.4 Noise and Clock Feedthrough

The lower range of signals that can be processed by the electronic devices is limited by several unwanted signals that appear at the output of the circuit. The RMS values of these electrical signals determine the

system noise level, and it represents the lowest limit for the incoming signals to be processed. In most of the cases the circuit cannot properly detect input signals smaller than the noise level.

The most critical noise sources are those due to (1) the employed elements (transistors, diodes, resistors, etc); (2) the noise induced by the clocks; (3) the harmonic distortion components generated due to the intrinsic nonlinear characteristics of the devices; and (4) the noise induced by the surrounding circuitry. In this section, types (1), (2), and (3) are considered. Using fully differential structures can further reduce the noise generated by the surrounding circuitry and coupled to the output of the SC circuit. These structures are partially treated in Section 17.5 but excellent references can be found in the literature [2,4,6,9,13].

17.4.1 Noise due to the Op-Amp

In an MOS transistor, the noise is generated by different mechanisms but there are two dominant noise sources: channel thermal noise and $1/f$ or flicker noise. A discussion of the nature of these noise sources follows.

17.4.2 Thermal Noise

The flow of the carriers due to the drain-source voltage takes places on the source-drain channel, mostly like in a typical resistor. Therefore, due to the random flow of the carriers, thermal noise is generated. For an MOS transistor biased in the linear region the spectral density of the thermal noise is approximately given by [1–4,12]

$$V_{\text{eqth}}^2 = 4kTR_{\text{on}} \tag{17.30}$$

where R_{on}, k, and T are the drain-source resistance of the transistor, the Boltzmann constant, and the temperature (in Kelvin degrees), respectively. In saturation region, the gate-referred spectral noise density can be calculated by the same expression but with R_{on} equal to δ/g_{m}, being g_{m} the small-signal transconductance of the transistor and δ a fitting parameter usually in the range of 0.7–1.

17.4.3 $1/f$ Noise

This type of noise is mainly due to the imperfections in the silicon–silicon oxide interface. The surface states and the traps in this interface randomly interfere with the charges flowing through the channel; hence the generated noise is strongly dependent of the technology. The $1/f$ noise (or flicker noise) is inversely proportional to the gate area because at larger areas more traps and surface states are present and some averaging occurs. The spectral density of the gate referred $1/f$ noise is commonly characterized as

$$V_{\text{eq}1/f}^2 = \frac{k_{\text{F}}}{WLf} \tag{17.31}$$

where the product WL, f, and k_{F} are the gate area of the transistor, the frequency in hertz, and the flicker constant, respectively. The spectral noise density of the MOS transistor is composed by both components, therefore the input referred spectral noise density of a transistor operated in its saturation region becomes

$$V_{\text{eq}}^2 = \frac{4\delta kT}{g_{\text{m}}} + \frac{k_{\text{F}}}{WLf} \tag{17.32}$$

17.4.4 Op-Amp Noise Contributions

In an op-amp, the output referred noise density is composed by the noise contribution of all transistors; hence the noise level is function of the op-amp architecture. A typical unbuffered folded cascode op-amp (folded cascode OTA) is shown in Figure 17.11. For the computation of the noise level, the contribution of each transistor has to be evaluated. Obtaining the OTA output current generated by the gate-referred noise of all the transistors can do this. For instance, the spectral density of the output-referred noise current due to M_1 is straightforwardly determined because the gate-referred noise is at the input of the OTA, leading to

$$i_{01}^2 = G_m^2 V_{eq1}^2 \tag{17.33}$$

where

G_m (equal to g_{m1} at low frequencies) is the OTA transconductance
V_{eq1}^2 is the input (gate) referred noise density of M_1

Similarly, the contributions of M_2 and M_5 to the spectral density of the output referred noise current are given by

$$\begin{aligned} i_{o2}^2 &= g_{m2}^2 v_{eq2}^2 \\ i_{o5}^2 &= g_{m5}^2 v_{eq5}^2 \end{aligned} \tag{17.34}$$

Usually the noise contributions of transistors M_3 and M_4 at medium frequencies are very small in comparison to the other components; this is a nice property of the cascode transistors. This is because their noise drain currents, due to the source degeneration implicit in the cascode transistors, are determined by the equivalent conductance associated with their sources instead of those by their transconductance. Since in a saturated MOS transistor the equivalent conductance is much smaller than the transistor transconductance, this noise drain current contribution can be neglected at low and medium frequencies; this is however not the case at very high frequencies where the parasitic capacitors play an important role. The noise contribution of M_6 is mainly common-mode noise evenly split in the

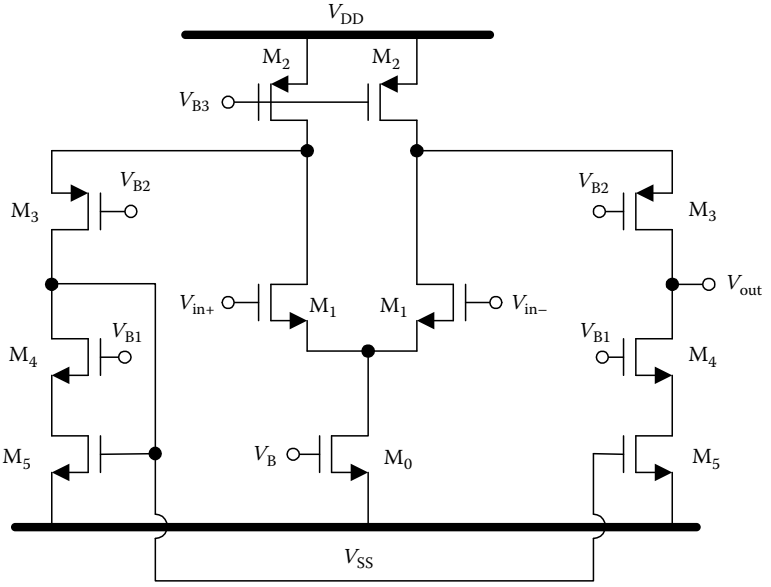

FIGURE 17.11 A folded cascode operational transconductance amplifier.

two arms by transistor M_1, therefore it is ideally canceled at the OTA output due to the current subtraction. At low frequencies, the spectral density of the total output referred noise current can be approximately calculated as

$$i_o^2 = 2\left(g_{m1}^2 V_{eq1}^2 + g_{m2}^2 v_{eq2}^2 + g_{m5}^2 v_{eq5}^2\right) \tag{17.35}$$

The factor 2 is the result of the pair of transistors M_1, M_2, and M_5. From this equation, the OTA input referred noise density is obtained by dividing the output noise current by the square of $G_m = g_{m1}$, yielding

$$v_{OTAin}^2 = 2v_{eq1}^2\left(1 + \frac{g_{m2}^2 v_{eq2}^2 + g_{m5}^2 v_{eq5}^2}{g_{m1}^2 v_{eq1}^2}\right) \tag{17.36}$$

According to this result, if g_{m1} is larger than g_{m2} and g_{m5}, the OTA input referred noise density is mainly determined by the OTA input stage. In that case and using Equation 17.32 and 17.36 yields

$$v_{OTAin}^2 \cong 2v_{eq1}^2 = \frac{2k_F}{W_1 L_1 f} + \frac{8\delta kT}{g_{m1}} = v_{eq/f1}^2 + 4kTR_{eqth} \tag{17.37}$$

where the factor 2 has been included in $v_{eq1/f}$ and R_{eqth}. In Equation 17.37, $v_{eq1/f}^2$ is the equivalent $1/f$ noise density and R_{eqth} is the equivalent resistance for noise, equal to $2\,\delta/g_{m1}$.

17.4.5 Noise in a Switched-Capacitor Integrator
