11.1.3.3 Pyrolytic Carbon Resistor

Carbon deposited in vacuum on a ceramic substrate performs very inexpensively and produces a quite good quality resistive layer. Pyrolytic carbon has graphite structure sp^3; three electrons create bonds and the fourth is a free electron. Surface resistance is 10 Ω/square up to 2 kΩ/square; the nominal resistance value is in range 10 Ω to 10 MΩ; encountered classes are 15, 10, 5, 3 (see Table 11.1); TCR ≡ −200 to −1000 ppm/K. About 50% of the produced resistors are carbon pyrolytic ones.

11.1.3.4 Thick Film Resistor

A thick film resistive layer is prepared from a composition called paste or ink that is a mixture of conducting particles and glass. Conducting particles have a metallic conduction mechanism. By mixing different quantities of both particles, we can obtain a high-range surface resistance of 1 Ω/square to 10 MΩ/square. This means that the nominal resistance range might be 0.5 Ω up to 1 GΩ; classes are 5, 3, 2, 1, 0.5; TCR = ±100 and ±50 ppm/K; in a resistive network, ΔTCR = 3 and 1 ppm/K.

The theory of conduction mechanisms is not well known. Several models of conduction mechanisms are used, but one of them proposed by Pike and Seager is used [9]. Each conductive particle is surrounded by glass. There particles form the chains of metal–insulator–metal (MIM). Electrons are passed through the insulator by tunneling. In the layer of very high resistivity, electrons travel according to the hopping effect [6]. Investigations show that for the very low resistivity layer, chains without glass [6] are formed. The formula for the total resistance of such a chain is as follows:

$$R(T) = R_{\mathrm{M_IM}} + R_{\mathrm{m}} + R_{\mathrm{c}} \tag{11.20}$$

where

$$R_{\mathrm{M_IM}} = \frac{1}{2} R_{\mathrm{bo}} \frac{\sin aT}{aT} \left(1 + \exp \frac{\Delta E}{T}\right) \tag{11.21}$$

$$R_{\mathrm{m}} = R_{\mathrm{mo}}(1 + bT) \tag{11.22}$$

$$R_{\mathrm{c}} = \kappa_3 p_c (T_s - T)^{-\frac{1}{3}} \tag{11.23}$$

where

$R_{\mathrm{M_IM}}$ is the resistance connected by tunneling [4]
R_{bo} is the resistance in $T = 0$
a is the distance between particles
ΔE is the activation energy
k is the Boltzmann constant
R_{m} is the resistance of the conduction particle (the resistivity value is much higher than in bulk material because its diameter is very small (0.5 μm) and grain effect occurs)
R_{mo} is the resistance in $T = 0$ K (obtained by line extrapolation)

b is the TCR of the conducting particle
R_c is the resistance of contact between two particles without glass)
T_s is the temperature of glass melting
k_3 is the constant coefficient

For high resistance, the most important parameter is R_{M_iM}. In that range of resistance, TCR is negative and the surrounding glass layers give large voltage coefficients of resistance, which is shown in Figure 11.30. For low resistance, VCR is negligible, and TCR is positive, which means that R_m and R_c are important while an influence of R_{M_iM} may be neglected.

Equations 11.20 through 11.23 also explain the physical meaning of T_m for curve 3 in Figure 11.4. For the very high resistivity layer, both tunneling and hopping conduction occur. Parameters for this sort of resistor are not particularly good, but only in that technology can we get high-ohmic resistor in the range of 10 MΩ up to 1 GΩ.

11.1.3.5 Polymer Resistor

About 70% of all potentiometers are manufactured as polymer resistor. The resistive layer consists of conductive particle (black carbon, graphite, as well as metal powder) and thermosetting or thermoplastic resin. Also, a polymer layer is used for printing resistors on PC boards or for manufacturing chips in SMT. The layer is deposited by screen printing, painting, or by some other methods. Classes are 20, 15, 10, 5; TCR = −1000 or ±400 ppm/K; surface resistance 50–1 MΩ/square; the nominal resistance range is from 100 Ω to 10 MΩ. Thermoplastic polymer resistors have generated great interest [7] recently. At the softening temperature of a polymer, a strong increase of resistance is observed. TCR ∼ 100%/K; and alter cooling resistance retains a previous value. This phenomenon is applied to the multifuse resistor, whose characteristics are shown in Figure 11.18a and b.

A multifuse is needed for protection of the electronic power circuit against fire. Polymer layers are also used in keyboards as very hard and uncorrodible contact material. For example, that layer contains carbon and copper powder.

11.1.3.6 Comparison of Parameters of Different Resistors—Suggestion for Application

Figures 11.20 and 11.21 present average instability $\overline{\delta}$ of resistors made in four technologies: metal thin film, thick film, pyrolytic carbon, and polymer carbon. An analysis of these figures, as well as Figure 11.19, gives us a clue as to how to choose a resistor for a specific application. For example, we would like to find a resistor of a nominal resistance value of 1 MΩ to operate under high humidity conditions. A thick film resistor would be the best. Taking into consideration the price, a pyrolytic carbon resistor, class 10 or 5, should be chosen. In an operational amplifier application, a thin film resistor or thick film network would be the best choice, although for a small-signal preamplifer considering the small noise level, a thin film resistor would be preferred. Considering our decision, we should pay attention to the results of the following tests: TCR = φ(R), endurance test φ(R) for 1000 h, humidity test, 21 days: δ = φ(R).

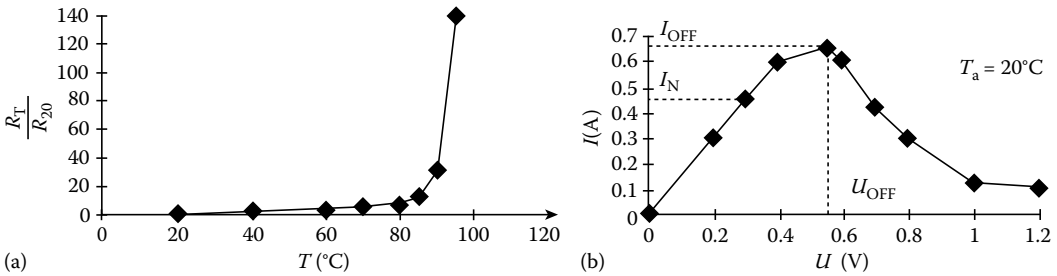

FIGURE 11.18 Characteristics of multifuse resistor. (a) Normalized resistance vs. ambient temperature and (b) current vs. voltage V_{off}—voltage above which current decreases.

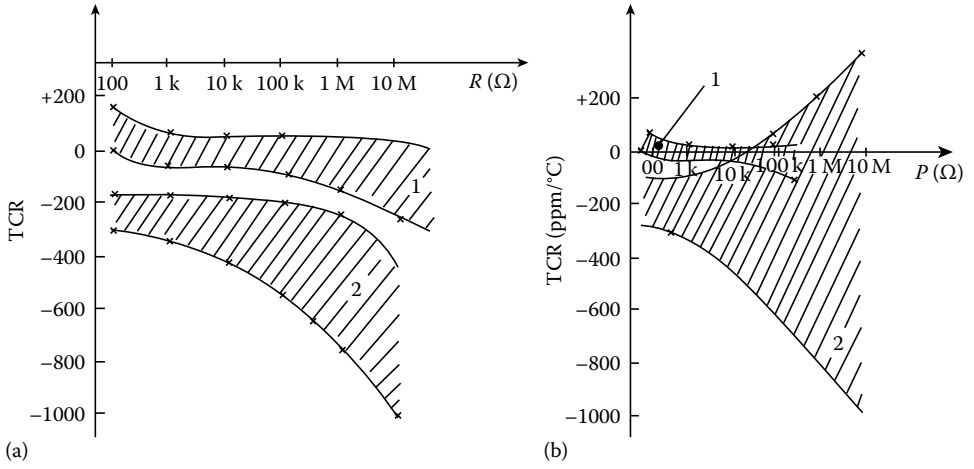

FIGURE 11.19 TCR dependence on nominal resistance value. (a) 1—thick film ruthenium-based resistors, 2—pyrolytic carbon resistors and (b) 1—thin film metal alloy resistors, 2—polymer carbon resistors. The envelope of the TCR range is calculated statistically at ±1.64 * s.

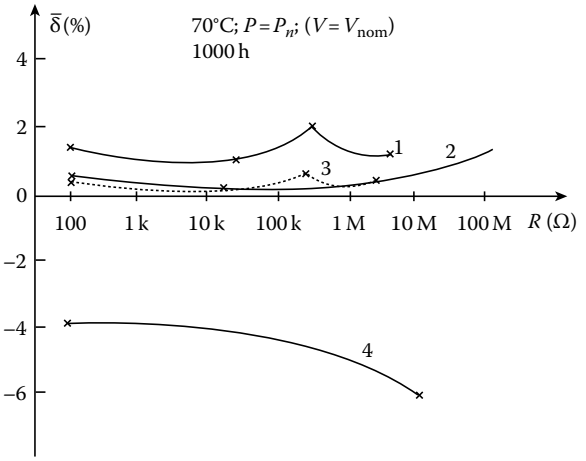

FIGURE 11.20 The average change $\bar{\delta}$ after 1000 h endurance test in relation to a nominal resistance value for different types of resistors. 1—pyrolytic carbon, 2—thick film ruthenium-based resistor, 3—thin film metal alloy, 4—polymer carbon. For the range 100 Ω–240 kΩ $P = P_n$, above 240 kΩ $P < P_n$ and $V = V_{max}$.

11.1.3.7 Influence of Ceramic Substrate on Parameters of Resistor

All resistive films are deposited on the ceramic substrate. Only polymer film can be put on the fenolic paper or on the epoxy resin substrate. Thick film, pyrolytic carbon, and metal alloy film are also deposited on the ceramic. Some of thin films may be deposited on the glass. It is observed that substrate affects the resistive layer in two ways as follows:

1. When ion current related to alkali metals in substrate flows. Its destructive effect is shown in Figure 11.22, where some pyrolytic carbon layers manufactured by the same technology were deposited on the three types of ceramic substrates. The densities of the ion current were 56, 7, and 0.5 μA/mm^2. The results of long-life stability changes for resistors deposited on various substrates differ greatly from each other. This effect is observed only at dc voltages and at high temperatures. The smaller thickness of a layer and the destructive effect of ion current are more remarkable.

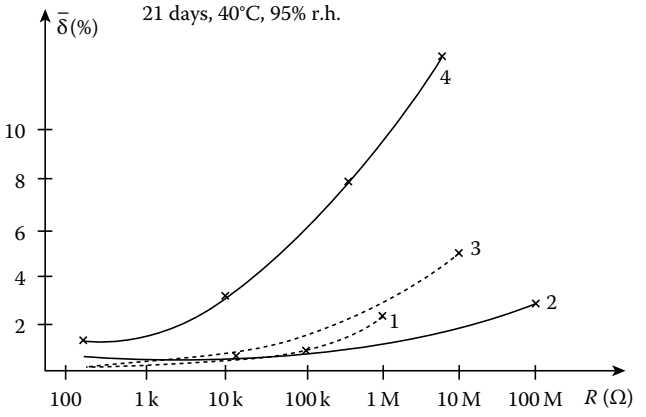

FIGURE 11.21 The average change δ after 21-day humidity test dependence on the nominal resistance value of different types resistors. 1—thin film metal alloy, 2—thick film ruthenium-based resistor, 3—pyrolytic carbon, 4—polymer carbon.

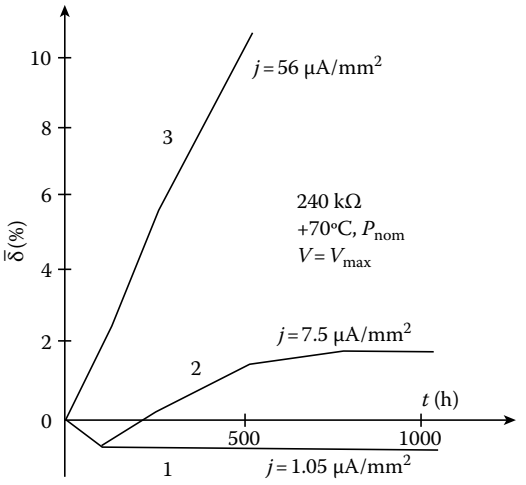

FIGURE 11.22 Influence of ion current density j on resistor stability $\bar{\delta}$ versus time during endurance test. $R = 240$ kΩ (critical nominal resistance value); j is measured according to GOST 10449-63, that is, 400°C and 400 V; distance of cut layer 0.5 mm.

During long-life tests at high temperatures, this phenomenon can also be observed for high-ohmic wirewound resistors [1].

2. When the thermal expansion coefficient of a layer and substrate are much different, thermal dilatability becomes a large problem and results in plus or minus changes of TCR [1]. Encapsulation of resistors with lacquer, cement, and transfer molding cover causes similar problems.

11.1.4 Dependence on Geometry of Material

The geometry of a resistive element affects either its high-frequency characteristic or its maximum temperature.

11.1.4.1 Influence of Resistive Element Shape on the Frequency Range

A wirebound resistor has many advantages but its inductance is very high. In Figure 11.23, different ways of resistive wire winding are presented in order to decrease parasitic inductance. A special wirewound resistor can work up to 200 kHz. For higher frequencies, a thin film resistor must be used. Though a film resistor can work at high frequencies up to 1 GHz, some limitations occur in this area (see Figure 11.24). For resistors of a low resistance value, that limitation is inductance of resistive elements and terminations. For resistors of a resistance above 10 kΩ, distributed capacitance is the main problem.

Figure 11.25 presents the part of thin film layer deposited on a cylindrical ceramic substrate. To get many more squares, cutting along the screw line is performed. Each step of the screw wind (Figure 11.27a) gives some elementary resistance R_r and elementary parasitic capacitance C_r. The maximum operating frequently f_m is given by Equation 11.24 as

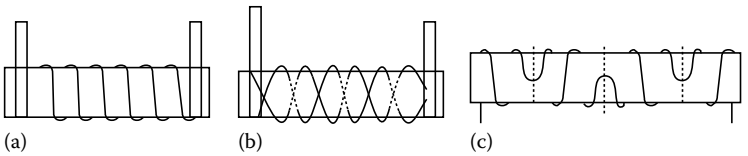

FIGURE 11.23 Different means of wire winding in wirewound resistors: (a) flat; (b) cross; and (c) bifilar.

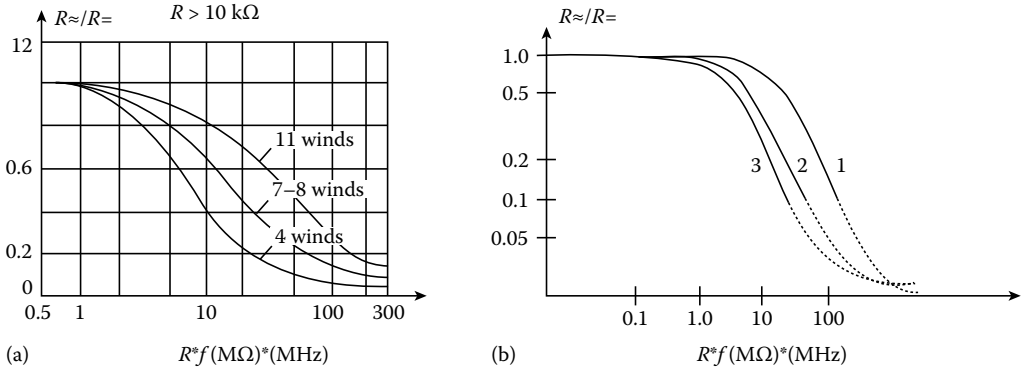

FIGURE 11.24 Dependence of $R_{\sim}/R_{=}$ on the product of nominal resistance value and frequency. (a) Pyrolytic carbon resistors, 0.25 W, cut according to screw line; different curves present resistors with different winds of cutting and (b) 1—thin film, 2—pyrolytic carbon, 3—thick film ruthenium-based resistor. (From Nowak, S., Wenta, A., and Kuzma, E., *Handbuch der Elektronik*, Vol. 2 and Ambroziak, A. et al., Vol. 7, Franzis-Verlag, Munich, 1979. With permission.)

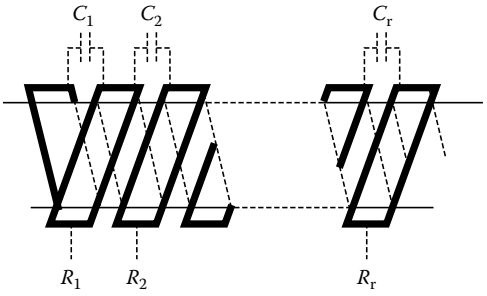

FIGURE 11.25 Part of a film resistor cut according to the screw line; R_r—elementary resistance, C_r—elementary capacitance.

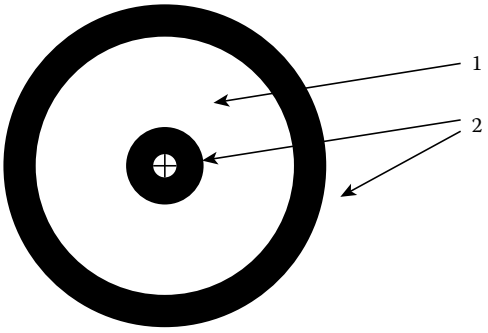

FIGURE 11.26 Coaxial resistor: 1—resistive layer, 2—electrode layer.

$$2\pi f_m = \frac{1}{R_r C_r} \tag{11.24}$$

where C_r is bigger when the thickness of the layer is greater and the groove becomes narrower, but also when ε_r of the insulating cover is high; R_r is smaller when Ω/square is lower.

This information suggests how to choose a resistor for high frequency. It is seen that a thin film with a low Ω/square is recommended. To reduce the termination capacitance for coaxial lines or cables, coaxial resistors are used (see Figure 11.26), which can work up to 20 GHz. For high-frequency applications,

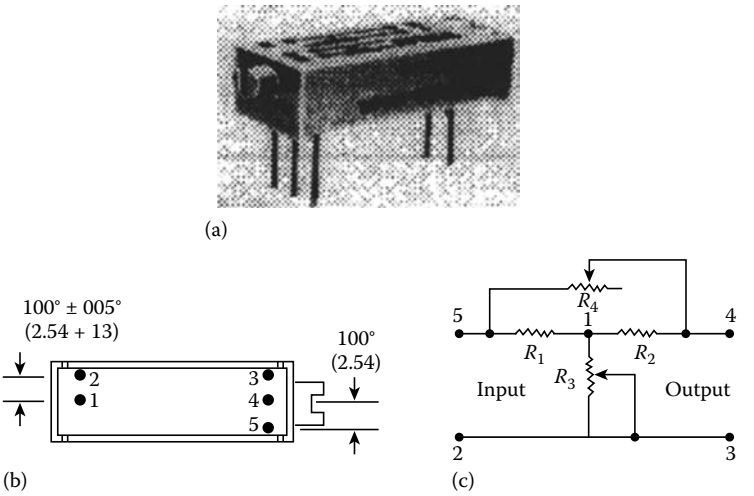

FIGURE 11.27 High-frequency attenuator: (a) overview; (b) pin localization; and (c) electrical circuit. (From *Philips Components Catalogue*, Eindhoven, 1989. With permission.)

special shapes of resistors have been designed (Figure 11.7). Strip resistors are connected to a microwave strip line. A special potentiometer of 75 Ω input and 75 Ω output works up to 1 GHz. This potentiometer has fluent regulation of the attenuation obtained by specific shapes of three resistive elements inside the potentiometer, which, in turn, are regulated by one appropriately shaped slider (a similar attenuator for 300 MHz is shown in Figure 11.27).

11.1.4.2 Sensitivity Improvement of Precision Potentiometer by Complication of Shape

In Figure 11.10, how a helipot works is explained. The wiper makes a rotation of 3600° and the precision is about 0.01%. The range of resistance is 100 Ω to 100 kΩ. The producers are Beckman, Bourns, and others.

11.1.4.3 Influence of Resistor Shape on Its Application

The typical requirement for resistor construction is to establish a uniform temperature on the entire surface of the resistive element. This problem does not appear in the designing of a fail-safe resistor. The fail-safe resistor is shown in Figure 11.28.

At the center of the resistive layer a narrow resistive path is placed [6]. Under normal working conditions, the resistance of the circuit is stable. When a defect occurs in the circuit, the current doubles or triples in path and breaks the fail-safe resistor. This is important in protection against fire and

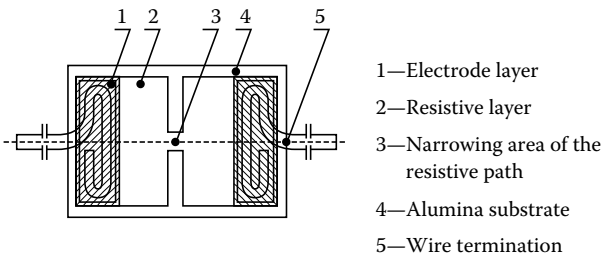

FIGURE 11.28 Fail-safe resistor.

avalanche devastation of the electronic set. The resistors utilizing the piezoresistive effect for pressure detection are also specially shaped.

11.1.5 Nonideal Linear Resistor

The main features of the nonideal resistor is its instability in time, which is described in the introduction to the section on resistors and instability related to temperature, presented in Sections 11.1.1.1 and 11.1.3.1. Catastrophic failure rate is estimated: for thin film resistors on the level of 10^{-9}/h, for thick film resistors on the level of 10^{-10}/h. Noise is also an important feature of the nonideal linear resistor.

11.1.5.1 Noise

Total noise is the sum of a number of factors, summarized as follows:

Thermal noise called Johnson noise or white noise: The value of thermal noise can be calculated from Equation 11.25:

$$V_{t\text{rms}} = \sqrt{4kRT\Delta f} \tag{11.25}$$

where

$V_{t\text{rms}}$ is the root-mean-square value of the noise voltage (V)
R is the resistance value (Ω)
k is the Boltzmann constant (1.38×10^{-23} J/K)
T is the temperature (K)
Δf is the frequency bandwidth (Hz) over which the noise energy is measured

The spectral density of thermal noise is constant in the total frequency bandwidth (white noise). Total noise is the sum of $V_{t\text{rms}}$ and current noise $V_{i\text{rms}}$:

$$V_{\text{rms}} = V_{t\text{rms}} + V_{i\text{rms}} \tag{11.26}$$

Current noise or structural noise: When dc voltage is applied to the resistor, dc current causes ac voltage fluctuation. That ac voltage fluctuation depends on the structure of the resistive element and an applied voltage. Density of that noise can be described by Equation 11.27:

$$\frac{V_{i\text{rms}}}{\Delta f} = cf^{-\gamma}V_{=}^{\alpha} \tag{11.27}$$

where

c, γ, and α are the constants
$V_{=}$ is the applied dc voltage
Δf is the frequency bandwidth

$\gamma = 0.98$–1.2; very often $\gamma = 1$ and this kind of noise is called "$1/f$ noise"; $\alpha = 1$–2 and depends on the structure of the resistive element.

$V_{i\text{rms}}$ is measured in μ V/V or in dB, where 0 dB = 1 μ V/V. For foil and wirewound resistors, $V_{i\text{rms}} = 0$ and this means that only thermal noise occurs there. Figure 11.29 illustrates simplified characteristics of current noise for different types of film resistors.

11.1.5.2 Voltage Coefficient of Resistance

A linear resistor can exhibit some deviations from Ohm's law (Equation 11.1). This nonlinearity, called the voltage coefficient of resistance (VCR), is measured in %/V and is calculated from Equation 11.28:

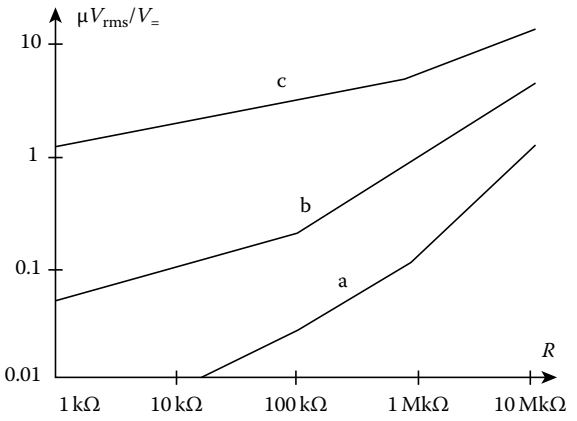

FIGURE 11.29 Simplified current noise characteristics versus nominal resistance value for different types of resistors: (a) thin film; (b) pyrolytic carbon; and (c) ruthenium-based thick film.

$$\text{VCR} = \frac{R_1 - R_2}{R_2(V_1 - V_2)} \times 100 \ [\%/V] \tag{11.28}$$

where

R_1 is the resistance at the rated voltage V_1

R_2 is the resistance at 10% of the rated voltage V_2

Metal alloy film resistors and pyrolytic resistors show a negligible small voltage coefficient but polymer resistors and thick film resistors have a remarkable one. In Figure 11.30, normalized R/R_{10} versus voltage stress for the ruthenium-based thick film resistors are presented, where R_{10} is resistance measured at stress 10 V/mm. Results are collected for low stress voltage in Figure 11.30a and for high stress voltage in Figure 11.30b.

It can be observed that for a resistor made of a low-resistivity ink up to 100 KΩ/square, VCR is small, but for inks of high resistance/square (e.g., 500 MΩ/square), VCR is large [6]. VCR depends on the ink producer, as well (see R310 in Figure 11.30b).

11.1.5.3 Rotational Noise and Contact Resistance Variation

When a potentiometer is supplied by dc voltage and its wiper is moving from the beginning to the end of resistive layer, some ac voltage appears on the output. It is noise, which is measured in $\text{mV/V}_{=}$. The IEC standard requires that for a quality potentiometer this noise has to be smaller than 2 $\text{mV/V}_{=}$. The CRV is important when the resistor works in series with the load or in a very sensitive instrument. This parameter is measured in percentage of total resistance (1% is a typical value). CRV and rotational noise decrease if a multipoint wiper is used in potentiometers, for example, a wiper made from 20 wires. That parameter is also important in the construction of a precision wirewound potentiometer where CRV must be smaller than 1%. The proper choice of materials for the slider and resistive wire is the best way to solve this problem.

11.1.5.4 Smoothness of Regulation Curve of Potentiometer

Exponential curve: In practice, an exponential resistive element consists of two or three linear segments of resistance. As a result, the line is not smooth but has some steps. Rotary noise also increases in that

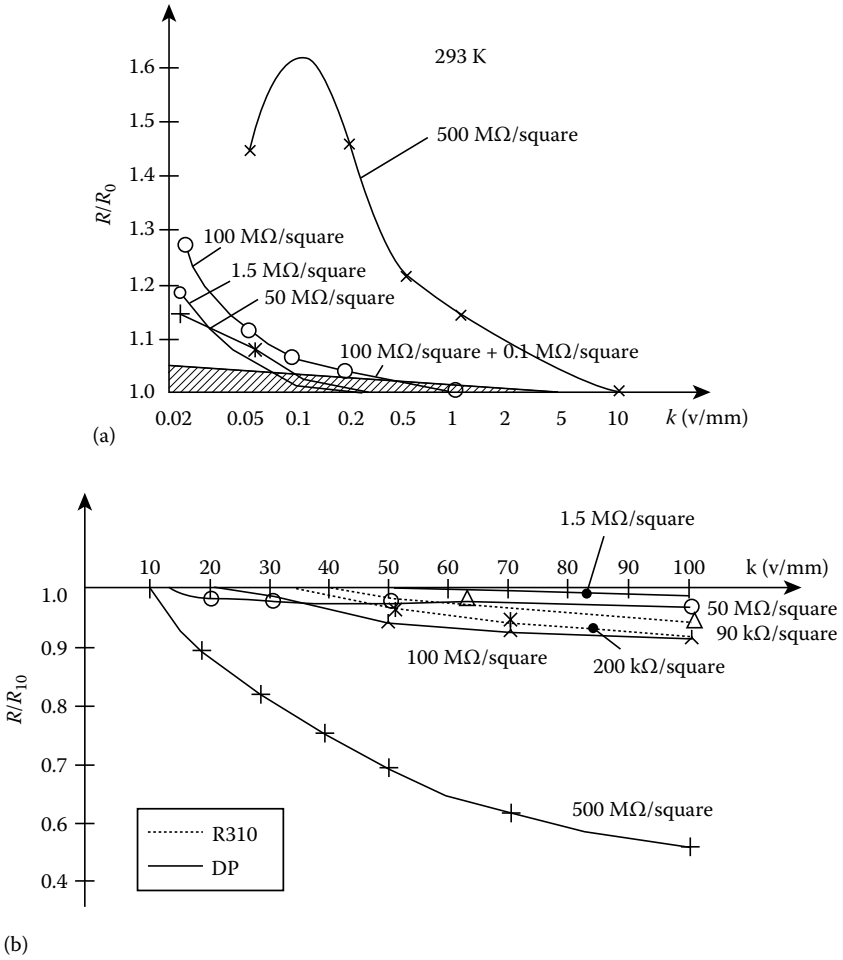

FIGURE 11.30 The change of resistance versus stress voltage for thick film resistors: (a) for low stress and (b) for high stress. (From Nowak, S., *Rozprawy Elektrotechniczne*, 35, 1989. With permission.)

area. More experienced producers use several segments and then the junction is not very sharp but is sawtooth shaped (see Figure 11.31).

Linear curve in a helipot precision potentiometer: In a precision potentiometer, the resistance of the resistive element should be proportional to the distance traveled by wiper.

In Figure 11.32, Δr_1 and Δr_2 are the maximum deviation from a single line. The nonproportionality NP of a precision potentiometer is described by Equation 11.29:

$$\mathrm{NP} = \frac{\Delta r_1 + \Delta r_2}{R_c} \times 100\% \tag{11.29}$$

The value of NP is 0.5%–0.01%. Such a good result is obtained by fluent control of the proportionality over winding of the wire.

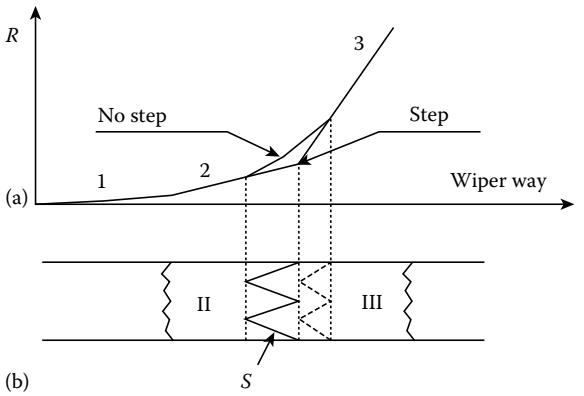

FIGURE 11.31 Shaping of exponential curve: (a) resistance versus wiper movement, the slopes 1, 2, 3 are proportional to resistivity of layer and $\rho_1 < \rho_2 < \rho_3$ and (b) junction of resistive layer area marked by *s* is the saw-tooth-shaped junction of segment II and segment III.

11.2 Capacitor

11.2.1 Introduction

A capacitor is a container of the electric energy W. This is expressed by the following equation:

$$W = \frac{CV^2}{2} \tag{11.30}$$

where

C is the capacitance expressed in F
V is the voltage on the capacitor plates expressed in V

Capacitance C of the multiplate capacitor can be described by the following equation:

$$C = \frac{x\varepsilon_r(N-1)A}{d}10^{-13} \tag{11.31}$$

where

ε_r is the relative dielectric constant of the insulator
d is the distance between the plates
N is the number of plates

A is the plate area, where $x = 0.0885$ for A and d expressed in centimeters or $x = 0.225$ for A and d in inches.

The relative dielectric constant value ε_r is equal to the ratio of capacity of a capacitor with plates separated by a dielectric to one separated only by vacuum. Dielectric constant values of various materials are presented in Table 11.6.

Fundamental parameters of capacitor are as follows: capacitance C, nominal voltage V_N, testing voltage V_t (note that $V_t = (2\text{–}3)V_N$), temperature coefficient of capacitance (TCC, for class 1 only), insulation resistance R_i (for dc voltage), and power PF (for ac voltage).

TABLE 11.6 Comparison of Capacitor Dielectric Constants

Dielectric	ε_r (Dielectric Constant)
Air or vacuum	1.0
Paper	2.0–6.0
Plastic	2.1–6.0
Mineral oil	2.2–2.3
Silicone oil	2.7–2.8
Quartz	3.8–4.4
Glass	4.8–8.0
Porcelain	5.1–5.9
Mica	5.4–8.7
Aluminum oxide	8.4
Tantalum pentoxide	26
Ceramic	12–400,000

Power factor (PF) is described by the following equation:

$$\mathrm{PF} = rC\omega = 2\pi frC \tag{11.32}$$

where r is an equivalent series resistance (ESR).

Its inversion is a quality factor Q, given by Equation 11.33. Because the power factor expresses total losses in capacitor, it is a sum of the dissipation factor and losses in electrodes as well as in terminations.

$$Q = \frac{1}{\mathrm{PF}} = \frac{1}{2\pi frC} \tag{11.33}$$

According to IEC Publ 384/1988, capacitors are divided into two salient groups: class 1 and class 2 but also more detailed classifications are commonly used because of the wide range of capacitances and very different applications. The main applications of capacitors include filtering, coupling, tuning, dc blocking, ac passing, bypassing, phase shifting, compensation, through feeding, isolation, energy storage, noise suppressing, motor starting, and so on. Contemporary capacitors cover the 0.1 pF up to 10 F capacity range and the 2.5 V to 100 kV voltage range. Connecting a dc voltage source to the capacitor plates we can observe the given capacitor is gradually charged and current flowing through the capacitor, large at the beginning, decreases in time to negligible small value. On the other hand, ac source causes the current I, given by Equation 11.34, flowing permanently through the capacitor.

$$I = \frac{V}{X_c} = \frac{V}{(1)/(2\pi fC)} = V2\pi fC \tag{11.34}$$

This current increases when capacitance, frequency, or applied voltage increase. The ac current can heat the capacitor, whose temperature would depend on its power factor, capacitor size, and cooling conditions. This phenomenon has to be taken into consideration in energetic 50 Hz equipment or in high-frequency power applications. Miniaturization and integration of electronic sets influence miniaturization of capacitors as well. The index υ', called "own volume" (volume per capacitance) and expressed in $\mathrm{cm}^3/\mu\mathrm{F}$, might be of use during selection of a capacitor for a given circuit. Nominal voltage V_N strongly affects the index υ' value. Table 11.7 presents the index υ' for capacitors with various dielectrics.

TABLE 11.7 υ' Index of Various Capacitors

Capacitor Definition	Main Parameters	υ' ($\mathrm{cm}^3/\mu\mathrm{F}$)
Variable air	500 pF/250 V	200,000
Mica	10 nF/500 V	250
Ceramic (rutile)	1000 pF/500 V	600
Ferroelectronic	40 nF/250 V	50
Ferroelectric multilayer	0.68 μF/50 V	1.5
Polystyrene	2 μF/160 V	300
Polyester (Mylar)	0.1 μF/160 V	12.4
Polycarbonate—metalized	0.15 μF/160 V	5.6
Electrolytic Al (HV)[a]	40 μF/350 V	1.3
Electrolytic Al (LV)[a]	120 μF/7 V	0.008
"Golden" capacitor	1 F/5.5 V	0.00001
Electrolytic Ta (wet)	10 μF/100 V	0.038
Electrolytic Ta (dry)	5.6 μF/10 V	0.0026

[a] HV, High voltage; LV, low voltage.

From the user's point of view, capacitors can be divided as follows: linear and nonlinear, fixed capacitors, adjusting capacitors, power energetic capacitors, start motor capacitors, and interference suppression capacitors.

11.2.2 Linear Capacitor

The linearity of a capacitor depends on the polarity of the dielectric used for its manufacture. Several different polarization mechanisms can contribute to the total polarization. The most important are the following:

1. Electron polarity that exists in the insulator with covalent bonds between atoms; electrical stress causes deformation of the orbital shape but electrons cannot go out of orbit (relaxation time τ is smaller than 10^{-15} s).
2. Ion polarity that occurs in glass and high-quality ceramic; under electrical stress ion centers are displaced ($\tau < 10^{-13}$ s).
3. Dipole polarity that occurs in a polar polymer dielectric. Electric field causes rotation of dipoles in the dielectric. Generally dielectric constant ε_r depends on frequency, temperature, and voltage, but in limited ranges of these factor ε_r is stable.
4. Domain polarity that appears in some insulators, for example, ferrodielectrics. They contain domains that rotate with electric field. This effect is called ferroelectricity because of the analogy to ferromagnetism and gives rise to very high dielectric constant ε_r up to 400,000 (see Table 11.6). It strongly depends on voltage, frequency, and temperature. Ceramic capacitors with a domain polarity mechanism and high dielectric constant are very popular in electronic equipment.

Only capacitors with electron polarity and ion polarity are classified in linear capacitor group 1.

The linear capacitor group consists of fixed capacitors in class 1, adjusting capacitors, energetic capacitors, high-voltage capacitors, and interference suppression capacitors.

11.2.2.1 Fixed Capacitor—Class 1

The main feature of a fixed linear capacitor with class 1 dielectric materials is its stability in time and under temperature. By analogy to resistors we can introduce dynamic tolerance Δ (see Section 11.1.1.2) for capacitance. Production tolerances δp ($\pm$) for class 1 capacitors are $\pm 0.25\%$, $\pm 0.5\%$, $\pm 1\%$, $\pm 2\%$, $\pm 5\%$, $\pm 10\%$, and $\pm 20\%$. The instability δ_{max} expressed by Equation 11.35 after the endurance test is up to 3% (IEC Publ. 384–8).

$$\delta_{max} = \overline{\delta} + 1.64^{*}s \tag{11.35}$$

where $\overline{\delta}$ and s are in accordance with the formula (Equations 11.4 and 11.6), respectively, and

$$\delta_i = \frac{C_i(t) - C_i(0)}{C_i(0)} \times 100\% \tag{11.36}$$

δ_{max} for capacitor is larger than for a stable resistor. This also means that dynamic tolerance Δ for capacitors is larger than for resistors, which should be considered during active rc filter design.

The TCC, given in Table 11.8, describes temperature stability of capacitors. Negative TCC capacitor may be used to compensate positive temperature coefficient of inductance in resonant LC circuit.

The next important parameter of capacitors in class 1 is a power factor that is required to be smaller than 30×10^{-4}. Ceramic capacitors with low ε_r as well as styroflex and mica capacitors meet these conditions, which renders them very suitable for resonant circuits, stable analog filters, integrator circuits, and other circuits, where stable capacitance and small losses are necessary.

TABLE 11.8 TCC and Max Capacitance of Monolithic Ceramic Capacitor

		Maximum Capacitance (pF)				
Dimension $a \times b$ (mm)		NP 0	N 75	N 150	N 750	Ferrodielectric
	TCC ppm/K	0 ± 30	-75 ± 30	-150 ± 30	-750 ± 30	Large
4×4		47	47	47	150	10,000
8×8		680	680	680	1,600	470,000
10×10		4,700	4,700	4,700	6,800	1,000,000[a]

[a] Some producers offer maximum capacitance $C = 4.7$ μF at dimensions of 10×10 mm.

(From Nowak, S., *Rozprawy Elektrotechniczne*, 4, 1989.) (b) Tubular taped (connected in tapes for automatic assembling). (From Taiyo Yuden Co. Ltd., *Tubular Ceramic Capacitors Catalogue*, Tokyo, 1988.) (c) Aluminum electrolytic (wet) with axial terminations. (d) Tantalum electrolytic (dry) with radial terminations. (e) Polystyrene foil with axial terminations. (f) Metalized film. (From Nowak, S., *Rozprawy Elektrotechniczne*, 4, 1989. With permission.)

Ceramic capacitors are produced as tubular, disk, and multilayer (monolithic) capacitors. Disk and tubular ones are inexpensive. Multilayer capacitors are rather expensive but they have small dimensions and low index υ'. Figure 11.33 presents some types of fixed capacitors.

11.2.2.2 Adjustable (Variable) Capacitor

An adjustable capacitor is an electronic component whose capacitance can be mechanically regulated by the user. For example, an AM radio set tuner is adjusted using a variable capacitor of 10 up to 500 pF. The dielectric used in this type of capacitor is either air or plastic foil. The majority of variable capacitors are trimmer capacitors for precision adjustment of reactance in electronic circuits. Their insulator layer is made of air, ceramic of class 1, mica, polystyrene, or Teflon. Typical trimmer capacitors are shown on Figure 11.34.

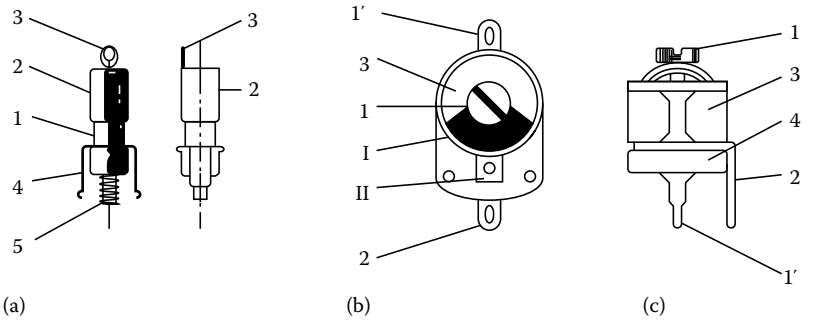

FIGURE 11.34 Typical trimmer capacitors: (a) tubular ceramic: 1—ceramic tube, 2—hot electrode, 3—soldering point, 4—earthed electrode, 5—screw for capacitance regulation; (b) flat ceramic: I—grounded electrode (plate), 1—roller for capacitance regulation (electrically connected with termination 1′); II—hot electrode connected with termination 2, 3—ceramic plate; and (c) Cylindrical air: 1—grounded roller (screw) connected with termination 1′, 2—hot electrode, 3—coaxial cylinders; capacitance regulation is achieved by moving cylinders up and down.

They have the following capacitance ranges: air trimmer, 1–15 pF; tubular ceramic trimmer, 0.1–7 pF; disk trimmer, 10–50 pF; special disk trimmer, 100 pF maximum. The power factor is small $(1\text{–}20) \times 10^{-4}$. Insulating resistance is above 10^{10} Ω. Nominal voltage is 100–500 V.

11.2.2.3 Energetic Power Capacitor

To compensate inductance in electrical engines and other equipment, energetic power capacitors are used. Besides capacitance, it is important to know their resistance power expressed in VAr (between vectors of voltage and of current, there is an angle 90°). They are rather large in size and weight of 10–50 kg per unit. The smaller ones are capacitors used to discharge lamps. They have a capacitance range 2.5–20 μF and ac working voltage of 150 V and effective voltage up to 550 V. Starting motor capacitors also belong to this group of power capacitor. The majority of power capacitors have paper, polypropylene, or mixed dielectrics, and they are impregnated in vacuum against flashover. An impregnant substance, such as mineral or synthetic oil is used. It is very important to match the dielectric constant of the oil with that of the fixed dielectric because it will guarantee uniform distribution of the electric field inside the unit. In some capacitors of smaller size, polypropylene without an impregnant is used as an insulator. Electrodes are made of aluminum foil or deposited with thin metal film on the dielectric. The power factor of these capacitors is required to be low with respect to heat dissipation. According to IEC Publ. 384-17 the maximum power factor is $<50 \times 10^{-4}$ at working frequency and for 1.25 V_N of nominal voltage.

Under overheating, the capacitor reliability falls and lifetime shortens. Polypropylene is chosen as the insulator material because of its good dielectric properties. For example, its PF = (6–7) $\times 10^{-4}$, $\varepsilon_r = 2.1$, TCC = −200 ppm/K and over the temperature range up to 110°C it is stable. The elementary cylindrical section of the power capacitor presented in Figure 11.35a depicts two polypropylene foils on which electrodes (Ia and IIa) were evaporated in vacuum. It is important to provide a fixed, multipoint junction between electrodes (Ia and Ib) and (IIa and IIb). It shortens the path of the current, which at ac voltage is high. That construction reduces the equivalent series inductance (ESI) of the capacitor at high frequencies.

11.2.2.4 High-Voltage Capacitor

A high-voltage capacitor for dc voltage and low frequencies is made of polymer foil, but for high-frequencies ceramic capacitors are preferred. They can be disk shaped up to 6 kV (Figure 11.36) or tube shaped for very high-voltage applications. It is easier to protect a tube-shaped capacitor against flashover.

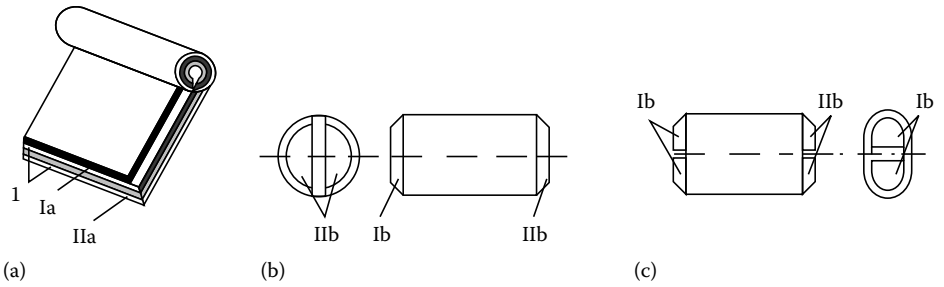

FIGURE 11.35 Metalized polypropylene capacitor. (a) The roll during winding; (b) cylindrical roll; and (c) flat roll: 1—polypropylene foils, Ia, IIa—metalized layer deposited in vacuum, plates (electrodes) of capacitor, Ib, IIb—contacts, deposited by high-pressure airbrush with melted metal.

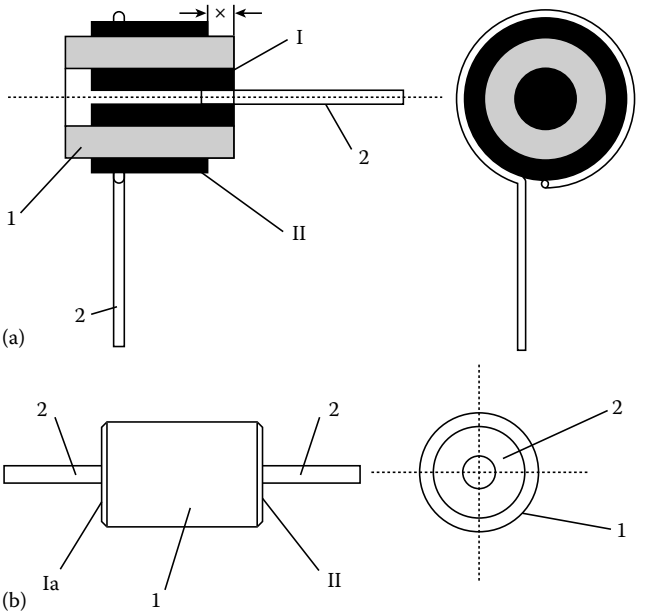

FIGURE 11.36 High-voltage ceramic capacitor. (a) Tubular: 1—inner, high-voltage electrode, II—grounded electrode, 1—ceramic tube, 2—wire terminations and (b) disc (bar) ceramic: I—ceramic bar, 2—wire termination, Ia, IIa—plates of capacitor, made by screen printing; x—distance for high voltage.

Some additional information will be presented in Section 11.2.5.3. To gain a high-voltage level, it is sometimes necessary to connect several capacitors in series. In this case, initially we must select an elementary capacitor. In order to get equal voltage drops on each element, we should choose elementary capacitors having the same capacitance for ac voltage and the same insulating resistance for dc voltage.

Dielectric absorption: According to Equation 11.30, high electrical energy can be stored in power and high-voltage capacitors. Danger to human life may exist even several hours after switching off the circuits that contain such capacitors. Also, capacitors discharging by short circuiting are not nearly safe enough. Because of dielectric absorption, some dangerous charge remains on the capacitor electrodes. To prevent accidents, high-energy capacitors should be shunted by high-ohmic resistors.

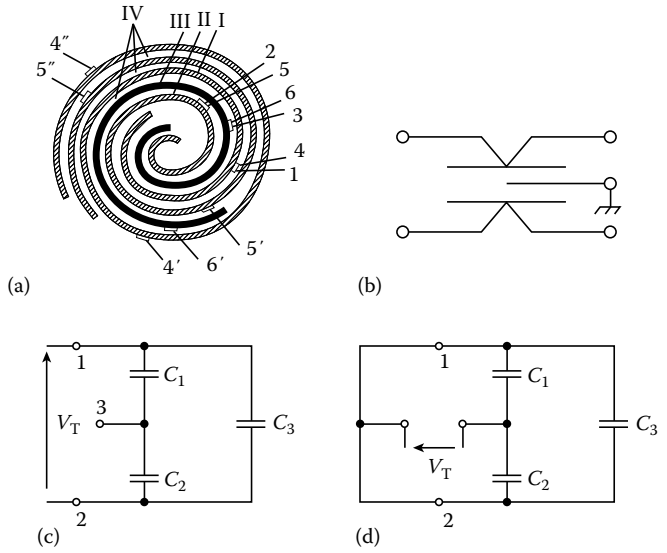

FIGURE 11.37 Capacitor for radio interference suppression: (a) construction principle of three capacitance interference suppression capacitor; I,II,III—Al foil electrode, IV—polymer foil insulator, 1,2,3—wire terminations, 1,2—wire leaded through, 4,5,6,4′,5′,6′,4δ,5δ—pretinned copper foil contact; (b) electrical circuit; (c) circuit for testing in class *X*; and (d) circuit for testing in class *Y*.

11.2.2.5 Interference Suppression Capacitor

This type of capacitor is characterized by low inductance. To accomplish this, a specific construction has been developed, where two or three capacitors are joined in a special way and put into one encapsulation. Figure 11.37 presents an example of this construction. Interference suppression capacitors are divided into two classes: *X* or *Y*. Capacitors of class *X* fulfill lower safety requirements because their breakdown is not dangerous to human life. Capacitors of class *Y* are used in extremely dangerous environments, where, for example, breakdown causes a short circuit between the body of the equipment and an energetic phase of 50 Hz. Properties of these two types of capacitors vary. For example, the 4 μF/250 V capacitor that belongs to the *X* class, has a test voltage on the level of 1100 V; however, one of the *Y* class has to withstand 2250 V. Also, circuits for testing these two types of capacitors (according to IEC Publ. 38414, 1993) differ from each other (see Figure 11.37c and d).

In Figure 11.37b, a lead-through capacitor is shown. The first capacitor is positioned between the two leads. The second and the third leads are arranged between separate leads and the ground. For radio frequencies, polymer capacitors may be used but for very high frequencies, ceramic ones are preferred. A special kind of feed-through ceramic capacitor is shown in Figure 11.38. It should be noted that automotive capacitors have to fulfill some additional requirements to withstand ignition system pulses.

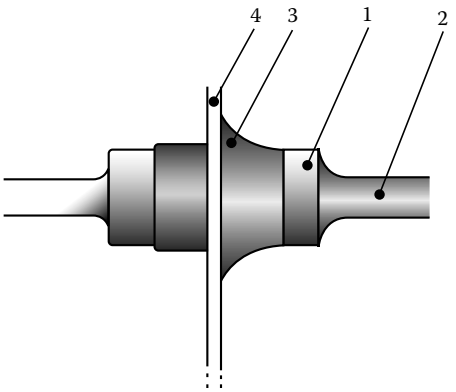

FIGURE 11.38 Feed-through capacitor: 1—ceramic tube, 2—wire termination lead through, connected with the inner electrode of the capacitor, 3—external electrode, 4—metal plate. Connection between 3 and 4 is made by soldering.

11.2.3 Nonlinear Capacitor

As was described in Section 11.2.2.1, the dipole and domain polarity mechanism in a dielectric is related to the nonlinearity of the capacitors. Ferrodielectric capacitors and polar polymer capacitors are nonlinear capacitors.

11.2.3.1 Ferrodielectric Capacitor

Ferrodielectric ceramic capacitors are known for strong dependence of their capacitance on temperature, voltage, and frequency. They are constructed in tubular, disk, and monolithic multilayer versions. Each version fulfills requirements of class 2 ceramics. By mixing different kinds of ceramics, we can get a dielectric composition of ε_r ranging from 1000 up to 30,000. The maximum available ε_r is 400,000 (see Table 11.6). Nevertheless, it should be noted that for production scale, such a dielectric constant is not reached because of its poor stability. Figure 11.39 shows the effect of capacitance instability $\Delta C/C$ versus voltage stress for different ε_r values.

If the 25% of change δ in capacitance is required, the maximum bias dc is 2000 V/mm (for $\varepsilon_r = 2000$); for stronger stress the change will be much greater. Great valve of ε_r, low series inductance, and small dimensions make ferrodielectric capacitors very useful in high-frequency applications up to 1 GHz. We can divide the class 2 ceramics into five subclasses: 2B, 2C, 2D, 2E, and 2F. Maximal changes of capacitance in the maximum category temperature are presented in Table 11.9. This means that the ferromagnetic capacitor must have minimal capacitance but its stability is not as important. Figure 11.40 presents the dependence of the relative change $\Delta\varepsilon/\varepsilon_r$ [3] on temperature for various dielectric constants. Higher values of ε_r show larger inequality of curves. Changes are larger when voltage stress is smaller than what is depicted in Figure 11.40c.

Figure 11.41 illustrates the influence of frequency on capacitance and power factor. It can be noted that up to 1 GHz the changes are acceptable.

Production tolerance δ_p also differs from values in class 1, for example, −40, +80%; −20, +80%; −20, +50%; ±20, ±10%.

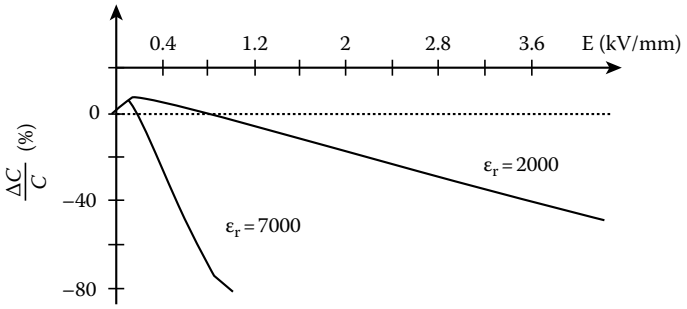

FIGURE 11.39 Dependence of capacitance on stress voltage at different ε_r of ceramic capacitor of class 2.

TABLE 11.9 Maximal Changes of Capacitance in the Maximum Category Temperature

Subclass	Maximal Changes of C_n[%]
2B	+10, −15
2C	+20, −30
2D	+20, −40
2E	+22, −70
2F	+30, −90

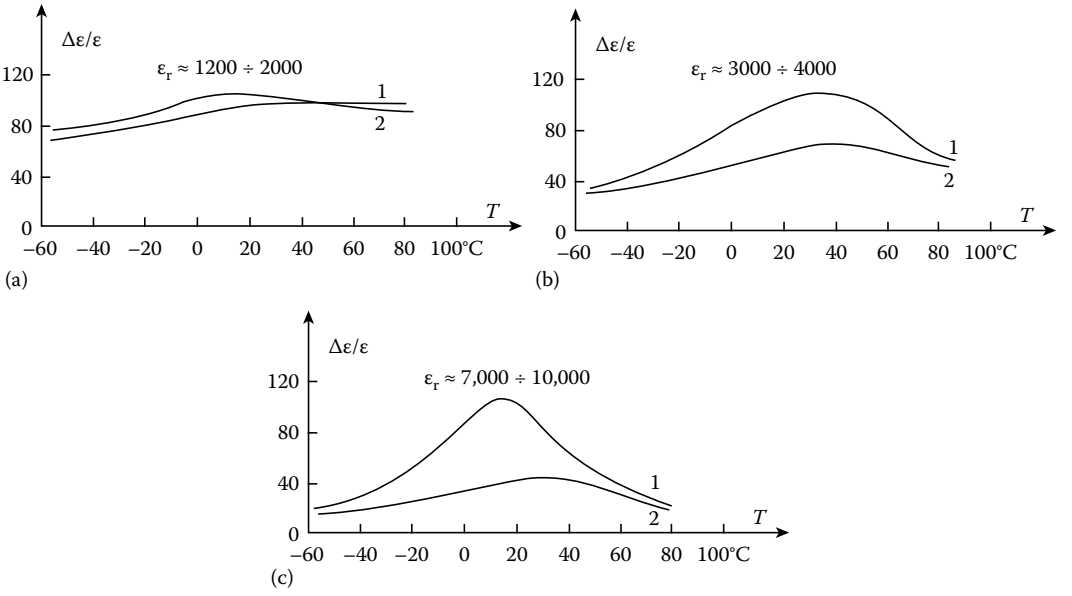

FIGURE 11.40 Normalized change of dielectric constant $\Delta\varepsilon/\varepsilon_r$ vs. temperature for class 2 ceramic. (a) Dielectric constant $\varepsilon_r = 1200–2000$; (b) dielectric constant $\varepsilon_r = 3000–4500$; and (c) dielectric constant $\varepsilon_r = 7{,}000–10{,}000$th; curve 1 at very low voltage; curve 2 at bias 8 kV/mm. (From Nowak, S. et al. *Handbuch der Electronik*, Vols. 2 and 3, Franzis-Verlag, Munich, 1979. With permission.)

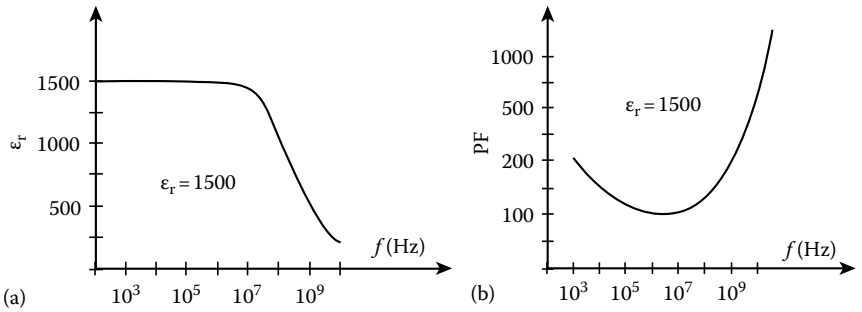

FIGURE 11.41 Dependence of dielectric constant and power factor on frequency. (a) ε_r vs. frequency and (b) PF vs. frequency. (From Nowak, S. et al. *Handbuch der Electronik*, vols. 2 and 3, Franzis-Verlag, Munich, 1979. With permission.)

Series of nominal voltage are 25, 40, 63, 100, 160, 250(200), 400(500), 630, 1000, and 1600 V. The maximal power factor is 350×10^{-4}; after an endurance test, it can increase up to 500×10^{-4} or 700×10^{-4}.

11.2.3.2 Polar Polymer Dielectric Capacitor

Miniaturization of a capacitor is so important in the design of electronic circuits that often a capacitor less stable but smaller in size may be chosen. The polar polymer capacitor exhibits such a feature; as an example, a metalized polycarbonate foil (macrofol) capacitor is used. Its construction is similar to the polypropylene capacitor shown in Figure 11.35. Polycarbonate foil of 3 μm thick is selectively covered by a thin (≤0.5 μm) layer of Al in the PVD process. An aluminum layer (marked by Ia and IIa) functions as the electrode of the capacitor. Very often a flat coil is used (see Figure 11.35c) in capacitor construction; contacts Ib and IIb are deposited by a high pressure airbrush with melted metal; terminations are connected to the contacts by soldering; encapsulation is made by epoxy cover. It is a class 2 capacitor; the voltage series range is 63, 100, 160, and 250 V (for different polycarbonate foil thicknesses).

Capacitances in series E-6 and E-12 range from 4.7 nF up to 10 μF. The power factor is $\leq 30 \times 10^{-4}$ and decreases with increasing temperature. The maximal frequency is about 1 MHz; at frequencies above 100 kHz, the power factor increases up to 200×10^{-4} and the capacitance decreases several percent. The climatic categorization is −55/+100/56; the time constant is $R_i \geq 5000$ s. It operates at both dc and ac voltages (e.g., dc voltage of 630 V corresponds to ac voltage of 220 V_{rms}).

11.2.4 Dependence on Material Properties

Dielectrics have played a fundamental role in capacitor performance (see Tables 11.6 and 11.7). Air capacitors, mineral oil capacitors, and mica capacitors, as well as polystyrene and Teflon capacitors mentioned above, are ranked as class 1 capacitors. Capacitors with natural dielectrics (air, oil, mica) are primarily older types. Perspective dielectrics for capacitors are polymer, ceramics type I and type II, thin film oxide (electrolytic), and electric double layer.

11.2.4.1 Nonorganic Capacitor

Nonorganic insulating materials are often used as dielectrics in capacitors. Class 1 and class 2 ceramics were described earlier. A large group of capacitors is based on oxide thin film. Commonly used electrolytic capacitors are aluminum oxide and tantalum oxide capacitors. Although the ε_r of an oxide is not high, oxide film thickness can be very small, so capacitance per 1 cm^3 is large. Oxide film is made by an electrochemical process. Popular oxides Al_2O_3 and Ta_2O_5 are utilized in aluminum electrolyte and tantalum electrolyte capacitor fabrication. The positive electrode is a metal (Al or Ta) and the negative electrode is a conductive electrolyte. Figure 11.42a depicts a segment of a wet aluminum foil electrolytic capacitor.

Foil is etched to get a large active surface; the growth coefficient of the surface is above 10 and theoretically for low voltage is 100. On the active surface, a thin layer of Al_2O_3 is produced electrochemically. It functions as a dielectric layer of the capacitor and its ε_r equals 8.4. The negative electrode is made as a conductive flux that usually is connected to the Al cover. The dc voltage range is from 6 up to 600 V. The capacitance range is from 4.7 μF to 10 mF in series E-3. In the reverse direction, the dielectric does not withstand high voltages and the maximal admitted voltage is only 10% of nominal voltage. During operation, the capacitors show better parameters than during storage because of the smaller value of the leakage current. A tantalum capacitor is also produced as a foil capacitor, but the dry tantalum capacitor is more popular. Figure 11.42b shows a segment of that capacitor where tantalum balls (0.3 mm diameter) are sintered and function as the positive electrode. A thin film of Ta_2O_5 is produced by an electrochemical process on the surface of each ball. In the next step, a conductive layer (e.g., a colloidal graphite layer) is deposited on Ta_2O_5 film in a chemical process. At the end, a contact for a negative electrode is made. An anode termination is welded to sintered balls and a cathode termination can be soldered to the negative electrode contact. Encapsulation is

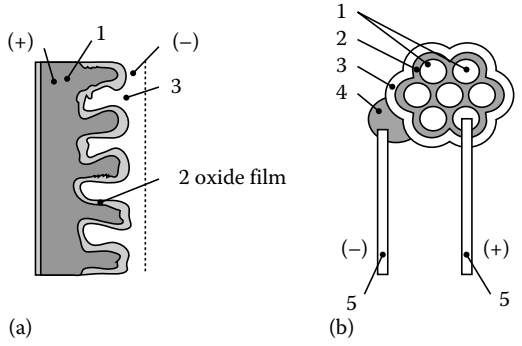

FIGURE 11.42 Segment of electrolytic capacitor. (a) Al_2O_3 wet capacitor 1—Al foil, 2—oxide layer, 3—fluid (negative electrode) and (b) Ta_2O_5 dry capacitor 1—tantalum balls, 2—Ta_2O_5 layer, 3—conductive layer (negative electrode), 4—contact for negative termination.

made using a tixotropic lacquer. Tantalum oxide electrolytic dry capacitors are produced for low dc voltages from 4 to 50 V. The tantalum capacitor shows a smaller leakage current and higher work temperature, up to 125°C. The aluminum capacitor can usually work nominally up to 70°C and up to 85°C maximum. Also, the tantalum capacitor exhibits better high-frequency characteristics. It is really a miniature capacitor; its υ' index is very small (see Table 11.7). Al and Ta electrolytic capacitors are applied to do circuits but can also work at small ac voltage (ac amplitude must be smaller than 10%–15% of dc nominal values). In a wet electrolytic capacitor, self-regeneration exists; that is, after a short breakdown, the capacitor can work further because the layer of oxide is regenerated around the breakdown point. Several firms manufacture bipolar electrolytic capacitors for ac voltages.

11.2.4.2 Super Capacitor (with Electric Double Layer)

The super capacitor, also called the golden capacitor or golden series capacitor, has capacitances up to 10 F and its υ' index is about 0.00001 $cm^3/\mu F$. The origin of that capacitor comes from Helmholtz (1879), who discovered the electric double layer that exists on the interface of two different materials. The layer can store an electric charge. The charge value of the electric double layer increases as the effective contact surface and/or electric field go higher. The right choice of both materials and preparation technology can lead to a very thin (several angstroms) electric double layer for 1.2 V in one call. Cells are connected in series for higher nominal voltage values, which typically achieve 2.5 up to 11 V for the whole super capacitor. In known practical constructions of super capacitors, small particles of activated carbon (with a large effective surface) are used in contact with diluted sulfuric acid; carbon in contact with acid yields the electric double layer. Carbon is the positive pole and acid connected with the metal case is the negative pole. The leakage current of supercap is very small, the time constant of the supercap is very high (over 1 month), and therefore it is very useful for backup purposes, such as maintaining the proper voltage level for reliable data storage of CMOS memories during host power supply failure.

Supercapacitors are sometimes classified as electrolytic capacitors because of their inner wet solution, but the general principles of operation are quite different. Supercaps are manufactured by many companies, such as NEC and Panasonic, and others.

11.2.4.3 Organic Capacitor

This group includes paper and polymer capacitors. The paper capacitor is an obsolete construction and today it is not very popular because paper drying and impregnation are rather expensive. Also, the parameters of paper capacitors are not sufficient. The family of polymer capacitors is very large and some of them were described in Section 11.2.3.

Table 11.10 presents the features of various polymer capacitors. Special attention should be paid to the Teflon capacitor, for instance, that the maximum operating temperature is 280°C and the power factor is ca. 6×10^{-4}; also, instability δ is $<0.5\%/1000$ h.

For dc and low frequency operation, polyethylenetereftalate (Mylar) foil capacitor is very popular. It withstands different fluxes and high temperatures up to 150°C. Its stability and power factor are quite good, but only for low frequencies.

11.2.5 Dependence on Geometry of Material

11.2.5.1 Influence of Capacitor Construction on Equivalent Series Inductance and Equivalent Series Resistance

Equivalent series inductance (ESI) with capacitance C causes self-resonance at resonant frequency f_0. Above frequency f_0, it has an inductance feature so it cannot fulfill its main function. So, reduction of ESI is a very important matter. Figure 11.43 shows the simplest rolling polymer capacitor with two terminations marked 3 and 4.

During charging and discharging, current is flowing through capacitor electrodes that are marked 2 and 5. The electrodes are insulated by polymer foils marked by 6 in Figure 11.43. Such a construction

TABLE 11.10 Features of Various Polymer Capacitors

Capacitor Name	υ' $cm^3/\mu F$	Class	δ_{max} after 1000 h (%)	Smallest $t\delta_p$ (%)	Power Factor $\times 10^{-4}$	TCC (ppm/K)	Maximum Work Temperature (°C)	Remarks	
Polystyrene	300	1	0.5	±0.5	2–5	−100	70	For telecommunications filter	Neutral polymer

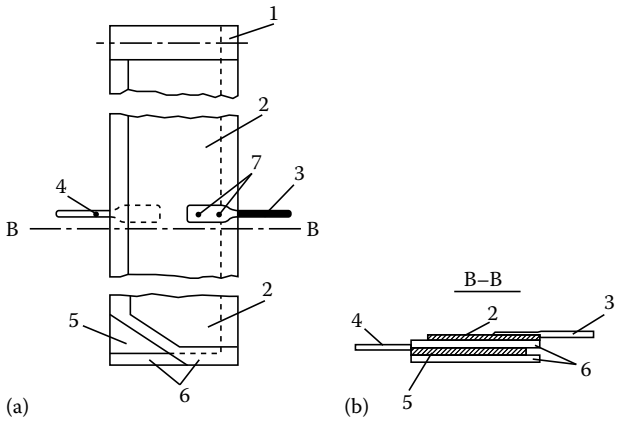

FIGURE 11.43 Simply polymer capacitor construction. (a) 1—start part of roll, 2—Al foil (electrode I), 3,4—wire terminations, 5—Al foil (electrode II), 6—polymer dielectric foil, 7—welding points and (b) cross section B–B.

creates a roll which, in turn, adds significant ESI to the capacitor. The simplest way of decreasing ESI is to supply some additional terminations and connect them in parallel. The maximum number of contacts is shown in Figure 11.35. Contacts are deposited with melted metal on the electrode by using a high-pressure airbrush. In that case, minimal ESI occurs. In this way, equivalent series resistance (ESR) also decreases, because the distance through which current is flowing becomes much shorter. Very small ESI occurs with the feed-through capacitor shown in Figure 11.38.

11.2.5.2 Influence of Plate Shape on Tuning Frequency in Air Variable Capacitors

A variable capacitor consists of standing plates that are insulated usually from the ground and rotary plates that are connected to the ground.

Variable capacitors are used for tuning an LC circuit, for example, to select the proper radio station. As we see from Equation 11.37, resonant frequency f_0 is not proportional to C. Proportionality is achieved by special shaping of the plates as a function of the rotation angle. The modified shape of plate is illustrated in Figure 11.44.

$$f_0 = \frac{1}{2\pi\sqrt{LC}} = \frac{b}{\sqrt{C}} \tag{11.37}$$

Equation 11.37 shows the resonant frequency of the LC circuit.

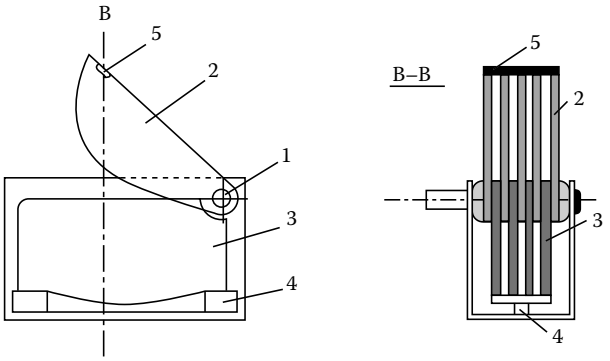

FIGURE 11.44 Rotary capacitor construction. Shape of plates is modified in relation to the circle: 1—shaft, 2—moving plates, 3—standing plates, 4—insulator, 5—insulating traverse.

11.2.5.3 Shape of the High-Voltage Capacitor

The operation of a capacitor at high voltages is always accompanied by many problems, for example, how to achieve the proper distance between capacitor electrodes.

Two drawings in Figure 11.36 help us to overcome this obstacle by using either of the following:

1. A disk capacitor with a high dielectric thickness (actually, it is a bar instead of a disk); when the thickness of the dielectric increases, capacitance decreases.
2. A tubular capacitor when the thickness of the dielectric is satisfactory for high voltage, but the electrodes are far enough from each other with respect to flashover protection.

11.2.5.4 Chip Capacitor

SMT requires electronic components with easily solderable contacts without wire terminations.

Usually those contacts are pretinned during chip production. Figure 11.45a and b shows us a tantalum electrolytic capacitor chip and a ceramic monolythic capacitor chip, respectively. The capacitance of each of these two devices can range from 10 pF up to 10 mF and from 10 pF to 10 nF, respectively, in classes 2 and 1.

11.2.6 Nonideal Linear Capacitor

The main source of capacitance instability of the capacitor is the operating frequency. Its influence on dielectric polarity was described in Section 11.2.2. The change of capacitance with frequency increase in capacitors belonging to the class 1 might be also observed. Furthermore, an ESR decreases the effective capacitance C_{ef} according to the following equation:

$$C_{ef1} = \frac{C}{1 + \omega^2 r^2 C^2} \tag{11.38}$$

where $r = \text{ESR}$ is calculated from the power factor (PF), which is measured at the operating frequency, and C is the capacitance at low frequencies.

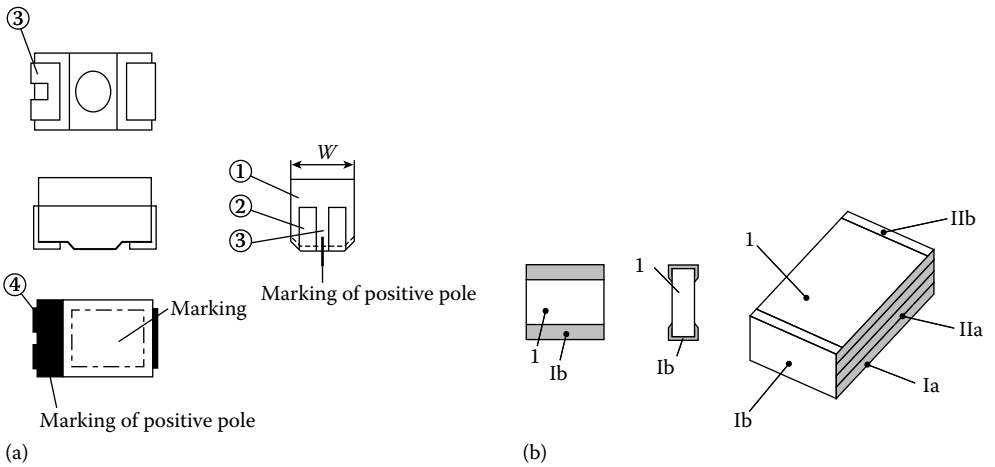

FIGURE 11.45 Chip capacitor. (a) Tantalum pentoxide capacitor. Positive pole is marked by a black bar and double external electrode; 1—plastic encapsulation, 2—external electrode for soldering, 3—cutting in positive electrode, 4—black bar and (b) ceramic multilayer monolithic capacitor, 1—ceramic layers, Ia,IIa—capacitor electrodes (plates), Ib,IIb—external electrodes.

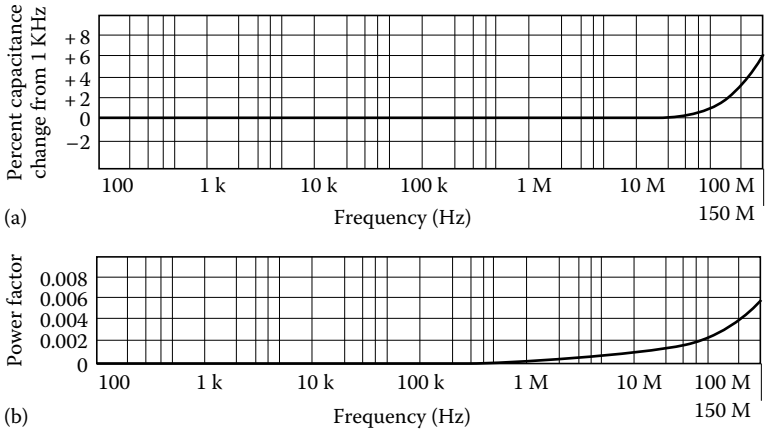

FIGURE 11.46 Dependence of capacitance and power factor vs. frequency for ceramic NPO capacitor—class 1: (a) capacitance and (b) power factor. (From Sprague Electric Co., Monolithic ceramic chip capacitors, *Sprague Eng. Bull.*, Brussels. With permission.)

$$r = \frac{\mathrm{PF}}{\omega C} \tag{11.39}$$

On the other hand, an ESI increases the effective capacitance according to the following Equation 11.40:

$$C_{\mathrm{ef2}} = \frac{C}{1 - \omega^2 \mathrm{LC}} \tag{11.40}$$

where ESI $= L$ can be measured at the self-resonant frequency (see Equation 11.37).

The ESR and ESI Data Cards for a given capacitor can be obtained from its manufacturer. Figure 11.46 shows the dependence of capacitance and power factor on frequency for class 1 ceramic capacitors.

Figure 11.41 presents data for class 2 ceramic capacitors. In a ceramic multilayer capacitor, migration of metal particles through the dielectric is observed, which causes an increase of capacitance and sometimes breakdown. The problem can be solved by roll pressing of two wet ceramic layers into one dielectric during a production process.

Self-regeneration of capacitor: The phenomenon of self-regeneration is exhibited in metalized dielectric capacitors as well as electrolyte capacitors. It is useful in some situations (e.g., in long-life tests), but sometimes it is harmful (e.g., in pulse counting equipment). To solve that problem, we should use a derated capacitor (for 25 V work voltage, 40 V nominal voltage is needed) or change the type of capacitor.

Leakage current of electrolytic capacitor: The insulating resistance R_{i} in an electrolytic capacitor is not as high as in other capacitors. The result of law R_{i} is dc current called leakage current I_{L}. For aluminum electrolytic capacitors, Siemens Matsushita Components Company in their catalog [6] proposes to join I_{L} in μA with capacitance C in μF and working voltage V_{w} in V. According empirical rule (Equation 11.41)

$$I_{\mathrm{L}} \leq 0.03\, CV_{\mathrm{W}} + 20\ \mu\mathrm{A} \tag{11.41}$$

for normal types and

$$I_{\mathrm{L}} \leq 0.006\, CV_{\mathrm{W}} + 4\ \mu\mathrm{A} \tag{11.42}$$

for special long-life capacitors, where $V_{\mathrm{w}} \leq V_{\mathrm{N}}$.

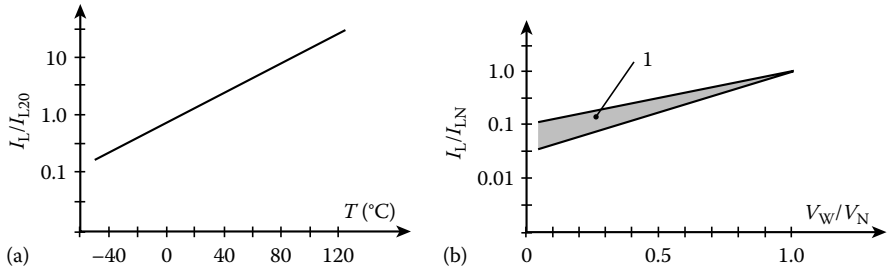

FIGURE 11.47 Leakage current of tantalum electrolytic capacitor. (a) Dependence of leakage current versus temperature and (b) dependence of leakage current vs. working voltage; 1—typical range of I_L. (From AVX Corporation Ltd., *AVX Tantalum Capacitors Catalogue*, Great Britain, 1990. With permission.)

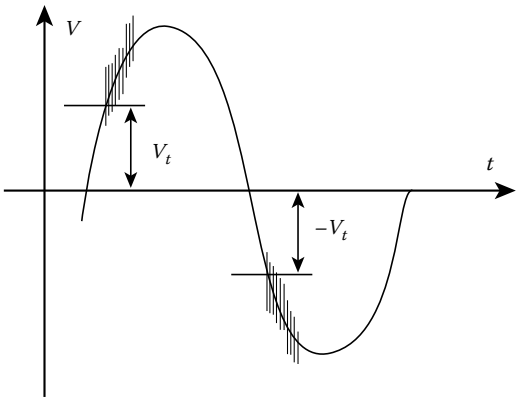

FIGURE 11.48 Ionization threshold in a 50 Hz capacitor. V_t—threshold voltage on which ionization can start.

Tantalum electrolytic capacitors show smaller leakage currents and at a temperature 20°C their value is 0.5 up to 20 μA. That value also depends on C, V_w, and temperature. Dependence I_L on ambient temperature T is shown in Figure 11.47a, and influence of working voltage value V_w is shown in Figure 11.47b. Those data are taken from the 1990 catalogue of the AVX Corporation Ltd. (Great Britain).

It is necessary to know that after long-time storage, the leakage current is going up. To prevent this, one should switch on the testing device containing the capacitors several hours before using.

Noise in capacitor: Foil capacitors can generate noise when contact between termination and electrode plate is not sufficiently fixed. In Figure 11.43, the welding points of contact are introduced (marked 7) to improve the quality of a contact. Some producers do not use welding because at nominal voltages the noise generated by contact is negligible. You should pay attention to the fact that for very low signals poor contacts affect noise in a significant way. Welding removes that effect.

Ionization threshold: In a power capacitor, an ionization of the dielectric is possible; Figure 11.48 shows the effect of this process.

Although breakdown does not occur, the capacitor life shortens when operating voltage approaches maximum.

Threshold is a minimal value V_T of voltage at which ionization starts. This causes heterogeneity of the dielectric, for example, polypropylene and air between plates. Flat rolling of the dielectric layer is strongly suggested for use in a power capacitor, as well as vacuum impregnation of the capacitor.

Insulating resistance R_i: When a capacitor is used as a component of an RC time constant, insulation resistance should be taken into consideration. In that case, foil polymers (particularly polystyrene or Teflon capacitors, where R_i is greater than 100 GΩ) are preferred. Also, protection against dirt and humidity by hermetization improves R_i.

11.3 Inductor

11.3.1 Basics

An inductor is a device consisting of one or more associate windings, with or without a magnetic core, for introducing inductance into an electric circuit [1]. The origin of the word is from Latin: inducere–excite, induce, incite. Other appellations in use include inductance coil and coil, which are synonyms, and inductance, winding, bobbin, self, and self-inductance, which are jargon, as well as reactor and choke. Reactor and choke are inductors but not every inductor is a reactor or choke. The alphabetical symbol of inductor is *L*. Units of inductance include 1 henry = 1 H = 1 Vs/A and its submultiples nH (10^{-9}), μH (10^{-6}), and mH (10^{-3}).

Inductor graphical symbols:

Generally inductor or ideal inductor;

Inductor with magnetic core, cored inductor;

Inductive reactance $X_L = \omega L$;

Cored inductor with continuously changed inductance; cored inductor with adjuster;

Cored inductor—core with air gap;

Cored inductor, core of bonded magnetic powder.

Working frequency range of inductors (as lumped devices): from acoustic frequencies to roughly 1 GHz.

11.3.1.1 Basic Relationships and Influencing Factors

The main electrical attribute of the inductor is the inductance *L*. The inductance is the property of the electric circuit, whereby an electromotive force is induced in that circuit by a change of current in the circuit [1].

The electromotive force (voltage) *e* induced in the winding of the inductor is given by Faraday's law, which can be written in various equivalent forms:

$$e = -n\frac{\mathrm{d}\Phi}{\mathrm{d}t} = -\frac{d}{\mathrm{d}t}(Li) = -\left(L\frac{\mathrm{d}i}{\mathrm{d}t} + i\frac{\mathrm{d}L}{\mathrm{d}t}\right) \tag{11.43}$$

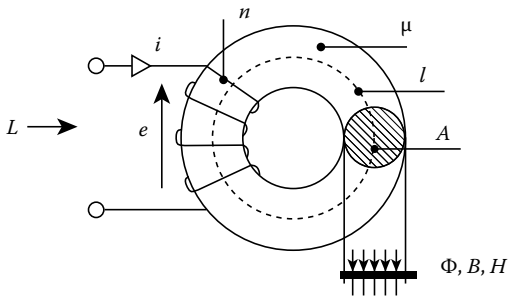

FIGURE 11.49 Inductor of a toroidal shape.

where $n\Phi =$ total magnetic flux linked with the current i flowing through all the n turns forming the winding of inductor having an inductance L.

Equation 11.43 shows that the circuit "senses" the inductance only when the current in the circuit is changing and/or the inductance itself is changing. Generally, the inductance L can depend on the magnitude of current i and inversely a change in the magnitude of L can cause a change in amplitude of i, so e is an implicit function $e[i(t), L(i, t), t]$. The well-known expression $e = -L\mathrm{d}i/\mathrm{d}t$ is fulfilled only if L is a constant independent of current, i, and time t (this restriction is often forgotten).

In terms of the electromagnetic field theory, the inductance L is given by

$$L = \frac{\Phi}{i} = n \oint_A B\mathrm{d}A \Big/ \oint_l H\mathrm{d}l \tag{11.44}$$

where

B is the normal component of the magnetic induction (flux density) through the area A
H is the magnetic field strength along its path l

For more details about various forms of the electromagnetic field equations see courses on the theory of electromagnetic field, for example, Ref. [2].

In case of a radially thin toroid (i.e., in which $A/l \to 0$) and $\mu =$ const, the magnetic induction B, and field strength H, can be assumed as uniform, that is, $\Phi = BA$; $B = \mu_0\mu H$; $H = ni/l$, the inductance L for a shape shown in Figure 11.49 is

$$L = \mu_0\mu n^2 A/l \tag{11.45}$$

where

μ_0 is the $4\pi 10^{-7}$ (H/m) is the magnetic constant
μ is the magnetic permeability of the medium filling up the shape of the toroid

Equation 11.45 can be expressed in different equivalent forms; their use is optional.

$$L = A_L n^2, \qquad A_L = \mu_0\mu\ A/l, \quad A_L = L/n^2 \tag{11.46a}$$

$$L = \mu A_{L0} n^2, \qquad A_{L0} = \mu A/l, \qquad A_{L0} = A_L/\mu \tag{11.46b}$$

$$L = \mu_0 G_m n^2, \qquad G_m = \mu A/l, \qquad G_m = \mu G_{m0} \tag{11.46c}$$

$$L = \mu_0 n^2 R_m, \qquad R_m = l/\mu A, \qquad R_m = 1/G_m \tag{11.46d}$$

$$L = \mu_0\mu G_{m0} n^2, \quad G_{m0} = A/l, \qquad G_{m0} = G_m/\mu \tag{11.46e}$$

$$L = \mu_0\mu n^2/R_{m0}, \quad R_{m0} = l/A, \qquad R_{m0} = 1/G_{m0} \tag{11.46f}$$

where

A_L is the inductance factor of inductor
A_{L0} is the inductance factor of the winding or core shape (at $\mu = 1$)
G_m and R_m are the core permeance and reluctance, respectively
G_{m0} and R_{m0} are the permeance and reluctance of core shape (at $\mu = 1$) inductance L is in H if l is in m and A in m^2

If μ, *B*, and *H* cannot be assumed to be uniform, Equations 11.45 and 11.46 take more complicated forms issuing from Equation 11.44.

The following fundamental observations can be inferred from Equations 11.43 through 11.45:

1. The inductance *L* of the inductor depends on three factors:
   - Square of number of turns n^2 of the winding.
   - Geometrical configuration of the magnetic flux Φ produced by the current *i;* this configuration is represented by the permeance or reluctance of the shape G_{m0} or R_{m0}, containing the magnetic flux.
   - Magnetic properties of the medium or media filling up the shape associated with the carrying current winding, producing a magnetic flux Φ; these properties are represented by the magnetic permeability μ. *Note:* Magnetic permeability, depending on the approach, can be considered as a scalar (number), complex quantity, or a tensor.
2. The voltage induced across the inductor of inductance *L* depends on the following:
   - Rate of change of the current flowing in the inductor winding $\mathrm{d}i/\mathrm{d}t$.
   - Changes in time of the inductance of inductor $\mathrm{d}L/\mathrm{d}t$*;* these changes result from the influence of external factors on inductance *L,* because

$$\frac{\mathrm{d}L}{\mathrm{d}t} = \sum_{\nu} \frac{\partial L}{\partial \xi_\nu} \frac{\partial \xi_\nu}{\partial t} = \sum_{\nu} \left[\frac{\partial L}{\partial \mu} \frac{\partial \mu}{\partial \xi_\nu} \frac{\partial \xi_\nu}{\partial t} + \frac{\partial L}{\partial A} \frac{\partial A}{\partial \xi_\nu} \frac{\partial \xi_\nu}{\partial t} + \frac{\partial L}{\partial !} \frac{\partial l}{\partial \xi_\nu} \frac{\partial \xi_\nu}{\partial t} \right] \tag{11.47}$$

$\nu = 1, 2, 3, \ldots$, ξ = external stressing factors such as time, temperature, mechanical stresses, static and time-varying voltage or magnetic induction, current or magnetic field strength, frequency, moisture, radiation (nuclear, cosmic), and so on.

The term $\mathrm{d}L/\mathrm{d}t$ (Equation 11.47), often forgotten in considerations, is however, of importance because it is responsible for any instability or variability introduced into an electric circuit by the inductors. Examples of various $\mathrm{d}L/\mathrm{d}t$ contributions are listed in Table 11.11.

11.3.1.2 Inductor: Qualifiers and Attributes

Different qualifiers are, in practice, applied to inductors, depending on the approach and related attributes. The most frequently used are listed in Table 11.12. These qualifiers are used separately or in combination, for example, air inductor or linear cored inductor.

TABLE 11.11 Exemplification of Various Stressing Factors ξ Causing Changes in Inductance *L*

	Influencing	
Stressing Factor ξ	Permeability μ, $\mathrm{d}\mu/\mathrm{d}\xi$, for Example	Physical Dimensions *A* and *l* of Winding and/or Core; $\mathrm{d}A/\mathrm{d}\xi$ and $\mathrm{d}l/\mathrm{d}\xi$, for Example
Temperature	Temperature changes of permeability	Thermal changes of dimensions
Mechanical tensile, contracting or torsion stress	Reversible changes of permeability under mechanical stresses, piezomagnetic effects, mechanomagnetic after-effects (relaxations)	Changes of dimensions under mechanical stresses; mechanical relaxations of dimensions of core or winding
Magnetic induction *B* or magnetic field strength *H* (changes of static, time-varying or combined magnitude)	Strong and, generally, nonlinear dependence of μ on *B* and *H*; disturbance of the magnetic state of core material	Ponderometric effects in winding at, for example, high current intensities or pulses; mechanical relaxation of winding or coil formers

TABLE 11.11 (continued) Exemplification of Various Stressing Factors ξ Causing Changes in Inductance *L*

	Influencing	
Stressing Factor ξ	Permeability μ, dμ/dξ, for Example	Physical Dimensions *A* and *l* of Winding and/or Core; d*A*/dξ and d*l*/dξ, for Example
Frequency	Strong dependence of μ on frequency: eddy-current effects (magnetic skin and proximity effects), magnetic resonances (wall resonance, dimensional resonance, spin resonance), relaxation effects	Skin and proximity effects in wires cause change of current density distribution in conductor, thus, the change of effective dimensions of coil
Humidity, moisture, aggressive agents (salts, acids, etc.)	Corrosion effects in metallic cores, therefore structural changes of magnetic material; changes of dielectric properties in ferrites	Various agents' effects as changes of dimensions and electrical and dielectric properties of coil formers, winding and interwinding insulation layers, substrates, etc.
Irradiation	Structural changes in magnetic material	Structural changes in materials of coils, conductors, insulation, dielectric properties of coil formers, substrates, etc.
Time	Changes of μ: reversible effects (disaccommodation and accommodation), irreversible effects (so-called aging), thermal fluctuation effects in nonneutral states	For example, aging and rheological effects affecting materials of coil formers, insulation; diffusion effects between metallic conductors deposited, for example, on ceramic substrate

TABLE 11.12 Inductor Qualifiers and Attributes

Inductor Qualifier	Inductor: Attribute or Quality
Ideal, perfect	Linear inductor having only a ''pure'' inductance, that is, no power loss is related to the flow of time-varying current through the inductor winding. In the ideal inductor, the current of sine wave lags the induced voltage by angle $\varphi = 90^\circ$ ($\pi/2$ rad). The concept of the ideal inductor is used only in idealized or simplified circuit analysis.
Nonideal	Usually a linear inductor in which the power loss in the winding and core is taken into account. The current of sine wave lags the induced voltage by angle $0^\circ \leq \varphi < 90^\circ$ (90° for ideal, power loss-free inductor; 0° for pure resistor). The concept of nonideal inductor is used as a first order approximation of a real inductor.
Linear	Inductor, ideal or nonideal, for which the induced voltage drop across it is proportional to the flowing time-varying current in its steady state. Linear inductor can be described or be used to describe the circuit in terms of transfer function. An air inductor is an example of linear inductor.
Nonlinear	Inductor for which the induced voltage drop is not proportional to the time-varying current flowing by it. As a rule, cored inductors (specifically if a core forms a closed magnetic circuit) are nonlinear. This is a consequence of the strong nonlinear dependence of magnetic induction *B*, proportional to voltage $u = \mathrm{d}L/\mathrm{d}t$, on magnetic field strength *H*, proportional to current *i*.
Real	Inductor with electrically behavioral aspects and characteristics that are all taken into account, for example, magnetic power loss, magnetic flux leakage, self-winding and interwinding capacitances and related dielectric power loss, radiation power loss, parasitic couplings, and so on, and dependences of these factors on frequency, induction, temperature, time, etc.
Air	Inductor not containing magnetic materials as constituents or in its magnetically perceptible vicinity.
Cored	Inductor in which a magnetic material in the form of a core serves intentionally as a path, complete or partial, for guidance of magnetic flux generated by current flowing through inductor winding.
Lumped or discrete	Inductor assumed to be concentrated at a single point.
Distributed	Inductor with inductance and other properties that are distributed over a physical distance(s) which is (are) comparable to a wavelength.

11.3.1.3 Basic Functions of the Inductor

The inductor has to perform four basic functions:

- Impede (oppose) any change in the existing current; as the change is more rapid the opposition is stronger.
- Lag (to shift) the current in respect to induced voltage up to 90° for a sine wave.
- Differentiate the current waveform.
- Store the magnetic energy; this when in combination with electrical energy stored in capacitor, results in electrical resonance (LC—resonance).

The more the real inductor approaches the ideal inductor, the higher the degree in performing these functions.

11.3.1.4 Parameters Characterizing the Inductor

Primary parameters:

- Inductance L (for all excitation levels)
- Power loss at low and middle excitation levels expressed facultatively in terms of
  Resistance R = power loss/(square or rms value of current)
  Tangent of loss angle δ, $\text{tg}\delta = R/2\pi fL$
  Quality factor $Q = 2\pi fL/R = 1/\text{tg}\delta$
- Power loss at high excitation levels is expressed directly in watts or in watts per unit of weight or unit of volume

Secondary Parameters (Selected):

- dc winding resistance
- Self-capacitance
- Self-resonance frequency
- Temperature coefficient or factor of inductance
- Time instability
- Hysteresis loss
- Pulse inductance
- Adjustment range
- Harmonic distortion
- Magnetic radiation
- Influence of the static magnetic field
- Inductance rise factor
- Maximum winding temperature
- Temperature rise
- Immunity from mechanical stresses and environmental exposures
- Acoustic noise

To determine these parameters, the following should be specified: frequency, excitation level (voltage or current), temperature, parameters of measuring coil (winding), type of magnetic conditioning to be used, and other details of measuring procedure, as well as conditions needed to ensure the required accuracy and repeatability of measurement.

The relevant measuring methods are described, for example, in Refs. [3–5] while their methodological basics are summarized in the item Magnetic Materials Measurements: Basic Methodological Principles. See also item International Standards on Inductors, point 4. Measuring Methods and Procedures.

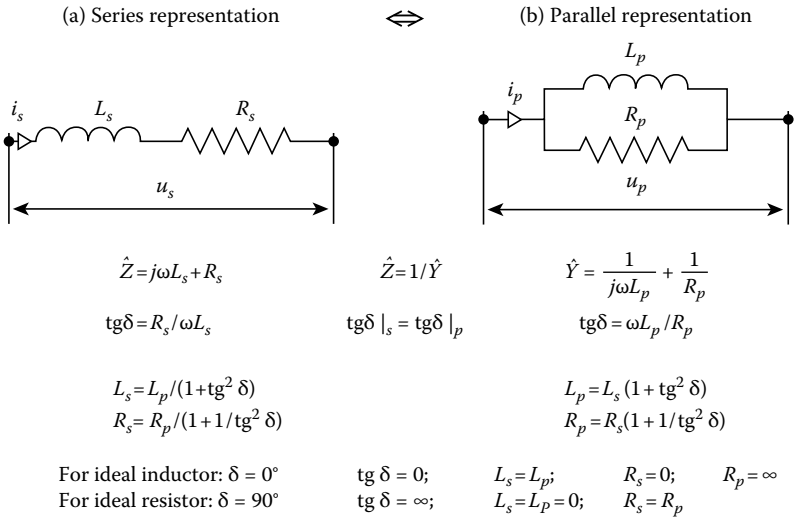

FIGURE 11.50 Equivalent circuit representation of the inductor and the respective expressions. *Note:* When subscript *s* is omitted, symbols *L* and *R* always refer to the series representation.

11.3.1.5 Circuit Representation of Inductor

Circuit representation of the ideal inductor is that as shown by the first inductor graphical symbol. For a nonideal linear inductor, a series or parallel representation is used (Figure 11.50).

The transformation of a nonideal inductor shown in Figure 11.50 is a purely formal operation serving only for the circuit analysis. Transformation results calculated for one specified frequency and specific operating conditions (e.g., *B*, temperature) can be extended over other frequencies and conditions only when *L* and *R* appear to be independent of these factors: $L = \text{const}$ and $R = \text{const}$.

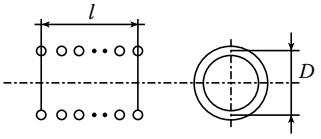
Series and parallel connections of inductors: When individual inductors are connected in series (with no mutual inductive couplings), the total inductance $L_t = L_{ts}$ will be a sum of individual inductances L_i:$L_{ts} = \Sigma_i L_i$; similarly the equivalent loss resistances: $R_{ts} = \Sigma_i R_i$.

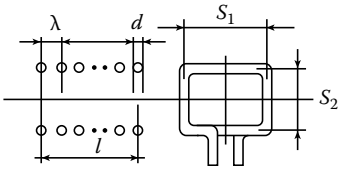
When individual inductors are connected in parallel, the total inductance $L_t = L_{tp}$ and resistance R_{tp} will be $L_{tp} = 1/\Sigma_i 1/L_i$ and $R_{tp} = 1/\Sigma_i 1/R_i$, respectively.

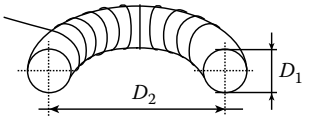
Thus, the series connection of inductors always increases a resultant inductance, parallel connection decreases. *Note:* These connections rules (laws) apply only for sine waveforms in the steady state and these rules are applicable neither to the nonlinear inductors nor to transient states.

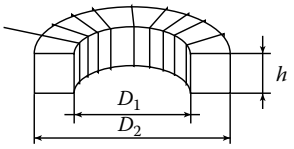
11.3.2 Air Inductor

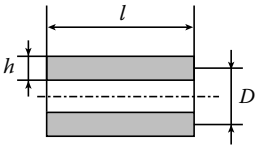
This type of inductor is assumed to be linear. This means that at stressing factors that are fixed, the inductance *L* and resistance *R* are characteristic constants, independent of the flowing current or applied voltage.

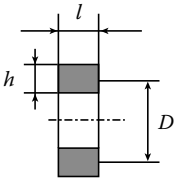












Selected formulas for the inductance of some air inductors are given below. In Table 11.13 corresponding draftings are depicted. All dimensions of coils shown in Table 11.13 are in cm; $n = \text{number of turns}$. For more formulas for calculation of the inductance of air inductors see, for example, Refs. [14,15].

- Single-layer cylindrical coil with a circular conductor, Table 11.13a:

$$L_0 = KDn^2 \times 10^{-9}\ \text{(H)} \tag{11.48a}$$

where $K = \text{coefficient}$ whose values are listed in Appendix 11.A.

TABLE 11.13 Inductance L_0 of Various Air Inductors Dimensionally Similar but Having the Same Number of Turns

	Winding (Coil) Dimensions	When Coil Dimensions Are (cm)	Inductance L_0 for $n = 100$ Turns Is (μH)
(a)		$D_1 = 2$ $l = 10$	19
(b)		$s_1 = 1.5$ $s_2 = 2.5$ λ = 0.05 $l = 10$ $d = 0.05$ $G(0.6;4) = 0.4$ $H(1;100) = 0$	32
(c)		$D_1 = 1$ $D_2 = 3$ $D_1 = 2$ $D_2 = 3$	10.3 41
(d)		$D_1 = 2$ $D_2 = 4$ $h = 1$ $D_1 = 1$ $D_2 = 5$ $h = 2$	13.9 64.4
(e)		$D = 2$ $h = 0.5$ $l = 4$	74
(f)		$D = 2$ $h = 0.5$ $l = 0.2$	245

- Single-layer rectangular coil with a circular conductor, Table 11.13b:

$$L_0 = pn^2(G + H) \times 10^{-9} \text{ (H)} \tag{11.48b}$$

where

$G = f_g(S_1/S_2;\ l/S_2)$

$H = f_h(d/\lambda, n)$ = tabulated coefficients [14,15]

- Single-layer toroidal coil, Table 11.13c:

$$L_0 = 2\pi n^2 \left(D - \sqrt{D^2 - D_1^2} \right) \times 10^{-9} \text{ (mH)} \tag{11.48c}$$

- Single-layer ring coil, Table 11.13d:

$$L_0 = 2hn^2 \ln(D_z/D_w) \times 10^{-9} \text{ (H)} \tag{11.48d}$$

- Multilayer long cylindrical coil, Table 11.13e:

$$L_0 = Dn^2[K - 2\pi h(0.693 + \gamma)/l] \times 10^{-9} \text{ (H)} \tag{11.48e}$$

where
K is the coefficient as for the single-layer cylindrical coil
γ is the coefficient whose values are listed in Appendix 11.B

- Multilayer short cylindrical coil, Table 11.13f:

$$L_0 \cong \frac{25\pi D^2 n^2}{3D + 9l + 10h} \times 10^{-9} \text{ (H)} \tag{11.48f}$$

Design guidance: As can be observed, $L = \psi D n^2$, where ψ is a function of two factors: l/D and h/d; and the inductance of air inductor increase when

- Outer diameter of winding increases
- Ratio of outer to inner winding diameter decreases
- Width of winding decreases
- Diameter of wire decreases

This can also be inferred from the last column of Table 11.13 comparing the values of L_0 for dimensionally similar air inductors.

Inductance L_0 can be readily calculated for a specified shape, dimensions, and number of turns of winding. However, this is not a design approach, because the design problem to be solved is inverse: to determine for a given value of L_0 the dimensions, shape, and number of turns of winding. However, such calculations are impossible to perform. This is a consequence of the given geometry of winding of n turns, which results in one and only one geometry of the magnetic flux Φ, therefore, in only one value of the inductance L_0. Inversely, to a given value of L_0 an infinite number of winding geometries may be attributed at any n value.

Thus, the theoretical problem is to obtain the dimensions of the winding in combination with the suitable number of turns n from the specified value of L_0 is mathematically insolvable.

Therefore, the solutions are determined by experimental or iterative numerical methods.

Quality factor of air inductors: Usually it is required that the inductor would have the maximum Q factor or time constant L/R.

For the following cases in Table 11.14: (a) fixed copper (wire) volume; (b) fixed length of wire; and (c) fixed coil volume, the L/R reaches maximum at following proportions of the coil winding.

TABLE 11.14 Dimensional Proportions of Coil Providing Its Maximum Time Constant L/R

		Case	
Winding		$(a)+(b)$	(c)
Cylindrical, single layer		$D \approx 3l$	$D = (1.3–2)l$
Cylindrical	Long	$D = 5h + 3l$	$D = (1.3–1.6)l$
Multilayer	Short		$D = (4–8)l$
			$D = (5–7)h$
Single layer	Toroidal	$D_2 \approx 3D_1$	—
	Ring	$D_2 \approx 1.6D_1$	—

Quality factor of air inductor extends from several units to several hundred and depends on

- Shape and dimensional proportions of winding (Table 11.14)
- Wire pitch and the wire arrangement
- Operating frequency
- Oil self-capacitance
- Material properties of coil former or substrate, wire insulation, proximity of conducting and/or magnetic parts

11.3.2.1 Typical Frequency Ranges of Air Inductors When in Use

In resonant circuits:

- Cylindrical multilayer 50–1000 kHz
- Cylindrical single layer 1 MHz–2 GHz

As chokes:

- Multilayer (multisectional) 10–1000 kHz
- Single-layer 500 kHz–800 MHz

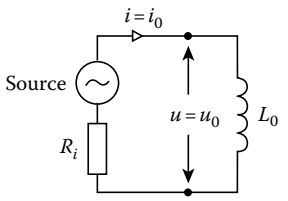
Conductors (wires) used

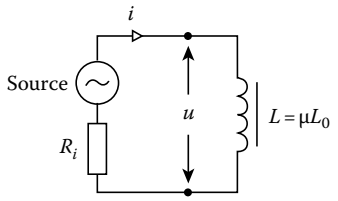
- Solid insulated: dc–200 MHz
- Solid uninsulated: 100 MHz–1 GHz
- Stranded (litz wire): 50 kHz–10 MHz
- Tubular: 3 MHz–3 GHz
- Cu-coated metal: 30 MHz–3 GHz
- Sn- or Ag-coated metal: 0.2–3 GHz
- Sn, Ag, Au conducting path: 0.2–3 GHz

11.3.2.2 Advantages of Air Inductors

- High stability of properties versus temperature, time, and magnetic excitation levels (when compared with cored inductors).
- Very low dependence of inductance on frequency (related mainly to changes of effective dimensions of winding due to skin and proximity effects in wires), therefore, a practically linear dependence of $X_L = \omega L$ on frequency.
- Insaturable dependence of B on i (as opposed to cored inductors) allows the air inductors to produce very high pulses of induction B.

11.3.2.3 Disadvantages of Air Inductors





- Practical inability to obtain dimensionally small inductors of high inductance L, therefore, inherent inability to miniaturization.
- Air inductor acts both as an emitting and receiving antenna, therefore, it is (a) a source of unwanted electromagnetic radiation to surrounding circuitry and environment; (b) a receiver of electromagnetic signals introducing them into circuit as disturbance (usually)—electromagnetic interference (EMI). These strong coupling features make the air inductor a highly incompatible component in electronic circuitry, especially miniaturized, and in electronic and electrical environments.
- Air inductors are made, as a rule, as inductors of fixed value of inductance L. If a change of L is required, connections to some wires (taps) positioned between winding extremities, or a sliding contact to wires for single-layer windings, enable the inductance to be changed.

11.3.3 Cored Inductor

Reason for using the magnetic material in inductors: If a winding of inductance L_0 produces in vacuum (in air) a magnetic flux Φ_0 distributed over some volume and that this volume is completely filled up with a magnetic material of permeability μ, then the inductance L of the so combined winding with the magnetic material is $L = \mu L_0$.

Cored inductor and its parameters in electric circuit: In Table 11.15 the parameters of the inductor are compared for cases when it is immersed in air ($\mu = 1$) and in magnetic material of permeability μ. It is

TABLE 11.15 Inductor-Related Parameters

	Magnetic Material of Permeability, μ		
	Absent	Present, Fully Coupled with Winding	
Parameter	Any Source	Case (a): Constant emf Source ($R_i = 0$)	Case (b): Constant Current Source ($R_i = \infty$)
u =	u_0	u_0	μu_0
i =	i_0	i_0/μ	i_0
B =	B_0	B_0	μB_0
Φ =	Φ_0	Φ_0	$\mu\Phi_0$
H =	H_0	H_0/μ	H_0
L = [a]	L_0	μL_0	μL_0
[a]$L = \Phi/i$ =	$\Phi_0/i_0 = L_0$	$\Phi_0/(i_0/\mu) = \mu L_0$	$\mu\ \Phi_0/i_0 = \mu L_0$
			

Note: Voltage drop u, current i, induction B, magnetic flux Φ, field strength H, inductance L at the absence and presence of magnetic material fully coupled with inductor winding is shown for two limit cases: (a) inductor operates in circuit of constant emf ($R_i = 0$) and (b) in circuit of constant current ($R_i = \infty$).

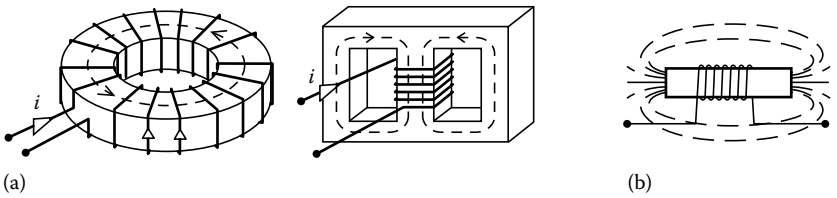


FIGURE 11.51 Examples of (a) closed magnetic circuits and (b) open magnetic circuit.

supposed that the magnetic flux Φ_0 produced by the inductor winding runs completely through the magnetic material (the case of the complete coupling of winding with the magnetic material).

In case (a), the voltage drop across inductor, magnetic induction, and flux remain unchanged while the current through inductor and magnetic field decreases μ times; in case (b), the current and magnetic field remain unchanged, whereas the voltage drop, magnetic induction, and flux increases μ times. The only parameter that increases μ times in all the cases, limit and intermediate ones, $0 < R_i < \infty$, is the inductance $L = \mu L_0$.

The main reason for applying the magnetic material as a core in inductor is to increase its inductance.

Inductor, magnetic core, closed and open magnetic circuit: If the magnetic flux Φ generated by a winding runs for the most of its part through the core being in the possibly strongest coupling with that winding, it is said that this core forms a closed or nearly closed magnetic circuit.

If at the possibly strongest coupling of a winding with a core, the flux Φ runs for its nonnegligible part also through the outside of the core, it is said that the core forms an open magnetic circuit.

The ring core and EE-core illustrate the closed magnetic circuits (Figure 11.51a), whereas the rod core illustrates the open magnetic circuit (Figure 11.51b).

11.3.3.1 Closed Magnetic Circuit

Equivalent dimensions and parameters: The permeance G_m of a toroidal core having a very small radial thickness, magnetic path length l, a uniform cross-section area A, and permeability μ, is given by Equation 11.46c.

If the shape of a core differs from the above radially thin toroid, the calculation of permeance becomes very complex, including the problem formulation and mathematics. To overcome these difficulties, a simplified standard procedure is recommended [3]: a core having the shape different from radially thin toroid, nonuniform cross-sections along magnetic path and often, nonuniform permeability, is replaced by a hypothetic equivalent toroid or ring having the same permeance as the nonuniform core (Figure 11.52).

The parameters of equivalent toroid: the equivalent magnetic path length l_e, equivalent area A_e, equivalent volume V_e, and equivalent permeability μ_e are calculated from the following formulas:

$$l_e = C_1^2/C_2; \quad A_e = C_1/C_2; \quad V_e = l_e A_e = C_1^3/C_2^2 \tag{11.49}$$

and equivalent magnetic parameters:

$$\begin{aligned} &\mu_e = C_1 \Big/ \sum_{i=1}^{v} \frac{l_i}{\mu_i A_i}; \quad B_e = \frac{u}{\omega n} \cdot \frac{C_2}{C_1}; \\ &H_e = ni\frac{C_2}{C_1^2}; \quad \Phi_e = \frac{u}{\omega n} \cdot \frac{C_1^2}{C_2^2} \end{aligned} \tag{11.50}$$

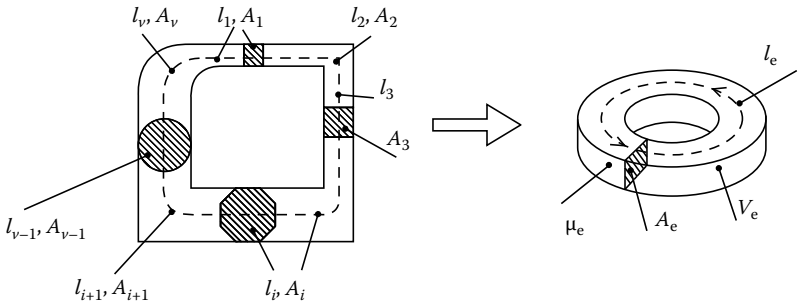

FIGURE 11.52 Nonuniform core and its equivalent toroid or ring having the same permeance.

The core coefficients C_1 and C_2 are calculated as

$$C_1 = \sum_{i=1}^{\nu} \frac{l_i}{A_i}; \quad C_2 = \sum_{i=1}^{n} \frac{l_i}{A_i^2} \tag{11.51}$$

Therefore, the permeances G_m and G_{m0} and reluctances R_m and R_{m0} are

$$G_m = \mu/C_1; \quad G_{m0} = 1/C_1; \quad R_m = C_1/\mu; \quad R_{m0} = C_1 \tag{11.52}$$

Inductance L is

$$L = A_L n^2 = \mu_e A_{L0} n^2 = \mu_0 G_m n^2 = \mu_0 \mu_e G_{m0} n^2 = \mu_0 \mu_e n^2 / C_1 \tag{11.53}$$

The core coefficients C_1, C_2, as well as equivalent dimensions l_e, A_e, and V_e for standardized cores are specified in relevant IEC standards and in core manufacturers' catalogs.

The previously described procedure is a standard averaging procedure (line and surface integrals are replaced by summation) of internationally accepted applicability. This procedure is commonly used in engineering, design, and measuring practice.

Air gap: Reason for introduction: An intentional air gap is introduced into a magnetic circuit of inductors to improve its performance, namely

- To decrease the magnetic material nonlinearity and/or lessen the effect of static magnetic field (bias field) on inductance
- To lessen the magnetic power loss
- To lessen excessive instabilities of the core magnetic material (e.g., thermal)
- To make possible a smooth adjustment of inductance to a very precise value by a special adjusting device or a specially shaped air gap

A closed magnetic circuit of a complicated shape (the EE core—by way of example) made of a material of magnetic permeability μ, and with a small air-gap of length l_g, is shown in Figure 11.53(a). A notional transformation of that circuit into equivalent successive ring cores is presented in Figure 11.53(b). Related permeabilities μ_e and μ_{eg} are also indicated there.

The length of intentional air-gap l_g is usually small compared with magnetic path length l. A ratio l_g/l usually does not exceed a fraction of a percent.

Effect of an air gap on core permeability: The inductance of an inductor having a core with air-gap (at the complete magnetic coupling between winding(s) and core) is given by

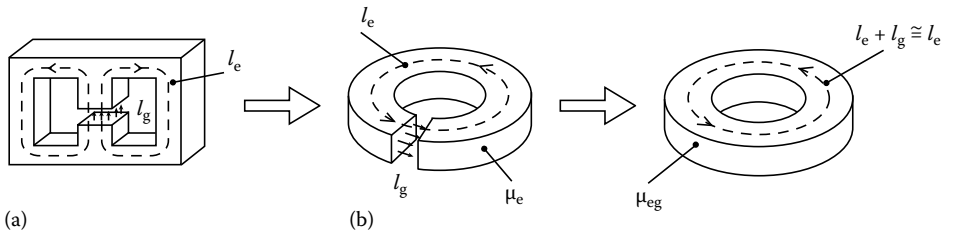

FIGURE 11.53 Ring cores (b) equivalent to the EE gapped core (a).

$$L = \frac{\mu_0 \mu_e n^2}{C_1 \left[1 + (\mu_e - 1)\frac{l_g}{l_e}\right]} = \frac{\mu_0 \mu_{eg} n^2}{C_1} \tag{11.54}$$

where

$$\mu_{eg} = \mu_e \left[1 + (\mu_e - 1)\frac{l_g}{l_e}\right]^{-1} \tag{11.55}$$

μ_{eg} = equivalent permeability of the core with air-gap. The dependence (Equation 11.55) is shown in Figure 11.54.

Equation 11.55 and Figure 11.52 ignore a bulging of the magnetic flux traversing the air gap, Figure 11.55.

Roughly, the bulging is greater as the term $(\mu_e - 1)l_g/l_e = p$ is larger. The bulging, expressed as an apparent increase of the air-gap area $A'_g/A_e = \kappa_g$, becomes perceptible at $p > 1$. The ratio κ_g, known as the bulging factor, can attain an amount of 2 for $p = 30$–60.

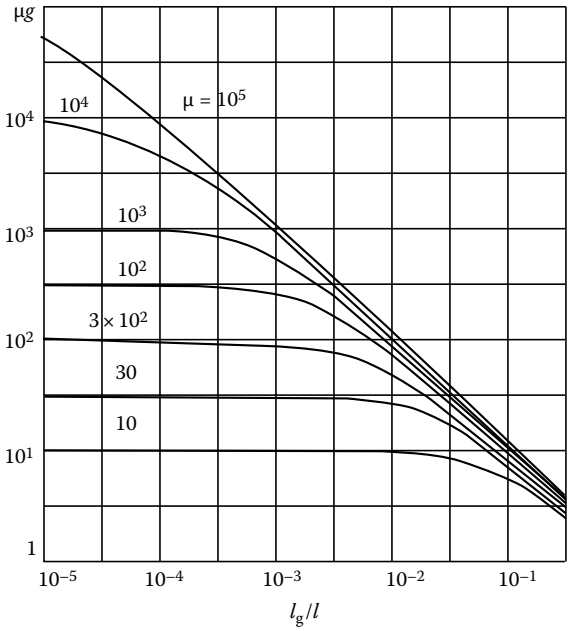

FIGURE 11.54 Equivalent permeability of the core with air-gap versus l_g/l.

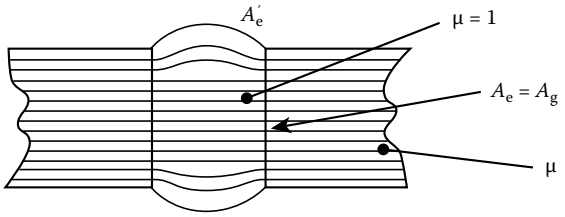

FIGURE 11.55 Bulging of the magnetic flux traversing the air-gap.

A change in flux distribution within the core, resulting from the occurrence of a large reluctance of the air gap in the magnetic circuit, is also ignored in Equation 11.55. In effect, the value of inductance L for larger air gaps is usually higher than that resulting from Equation 11.54.

As the air gap increases, the inductance L becomes less and less dependent on any variation of the magnitude of permeability μ_e. This effect is known as the linearization of cored inductor by the air-gap.

The air-gap effect can be summarized as follows:

The cored inductor winding perceives not the core with material permeability μ, but a core with reduced permeability μ_g lower than μ (or μ_{eg} when dealing with μ_e). Reduction of permeability of gapped core follows (Equation 11.55) depicted in Figure 11.54.

The higher the permeability, the greater the reduction of μ, for example, the air-gap of the same (relative) length $l_g/l = 0.01$ reduces material permeability $\mu = 10{,}000$ by a factor of 100 and that of $\mu = 10$ only by a factor of about 1.1. The use of high permeability materials as cores with larger air gaps is not effective.

Inductor with incomplete coupling: In real cases, the magnetic material forming the core of the inductor does not occupy the whole space where the magnetic flux Φ_0, emanating from the winding, is distributed. The following simplified quantitative approach is in use.

The flux Φ_0 is a sum of a leakage flux Φ_l, which runs completely outside the core and a hypothetical flux Φ_h, which runs completely inside the hypothetical equivalent toroid of permeability μ_e (or μ_{eg}): $\Phi_0 = \Phi_h + \Phi_l$. These three fluxes are related with three respective inductances: $L_0 =$ inductance of winding without core, $L_h =$ inductance of the shape of the hypothetical equivalent toroid, and $L_l =$ leakage inductance whose flux Φ_l does not penetrate into the core:

$$L_0 = L_h + L_l \tag{11.56}$$

Therefore, the inductance of the cored inductor with leakage is

$$L = \mu_e L_h + L_l = (\mu_e - 1)L_h + L_0 \tag{11.57}$$

This formula is very convenient to determine the equivalent permeability from an actual measurement. Because $L_h = \mu_0 n^2/C_1$, L and L_0 are taken from measurement, the equivalent permeability μ_e (or μ_{eg} for the gapped core) can be determined:

$$\mu_e = \frac{L - L_0}{\mu_0 n^2} C_1 + 1 \quad \text{or} \quad \mu_e = \frac{A_L - A_{L0}}{\mu_0} C_1 + 1 \tag{11.58}$$

For phenomenal considerations a so-called winding coupling coefficient $L_h/L_0 = k_w$ introduced. Then,

$$L = L_0[(\mu_e - 1)k_w + 1] \tag{11.59}$$

Apparent permeability: A commonly used parameter quickly characterizing the cored inductor is the apparent permeability μ_{app}:

$$\mu_{app} = L/L_0 = (\mu_e - 1)k_w + 1 \tag{11.60}$$

Equation 11.60 demonstrates whether the winding is completely coupled with the core; then $k_w = 1$, $\mu_{app} = \mu_e$; if $k_w = 0$, $\mu_{app} = 1$: the inductor is coreless; for $0 < k_w < 1$ always $\mu_{app} < \mu_e$ as in most of the real cases. The coupling coefficient is readily calculated from the formula:

$$k_w = (\mu_{app} - 1rrb)/(\mu_e - 1) \tag{11.61}$$

μ_{app} shows directly how many times the presence of the core, being in a given coupling with the winding, increases its inductance L_0.

Low winding coupling strongly lowers the effect of high permeability on the inductance of cored inductor. The high permeability materials are effective only for windings strongly coupled with the core. Such are monolayer windings of the thinnest possible wire, tightly fitting the core along its whole length, with no spacing between neighboring turns. This is in distinct opposition to other practical requirements, such as current load, low self-capacitance, interwire insulation and electrical breakdown, and ease of manufacturing.

Leakage coefficient: Also for the phenomenal considerations, the inductor leakage coefficient $\sigma = L_l/L$ is used. It shows what part of the total inductance L is not related with the core and its properties. The leakage coefficient is calculated as

$$\sigma = (\mu_e - \mu_{app})/\mu_{app}(\mu_e - 1) \quad \text{or} \quad \sigma = (1 - k_w)/\mu_{app} \tag{11.62}$$

If $k_w = 1$ or equivalently $\mu_e = \mu_{app}$, $\sigma = 0$, the inductor is leakage-free; if $k = 0$, then $\mu_{app} = 1$ and $\sigma = 1$, which results in $L = L_0 = L_l$— the leakage inductance is the inductance L_0 of the coreless winding.

Summarizing:

- Coupling coefficient k_w shows the part of the winding flux that is instrumental in carrying the core properties into the inductor properties.
- Leakage coefficient σ shows what part of total inductor properties has no relation with the core properties.
- Core, when not completely coupled with the winding, increases its inductance by amount of only μ_{app}.
- Apparent permeability μ_{app} of the real cored inductor is always lower than the core permeability μ, μ_e, or μ_{eg}.

Joint effect of the air gap and coupling on the cored inductor inductance: Combining the effect of air-gap (Equation 11.55) and that of coupling (Equation 11.59), the formula for the inductance of cored inductor is

$$L = \frac{\mu_e L_0 k_w}{1 + (\mu_e - 1)l_g/\kappa_g l_e} - \left(L_0 - \frac{\mu_0 n^2}{C_1}\right) \tag{11.63}$$

In this formula, two terms are to be distinguished: the first term, being roughly proportional to μ_e, is generally of nonlinear character and carries in itself all magnetic material properties including its instabilities. The second term, between parentheses, being effectively an air coreless inductance, is of purely linear character. Magnetic material properties ''enter'' inductor properties only by the first term.

As the air-gap and leakage become larger, the share of the first term decreases for the benefit of the second term: the inductor linearizes or stabilizes. For the sake of example: for an inductor with an EE42/20 ferrite core of material permeability $\mu \cong 1800$, the ratio of the first to the second term for ungapped core is about 450. If an air-gap of length $l_g = 1$ mm is cut in that core, this ratio drops to about 30. Thus, the linearization here reaches an amount of about 15. This effect is called the linearization or stabilization by the air-gap and/or by the leakage (or coupling).

A cored inductor with coupling $k_w = 1$ and with no air-gap behaves as a pure magnetic material itself, whereas for $k_w = 0$ it becomes a coreless air inductor having the inductance L_0.

11.3.3.2 Open Magnetic Circuit

The most commonly used open magnetic circuit is a cylindrical rod core. The inductor is built by axially placing the rod core inside a cylindrical coil as it is illustrated in Figure 11.56.

Inductors of this type are built as variable and fixed inductance inductors. To vary the inductance, the rod core is moved axially inside the coil. The central axial position of the rod in relation to the coil corresponds to the maximum inductance. In fixed inductance inductors, the movement between the core and coil is not provided.

If the rod core is enclosed by a centrally placed winding, as shown in Figure 11.56, the inductance of such an inductor can be calculated from the following empirical formula:

$$L = L_0[(\mu_r mq - 1)k_{wr} + 1] = L_0\mu_{app} \tag{11.64}$$

where

L_0 is the inductance of the winding without core
μ_r is the equivalent (effective) magnetic permeability of the rod, of similar significance as μ_e for the closed magnetic circuit
m and q are experimentally determined coefficients
k_{wr} is the coupling coefficient

The permeability of the rod μ_r is a complicated function of the material permeability μ and of the ratio of the rod length to the rod diameter l_r/d_r [13]. This function is shown in Figure 11.57a.

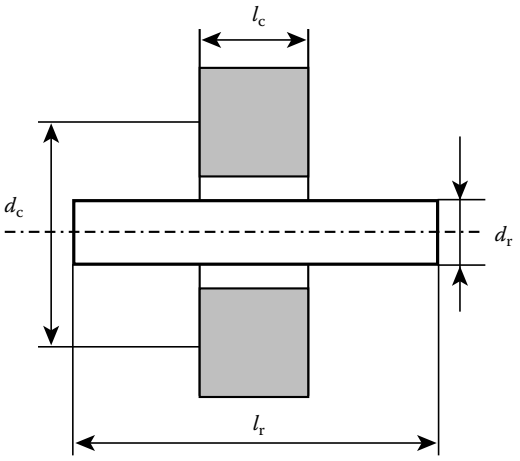

FIGURE 11.56 Open magnetic circuit having a rod core.

The experimental coefficients $m = f(l_c/l_r)$ and $q = f(d_c/d_r)$ are given in Figure 11.57b. The coupling coefficient k_{wr} is

$$k_{wr} = A_{Lh}/A_{L0}[\text{nH}]/[\text{nH}] \tag{11.65}$$

where

$A_{Lh} = Kd_r$, K is the coefficient listed in Appendix 11.A
$A_{L0} = L_0/n^2$, and $L_0 =$ winding inductance

The inaccuracy of the above calculations of L and μ_{app} does not exceed several percent.

As can be inferred from Figure 11.57b, the maximum inductance L is obtained for $mq = 1$, that is, for $l_c \cong 0.83l_r$ and $d_c = d_r$: that is, for the winding of width nearly equal to the rod length and closely fitting the rod diameter. As the winding diameter d_c is larger and winding width is narrower, the core contributes less to the inductor inductance L.

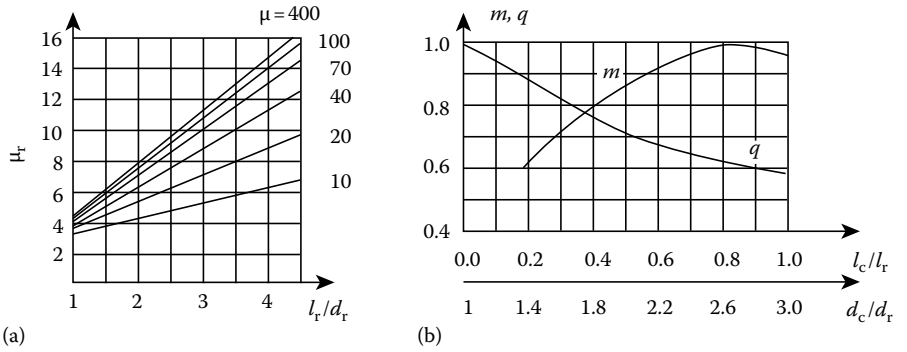

FIGURE 11.57 (a) Equivalent permeability of the rod μ_r versus ratio l_r/d_r for different material permeabilities μ and (b) experimental coefficients m vs. l_c/l_r and q vs. d_c/d_r.

It is often of great importance to estimate the material permeability of the rod core. The calculation inverse to that of Equation 11.64 can allow it: first one calculates $\mu_r = (\mu_{app} - 1 + k_{wr})/mqk_{wr}$, next for the so determined μ_r and given $l/_r/d_r$, the material permeability μ can be found from Figure 11.57a. This method, however, can practically distinguish $\mu < 400$ only and needs to gather very accurate input data and may provide with only approximate μ-values providing that $\mu < 400$.

11.3.3.3 Emerging Inductor-Related Advances

- Ongoing adaption of inductor core's shapes and windings to:
- surface mount technologies (SMT),
- Denser packing (per volume unit) of more and more miniaturized components
- Automatic assembling

Example: low-profile type of ferrite cores.

- Expanding applications of "lumped" inductors over:
- UHF range (300 MHz–3 GHz)

Example: Planar spiral-type inductors and microinductors:

- Frequency range of 300 MHz–1 GHz

Example: "quasi-microwave-range" inductors (air-, cored-, wound, and planar ones).

- Nanocrystalline-core inductors.
- Inductor-based probes, sensors, and microsensors.

11.3.3.4 Power Loss in Inductor

Power loss (in an inductor) is a power that is converted in an inductor into heat and radiation. The total power loss in the inductor is admitted to be a sum of the following contributory losses:

- Resistive loss in winding R_{res}.
- Magnetic loss in core magnetic material R_μ.
- Dielectric loss related to self-capacitance and other parasitic capacitances of the inductor R_d.
- Other losses, for example, radiation loss due to the electromagnetic radiation leaving inductor, loss due to dimensional resonance in the core, loss due to piezomagnetic effects. These losses are not discussed here.

For linear inductors and in the linear range of cored inductors, the power loss P_L is expressed as a tangent of the loss angle δ, tgδ, (Figure 11.50), or equivalently, as the Q-factor ($Q = 1/\text{tg}\delta$). The inductor power loss P_L and tgδ are related by the expressions

$$P_L = \frac{u_{rms}^2}{\omega L_p}\text{tg}\delta = i_{rms}^2 \omega L_s \text{tg}\delta \tag{11.66}$$

where

u_{rms} is the rms value of voltage drop across the inductor
i_{rms} is the rms value of current flowing through the inductor

At high excitation levels, especially in a nonlinear range, the power loss of inductors is expressed directly in watts

Resistive loss in winding: A loss due to a dc resistance (ohmic resistance) of a winding conductor increased by increments due to skin and proximity effects R_{res} referred to the inductive reactance of inductor ωL is

$$\text{tg}\delta_{res} = R_{res}/\omega L \tag{11.67}$$

The precise determination of R_{res}, and especially, a determination of skin and proximity effect contributions, is rather difficult. If an optimization of such winding parameters as a type of conductor (solid, stranded), its diameter, etc., is sought, then a necessary calculation needs a theoretical background [13]. R_{res} has a linear voltage–current character.

Magnetic loss: Depending on whether the excitation level is (1) low, (2) middle, (3) or high, three representations of magnetic loss are accustomed. They are presented next.

(1) Low B (or H) amplitude excitation: A range of B or H amplitudes exists at which μ (B or H) = const.

This corresponds to the case of cored inductors operating at small-signal levels. For this range the notions of complex inductance $\hat{L}$ and complex permeability $\hat{\mu}$ are used.

In series representation—$\hat{Z} = j\omega L + R_s = j\omega\hat{L}_s$:

$$\hat{L}_s = \hat{\mu}_s L_0, \quad \hat{\mu}_s = \mu_s' - j\mu_s'', \quad L_s = \mu_s' L_0, \quad \text{and} \quad R_s = \omega L_0 \mu_s'' \tag{11.68}$$

In parallel representation—$\hat{Y} = 1/j\omega L_p + 1/R_p = 1/\omega\hat{L}_p$:

$$\hat{L}_p = \hat{\mu}_p L_0, \quad 1/\hat{\mu}_p = 1/\mu_p' - 1/j\mu_p'', \quad L_p = \mu_p' L_0, \quad \text{and} \quad R_p = \omega L_0 \mu_p'' \tag{11.69}$$

Magnetic loss tangent tgδμ:

$$\text{tg}\delta_\mu = \mu_s''/\mu_s' = \mu_p'/\mu_p'' \tag{11.70}$$

$$\mu_p' = \mu_s'\left(1 + \text{tg}^2\delta_\mu\right); \quad \mu_p'' = \mu_s''\left(1 + 1/\text{tg}^2\delta_\mu\right) \tag{11.71}$$

In these formulas, $\mu'(=\mu_s'$ or $\mu_p')$ and μδ ($=\mu\delta_s$ or $\mu\delta_p$) are real and imaginary components of the complex magnetic permeability $\hat{\mu}(=\hat{\mu}_s$ or $\hat{\mu}_p)$ in series or parallel representation, respectively.

Note: When the subscript at μ is deleted, the symbol always refers to the series representation.

The complex permeability $\hat{\mu}$ and related parameters are restricted to linear voltage–current (or *B*–*H*) dependences of permeability and loss. It means that μ' represents the dynamic initial permeability and $\mu\delta$ the power loss, which are related solely to only reversible magnetization processes in magnetic material. In that convention the magnetic loss at low excitations is presented usually in form of $\text{tg}\delta\ \mu(f)$ or relative (magnetic) loss factor $\text{tg}\delta\ \mu/\mu_{i(st)}$ ($\mu_{i(st)}$ = static initial permeability).

All previous considerations concerning the contribution of magnetic permeability to the cored inductor properties are extendable to deal with the magnetic loss. With that intent, the permeability μ or μ_e appearing in the formulas of interest should be replaced by the complex permeability $\hat{\mu}$. This simple formal operation results, however, in a serious complication of calculation because of the dealing with complex numbers.

One of the most important results is that the air-gap reduces the loss resistance R_s and $\text{tg}\delta\ \mu$ by the ratio μ'_{eg}/μ':

$$R_{sg} = R_s(\mu'_{eg}/\mu'); \quad \text{tg}\delta_{\mu g} = \text{tg}\delta_{\mu}(\mu'_{eg}/\mu') \tag{11.72}$$

On the other hand, the power loss in magnetic material P_μ remains unchanged for the same core, gapped or ungapped, if it operates at the same induction B; this is because

$$P_\mu = \left(\omega B_p^2 V_e/2\mu_0\right) \times (\text{tg}\delta_\mu/\mu') = \left(\omega B_p^2 V_e/2\mu_0\right) \times \left(\text{tg}\delta_{\mu eg}/\mu'_{eg}\right) \tag{11.73}$$

where

B_P is the peak value of B

V_e is the core equivalent volume

(2) Middle B (or H) amplitude excitations: A range of B or H amplitudes exists where magnetic permeability increases linearly with H: $\mu = \mu_i + \nu H$, magnetic induction B is a parabolic function of H and the hysteresis effects occur (Rayleigh range). The magnetic loss $\text{tg}\delta_\mu$ is here expressed as a sum of eddy-current loss $\text{tg}\delta_F$, residual loss $\text{tg}\delta_n$, and hysteresis loss $\text{tg}\delta_h$:

$$\text{tg}\delta_\mu = \text{tg}\delta_h + \text{tg}\delta_F + \text{tg}\delta_n \tag{11.74}$$

$\text{tg}\delta_h$ is proportional to H or B, $\text{tg}\delta_F$ to frequency, $\text{tg}\delta_n$ is assumed to be a constant. This is visible when other notation (given by Legg) is used:

$$R_s/\mu fL = aB_P + ef + c = 2\pi\text{tg}\delta_\mu/\mu' \tag{11.75}$$

where

a, e, and *c* are the hysteresis, eddy current, and residual loss coefficients, respectively

B_P is the peak value of induction B

The particular loss tangents can be determined as shown in Figure 11.58.

(3) High B (or H) amplitude excitations: A range of the strongest dependence of the permeability μ on induction B (or field strength H) exists, therefore, of the strongest nonlinearity of μ versus excitation. As a rule, the power inductors and transformers operate in that range. In this range, the magnetic power loss P_μ is being expressed by the heuristic Steinmetz expression:

$$P_\mu = \eta f^m B_p^n \tag{11.76}$$

where η = numerical coefficient m and n are experimentally determined Steinmetz exponents, which are approximately constant for a given magnetic material, for example, for power ferrites

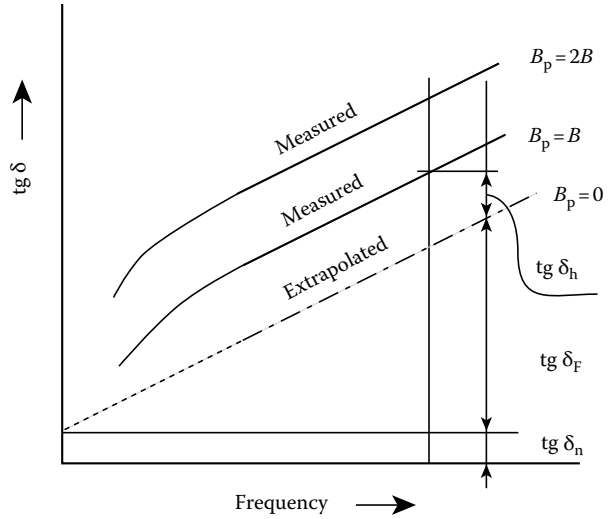

FIGURE 11.58 Determination of the magnetic loss tangents according to (Equation 11.74).

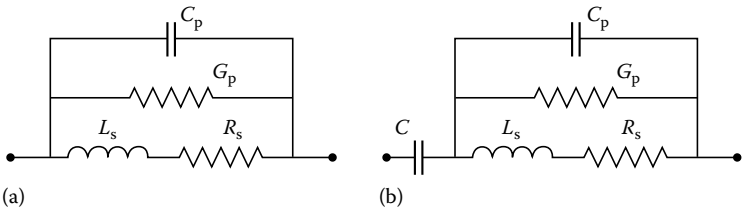

FIGURE 11.59 Self-capacitance C_P and conductance G_P of an inductor L_s, R_s in (a) intentionally nonresonant circuit; (b) in an intentionally series resonant circuit.

$1.2 < m < 1.4$ and $2 < n < 3$ at frequencies between 10 and 100 kHz. For Fe-Si alloys: $1.3 < n < 1.4$ and $1.6 < m < 1.8$ for $f < 500$ Hz. The plots log P_μ versus log f or versus log B_P are therefore straight lines. If these plots deviate from the straight lines, the constancy of exponents m and n deteriorates and the applicability of Equation 11.76 becomes less useful.

Dielectric loss: Every real inductor is inevitably associated with a shunting parasitic capacitance, called self-capacitance C_P, and accompanied conductance $G_P \supseteq C_P$ and G_P result from various capacitive and conductive couplings distributed over a real geometrical assembly of various materials (conducting, insulating) forming the physical body of the inductor. In practice, C_P and G_P are assumed to be as lumped, connected in parallel inductor elements of loss tangent $\text{tg}\delta_d = G_P/\omega C_P$. It is advisable to consider the contribution of $\text{tg}\delta_d$ to overall inductor loss for two cases (1) and (2) [13].

1. Inductor (L_s of $\text{tg}\delta = R_s/\omega L_s$) operating in an intentionally nonresonant circuit, Figure 11.59a

$$\text{tg}\delta_p = \omega^2 L_s C_P \text{tg}\delta_d = \text{tg}\delta_d (f/f_0)^2 \tag{11.77}$$

   where $f_0 = (1/2\Pi)\sqrt{L_s C_P}$ = inductor self-resonant frequency.
2. The same inductor operating in a series LC intentional resonant circuit, Figure 11.57b and, due to the resonant circumstances, $\text{tg}\delta_p$ contributes in that case as $\text{tg}\delta_{pr}$:

TABLE 11.16 Summary of Power-Loss Expressions for the Sinusoidally Excited Inductor

Loss Representation	Low Excitation ($\mu' = \text{const}$)	Middle Excitation ($\mu = \mu_i + \nu H$)	High Excitation (μ—strongly nonlinear)
$\text{tg}\delta_t =$	$\text{tg}\delta_{tl} = \underbrace{\text{tg}\delta_{res} + \overbrace{\mu''/\mu'}^{\text{tg}\delta_\mu^{(b)}}}_{\text{tg}\delta} + \text{tg}\delta_c^{(a)}$	$\text{tg}\delta_{tm} = \underbrace{\text{tg}\delta_{res} + \overbrace{\text{tg}\delta_h + \text{tg}\delta_F + \text{tg}\delta_n}^{\text{tg}\delta_\mu^{(b)}}}_{\text{tg}\delta} + \text{tg}\delta_c^{(a)}$	Not applicable
$R_s =$	$\omega L_s \cdot \text{tg}\ \delta_{tl}$	$\omega L_s \cdot \text{tg}\ \delta_{tm}$	Not applicable
$R_p =$	$R_s(1 + 1/\text{tg}^2\ \delta_{tl})$	$R_s(1 + 1/\text{tg}^2\ \delta_{tm})$	Not applicable
$P_L =$	$i_{rms}^2 \cdot \omega L_s \text{tg}\delta_{tl}$ or $u_{rms}{}^2 \cdot \text{tg}\delta_{tl}/\omega L_p$	$i_{rms}^2 \cdot \omega L_s \text{tg}\delta_{tm}$ or $u_{rms}{}^2 \cdot \text{tg}\delta_{tm}/\omega L_p$	$u_{rms}^2 \left(\frac{R_{res}}{R_{res}^2 + \omega^2 L_0^2} + \omega C_p \text{tg}\delta_d\right)^c$
$P_\mu =$	$\left(\omega B_p^2 V_e/2\mu_0\right) \cdot \left(\mu''/\mu'^2\right)$	$\left(\omega B_p^2 V_e/2\mu_0\right) \cdot \left(\text{tg}\delta_\mu/\mu'\right)$	$\eta f^m B_p^n$

Distinction: low, middle, and high excitation apply only to the cored inductors.

$\text{tg}\delta_t$ = total loss tangent; $\text{tg}\delta_{tl}$ = total loss tangent at low excitation level; $\text{tg}\ \delta_{tm}$ = total loss tangent at middle excitation level.

[a] $\text{tg}\delta_c$ { $\text{tg}\delta_p = \text{tg}\delta_d \cdot (f/f_0)^2$ for inductor operating in a nonresonant circuit, Figure 11.59a; $\text{tg}\delta_{pr} = (2\text{tg}\delta + \text{tg}\delta_d) \cdot (f/f_0)^2$ for inductor operating in a series resonant circuit, Figure 11.59b

[b] For air inductors: $\text{tg}\delta_\mu = 0$ because $\mu' = 1$ and μ'', $\text{tg}\delta_h$, $\text{tg}\delta_F$, $\text{tg}\delta_n$, P_μ equal zero.

[c] For air inductor. For cored inductor P_L is practically not calculable because of the distorted signal.

$$\text{tg}\delta_{pr} = \omega^2 L_s C_p (2\text{tg}\delta + \text{tg}\delta_d) = (2\text{tg}\delta + \text{tg}\delta_d)(f/f_0)^2 \tag{11.78}$$

Because the value of $\text{tg}\delta_d$ may come up even to 0.1, the product $L_s C_p$ should be as low as possible to make the self-resonant frequency $f_0 \gg f$. As an example, for an inductor having $\text{tg}\delta = 0.004$ (Q-factor = 250) and $\text{tg}\delta_d = 0.02$, $(f/f_0)^2 = 0.1$, the degraded Q-factor attains 170 in case (1) and 150 and in case (2). Additionally, $\text{tg}\delta_d$ is very sensible to any climatic factors and different agents; the case is known that a low value $\text{tg}\delta_d$ increased by nearly 200 times in a hot humidity environment.

Inductor total power loss: Different representations of total power loss in inductor are summarized in Table 11.16.

11.3.4 Nonlinearity in Inductors

The cored inductors are nonlinear except when the excitation does not exceed the level where $\mu(B$ or $H) = \text{const}$. The most current three characteristics of inductor expose the extent of nonlinearity:

- Inductance versus ac current or applied voltage
- Inductance versus dc bias current or voltage with superimposed ac current or voltage
- Harmonic content versus specified excitation

The nonlinearity of a cored inductor is due to hysteretic properties of the core material, which result in coercive and remanence effects. That peculiarity of magnetic material causes both multivalent and multivalued characters of nonlinearity in cored inductors. In addition, in many circumstances the nonlinearity can also be time dependent, for example, the harmonic content can vary with time.

Generally, the nonlinearity occurs when the core permeability becomes excitation dependent. Such excitation-dependent permeability is termed as amplitude permeability μ_a.

Numerous phenomenal expressions are used for dependence of amplitude permeability μ_a on excitation. The most well known are expressions for the Rayleigh range of excitations given by

$$\text{Rayleigh:} \quad \mu_a = \mu_i + \nu H; \tag{11.79}$$

$$\text{Peterson:} \quad \mu_a = \alpha_0 + \alpha_1 H + \alpha_2 H^2 + \cdots \tag{11.80}$$

where

μ_i is the initial permeability
ν is the Rayleigh constant
α_0, α_1, α_2, and so on are the Peterson coefficients

Today, these expressions are of lesser importance because any experimentally obtained dependence of an inductor on excitation can be numerically processed and used for overall nonlinear analysis (e.g., of signal distortion) in a given circuit. All previously given relationships between the permeability and inductance are to be observed in that analysis.

A practical manner of lowering the nonlinearity of an inductor (for a given core material) is to increase the air-gap length and/or to decrease the coupling coefficient k_w, or to lower the induction B in the core.

For the sake of an example, the third harmonic content, $\text{THC} = \text{emf}_{3f}/\text{emf}_f$ of the ungapped core is related to tangent of material hysteresis loss $\text{tg}\delta_h$ in the Rayleigh range by the formula

$$\text{THC} = 0.6\text{tg}\delta_h \tag{11.81}$$

For the gapped core, this formula transforms into

$$\text{THC}_{\text{gapped}} = \text{THC}_{\text{ungapped}} \times (\mu_{eg}/\mu) \tag{11.82}$$

Generally, for a given core material, the most nonlinear inductor is that equipped with a core having an ungapped magnetic circuit (e.g., a toroid); the least nonlinear is the inductor having an open short core (e.g., a rod core of low length to diameter ratio).

The nonlinear core related relationships are strongly frequency dependent and, nearly as a rule, decrease as the frequency increases.

11.3.5 Magnetic Core Materials

For inductor core applications, three families of soft magnetic materials are concerned:

- Ferrites, mainly Mn–Zn and Ni–Zn, being solid polycrystalline ceramics in whatever form they may be
- Iron and/or nickel based alloys (Fe, Fe–Si, Fe–Ni, Fe–Co, Ni–Mn, Ni–Mn–Mo, etc.) in the form of laminations, strips, and ribbons
- Pure iron and Fe–Ni or Ni–Mn, etc., alloys in the form of fine powders (2–150 μm) with individual particles that are bonded and electrically insulated by polymers

The most distinctive features of these three families are listed in Table 11.17.

Recently developed amorphous and nanocrystalline magnetic materials gained as of yet a moderate use in inductor applications. Some ring power chokes used as core-wound amorphous ribbons have advantageous properties at the kHz range.

The basic characteristics of magnetic materials for inductor applications are depicted in Figure 11.60.

11.3.6 Magnetic Materials Measurements: Basic Methodological Principles

For the measurements of magnetic properties and characteristics of a magnetic material as, for example, its magnetic permeability, quality factor or power loss, the sample (core) being made of that material shall have a ring or toroidal shape in which:

TABLE 11.17 Three Main Families of Magnetic Materials Used as Cores in Inductors

Family	B_s (T)	μ_i	ρ (Ωm)	f_w
Ferrites	Low: <0.6	8–20,000	High: 10^0–10^9	1 kHz–2 GHz
Fe, Ni alloys	High: 0.8–2.4	200–100,000	Low: (1–50)10^{-9}	dc—400 Hz (up to 50 kHz)[a]
Bonded powders	Medium: <1.2	4–150	Low: $\sim 10^{-7}$	dc—100 kHz (up to 10 MHz)[a]

B_s = saturation induction; μ_i = initial permeability; ρ = dc resistivity; f_w = typical working frequency range.
[a] For very small material thickness.

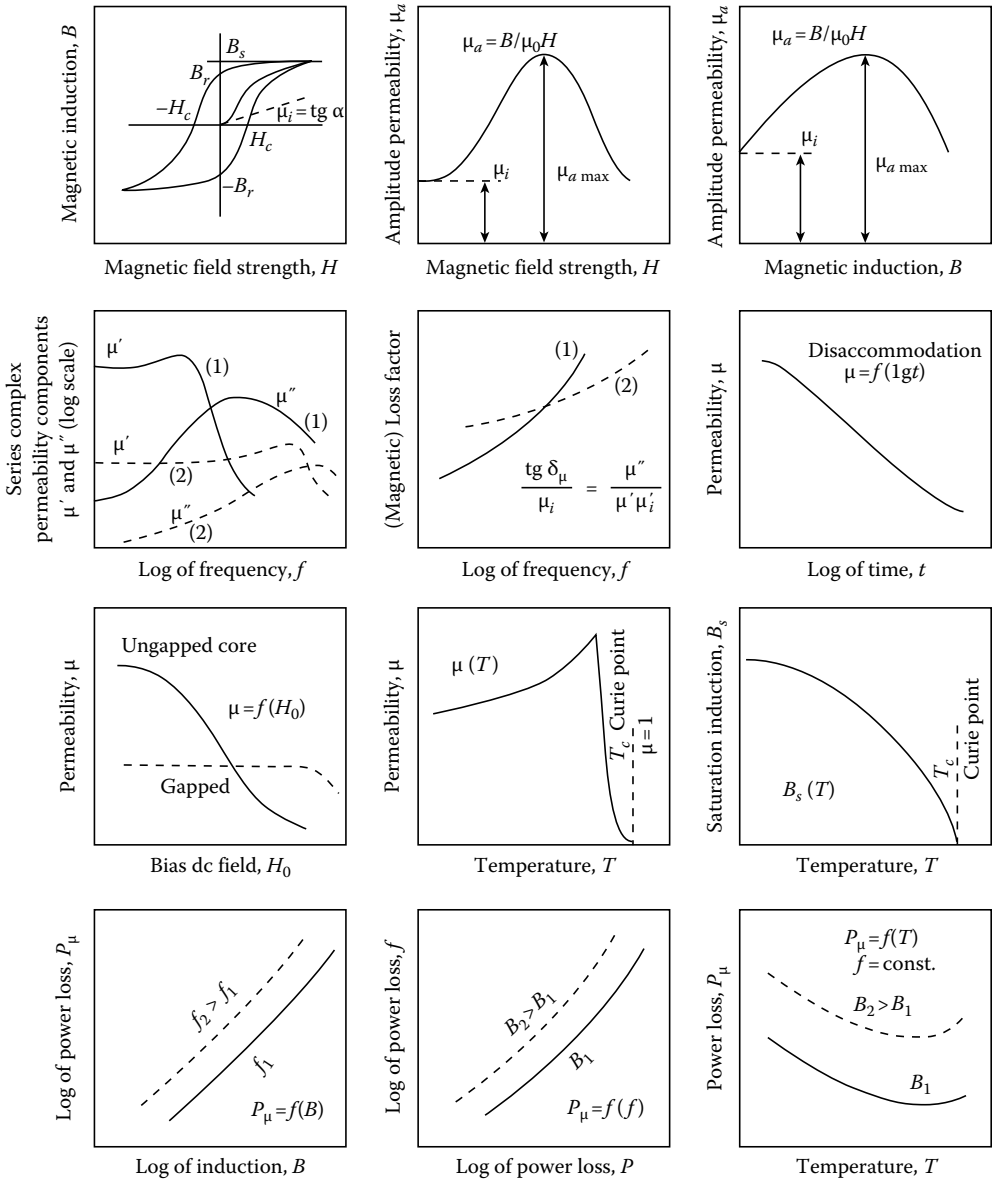

FIGURE 11.60 Basic characteristics of magnetic materials essential for inductor applications.

1. There are no transversal (to the magnetic flux path) air gaps.
2. The ratio of outer to inner diameter shall not be greater than 1.4.
3. The measuring winding(s) shall be distributed uniformly along the circumference of the core, close to its surface, so as to get the inductive coupling coefficient between the core and the winding(s) approaching one. (This stipulation becomes more critical as the magnetic permeability of the core is low.)

Besides, the core to be measured shall be magnetically or thermally conditioned (past terms: neutralized, demagnetized) to arrive at a well-defined and reproducible magnetic state of the material.

This operation shall take place at a determined period of time before the start of each measurement or before a sequence of measurements, depending on a prescribed measuring procedure.

11.3.7 Physical Irregularities

Physical irregularity stands for inconsistency of the state or quality of the core surface, bulk or shape with their intended regularity.

The irregularities and their locations give, as a rule, a detrimental or critical effect on functional properties of magnetic cores, components and devices and, in consequence, on their applicative usefulness.

A detailed categorization, related nomenclature, and graphical examplification of most physical irregularities occurring in ferrite cores are provided in the International Standard IEC 60401-1: *Terms and nomenclature for cores made of magnetically soft ferrit—Part 1: Terms used for physical irregularities.*

11.3.8 International Standards on Inductors

International standardization activities on inductors, their attributes, applications and testing are managed by the Technical Committee 51 (TC51) ''Magnetic Components and Ferrite Materials'' of the International Electrotechnical Commission (IEC).

The International Standards (Publications) issued by the IEC/TC51 in years 1972-2007, in a number of 62, can be classified into 6 groups as below:

1. Terminology and specific nomenclature (6 Stds)
2. Shapes and dimensions (19 Stds)
3. Design and calculations: guidelines and formulas (3 Stds)
4. Measuring methods and procedures (13 Stds)
5. Specific features and characteristics (19 Stds)
6. Marketing (2 Stds)

The list of the current IEC/TC51 Standards is available at http://www.iec.ch. Some of them are given, for example, in Refs. [6–12].

Defining Terms

Amplitude permeability: The permeability obtained from the peak value of the induction and the peak value of the applied field strength when the field is varying periodically with time, the average of the field over the time is zero, and the material is initially in a neutral state.

Choke: A device, being an inductor, used in a special application to impede the current in a circuit over a specified frequency range while allowing relatively free passage of the current at lower frequencies.

Complex permeability: The complex quotient of the induction in the material and the product of magnetic constant and field strength, at the excitation range, where both the induction and field vary sinusoidally with time.

Inductor: A device consisting of one or more associate windings, with or without magnetic core, for introducing inductance into an electric circuit.

Initial permeability: The limiting value of the amplitude permeability when the field strength is vanishingly small.

Loss angle of inductor: The angle by which the fundamental component of passing current lags the fundamental component of the fundamental voltage.

Magnetic core: A configuration of magnetic material, which is placed in a specific geometrical position in relation to current-carrying conductors and whose magnetic properties are essential to its use.

Magnetic power loss: The power loss in a magnetic material when it is magnetized.

Physical irregularity: The inconsistency of the state or quality of the magnetic core surface, bulk, or shape with their intended regularity.

Planar (or chip) inductor: An inductor consisting of a small piece of chip-like, nonconductive magnetic or nonmagnetic material—substrate—onto which is deposited, etched, or printed a conductive pattern in the form of a circular or rectangular spiral. Planar inductors may be structured as single or multilayered devices.

Power loss: The power expended without useful work and converted into heat and/or nonintended radiation.

Quality factor: The magnitude of the ratio of the inductor effective reactance to its effective resistance at a given frequency (reciprocal of the tangent of the loss angle of the inductor).

Tangent of the loss angle (of inductor): The magnitude of the ratio of the inductor effective resistance to its effective reactance at a given frequency (reciprocal of the quality factor of the inductor).

Tangent of the magnetic loss angle: The ratio of the imaginary component of the complex permeability (of a material) to its real component.

Winding: A conductive path, usually of wire, consisting of one (single-loop winding) or more turns, usually forming a spiral.

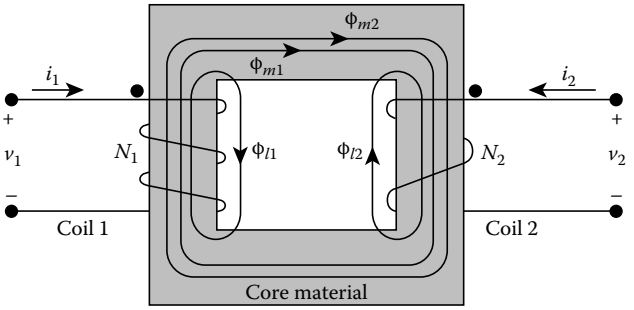
11.4 Transformer

11.4.1 Introduction



The transformer is a two-port passive circuit element that consists of two coils that are coupled magnetically, but have no conductive coupling. It is shown diagrammatically in Figure 11.61, where the dots by one end of each coil indicate that the magnetic fluxes, Φ_{m1} and Φ_{m2} are in the same direction when both currents either enter or leave by the dot marked terminal. Coil 1 is connected to the transformer input terminals and is called the primary winding. Coil 2 is called the secondary winding and is connected to the transformer output terminals.

A transformer can be used to connect a source to a load and comes in a wide range of sizes. The sizes include very large power-distribution transformers and very small transformers used in electronic equipment. The coils of some transformers used in electronic equipment are wound on a nonmagnetic core such as plastic. These transformers are called air-core transformers. All transformers used in power-distribution systems and some transformers used in electric equipment use an iron core, which produces a coupling coefficient of nearly unity. The coupling coefficient for an air-core transformer seldom exceeds 0.5.

Four major characteristics of transformers are as follows:

1. Accept energy at one voltage and deliver it at a different voltage.
2. Change the load impedance as seen by the source.
3. Provide conductive isolation between two portions of a circuit.
4. Produce bandpass signal filters when combined with capacitors.

The first characteristic indicated is commonly used in electric power-distribution systems since higher voltages are desired for electric energy transmission than can be safely used by the customer. The higher

N_1 = number of turns in coil 1

N_2 = number of turns in coil 2

Φ_{l1} = leakage flux due to current i_1

Φ_{l2} = leakage flux due to current i_2

Φ_{m1} = magnetizing flux due to current i_1

Φ_{m2} = magnetizing flux due to current i_2

$\Phi_1 = \Phi_{l1} + \Phi_{m1}$
= total flux due to current i_1

$\Phi_2 = \Phi_{l1} + \Phi_{m2}$
= total flux due to current i_2

$k_2 = \dfrac{\Phi_{m1}}{\Phi_1}$
= coupling factor for coil 1

$k_2 = \dfrac{\Phi_{m2}}{\Phi_2}$
= coupling factor for coil 2

$k_1 = \sqrt{k_1 k_2}$ = transformer coupling coefficient < 1

FIGURE 11.61 Transformer diagram and definitions.

transmission voltage produces lower transmission current, which requires smaller transmission line conductors.

The output stage of an audio amplifier may include a transformer to provide the second and third characteristics listed. In this way, the low impedance of the speaker is matched to the higher output impedance of the power amplifier to yield maximum power transfer for the signal. The isolation property permits the isolation of dc biasing voltages in the amplifier from the speaker coil to avoid magnetic flux saturation in the coil.

Finally, a transformer may be used with capacitors for interstage coupling in a radio frequency amplifier. The inductance of the transformer coils and the capacitance of the capacitors can be adjusted to produce bandpass filtering for signals.

This section presents linear mathematical models for transformers. The models are in terms of phasors and impedances; that is, they are frequency-domain models. The section begins with a first-order model known as the ideal transformer. A nonideal linear transformer model that includes transformer inductive and resistive effects is then shown.

11.4.2 Ideal Transformer

The ideal transformer models the first three transformer characteristics listed above with an ideal, lossless, circuit element. It is a reasonably good model for a transformer with a nearly unity coefficient

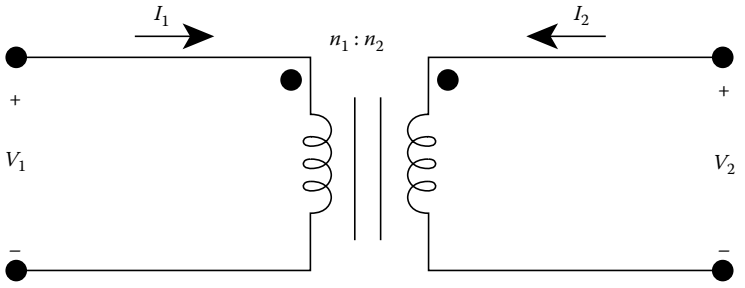


FIGURE 11.62 Circuit symbol for the ideal transformer.

of coupling and primary and secondary coil inductive impedances that are very large with respect to source and load impedances. Well-designed, iron-core transformers have approximately these characteristics over a reasonable range of frequencies and terminating impedances. A circuit symbol that is often used for an ideal transformer is shown in Figure 11.62, where $a = n_1/n_2 \cong N_1/N_2$ is the effective turns ratio. In place of the lines between the coils, which are intended to indicate the similarity to an iron-core transformer, the word ideal or the equation $k = 1$ may be written below the coils to identify an ideal transformer.

The equations that represent the ideal transformer model are $\boldsymbol{V}_2 = \boldsymbol{V}_1/a$ and $\boldsymbol{I}_2 = -a\boldsymbol{I}_1$. Thus, the voltages are in the same ratio as the effective turns ratio. Also, the ideal transformer is lossless since the complex power supplied by the source $\boldsymbol{V}_1\boldsymbol{I}_1^*$ equals the complex power absorbed by the load $-\boldsymbol{V}_2\boldsymbol{I}_2^*$. The hybrid-$h$-parameter two-port equation that represents the ideal transformer model is

$$\begin{bmatrix} V_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} 0 & a \\ -a & 0 \end{bmatrix} \begin{bmatrix} I_1 \\ V_2 \end{bmatrix} \tag{11.83}$$

If the load impedance $\boldsymbol{Z}_L$ is connected to the output terminals of an ideal transformer, then $\boldsymbol{V}_2 = -\boldsymbol{I}_2\boldsymbol{Z}_L$. In this case, the impedance seen by a source connected to the input terminals is

$$Z_{eq} = \frac{V_1}{I_1} = \frac{(aV_2)}{\left(-\frac{1}{a}I_2\right)} = a^2 Z_L \tag{11.84}$$

Thus, the impedance seen by the source is the square of the effective turns ratio times the load impedance.

11.4.3 Nonideal Transformer

The ideal transformer is not an adequate transformer model when the coefficient of coupling is not near unity and/or the load and source impedances are not negligible with respect to the transformer-coil inductive impedances. Also, it cannot be used to investigate the signal filtering that can be performed with a transformer and capacitors. In these cases, a more detailed model is required.

11.4.3.1 Linear Transformer

The linear transformer model is shown in Figure 11.63. R_1 and R_2 are the resistances and L_1 and L_2 are the self-inductances of the two transformer coils. M is the mutual inductance corresponding to the magnetic coupling of the coils.

The linear transformer is a reasonable model for an air-core transformer since the magnetic flux is proportional to the current. The self-inductances are

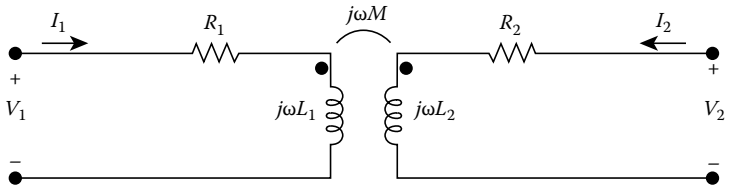

FIGURE 11.63 Linear transformer model.

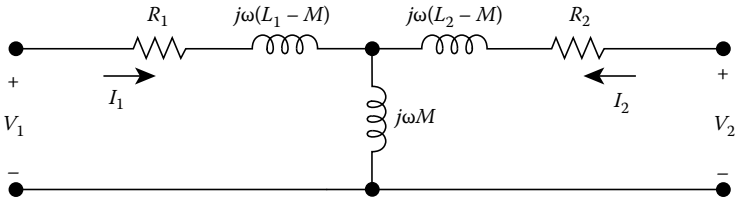

FIGURE 11.64 Equivalent *T*-network representation of a linear transformer.

$$L_1 = N_1 \frac{\Phi_1}{\mathbf{i}_1}; \quad L_2 = N_2 \frac{\Phi_2}{\mathbf{i}_2} \tag{11.85}$$

and the mutual inductance is

$$M = k\sqrt{L_1 L_2} \tag{11.86}$$

From Figure 11.63, the impedance-parameter two-port equations for the linear-transformer model are

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} R_1 + j\omega L_1 & j\omega M \\ j\omega M & R + j\omega L_2 \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} \tag{11.87}$$

Except for its isolation characteristics, the linear transformer in Figure 11.63 can be represented by the equivalent *T*-network shown in Figure 11.64, since this network produces Equation 11.87. The *T*-network is completely equivalent to the nonisolating linear transformer that is produced when the lower ends of the two coils are conductively connected.

11.4.3.2 Leakage and Magnetizing Inductances

The nonideal linear-transformer circuit model can be changed, so it is expressed in terms of leakage inductance and magnetizing inductance instead of self-inductance and mutual inductance. This is convenient because the effects produced by the coil resistance and leakage inductance are nearly linear. Thus, the approximation required to produce a linear model is primarily contained in the magnetizing inductance.

From Figure 11.61 and Equation 11.85, the magnetizing and leakage inductances for coil 1 are, respectively,

$$L_{m1} = \frac{N_1 \Phi_{m1}}{i_1} = k_1 L_1 \tag{11.88}$$

and

$$L_{\ell 1} = \frac{N_1 \phi_{\ell 1}}{i_1} = (1 - k_1) L_1 \tag{11.89}$$

Therefore,

$$L_1 = L_{\ell 1} + L_{m1} \tag{11.90}$$

Similarly, for coil 2,

$$L_{m2} = \frac{N_2 \phi_{m2}}{i_2} = k_2 L_2 \tag{11.91}$$

$$L_{\ell 2} = \frac{N_2 \phi_{\ell 2}}{i_2} = (1 - k_2) L_2 \tag{11.92}$$

and

$$L_2 = L_{\ell 2} + L_{m2} \tag{11.93}$$

are the magnetizing, leakage, and self-inductances.

Using Figure 11.61 and Equation 11.86, we can write the mutual inductance as

$$\begin{aligned} M &= \sqrt{k_1 k_2}\sqrt{L_1 L_2} = \sqrt{k_1 L_1 k_2 L_2} \\ &= \sqrt{L_{m1} L_{m2}} \\ &= a L_{m2} = \left(\frac{1}{a}\right) L_{m1} \end{aligned} \tag{11.94}$$

where

$$\sqrt{\frac{L_{m1}}{L_{m2}}} \equiv \frac{n_1}{n_2} = a \cong \frac{N_1}{N_2} \tag{11.95}$$

is the effective turns ratio. How closely the effective turns ratio n_1/n_2 approximates the actual turns ratio N_1/N_2 depends on how completely all magnetic flux links all coil turns. This is a function of the coil and core geometry.

11.4.3.3 Circuit Model

Substitution of the leakage inductances, magnetizing inductances, and effective turns ratio into Equation 11.87 produces an alternate form for the impedance-parameter two-port equations for the linear transformer model. These equations are

$$\begin{aligned} \mathrm{V}_1 &= [R_1 + j\omega(L_{\ell 1} + L_{m1})] I_1 + j\omega L_{m1} \left(\frac{1}{a}\right) I_2 \\ &= (R_1 + j\omega L_{\ell 1}) I_1 + j\omega L_{m1} (I_1 - I_{\mathrm{a}}) \end{aligned} \tag{11.96}$$

and

$$\begin{aligned} V_2 &= j\omega L_{m1} \left(\frac{1}{a}\right) I_1 + [R_2 + j\omega(L_{\ell 2} + L_{m2})] I_2 \\ &= \left(\frac{1}{a}\right) V_{\mathrm{a}} + (R_2 + j\omega L_{\ell 2}) I_2 \end{aligned} \tag{11.97}$$

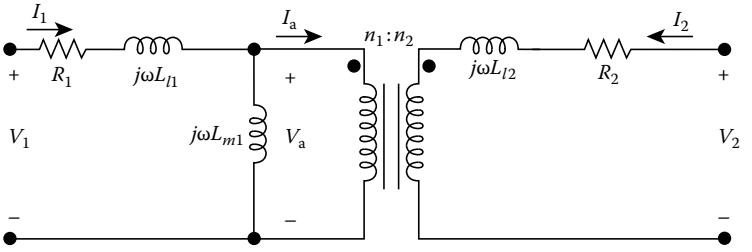

FIGURE 11.65 Linear circuit model for a nonideal transformer.

where

$$I_a = -\left(\frac{1}{a}\right) I_2 \tag{11.98}$$

and

$$\begin{aligned} \mathrm{V_a} &= j\omega L_{m1}\mathrm{I_1} + j\omega a L_{m2}\mathrm{I_2} \\ &= j\omega L_{m1}(\mathrm{I_1} - \mathrm{I_a}) \end{aligned} \tag{11.99}$$

The transformer circuit model that produces Equations 11.96 through 11.99 is depicted in Figure 11.65.

The only energy losses in the transformer that are accounted for by the linear model depicted in Figure 11.65 are the heating losses in the coils (called copper losses). An iron-core transformer also has heating losses in the core material (called core losses). The core losses have two components. The first component is hysteresis losses. Hysteresis is the nonlinear phenomenon that causes the magnetic flux response to increasing current to be different from the response to decreasing current. The plot of flux as a function of current traces out a closed curve called a hysteresis loop. The area inside this loop is proportional to the energy that produces core heat.

The second component of transformer core losses is eddy-current losses. This is a heating loss caused by currents (called eddy currents) that flow in the transformer core due to the voltage induced in the core material by the changing flux. The eddy-current losses can be decreased by laminating the core material to reduce the voltage induced in an eddy-current path and thus the eddy-current value.

Core losses are caused by nonlinear effects in the magnetic circuit formed by the transformer core. However, they can be approximately included in a linear transformer circuit model by introducing a resistance in parallel with the magnetizing inductance. This improves the linear model accuracy in modeling terminal-characteristics of the transformer. The resulting circuit model is shown in Figure 11.66, where I_{el} is

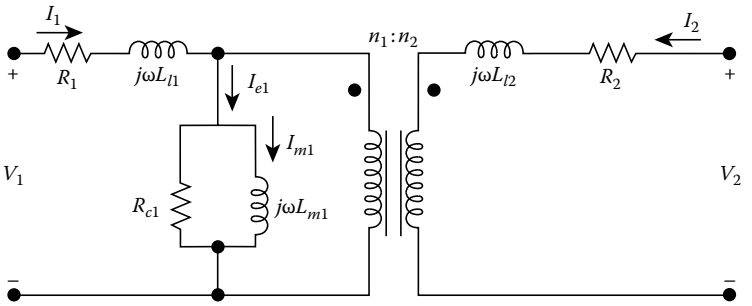

FIGURE 11.66 Linear circuit model for a nonideal transformer—including core losses.

called the excitation current, I_{ml} is called the magnetization current, and R_{cl} is the resistance used to model the core losses.

Defining Terms

Transformer: A two-port passive circuit element consisting of two magnetically coupled coils that are not conductively connected.
Air-core transformer: A transformer with a nonmagnetic core.
Source: Signal generator that supplies energy to a network.
Load: Device that converts electrical energy supplied to a useful output. Modeled as an impedance.
Magnetic flux: A magnetic field descriptor. It is thought of as lines indicating the direction of force that the magnetic field produces on a moving charge. The density of the lines indicates the force.
Primary winding: Transformer input coil.
Secondary winding: Transformer output coil.
Leakage inductance: Magnetic flux that links only one coil.
Magnetizing inductance: Magnetic flux that links both coils.

Further Information

More detailed developments of linear transformer circuit models can be found in most circuit analysis texts. Two example texts are Refs. [1,3].

Power transformers and their models are presented in considerable detail in electrical machinery texts such as Ref. [6]. These presentations also extend to multiple-coil, three-phase transformers, and tapped transformers. Included in most electrical machinery texts are in-depth discussions of hysteresis and eddy currents, and of methods for reducing losses due to these effects. Also included are procedures for measuring the parameters for transformer circuit models.

The use of transformers in electronic circuits is considered in electronic circuit design texts and reference books such as Refs. [4,8]. Amplifier circuit models that include transformer circuit models are developed in some texts for tuned transformer coupled amplifier stages and transformer coupled load impedances. It is demonstrated how these models can be used to determine amplifier frequency response and power transfer to the load. Other uses indicated for transformers in electronic circuits occur in power supplies and isolation amplifiers.

11.5 Semiconductor Diode

Semiconductor diodes are made out of p–n semiconductor junctions. Nonlinear current–voltage characteristics of such junctions are used to rectify and shape electrical signals. Exponential current–voltage characteristics are sometimes used to build logarithmic amplifiers. The variations of junction capacitances with applied voltages are used to tune high-frequency electronic circuits. The semiconductor p–n junction illuminated by light will generate a voltage on its terminals. Such a diode is known as a solar battery. Also, the reverse diode current is proportional to the light intensity at the junction. This phenomenon is used in photodiodes. If a diode is biased in the forward direction, it can generate a light. In order to obtain high emission efficiency the light emitting diode (LED) should be made out of a semiconductor material with a direct energy band structure. This way electrons and holes can recombine directly between valence and conduction bands. Typically, LEDs are fabricated using various compositions of $Ga_yAl_{1-y}As_xP_{1-x}$. The wavelength of generated light is inversely proportional to the potential gap of a junction material. When a light intensity is enhanced by additional micromirrors, then laser action occurs. The silicon diodes are not emitting light because the silicon has an *indirect* band structure and the probability of direct band-to-band recombination is very small.

When both sides of the junction are very heavily doped, then for small forward-biasing voltages (0.1–0.3 V), a large tunneling current may occur. For larger forward voltages (0.4–0.5 V), this tunneling current vanishes. This way the current–voltage characteristic has a negative resistance region somewhere between 0.2 and 0.4 V (Figure 11.68d). Germanium and other silicon semiconductors are used to fabricate tunnel diodes. The backward diode has slightly lower impurity concentrations than the tunnel diode and the tunneling current in the forward direction does not occur (Figure 11.68e). The backward diode is characterized by very sharp knee near zero voltage, and it is used for detection (rectifications) of signals with very small magnitude.

Diodes with high breakdown voltage have a p–i–n structure with an impurity profile shown in Figure 11.67d. Similar p–i–n structure is also used in microwave circuits as a switch or as an attenuating resistor. For reverse biasing, such a microwave p–i–n diode represents an open circuit with a small parasitic junction capacitance. In the forward direction this diode operates as a resistor whose conductance is proportional to the biasing current. At very high frequencies, electrons and holes will oscillate rather than flow. Therefore, the microwave p–i–n diode exhibits linear characteristics even for large modulating voltages. Another interesting ''diode'' structure has the impurity profile shown in Figure 11.67f. When reverse biasing exceeds the breakdown voltage, this element generates a microwave signal with a frequency related to the electron transient time through structure. Such a diode is known as an IMPATT (IMPact Avalanche Transit Time) diode.

The switching time of a p–n junction from the forward to the reverse direction is limited by the storage time of minority carriers injected into the vicinity of the junction. Much faster operation is possible in the Schottky diode, where minority carrier injection does not exist. Another advantage of the Schottky diode is that the forward voltage drop is smaller than in the silicon p–n junction. This diode uses the metal–semiconductor contact for its operation. Schottky diodes are characterized by relatively small reverse breakdown voltage, rarely exceeding 30 V.

11.5.1 Nonlinear Static *I–V* Characteristics

Semiconductor diodes are characterized by nonlinear current–voltage characteristics. Typical *I–V* diode characteristics are shown in Figure 11.68. In the case of a common silicon diode, the forward-direction current increases exponentially at first, and then is limited by an ohmic resistance of the structure. A very small reverse current at first increases slightly with applied voltage and then starts to multiply near the breakdown voltage (Figure 11.69). The current at the breakdown is limited by ohmic resistances of the structure.

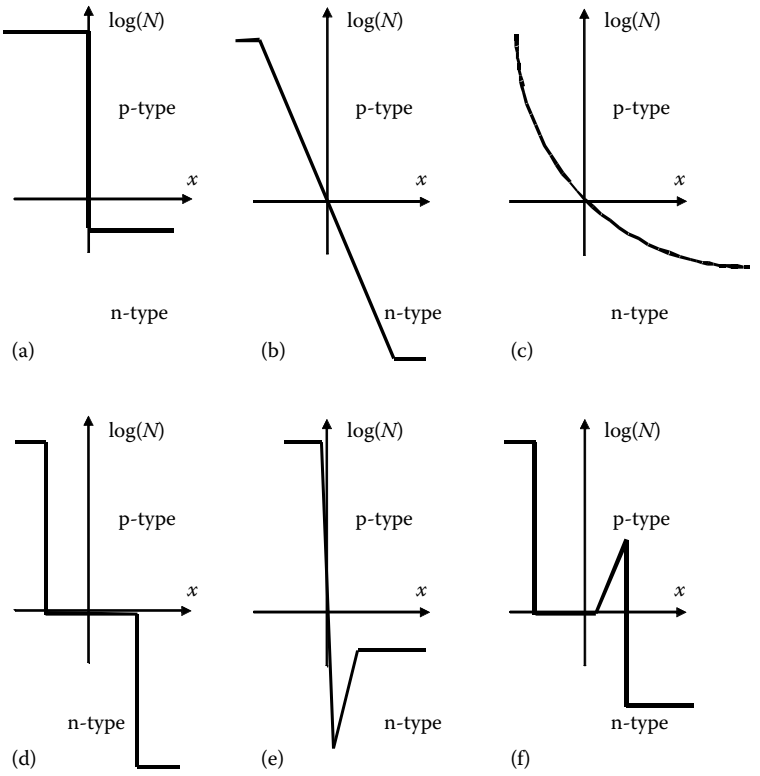

FIGURE 11.67 Impurity profiles for various diodes: (a) step junction; (b) linear junction; (c) diffusion junction; (d) p–i–n junction; (e) p–n^+–n junction; (f) p–i–p–n junction.

11.5.1.1 p–n Junction Equation

The n-type semiconductor material has a positive impurity charge attached to the crystal lattice structure. This fixed positive charge is compensated by free moving electrons with negative charges. Similarly, the p-type semiconductor material has a lattice with a negative charge that is compensated by free moving holes, as Figure 11.70 shows. The number of majority carriers (electrons in p-type and holes in n-type materials) is approximately equal to the donor or acceptor impurity concentrations, that is, $n_n = N_D$ and $p_p = N_A$. The number of minority carriers (electrons in p-type and holes in n-type) can be found using the equations

$$n_p = \frac{n_i^2}{p_p} \approx \frac{n_i^2}{N_A} \quad p_n = \frac{n_i^2}{n_n} \approx \frac{n_i^2}{N_D} \tag{11.100}$$

The intrinsic carrier concentration n_i is given by

$$n_i^2 = \xi T^3 \exp\left(-\frac{V_g}{V_T}\right); \quad V_T = \frac{kT}{q} \tag{11.101}$$

where

$V_T = kT/q$ is the thermal potential ($V_T = 25.9$ mV at 300 K)
T is the absolute temperature in K
$q = 1.6 \times 10^{-16}$ C is the electron charge

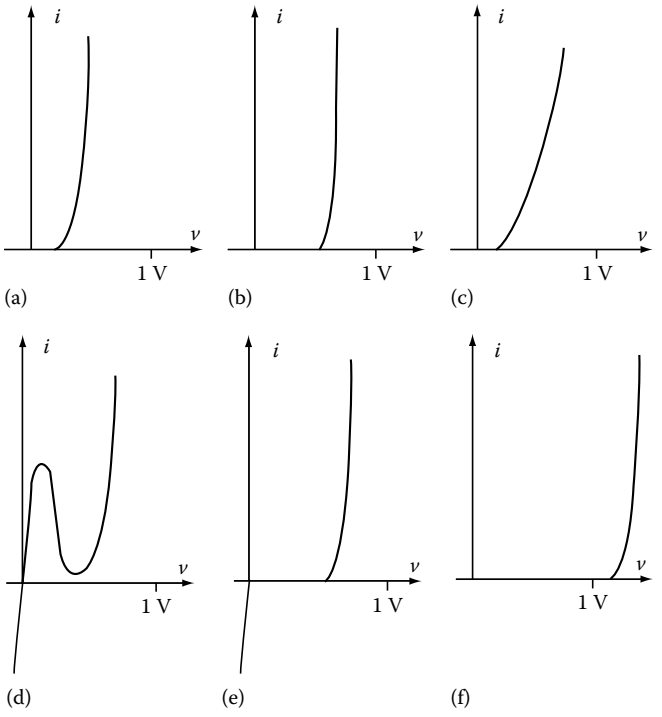

FIGURE 11.68 Forward current–voltage characteristics of various types of diodes: (a) germanium diode; (b) silicon diode; (c) Schottky diode; (d) tunnel diode; (e) backward diode; and (f) LED diode.

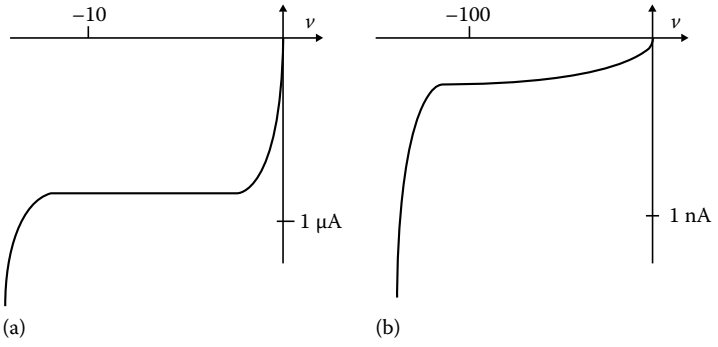

FIGURE 11.69 Reverse current–voltage characteristics: (a) germanium diode and (b) silicon diode.

$k = 8.62 \times 10^{-5}$ eV/K is the Boltzmann constant
V_g is potential gap ($V_g = 1.124$ V for silicon)
ξ is a material constant

For silicon, intrinsic concentration n_i is given by

$$n_i = 7.98 \times 10^{15} T^{\frac{3}{2}} \exp\left(-\frac{6522}{T}\right) \tag{11.102}$$

For silicon at 300 K, $n_i = 1.5 \times 10^{10}$ cm^{-2}.

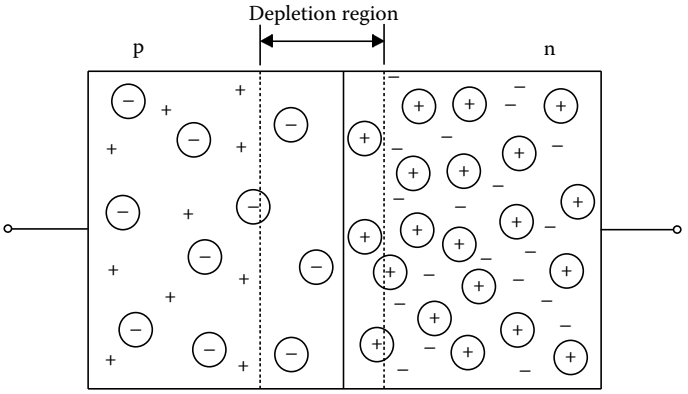

FIGURE 11.70 Illustration of the p–n junction.

When a p–n junction is formed, the fixed electrostatic lattice charges form an electrical field at the junction. Electrons are pushed by electrostatic forces deeper into the n-type region and holes into the p-type region, as illustrated in Figure 11.70. Between n-type and p-type regions, a depletion layer exists with a built-in potential, which is a function of impurity doping level and intrinsic concentration n_i:

$$V_{pn} = V_T \ln\left(\frac{N_A N_D}{n_i^2}\right) = V_T \ln\left(\frac{n_n p_p}{n_i^2}\right) = V_T \ln\left(\frac{n_n}{n_p}\right) = V_T \ln\left(\frac{p_p}{p_n}\right) \tag{11.103}$$

The junction current as a function of biasing voltage is described by the diode equation:

$$i = I_s\left[\exp\left(\frac{v}{V_T}\right) - 1\right] \tag{11.104}$$

where

$$I_s = Aqn_i^2 V_T\left(\frac{\mu_p}{\int_0^{L_p} n_n dx} + \frac{\mu_n}{\int_0^{L_n} p_p dx}\right) \tag{11.105}$$

where

$n_n \approx N_D$

$p_P \approx N_A$

μ_n and μ_p are the mobility of electrons and holes

L_n and L_p are the diffusion length for electrons and holes, and A is the device area

In the case of diodes made of silicon or other semiconductor materials with a high energy gap, the reverse-biasing current cannot be calculated from the diode Equation 11.104. This is due to the carrier generation-recombination phenomenon. Lattice imperfection and most impurities are acting as generation-recombination centers. Therefore, the more imperfections there are in the structure, the larger the deviation from ideal characteristics.

11.5.1.2 Forward *I–V* Diode Characteristics

The diode Equation 11.104 was derived with an assumption that injected carriers are recombining on the other side of the junction. The recombination within the depletion layer was neglected. In real forward-biased diodes, electrons and holes are injected through the depletion region and they may recombine there. The recombination component of the forward-biased diode is given by

$$i_{\text{rec}} = qwA\frac{n_{\text{i}}}{2\tau_0}\exp\left(\frac{v}{2V_T}\right) = I_{r0}\exp\left(\frac{v}{2V_T}\right) \tag{11.106}$$

where

w is the depletion layer thickness

τ_0 is the carrier lifetime in the depletion region

The total diode current $i_T = i + i_{\text{rec}}$ where i and i_{rec} are defined by Equations 11.104 and 11.106. The recombination component dominates at low current levels, as Figure 11.71 illustrates.

Also in very high current levels, the diode Equation 11.104 is not valid. Two phenomena cause this deviation. First, an ohmic resistance always plays an important role for large current values. The second deviation is due to high concentration of injected minority carriers. For very high current levels, the injected minority carrier concentrations may approach, or even become larger than the impurity concentration. An assumption of the quasi-charge neutrality leads to an increase of the majority carrier concentration. Therefore, the effective diode current is lower, as can be seen in Equation 11.105. The high current level in the diode follows the relation

$$i_{\text{h}} = I_{\text{h0}}\exp\left(\frac{v}{2V_T}\right) \tag{11.107}$$

Figure 11.71 shows the diode *I–V* characteristics, which include generation-recombination, diffusion, and high current phenomena. For modeling purposes, the forward diode current can be approximated by

$$i_{\text{D}} = I_0\exp\left(\frac{v}{\eta V_T}\right) \tag{11.108}$$

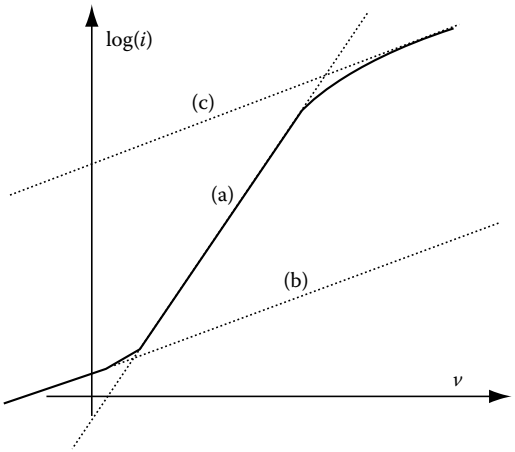

FIGURE 11.71 Current–voltage characteristics of the p–n junction in the forward direction: (a) diffusion current; (b) recombination current; and (c) high-level injection current.

where η has a value between 1.0 and 2.0. Note, that the η coefficient is a function of current, as can be seen in Figure 11.71. It has a larger value for small and large current regions and it is close to unity in the medium current region.

11.5.1.3 Reverse *I–V* Characteristics

The reverse leakage current in silicon diodes is mainly caused by the electron–hole generation in the depletion layer. This current is proportional to the number of generation-recombination centers. These centers are formed either by a crystal imperfection or deep impurities, which create energy states near the center of the energy gap. Once the reverse voltage is applied, the size of the depletion region and the number of generation-recombination centers increase. Thus, the leakage current is proportional to the thickness of the depletion layer $w(v)$. For a step-abrupt junction

$$w = \sqrt{\frac{2\varepsilon\varepsilon_0\left(V_{\text{pn}} - v\right)}{qN_{\text{eff}}}} \tag{11.109}$$

For other impurity profiles, w can be approximated by

$$w = K\left(V_{\text{pn}} - v\right)^{\frac{1}{m}} \tag{11.110}$$

The reverse-diode current for small and medium voltages can therefore be approximated by

$$i_{\text{rev}} = Aw(v)\frac{qn_{\text{i}}}{2\tau_0} \tag{11.111}$$

where n_i is given by Equation 11.101 and w by Equations 11.109 or 11.110. The reverse current increases rapidly near the breakdown voltage. This is due to the avalanche multiplication phenomenon. The multiplication factor is often approximated by

$$m = \frac{1}{1 - \left(\frac{v}{BV}\right)^m} \tag{11.112}$$

where BV stands for the breakdown voltage and m is an exponent chosen experimentally. Note that, for the reverse biasing, both v and BV have negative values and the multiplication factor M reaches an infinite value for $v = \text{BV}$.

11.5.2 Diode Capacitances

Two types of capacitances are associated with a diode junction. One capacitance, known as diffusion capacitance, is proportional to the diode current. This capacitance exists only for the forward-biased condition and has the dominant effect there. The second capacitance, known as the depletion capacitance, is a weak function of the applied voltage.

11.5.2.1 Diffusion Capacitance

In a forward-biased diode, minority carriers are injected into opposite sides of the junction. Those minority carriers diffuse from the junction and recombine with the majority carriers. Figure 11.72 shows the distribution of minority carriers in the vicinity of the junction of uniformly doped n-type and p-type regions. The electron charge stored in the p-region corresponds to the area under the curve, and it is equal to $Q_{\text{n}} = qn_0L_{\text{n}}$. Similarly, the charge of stored holes $Q_{\text{p}} = qp_0\ L_{\text{p}}$. The storage charge can also be expressed as $Q_{\text{n}} = I_{\text{n}}\ \tau_{\text{n}}$ and $Q_{\text{p}} = I_{\text{p}}\ \tau_{\text{p}}$, where I_{n} and I_{p} are electron and hole currents at the junction and

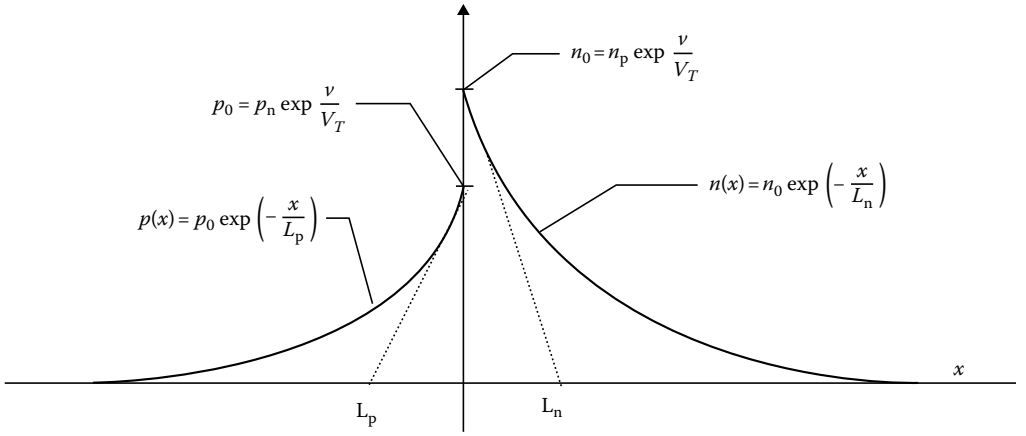

FIGURE 11.72 Minority carrier distribution in the vicinity of the p–n junction biased in the forward direction.

τ_n and τ_p are the lifetimes for minority carriers. Assuming $\tau = \tau_n = \tau_p$ and knowing that $I = I_p + I_n$ the total storage charge at the junction is $Q = I\tau$. The diffusion capacitance can be then computed as

$$C_{dif} = \frac{dQ}{dv} = \frac{d}{dv}\left[\tau I_0 \exp\left(\frac{v}{\eta V_T}\right)\right] = \frac{\tau I_B}{\eta V_T} \tag{11.113}$$

As one can see, the diffusion capacitance C_{dif} is proportional to the storage time τ and to the diode biasing current I_B. Note that the diffusion capacitance does not depend on the junction area, but only on the diode current. The diffusion capacitances may have very large values. For example, for 100 mA current and $\tau = 1$ μs, the junction diffusion capacitance is about 4 μF. Fortunately, this diffusion capacitance is connected in parallel to the small-signal junction resistance $r = \eta V_T / I_B$, and the time constant r. C_{dif} is equal to the storage time τ.

11.5.3 Depletion Capacitance

The reversed-biased diode looks like a capacitor with two ''plates'' formed of p-type and n-type regions and a dielectric layer (depletion region) between them. The capacitance of a reversed-biased junction can then be written as

$$C_{dep} = A\frac{\varepsilon}{w} \tag{11.114}$$

where

A is a junction area
ε is the dielectric permittivity of semiconductor material
w is the thickness of the depletion layer

The depletion layer thickness w is a weak function of the applied reverse-biasing voltage. In the simplest case, with a step-abrupt junction, the depletion capacitance is

$$C_j = \sqrt{\frac{qN_{eff}\varepsilon\varepsilon_0}{2(V_{pn} - v)}}; \quad \frac{1}{N_{eff}} = \frac{1}{N_D} + \frac{1}{N_A} \tag{11.115}$$

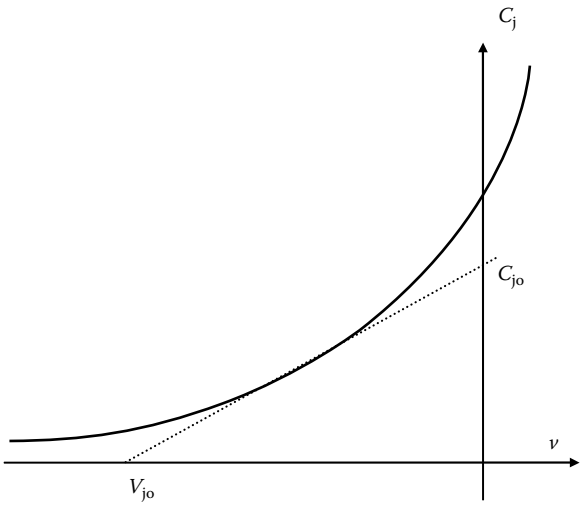

FIGURE 11.73 Capacitance–voltage characteristics for reverse-biased junction.

The steepest capacitance–voltage characteristics are in $p^+ - i - p - n^+$ diodes with the impurity profiles shown in Figure 11.67f. In general, for various impurity profiles at the junction, the depletion capacitance C_j can be approximated by

$$C_j = C_{j0}\left(1 - \frac{v}{V_{pn}}\right)^{\frac{1}{m}} \tag{11.116}$$

or using linear approximation as shown in Figure 11.73:

$$C_j = C_{j0}\left(1 - \frac{v}{V_{j0}}\right) \tag{11.117}$$

11.5.4 Diode as a Switch

The switching time of the p–n junction is limited mainly by the storage charge of injected minority carriers into the vicinity of the junction (electrons injected in p-type region and holes injected in n-type region). When a diode is switched from the forward to the reverse direction, these carriers may move freely through the junction. Some of the minority carriers recombine with time. Others are moved away to the other side of the junction. The diode cannot recover its blocking capability as long as a large number of the minority carriers exist and can flow through the junction. An example of the current–time characteristics of a diode switching from the forward to the reverse direction is shown in Figure 11.74. A few characteristics that are shown in the figure are for the same forward current and different reverse currents. Just after switching, these reverse currents are limited only by external circuitry. In this example, shown in Figure 11.74, most of the minority carriers are moved to the other side of the junction by the reverse current, and the recombination mechanism is negligible. Note that the larger the reverse current flowing after switching, the shorter the time required to recover the blocking capability. This type of behavior is typical for commonly used high-voltage diodes.

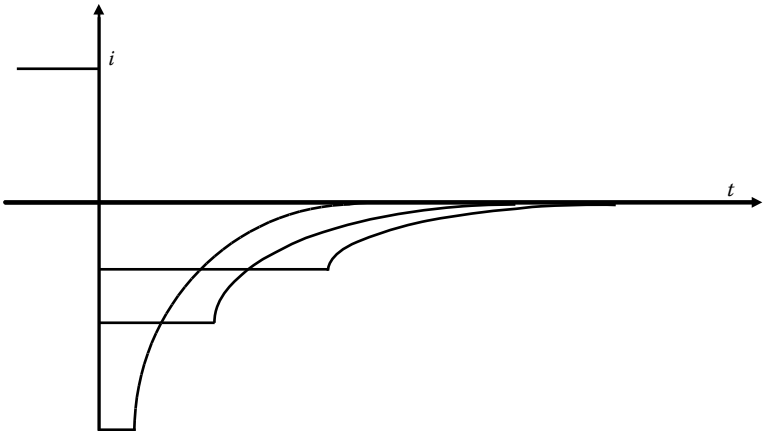

FIGURE 11.74 Currents in diode with large minority carrier lifetimes after switching from the forward to the reverse direction.

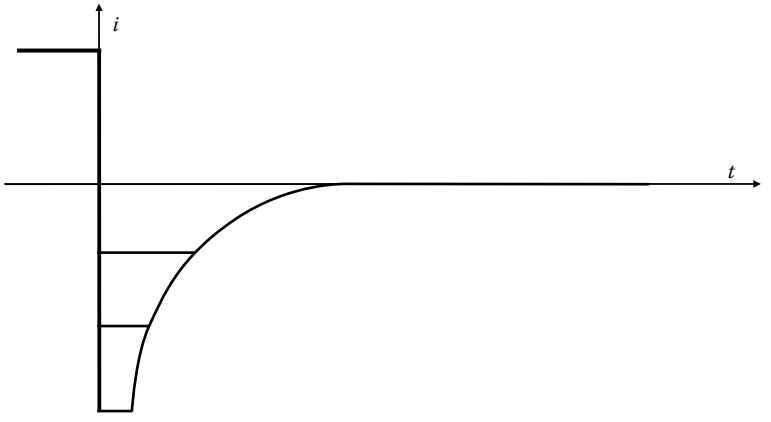

FIGURE 11.75 Currents in diode with small minority carrier lifetimes after switching from the forward to the reverse direction.

In order to shorten the switching time, diodes sometimes are doped with gold or other deep-level impurities to create more generation centers and to increase the carrier recombination. This way, the minority carrier lifetimes of such switching diodes are significantly reduced. The switching time is significantly shorter, but it is almost independent of the reverse-diode current after switching, as shown in Figure 11.75. This method of artificially increasing recombination rates has some severe disadvantages. Such switching diodes are characterized by very large reverse leakage currents and small breakdown voltages.

The best switching diodes utilize metal–semiconductor contacts. They are known as Schottky diodes. In such diodes there is no minority carrier injection phenomenon; therefore, these diodes recover the blocking capability instantaneously. Schottky diodes are also characterized by a relatively small (0.2–0.3 V) voltage drop in the forward direction. However, their reverse leakage current is larger, and the breakdown voltage rarely exceeds 20–30 V. Lowering the impurity concentration in the

semiconductor material leads to slightly larger breakdown voltages, but at the same time, the series diode resistances increase significantly.

11.5.5 Temperature Properties

Both forward and reverse diode characteristics are temperature dependent. These temperature properties are very important for correct circuit design. The temperature properties of the diode can be used to compensate for the thermal effects of electronic circuits. Diodes can be used also as accurate temperature sensors. The major temperature effect in a diode is caused by the strong temperature dependence of the intrinsic concentration n_i (Equations 11.101 and 11.102) and by the exponential temperature relationship of the diode Equation 11.104. By combining Equations 11.101 and 11.104 and assuming the temperature dependence of carrier mobilities, the voltage drop on the forward-biased diode can be written as

$$v = \eta\left[V_T \ln\left(\frac{i}{\xi T^a}\right) + V_g\right] \tag{11.118}$$

or diode current

$$i = I_0\left(\frac{T}{T_0}\right)^{\alpha} \exp\left(\frac{(v/\eta) - V_g}{V_{T_0}}\frac{T_0}{T}\right) \tag{11.119}$$

where

V_g is the potential gap in semiconductor material, $V_g = 1.124$ V for silicon and $V_g = 1.424$ V for GaAs
α is a material coefficient ranging between 2.5 and 4.0

The temperature dependence of the diode voltage drop dv/dT can be obtained by calculating the derivative of Equation 11.118

$$\frac{dv}{dT} = \frac{v - \eta\left(V_g + \alpha V_T\right)}{T} \tag{11.120}$$

For example, in the case of the silicon diode with a 0.6 voltage drop and assuming $\eta = 1.1$, $\alpha = 3.0$, and $T = 300$ K, the $dV/dT = 1.87$ mV/°C.

The reverse-diode current is a very strong function of the temperature. For diodes made of semiconductor material with a small potential gap, such as germanium, the diffusion component dominates. In this case, the reverse current is proportional to

$$i_{rev} \propto T^{\alpha} \exp\left(-\frac{qV_g}{kT}\right) \tag{11.121}$$

For diodes made of silicon and semiconductors with a higher energy gap, the recombination is the dominant mechanism. In this case, reverse leakage current is proportional to

$$i_{rev} \propto T^{\alpha} \exp\left(-\frac{qV_g}{2kT}\right) \tag{11.122}$$

Using Equation 11.122, one may calculate that for silicon diodes at room temperatures, the reverse leakage current doubles for about every 10°C.

The breakdown voltage is also temperature dependent. The tunneling effect dominates in diodes with small breakdown voltages. This effect is often known in literature as the Zener breakdown. In such diodes the breakdown voltage decreases with the temperature. The avalanche breakdown dominates in diodes with large breakdown voltages. When the avalanche mechanism prevails, then the breakdown voltage increases 0.06%/°C–0.1%/°C. For medium-range breakdown voltages, one phenomenon compensates the other, and temperature-independent breakdown voltage can be observed. This zero temperature coefficient exists for diodes with breakdown voltages equal to about $5V_g$. In the case of the silicon diode, this breakdown voltage, with a zero temperature coefficient, is equal to about 5.6 V.

11.5.6 Piecewise Linear Model

Nonlinear diode characteristics are often approximated by a piecewise linear model. A few possible approaches can be used to linearize the diode characteristics (see Figure 11.76). The parameters of the most accurate linearized diode model are shown in Figure 11.77a, and the linearized diode equivalent circuit is shown in Figure 11.77b.

The modified diode Equation 11.108 also can be written as

$$v = \eta V_T \ln\left(\frac{i}{I_0}\right) \tag{11.123}$$

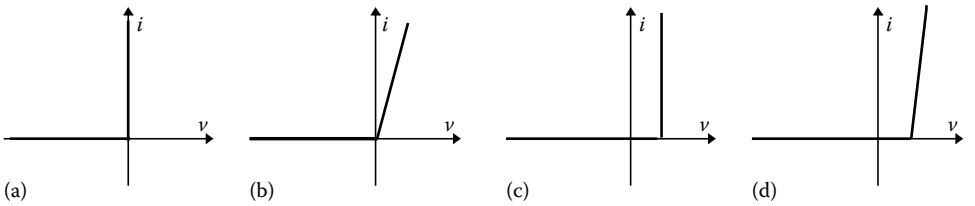

FIGURE 11.76 Various ways to linearize diode characteristics.

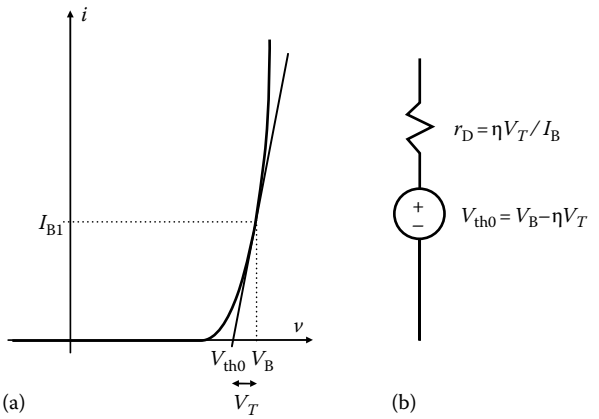

FIGURE 11.77 Linearization of the diode: (a) diode characteristics and (b) equivalent diagram.

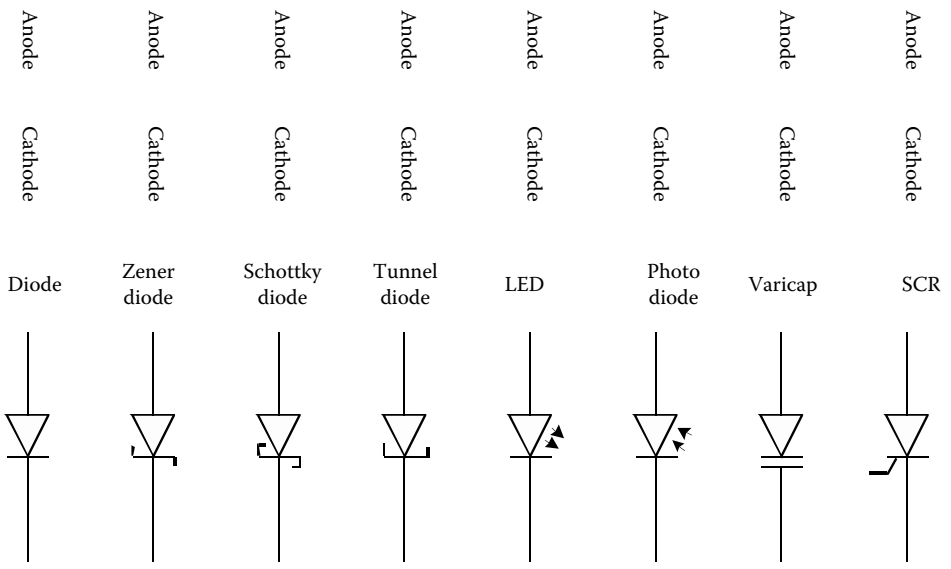

FIGURE 11.78 Symbols used for various types of diodes.

For the biasing points V_B and I_B, the small-signal diode resistance dv/di can be computed from Equation 11.123 as

$$r = \frac{dv}{di} = \frac{\eta V_T}{I_B}; \quad V_{th0} = V_B - \eta V_T \tag{11.124}$$

and it is only the function of the thermal potential V_T and the biasing current I_B. Note that the small-signal diode resistance is almost independent of the diode construction or semiconductor material used. If one requires that this linearized diode have I_B current for V_B voltage, then the piecewise diode characteristics should be as in Figure 11.77a. The equivalent Thevenin and Norton circuits are shown in Figure 11.77b. In the case of large-signal operation, the diode can be approximated by shifting the characteristics to the left by ΔV. In this case, the threshold voltage becomes $V_{th0} = V_B - 2V_T$ instead of $V_{th0} = V_B - \eta^{VT}$.

12.1 Introduction

Passive energy storage elements are widely used in radio-frequency (RF) circuits. Although their impedance behavior often can be mimicked by compact active circuitry, it remains true that passive elements offer the largest dynamic range and the lowest power consumption. Hence, the highest performance will always be obtained with passive inductors and capacitors. Unfortunately, standard integrated circuit technology has not evolved with a focus on providing good passive elements. This chapter describes the limited palette of options available, as well as means to make the most use out of what is available.

12.2 Fractal Capacitors

Of capacitors, the most commonly used are parallel-plate and MOS structures. Because of the thin gate oxides now in use, capacitors made out of MOSFETs have the highest capacitance density of any standard IC option, with a typical value of approximately 7 fF/μm^2 for a gate oxide thickness of 5 nm. A drawback, however, is that the capacitance is voltage dependent. The applied potential must be well in excess of a threshold voltage in order to remain substantially constant. The relatively low breakdown voltage (on the order of 0.5 V/nm of oxide) also imposes an unwelcome constraint on allowable signal amplitudes. An additional drawback is the effective series resistance of such structures, due to the MOS channel resistance. This resistance is particularly objectionable at radio frequencies, since the impedance of the combination may be dominated by this resistive portion.

Capacitors that are free of bias restrictions (and that have much lower series resistance) may be formed out of two (or more) layers of standard interconnect metal. Such parallel-plate capacitors are quite linear and possess high breakdown voltage, but generally offer two orders of magnitude lower capacitance density than the MOSFET structure. This inferior density is the consequence of a conscious and continuing effort by technologists to keep low the capacitance between interconnect layers. Indeed, the vertical spacing between such layers generally does not scale from generation to generation. As a result, the disparity between MOSFET capacitance density and that of the parallel-plate structure continues to grow as technology scales.

A secondary consequence of the low density is an objectionably high capacitance between the bottom plate of the capacitor and the substrate. This bottom-plate capacitance is often a large fraction of the main capacitance. Needless to say, this level of parasitic capacitance is highly undesirable.

In many circuits, capacitors can occupy considerable area, and an area-efficient capacitor is therefore highly desirable. Recently, a high-density capacitor structure using lateral fringing and fractal geometries has been introduced [1]. It requires no additional processing steps, and so it can be built in standard digital processes. The linearity of this structure is similar to that of the conventional parallel-plate capacitor. Furthermore, the bottom-plate parasitic capacitance of the structure is small, which makes it appealing for many circuit applications. In addition, unlike conventional metal-to-metal capacitors, the density of a fractal capacitor increases with scaling.

12.2.1 Lateral Flux Capacitors

Figure 12.1a shows a lateral flux capacitor. In this capacitor, the two terminals of the device are built using a single layer of metal, unlike a vertical flux capacitor, where two different metal layers must be used. As process technologies continue to scale, lateral fringing becomes more important. The lateral spacing of the metal layers, s, shrinks with scaling, yet the thickness of the metal layers, t, and the vertical spacing of the metal layers, t_{ox}, stay relatively constant. This means that structures utilizing lateral flux enjoy a significant improvement with process scaling, unlike conventional structures that depend on vertical flux. Figure 12.1b shows a scaled lateral flux capacitor. It is obvious that the capacitance of the structure of Figure 12.1b is larger than that of Figure 12.1a.

Lateral flux can be used to increase the total capacitance obtained in a given area. Figure 12.2a is a standard parallel-plate capacitor. In Figure 12.2b, the plates are broken into cross-connected sections [2]. As can be seen, a higher capacitance density can be achieved by using lateral flux as well as vertical flux. To emphasize that the metal layers are cross connected, the two terminals of the capacitors in Figure 12.2b are identified with two different shadings. The idea can be extended to multiple metal layers as well.

Figure 12.3 shows the ratio of metal thickness to minimum lateral spacing, t/s, versus channel length for various technologies [3–5]. The trend suggests that lateral flux will have a crucial role in the design of capacitors in future technologies.

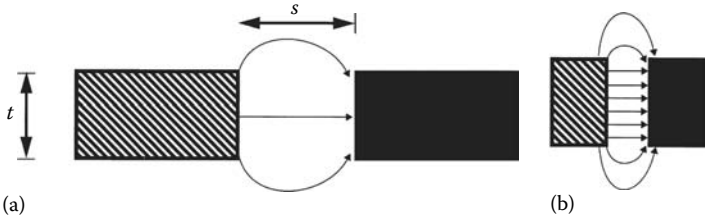

FIGURE 12.1 Effect of scaling on lateral flux capacitors: (a) before scaling and (b) after scaling.

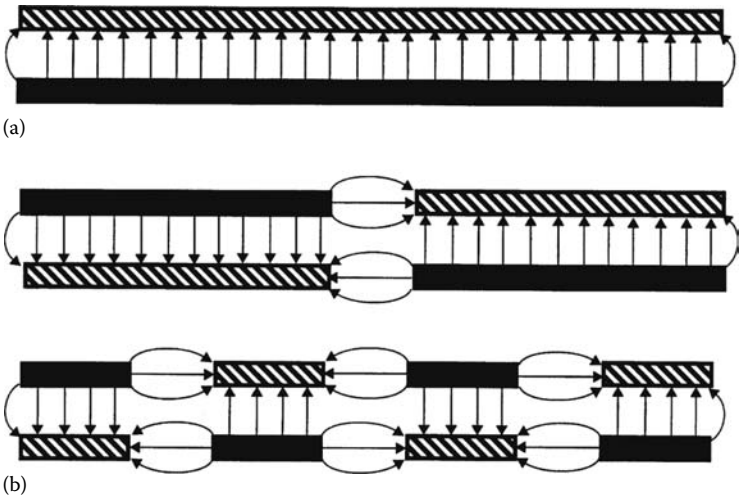

FIGURE 12.2 Vertical flux vs. lateral flux: (a) a standard parallel-plate structure and (b) cross-connected metal layers.

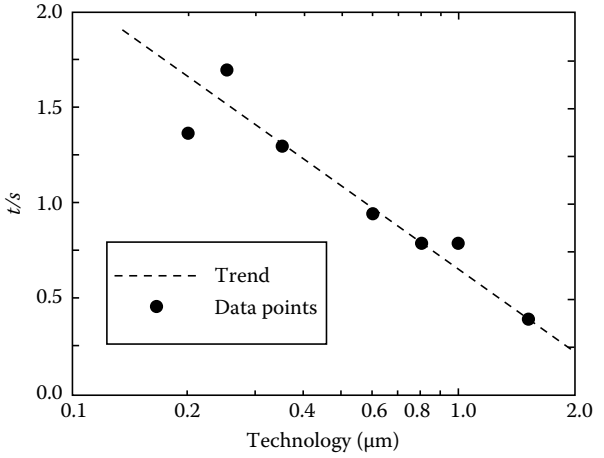

FIGURE 12.3 Ratio of metal thickness to horizontal metal spacing vs. technology (channel length).

The increase in capacitance due to fringing is proportional to the periphery of the structure; therefore, structures with large periphery per unit area are desirable. Methods for increasing this periphery are the subject of the following sections.

12.2.2 Fractals

A fractal is a mathematical abstract [6]. Some fractals are visualizations of mathematical formulas, while others are the result of the repeated application of an algorithm, or a *rule*, to a *seed*. Many natural phenomena can be described by fractals. Examples include the shapes of mountain ranges, clouds, coastlines, etc.

Some ideal fractals have finite area but infinite perimeter. The concept can be better understood with the help of an example. *Koch islands* are a family of fractals first introduced as a crude model for the shape of a

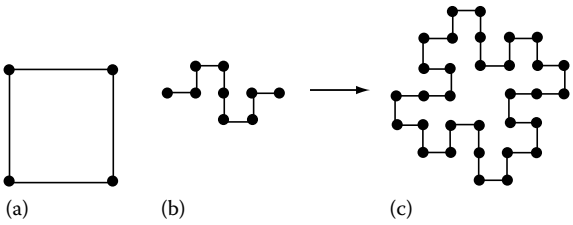

FIGURE 12.4 Construction of a Koch curve: (a) an initiator, (b) a generator, and (c) first step of the process.

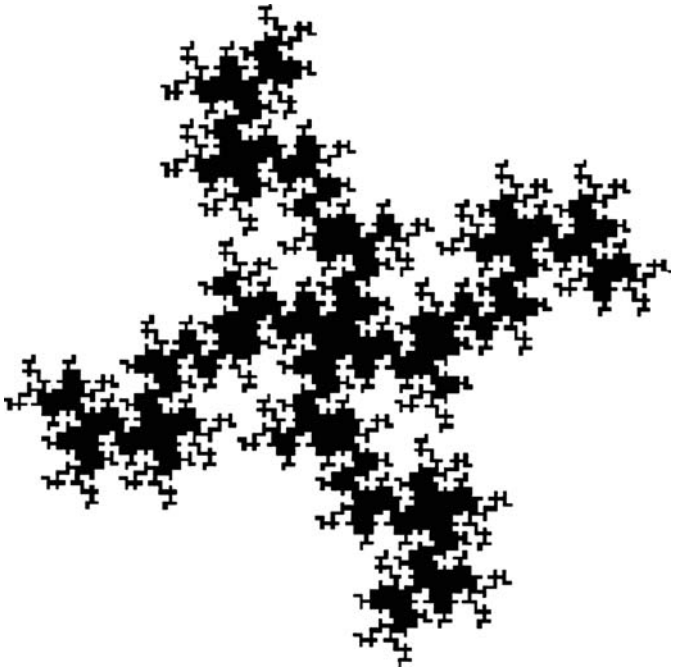

FIGURE 12.5 A Koch island with $M = 4$, $N = 32$, and $r = 1/8$.

coastline. The construction of a Koch curve begins with an *initiator*, as shown in the example of Figure 12.4a. A square is a simple initiator with $M = 4$ sides. The construction continues by replacing each segment of the initiator with a curve called a *generator*, an example of which is shown in Figure 12.4b that has $N = 8$ segments. The size of each segment of the generator is $r = 1/4$ of the initiator. By recursively replacing each segment of the resulting curve with the generator, a fractal border is formed. The first step of this process is depicted in Figure 12.4c. The total area occupied remains constant throughout the succession of stages because of the particular shape of the generator. A more complicated Koch island can be seen in Figure 12.5. The associated initiator of this fractal has four sides and its generator has 32 segments. It can be noted that the curve is self-similar, that is, each section of it looks like the entire fractal. As we zoom in on Figure 12.5, more detail becomes visible, and this is the essence of a fractal.

Fractal dimension, D, is a mathematical concept that is a measure of the complexity of a fractal. The dimension of a flat curve is a number between 1 and 2, which is given by

$$D = \frac{\log(N)}{\log\left(\frac{1}{r}\right)} \tag{12.1}$$

where

N is the number of segments of the generator

r is the ratio of the generator segment size to the initiator segment size

The dimension of a fractal curve is not restricted to integer values, hence, the term "fractal." In particular, it exceeds 1, which is the intuitive dimension of curves. A curve that has a high degree of complexity, or D, fills out a two-dimensional flat surface more efficiently. The fractal in Figure 12.4c has a dimension of 1.5, whereas for the border line of Figure 12.5, $D = 1.667$.

For the general case where the initiator has M sides, the periphery of the initiator is proportional to the square root of the area:

$$P_0 = k \cdot \sqrt{A} \tag{12.2}$$

where k is a proportionality constant that depends on the geometry of the initiator. For example, for a square initiator, $k = 4$; and for an equilateral triangle, $k = 2 \cdot \sqrt[4]{27}$. After n successive applications of the generation rule, the total periphery is

$$P = k\sqrt{A} \cdot (Nr)^n \tag{12.3}$$

and the minimum feature size (the resolution) is

$$l = \frac{k\sqrt{A}}{M} \cdot r^n \tag{12.4}$$

Eliminating n from Equations 12.3 and 12.4 and combining the result with Equation 12.1, we have

$$P = \frac{k^D}{M^{D-1}} \cdot \frac{(\sqrt{A})^D}{l^{D-1}} \tag{12.5}$$

Equation 12.5 demonstrates the dependence of the periphery on parameters such as the area and the resolution of the fractal border. It can be seen from Equation 12.5 that as l tend toward zero, the periphery goes to infinity; therefore, it is possible to generate fractal structures with very large perimeters in any given area. However, the total periphery of a fractal curve is limited by the attainable resolution in practical realizations.

12.2.3 Fractal Capacitor Structures

The final shape of a fractal can be tailored to almost any form. The flexibility arises from the fact that a wide variety of geometries can be used as the initiator and generator. It is also possible to use different generators during each step. This is an advantage for integrated circuits where flexibility in the shape of the layout is desired.

Figure 12.6 is a three-dimensional representation of a fractal capacitor. This capacitor uses only one metal layer with a fractal border. For a better visualization of the overall picture, the terminals of this square-shaped capacitor have been identified using two different shadings. As was discussed before, multiple cross-connected metal layers may be used to improve capacitance density further.

One advantage of using lateral flux capacitors in general, and fractal capacitors in particular, is the reduction of the bottom-plate capacitance. This reduction is due to two reasons. First, the higher density of the fractal capacitor (compared to a standard parallel-plate structure) results in a smaller area. Second, some of the field lines originating from one of the bottom plates terminate on the adjacent plate, instead of the substrate, which further reduces the bottom-plate capacitance as shown in Figure 12.7. Because of

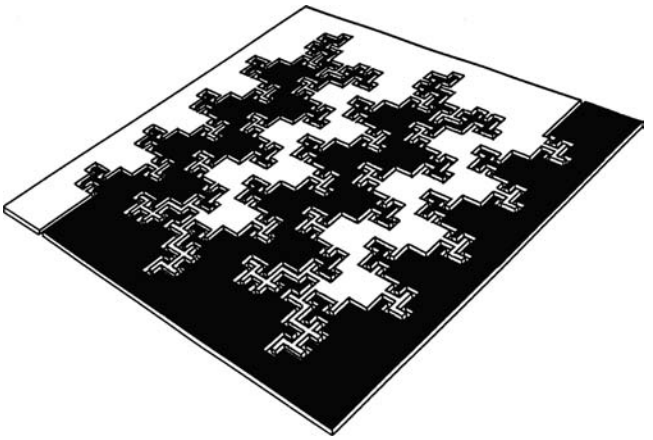

FIGURE 12.6 Three-dimensional representation of a fractal capacitor using a single metal layer.

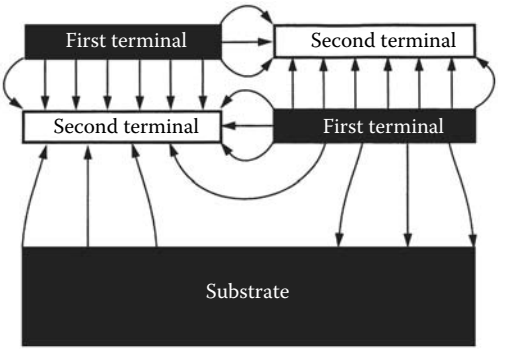

FIGURE 12.7 Reduction of the bottom-plate parasitic capacitance.

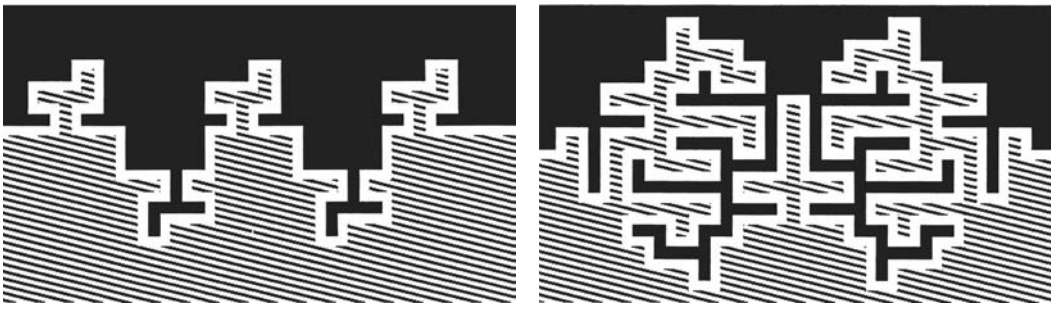

FIGURE 12.8 Fractal dimension of (a) is smaller than (b).

this property, some portion of the parasitic bottom-plate capacitor is converted into the more useful plate-to-plate capacitance.

The capacitance per unit area of a fractal structure depends on the dimension of the fractal. To improve the density of the layout, fractals with large dimensions should be used. The concept of fractal dimension is demonstrated in Figure 12.8. The structure in Figure 12.8a has a lower dimension compared to the one in Figure 12.8b, so the density (capacitance per unit area) of the latter is higher.

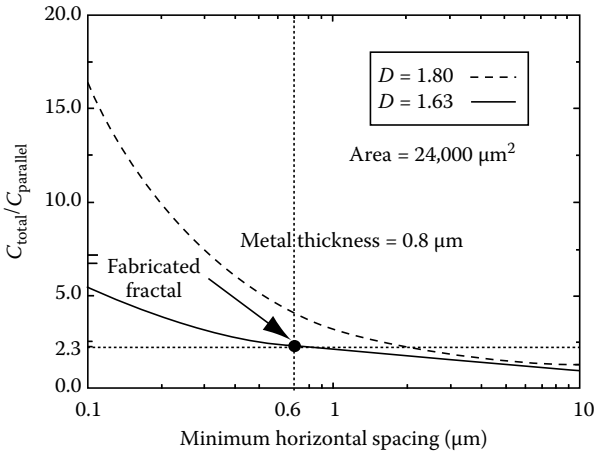

FIGURE 12.9 Boost factor vs. horizontal spacing.

To demonstrate the dependence of capacitance density on dimension and lateral spacing of the metal layers, a first-order electromagnetic simulation was performed on two families of fractal structures. In Figure 12.9, the boost factor vs. horizontal spacing of the metal layers is plotted. The *boost factor* is defined as the ratio of the total capacitance of the fractal structure to the capacitance of a standard parallel-plate structure with the same area. The solid line corresponds to a family of fractals with a moderate fractal dimension of 1.63, while the dashed line represents another family of fractals with $D = 1.80$, which is a relatively large value for the dimension. In this first-order simulation, it is assumed that the vertical spacing and the thickness of the metal layers are kept constant at a 0.8 μm level. As can be seen in Figure 12.9, the amount of boost is a strong function of the fractal dimension as well as scaling.

In addition to the capacitance density, the quality factor, Q, is important in RF applications. Here, the degradation in quality factor is minimal because the fractal structure automatically limits the length of the thin metal sections to a few microns, keeping the series resistance reasonably small. For applications that require low series resistance, lower dimension fractals may be used. Fractals thus add one more degree of freedom to the design of capacitors, allowing the capacitance density to be traded for a lower series resistance.

In current IC technologies, there is usually tighter control over the lateral spacing of metal layers compared with the vertical thickness of the oxide layers, from wafer to wafer and across the same wafer. Lateral flux capacitors shift the burden of matching away from oxide thickness to lithography. Therefore, by using lateral flux, matching characteristics can improve. Furthermore, the pseudorandom nature of the structure can also compensate, to some extent, the effects of nonuniformity of the etching process. To achieve accurate ratio matching, multiple copies of a unit cell should be used, as is standard practice in high-precision analog circuit design.

Another simple way of increasing capacitance density is to use an interdigitated capacitor depicted in Figure 12.10 [2,7]. One disadvantage of such a structure compared to fractals is its inherent parasitic inductance. Most of the fractal geometries randomize the direction of the current flow and thus reduce the effective series inductance; whereas for interdigitated capacitors, the current flow is in the same direction for all the parallel stubs. In addition, fractals usually have lots of rough edges that accumulate electrostatic energy more efficiently compared to interdigitated capacitors, causing a boost in capacitance (generally of the order of 15%). Furthermore, interdigitated structures are more vulnerable to nonuniformity of the etching process. However, the relative simplicity of the interdigitated capacitor does make it useful in some applications.

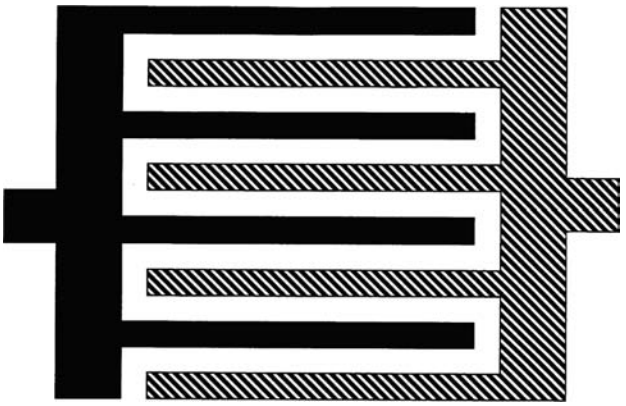

FIGURE 12.10 An interdigitated capacitor.

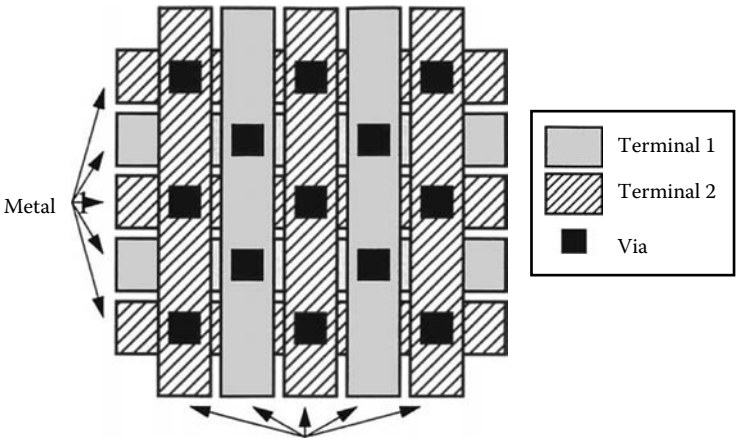

FIGURE 12.11 A woven structure.

The woven structure shown in Figure 12.11 may also be used to achieve high capacitance density. The vertical lines are in metal-2 and horizontal lines are in metal-1. The two terminals of the capacitor are identified using different shades. Compared to an interdigitated capacitor, a woven structure has much less inherent series inductance. The current flowing in different directions results in a higher self-resonant frequency. In addition, the series resistance contributed by vias is smaller than that of an interdigitated capacitor, because cross-connecting the metal layers can be done with greater ease. However, the capacitance density of a woven structure is smaller compared to an interdigitated capacitor with the same metal pitch, because the capacitance contributed by the vertical fields is smaller.

12.3 Spiral Inductors

More than is so with capacitors, on-chip inductor options are particularly limited and unsatisfactory. Nevertheless, it is possible to build practical spiral inductors with values up to perhaps 20 nH and with Q values of approximately 10. For silicon-based RF ICs, Q degrades at high frequencies due to energy dissipation in the semiconducting substrate [8]. Additionally, noise coupling via the substrate at GHz frequencies has been reported [9]. As inductors occupy substantial chip area, they can potentially

be the source and receptor of detrimental noise coupling. Furthermore, the physical phenomena underlying the substrate effects are complicated to characterize. Therefore, decoupling the inductor from the substrate can enhance the overall performance by increasing Q, improving isolation, and simplifying modeling.

Some approaches have been proposed to address the substrate issues; however, they are accompanied by drawbacks. Some [10] have suggested the use of high-resistivity (150–200 Ω-cm) silicon substrates to mimic the low-loss, semi-insulating GaAs substrate, but this is rarely a practical option. Another approach selectively removes the substrate by etching a pit under the inductor [11]. However, the etch adds extra processing cost and is not readily available. Moreover, it raises reliability concerns such as packaging yield and long-term mechanical stability. For low-cost integration of inductors, the solution to substrate problems should avoid increasing process complexity.

In this section, we present the *patterned ground shield* (PGS) [12], which is compatible with standard silicon technologies, and which reduces the unwanted substrate effects. The great improvement provided by the PGS reduces the disparity in quality between spiral inductors made in silicon and GaAs IC technologies.

12.3.1 Understanding Substrate Effects

To understand why the PGS should be effective, consider first the physical model of an ordinary inductor on silicon, with one port and the substrate grounded, as shown in Figure 12.12 [8]. An on-chip inductor is physically a three-port element including the substrate. The one-port connection shown in Figure 12.12 avoids unnecessary complexity in the following discussion and at the same time preserves the inductor characteristics. In the model, the series branch consists of L_s, R_s, and C_s. L_s represents the spiral inductance, which can be computed using the Greenhouse method [13] or well approximated by simple analytical formulas to be presented later. R_s is the metal series resistance whose behavior at RF is governed by the eddy current effect. This resistance accounts for the energy loss due to the skin effect in the spiral interconnect structure as well as the induced eddy current in any conductive media close to the inductor. The series feedforward capacitance, C_s, accounts for the capacitance due to the overlaps between the spiral and the center-tap underpass [14]. The effect of the interturn fringing capacitance is usually small because the adjacent turns are almost at equal potentials, and therefore it is neglected in this model. The overlap capacitance is more significant because of the relatively large potential difference between the spiral and the center-tap underpass. The parasitics in the shunt branch are modeled by C_{ox}, C_{Si}, and R_{Si}. C_{ox} represents the oxide capacitance between the spiral and the substrate. The silicon substrate capacitance and resistance are modeled by C_{Si} and R_{Si}, respectively [15,16]. The element R_{Si} accounts for the energy dissipation in the silicon substrate.

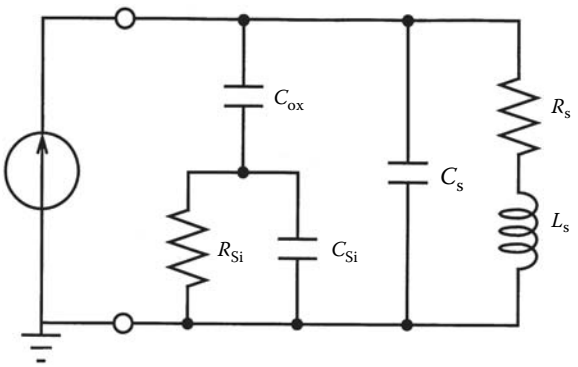

FIGURE 12.12 Lumped physical model of a spiral inductor on silicon.

Expressions for the model element values are as follows:

$$R_s = \frac{\rho l}{\delta w\left(1 - e^{-\frac{t}{\delta}}\right)} \tag{12.6}$$

$$C_s = nw^2 \cdot \frac{\varepsilon_{ox}}{t_{oxM1-M2}} \tag{12.7}$$

$$C_{ox} = \frac{\varepsilon_{ox}}{2t_{ox}} \cdot l \cdot w \tag{12.8}$$

$$C_{Si} = \frac{1}{2} \cdot l \cdot w \cdot C_{sub} \tag{12.9}$$

$$R_{Si} = \frac{2}{l \cdot w \cdot G_{sub}} \tag{12.10}$$

where

ρ is the DC resistivity of the spiral
t is the overall length of the spiral windings
w is the line width
δ is the skin depth
n is the number of crossovers between the spiral and center-tap (and thus $n = N - 1$, where N is the number of turns)
$t_{oxM1-M2}$ is the oxide thickness between the spiral and substrate
C_{sub} is the substrate capacitance per unit area
G_{sub} is the substrate conductance per unit area

In general, one treats C_{sub} and G_{sub} as fitting parameters.

Exploration with the model reveals that the substrate loss stems primarily from the penetration of the electric field into the lossy silicon substrate. As the potential drop in the semiconductor (i.e., across R_{Si} in Figure 12.12) increases with frequency, the energy dissipation in the substrate becomes more severe. It can be seen that increasing R_p to infinity reduces the substrate loss. It can be demonstrated that R_p approaches infinity as R_{Si} goes either to zero or infinity. This observation implies that Q can be improved by making the silicon substrate either a perfect insulator or a perfect conductor. Using high-resistivity silicon (or etching it away) is equivalent to making the substrate an open circuit. In the absence of the freedom to do so, the next best option is to convert the substrate into a better conductor. The approach is to insert a ground plane to block the inductor electric field from entering the silicon. In effect, this ground plane becomes a pseudosubstrate with the desired characteristics.

The ground shield cannot be a solid conductor, however, because image currents would be induced in it. These image currents tend to cancel the magnetic field of the inductor proper, decreasing the inductance. To solve this problem, the ground shield is patterned with slots orthogonal to the spiral as illustrated in Figure 12.13. The slots act as an open circuit to cut off the path of the induced loop current. The slots should be sufficiently narrow such that the vertical electric field cannot leak through the patterned ground shield into the underlying silicon substrate. With the slots etched away, the ground strips serve as the termination for the electric field. The ground strips are merged together around the four outer edges of the spiral. The separation between the merged area and the edges is not critical. However, it is crucial that the merged area does not form a closed ring around the spiral since it can potentially support the unwanted loop current. The shield should be strapped with the top layer metal to provide a low-impedance path to ground. The general rule is to prevent negative mutual coupling while minimizing the impedance to ground.

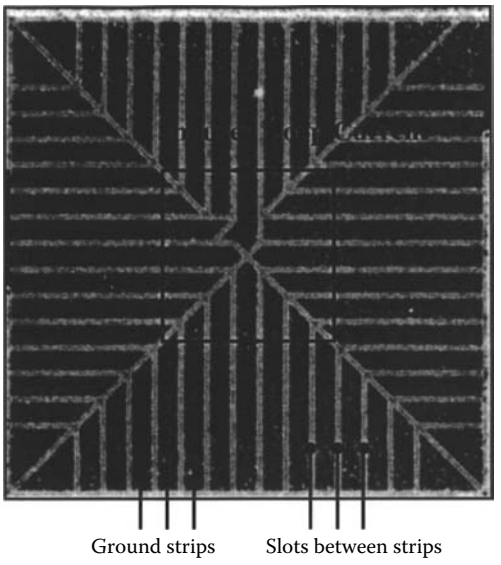

FIGURE 12.13 A close-up photo of the patterned ground shield.

The shield resistance is another critical design parameter. The purpose of the patterned ground shield is to provide a good short to ground for the electric field. Because the finite shield resistance contributes to energy loss of the inductor, it must be kept small. Specifically, by keeping the shield resistance small compared to the reactance of the oxide capacitance, the voltage drop that can develop across the shield resistance is very small. As a result, the energy loss due to the shield resistance is insignificant compared to other losses. A typical on-chip spiral inductor has parasitic oxide capacitance between 0.25 and 1 pF, depending on the size and the oxide thickness. The corresponding reactance due to the oxide capacitance at 1–2 GHz is of the order of 100 Ω and hence a shield resistance of a few ohms is sufficiently small not to cause any noticeable loss.

With the PGS, one can expect typical improvements in Q ranging from 10% to 33%, in the frequency range of 1–2 GHz. Note that the inclusion of the ground shields increases C_p, which causes a fast roll-off in Q above the peak-Q frequency and a reduction in the self-resonant frequency. This modest improvement in inductor Q is certainly welcome, but is hardly spectacular by itself. However, a more dramatic improvement is evident when evaluating inductor–capacitor resonant circuits. Such LC tank circuits can absorb the parasitic capacitance of the ground shield. The energy stored in such parasitic elements is now part of the circuit; therefore, the overall circuit Q is greatly increased. Improvements of factors of approximately two are not unusual, so that tank circuits realized with PGS inductors possess roughly the same Q as those built in GaAs technologies.

As stated earlier, substrate noise coupling can be an issue of great concern owing to the relatively large size of typical inductors. Shielding by the PGS improves isolation by 25 dB or more at GHz frequencies. It should be noted that, as with any other isolation structure (such as a guard ring), the efficacy of the PGS is highly dependent on the integrity of the ground connection. One must often make a trade-off between the desired isolation level and the chip area that is required to provide a low-impedance ground connection.

12.3.2 Simple, Accurate Expressions for Planar Spiral Inductances

In Section 12.3.1, a physically based model for planar spiral inductors was offered, and reference was made to the Greenhouse method as a means for computing the inductance value. This method uses as computational atoms the self- and mutual inductances of parallel current strips. It is relatively straightforward to apply, and yields accurate results. Nevertheless, simpler analytic formulas are generally preferred for design since important insights are usually more readily obtained.

As a specific example, square spirals are popular mainly because of their ease of layout. Other polygonal spirals have also been used to improve performance by more closely approximating a circular spiral. However, a quantitative evaluation of possible improvements is cumbersome without analytical formulas for inductance.

Among alternative shapes, hexagonal and octagonal inductors are used widely. Figures 12.14 through 12.16 show the layout for square, hexagonal, and octagonal inductors, respectively. For a given shape, an inductor is completely specified by the number of turns n, the turn width w, the turn spacing s,

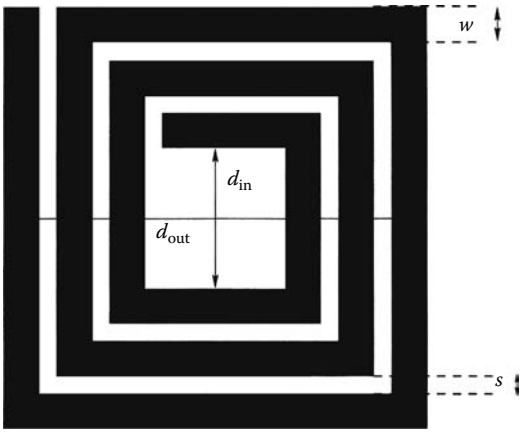

FIGURE 12.14 Square inductor.

and any one of the following: the outer diameter d_{out}, the inner diameter d_{in}, the average diameter $d_{avg} = 0.5(d_{out} + d_{in})$, or the fill ratio, defined as $\rho = (d_{out} - d_{in})/(d_{out} + d_{in})$. The thickness of the inductor has only a very small effect on inductance and will therefore be ignored here.

We now present three approximate expressions for the inductance of square, hexagonal, and octagonal planar inductors. The first approximation is based on a modification of an expression developed by Wheeler [17]; the second is derived from electromagnetic principles by approximating the sides of the spirals as current sheets; and the third is a monomial expression derived from fitting to a large database of inductors (whose exact inductance values are obtained from a three-dimensional electromagnetic field solver). All three expressions are accurate, with typical errors of 2% to 3%, and very simple, and are therefore excellent candidates for use in design and optimization.

12.3.2.1 Modified Wheeler Formula

Wheeler [17] presented several formulas for planar spiral inductors, which were intended for discrete inductors. A simple modification of the original Wheeler formula allows us to obtain an expression that is valid for planar spiral integrated inductors:

$$L_{mw} = K_1 \mu_0 \frac{n^2 d_{avg}}{1 + K_2 \rho} \tag{12.11}$$

where

ρ is the fill ratio defined previously

K_1 and K_2 are coefficients and are layout dependent, shown in Table 12.1

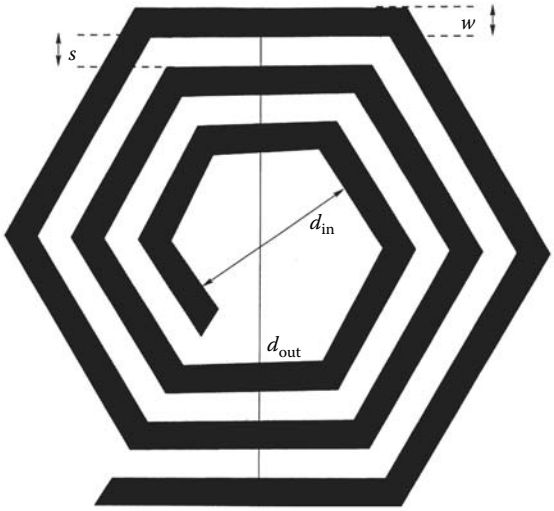

FIGURE 12.15 Hexagonal inductor.

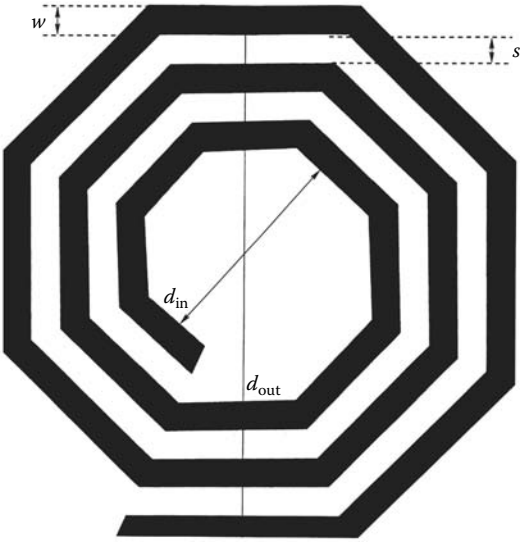

FIGURE 12.16 Octagonal inductor.

TABLE 12.1 Coefficients for Modified Wheeler Formula

Layout	K_1	K_2
Square	2.34	2.75
Hexagonal	2.33	3.82
Octagonal	2.25	3.55

The fill factor ρ represents how hollow the inductor is: for small ρ we have a hollow inductor ($d_{out} \cong d_{in}$), and for a large ρ we have a filled inductor ($d_{out} \gg d_{in}$). Two inductors with the same average diameter but different fill ratios will, of course, have different inductance values; the filled one has a smaller inductance because its inner turns are closer to the center of the spiral, and so contribute less positive mutual inductance and more negative mutual inductance. Some degree of hollowness is generally desired because the innermost turns contribute little overall inductance, but significant resistance.

12.3.2.2 Expression Based on Current Sheet Approximation

Another simple and accurate expression for the inductance of a planar spiral can be obtained by approximating the sides of the spirals by symmetrical current sheets of equivalent current densities [18]. For example, in the case of the square, we obtain four identical current sheets: the current sheets on opposite sides are parallel to one another, whereas the adjacent ones are orthogonal. Using symmetry and the fact that sheets with orthogonal current sheets have zero mutual inductance, the computation of the inductance is now reduced to evaluating the self-inductance of one sheet and the mutual inductance between opposite current sheets. These self- and mutual inductances are evaluated using the concepts of geometric mean distance (GMD) and arithmetic mean distance (AMD) [18,19]. The resulting expression is

$$L_{GMD} = \frac{\mu n^2 d_{avg}}{\pi}(c_1(\log c_2/\rho) + c_3\rho) \tag{12.12}$$

where the coefficients c_i are layout dependent and are listed in Table 12.2.

TABLE 12.2 Coefficients for Current-Sheet Inductance Formula

Layout	c_1	c_2	c_3
Square	2.00	2.00	0.54
Hexagonal	1.83	1.71	0.45
Octagonal	1.87	1.68	0.60

TABLE 12.3 Coefficients for Monomial Inductance Formula

Layout	b	α_1	α_2	α_3	α_4	α_5
Square	1.66×10^{-3}	−1.33	−0.13	2.50	1.83	−0.022
Hexagonal	1.33×10^{-3}	−1.46	−0.16	2.67	1.80	−0.030
Octagonal	1.34×10^{-3}	−1.35	−0.15	2.56	1.77	−0.032

A detailed derivation of these formulas can be found in Ref. [20]. Because this formula is based on a current sheet approximation, its accuracy worsens as the ratio s/w becomes large. In practice, this is not a problem because practical integrated spiral inductors are built with $s < w$. The reason is that a smaller spacing improves the interwinding magnetic coupling and reduces the area consumed by the spiral. A large spacing is only desired to reduce the interwinding capacitance. This is rarely a concern as this capacitance is always dwarfed by the underpass capacitance [8].

12.3.2.3 Data-Fitted Monomial Expression

Our final expression is based on a data-fitting technique, in which a population of thousands of inductors are simulated with an electromagnetic field solver. The inductors span the entire range of values of relevance to RF circuits. A monomial expression is then fitted to the data, which ultimately yields

$$L_{\text{mon}} = \beta d_{\text{avg}}^{\alpha 1} w^{\alpha 2} d_{\text{avg}}^{\alpha 3} n^{\alpha 4} s^{\alpha 5} \tag{12.13}$$

where the coefficients β and α_i are layout dependent, and given in Table 12.3.

Of course, it is also possible to use other data-fitting techniques; for example, one which minimizes the maximum error of the fit, or one in which the coefficients must satisfy given inequalities or bounds. The monomial expression is useful because, similar to the other expressions, it is very accurate and very simple. Its real value, however, is that it can be used for the optimal design of inductors and circuits containing inductors, using geometric programming, which is a type of optimization method that requires monomial models [21,22].

Figure 12.17 shows the absolute error distributions of these expressions. The plots show that typical errors are in the 1%–2% range, and most of the errors are below 3%. These expressions for inductance, while quite simple, are thus sufficiently accurate that field solvers are rarely necessary.

These expressions can be included in a physical, scalable lumped-circuit model for spiral inductors where, in addition to providing design insight, they allow efficient optimization schemes to be employed.

12.4 On-Chip Transformers

Transformers are important elements in RF circuits for impedance conversion, impedance matching, and bandwidth enhancement. Here, we present an analytical model for monolithic transformers that is suitable for circuit simulation and design optimization. We also provide simple expressions for calculating the mutual coupling coefficient (k).

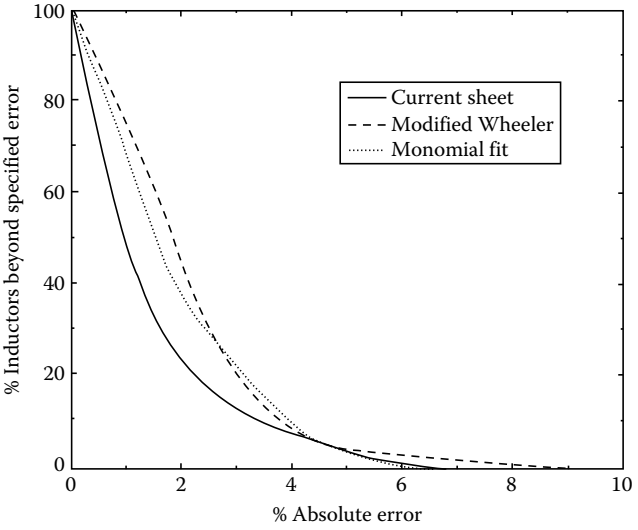

FIGURE 12.17 Error distribution for three formulas, compared with field solver simulations.

We first discuss different on-chip transformers and their advantages and disadvantages. We then present an analytical model along with expressions for the elements in it and the mutual coupling coefficient.

12.4.1 Monolithic Transformer Realizations

Figures 12.18 through 12.23 illustrate common configurations of monolithic transformers. The different realizations offer varying trade-offs among the self-inductance and series resistance of each port, the

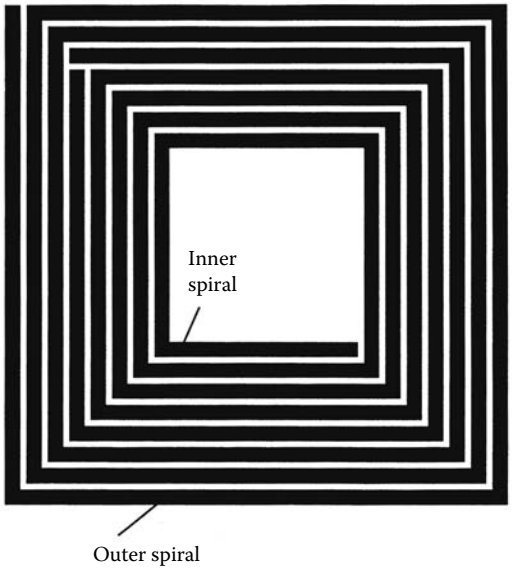

FIGURE 12.18 Tapped transformer.

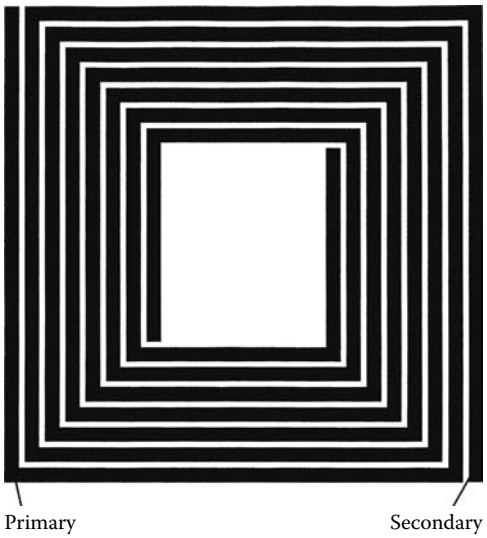

FIGURE 12.19 Interleaved transformer.

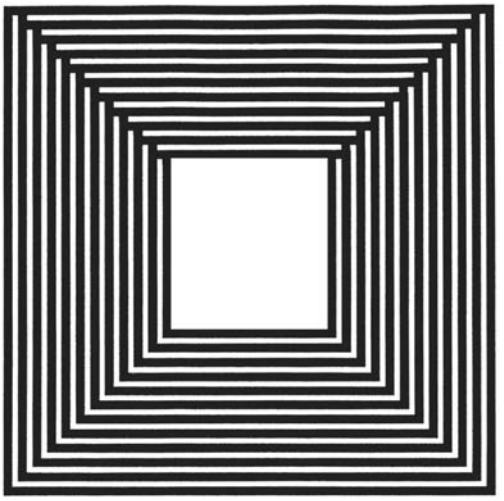

FIGURE 12.20 Stacked transformer with top spiral overlapping the bottom one.

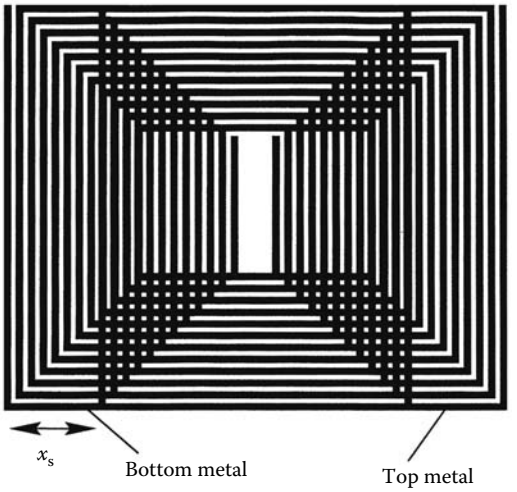

FIGURE 12.21 Stacked transformer with top and bottom spirals laterally shifted.

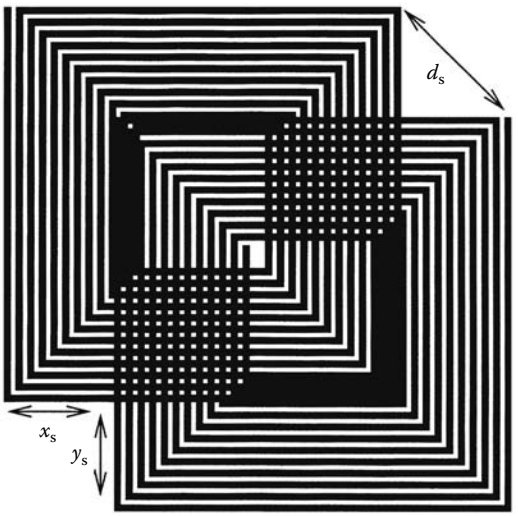

FIGURE 12.22 Stacked transformer with top and bottom spirals diagonally shifted.

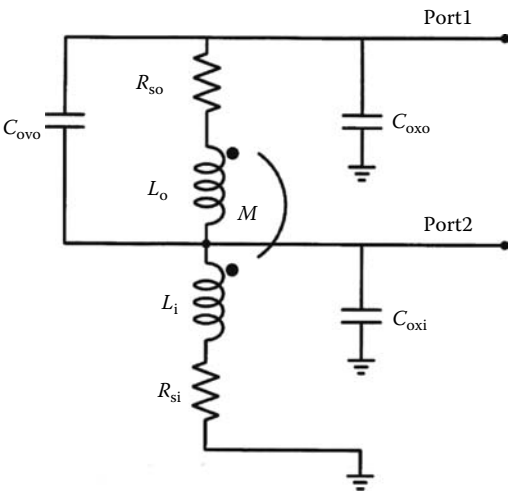

FIGURE 12.23 Tapped transformer model.

mutual coupling coefficient, the port-to-port and port-to-substrate capacitances, resonant frequencies, symmetry, and area. The models and coupling expressions allow these trade-offs to be systematically explored, thereby permitting transformers to be customized for a variety of circuit design requirements.

The characteristics desired of a transformer are application dependent. Transformers can be configured as three- or four-terminal devices. They may be used for narrowband or broadband applications. For example, in single-sided to differential conversion, the transformer might be used as a four-terminal narrowband device. In this case, a high mutual coupling coefficient and high self-inductance are desired, along with low series resistance. On the other hand, for bandwidth extension applications,

the transformer is used as a broadband three-terminal device. In this case, a small mutual coupling coefficient and high series resistance are acceptable, while all capacitances need to be minimized [23].

The tapped transformer (Figure 12.18) is best suited for three-port applications. It permits a variety of tapping ratios to be realized. This transformer relies only on lateral magnetic coupling. All windings can be implemented with the top metal layer, thereby minimizing port-to-substrate capacitances. Because the two inductors occupy separate regions, the self-inductance is maximized while the port-to-port capacitance is minimized. Unfortunately, this spatial separation also leads to low mutual coupling ($k = 0.3$–0.5).

The interleaved transformer (Figure 12.19) is best suited for four-port applications that demand symmetry. Once again, capacitances can be minimized by implementing the spirals with top level metal so that high resonant frequencies may be realized. The interleaving of the two inductances permits moderate coupling ($k = 0.7$) to be achieved at the cost of reduced self-inductance. This coupling may be increased at the cost of higher series resistance by reducing the turn width (w) and spacing (s).

The stacked transformer (Figure 12.20) uses multiple metal layers and exploits both vertical and lateral magnetic coupling to provide the best area efficiency, the highest self-inductance, and highest coupling ($k = 0.9$). This configuration is suitable for both three- and four-terminal configurations. The main drawback is the high port-to-port capacitance, or equivalently a low self-resonant frequency. In some cases, such as narrowband impedance transformers, this capacitance may be incorporated as part of the resonant circuit. Also, in multilevel processes, the capacitance can be reduced by increasing the oxide thickness between spirals. For example, in a five-metal process, 50%–70% reductions in port-to-port capacitance can be achieved by implementing the spirals on layers five and three instead of five and four. The increased vertical separation will reduce k by less than 5%. One can also trade off reduced coupling for reduced capacitance by displacing the centers of the stacked inductors (Figures 12.21 and 12.22).

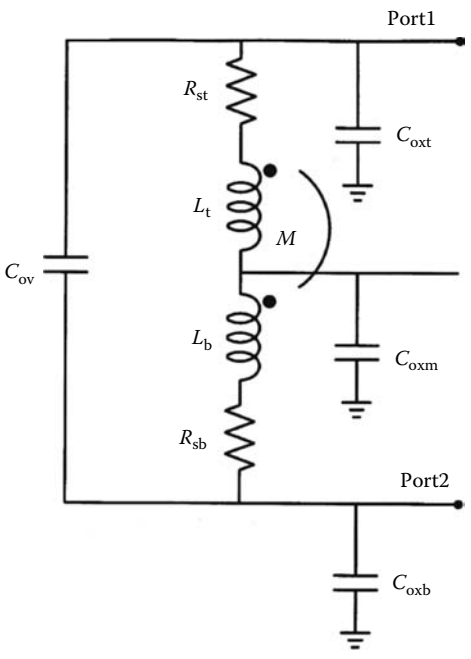

FIGURE 12.24 Stacked transformer model.

12.4.2 Analytical Transformer Models

Figures 12.23 and 12.24 present the circuit models for tapped and stacked transformers, respectively. The corresponding element values for the tapped transformer model are given by the following equations (subscript o refers to the outer spiral, i to the inner spiral, and T to the whole spiral):

$$L_T = \frac{9.375\mu_0 n_T^2 AD_T{}^2}{11OD_T - 7AD_T} \tag{12.14}$$

$$L_o = \frac{9.375\mu_0 n_o^2 AD_o{}^2}{11OD_o - 7AD_o} \tag{12.15}$$

$$L_i = \frac{9.375\mu_0 n_i^2 AD_i{}^2}{11OD_i - 7AD_i} \tag{12.16}$$

$$M = \frac{L_T - L_o - L_i}{2\sqrt{L_o L_i}} \tag{12.17}$$

$$R_{so} = \frac{\rho l_o}{\delta w\left(1 - e^{-\frac{t}{\delta}}\right)} \tag{12.18}$$

$$R_{si} = \frac{\rho l_i}{\delta w\left(1 - e^{-\frac{t}{\delta}}\right)} \tag{12.19}$$

$$C_{ovo} = \frac{\varepsilon_{ox}}{t_{ox,t-b}} \cdot (n_o - 1)w^2 \tag{12.20}$$

$$C_{oxo} = \frac{\varepsilon_{ox}}{2t_{ox}} \cdot l_o w \tag{12.21}$$

$$C_{oxi} = \frac{\varepsilon_{ox}}{2t_{ox}} \cdot (l_o + l_i)w \tag{12.22}$$

where

ρ is the DC metal resistivity
δ is the skin depth
$t_{ox,t-b}$ is the oxide thickness from top level metal to bottom metal
n is the number of turns
OD, AD, and ID are the outer, average, and inner diameters, respectively
l is the length of the spiral
w is the turn width
t is the metal thickness
A is the area

Expressions for the stacked transformer model are as follows (subscript ''t'' refers to the top spiral and b to the bottom spiral):

$$L_t = \frac{9.375\mu_0 n^2 \mathrm{AD}^2}{11\mathrm{OD_T} - 7\mathrm{AD_T}} \tag{12.23}$$

$$L_b = L_t \tag{12.24}$$

$$k = 0.9 - \frac{d_s}{\mathrm{AD}} \tag{12.25}$$

$$M = k\sqrt{L_t L_b} \tag{12.26}$$

$$R_{st} = \frac{\rho_t l}{\delta_t w\left(1 - e^{-\frac{t_t}{\delta_t}}\right)} \tag{12.27}$$

$$R_{sb} = \frac{\rho_b l}{\delta_b w\left(1 - e^{-\frac{t_b}{\delta_b}}\right)} \tag{12.28}$$

$$C_{ov} = \frac{\varepsilon_{ox}}{2t_{ox,t-b}} \cdot l \cdot w \cdot \frac{A_{ov}}{A} \tag{12.29}$$

$$C_{oxt} = \frac{\varepsilon_{ox}}{2t_{oxt}} \cdot l \cdot w \cdot \frac{A - A_{ov}}{A} \tag{12.30}$$

$$C_{oxb} = \frac{\varepsilon_{ox}}{2t_{ox}} \cdot l \cdot w \tag{12.31}$$

$$C_{oxm} = C_{oxt} + C_{oxb} \tag{12.32}$$

where

t_{oxt} is the oxide thickness from top metal to the substrate
t_{oxb} is the oxide thickness from bottom metal to substrate
k is the coupling coefficient
A_{ov} is the overlap area of the two spirals
d_s is the center-to-center spiral distance

The expressions for the series resistances (R_{so}, R_{si}, R_{st}, and R_{sb}), the port-substrate capacitances (C_{oxo}, C_{oxi}, C_{oxt}, C_{oxb}, and C_{oxm}), and the crossover capacitances (C_{ovo}, C_{ovi}, and C_{ov}) are taken from Ref. [8]. Note that the model accounts for the increase in series resistance with frequency due to skin effect. Patterned ground shields (PGS) are placed beneath the transformers to isolate them from resistive and capacitive coupling to the substrate [12]. As a result, the substrate parasitics can be neglected.

The inductance expressions in the foregoing are based on the modified Wheeler formula discussed earlier [24]. This formula does not take into account the variation in inductance due to conductor thickness and frequency. However, in practical inductor and transformer realizations, the thickness is small compared to the lateral dimensions of the coil and has only a small impact on the inductance. For typical conductor thickness variations (0.5–2.0 μm), the change in inductance is within a few percent for practical inductor geometries. The inductance also changes with frequency due to changes in current distribution within the conductor. However, over the useful frequency range of a spiral, this variation is negligible [12]. When compared with field solver simulations, the inductance expression exhibits a maximum error of 8% over a broad design space (outer diameter OD varying from 100 to 480 μm, L varying from 0.5 to 100 nH, w varying from 2 μm to 0.3 OD, s varying from 2 μm to w, and inner diameter ID varying from 0.2 to 0.8OD).

For the tapped transformer, the mutual inductance is determined by first calculating the inductance of the whole spiral (L_T), the inductance of the outer spiral (L_o), the inductance of the inner spiral (L_i), and then using the expression $M = (L_T - L_o - L_i)/2$. For the stacked transformer, the spirals have identical lateral geometries and therefore identical inductances. In this case, the mutual inductance is determined by first calculating the inductance of one spiral (L_T), the coupling coefficient (k) and then using the expression $M = kL_T$. In this last case, the coupling coefficient is given by $k = 0.9 - d_s/(\text{AD})$ for $d_s < 0.7\text{AD}$, where d_s is the center-to-center spiral distance and AD is the average diameter of the spirals. As d_s increases beyond 0.7AD, the mutual coupling coefficient becomes harder to model. Eventually, k crosses zero and reaches a minimum value of approximately -0.1 at $d_s = \text{AD}$. As d_s increases further, k asymptotically approaches zero. At $d_s = 2\text{AD}$, $k = -0.02$, indicating that the magnetic coupling between closely spaced spirals is negligible.

The self-inductances, series resistances, and mutual inductances are independent of whether a transformer is used as a three- or four-terminal device. The only elements that require recomputation are the port-to-port and port-to-substrate capacitances. This situation is analogous to that of a spiral inductor being used as a single- or dual-terminal device.

As with the inductance formulas, the transformer models obviate the need for full field solutions in all but very rare instances, allowing rapid design and optimization.

13.1 Lumped Circuit Approximation

Most texts on circuits, whether they deal with linear or nonlinear circuits, consider only lumped circuits. If this is not the case, such is normally stated explicitly (see, e.g., Section III, in *Feedback, Nonlinear, and Distributed Circuits*). A physical circuit is considered to be a lumped circuit, if its size is small enough that for the situation under discussion, electromagnetic waves propagate across the circuit virtually instantaneously. If this is satisfied, voltages across ports and currents through terminals are well defined and, therefore, well suited to describe and analyze the behavior of a circuit.

To check whether an actual circuit is lumped or not, the largest extension d of the circuit in any spatial dimension is compared to the shortest wavelength λ of interest or with the shortest time interval τ of interest. If

$$d \ll \lambda = c/f, \quad d \ll \tau c \tag{13.1}$$

is fulfilled, the circuit is lumped. In Equation 13.1, c is the propagation velocity of electromagnetic waves in the medium under consideration, and f is the frequency corresponding to the wavelength λ as well as to the period τ.

13.2 Circuit Elements and Connecting Multiport

It is obvious that a nonlinear circuit is described by a set of nonlinear equations, which, generally speaking, can be solved only approximately. Moreover, we may not find a unique solution, but a set of different solutions. Because of this complicated situation (compared to the simple solution of a linear

circuit), it is even more important here to exploit the structure of the equations that reflect the structural properties of the circuit. The most important step in this direction is to partition the circuit into two parts: one containing all circuits elements separately and one containing the interconnections thereof only. The latter is called the connecting multiport (CMP). This partitioning is demonstrated with a real circuit in Figure 13.1; it is obvious that this partitioning is completely independent of the nature of the utilized circuit elements: linear or nonlinear, two-terminal or multiterminal, time-variant, time-invariant, passive or active, and so forth.

The equations that describe the CMP are merely Kirchhoff's current and voltage laws (KCL, KVL) (Section 13.4), which are, of course, linear, while nonlinearities show up in the description of the circuit elements. First, the circuit element is described, and then some details of the CMP are discussed.

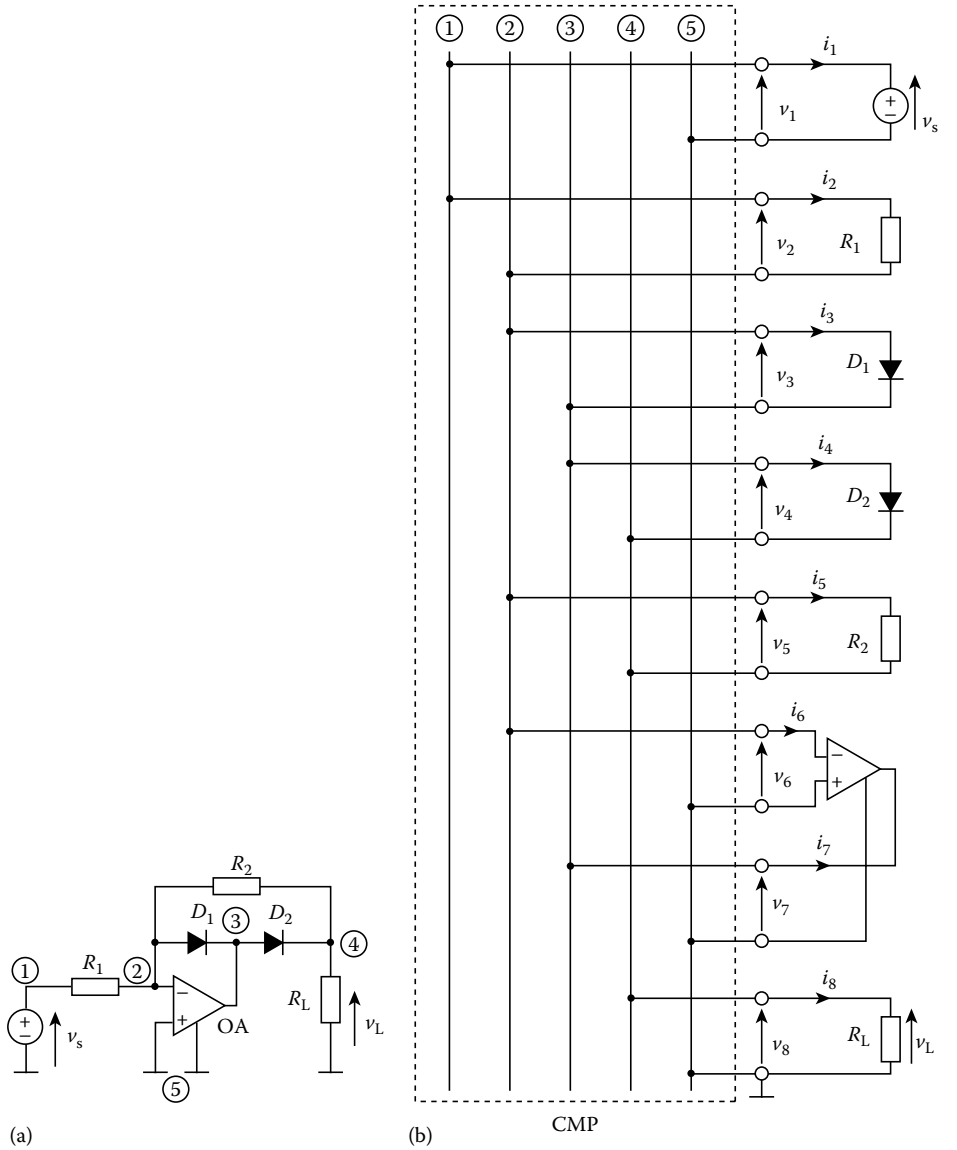

FIGURE 13.1 (a) A nonlinear circuit conventionally drawn. (b) Partitioning into CMP and circuit elements.

13.3 Characterizations of Circuit Elements

This section characterizes a circuit element, two-terminal or multiterminal, with algebraic equations. This necessitates a proper choice of variables. Because of the algebraic nature of this discussion, differential or integral operators cannot be used. Let us begin with a formal discussion, using variables x and y without elaborating on their physical meaning. Later, these methods are applied to specific circuit elements of practical relevance, and voltages, currents, charges, and fluxes are utilized instead of x and y.

13.3.1 Formal Methods of Characterization

A relation between variables x and y can be given in an implicit form

$$\mathcal{F} \subset R \times R,\ x \in R,\ y \in R \quad \mathcal{F} = \{(x,y) | f(x,y) = 0\} \tag{13.2}$$

Here, $\mathcal{F}$ is the characteristic of a two-terminal device which is described by a single implicit equation, $f(x, y) = 0$. Note that this equation is not unique. Various equivalent forms of $f(x, y) = 0$, exist which look quite different, but define the same one-port:

$$g(x,y) = e^{f(x,y)} - 1 = 0 \Leftrightarrow f(x,y) = 0 \tag{13.3}$$

The two functions f and g are quite different, but the tuples (x, y) defined by them constitute the same set $\mathcal{F}$.

A simple example for such an implicit description is

$$f(x,y) = (y/y_0) - \arctan(x/x_0) = 0 \tag{13.4}$$

the plot of which in the (x, y)-plane is shown in Figure 13.2.

An alternative to the aforementioned implicit form is a parametric description, in which we use an additional parameter $\lambda \in R$ to express the port variables as functions of this parameter:

$$x = f_x(\lambda), \quad y = f_y(\lambda) \tag{13.5a}$$

with every tuple

$$(x,y) = \big(f_x(\lambda), f_y(\lambda)\big) \in \mathcal{F} \tag{13.5b}$$

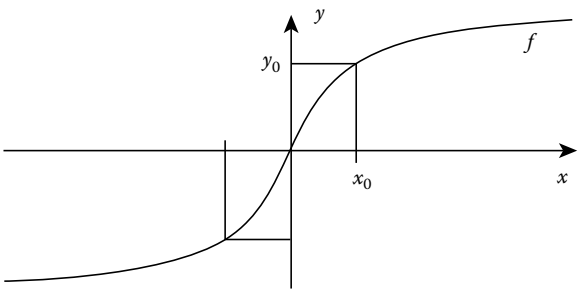

FIGURE 13.2 Plot of the one-port characteristic (Figure 13.1).

being an admissible element of $\mathcal{F}$. Using Equation 13.4 with $\lambda = y/y_0$ we have $x/x_0 = \tan\lambda$ and, therefore,

$$x = f_x(\lambda) = x_0 \tan\lambda, \quad y = f_y(\lambda) = y_0\lambda, \quad \lambda \in (-\pi/2,\pi/2) \tag{13.6}$$

Parameterized descriptions are also not unique, but if the parameter is properly chosen (so that f_x and f_y are continuous and differentiable), they are quite advantageous to work with.

The most favorable description in practical applications is explicit, but it exists only if the relation (Equation 13.2) is unique in at least one of the variables x or y. If y is a function of x (or vice versa), we write

$$y = f(x), \quad x = g(y) \tag{13.7}$$

For this example, both explicit versions do exist:

$$y = y_0 \arctan(x/x_0), \quad x = x_0 \tan(y/y_0), \quad y \in (-y_0\pi/2, y_0\pi/2) \tag{13.8}$$

All these descriptive methods can be extended in a straightforward manner to the multiterminal case by simply replacing the scalars x and y by vectors $\boldsymbol{x}$ and $\boldsymbol{y}$ and the functions f and g by vectors of functions $\boldsymbol{f}$ and $\boldsymbol{g}$.

The formal approach is applied to actual circuit elements in the following section.

13.3.2 Resistive Elements

A resistive element is, by definition, uniquely characterized by one of the aforementioned algebraic descriptions, where x and y are replaced by voltage, v, and current, i. This relation may depend on time, t (time-variant circuit element), but not on the history of the variables v and i.

Many important circuit elements can be modeled resistively, as far as their main property is concerned. This is true for most semiconductor devices such as diodes, bipolar transistors, field effect transistors, operational amplifiers (op-amps), and so forth. This section concentrates on the main effect, leaving a more detailed description, including parasitics, to later sections.

An example of a time-variant (nonautonomous) resistive one-port is given in Figure 13.3

$$\mathcal{F}(t) = \{(v(t), i(t)) | i(t) = I_s(\exp(v(t)/V_T) - 1) - i_L(t)\} \tag{13.9}$$

Using a reverse saturation current $I_s = 10$ μA and a thermal voltage $V_T = 25$ mV the individual characteristics in Figure 13.3b are obtained, illustrating the nonautonomous nature of the device with

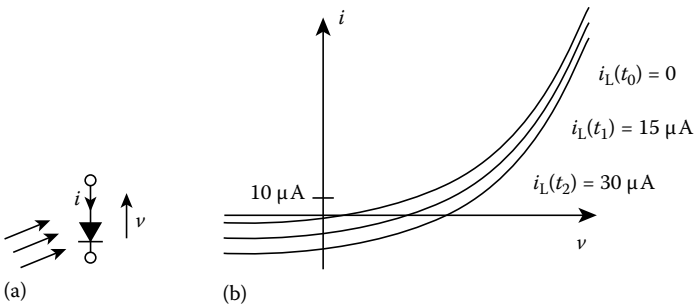

FIGURE 13.3 (a) Device symbol of a photodiode. (b) Device i–v characteristic.

the photocurrent i_L as the controlling parameter, which itself depends on the light intensity, which is assumed to be time dependent.

An ordinary *pn*-junction diode is nothing more than a special case of Equation 13.9, i.e., $i_L = 0$.

Given the device characteristic in graphical form such as Figure 13.3b, which may be the summary of a set of measurements, it is easy to check as to whether explicit descriptions $i = g(u)$ or $u = f(i)$ exist or not. A simple example of a device for which $i = g(u)$ does exist, but g does not have an inverse, is the tunnel diode (Figure 13.4).

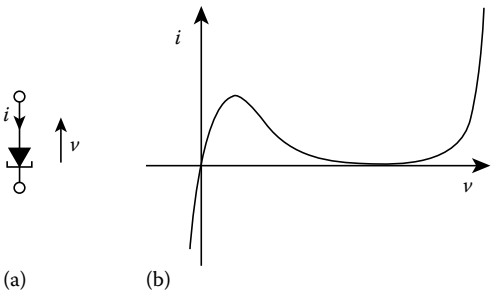

FIGURE 13.4 (a) Symbol and (b) v–i characteristic of a tunnel diode.

Many more nonlinear resistive one-ports or models thereof can be found, but the basic concept is always the same. Therefore, we proceed with an important example of a multiterminal device, the transistor. Again, we have a multitude of various transistors [bipolar *npn* and *pnp*, unipolar field-effect insulated gate transistors (MOSFET) and junction type (JFET), *n*- and *p*-channel, enhancement and depletion, etc.]. Here, we demonstrate only the basic idea of a resistive two-port (or three-terminal *e*mitter, collector, base) model of a bipolar *npn* transistor. Many more details are given in Section II of *Feedback, Nonlinear, and Distributed Circuits*.

The so-called Ebers–Moll equations describe a bipolar *npn* transistor:

$$\begin{aligned} i_e &= -I_{es}(\exp(-v_{eb}/V_T) - 1) + \alpha_R I_{cs}(\exp(-v_{cb}/V_T) - 1) = -i_1 + \alpha_R i_2 \\ i_c &= \alpha_F I_{es}(\exp(-v_{eb}/V_T) - 1) - I_{cs}(\exp(-v_{cb}/V_T) - 1) = \alpha_F i_1 - i_2 \end{aligned} \tag{13.10}$$

which is an explicit two-port description

$$\mathbf{i} = \mathbf{f}(\mathbf{v}) \tag{13.11}$$

with

$$\mathbf{i} = \begin{bmatrix} i_e \\ i_c \end{bmatrix} \quad v = \begin{bmatrix} v_{eb} \\ v_{cb} \end{bmatrix}$$

using the base b as the common terminal. α_F and α_R are the forward and reverse current gain of the transistor in common base configuration as shown in Figure 13.5.

As with any device having more than two terminals, the device characteristics cannot be represented simply as a curve in a plane. In general it is a hypersurface in a multidimensional space. Especially in the

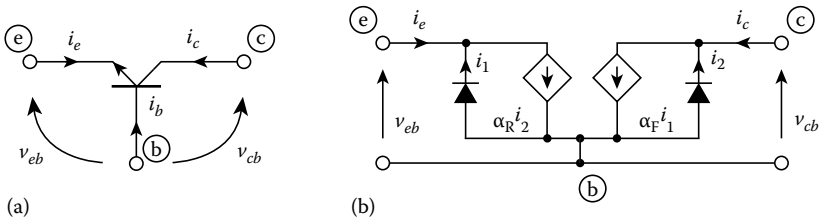

FIGURE 13.5 (a) Symbol and (b) equivalent circuit with two linear CCCSs and two diodes exactly representing Ebers–Moll equation (Equation 13.10).

case of the three-terminal transistor, it is a two-dimensional surface in four-dimensional space. Because this is not easy to visualize, it is normally split into two three-dimensional representations, which commonly are given as follows:

$$\begin{aligned} i_b &= f_1(v_{be}, v_{ce}) \approx f_1(v_{be}) \\ i_c &= f_2(v_{be}, v_{ce}) \approx f_2'(v_{ce}, i_b) \end{aligned} \tag{13.12}$$

To obtain Equation 13.12 from Equation 13.10, we must use

$$i_b = -i_e - i_c, \quad v_{ce} = v_{cb} - v_{eb}, \quad v_{be} = -v_{eb}$$

and i_b is almost independent of v_{ce}. The first of the two equations (Equation 13.12) is already well suited for having a v–i characteristic plotted in a v_{eb}–i_b-plane. The second equation is normally plotted in the v_{ce}–i_c-plane, with i_b as a parameter.

The device characteristics of this bipolar *npn* transistor, as well as those of many other multiterminal semiconductor devices, are today quite standard; they are given in data sheets and used by designers (discussed further in Section II of *Feedback, Nonlinear, and Distributed Circuits*). These nonlinear models are the basis for deriving linearized small signal models, where they are needed.

Finally, we look at a higher level model of a multiterminal device, and model a complete op-amp (containing a multitude of transistors) using a very simple, but nevertheless very powerful resistive model. An op-amp, at a rather high level of abstraction, is a four-terminal device, as depicted in Figure 13.6. In this figure, everything dealing with power supply, biasing, and offset compensation has been hidden. In this very simple model, we assume the input currents to be zero and the output voltage to depend only on the difference of the two input voltages (common mode gain is zero):

$$v_d = v_+ - v_- \tag{13.13}$$

in the following way:

$$v_0 = \begin{cases} V_{\text{sat}} & v_d & \geq & V_{\text{sat}}/A_0 \\ A_0 v_d & |v_d| & \leq & V_{\text{sat}}/A_0 \\ -V_{\text{sat}} & v_d & \leq & -V_{\text{sat}}/A_0 \end{cases} \tag{13.14}$$

Therefore, we have a piecewise linear transfer characteristic, consisting of three pieces (Figure 13.7). According to the three pieces (I, II, and III) we have three equivalent circuits (Figure 13.8). Even if we increase our idealization to $A_0 \to \infty$, the equivalent circuit in Figure 13.8b reduces from the voltage-controlled voltage source (VCVS) to a nullor. (It is worth emphasizing that this surprisingly simple model of such a complex nonlinear functional unit as an op-amp is capable of capturing all of the main effects of such a multitransistor circuit. For many practically important applications, it provides an accurate prediction of the behavior of real circuits.)

If we are not satisfied with resistive models because of the bandwidth of signals to be processed, the model must be refined by including elements with memory. First, we need to set up a way to describe memory-possessing elements (Section 13.3.3) and then combine this with the resistive model into a dynamic model (Section 13.3.5).

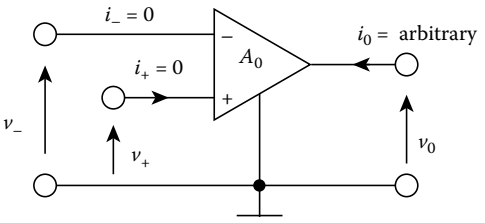

FIGURE 13.6 Symbolic representation of an op-amp.

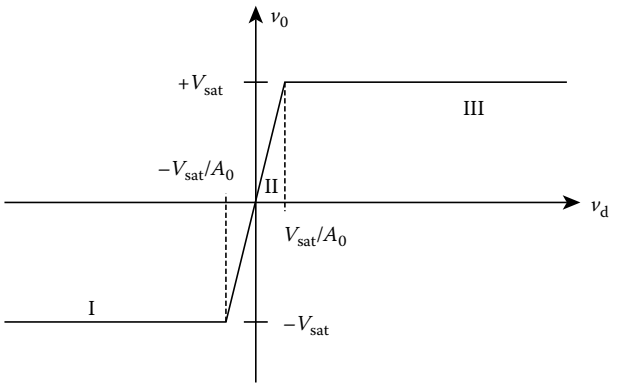

FIGURE 13.7 PWL transfer characteristic of an op-amp.

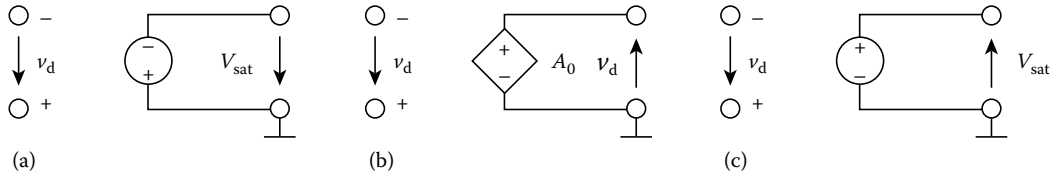

FIGURE 13.8 Equivalent circuit for an op-amp (a) in the negative saturation region I ($v_d \leq -V_{sat}/A_0$), (b) in the linear region II ($v_d \leq V_{sat}/A_0$), and (c) in the positive saturation region III ($v_d \geq V_{sat}/A_0$).

13.3.3 Reactive Elements

To use algebraic description and to plot a characteristic such as a curve in an x–y-plane, we have to extend the set of variables from v and i (resistive case) to charge q and flux ϕ

$$q(t) = q(t_0) + \int_{t_0}^{t} i(\tau)\mathrm{d}\tau \quad \phi(t) = \phi(t_0) + \int_{t_0}^{t} v(\tau)\mathrm{d}\tau \tag{13.15}$$

If the integrals exist for $t_0 \to -\infty$ and if $q(-\infty) = 0$ and $\phi(-\infty) = 0$, we can write

$$q(t) = \int_{-\infty}^{t} i(\tau)\mathrm{d}\tau \quad \phi(t) = \int_{-\infty}^{t} v(\tau)\mathrm{d}\tau$$

which simply means to ignore the initial conditions of charge q and flux ϕ, which are unimportant for the electrical behavior of the component and the circuit.

With this in mind, we define a capacitive (inductive) one-port in the following way:

$$\mathcal{F}_C = \{(v, q) | f_C(v, q) = 0\}, \quad \mathcal{F}_L = \{(i, \phi) | f_L(i, \phi) = 0\} \tag{13.16}$$

Other than this implicit algebraic description, parameterized or even explicit descriptions may exist, similar to the resistive case dealt with previously.

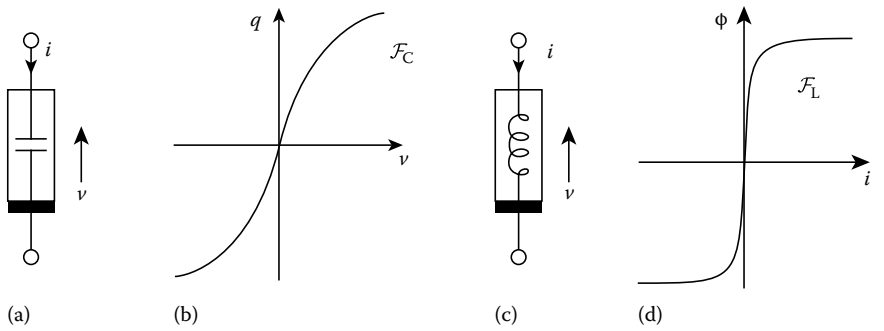

FIGURE 13.9 (a) Symbol and (b) characteristic of capacitor with dielectric material and (c) symbol and (d) characteristic of an inductor with ferromagnetic material.

Figure 13.9 gives examples of some nonlinear characteristics of a capacitive and an inductive reactance. It is obvious that this concept can be extended to the multiterminal case by replacing the scalars v and q or i and ϕ by vectors $\boldsymbol{v}$ and $\boldsymbol{q}$ or $\mathbf{i}$ and ϕ, respectively. This is useful when creating a first-order model of a multiport transformer.

13.3.4 Memristive Elements

After having dealt with resistive and reactive elements and considering all the variables and their interrelations that we used (Figure 13.10), an interesting question remains: What about an element with an algebraic characterization in the q–ϕ-plane? Because this missing element is characterized by an algebraic relation between the integral of current and the integral of voltage, it is a resistive element with memory, and is therefore called a memristor:

$$\mathcal{F}_M = \{(q, \phi) | f_M(q, \phi) = 0\} \tag{13.17}$$

A real-world example of a memristor is the so-called Coulomb cell, which consists of a gold anode immersed in an electrolyte in a silver can cathode. Memristive descriptions, although not widely utilized, are very useful for modeling the behavior of electrochemical elements.

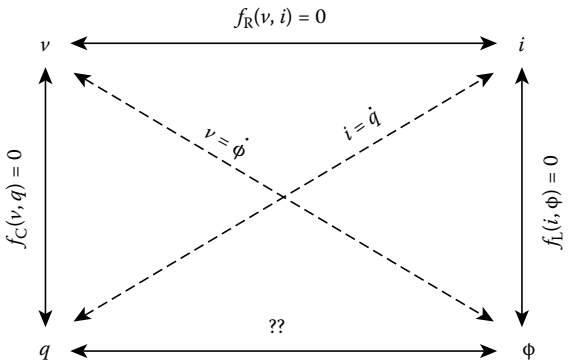

FIGURE 13.10 Interrelation between variables.

13.3.5 Dynamic Models

Only a few examples are illustrated in this section, comprising resistive and reactive elements, in order to achieve a realistic description of electronic devices, including dynamical effects.

A *pn*-junction was described resistively earlier in the chapter, with an exponential *v*–*i* characteristic, neglecting dynamical effects. To remove this shortcoming, we use the more elaborate dynamic model depicted in Figure 13.11, which consists of a resistive *pn*-junction in parallel with a nonlinear capacitor. This extension can, of course, be carried on for the (multiterminal) transistor case, where we use dynamic diode models (Figure 13.12).

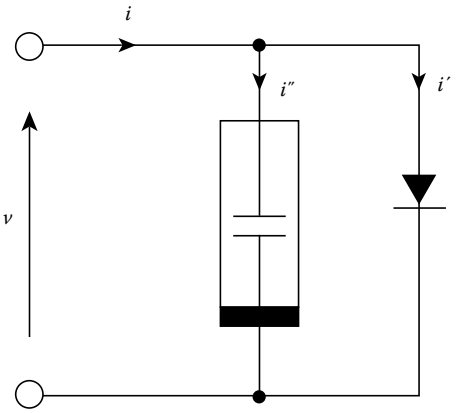

FIGURE 13.11 Dynamic *pn*-junction model.

The combination of the resistive and reactive models in one circuit leads to a description that makes use of differential and integral operators. It is almost always possible to reduce this to a set of nonlinear ordinary differential and algebraic equations. We return to this point later, but first we conclude this section with a dynamic model of an op-amp (Figure 13.13), making use of nonlinear controlled sources (VCVS) and voltage-controlled circuit sources (VCCS). This simple model accounts for the following important practical properties of a real-world op-amp:

- First-order, low-pass behavior in the linear region of the controlled sources.
- Slew rate limitation is incorporated by the nonlinearity of $g_m(v_d)$ of the VCCS (Figure 13.14).
- Output voltage saturation is modeled with the aid of the nonlinearity of $\mu(v_c)$ (Figure 13.15).

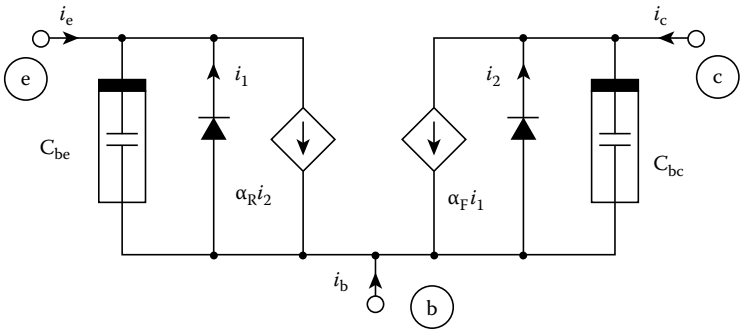

FIGURE 13.12 Dynamic transistor model.

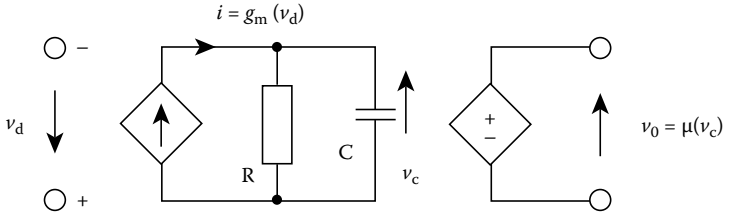

FIGURE 13.13 Dynamic op-amp model.

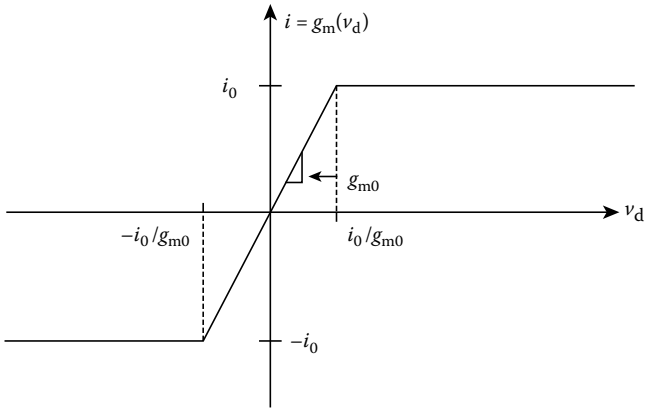

FIGURE 13.14 Nonlinear VCCS in the input stage of the op-amp.

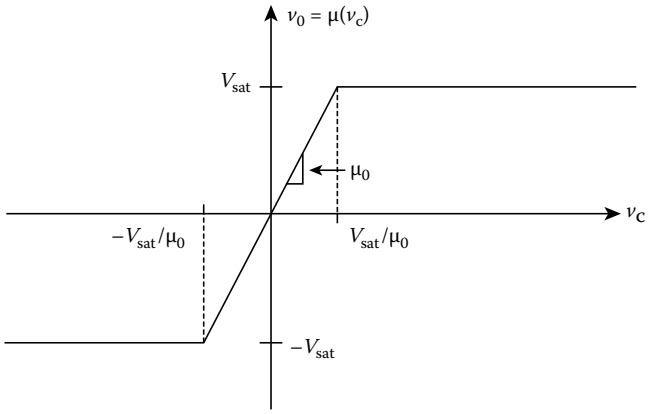

FIGURE 13.15 Nonlinear VCVS in the output stage of the op-amp.

The 3 dB bandwidth of this op-amp is given by $\omega_{3\ dB} = 1/(RC)$ with a 20 dB/decade roll-off. The slew rate is given by $SR = i_0/C$, while the DC open-loop gain $A_0 = g_{m0}\, R\mu_0$.

Using this simple model, not all, but some, of the most important nonlinear dynamical effects are properly described.

13.4 Connecting Multiport

After having dealt with the description of the circuit elements, we return to the interconnection structure, which is summarized in the CMP (Figure 13.1b). This multiport is linear, lossless, and reciprocal and its description stated in implicit form is simply KCL and KVL equations

$$\begin{bmatrix} \mathbf{B} & 0 \\ 0 & \mathbf{A} \end{bmatrix} \begin{bmatrix} \mathbf{v} \\ \mathbf{i} \end{bmatrix} = \begin{bmatrix} \mathbf{B} \\ 0 \end{bmatrix} \mathbf{v} + \begin{bmatrix} 0 \\ \mathbf{A} \end{bmatrix} \mathbf{i} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \Rightarrow \mathbf{Bv} = 0 \quad \text{and} \quad \mathbf{Ai} = 0 \tag{13.18}$$

From Equation 13.18, the linearity is obvious, while the losslessness and reciprocity can be proven easily by making use of

$$\mathbf{BA}^{\mathrm{T}} = 0 \quad \mathbf{AB}^{\mathrm{T}} = 0 \quad \text{rank } \mathbf{A} + \text{rank } \mathbf{B} = b \tag{13.19}$$

(b is the number of ports of the CMP).

In addition to the perfect wires, which are the ingredients of CMP, ideal transformers (which are also linear, lossless, and reciprocal) can be accommodated in the CMP without changing the structure of Equations 13.18 and 13.19. **A** is an $(n-1) \times b$ incidence matrix containing the coefficients of any $(n-1)$ linearly independent nodal equations (or supernodal or cutset equations), while **B** is a $(b-(n-1)) \times b$ incidence matrix, the entries of which are the coefficients of any $(b-(n-1))$ linearly independent loop equations (or fundamental-loop equations).

13.5 Tableau Formulation

Combining the description of the CMP and the description of all circuit elements into one tableau, all information about the circuit under consideration is at our fingertips:

$$\begin{aligned} &\begin{bmatrix} \mathbf{B} & \mathbf{0} \\ \mathbf{0} & \mathbf{A} \end{bmatrix} \begin{bmatrix} \mathbf{v} \\ \mathbf{i} \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \end{bmatrix}, \quad b \text{ linear algebraic equations} \\ &\mathbf{f}(\dot{\mathbf{v}}, \mathbf{v}, \dot{\mathbf{i}}, \mathbf{i}, t) = \mathbf{0}, \quad b \text{ nonlinear differential equations} \end{aligned} \tag{13.20}$$

This set of equations is not unique, although their solution is unique for properly modeled circuits. Instead of using derivatives $\dot{\mathbf{v}} = \mathrm{d}\mathbf{v}/\mathrm{d}t$, $\mathbf{i} = \mathrm{d}\mathbf{i}/\mathrm{d}t$, we could have used integrals, or we could have formulated the equations with $\mathbf{q}$, ϕ,$\dot{\mathbf{q}}$, $\dot{\phi}$ as variables.

It is important to note that at least half of the equations are linear. To solve the nonlinear equations numerical techniques are commonly used, however, this is beyond the scope of this chapter.

14.1 Controlled Sources

14.1.1 Introduction

Controlled sources generate a voltage or current whose value depends on, or is controlled by, a voltage or current that exists at some other point in the circuit. Four such sources exist: (1) voltage-controlled current source (VCCS), (2) voltage-controlled voltage source (VCVS), (3) current-controlled current source (CCCS), and (4) current-controlled voltage source (CCVS). In an ideal controlled source, the generated voltage or current does not vary with the load to which it is connected; this implies a zero output impedance for a voltage source and an infinite output impedance for a current source. In practice, actual controlled sources have finite output impedance, which causes the generated source to vary somewhat with the load. Circuit representations of the four ideal controlled sources are given in Figure 14.1. The input terminals on the left represent the controlling voltage or current, and the output terminals on the right represent the controlled voltage or current; the value of the controlled source is proportional to the controlling input through the constants g, μ, β, and r.

14.1.2 Voltage-Controlled Current Source

A VCCS produces an output current that is proportional to an input control voltage. The idealized small-signal low-frequency behavior of a field-effect transistor (FET) can be characterized by a VCCS, as illustrated in the equivalent circuit for an n-channel metal-oxide-semiconductor field-effect transistor (MOSFET) in Figure 14.2. In the circuit model, the small-signal drain current i_d of the transistor is proportional to the small-signal gate-to-source voltage v_{gs} through the transconductance parameter g_m.

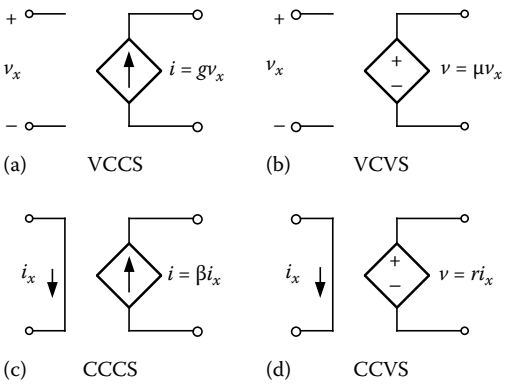

FIGURE 14.1 Circuit representations of ideal controlled sources.

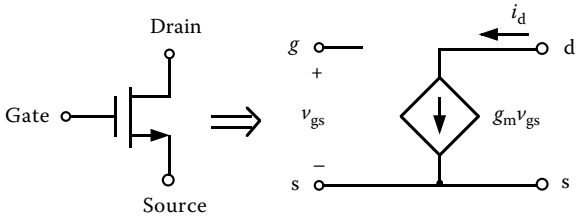

FIGURE 14.2 Small-signal equivalent circuit of a MOSFET.

14.1.2.1 SPICE Format

The format for a VCCS in the circuit simulation program SPICE [1] is illustrated in Figure 14.3. In the data statement, GXXX represents the source name containing up to eight alphanumeric characters (the first character G signifying a VCCS), N+ and N– are the positive and negative nodes of the source, NC+ and NC– are the positive and negative nodes between which the controlling voltage is measured, and VALUE is the multiplicative constant giving the value of the current source. The convention used is that positive current flows from the N+ node through the source to the N– node.

Figure 14.4 is an example of a circuit using a VCCS. The SPICE data specification for the source is: GS1 8 6 3 6 3.4.

14.1.2.2 Circuit Implementation

A circuit implementing a VCCS using an operational amplifier (op-amp) is depicted in Figure 14.5. Assuming the op-amp to be ideal, it is easy to show that $I_o = gV_x$, where $g = 1/R_1$, as indicated in the figure.

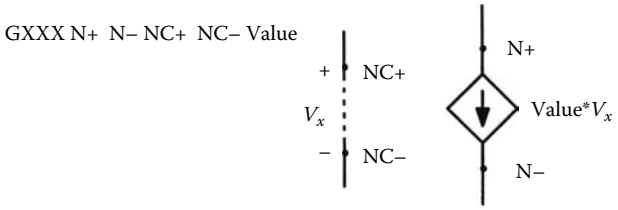

FIGURE 14.3 SPICE format for a VCCS.

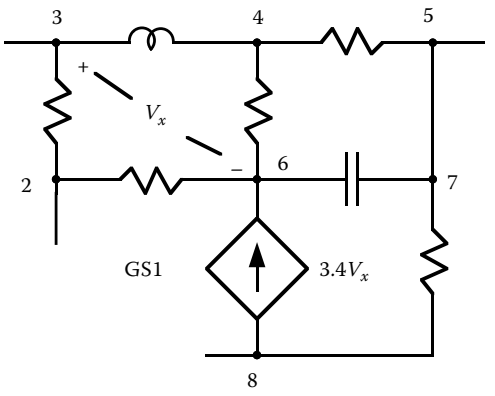

FIGURE 14.4 Example showing a portion of a circuit using a VCCS.

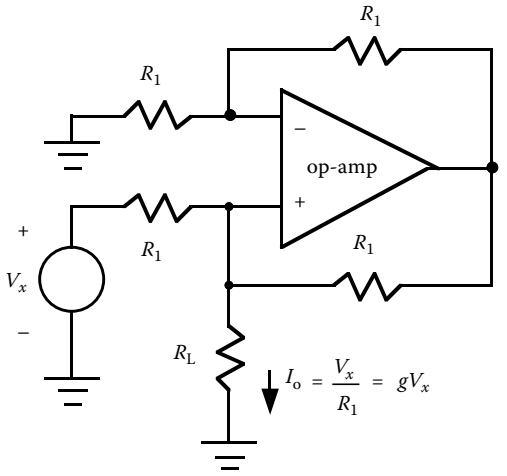

FIGURE 14.5 Op-amp implementation of a VCCS.

An alternate form of the VCCS circuit that uses fewer components is illustrated in Figure 14.6. In the circuit, Q_1 and Q_2 form a current mirror which, due to their equal base–emitter voltages, have the same collector currents, which are reflected in the collector currents of Q_3 and Q_4, causing them to have the same base–emitter voltages; the voltage at the emitter of Q_4 is thus equal to the input control voltage V_x. The emitter current of Q_4 is thus equal to V_x/R_1, which is then (neglecting base currents) equal to the collector current of Q_2. This current is mirrored by Q_5 giving the voltage-controlled output current I_o. This circuit derives from a general form of this configuration called a current conveyor [2]. With this circuit (and as with all practical current sources), the output current is not totally independent of the output voltage across the source, but instead, I_o shows a slight increase with increasing voltage. This is due to the finite output resistance of the source; in the circuit of Figure 14.6, this resistance is equal to the collector-to-emitter resistance of transistor Q_5. For an integrated circuit transistor, this resistance may be of the order of 50 kΩ or so.

14.1.3 Voltage-Controlled Voltage Source

A VCVS produces an output voltage that is proportional to an input control voltage. A voltage amplifier can be thought of as a VCVS; the output voltage is equal to the input voltage multiplied by the voltage gain, μ, of the amplifier.

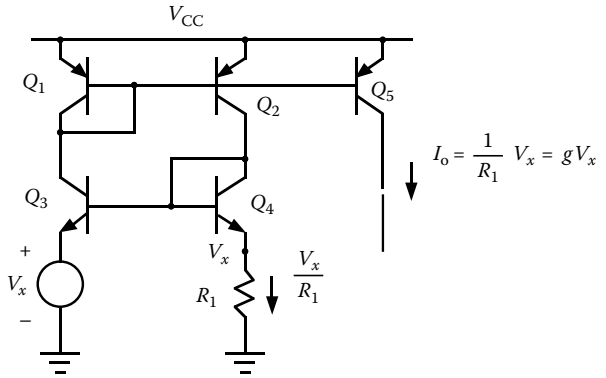

FIGURE 14.6 Circuit that implements a VCCS.

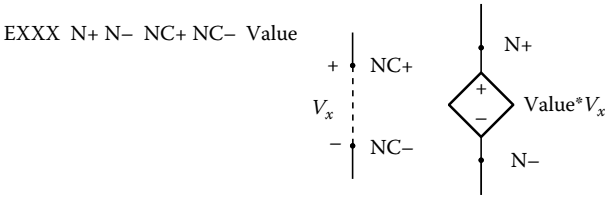

FIGURE 14.7 SPICE format for a VCVS.

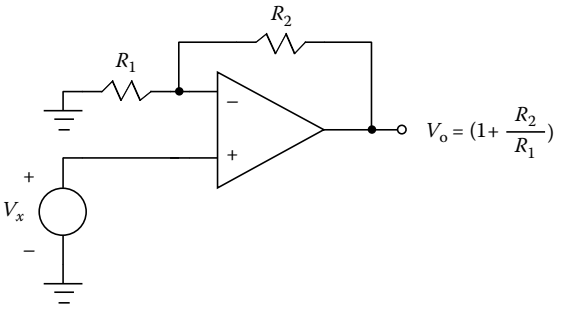

FIGURE 14.8 Circuit implementation of a VCVS using an op-amp.

14.1.3.1 SPICE Format

The SPICE format for a VCVS is given in Figure 14.7. The first character E in the source name signifies a VCVS. The output voltage of the source is given by the product of the VALUE constant and the control voltage V_x.

14.1.3.2 Circuit Implementation

Figure 14.8 is an implementation of the VCVS using an op-amp. Here $V_o = \mu V_x$ where $\mu = 1 + R_2/R_1$. The VCCS circuit of Figure 14.6 can be modified to produce a VCVS. In Figure 14.9, current sensing resistor R_2 develops a voltage drop equal to $V_x R_2/R_1$, which is buffered by a unity-gain stage to reduce loading effects on R_2. The output voltage V_o is thus proportional to the input control voltage V_x. The buffer should have a low output impedance to minimize variations in the output voltage, V_o, with load current drawn by the source.

14.1.4 Current-Controlled Voltage Source

A CCVS produces an output voltage that is proportional to an input control current. In this context, a CCVS may be thought of as a current-to-voltage transducer; the output voltage is equal to the input voltage multiplied by the transresistance, r, of the transducer.

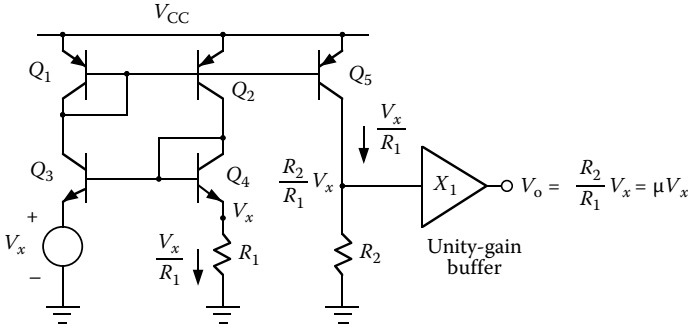

FIGURE 14.9 Circuit that implements a VCVS.

14.1.4.1 SPICE Format

The SPICE format for a CCVS is given in Figure 14.10. The first character *H* in the source name signifies a CCVS. There are no ammeters in SPICE, so currents are measured through voltage sources. VNAME is the voltage source through which the control current I_x is measured. The output voltage of the source is given by the product of VALUE and I_x. If the point in the circuit at which the control current is to be measured does not contain a voltage source, a test voltage source of zero value can be inserted in the circuit.

Figure 14.11 is an example of a circuit using a CCVS. The data statement for the source is HVS2 3 2 VTEST 0.2.

VTEST is a zero-valued voltage source inserted into the circuit to measure the control current I_x. Its data statement is VTEST 6 7 0.

14.1.4.2 Circuit Implementation

An op-amp implementation of a CCVS is given in Figure 14.12. Here, $V_o = rI_x$ where $r = R_1 + R_2$. A simple circuit implementing a CCVS is shown in Figure 14.13. In the current mirror comprising

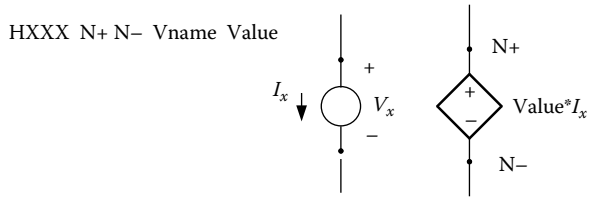

FIGURE 14.10 SPICE format for a CCVS.

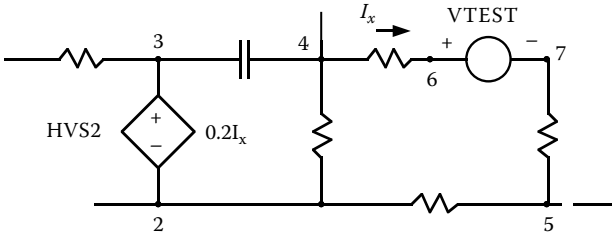

FIGURE 14.11 Example showing a portion of a circuit using a CCVS.

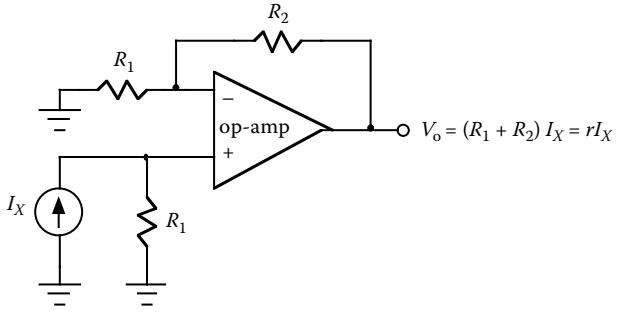

FIGURE 14.12 op-amp implementation of a CCVS.

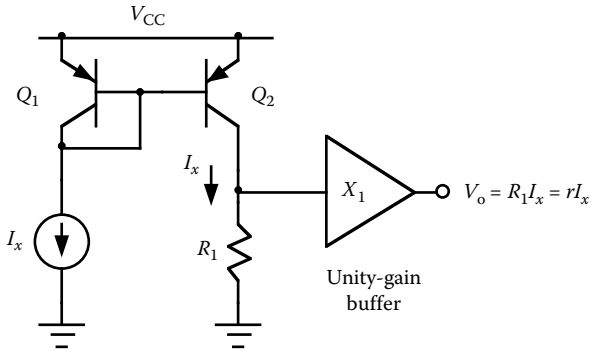

FIGURE 14.13 Circuit that implements a CCVS.

transistors Q_1 and Q_2, the collector current of Q_2 is equal (neglecting base currents) to the control current I_x. The voltage across R_1 is then equal to $R_1 I_x$, which after the buffer, is the current-controlled output voltage.

14.1.5 Current-Controlled Current Source

A CCCS produces an output current that is proportional to the input control current. The idealized large-signal (and small-signal as well) low-frequency behavior of a bipolar transistor can be characterized by a CCCS, as illustrated in the equivalent circuit for an NPN transistor in Figure 14.14. In the circuit model, the collector current I_C is proportional to the base current I_B through the current gain parameter β_F.

14.1.5.1 SPICE Format

The SPICE format for a CCCS is given in Figure 14.15. The first character F in the source name signifies a CCCS. The output current is given by the product of the VALUE constant and the control current I_x. As with the CCVS, the controlling current is measured through an independent voltage source.

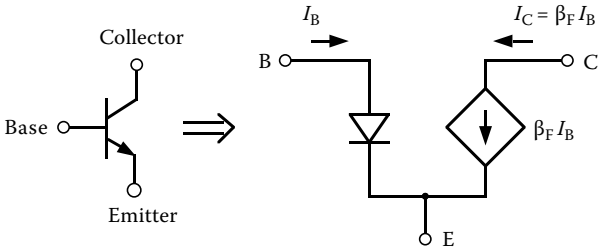

FIGURE 14.14 Large-signal equivalent circuit of a bipolar transistor.

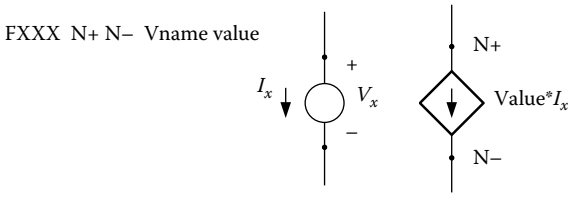

FIGURE 14.15 SPICE format for a CCCS.

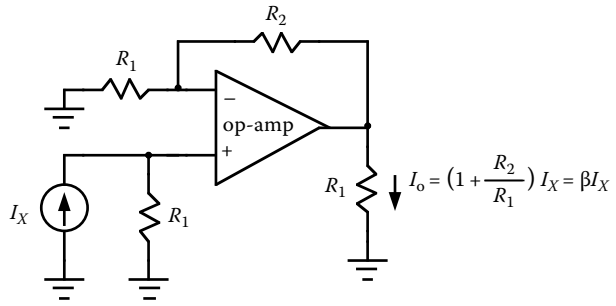

FIGURE 14.16 op-amp implementation of a CCCS.

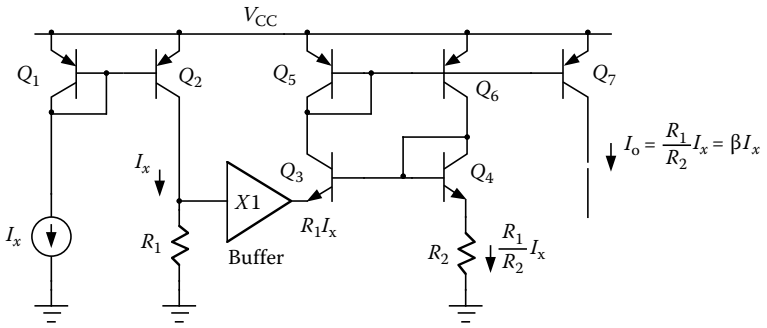

FIGURE 14.17 Circuit that implements a CCCS.

14.1.5.2 Circuit Implementation

Figure 14.16 is an op-amp implementation of a CCCS. Here, $I_o = \beta I_x$ where $\beta = 1 + R_2/R_1$.

The CCVS circuit in Figure 14.13 can be combined with the VCCS circuit in Figure 14.6 to produce a CCCS, as illustrated in Figure 14.17. The output voltage of the CCVS stage is equal to $R_1 I_x$, which, applied at the emitter of Q_3, is the input voltage of the VCCS stage; the output current is equal to $(R_1/R_2)I_x$, and thus proportional to the input control current.

14.2 Signal Converters

An accessible terminal pair of a network, regarded as a single entity to which an independent 2-terminal signal generator (source or input) is to be connected, is called a port of the network. An equivalent view of a port of a network is an accessible terminal pair such that the current entering one of the terminals of the pair is the same current leaving the other terminal of the pair. Thus, an accessible terminal pair of a network is a port when this terminal pair is terminated by (connected to) a 1-port network. For a given port of a network, the port voltage (the voltage drop between the two terminals) and the port current

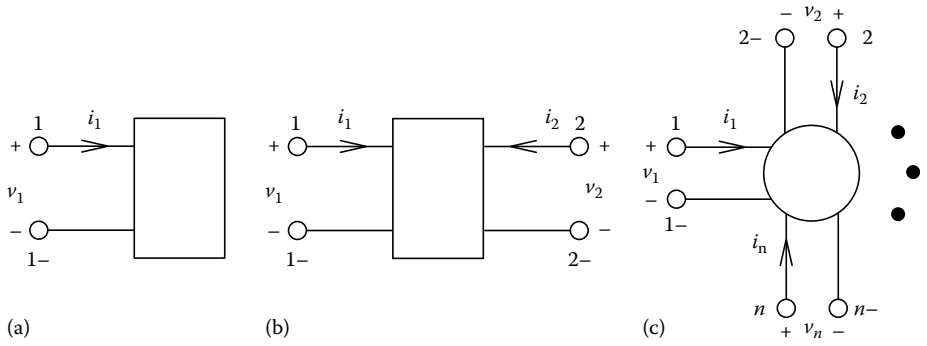

FIGURE 14.18 (a) A 1-port. (b) A 2-port. (c) An *n*-port.

(the current entering one of the terminals) are to be associated as follows: the positive sign for the voltage (drop) is always assumed at the terminal at which the current (positive charges) enters the network. A 1-port, 2-port, and general *n*-port are illustrated in Figure 14.18.

In linear network theory, a class of *n*-ports (particularly $n = 2$), known as signal converters, has become salient as crucial building blocks. These 2-port signal converters include the various versions of the ''transformer,'' ''controlled source,'' and ''operational amplifier'' found elsewhere in Section II. This section will introduce the 2-port signal converters known as the ''gyrator'' and ''negative impedance converter (NIC).'' As extensions of these, the ($n \geq 2$)-port ''circulator'' is developed and, as special cases, the 1-ports known as ''nullator'' and ''norator'' (properly viewed as degenerate cases) and the 2-port known as ''nullor'' are given.

One of the most general external descriptions of a linear *n*-port network is the ''scattering'' matrix. In many cases, a linear *n*-port network may be externally described by one or more of the ''open-circuit impedance,'' ''short-circuit admittance,'' ''hybrid,'' ''inverse hybrid,'' ''chain (transmission),'' or ''inverse chain (inverse transmission)'' matrix. For details of these *n*-port descriptions, see [1]. As necessary or convenient, any of the above *n*-port descriptions will be utilized in this section.

14.2.1 Gyrator

The concept of reciprocity satisfied by a linear *n*-port network ($n = 2$, in particular) will be useful in the present context.

Definition: A linear *n*-port network is said to be a reciprocal linear *n*-port network if the port voltages and currents satisfy

$$\sum_{k=1}^{n} \left[v_k^{(1)} i_k^{(2)} - v_k^{(2)} i_k^{(1)} \right] = 0 \tag{14.1}$$

where $v_k^{(1)}$, $i_k^{(1)}$ and $v_k^{(2)}$, $i_k^{(2)}$ are any two distinct sets of port voltages and currents that satisfy Kirchhoff's laws for the linear *n*-port. If Equation 14.1 is not satisfied, the linear *n*-port is said to be nonreciprocal. [Note: for many useful linear *n*-port networks, Equation 14.1 can be derived from Tellegen's theorem in Chapter 7].

The idea of isolating the nonreciprocity of a linear passive *n*-port in a single network building block was first advanced by Tellegen [2]. The linear passive 2-port developed there, christened the gyrator, was

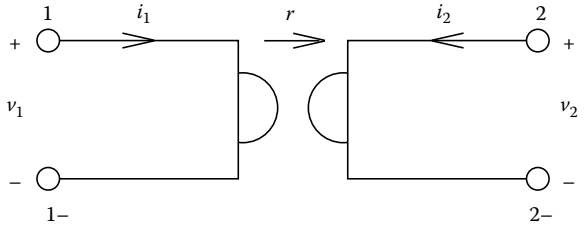

FIGURE 14.19 The ideal 2-port gyrator.

shown to be necessary and sufficient for this purpose. This (ideal) 2-port gyrator is described by the skew-symmetric open-circuit impedance matrix

$$\mathbf{Z} = \begin{bmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{bmatrix} = \begin{bmatrix} 0 & -r \\ r & 0 \end{bmatrix} \tag{14.2}$$

where r (the gyrator transfer impedance parameter) is a real positive number, and is depicted in Figure 14.19.

It can be observed that $v_1 = -ri_2$ and $v_2 = ri_1$ (so the signal conversion is clear), and by multiplying these together to obtain $rv_1i_1 = -rv_2i_2$ or $v_1i_1 + v_2i_2 = 0$, then no energy is generated, dissipated, or stored. Thus, the ideal gyrator is a lossless passive nonreciprocal 2-port. Also easily shown is that, if port 2 is terminated with the 1-port (driving-point) impedance Z, then the driving-point impedance seen at port 1 is $Z_{11} = -z_{12}z_{21}/Z = r^2/Z$ so that the ideal 2-port gyrator is also an ideal impedance invertor. This leads to another attribute of the ideal 2-port gyrator as a fundamental building block for the synthesis of linear networks. If Z in the above is the impedance of an ideal capacitor C, i.e., $Z = 1/sC$, then

$$Z_{11'} = \frac{r^2}{Z} = r^2sC = L_{11'}s \tag{14.3}$$

which means that the driving-point impedance $Z_{11'}$ is exactly equivalent to the impedance of an ideal inductor $L_{11'} = r^2C$. This opens a viable avenue to the inductorless synthesis of linear passive *RLC* networks.

The ideal 2-port gyrator is a 4-terminal passive network (device or element). For network (and physical realization) purposes, however, it is usually implemented with active elements (and thus considered as an "active" building block) and results in a 3-terminal or "common ground" 2-port. For this reason, the simulation of a nongrounded ("floating") inductor in a network is not straightforward. The active realization of the ideal gyrator also results in a nonideal gyrator (i.e., in general $z_{11} \neq 0$, $z_{22} \neq 0$, $z_{12} \neq -z_{21}$). These concerns are treated elsewhere [3].

A circuit using two operational amplifiers and *R*'s and a single capacitor for inductor simulation (and thus a gyrator simulation) was proposed by Antoniou [4]. This circuit has subsequently become very widely used. Assuming ideal operational amplifiers and general *RC* 1-ports, this circuit is illustrated in Figure 14.20.

Analysis yields

$$Z_{11} = \frac{V_1}{I_1} = \left(\frac{Z_1Z_3}{Z_2Z_4}\right)Z_5 \tag{14.4}$$

For Equation 14.4 to appear as Equation 14.3, two choices exist because either Z_2 or Z_4 must be the impedance of the capacitor. The simplest choices then are

1. $Z_1 = R_1$, $Z_2 = \dfrac{1}{C_2s}$, $Z_3 = R_3$, $Z_4 = R_4$, $Z_5 = R_5$ results in

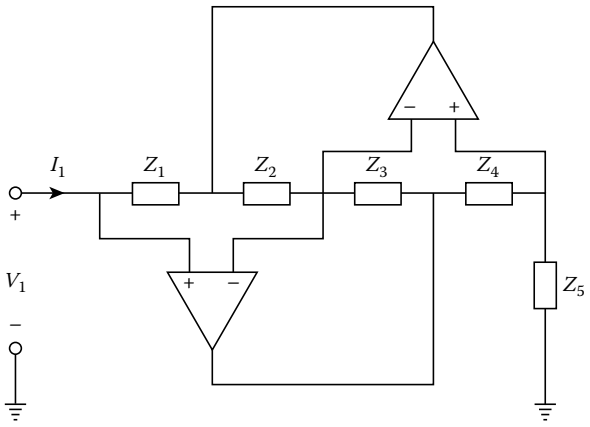

FIGURE 14.20 Antoniou's circuit.

$$Z_{11} = \left(\frac{R_1 R_3 R_5}{R_4}\right) C_2 s = L_{11} s$$

2. $Z_1 = R_1, \quad Z_2 = R_2, \quad Z_3 = R_3, \quad Z_4 = \dfrac{1}{C_4 s}, \quad Z_5 = R_5$ results in

$$Z_{11} = \left(\frac{R_1 R_3 R_5}{R_2}\right) C_4 s = L_{11} s$$

These are known as type-*A* and type-*B* simulations, respectively. Assume the capacitor in *A* and *B* above is removed (pliers-type entry) from Figure 14.20, thus forming a 2-port. With the proper choice of numbering port 2 terminals, the resulting 2-port is a 4-terminal ideal gyrator. On the other hand, forming the second port by removing Z_5 from Figure 14.20, and the obvious choice of numbering port 2 terminals, results in a grounded 2-port impedance converter with

$$Z_{11} = \left(\frac{Z_1 Z_3}{Z_2 Z_4}\right) Z_5 = K(s) Z_5 \tag{14.5}$$

This is Antoniou's generalized impedance convertor (GIC).

The rational function $K(s)$ in Equation 14.5 can, in general, be any function subject to Z_1, Z_2, Z_3, and Z_4 being the driving-point impedances of *RC* 1-port networks. So if the GIC of Equation 14.5 has $Z_1 = 1/C_1 s$, $Z_2 = R_2$, $Z_3 = R_3$, but $Z_4 = R_4$ and $Z_5 = 1/C_5 s$, then

$$Z_{11}(s) = \frac{R_3}{C_1 C_5 R_2 R_4 s^2} = \frac{1}{D s^2} \tag{14.6}$$

so that for sinusoidal excitations ($s = j\omega$)

$$Z_{11}(j\omega) = \frac{-1}{D\omega^2} = R_{11}\left(\omega^2\right) \tag{14.7}$$

Thus, Z_{11} of Equation 14.7 is a frequency-dependent negative resistance (FDNR). Alternate realizations of FDNR are possible. The FDNR element plays an important role in the design of active *RC* networks.

14.2.2 Voltage Negative Impedance Converter

Suppose a 2-port signal converter such that, with one of its ports terminated with an impedance, the driving-point impedance at the other port is proportional to the negative of the terminating impedance. Such a 2-port is known as an NIC [5]. For a general 2-port terminated at port 2 with the impedance $Z = 1/Y$, the driving-point impedance seen at port 1 is, in terms of the hybrid parameters of the 2-port,

$$Z_{11} = \frac{h_{11} - h_{12}h_{21}}{h_{22} + Y} \tag{14.8}$$

Hence, necessary and sufficient conditions for a 2-port to be an NIC is that $h_{11} = 0$, $h_{22} = 0$, and $h_{12}h_{21} > 0$, so Equation 14.8 becomes

$$Z_{11} = -h_{12}h_{21}Z = -kZ \tag{14.9}$$

where $k > 0$ is called the negative impedance parameter. Now $h_{12}h_{21} > 0$ holds in two cases for h_{12} and h_{21} real:

$$1.\quad h_{12} < 0 \quad \text{and} \quad h_{21} < 0 \tag{14.10}$$

$$2.\quad h_{12} > 0 \quad \text{and} \quad h_{21} > 0 \tag{14.11}$$

Consider an NIC satisfying Equation 14.10. From the hybrid description, this 2-port signal converter has $v_1 = h_{12}v_2$ and since $h_{12} < 0$ this implies a voltage reversal between the ports, while $i_2 = h_{21}i_1$ and because $h_{21} < 0$ this implies the current direction remains the same. For this reason, Equation 14.10 defines a voltage inversion negative impedance converter (VNIC).

14.2.3 Current Negative Impedance Converter

Consider an NIC satisfying Equation 14.11. From the hybrid description, this 2-port signal converter has $v_1 = h_{12}v_2$ and since $h_{12} > 0$, this implies no voltage reversal between the ports, while $i_2 = h_{21}i_1$ and because $h_{21} > 0$ this implies the current directions have reversed. For this reason, Equation 14.11 defines the current inversion negative impedance converter (INIC).

As with the gyrator, for network (and physical realization) purposes, the NIC is implemented with active devices but for a more fundamental reason. Consider k in Equation 14.9 to be 1 with $h_{12} = h_{21}$ to be either 1 or -1. Then for VNIC or INIC this implies $v_1i_1 - v_2i_2 = 0$ so the NIC is inherently active. Any physical realization of the NIC will result in a nonideal NIC (i.e., in general $h_{11} \neq 0$, $h_{22} \neq 0$, $h_{12}h_{21} \neq 1$). These concerns are treated elsewhere, e.g., Ref. [3].

An obvious use of an NIC in active network synthesis is to obtain negative elements, i.e., negative resistor or inductor or capacitor from positive resistor or inductor or capacitor, respectively. Another way an NIC is used in active network synthesis is the partitioning of a network using an NIC. Consider two cascaded 2-ports as shown in Figure 14.21 to form an overall 2-port.

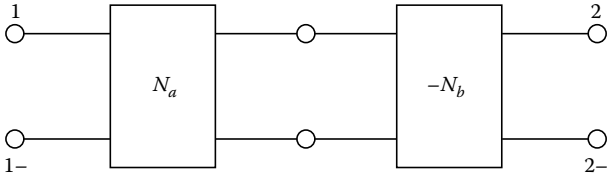

FIGURE 14.21 Cascade of 2-ports designated N_a and $-N_b$.

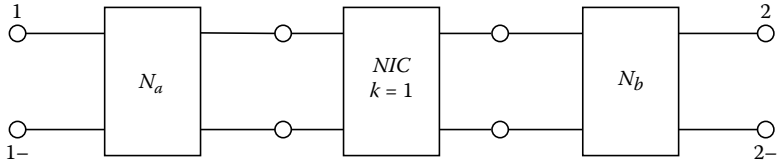

FIGURE 14.22 Equivalent to Figure 14.21.

Suppose in Figure 14.21, N_a is a 2-port with all positive elements and $-N_b$ is a 2-port with all negative elements. Then it can be shown that the overall 2-port shown in Figure 14.22 with an NIC of $k = 1$, and with N_b being the same as $-N_b$ in Figure 14.21, except it is now composed of all positive elements, is equivalent to the overall 2-port shown in Figure 14.21. These and other methods of using NIC's in active *RC* synthesis may be found elsewhere, e.g., Ref. [3].

14.2.4 Circulator

As discussed in Section 14.2.1, the gyrator is the basic representation of nonreciprocity in linear networks. It is quite natural to believe this property can also be exploited to derive a means of controlling the power flow in n-port ($n \geq 2$) linear networks from the input port to the remaining ports in a prescribed manner. This is indeed the situation and the most important of such n-ports are known as circulators.

Circulators are best described in terms of the scattering matrix, since this makes their function very clear. A brief discussion of the scattering description for a 2-port network (extended in a natural way for n-port ($n > 2$) networks) follows, see Ref. [6]. Consider the terminated 2-port in Figure 14.23.

Assume $r_{01} > 0$ and $r_{02} > 0$. Define incident and reflected power waves $\boldsymbol{a} = [a_1\ a_2]'$ and $\boldsymbol{b} = [b_1\ b_2]'$, respectively, where the prime denotes matrix transpose, as

$$\boldsymbol{a} = (1/2)\boldsymbol{R}_0^{-1/2}(\boldsymbol{V} + \boldsymbol{R}_0\boldsymbol{I}) \tag{14.12}$$

$$\boldsymbol{b} = (1/2)\boldsymbol{R}_0^{-1/2}(\boldsymbol{V} - \boldsymbol{R}_0\boldsymbol{I}) \tag{14.13}$$

where

$\boldsymbol{R}_0 = \text{diag}(r_{01}, r_{02})$
$\boldsymbol{V} = [V_1\ V_2]'$
$\boldsymbol{I} = [I_1\ I_2]'$

Assume that $\boldsymbol{V} = \boldsymbol{Z}\boldsymbol{I}$ for the 2-port and because Equations 14.12 and 14.13 are also linear relations between $\boldsymbol{V}$ and $\boldsymbol{I}$, then $\boldsymbol{a}$ and $\boldsymbol{b}$ are also linearly related as

$$\boldsymbol{b} = \boldsymbol{S}\boldsymbol{a} \tag{14.14}$$

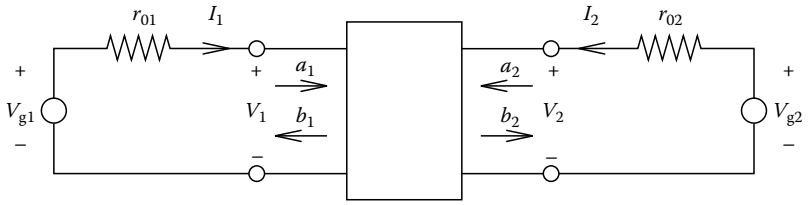

FIGURE 14.23 General terminated 2-port network.

where $\boldsymbol{S}$ is the scattering matrix with respect to $\boldsymbol{R}_0$. For the 2-port network in Figure 14.23, Equation 14.14 is explicitly

$$\begin{aligned} b_1 &= S_{11}a_1 + S_{12}a_2 \\ b_2 &= S_{21}a_1 + S_{22}a_2 \end{aligned} \tag{14.15}$$

Hence, the scattering parameters are determined as

$$S_{jj} = \frac{b_j}{a_j}, \quad \text{for } a_k = 0 \text{ and } k \neq j \tag{14.16}$$

and

$$S_{kj} = \frac{b_k}{a_j}, \quad \text{for } a_k = 0 \text{ and } k \neq j \tag{14.17}$$

The parameter S_{jj} is called the reflection coefficient at the jth port and S_{kj} is called the transmission coefficient from port j to port k. The conditions in Equations 14.16 and 14.17, together with Equations 14.12 and 14.13, imply.

$$S_{jj} = \frac{(Z_{jj} - r_{0j})}{(Z_{jj} + r_{0j})} \tag{14.18}$$

and

$$S_{kj} = -2\sqrt{r_{0j}r_{0k}}\,\frac{I_k}{V_{gj}} \tag{14.19}$$

The network is said to be matched at port j if $S_{jj} = 0$, or from Equation 14.18, $r_{0j} = Z_{jj}$. Also from Equation 14.19 and $|S_{kj}|^2 = |b_k|^2/|a_j|^2$, it is clear that $|S_{kj}|^2$ is the power gain of the terminated n-port from the source at port j to the load resistor r_{0k} at port k. For example, consider the ideal 2-port gyrator with gyration transfer parameter $r > 0$ and $r_{01} = r_{02} = r$. Here,

$$\mathbf{S} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} = \begin{bmatrix} 0 & -1 \\ 0 & 1 \end{bmatrix} \tag{14.20}$$

The simplest type of circulator is the 2-port circulator. Consider the 2-port in Figure 14.24, which has (for $r_{01} = r_{02} = 1$)

$$\mathbf{S} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \tag{14.21}$$

This 2-port circulator has unity power transmission from port 1 to port 2, but zero power transmission from port 2 to port 1, and is also called an isolator or one-way line.

Now a 3-port circulator may be defined by the scattering matrix

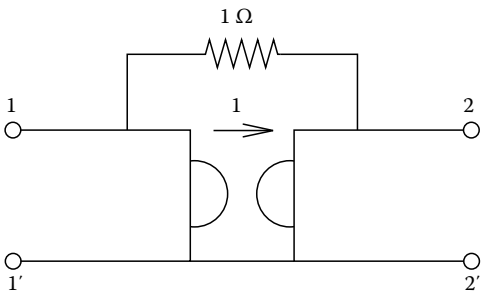

FIGURE 14.24 2-Port circulator.

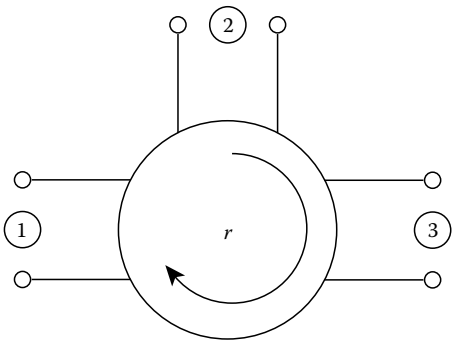

FIGURE 14.25 Matched 3-port circulator.

$$\mathbf{S} = \begin{bmatrix} S_{11} & S_{12} & S_{13} \\ S_{21} & S_{22} & S_{23} \\ S_{31} & S_{32} & S_{33} \end{bmatrix} = \begin{bmatrix} 0 & 0 & S_{13} \\ S_{21} & 0 & 0 \\ 0 & S_{32} & 0 \end{bmatrix} \tag{14.22}$$

with each nonzero $S_{kj} = \pm 1$, so it has unity power transfer from port 1 to 2, 2 to 3, and 3 to 1. This 3-port circulator is usually depicted as shown in Figure 14.25, where the + and − terminals of each port depend on the selection of each nonzero S_{kj} in Equation 14.22. Likewise, a 4-port circulator may be defined by the scattering matrix

$$\mathbf{S} = \begin{bmatrix} S_{11} & S_{12} & S_{13} & S_{14} \\ S_{21} & S_{22} & S_{23} & S_{24} \\ S_{31} & S_{32} & S_{33} & S_{34} \\ S_{41} & S_{42} & S_{43} & S_{44} \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 & S_{14} \\ S_{21} & 0 & 0 & 0 \\ 0 & S_{32} & 0 & 0 \\ 0 & 0 & S_{43} & 0 \end{bmatrix} \tag{14.23}$$

with each nonzero $S_{kj} = \pm 1$, and depicted as suggested in Figure 14.25. Similarly, the n-port ($n > 4$) circulator may be defined and depicted as suggested in Figure 14.25. See Ref. [6] for details.

14.2.4.1 Nullator

It is a fact that every linear passive n-port network has a scattering description. However, to complete the description of general linear n-port networks (which may not have a scattering description), a few "pathological" or "degenerate" 1- and 2-ports must be included [7]. The first of these is the 1-port linear network denoted as the "nullator." For the exact configuration obtained by terminating Figure 14.25 (with normalization parameters equal to unity) at port 2 with $-1\ \Omega$ and at port 3 with $+1\ \Omega$, the driving-point relations seen at port 1 are

$$V_1 = I_1 = 0 \tag{14.24}$$

so the resulting 1-port is at once a short and open circuit! This linear 1-port has been designated as the nullator. The circuit symbol for the nullator is depicted in Figure 14.26.

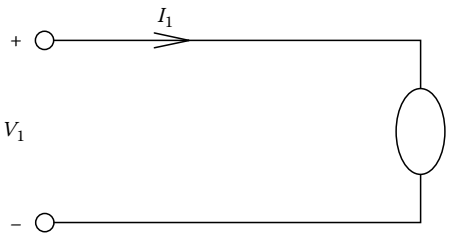

FIGURE 14.26 Nullator ($V_1 = I_1 = 0$).

14.2.4.2 Norator

Another degenerate 1-port can be obtained from the exact configuration obtained by terminating Figure 14.25 (with unity normalization parameters) at port 2 with $+1\ \Omega$ and at port 3 with $-1\ \Omega$. The resulting driving-point relations seen at port 1 are that

$$V_1 \text{ and } I_1 \text{ are completely independent} \tag{14.25}$$

This (nonreciprocal) linear 1-port has been designated as the norator. The circuit symbol for the norator is shown in Figure 14.27.

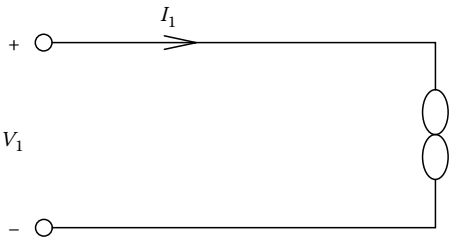

FIGURE 14.27 The norator (V_1 and I_1 are arbitrary).

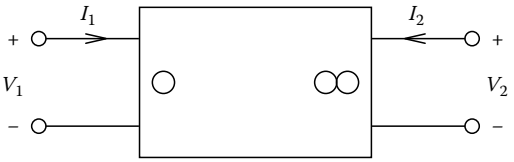

FIGURE 14.28 The nullor ($V_1 = I_1 = 0$, V_2, and I_2 arbitrary).

14.2.4.3 Nullor

The final building block for the most general n-port linear network is the 2-port designated as the nullor. It is defined as a 2-port which, at port 1, demands $V_1 = I_1 = 0$ while simultaneously at port 2, V_2 and I_2 are arbitrary! These relations can be obtained from a 4-port circulator with two of its ports appropriately terminated with negative and positive resistors. The symbol for the nullor is given in Figure 14.28. Both 4 and 3 terminal equivalent circuits exist for the nullor.

These singular network elements, the nullator, the norator, and the nullor, have been used to generate realizable circuits for the various signal converters discussed in this section. They have also been used to obtain realizable circuits for other widely used circuit elements such as the family of controlled sources, op-amps, transistors, etc. See Refs. [3,7] for the applications mentioned above.

Of course, many references are possible for the use of the network elements discussed in this section. Among others, Refs. [8,9] contain extensive bibliographies.

Defining Terms

Reciprocal linear *n*-port: The port voltages and currents satisfy Equation 14.1 and its restrictions.
Ideal gyrator: The basic nonreciprocal 2-port satisfying Equation 14.2.
GIC: A 2-port that satisfies Equation 14.5 and its conditions.
FDNR: A 1-port that has the driving-point impedance of Equation 14.7.
VNIC: A 2-port satisfying Equation 14.10 and foregoing conditions.
INIC: A 2-port satisfying Equation 14.11 and foregoing conditions.
The *n*-port ($n \geq 3$) circulator: Described by its n-port scattering matrix with main-diagonal elements zero and off-diagonal elements restricted to only one per row or column of unity magnitude.
Nullator: A 1-port such that $V_1 = I_1 = 0$.
Norator: A 1-port such that V_1 and I_1 and arbitrary.
Nullor: A 2-port such that $V_1 = I_1 = 0$, while V_2 and I_2 are arbitrary.

15.1 Introduction

15.1.1 Need for Amplification

The field of electronics includes many applications wherein important information is generated in the form of a voltage or current waveform. Often this voltage is too small to perform the function for which it is intended. Examples of this situation are the audio microphone in a sound amplification signal, the infrared diode detector of a heat-seeking missile, the output of the light intensity sensor of a CD player,

Much of the material from Sections 4, 5, and 6 comes from D. J. Comer and D. T. Comer, *Fundamentals of Electronic Circuit Design*. Copyright 2003 by John Wiley & Sons, Inc.

the output of a receiving antenna for an amplitude modulation (AM) or frequency modulation (FM) signal, the cell phone signal received by the base station before retransmission, and the output of a receiving dish antenna in a satellite TV system. Each of these signals have peak voltages in the range of hundreds of microvolts to hundreds of millivolts. To transmit a signal over phone lines or through the atmosphere and then activate a speaker or to illuminate a cathode-ray tube or other type of TV display may require a signal of several volts rather than millivolts.

An audio amplification system may require peak voltages of tens of volts to drive the speaker. The speakers in a CD system or in radio receivers may also require several volts to produce appropriate levels of volume. The video information for a TV signal may need to be amplified to a value of thousands of volts to drive the picture tube or display. Even in computer systems, the signals recovered from the floppy or hard disk drives must be amplified to logic levels to become useful. Amplification of each of these signals is imperative to make the signal become useful in its intended application. Consequently, amplifiers make up a part of almost every electronic system designed today.

At the present time, the bipolar junction transistor (BJT) and the metal-oxide semiconductor field-effect transistor (MOSFET) are the major devices used in amplification of electronic signals.

15.1.2 Brief History of Amplifying Devices

Amplification is so important that the so-called ''era of electronics'' was ushered in only after the development of the triode vacuum tube that made amplification possible in 1906 [1]. This device enabled public address systems and extended distances over which telephone communications could take place. Later, this element allowed the small signal generated by a receiving antenna located miles away from a transmitter to be amplified and demodulated by a radio receiver circuit. Without amplifiers, communications over long distances would be difficult if not impossible.

Improvement of the vacuum tube continued for several years with the tetrode and pentode tubes emerging in the late 1920s. These devices enabled the rapid development of AM radio and television. Vacuum tubes dominated the electronics field well into the 1950s serving as the basic element in radio, television, instrumentation, and communication circuits.

The forerunner of the BJT, the point-contact transistor, was invented in 1947 [2]. The BJT followed shortly and grew to dominance in amplifier applications by the mid 1960s. From then until the 1990s, this device had no peer in the electronics field. In the 1990s, the MOSFET became important as an amplifying device; however, the silicon BJT along with the newer heterojunction BJT (HBT), continue to be used in many amplifier applications.

15.2 Amplifier Types and Applications

Amplifiers can be classified in various ways. The input and output variables can be used to describe the amplifier. The frequency range of the output variable or the power delivered to a load can also describe a major characteristic of an amplifier. In the case of an operational amplifier (op-amp), the mathematical operations that can be performed by the circuit suggest the name of the amplifier.

15.2.1 Input and Output Variables

Electronic transducers generally produce either voltage or current as the quantity to be amplified. After amplification, the signal variable of interest could again be voltage or current, depending on the circuit or device driven. A given amplifier can then have either current or voltage as the input signal and current or voltage as the output signal. As the input variable changes, the amplifier produces a corresponding output variable change. Gain of an amplifier is defined as the ratio of output variable change to the input variable change as shown in Figure 15.1.

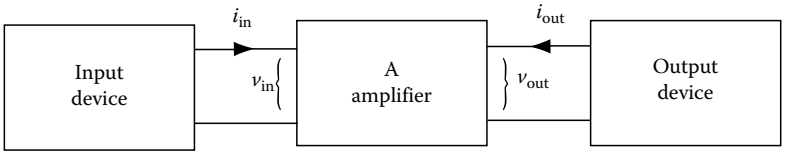

FIGURE 15.1 Amplifier circuit.

TABLE 15.1 Amplifiers Based on Output/Input Ratio

Input Variable	Output Variable	Gain	Amplifier Type
Voltage	Voltage	v_{out}/v_{in}	Voltage amplifier
Current	Current	i_{out}/i_{in}	Current amplifier
Voltage	Current	i_{out}/v_{in}	Transadmittance amplifier
Current	Voltage	v_{out}/i_{in}	Transimpedance amplifier

There are four possible ratios for the gain. These are summarized in Table 15.1 along with the corresponding amplifier type.

The voltage amplifier is used more often than the others, but each has specific applications. Some photo detectors generate output current proportional to the light intensity and this current is the input variable to the amplifier. The output variable may be voltage for this application. There are other occasions when an amplifier must generate an output current that is proportional to the input variable, thus, a given application may require any one of the four possible types listed in Table 15.1.

15.2.2 Frequency Range

The frequency range over which an amplifier exhibits useful gain is an important specification. An audio amplifier may have a relatively constant gain from tens of hertz up to nearly 20 kHz. The magnitude of this constant gain is often called the midband gain. Those frequencies at which the magnitude of gain falls by 3 dB from the midband value are called 3-dB frequencies. For a high-fidelity audio amplifier, the lower 3-dB frequency may be 20 Hz while the upper 3-dB frequency may be 20 kHz. The bandwidth of this amplifier extends from 20 Hz to 20 kHz. In spite of the relatively small absolute bandwidth, this type of amplifier is referred to as a wideband amplifier. The ratio of the upper 3-dB frequency to the lower 3-dB frequency is 20,000/20 which is 1000 in this case.

Another important type of amplifier is that used in radio receiver circuits. The receiver for an AM signal consists of several stages that amplify over a frequency range from about 450 kHz to about 460 kHz. The gain may be maximum at 455 kHz, but drops very rapidly toward zero when the frequency is below 450 kHz or above 460 kHz. This type of amplifier is called a narrowband amplifier because the ratio of upper 3-dB frequency to lower 3-dB frequency has a near-unity value of 460/450 in this case.

15.2.3 Output Power

Some audio speakers may require hundreds of watts of power to operate at the desired level. An LED display may only require milliwatts of power. The amplifiers that drive these devices can be classified as high power or low power, respectively. While there are no fixed power values to differentiate, amplifiers that generate outputs in the milliwatt range are called low-power amplifiers or simply amplifiers. Amplifiers that produce outputs in the watt to several watt range are called power amplifiers or high-power amplifiers. The bulk of integrated circuit (IC) amplifiers are used in low-power applications although pulse-width modulation (PWM) IC amplifier stages can deliver several watts of power to a load.

15.2.4 Distortion in Power Stages

There are two major causes of nonlinear distortion in BJT stages [3]. The first is the change of current gain β with changes in I_C or V_{CE}. If an undistorted base current enters the device, the output current is distorted as a result of the change in current gain as the output quantities vary. This effect can also be explained for a common-emitter stage in terms of the output characteristics which show unequal spacing as I_C or V_{CE} is changed. Obviously, if the output signal amplitude is limited, less distortion occurs. In power stages, very large output-current changes may be prevalent, and higher distortion levels are to be expected.

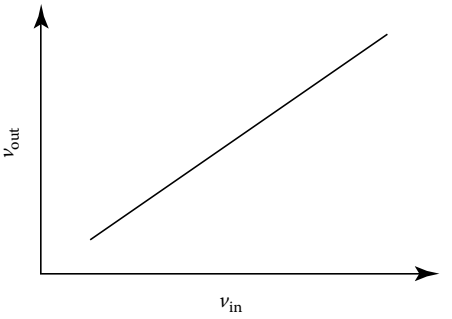

FIGURE 15.2 Transfer characteristics of a distortion-free amplifier.

The second important cause of distortion arises from the nonlinearity of the base–emitter characteristics of the transistor. When a voltage source drives a common-emitter stage with little series resistance, the base current can be quite distorted. This current varies with voltage in the same way that diode current varies with diode voltage. It is possible to use this input distortion to partially offset the output distortion; however, feedback techniques are most often used in distortion reduction. A perfect, distortion-free amplifier would have transfer characteristics that form a straight line as shown in Figure 15.2.

The BJT with no emitter degeneration has a collector current that relates to base–emitter voltage given by

$$I_C = \beta K_1 e^{qV_{BE}/kT}$$

where k is Boltzmann's constant. This function is highly nonlinear, and only small variations of V_{BE} can be applied to approximate linear behavior. An emitter resistance or emitter degeneration can be added to make the circuit more linear at the expense of reduced gain. This amounts to feedback to improve the nonlinear distortion. Another method of reducing distortion is to use several cascaded stages to achieve a very high gain; then feedback is applied around the amplifier to decrease the distortion.

15.2.4.1 Total Harmonic Distortion

In an amplifier circuit, the output signal should ideally contain only those frequency components that appear in the input signal. The nonlinear nature of amplifying devices introduces extraneous frequencies in the output signal that are not contained in the input signal. These unwanted signals are referred to as harmonic distortion. One measure of the amplifier's performance is called the total harmonic distortion (THD).

If a sinusoidal signal is applied to the amplifier input, the output will also contain a major component of this signal at the fundamental frequency, with amplitude designated v_f. In addition, there will be smaller harmonic components in the output signal. These amplitude values will be designated v_2, v_3, $v_4, \ldots, v_n, \ldots$ Fortunately, in engineering applications, the harmonics decrease in amplitude as frequency increases. Thus, perhaps only the second or third harmonic is large enough to affect the THD. The THD can defined as a percentage by

$$\text{THD} = \frac{\sqrt{v_2^2 + v_3^2 + v_4^2 + \cdots}}{v_f} \times 100 \tag{15.1}$$

In dB, this parameter becomes

$$\text{THD} = 10 \log\left(\frac{v_2^2 + v_3^2 + v_4^2 + \cdots}{v_f^2}\right) \tag{15.2}$$

The THD of an amplifier is a major specification used to characterize the amplifier performance.

15.2.4.2 Intercept Points

The unwanted harmonic distortion of an amplifier is a function of output signal size. As the signal becomes larger, the linear output will increase, and so will the distortion. In fact, unwanted components due to harmonic distortion may increase more rapidly than the linear component.

Typically, an amplifier with a small output signal, compared to the size of the active region, will have a large linear output component or fundamental component relative to the harmonic components. As signal size increases, the size of the second or third harmonic may become as large as the fundamental component. Generally, this will not occur before the output signal reaches the extremes of the active region; consequently it would be impossible to measure the size of the output signal that results in a harmonic component that is equal in amplitude to the fundamental component.

The concept of the intercept point allows this output to be approximated. A plot, often in dB, is made of the input power versus the output power of the fundamental component. This plot is a straight line with a slope of unity for smaller output signals. As the output approaches the edges of the active region, the output power increases much more slowly than does the input power. Finally, the output power is limited to some fixed value as the output signal size is limited by the active region boundaries. Figure 15.3 shows this variation.

For small signals, each harmonic component is small. The third harmonic is plotted in Figure 15.3 in addition to the fundamental component. As input power is increased, the third harmonic component may increase at three times the rate of increase in the fundamental component. Before the input power is high enough to significantly limit the fundamental power, a straight-line extension is added to the fundamental power plot and the third harmonic power plot. The point where these two extensions intersect is called the third-order intercept point (TOI). Note that this point often falls beyond the actual output power that can be achieved by the amplifier. The TOI is specified in terms of the input power required at this point. For example, in Figure 15.3, the TOI is −10 dB. The higher the intercept point, the more linear is the amplifier.

A second-order intercept can also be defined in much the same way as the TOI is defined. For communication amplifiers, the TOI is generally more important than the second-order intercept because the third-order term can result in a frequency that falls within the desired passband of the amplifier. The TOI is an oft-used specification for power stages as well as high-frequency amplifiers.

15.2.5 Operational Amplifiers

The op-amp was developed long before the IC was invented. It was used in analog computers that were designed to solve differential equations by simulation. This amplifier formed the basis of circuits that

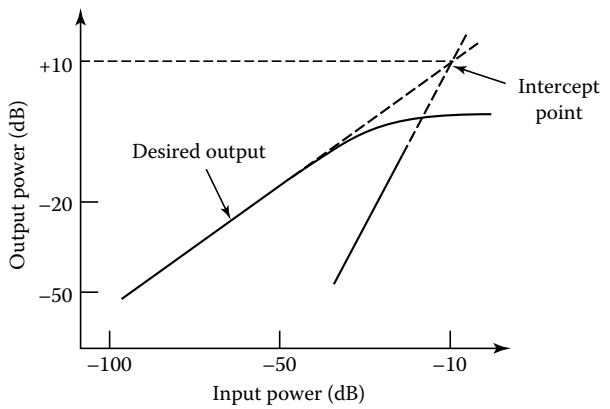

FIGURE 15.3 Amplifier output power versus input power.

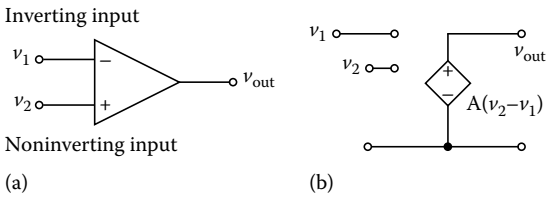

FIGURE 15.4 (a) Symbol for the op-amp. (b) Ideal equivalent circuit.

performed mathematical operations such as weighting, summing, subtracting, and integrating electrical signals. The op-amp has two features that allow these operations to be accomplished. The first feature is a differential input to allow subtraction. The second feature is that a virtual ground can be created when a feedback resistor is connected between the amplifier output and the inverting or negative input terminal. This virtual ground allows perfect summation of currents into the inverting terminal and also allows perfect integration of an input signal.

Before the IC op-amp was developed, the discrete circuit op-amp was quite expensive and large, perhaps costing $200 and occupying a volume of 250 cm^3. With its low cost and small size, the IC op-amp has now made a rarely used component one of the most popular IC chips in the electronics field. The major limitation of the op-amp is its frequency response that limits its use in very high frequency applications.

The near-ideal op-amp has a very high gain, a high input impedance, and a low output impedance. The symbol for this device is shown in Figure 15.4a along with the ideal equivalent circuit of Figure 15.4b.

15.3 Differences between Discrete and IC Amplifier Design

Prior to the early 1960s, electronic circuits were constructed from discrete component circuits. Discrete resistors, capacitors, inductors, and transistors are packaged individually to be connected with wires or printed circuit board (PCB) conductors to create a functioning electronic circuit. The discrete component circuit is still required in certain applications in the twenty-first century, but the IC is now the dominant form of implementation for an electronic system. There are major differences in the design principles used for the IC and the discrete circuit as the following section will explain [4].

15.3.1 Component Differences

Discrete resistors, capacitors, and inductors are available in a very large range of values. Although many amplifier circuits are designed with element values of 5%–10% tolerances, very precise values can be obtained at a higher cost. The range of resistor values extends from a few ohms to many megohms and capacitor values range from femtofarads to hundreds of microfarads. Metal core or air core inductors are available over a wide range of values as also are transformers with a wide choice of turns ratios.

For most standard fabrication processes, the IC chip becomes too large to be useful when the total resistance of resistors on the chip exceed some value such as 100 kΩ. The same applies if the total capacitance exceeds perhaps 50 to 100 pF. It is only in the last decade that inductors could be fabricated on a chip. Even now, integrated inductors with limited values in the nanohertz range are possible and losses may limit Q-values to the range of 2–8 [5].

A major problem with IC components is the lack of precise control of values. Resistors or capacitors are typically fabricated with an absolute accuracy of around 20%. It is possible, however, to create resistive ratios or capacitive ratios that approach a 0.1% accuracy, even though absolute value control is very poor in standard processes.

The cost of a discrete circuit is determined by different variables than that of the IC. This results in a design philosophy for ICs that differs from that of discrete component circuits. Before ICs were available, a designer attempted to minimize the number of transistors in a circuit. In fact, some companies

estimated the overall component cost of a circuit by multiplying the number of transistors in the circuit by some predetermined cost per stage. This cost per stage was determined mainly by the transistor cost plus a small amount added to account for the passive component cost. The least expensive item in the discrete circuit is generally the resistor which may cost a few cents.

In an IC, the greatest cost is often associated with the component that requires the most space. The BJT typically requires much less space than resistors or capacitors and is the least expensive component on the chip. An IC designer's attempt to minimize space or simplify the fabrication process for a given circuit generally results in much larger numbers of transistors and smaller numbers of resistors and capacitors than the discrete circuit version would contain. For example, a discrete circuit bistable flip-flop of 1960 vintage contained two transistors, six resistors, and three capacitors. A corresponding IC design had 18 transistors, 2 resistors, and no capacitors.

Matching of components in IC design can be considerably better than discrete design, but also presents unique problems as well. Components that are made from identical photographic masks can vary in size and value because of uneven etching rates influenced by nearby structures or by asymmetrical processes. Dummy components must often be included to achieve similar physical environments for all matched components. Certain processes must be modified to result in symmetrical results. Metal conductors deposited on the IC chip can introduce parasitics or modify performance of the circuit if placed in certain areas of the chip, thus care must be taken in placing the metal conductors. Of course, these kinds of considerations are unnecessary in discrete circuit design.

While discrete circuits can use matched devices such as differential stages, often single-ended stages can be designed to meet relatively demanding specifications. Discrete components can be produced with very tight tolerances to lead to circuit performance that falls within the accuracy of the specifications. Circuit design can be based on the absolute accuracy of key components such as resistors or capacitors. Although it may add to the price of a finished circuit, simple component tuning methods can be incorporated into the production of critical discrete circuits.

Since the absolute values of resistors and capacitors created by standard processes for ICs cannot be determined with great accuracy, matching of components and devices is used to achieve acceptable performance. Differential stages are very common in IC design since matched transistors and components are easy to create even if absolute values cannot be controlled accurately.

Some analog circuits do not require high component densities while others may pack a great deal of circuitry into a small chip space. For low density circuits, more resistors and small capacitors may be used, but for high density circuits, these elements must be minimized. Section 15.4 considers circuits that replace resistors and capacitors with additional BJTs in IC amplifier building blocks. The BJT current mirror, which is quite popular in biasing of IC amplifiers is discussed in [4]. This circuit is also used to replace the load resistance of a conventional amplifier to make it easier to integrate on a chip.

15.3.2 Parasitic Differences

One advantage of an IC is the smaller internal capacitance parasitics of each device. A proper layout of an IC leads to small parasitic device capacitances that can be much less than corresponding values for discrete devices. Although the discrete and IC device may be fabricated with similar processes, the collector and emitter of the IC device are typically much smaller and usually connect to fine pitch external leads/connectors. The discrete device must make external connections to the base, collector, and emitter and these external connections can add a few picofarads of capacitance. An on-chip IC device generally connects to another device adding minimal parasitic capacitance. However, external connects from the chip to the package must be carefully designed to minimize parasitic capacitance as signals are brought off chip.

Another difference relates to the parasitic capacitance associated with IC resistors and inductors. These elements have capacitance as a result of the oxide dielectric between metal layers and the chip substrate. The frequency response of IC resistors and inductors must be considered in critical designs.

At higher frequencies (above approximately 1 GHz) other considerations influence the IC design. In order to maintain the advantage of low cost in IC circuits over discrete realizations, the devices on the chip are made much smaller than their discrete counterparts. Current and power levels must be limited in the smaller devices to avoid gain roll-off due to high-level injection effects or overheating. The lower currents necessitate higher impedance levels in most bipolar chip designs.

For many analog circuits, terminations of 50 Ω are used at I/O ports. This requires large current magnitudes to reach the specified voltage levels. For example, a 20 mA peak current would be required to develop a peak voltage of 1 V. This is not a difficult problem in discrete circuit design using PC boards. The limitation on current and power in the chip design leads to less flexibility with higher impedance interconnects to develop acceptable voltages. High frequency chip designs must also deal with bond wire or other package inductance in the range of 0.1–0.5 nH and the package capacitance that may reach 5 pF. A buffer is often needed to generate the off-chip signals with sufficient current to develop the specified voltages, but IC chip heating due to power dissipation of the buffer stage must be carefully considered. Common thermal centroid techniques are used to prevent unbalanced heating of matched devices.

15.4 Building Blocks for IC Amplifiers

This section discusses several single-stage amplifying circuits that may be combined with other stages to create a high-performance amplifier.

15.4.1 Small-Signal Models

Most amplifier circuits constrain the BJT stages to active region operation. In such cases, the models can be assumed to have constant elements that do not change with signal swing. These models are linear models. The quiescent or bias currents are first found using a nonlinear model to allow the calculation of current-dependent element values for the small-signal model. For example, the dynamic resistance of the base–emitter diode, r_e, is given by

$$r_e = \frac{kT}{qI_E} \tag{15.3}$$

where I_E is the dc emitter current. Once I_E is found from a nonlinear dc equivalent circuit, the value of r_e is calculated and assumed to remain constant as the input signal is amplified.

The equivalent circuit [6] of Figure 15.5 shows the small-signal hybrid-π model that is closely related to the Gummel-Poon model and is used for ac analysis in the Spice program.

The capacitance, C_π, accounts for the diffusion capacitance and the emitter–base junction capacitance. The collector–base junction capacitance is designated C_μ. The resistance, r_π, is equal to $(\beta + 1)r_e$. The transconductance, g_m, is given by

$$g_m = \frac{\alpha}{r_d} \tag{15.4}$$

The impedance, r_o, is related to V_A, the Early voltage, and I_C, collector current at $V_{CE} = 0$ by

$$r_o = \frac{V_A}{I_C} \tag{15.5}$$

R_B, R_E, and R_C are the base, emitter, and collector resistances, respectively.

In many high-frequency, discrete amplifier stages and in some high-frequency IC stages, a small value of load resistance will be used. Approximate hand analysis can then be done by neglecting

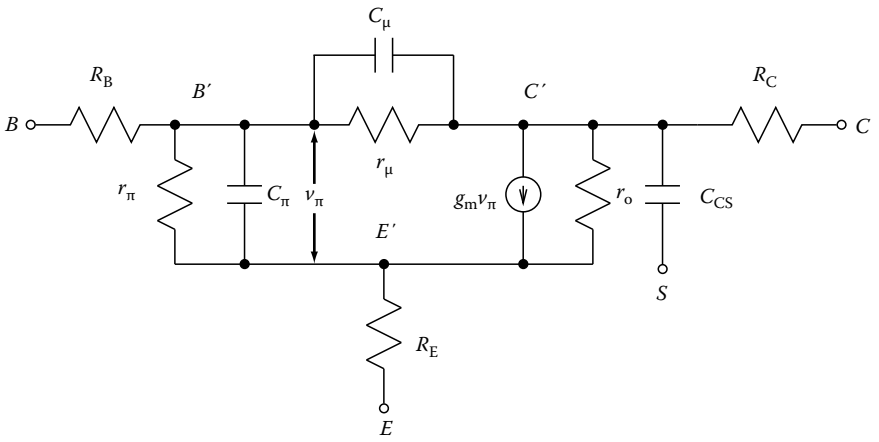

FIGURE 15.5 The hybrid-π small signal model for the BJT.

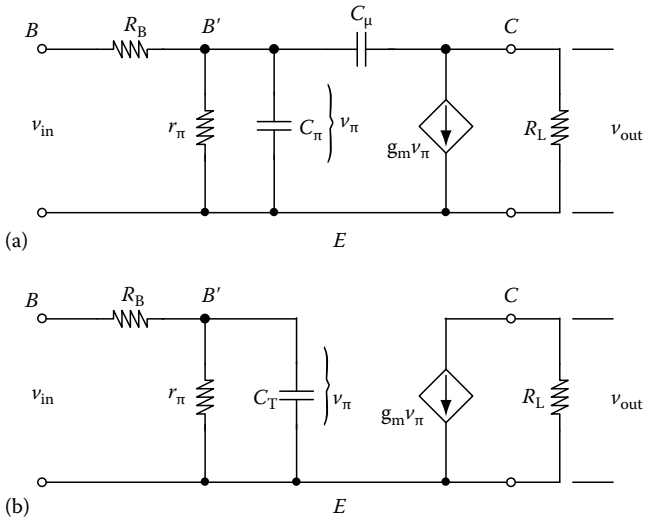

FIGURE 15.6 (a) Approximate equivalent circuit. (b) Unilateral equivalent.

the ohmic resistances, R_E and R_C along with C_{CS}, the collector to substrate capacitance. If the impedance r_o is much larger than the load resistance, R_L, of the high-frequency amplifying stage it can be considered an open circuit. The resulting model that allows relatively viable hand analysis is shown in Figure 15.6a.

For small values of load resistances, the effect of the capacitance can be represented by an input Miller capacitance that appears in parallel with C_π. This simplified circuit now includes two separate loops as shown in Figure 15.6b and is referred to as the unilateral equivalent circuit. Typically, the input loop limits the bandwidth of the amplifier stage. When driven with a signal generator having a source resistance of R_s, the upper 3-dB frequency can be approximated as

$$f_{high} = \frac{1}{2\pi R_{eq}(C_\pi + C_M)} \tag{15.6}$$

In this equation, the values of R_{eq} and C_M are

$$R_{eq} = r_\pi \parallel (r_b + R_s) \tag{15.7}$$

and

$$C_M = C_\mu(1 + |A|) = C_\mu(1 + g_m R_L) \tag{15.8}$$

where A is the gain of the stage from point B′ to the collector of the stage. Although C_μ is small, the resulting Miller effect increases this value to the point that it can dominate the expression for upper 3-dB frequency. In any case, it often has a major effect on frequency performance.

When higher impedance loads are used in a BJT as is often the case for IC amplifier design, the Miller effect approach becomes less accurate and the performance must be simulated to achieve more accurate results. However, the unilateral circuit that includes C_μ and C_{CS} from the collector to ground after reflecting the effects of C_μ to the input loop can be used to approximate the amplifier stage performance. Manually calculated results are generally within 5%–10% of simulation results.

15.4.2 Active Loads

In order to achieve high voltage gains and eliminate load resistors, active loads are used in BJT IC amplifier stages [4]. In a conventional common-emitter stage, the gain is limited by the size of the collector resistance. The midband voltage gain from base to collector of a common-emitter stage is given by

$$A_v = -\frac{\alpha R_C}{(r_e + R_E)}$$

It would be possible to increase this voltage gain by increasing R_C, however, making R_C large can lead to some serious problems. A large collector load requires a low quiescent collector current to result in proper bias. This may lead to lower values of β, since current gain in a silicon transistor typically falls at low levels of emitter current. In order to achieve a voltage gain of 1000 V/V, a collector load of perhaps 100–200 kΩ might be required. The low collector current needed for proper bias, a few microamps, would lead to a low value of β and a very high value of r_e. The desired high voltage gain may not be achievable under these conditions.

It would be desirable if the collector load presented a low resistance to dc signals, but presented a high incremental resistance. This combination of impedances would result in a stable operating point along with a high gain. A perfect current source with infinite incremental resistance along with a finite dc current flow satisfies the requirements, but is not a practical solution. On the other hand, circuits that approximate current sources are relatively easy to construct. A good approximation to the current source is obtained by using another transistor for the collector load of an amplifying transistor. Not only can this device present a low dc and high incremental impedance, it is a simple element to implement on a chip. This transistor that replaces the resistive load is referred to as an active load.

The circuit of Figure 15.7 demonstrates one type of BJT active load. The transistor $Q1$ is the amplifying element with $Q2$ acting as the load. Transistor $Q1$ looks into the collector of $Q2$. The incremental output impedance at the collector of a transistor having an emitter resistance in the low kiloohm range can easily exceed 500 kΩ. With such a high impedance, $Q2$ approximates a current source.

The dc collector currents of both transistors are equal in magnitude. This magnitude can be set to a value that leads to a reasonable value of β. Since $Q2$ has a very high output impedance, the midband

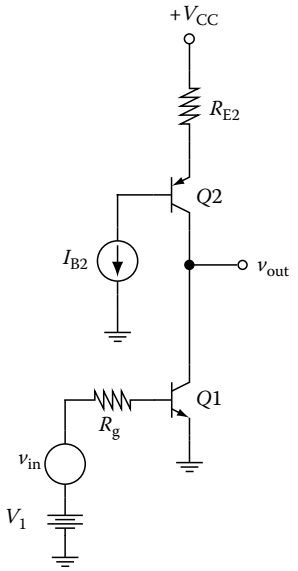

FIGURE 15.7 Active load amplifier.

voltage gain will be determined primarily by the collector-to-emitter resistance of $Q1$and can be calculated from

$$A_{MB} = \frac{-\beta_1 r_{ce1}}{R_g + r_{\pi 1}} \tag{15.9}$$

where r_{ce1} is the output impedance of $Q1$. If the generator resistance, R_g is negligible, this equation reduces to

$$A_{MB} = -\frac{r_{ce1}}{r_{e1}} = -\frac{(V_A + V_{CQ1})/I_C}{V_T/I_E} \approx -\frac{V_A + V_{CQ1}}{V_T} \tag{15.10}$$

For an Early voltage of $V_A = 80$ V and $V_T = 0.026$ V, a small-signal voltage gain exceeding -3000 V/V could result. In a normal application, this stage would drive a second stage. The input impedance of the second stage will load the output impedance of the first stage, further lowering the gain. Depending on the input impedance of the second stage and the impedance of the active load stage, the gain magnitude may still exceed 1000 V/V.

The concept of an active load that presents a large incremental resistance while allowing a large dc quiescent current is important in IC design. In addition to the current source load just considered, the current mirror stage can also be used to provide the active load of a differential stage as discussed in Section 15.4.3.

15.4.3 Common Emitter Stage

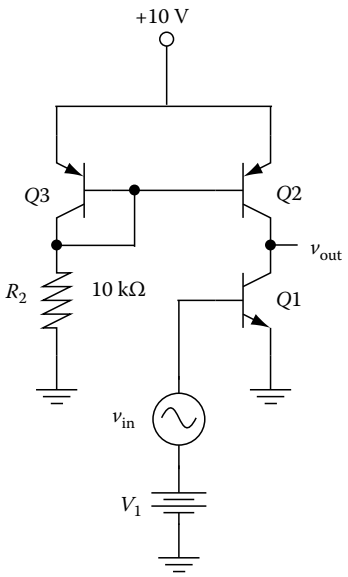

FIGURE 15.8 Common-emitter amplifier with current mirror active load.

A simple configuration for an IC amplifying stage is shown in Figure 15.8. In this stage, the output impedance of the current mirror is not large enough to be considered an open circuit as it was in the circuit of Figure 15.7. Thus, the analysis will have to account for this element.

The high frequency response of discrete BJT stages is often determined by the input circuit, including the Miller effect capacitance. The collector load resistance in a discrete stage is usually small enough that the output circuit does not affect the upper corner frequency. In the circuit of Figure 15.8, as in many IC amplifier stages, the output impedance is very high compared to the discrete stage. For this circuit, the output impedance of the amplifier consists of the output impedance of $Q2$ in parallel with that of $Q1$. This value will generally be several tens of kiloohms.

The equivalent circuit of the amplifier of Figure 15.8 is indicated in Figure 15.9. The value of R_{out} is

$$R_{out} = r_{o1} \,\|r_{o2} = r_{ce1}\| \, r_{ce2} \tag{15.11}$$

The capacitance in parallel with R_{out} is approximately

$$C_{out} = C_{\mu 1} + C_{\mu 2} + C_{cs1} + C_{cs2} \tag{15.12}$$

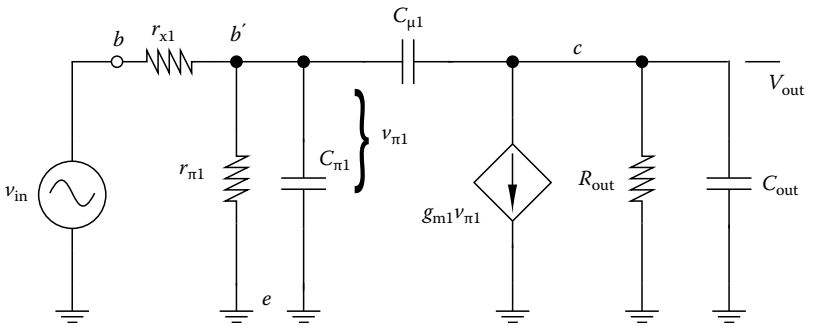

FIGURE 15.9 Equivalent circuit for the amplifier of Figure 15.8.

In this equation, $C_{\mu 1}$ and $C_{\mu 2}$ are the collector-to-base junction capacitances and C_{cs1} and C_{cs2} are the collector-to-substrate capacitances of the respective transistors. If no generator resistance is present, $C_{\mu 1}$ will also appear in parallel with the output terminal and ground. When R_g is present, we will still approximate the output capacitance with the same equation, although feedback effects between the output and the bases of $Q1$and $Q2$ actually modify the value slightly.

The midband gain is easy to evaluate as

$$A_{MB} = \frac{-\beta_1 R_{out}}{R_g + r_{x1} + r_{\pi 1}} \tag{15.13}$$

The upper corner frequency is now more difficult to evaluate than that of the discrete circuit with its low value of collector load resistance. In the discrete circuit, the input loop generally determines the overall upper corner frequency of the circuit. Although the Miller effect will be much larger in the IC stage, lowering the upper corner frequency of the input loop, the corner frequency of the output loop will also be smaller due to the large value of R_{out}. Both frequencies may influence the overall upper corner frequency of the amplifier.

As mentioned previously, it is difficult to manually calculate the upper corner frequency of the stage and an accurate value is generally found by simulation. An approximation of the upper corner frequency can be manually found by reflecting the bridging capacitance, C_μ, to both the input and the output. The value reflected to the input side, across terminals b' and e, is

$$(1 + |A_{b'c1}|)C_{\mu 1} \tag{15.14}$$

as in the discrete circuit amplifier. Thus, the total input capacitance in parallel with $r_{\pi 1}$ is

$$C_{in} = C_{b'e1} + (1 + |A_{b'c1}|)C_{\mu 1} \tag{15.15}$$

The major component of $C_{b'e1}$ is the diffusion capacitance, C_π, of $Q1$.

The upper corner frequency resulting from the input circuit of this stage is

$$f_{in\text{-}high} = \frac{1}{2\pi C_{in} R_{eq}} \tag{15.16}$$

where $R_{eq} = (R_g + r_{x1}) \| r_{\pi 1}$.

The upper corner frequency resulting from the output side of the stage is

$$f_{out\text{-}high} = \frac{1}{2\pi C_{out} R_{out}} \tag{15.17}$$

The approximate overall upper corner frequency, f_{2o}, must be found by considering a two-pole response. The overall response is expressed as

$$A(\omega) = \frac{A_{MB}}{\left(1 + jf/f_{\text{in-high}}\right)\left(1 + ff/f_{\text{out-high}}\right)} \tag{15.18}$$

It is easy to show that the overall upper corner frequency can be found by solving the equation

$$\left(\frac{f^2}{f_{\text{in-high}}^2 + 1}\right)\left(\frac{f^2}{f_{\text{out-high}}^2 + 1}\right) = 2 \tag{15.19}$$

Although this method is not as accurate as the simulation, results will often be within 5%–10%.

15.4.4 Common-Base Stage

The common-base stage shown in Figure 15.10 has an advantage and a disadvantage when compared to the common-emitter stage. The advantage is that the Miller effect, that is, the multiplication of apparent capacitance at the input, is essentially eliminated. The noninverting nature of the gain does not lead to an increased input capacitance. Furthermore, the capacitance between input (emitter) and output (collector) is generally negligible. The upper corner frequency is then higher than that of a comparable common-emitter stage.

The disadvantage is the low current and power gain of the common-base stage compared to the common-emitter stage. The low-frequency current gain for the common-base stage equals α and is slightly less than unity. In the common-emitter stage, the current gain equals β and may be over 200. Since voltage gain is similar for the two stages, the power gain is also much lower for the common-base stage. The input resistance at low frequencies is also much lower than that of the common-emitter stage and can load the previous stage.

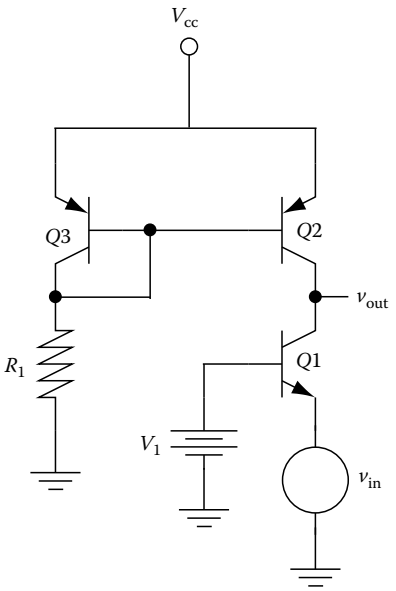

FIGURE 15.10 Common-base amplifier.

The equation for voltage gain is

$$A_{MB} = \frac{\alpha_1 R_{out}}{\frac{r_{x1}}{\beta+1} + r_{e1} + R_g} \tag{15.20}$$

where R_{out} is the parallel combination of r_{out1} and r_{ce2}. The output impedance of $Q1$ depends on the generator resistance, R_g, and ranges from r_{ce1} for $R_g = 0$ up to βr_{ce1} when R_g approaches infinity. The midband voltage gain is similar to that of the common-emitter stage.

The expression for voltage gain as a function of frequency is

$$A = \frac{A_{MB}}{\left(1 + j\dfrac{f}{f_{\text{in-high}}}\right)\left(1 + j\dfrac{f}{f_{\text{out-high}}}\right)} \tag{15.21}$$

where $f_{\text{in-high}}$ is the corner frequency of the input circuit and $f_{\text{out-high}}$ is the corner frequency of the output circuit. These values are

$$f_{\text{in-high}} = \frac{1}{2\pi C_{\pi 1}\left(r_{e1} \| R_g\right)} \tag{15.22}$$

$$f_{\text{out-high}} = \frac{1}{2\pi C_{\text{out}} r_{\text{out}}} \tag{15.23}$$

The output capacitance consists of the collector to base capacitances and the collector to substrate capacitances of both $Q1$ and $Q2$, that is,

$$C_{\text{out}} = C_{\mu 1} + C_{\mu 2} + C_{\text{cs1}} + C_{\text{cs2}} \tag{15.24}$$

Generally, the corner frequency of the input circuit is considerably higher than the corner frequency of the output circuit for high-gain IC stages and the overall upper corner frequency is approximated by $f_{\text{out-high}}$.

The midband voltage gain of the common-base and common-emitter stages decreases with increasing generator resistance. In multistage amplifiers, the generator resistance of one stage is the output resistance of the previous stage. If this value is large, the gain of the following stage may be small. Furthermore, the upper corner frequency of the common-emitter stage is affected by the generator resistance. Large values of R_{g} can lead to small values of upper corner frequency.

15.4.5 Emitter Follower

A stage that can be used to minimize the adverse effect on frequency response caused by a generator resistance is the emitter follower. Although this stage has a voltage gain near unity, it can be driven by a higher voltage gain stage while the emitter follower can drive a low impedance load. A typical stage is shown in Figure 15.11.

The output stage of the *npn* current mirror, $Q2$, serves as a high impedance load for the emitter follower, $Q1$. An equivalent circuit that represents the emitter follower of Figure 15.11 is indicated in Figure 15.12. For this circuit, $g_{\text{m1}} = \alpha_1 / r_{\text{e}} \approx 1/r_{\text{e}}$.

This circuit can be analyzed to result in a voltage gain of

$$A = \frac{\frac{C_{\pi 1}}{\Pi C\left(R_{\text{g}} + r_{\text{x1}}\right)}\left(j\omega + \frac{g_{\text{m1}} r_{\pi 1} + 1}{r_{\pi 1} C_{\pi 1}}\right)}{-\omega^2 + bj\omega + d} \tag{15.25}$$

where

$$\Pi C = C_{\text{out2}} C_{\mu 1} + C_{\text{out2}} C_{\pi 1} + C_{\pi 1} C_{\mu 1} \tag{15.26}$$

$$b = \frac{1}{\Pi C}\left(\frac{C_{\pi 1} + C_{\text{out2}}}{R_{\text{g}} + r_{\text{x1}}} + \frac{C_{\pi 1} + C_{\mu 1}\left(1 + g_{\text{m1}} r_{\text{ce2}}\right)}{r_{\text{ce2}}} + \frac{C_{\text{out2}} + C_{\mu 1}}{r_{\pi 1}}\right) \tag{15.27}$$

and

$$d = \frac{R_{\text{g}} + r_{\text{x1}} + r_{\pi 1} + r_{\text{ce2}}\left(g_{\text{m1}} r_{\pi 1} + 1\right)}{\Pi C\left(R_{\text{g}} + r_{\text{x1}}\right) r_{\pi 1} r_{\text{ce2}}} \tag{15.28}$$

Note that the output capacitance of $Q2$ can be approximated as the sum of $C_{\mu 2}$ and C_{cs2}.

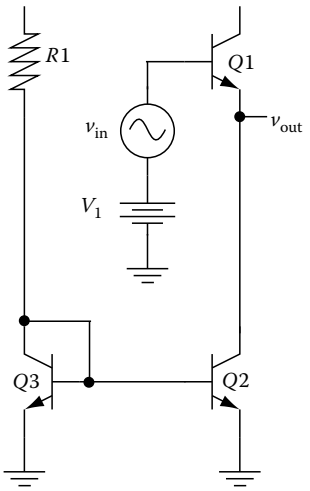

FIGURE 15.11 Emitter follower.

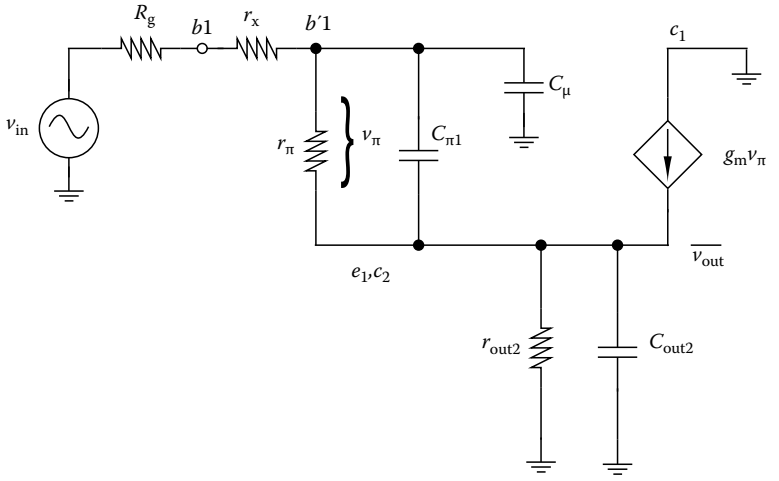

FIGURE 15.12 Equivalent circuit for the emitter follower.

The midband voltage gain is found from Equation 15.25 by letting $\omega \to 0$. This value is

$$A_{MB} = \frac{(1 + g_{m1} r_{\pi 1}) r_{ce2}}{R_g + r_{x1} + r_{\pi 1} + (1 + g_{m1} r_{\pi 1}) r_{ce2}} \tag{15.29}$$

This gain is very near unity for typical element values.

The bandwidth is more difficult to calculate since the response has one zero and two poles. The zero for the circuit of Figure 15.12 is typically larger than the lowest frequency pole. If these frequencies canceled, the larger pole would determine the corner frequency. Since they do not cancel, the overall upper corner frequency is expected to be smaller than the larger pole frequency. An accurate calculation can be made from Equation 15.25 when the parameters are known.

In high-frequency design, it must be recognized that the output impedance of the emitter follower can become inductive [7].

15.5 Compound Stage Building Blocks for IC Amplifiers

Several of the single stages of Section 15.4 can be combined to construct high-performance two-stage building blocks.

15.5.1 Cascode Amplifier Stage

One of the problems with the common-emitter stage using an active load is the Miller effect. This stage has a high voltage gain from base to collector. The circuit of Figure 15.8 has an inverting voltage gain, A_{MB}, that can be quite high, perhaps -700 V/V. The base-collector junction capacitance is multiplied by $(1 + |A_{MB}|)$ and reflected to the input loop. This capacitance adds to the diffusion capacitance from point b' to point e and can lower the upper corner frequency to a relatively small value.

On the other hand, the common-base stage of Figure 15.10 has essentially no Miller effect, but has a low input impedance and can load the impedance of the driving source. The cascade stage combines the best features of both the common-emitter and common-base stages. The cascode amplifier stage of Figure 15.13 minimizes the capacitance reflected to the input. The input impedance to the circuit is that

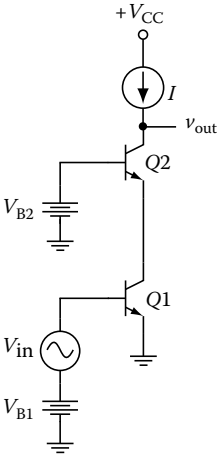

FIGURE 15.13 Cascode amplifier.

of the common-emitter stage and is two orders of magnitude higher than the common-base stage. In this circuit, the input capacitance is primarily composed of the diffusion capacitance of *Q*1. The voltage gain from base-to-collector of *Q*1 is quite low since the collector load of this device consists of the impedance looking into the emitter of *Q*2. This impedance is approximately equal to the base-emitter diode resistance of *Q*2 which is

$$r_{e2} = \frac{26}{1_{E2}}$$

With low voltage gain, the Miller effect of the first stage is minimized. The upper device passes the incremental signal current of *Q*1 to its collector and develops a large voltage across the current source impedance. There is no Miller multiplication of capacitance from the input of *Q*2 (emitter) to the output (collector) since the gain is noninverting and negligible capacitance exists between emitter and collector. Thus, the cascode stage essentially eliminates Miller effect capacitance and its resulting effect on upper corner frequency.

A high-frequency equivalent circuit of this stage is shown in Figure 15.14. The resistance R includes any generator resistance and the base resistance, r_{x1} of *Q*1. The resistance r_{cs} is the output resistance of the current source. The output capacitance is the sum of $C_{\mu 2}$, C_{cs2}, and any capacitance at the current source output. The resistance r_{out2} can be quite large since *Q*2 sees a large emitter resistance looking into the collector of *Q*1. This emitter load leads to negative feedback that increases the output resistance of *Q*2.

The midband voltage gain is calculated from the equivalent circuit of Figure 15.14 after eliminating the capacitors. This gain is found rather easily by noting that the input current to *Q*1is

$$i_{b1} = \frac{v_{in}}{R + r_{\pi 1}} \tag{15.30}$$

This current will be multiplied by β_1 to become collector current in *Q*1. This current also equals the emitter current of *Q*2. The emitter current of *Q*2 is multiplied by α_2 to become collector current of *Q*2. The output voltage is then

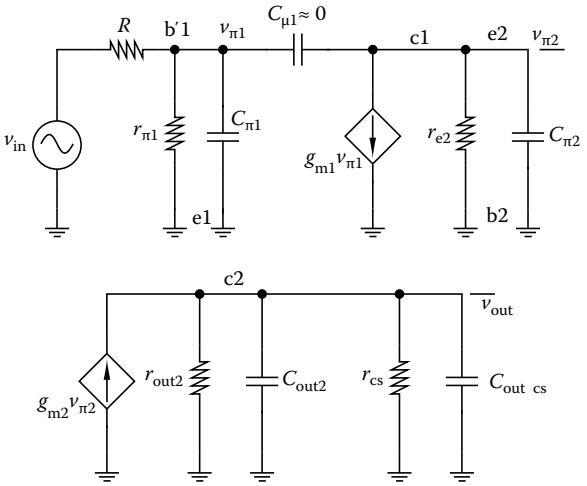

FIGURE 15.14 Equivalent circuit for the cascode amplifier.

$$v_{out} = i_{c2} \times R_3 \tag{15.31}$$

where $R_3 = r_{out2} || r_{cs}$. This resistance could be very large if the current source resistance, r_{cs}, is large. The value of r_{out2} will be high since the emitter of $Q2$ sees a resistance of r_{ce1}. Combining this information results in a midband voltage gain of

$$A_{MB} = \frac{-\beta_1 \alpha_2 R_3}{R + r_{\pi 1}} \tag{15.32}$$

If no generator resistance is present and if $R_3 = 100$ kΩ, this midband voltage gain might exceed 5000 V/V.

The gain as a function of frequency can be found as

$$A = A_{MB} \frac{1}{[1 + j\omega C_{\pi 1}(r_{\pi 1} \parallel R)]} \frac{1}{[1 + j\omega r_{e2} C_{\pi 2}]} \frac{1}{[1 + j\omega R_3 C_{out}]} \tag{15.33}$$

Typically, the corner frequency of the second frequency term in Equation 15.33, that is,

$$f_2 = \frac{1}{2\pi r_{e2} C_{\pi 2}}$$

is much higher than that of the first term,

$$f_{in\text{-}high} = \frac{1}{2\pi (r_{\pi 1} \parallel R) C_{\pi 1}}$$

This is especially true if R is large compared to $r_{\pi 1}$. In this case, since $r_{e1} \approx r_{e2}$ as a result of equal emitter currents, then $r_{e2} \ll (\beta + 1) r_{e1}$. For hand analysis of the cascode circuit, the second term in the expression for gain is often neglected.

The gain can then be written as

$$A = A_{MB} \frac{1}{1 + j\frac{f}{f_{in-high}}} \frac{1}{1 + j\frac{f}{f_{out-high}}} \tag{15.34}$$

where

$$f_{out\text{-}high} = \frac{1}{2\pi C_{out} R_3} \tag{15.35}$$

and $f_{in\text{-}high}$ was defined previously.

The capacitance C_{out} is the sum of the current source output capacitance and the output capacitance of $Q2$ giving

$$C_{out} = C_{out2} + C_{outcs}$$

If a current mirror with output stage $Q3$ generates the collector bias current for $Q1$ and $Q2$, the output capacitance is

$$C_{out} = C_{\mu 2} + C_{\mu 3} + C_{cs2} + C_{cs3}$$

15.5.2 Differential Stage

The differential pair or differential stage is very important in the electronic field. Virtually every op-amp chip includes a differential pair as the input stage. Some advantages of the differential stage are its relative immunity to temperature effects and power supply voltage changes, and its ability to amplify dc signals. The differential amplifier uses a pair of identical stages connected in a configuration that allows the temperature drift of one stage to cancel that of the other stage. The basic configuration of a differential stage is shown in Figure 15.15. The two devices can be connected and operated in several different configurations. The mode of operation most often used with the differential amplifier is the differential input-double-ended output mode. Differential input refers to a situation wherein the voltage appearing across the input of one stage is equal in magnitude, but opposite in polarity to the voltage appearing across the input of the other stage. Double-ended output refers to the fact that the output voltage is taken as the difference in voltage between the output voltage of each stage. In single-stage amplifiers, the output voltage appears between the circuit output and ground. This is called a single-ended output. In Figure 15.15, the double-ended output voltage is

$$v_{\text{out}} = v_{\text{o1}} - v_{\text{o2}}$$

or

$$v_{\text{out}} = v_{\text{o2}} - v_{\text{o1}}$$

depending on the choice of output terminals. If this differential pair used a single-ended output, it could be taken between the output of stage 1 and ground or the output of stage 2 and ground.

A second input mode that could be used is the common mode. If the same signal is applied to both inputs, the circuit is said to operate in common mode. If the amplifier stages have exactly equal gains, the signals v_{o1} and v_{o2} will be equal. The double-ended output signal would then be zero in the ideal differential stage operating in common mode. In practice the two amplifier gains will not be identical; thus, the common-mode output signal will have a small value. The common-mode gain A_{CM} is defined as

$$A_{\text{CM}} = \frac{v_{\text{o1}} - v_{\text{o2}}}{v_{\text{CM}}} = A_1 - A_2 \tag{15.36}$$

where v_{CM} is the common-mode voltage applied to both inputs and $A1$ and $A2$ are the voltage gains of the two stages.

The differential gain applies when the input signals v_1 and v_2 are not equal and the gain in this case is

$$A_{\text{D}} = \frac{v_{\text{o1}} - v_{\text{o2}}}{v_1 - v_2} = \frac{A_1 v_1 - A_2 v_2}{v_1 - v_2} = \frac{v_{\text{out}}}{v_1 - v_2} \tag{15.37}$$

where A_{D} is the differential voltage gain of the amplifier with a double-ended output. If the double-ended output had been defined as $v_{\text{o2}} - v_{\text{o1}}$ rather than $v_{\text{o1}} - v_{\text{o2}}$, only the algebraic sign of A_{D} would change.

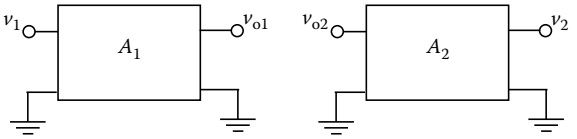

FIGURE 15.15 Differential pair.

In the general case, both common-mode and differential signals will be applied to the amplifier. This situation arises, for example, when the differential inputs are driven by preceding stages that have an output consisting of a dc bias voltage and an incremental signal voltage.

Using superposition, the output voltage for this case can be calculated from

$$v_{\text{out}} = A_{\text{D}}(v_1 - v_2) + A_{\text{CM}}v_{\text{CM}} \tag{15.38}$$

The common-mode input voltage can be found from

$$v_{\text{CM}} = \frac{v_1 + v_2}{2} \tag{15.39}$$

In the ideal situation with perfectly symmetrical stages, the common-mode input would lead to zero output, thus a measure of the asymmetry of the differential pair is the common-mode rejection ratio defined as

$$\text{CMRR} = 20\log\frac{|A_{\text{D}}|}{|A_{\text{CM}}|}\text{dB} \tag{15.40}$$

If $|A_{\text{D}}| = 100$ V/V and $|A_{\text{CM}}| = 0.01$ V/V, this value would be

$$\text{CMRR} = 20\log\frac{100}{0.01} = 80 \text{ dB}$$

The larger the CMRR, the smaller is the effect of A_{CM} on the output voltage compared to A_{D}.

A big advantage of the differential stage is in the cancellation of drift at the double-ended output. Temperature drifts in each stage are often common-mode signals. For example, the change in forward voltage across the base-emitter junction with constant current is about -2 mV/°C. As the temperature changes, each junction voltage changes by the same amount. These changes can be represented as equal voltage signals applied to the two inputs. If the stages are closely matched, very little output drift will be noted. The integrated differential amplifier can perform considerably better than its discrete counterpart since component matching is more accurate and a relatively uniform temperature prevails throughout the chip. Power supply noise is also a common-mode signal and has little effect on the output signal if the common-mode gain is low.

As previously mentioned, the mode of operation most often used with the differential amplifier is the differential input, double-ended output mode. In this configuration, the input voltage applied to one stage should be equal in magnitude, but opposite in polarity to the voltage applied to the other stage. One method of obtaining these equal magnitude, opposite polarity signals using only a single input source is shown in Figure 15.16.

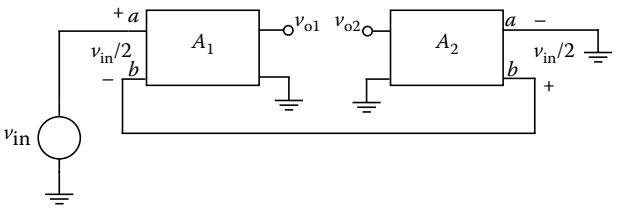

FIGURE 15.16 Differential input obtained from a single input source.

If the input resistances of both stages are equal, half of v_{in} will drop across each stage. While the voltage from terminal *a* to terminal *b* of stage 1 represents a voltage drop, the voltage across the corresponding terminals of stage 2 represents a rise in voltage. We can write

$$v_1 = \frac{v_{in}}{2}$$

and

$$v_2 = -\frac{v_{in}}{2}$$

Each stage has the same magnitude of input voltage, but is opposite in polarity to that of the other stage. From Equation 15.37 we can write the differential gain as

$$\begin{aligned} A_D &= \frac{v_{out}}{v_{in}} = \frac{v_{o2} - v_{o1}}{v_1 - v_2} = \frac{v_{o2} - v_{o1}}{v_{in}/2 - (-v_{in}/2)} \\ &= \frac{A_1 \frac{v_{in}}{2} + A_2 \frac{v_{in}}{2}}{\frac{v_{in}}{2} + \frac{v_{in}}{2}} = \frac{A_1 + A_2}{2} \end{aligned} \tag{15.41}$$

15.5.3 BJT Differential Pair

A BJT differential pair is shown in Figure 15.17.

15.5.3.1 Small-Signal Voltage Gain

Figure 15.18 represents a simple equivalent circuit for the BJT differential pair. The steps in calculating the single-ended or double-ended voltage gain of a differential pair are

1. Calculate the input current as $i_{in} = \frac{v_{in}}{R_{in}}$.
2. Note that the base currents are related to i_{in} by $i_{b1} = i_{in}$ and $i_{b2} = -i_{in}$.
3. Calculate collector currents as $i_{c1} = \beta_1 i_{b1}$ and $i_{c2} = \beta_2 i_{b2}$.
4. Calculate collector voltages from $v_{o1} = -i_c R_{Ceq1}$ and $v_{o2} = -i_2 R_{Ceq2}$, where

$$R_{Ceq} = R_C \parallel r_{out} \tag{15.42}$$

With these values, the single-ended or double-ended voltage gain can be found. In the normal situation, we assume perfectly symmetrical pairs with $\beta_1 = \beta_2 = \beta$ and $R_{C1} = R_{C2} = R_C$. We also assume that the bias current I splits equally between the two stages giving $I_{E1} = I_{E2} = I/2$.

The single-ended gain of the first stage of Figure 15.17 is found to be

$$A_{S1} = \frac{v_{o1}}{v_{in}} = \frac{-\beta R_{Ceq}}{2(\beta + 1) r_e} \tag{15.43}$$

The single-ended gain of the second stage equals this value in magnitude, but shows no phase inversion and therefore, has a positive algebraic sign.

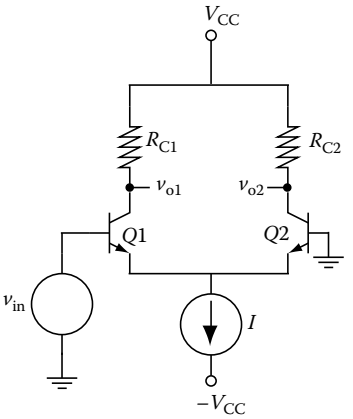

FIGURE 15.17 BJT differential pair.

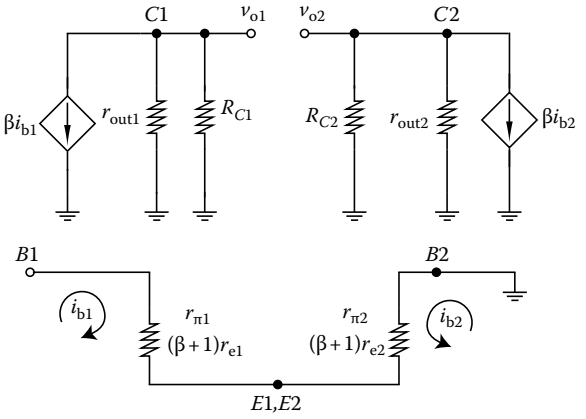

FIGURE 15.18 Equivalent circuit of the differential pair.

The double-ended differential gain is

$$A_D = \frac{v_{o2} - v_{o1}}{v_{in}} = \frac{\frac{\beta v_{in}}{2(\beta+1)r_e} R_{Ceq} - \left(\frac{-\beta v_{in}}{2(\beta+1)r_e} R_{Ceq}\right)}{v_{in}} = \frac{\beta R_{Ceq}}{(\beta+1)r_e} \tag{15.44}$$

This differential double-ended voltage gain is equal in magnitude to the voltage gain of a single transistor amplifier with a load of R_C and no external emitter resistance. The advantages of decreased temperature drift and good power supply rejection in critical applications, and a dc input reference of zero volts are typically far more important than the necessity of using an extra device, especially for IC chips.

The previous calculations for the differential pair assume there is no load across the output terminals. If this circuit drives a succeeding stage, the input impedance to this following stage will load the differential pair. One approach to this problem results from noting that when the collector of one BJT is driven positive by the input signal, the other collector moves an equal voltage in the opposite direction. Each end of the load resistor, R_L, is driven in equal but opposite directions. The midpoint of the resistor is always at 0 V, for incremental signals. To calculate the loaded voltage gain, a resistance of $R_L/2$ can be placed in parallel with each collector resistance to give an equivalent collector resistance of

$$R_{Ceq} = R_C \parallel R_L/2 \tag{15.45}$$

Equation 15.44 can now be used to calculate the loaded differential gain.

15.6 Operational Amplifiers

Very few circuits have had an impact on the electronics field as great as that of the op-amp circuit. This name is a shortened version of operational amplifier, a term that has a rather specific meaning. As mentioned in Section 15.2, before IC chips became available, operational amplifiers were expensive, high-performance amplifiers used primarily in a system called an analog computer. The analog computer was a real-time simulator that could simulate physical systems governed by differential equations. Examples of such systems are circuits, mechanical systems, and chemical systems. One popular use of the analog computer was the simulation of automatic control systems. The control of a space vehicle had to be designed on paper before test flights took place. The test flights could then be used to fine-tune the design. The analog computer was far more efficient than the digital computer of the day in simulating differential equations and was far less costly.

The op-amp was an important component of the analog computer that allowed several mathematical operations to be performed with electronic circuits. The op-amp could be used to create a summing circuit, a difference circuit, a weighting circuit, or an integrating circuit. Using these capabilities, complex differential systems can be created with an output voltage that represents the physical output variable of the simulated system. The time variable may be scaled, but for many simulations, the output represents a real-time solution.

One of the key features of an op-amp is the differential input to the amplifier. This allows differences to be formed, and also allows the creation of a virtual ground or virtual short across the input terminals. This virtual short is used in summing several current signals into a node without affecting the other input current signals. These signals are then summed and easily converted into an output voltage.

The virtual ground also allows the formation of rather accurate integrals the op-amp using an additional resistor and capacitor. This feature is essential in the simulation of differential equations.

Other amplifiers are sometimes mistakenly referred to as op-amps, but unless these amplifiers possess the capability to create a virtual ground and do mathematical operations, this is a misnomer.

The first IC op-amp was introduced by Fairchild Semiconductor Corporation in 1964. This chip, designated the μA702 or 702, was followed shortly by the 709 which was the first analog IC product to receive wide industry acceptance. The National LM101 and Fairchild 741 advanced the field and eliminated the external compensation capacitors required for the earlier models. The ensuing popularity and low price of the 741 allowed op-amps to be treated as a component rather than a subcircuit that must be designed.

Today, op-amps are available in bipolar (BJT), CMOS, and BiCMOS (BJT/CMOS) technologies and designers have the option of including dozens of op-amps and other circuits on a single chip. Modern op-amps generally use the same architecture developed in the LM101/741 circuits with performance improvements resulting from improved processing techniques.

The configuration of an op-amp offers one important advantage for IC amplifiers. This advantage is the op-amp's ability to allow the input signal to be referenced to any dc voltage, including ground, within the allowed input range. This eliminates the need for a large coupling capacitor to isolate a dc input transducer from an amplifier input.

15.6.1 Classical IC Op-Amp Architecture

While the technology used to implement op-amps has changed considerably over the years, the basic architecture has remained remarkably constant [4]. This section first discusses that architecture and some approaches to its implementation. After this topic is considered, the subject will turn to methods of specifying amplifier performance.

The architecture of many op-amps appears as shown in Figure 15.19. The first section is a differential amplifier required by all op-amps to allow a virtual ground and the implementation of mathematical operations. This stage is generally designed to have a very high differential voltage gain, perhaps a few thousand. The bandwidth is generally rather low as a result of the high voltage gain. In some cases, this differential amplifier will use an active load that will also convert the double-ended output of the differential stage to a single-ended output that will drive the second voltage amplifier.

The second stage of Figure 15.19 is a single-ended voltage amplifier with a relatively high voltage gain. This gain may reach values of 500 V/V. Often this stage is used to compensate the op-amp, a topic that will be discussed later in this chapter. For now it is sufficient to say that this stage will probably be an

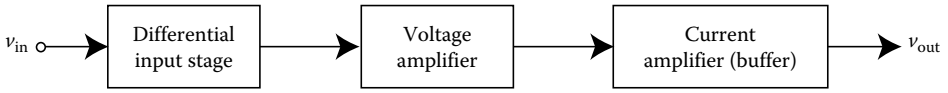

FIGURE 15.19 Classical op-amp architecture.

inverting stage that can multiply the apparent value of some capacitance placed between the input and output of the stage. The large capacitive load presented to the output of the first stage due to the Miller effect will lead to a very low upper corner frequency, perhaps 10–100 Hz, for the first stage.

The last stage is the output stage. It may be nothing more than an emitter follower that has a large current amplification along with a voltage gain that is near unity. This stage will have a very high upper corner frequency.

15.6.2 High-Gain Differential Stage

The normal way to achieve high voltage gains is to use an active load for the amplifying stages. The incremental resistance presented to the amplifying stage is very high while the dc voltage across the active load is small. One popular choice for an active differential stage load is the current mirror. This load provides very high voltage gain and also converts the double-ended output signal to a single-ended signal referenced to ground. Figure 15.20 shows a block diagram of such an arrangement.

With no input signal applied to the differential stage, the tail current splits equally between I_{diff1} and $I_{\text{diff 2}}$. The input current to the mirror equals this value of $I_{\text{tail}}/2$. This value is also mirrored to the output of the mirror giving $I_{\text{out}} = I_{\text{tail}}/2$. We will assume that the voltage between the current mirror output and the second differential stage is approximately zero, although this assumption is unnecessary to achieve the correct result.

When a signal is applied to the differential input, it may increase the current I_{diff1} by a peak value of ΔI. The input current to the mirror now becomes

$$I_{\text{in}} = \frac{I_{\text{tail}}}{2} + \Delta I$$

The output current from the mirror also equals this value. However, the input signal to the differential stage will decrease I_{diff2} by the same amount that I_{diff1} increases. Thus, we can write

$$I_{\text{diff2}} = \frac{I_{\text{tail}}}{2} - \Delta I$$

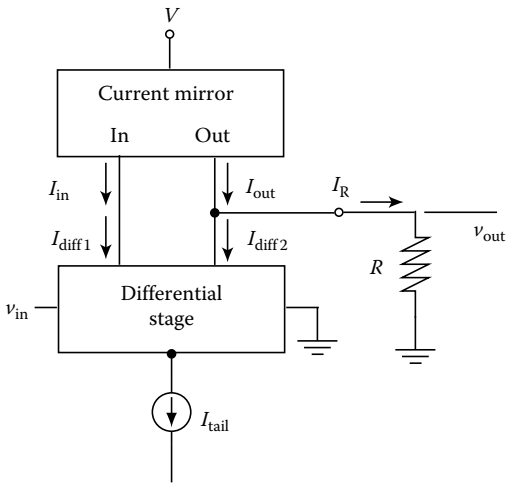

FIGURE 15.20 Differential stage with current mirror load.

The current to the resistance R increases from its quiescent value of zero to

$$I_{\text{R}} = I_{\text{out}} - I_{\text{diff2}} = 2\Delta I$$

The incremental output voltage resulting is then

$$v_{\text{out}} = 2R\Delta I \tag{15.46}$$

When an incremental input signal is applied to the differential pair, half of this voltage will drop across each base–emitter junction of the pair. This results in equal incremental differential stage currents in the two output devices, but they will be in opposite directions. An incremental input signal, v_{in}, will produce incremental currents of

$$i_{\text{diff1}} = \Delta I = \frac{g_{\text{m}} v_{\text{in}}}{2} \tag{15.47}$$

and

$$i_{\text{diff2}} = -\Delta I = -\frac{g_{\text{m}} v_{\text{in}}}{2} \tag{15.48}$$

where g_{m} is the transconductance of devices 1 and 2. Assuming negligibly large output resistances of the current mirror and the differential stage, the incremental output voltage becomes

$$v_{\text{out}} = 2i_{\text{diff1}} R = g_{\text{m}} R v_{\text{in}}$$

with a resulting midband voltage gain of

$$A_{\text{MB}} = g_{\text{m}} R \tag{15.49}$$

If the output resistances of the mirror and differential stage are significant, the voltage gain can be found by combining these resistances in parallel with the load resistance to form $R_{\text{eff}} = R_{\text{out}} \| R$. This resistance then replaces R in Equation 15.49. The load resistance may, in fact, be the incremental input resistance of the following stage. Very large values of voltage gain can result from this configuration. For the BJT, the transconductance is given by $g_{\text{m}} = \alpha / r_{\text{e}} \approx 1/r_{\text{e}}$.

While this expression for voltage gain is the same as that for the differential gain of a resistive load stage, given by Equation 15.44, two significant points should be made. First of all, the impedance R can be much greater than any resistive load that can be used in a differential stage. Large values of R in the differential stage would cause saturation of the stages for reasonable values of tail currents. In addition, large values of R are more difficult to fabricate on an IC chip. The current mirror solves this problem. The second point is that the output voltage of the differential pair with a current mirror load is a single-ended output which can be applied to a following simple amplifier stage. However, the rejection of common-mode variables caused by temperature change or power supply voltage changes is still in effect with the current mirror stage. If a resistive load differential stage must provide a single-ended output, the gain drops by a factor of 2, compared to the double-ended output, and common-mode rejection no longer takes place.

15.6.3 Second Amplifier Stage

Before the purpose of the second amplifier stage can be fully understood, a discussion on circuit stability must take place.

15.6.3.1 Feedback and Stability of the Op-Amp

The op-amp is used in a feedback configuration for essentially all amplifying applications. Because of nonideal or parasitic effects, it is possible for the feedback amplifier to exhibit unstable behavior. Oscillations at the output of the amplifier can exist, having no relationship to the applied input signal. This, of course, negates the desired linear operation of the amplifier. It is necessary to eliminate any undesired oscillation signal from the amplifier.

The open-loop voltage gain of a three-stage amplifier such as that of Figure 15.19 may be represented by a gain function of

$$A = \frac{A_{\text{MB}}}{\left(1 + j\frac{\omega}{P_1}\right)\left(1 + j\frac{\omega}{P_2}\right)\left(1 + j\frac{\omega}{P_3}\right)} \tag{15.50}$$

where P_1, P_2, and P_3 are the dominant poles of gain stages 1, 2, and 3. The quantity A_{MB} is the low-frequency or midband gain of the amplifier.

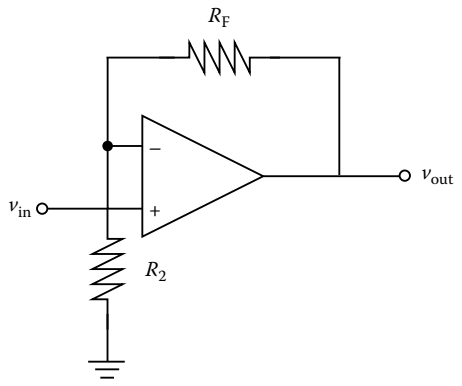

FIGURE 15.21 Noninverting op-amp stage.

When this op-amp is used in a negative feedback configuration such as that shown in Figure 15.21, the loop gain must be analyzed to see if the conditions for oscillation occur. The feedback factor for this circuit is

$$F = \frac{R_2}{R_2 + R_F} \tag{15.51}$$

In order to check the stability of this circuit, a zero volt input signal (short circuit) can be applied to the noninverting input terminal. The loop gain from inverting terminal to output and back to inverting terminal can then be found with the noninverting terminal shorted to ground. When this is done, it is found [4] that the amplifier is unstable for most practical values of R_F and R_2. The worst case condition occurs as R_2 approaches infinity and R_F approaches zero as in the case of a unity-gain voltage buffer.

One measurement of stability is referred to as the phase margin. This quantity is defined in terms of the phase shift of AF that exists when the magnitude of AF has dropped to unity. The number of degrees less than $-180°$ at this frequency is called the phase margin. Most amplifiers target a phase margin of 45°or more.

One possibility to achieve a reasonable phase margin is to intentionally modify one of the three upper corner frequencies of the op-amp. For example, if the pole associated with the first stage is lowered by several factors, the amplifier can become stable, even when used as a unity-gain voltage buffer.

The frequency response of this gain is sketched in Figure 15.22 for a midband gain of 300,000. We note that the magnitude of this gain has fallen below a value of unity (0 dB) before the second upper corner frequency of 2×10^6 is reached. The phase shift of AF at the frequency where the magnitude has dropped to unity may be $-130°$ resulting in a phase margin of 50°. Normally, engineers do not destroy bandwidth of a stage intentionally, however in this case it is necessary to stabilize the operation of the op-amp in the feedback configuration.

Lowering the upper corner frequency of one stage is not a trivial matter. While it may not need to be reduced to 10 rad/s in a practical op-amp, it is often lowered to 10–100 Hz. A capacitor must be added to the appropriate point in the stage to drop this frequency, but a relatively large capacitor is required. In the early days of the IC op-amp, the two terminals between which a capacitor was to be

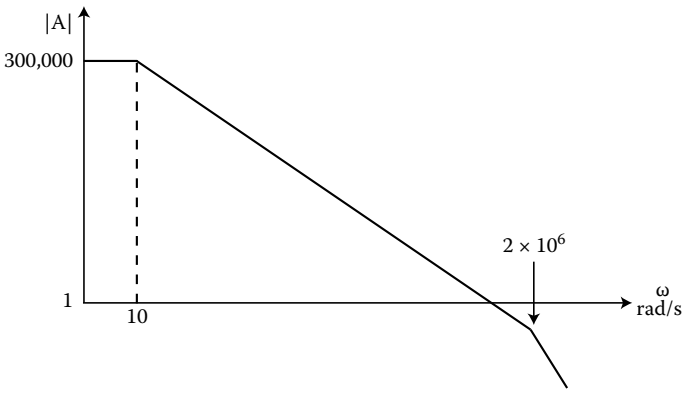

FIGURE 15.22 Op-amp frequency response.

added were connected to two external pins of the chip. A discrete capacitor of sufficient value was then added externally.

In 1967, the capacitor was added to the IC chip using the Miller effect to multiply the capacitor value. Returning to Figure 15.19, it is seen that a capacitor can be added between input and output of the second stage. This is typically a capacitor of value 30 pF that, due to the Miller effect, is multiplied by a factor of $(A_2 + 1)$ where $-A_2$ is the gain of the second stage. The Miller capacitance is reflected to the input of the second stage that loads the output of the first stage. This large effective capacitance, driven by the large output impedance of the first stage produces a very low upper corner frequency for the first stage.

In a 741 op-amp design, the gain A_2 is approximately -400 V/V. With a 30 pF capacitance bridging input to output, the effective capacitance at the input is about 0.012 μF. This creates a bandwidth for the op-amp of 10 Hz or 62.8 rad/s.

This method of solving the instability problem is referred to as dominant pole compensation. The lower value of pole frequency is seen from Figure 15.22 to dominate the amplifier performance up to frequencies above the useful range of gain.

It should be mentioned that op-amps for specific applications may not need to be stabilized for the unity gain configuration. The minimum gain required by the amplifier may be 2 V/V or 3 V/V or some other value that is easier to compensate. In such cases, the dominant pole need not be decreased to the level of the general purpose op-amp. The resulting frequency performance of the op-amp can then be higher than that of the general purpose stage.

15.6.4 Op-Amp Specifications

There are several nonideal effects in the op-amp that detract from its overall performance. Mismatching of devices in the input differential pair, required bias currents, and junction voltage temperature effects can degrade the performance. These effects are described in terms of the following specifications. The diagram of Figure 15.23 is used to define various terms used in these definitions.

Input offset voltage (V_{OS}): Mismatch of the transistors in the differential input stage leads to a finite output dc voltage when both inputs are shorted to ground. This finite output voltage is called the output offset voltage. A slight voltage mismatch in the differential pair is amplified by succeeding stages to create a larger voltage at the output. Inaccurate biasing of later stages also contribute to the output offset. Inaccuracies in later stages are amplified by smaller factors than are early stage inaccuracies.

The input offset voltage is the voltage that must be applied across the differential input terminals to cause the output voltage of the op-amp to equal zero. Theoretically, this voltage could be found by measuring the output voltage when the input terminals are shorted, then dividing this value by the gain of the op-amp. In practice, this may not be possible as the gain may not be known or the output offset may exceed the size of the active region. The value of V_{OS} is typically a few millivolts for monolithic or IC op-amps.

Input offset voltage drift (TCV_{OS}): Temperature changes affect certain parameters of the transistors, leading to a drift in the output dc offset voltage with temperature. In BJT devices, the voltage across the base-to-emitter junction for a constant emitter current drops by approximately 2 mV/°C. Small drifts of voltage in early stages will be amplified by following stages to produce relatively large drifts in output voltage. Because the output dc signal may not exist within the active region of the op-amp, the drift is again referred to the input.

The input offset voltage drift is defined as the change in V_{OS} for a 1°C change in temperature (near room temperature). A value of 10–20 μV/°C is typical for IC op-amps.

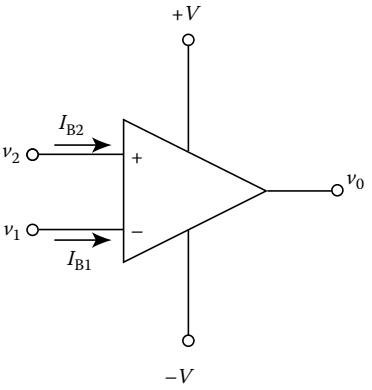

FIGURE 15.23 Op-amp.

Input bias current (I_B): A BJT differential stage will require a finite amount of base current for biasing purposes. This is true even if both inputs are grounded. The input bias current of an op-amp is defined as the average value of bias current into each input with the output driven to zero. The two bias currents are generally slightly different so I_B is

$$I_B = \frac{(I_{B1} + I_{B2})}{2} \tag{15.52}$$

Input offset current (I_{OS}): The input offset current is the difference between the two input bias currents when the output is at zero volts. This parameter is

$$I_{OS} = |I_{B1} - I_{B2}| \tag{15.53}$$

Common-mode input voltage range (CMVR): The voltage range over which the inputs can be simultaneously driven without causing deterioration of op-amp performance is called the common-mode voltage range or CMVR. In most op-amps, the CMVR is a few volts less than the rail-to-rail value of the power supplies. In many applications, both inputs are forced to move together due to the virtual short between the input terminals when negative feedback is used.

Common-mode rejection ratio (CMRR): The ratio of input common-mode voltage to change in input offset voltage is called the common-mode rejection range or CMRR. An equivalent definition is the ratio of differential voltage gain to common-mode voltage gain. IC op-amps range from 80 to 100 dB for the CMRR. This parameter was mentioned earlier in the chapter and is a measure of the mismatch of incremental gain from each of the two inputs to output. If the incremental gains from each input to output were equal, the CMRR would be infinite.

Power supply rejection ratio (PSRR): The power supply rejection ratio or PSRR is the ratio of change in the input offset voltage to a unit change in one of the power supply voltages. An op-amp with two power supplies requires that a PSRR be specified for each power supply.

15.7 Wideband Amplifiers

The development of wideband amplifiers with discrete circuits progressed rapidly during World War II with vacuum tubes and into the 1960s with BJT circuits. Although many important techniques were perfected between 1940 and 1960, these methods are not generally applicable to wideband IC design. Many of these approaches to wideband amplifier design required relatively large inductors for shunt peaking and relatively large coupling capacitors to ac couple individual stages. While small inductors are now available on IC chips, the range of values limit their usage. Likewise, the limitation on IC capacitor sizes precludes the use of coupling capacitors for IC amplifiers. These difficulties are mitigated in IC design by using additional transistors, however, the benefit of past theoretical developments is then largely unused. Furthermore, the absence of coupling capacitors in IC amplifiers leads to a much stronger interaction between dc and ac design of each stage than is present in discrete design. Two of the more popular methods of IC wideband amplifier design that overcome the limitations on IC circuits are based on composite stages or feedback cascades [7,8].

15.7.1 Composite or Compound Stages

The wideband amplifier of Figure 15.24 is a classic architecture on which many present amplifiers are based. This schematic is for the RCA CA3040 [8]. The input is a buffered, differential, cascode pair. The transistors T_1 and T_4 are emitter follower stages while the pair of devices T_2 and T_3 forms a cascode

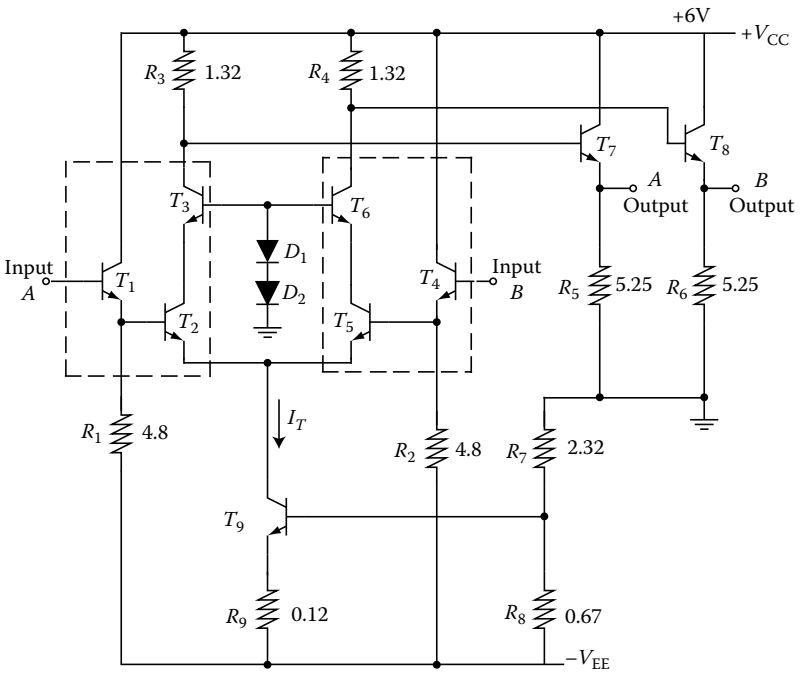

FIGURE 15.24 RCA CA3040 wideband amplifier.

stage as also does the pair of devices T_5 and T_6. Transistor T_9 with its emitter degeneration resistance forms a high output impedance current source. Transistors T_7 and T_8 buffer the output signals to allow relatively high output currents.

Since the input is differential, the input signal can be referenced to ground eliminating the need for a coupling capacitor. The frequency response of the gain extends from dc up to approximately 55 MHz with a constant gain of 30 dB.

The Motorola MC1490 [8] is another typical wideband amplifier chip that can be used for radio frequency or audio applications. It has a power gain of 50 dB at 10 MHz and 35 dB at 100 MHz. It also has a built-in automatic gain control to allow usage as an intermediate frequency amplifier.

15.7.2 Feedback Cascades

The circuit of Figure 15.25 shows the schematic of the MC1553 wideband amplifier using a feedback triple [7]. Transistors T_1, T_2, and T_3 make up the feedback triple using resistor R_F to create a feedback path. This path establishes the incremental voltage gain and also provides dc feedback to keep T_1, T_2, and T_3 in their active regions. There is a second feedback path from the current mirror output transistor T_6, but this is primarily dc feedback. The capacitor C_B is a large, external bypass capacitor that must be added to the circuit to decouple the ac feedback to the input stage. This IC amplifier has a voltage gain of 50 V/V with a bandwidth of 50 MHz.

Although the capacitor C_B is required in some applications, if the amplifier is driven by a low impedance source, it is unnecessary to add this element.

In recent years, both wideband and narrowband amplifiers in the 1–6 GHz range have become more significant. Many companies that provide amplifiers in this frequency range use HBT designs with SiGe, GaAs, GaN, or other material to achieve the necessary frequency performance.

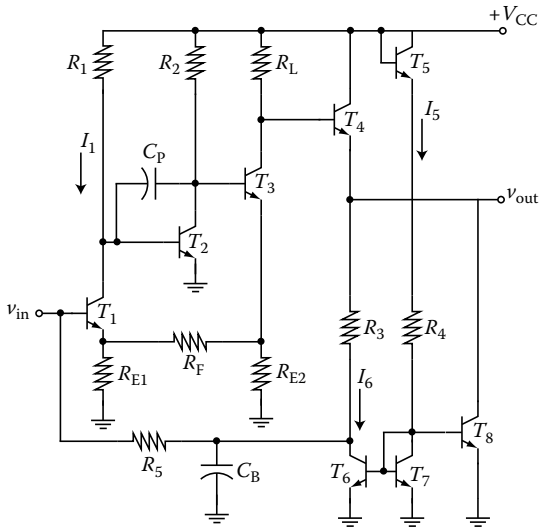

FIGURE 15.25 MC1553 wideband amplifier.

15.8 IC Power Output Stages [3]

If an IC power amplifier is to occupy a relatively small volume, the output power will be limited. This is due to the limitation imposed on the thermal conductivity of a small-area power device. A discrete transistor mounted on a large heat sink will exhibit a much higher thermal conductivity than that of the smaller IC chip. This limits the power that can be dissipated by the output device or devices of the IC as the junction temperature will be higher with the lower thermal conductivity of the IC chip. Typically, this limitation leads to an IC power output stage that is implemented in a high-efficiency configuration. Generally, the output stage for power outputs in the range of a few watts will use a class-B configuration while those with tens or hundreds of watts will use a class-D configuration.

One of the most significant limitations on dissipation is the junction temperature. As the temperature rises, several potentially dangerous effects may occur. First, the solder or alloys used in the transistor can be softened or even melted. Second, the impurity profiles in the doped regions can be affected if elevated temperatures exist for long periods of time. A third result of higher temperatures is the increase in collector leakage current. In power transistors, this current doubles for an incremental increase in temperature of 7°C–10°C. The leakage current, I_{co}, at temperature T_2 can be related to I_{co} at temperature T_1 by

$$I_{co}(T_2) = I_{co}(T_1) \times 2^{(T_2 - T_1)/T_K}$$

where T_K can range from 7°C to 10°C. For a temperature increase of 100°C, the minimum factor of increase in I_{co} is 1024 ($2^{100/10}$), whereas the maximum factor is approximately 20,000 ($2^{100/7}$). This marked increase in I_{co} can lead to increased power dissipation which leads to an increased temperature followed by a further increase in I_{co}. In some cases, this feedback effect is large enough to cause thermal runaway and destroy the transistor. This effect is minimized by placing a resistance in the emitter to decrease the forward bias on the base–emitter junction as current increases.

In other situations, the leakage current can approach the value of the quiescent collector current. Since leakage current is not controlled by the applied input signal, its effects can severely limit the amplifying

properties of the stage. For these reasons, the manufacturer places a limit on the maximum allowable junction temperature of the device.

The maximum junction temperature is therefore an important quantity that limits the power a transistor can deliver. The junction temperature will be determined by the power being dissipated by the transistor, the thermal conductivity of the transistor case, and the heat sink that is being used. The collector junction is the point at which most power is dissipated; hence, it is this junction that concerns us here.

Basically, manufacturers specify the allowable dissipation of a transistor in two ways. One way is to specify the maximum junction temperature along with the thermal resistance between the collector junction and the exterior of the case. Although this method is very straightforward, it incorrectly implies that the allowable power increases indefinitely as the transistor is cooled to lower temperatures. Actually, there is a maximum limit on the allowable dissipation of the transistor which is reflected by the second method of specification. This method shows a plot of allowable power dissipation versus the temperature of the mounting base. Quite often this plot shows power dissipation versus ambient temperature, where an infinite heat sink is used. However, if the transistor could be mounted on an infinite heat sink, the ambient temperature would equal the mounting base temperature; thus both plots convey the same information. This second method indicates the maximum allowable power dissipation, in addition to the maximum junction temperature.

The maximum limit on power dissipation ensures that chip temperature differentials do not become excessive as excess power is dissipated in collector regions. It also minimizes the possibility of excessive collector currents in typical applications.

15.8.1 Thermal Resistance

The thermal resistance of a material is defined as the ratio of the temperature difference across the material to the power flow through the material. This assumes that the temperature gradient is linear throughout. The symbol θ is used for thermal resistance, and

$$\theta = \frac{\Delta T}{P} = \frac{\text{Temperature difference across conductor}}{\text{Power flowing through conductor}} \tag{15.54}$$

The diagram of Figure 15.26 represents the thermal circuit of an IC chip, including the output transistor, surrounded by free air. Here, θ_{JM} is the thermal resistance from collector to mounting base and θ_A is the thermal resistance of that portion of air in contact with the mounting base; T_A is the temperature of air far away from the transistor; T_M is the mounting base temperature; T_J is the collector junction temperature. The power P will be determined by the electrical circuit that includes the output transistor; P, in turn, will determine the temperatures T_J and T_M. The temperature T_J can be written as

$$T_J = T_A + P(\theta_{JM} + \theta_A) \tag{15.55}$$

This equation shows that as more power is dissipated by the output transistor, T_J must rise.

For high-power IC chips mounted in a TO-3 package, θ_A is usually many times greater than θ_{JM}.

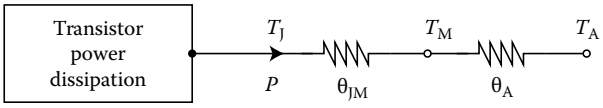

FIGURE 15.26 Transistor dissipating power in free air.

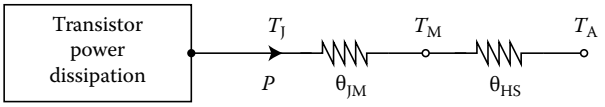

FIGURE 15.27 Transistor mounted on heat sink.

If θ_{JM} were 1°C/W, then θ_A might be 5°C/W to 20°C/W. Of course, θ_A depends on the area of the IC package.

The diagram of Figure 15.27 represents the thermal circuit of the IC chip mounted on a heat sink. The power that can be dissipated without exceeding the maximum junction temperature is found from solving the preceding equation to result in

$$P_{max} = \frac{T_J - T_A}{\theta_{JM} + \theta_{HS}} \tag{15.56}$$

The values of θ_{HS} presented between the chip case and free air might range from 0.4°C/W for air-cooled systems to 2°C/W for flat vertical-finned aluminum heat sinks to 8°C/W for cylindrical heat sinks that slide over the chip package. For each thermal circuit, the amount of allowable power dissipation is fixed.

15.8.2 Circuit or Conversion Efficiency

The efficiency of a power output stage is a measure of its effectiveness in converting dc power to ac output power. It is defined as

$$\eta = \frac{P_{out}}{P_S} \tag{15.57}$$

where

P_{out} is the average output power

P_S is the power supplied by the dc power supply

A useful relationship between the allowable dissipation of the chip and the maximum output power can be found by assuming that the power delivered from the dc source is dissipated by the output transistor and the load. This assumption would be very inaccurate for a class-A, resistive load stage, in which the resistor dissipates significant dc power. For many class-B or class-D stages, the assumption is not unreasonable. In equation form, this assumption is expressed by

$$P_S = P_{out} + P_T \tag{15.58}$$

where P_T is the actual dissipation of the output transistor or transistors.

In terms of the circuit efficiency, the transistor dissipation can be written as

$$P_T = (1 - \eta)P_S = (1 - \eta)\frac{P_{out}}{\eta} \tag{15.59}$$

Solving for P_{out} in terms of P_T leads to

$$P_{out} = \frac{\eta}{1 - \eta}P_T \tag{15.60}$$

The effect of circuit efficiency on output power can be demonstrated by assuming that the maximum allowable output stage dissipation is 5 W. If the circuit efficiency is 50% or $\eta = 0.5$, the maximum output power calculated from Equation 15.60 is also 5 W. If the efficiency is increased to 78.5%, the maximum efficiency of an ideal class-B stage, the maximum output power is found to be 18.26 W. Increasing the circuit efficiency to 98% a figure approached in a near-ideal class-D stage, the maximum output power becomes 245 W. In this case, an output stage that can dissipate 5 W delivers 245 W to the load. Although these calculations are based on some idealizations, it clearly shows the importance of using a circuit configuration that leads to a high value of efficiency. This explains the popularity of the class-B stage and the class-D stage in IC design as opposed to the class-A stage.

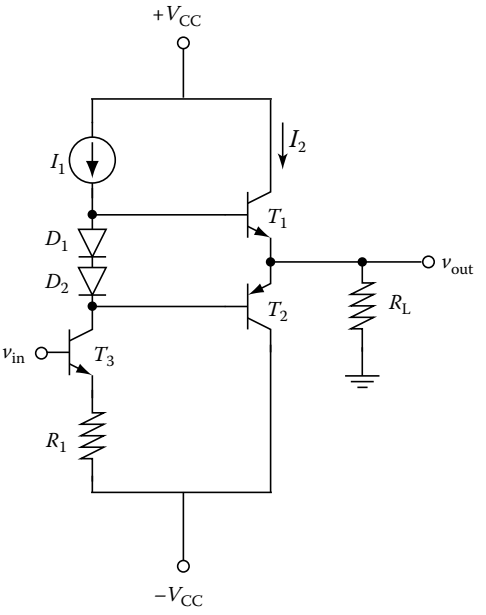

FIGURE 15.28 Class-B IC stage.

15.8.3 Class-B Output Stage

A class-B stage that can be integrated is shown in Figure 15.28. The current source I_1 consists of an IC current-source stage to provide a small bias current through diodes D_1 and D_2. A small quiescent collector current I_2 is necessary to reduce crossover distortion at the output. As v_{in} swings positive the input to T_2 goes negative, turning T_2 on while shutting T_1 completely off. A negative-going waveform at the amplifier input drives the bases of T_1 and T_2 positive to shut T_2 off and pass the signal to the output through T_1.

The amplifier can be made short-circuit proof by limiting the output current that can flow if the output terminal is accidentally shorted to one of the supplies. Figure 15.29 indicates the additional circuitry required for this purpose. The emitter–base junctions of transistors T_4 and T_5 are driven by the voltage drops across the resistances R_{E1} and R_{E2}. Under normal operating conditions, these voltages are too small to turn T_4 and T_5 on; thus, circuit operation is unaffected. If the output is short-circuited to the negative supply voltage, serious damage to device T_1 could result if transistor T_4 were not present. A large voltage would appear across T_1 and the base–emitter junction would be forward biased resulting in a high value of emitter current. The excessive power dissipation could destroy T_1 if the output were to be shorted to the negative supply or even to ground. When this occurs for the circuit of Figure 15.29, T_4 becomes sufficiently forward biased to divert the base-current drive from T_1. The maximum current that can flow in the output circuit is then limited to V_{BE4}/R_{E1}. Typical maximum currents for the short-circuit case range from 10 to 50 mA for modern IC amplifiers.

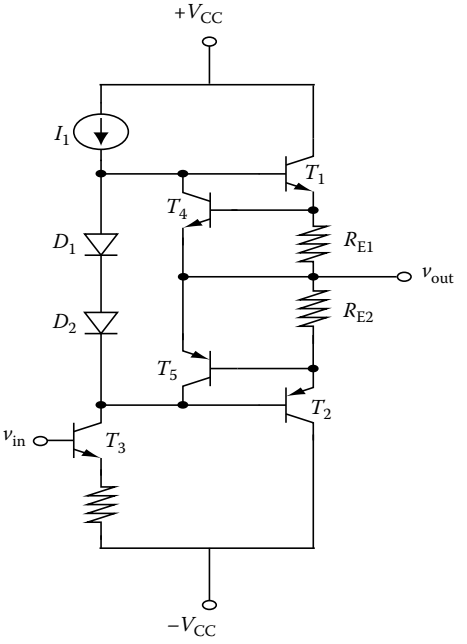

FIGURE 15.29 Class-B stage with short-circuit protection.

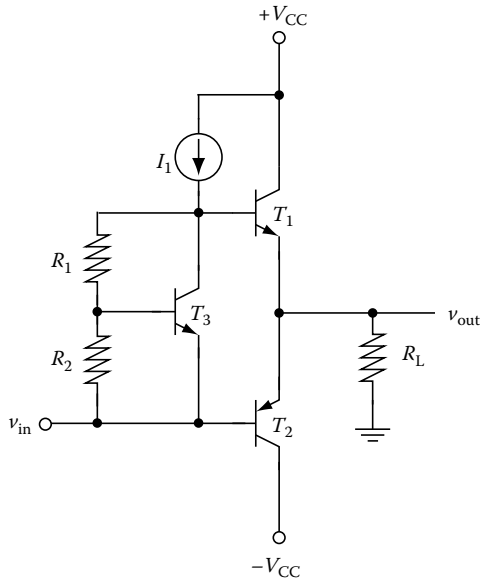

FIGURE 15.30 Bias circuit using V_{BE} multiplier.

The V_{BE} multiplier circuit often replaces the two diodes in Figures 15.28 and 15.29 to get better cancellation of the crossover voltage of the output devices. This circuit appears in Figure 15.30. If negligible base current flows in T_3, the voltage across R_1 and R_2 is

$$V_{CE3} = (1 + R_1/R_2)V_{BE3} \tag{15.61}$$

This voltage is found by noting that the drop across R_2 is constrained to be V_{BE3}, and this value must also equal

$$\frac{R_2}{R_1 + R_2} V_{CE3}$$

The voltage V_{CE3} is used to eliminate crossover distortion and can be adjusted by the ratio of the two resistors. Whereas the absolute values of individual resistors cannot be accurately determined in standard IC fabrication processes, the ratio of two resistors can be determined to the required accuracy.

There are several other output configurations based on the complementary emitter follower. A popular one is the Darlington output stage modified for IC amplifiers as shown in Figure 15.31. The current gain of this stage is very high, approximately equal to β^2. If high-gain *pnp* devices are available, a Darlington pair similar to the upper *npn* pair can replace devices T_2, T_4, and T_5. For the Darlington pairs, a larger difference of input bias voltage must be provided to the inputs of the respective pairs due to the larger voltage drop between each input and output which is now 2 $V_{BE(on)}$ instead of just $V_{BE(on)}$. The V_{BE} multiplier circuit can be designed to generate this increased bias voltage.

15.8.4 Class-D Output Stages

IC class-D amplifiers using PWM have been reported with efficiencies of 90% or more at 10 W output and a frequency response from 20 Hz to 20 kHz. Many IC chips are available that drive power BJTs or MOSFETs, delivering 30–50 W to a load. Larger discrete circuits report audio amplifiers based on the class-D stage that deliver 600 W per stereo channel [9]. This type of amplifier is often used in low-end car radios.

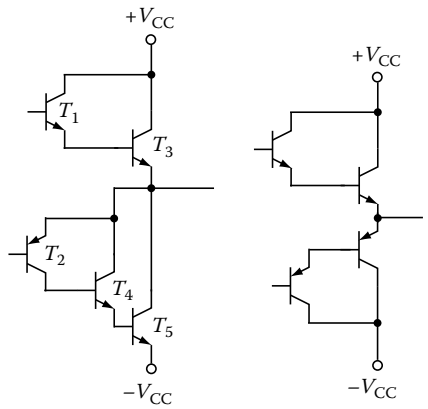

FIGURE 15.31 Modified Darlington and Darlington output stages.

PWM is used to reduce the power dissipated by the transistor while delivering a large power to the load. The varying load signal is applied by means of output devices that switch between on and off states. The resulting load voltage has a rectangular waveform that contains an average or dc value dependent on the duty cycle. In addition, the load voltage would also contain several ac components; however, these unwanted components can be filtered before reaching the load.

Any periodic waveform can be represented by a Fourier series consisting of a dc component (if present), a fundamental frequency component, and higher harmonics of the fundamental frequency. A rectangular wave switching

between $+V$ and $-V$ that remains positive for t^+ seconds is said to have a duty cycle of

$$d = \frac{t^+}{T} \tag{15.62}$$

where T is the repetition period of the waveform. A rectangular waveform with a 50% duty cycle contains no dc or average value, but a change of duty cycle will give the waveform an average value as shown in Figure 15.32. If the period, T, remains constant as the duty cycle is varied, the average value of a rectangular waveform of amplitude V is

$$V_{av} = V(2d - 1) \tag{15.63}$$

The average value varies directly with d. The Fourier coefficients of the ac components also vary as d is changed and new frequencies may be introduced, but in general, these components are of little interest to us as they can be easily eliminated. If, for example, the repetition frequency is 200 kHz, all ac components of the waveform will be greater than this value and far out of the audio range. Now if we vary the duty cycle sinusoidally at some low frequency, the average value will also vary sinusoidally. Mathematically, we can express this by saying that if $d = 0.5 + k \sin \omega t$, then the average value is

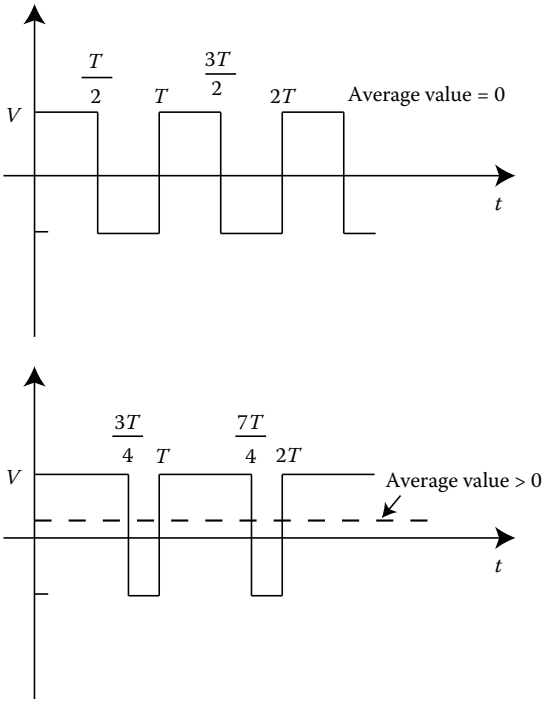

FIGURE 15.32 Rectangular waveforms with different duty cycles.

$$V_{av} = 2kV \sin \omega t \tag{15.64}$$

The waveform with variable duty cycle can be filtered by a low-pass filter to eliminate all frequencies above ω. The result is a low-frequency output sinusoid with an amplitude that varies in the same manner as the duty cycle. A block diagram of PWM amplification is shown in Figure 15.33.

The voltage control circuit must have a 50% duty cycle when the input signal is at zero volts. As v_{in} becomes nonzero, the duty cycle varies proportionally. The high-power switching stage amplifies this rectangular wave and applies the output to a low-pass circuit that allows only the changes in average value to pass to the load. The output signal is then proportional to the input signal, but can be at a much

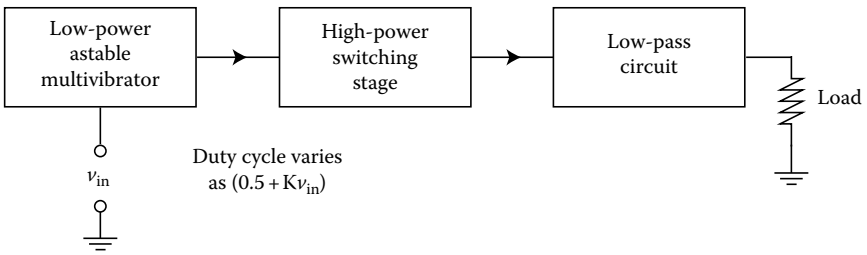

FIGURE 15.33 Architecture of a PWM amplifier.

higher power level than the input signal. The power output stage may dissipate only 5%–10% of the power delivered to the load.

The major advantage of PWM is that the output transistors need operate in only two states to produce the rectangular waveform: either fully on or fully off. In saturation we know that the very small voltage drop across a transistor leads to very low power dissipation. A very small dissipation is also present when the transistor is cut off. If switching times were negligible, no device power loss would occur during the transition between states. Actually, there is a finite switching time and this leads to an increased total dissipation of the output stages. Still, the efficiency figures for the class-D amplifier are very high, as reported earlier. This leads to higher possible power outputs and smaller chip areas for integrated PWM amplifiers. The stages can be direct-coupled to the load, which eliminates the necessity of capacitors. Nonlinear distortion can be less than that of class-B stages, and matching of transistors is unnecessary.

On the other hand, the disadvantages of this amplifier ultimately dictate the limits of usefulness of the PWM scheme. The upper frequency response is limited to a small fraction of the switching frequency. The operating frequency of power transistors generally decreases with higher power ratings. It follows that the upper corner frequency of the amplifier may be lower for higher power transistors. Furthermore, a low-pass filter may be required to eliminate the unwanted frequency components of the waveform. The generation of radio frequencies or electromagnetic interference by the switching circuits can also present problems in certain applications.

In addition to compound emitter followers, the power output stages can be designed in several arrangements. Figure 15.34 shows two possible configurations. The diodes appearing across the output transistors are present to protect the transistors against inductive voltage surges. If the filter is inductive,

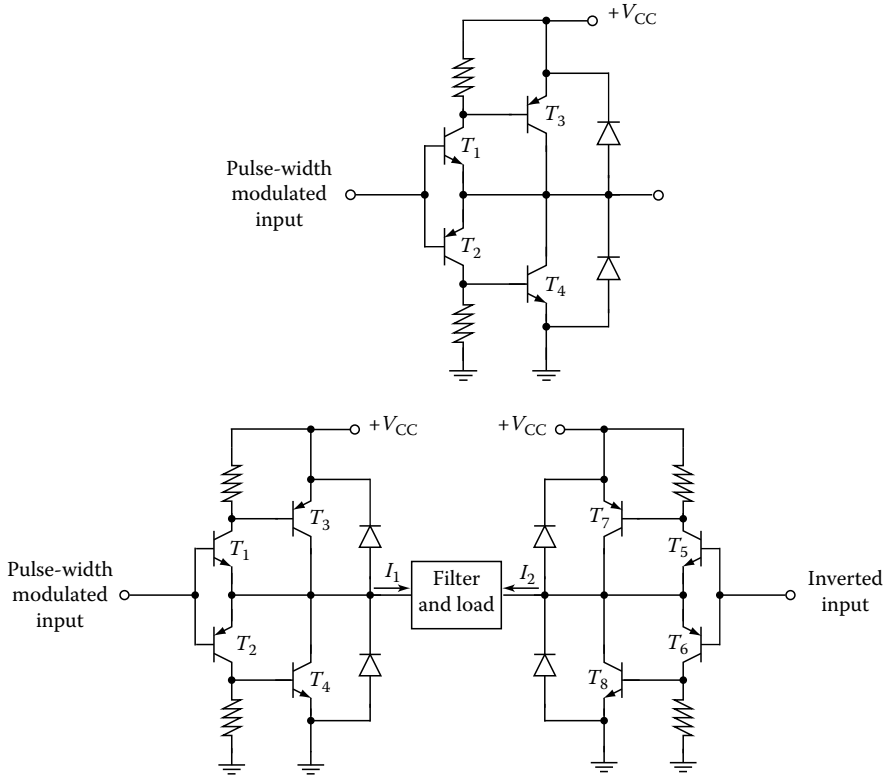

FIGURE 15.34 Class-D output stages.

the current reversals that occur over short switching times generate very large voltage spikes, unless the protective diodes are used.

In the push-pull circuit, the low-power, pulse-width modulated input turns T_1 and T_3 on when the signal is at its maximum value. Transistors T_2 and T_4 are off at this time and current is forced through the load. When the signal switches to the minimum value, T_1 and T_3 go off, while T_2 and T_4 turn on to pull current through the load.

Figure 15.34b shows a bridge circuit that can drive a floating load with a single power supply. When the input signal reaches its maximum value, T_1 and T_3 are on while T_2 and T_4 are held off. The input signal is inverted and applied to the bases of T_5 and T_6. This inverted signal is at its minimum value during the time when the normal input is maximum; thus, T_5 and T_7 will be off while T_6 and T_8 are on. Current will leave the collector of T_3, flow through the load, and enter the collector of T_8. When the input assumes the most negative value, T_1, T_3, T_6, and T_8 turn off while T_2, T_4, T_5, and T_7 turn on. Current now leaves the collector of T_7, flows through the load, and enters the collector of T_4. During this period, the load current flows in the opposite direction to that flowing when the input is maximum. The load current then reverses each time the input signal makes a transition.

In some applications, such as motor control or high-output audio systems, the load serves as a filter of high frequencies since these particular loads cannot respond to the switching frequencies.

16.1 Ideal Operational Amplifier

The operational amplifier, or op-amp, is a fundamental building block for many electronic circuits. Although the op-amp itself is composed of numerous transistors, it is usually treated as a single circuit element known as the ideal operational amplifier. The ability to treat the op-amp as an ideal circuit element simplifies its use in circuits such as amplifiers, buffers, filters, and data converters. With such varied uses, the op-amp has been implemented in many different forms. Nevertheless, the behavior of each of these different forms can still be characterized as an ideal op-amp.

16.1.1 Open-Loop Equivalent Circuit

The op-amp is primarily a high gain amplifier. Although the op-amp can be used on its own, most op-amps are part of larger circuits in which feedback is used to determine the circuit's overall transfer function. Consequently, the op-amp's precise behavior is only a secondary interest. To simplify preliminary circuit analysis and design, an abstraction of the practical op-amp, known as the ideal op-amp, is often used. The ideal op-amp is characterized by the following four parameters:

- Infinite gain
- Infinite bandwidth
- Draws no signal power at its inputs
- Is unaffected by loading of its output

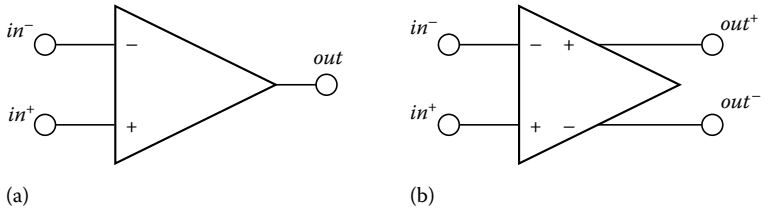

FIGURE 16.1 Circuit symbols for (a) the single-ended op-amp and (b) the fully differential op-amp.

Although such specifications are not achieved in practice, the nonidealities of practical op-amps (see Section 16.2) can be neglected in most applications.

The ideal op-amp is represented schematically as a triangle with two inputs and either one or two outputs, as shown in Figure 16.1. For the single output case, the output is referred to ground and the op-amp is known as a single-ended op-amp. For the two output case, the output is the difference between the out^+ and out^- outputs and the op-amp is known as a fully differential op-amp. Because the op-amp provides gain, it requires an external power source. For the ideal op-amp, the power supply has no effect on the amplifier's performance and is therefore not indicated in the circuit symbol.

Based on the above description, the op-amp's input can be stimulated with either a voltage or current. Also, the controlled output can be either a voltage or a current. Consequently, there are four possible implementations of the ideal op-amp: the voltage op-amp, the transimpedance op-amp, the current op-amp, and the transconductance op-amp, as shown in Table 16.1 and in Figure 16.2.

TABLE 16.1 Ideal Op Amp Types

Input	Output	Gain	Type
V	V	A_v	Voltage
I	V	R_m	Transimpedance
I	I	A_i	Current
V	I	G_m	Transconductance

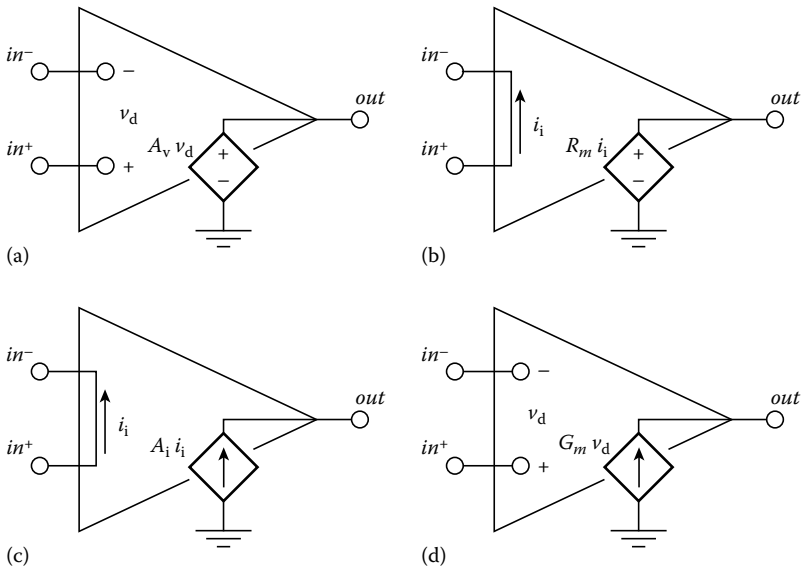

FIGURE 16.2 The four possible op-amp configurations: (a) the voltage op-amp, (b) the transimpedance op-amp, (c) the current op-amp, and (d) the transconductance op-amp.

For most applications, the op-amp is used in a closed-loop configuration with negative feedback. Due to the negative feedback, all four ideal op-amp types perform the same function. When the limitations of practical op-amps are considered, it will be found that different op-amps are preferred for different applications. Of the four types, the voltage op-amp is the most widely known. Therefore, the use of op-amps will be considered from the perspective of the voltage op-amp. Then, the other three types will be considered.

16.1.2 Voltage Op-Amps

The ideal voltage op-amp, illustrated in Figure 16.2a, is a voltage-controlled voltage source with infinite gain. If a potential difference v_d exists between the noninverting terminal in^+ and the inverting terminal in^- the op-amp's output voltage v_{out} will be

$$v_{out} = A_v v_d \tag{16.1}$$

where A_v is the differential gain and is both infinite and frequency independent. Note that only the differential voltage is amplified. As an ideal voltage-controlled voltage source, the op-amp has an infinite resistance and a zero output resistance. The properties of an ideal voltage op-amp may be summarized as follows:

- Infinite differential gain
- Zero common-mode gain
- Infinite bandwidth
- Infinite input resistance
- Zero output resistance

With these ideal properties, the op-amp is relatively easy to use in many circuit applications.

16.1.3 Op-Amp Circuit Applications

The op-amp can be used in both open-loop configurations and closed-loop configurations. If the op-amp is used open-loop, small voltages between the input terminals produced either a positive or negative infinite voltage due to the amplifier's infinite gain. Consequently, the op-amp can be used as a comparator. This application is discussed further in Section 16.1.4. In a closed-loop circuit, feedback allows the op-amp's output voltage to influence its input voltage (see Section 16.1.4). The op-amp can then be made to perform many complex operations.

16.1.3.1 Unity Gain Buffer

The simplest feedback that can be applied to the op-amp is depicted in Figure 16.3. The op-amp's output is connected to the inverting input and an input signal V_{in} is applied to the noninverting input. The feedback forces the voltage at in^- to equal V_{out}. By multiplying the differential voltage at the op-amp's input (i.e., $V_{in} - V_{out}$) by the op-amp's gain, V_{out} is found to be

$$V_{out} = A_v(V_{in} - V_{out}) \tag{16.2}$$

which can be rewritten as

$$\frac{V_{out}}{V_{in}} = \frac{1}{1 + 1/A_v} \tag{16.3}$$

because A_v is infinite, V_{out} equals V_{in}. Therefore, the circuit is a unity gain buffer. It is important to note that the op-amp's high gain and the use of negative feedback forces the voltage at the op-amp's two input

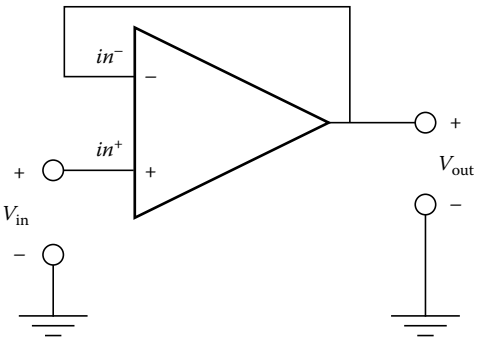

FIGURE 16.3 Unity gain buffer.

terminals to be equal. Hence if V_{in} is varied, V_{out} will follow or track it. The op-amp's two input terminals have the same potential, but no current flows between them. Therefore, a virtual short is said to exist between the inputs. The unity gain buffer draws no current from the signal source due to the op-amp's infinite input resistance and the op-amp's zero output resistance ensures that loading does not affect the voltage at V_{out}.

16.1.3.2 Simple Attenuator

If an output equal to a fraction of V_{in} is required, the circuit is illustrated in Figure 16.4a. The noninverting terminal is now a fraction of V_{in}. Because V_{out} tracks the voltage at the noninverting terminal, the circuit's output voltage will be

$$V_{out} = V_{in}\left[\frac{R_1}{R_1 + R_2}\right] \tag{16.4}$$

Due to the op-amp's infinite input resistance, the voltage divider formed by R_1 and R_2 is not loaded by the op-amp. Therefore, large values of R_1 and R_2 can be used to avoid loading the source voltage V_{in}.

16.1.3.3 The Noninverting Amplifier Configuration

Usually, it is more desirable to amplify a signal than to attenuate it. Therefore, instead of matching an attenuated V_{in} to V_{out}, at the op-amp's input, an attenuated V_{out} can be matched to V_{in}, as illustrated in Figure 16.4b. Due to the negative feedback and the op-amp's finite gain, the op-amp's two inputs have the same potential. Therefore,

$$V_{in} = V_{out}\left[\frac{R_1}{R_1 + R_2}\right] \tag{16.5}$$

which is more commonly written as

$$\frac{V_{out}}{V_{in}} = 1 + \frac{R_2}{R_1} \tag{16.6}$$

This circuit configuration is commonly referred to as the noninverting configuration [1]. Gains greater than or equal to unity can be achieved simply by changing the ratio of R_2 to R_1. The actual values of R_2

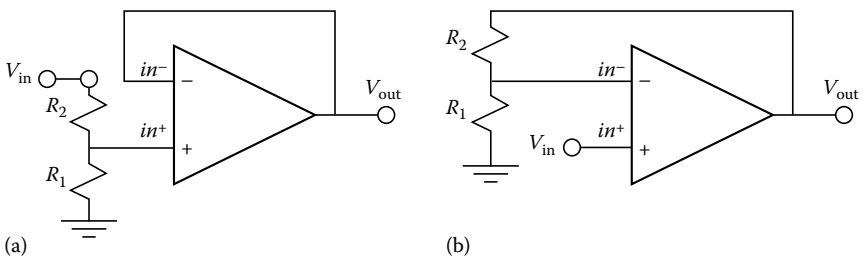

FIGURE 16.4 (a) A simple buffer attenuator and (b) the noninverting amplifier configuration.

and R_1 are unimportant. Only their ratio determines the gain. The op-amp's infinite input resistance ensures that no current is drawn from the source, therefore, V_{in} controls the voltage across R_1 but does not supply the current flowing through it.

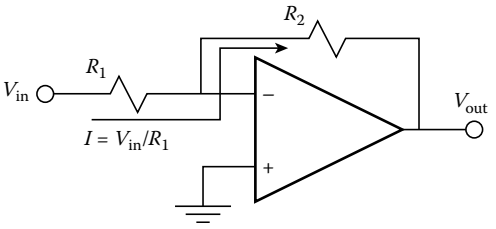

FIGURE 16.5 Inverting amplifier configuration.

16.1.3.4 The Inverting Configuration

If the source V_{in} can supply current, V_{in} can be connected directly to R_1, as illustrated in Figure 16.5. In this case the voltage across R_1 is still equal to V_{in} but of opposite polarity. The voltage at the op-amp's inverting input is now at ground potential, but no current flows to ground. Consequently, a virtual ground exists at the inverting input terminal. Because the current flowing through R_1 cannot flow to ground or into the op-amp, it flows through R_2, causing an output voltage of

$$V_{out} = 0 - R_2\left[\frac{V_{in}}{R_1}\right] \tag{16.7}$$

or

$$\frac{V_{out}}{V_{in}} = -\frac{R_2}{R_1} \tag{16.8}$$

This circuit configuration is commonly referred to as the inverting configuration [1]. Both amplification and attenuation can be achieved by changing the ratio of R_2 to R_1. A very important difference between the inverting and noninverting configurations is that the inverting configuration draws a current equal to V_{in}/R_1 from the source. Consequently, even though the op-amp itself has an infinite input resistance, the inverting configuration only has an input resistance equal to R_1. Fortunately, the gain only depends on the ratio of R_2 to R_1, thereby allowing both resistors to be increased, thus limiting the current drawn from V_{in}.

16.1.3.5 Frequency Dependent and Nonlinear Transfer Functions

Elements other than resistors can be used in both the inverting and noninverting configuration. By using the frequency-dependent elements Z_1 and Z_2 in place of R_1 and R_2, circuits with arbitrary frequency responses can be generated. Two examples of this are illustrated in Figure 16.6a through c. In Figure 16.6a, a capacitor has been added in series with R_1. The inverting amplifier now has the transfer function.

$$\frac{V_{out}}{V_{in}}(s) = \frac{-Z_2}{Z_1} \tag{16.9}$$

where Z_1 equals $(1 + R_1Cs)/(Cs)$ and Z_2 equals R_2. Therefore, the circuit's transfer function is

$$\frac{V_{out}}{V_{in}}(s) = \frac{-R_2Cs}{1 + R_1Cs} \tag{16.10}$$

which is a simple high-pass filter, as illustrated in Figure 16.6b. Alternatively, a capacitor can be added in parallel with R_2 as shown in Figure 16.6c. Now, Z_1 equals R_1 and Z_2 equals $R_2/(1 + R_2Cs)$, which results in the transfer function.

$$\frac{V_{out}}{V_{in}}(s) = \frac{-R_2}{R_1(1 + R_2Cs)} \tag{16.11}$$

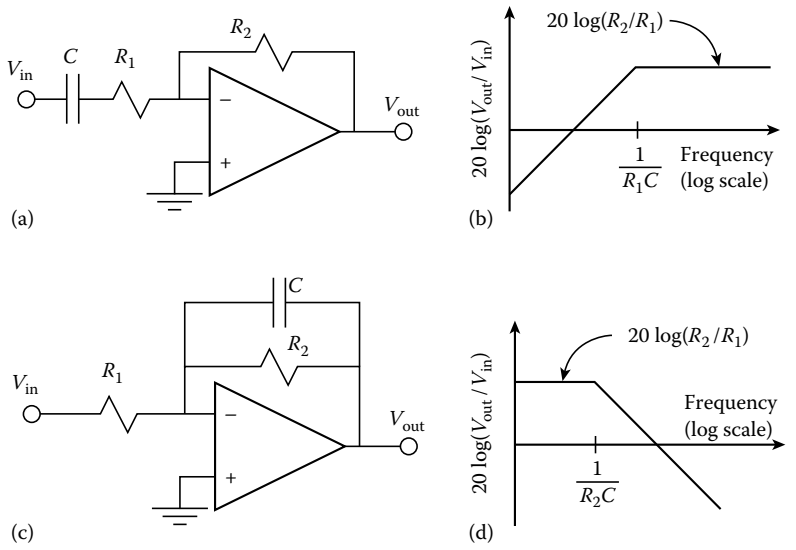

FIGURE 16.6 Frequency-dependent circuits using the inverting configuration and (a) a simple high-pass filter and (b) its frequency response; (c) simple low-pass filter and (d) its frequency response.

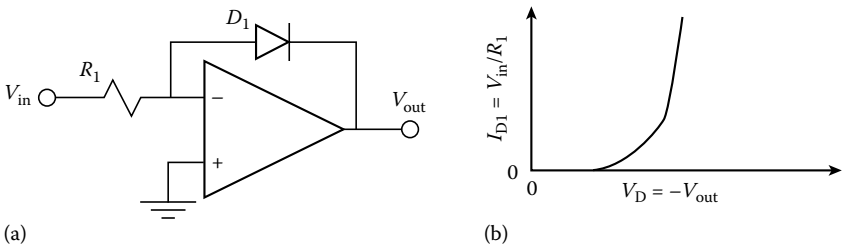

FIGURE 16.7 Obtaining the I–V characteristics of a diode: (a) circuit configuration and (b) oscilloscope display with V_{out} inverted.

This circuit performs as a low-pass filter, as illustrated in Figure 16.6d. By selecting Z_1 and Z_2, arbitrary transfer functions can be generated, thereby making op-amp circuits useful for implementing active filters (see Section II in *Passive, Active, and Digital Filters*). When designing arbitrary transfer functions, the resulting circuits must be stable if they are to perform correctly [2].

If nonlinear elements such as diodes are used in place of R_1 and R_2, nonlinear transfer functions can be obtained [2]. For example, the $I-V$ characteristics of a component can be obtained by replacing R_2 in the inverting configuration with the desired nonlinear element, as depicted in Figure 16.7a. Then, by applying V_{in} and V_{out} to an oscilloscope, the element's $I-V$ characteristic can be displayed directly as depicted in Figure 16.7b. Due to the diode's exponential characteristic, the circuit's output is the logarithm of its input

$$V_{out} = nV_T \ln\left(\frac{V_{in}}{R_1 I_S}\right) \tag{16.12}$$

The constants n and I_S are determined by the diode while V_T is the thermal voltage (see Section 11.5). Circuits of this type are made possible by the presence of the virtual ground at the op-amp's input.

16.1.3.6 Multiple Input Circuits

For the inverting configuration, the presence of the virtual ground at the op-amp's inverting input allow signals from many sources to be combined. As illustrated in Figure 16.8, the currents I_a and I_b are determined independently by V_a and V_b, respectively. These two currents are then summed at the virtual ground and forced through R_2. The resulting output is a weighted sum of V_a and V_b:

$$V_{out} = \frac{R_2}{R_{1a}} V_a - \frac{R_2}{R_{1b}} V_b \tag{16.13}$$

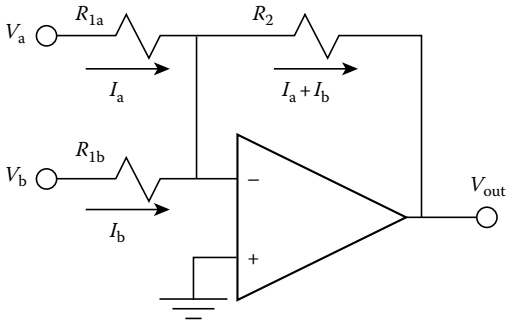

FIGURE 16.8 Weighted summer.

Any number of additional inputs can be added. The virtual ground prevents the different signals from interacting with each other.

The noninverting input can also be used in the multi-input circuit. In this case though, the op-amp's input is no longer at virtual ground and its output ceases to be a weighted sum of the inputs. For example, if V_1 and V_2 are applied to the circuit of Figure 16.9a, the output depends on both V_2 and the difference between V_2 and V_1:

$$V_{out} = V_2 + \frac{R_2}{R_1}(V_2 - V_1) \tag{16.14}$$

This output can also be written as a weighted difference between V_2 and V_1

$$V_{out} = \left(1 + \frac{R_2}{R_1}\right) V_2 - \frac{R_2}{R_1} V_1 \tag{16.15}$$

If, as in Figure 16.9b, V_2 is first attenuated by $R_2/(R_1 + R_2)$, a voltage only proportional to the difference between V_1 and V_2 can be obtained

$$V_{out} = \frac{R_2}{R_1}(V_2 - V_1) \tag{16.16}$$

where it is evident that the circuit amplifies the difference between its inputs and rejects the common-mode component. Consequently, the configuration is referred to as the differential configuration.

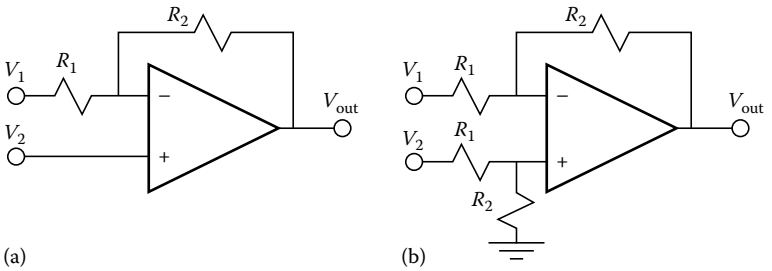

FIGURE 16.9 Circuits for finding weighted differences: (a) a circuit based in the inverting and noninverting configurations and (b) the differential configuration.

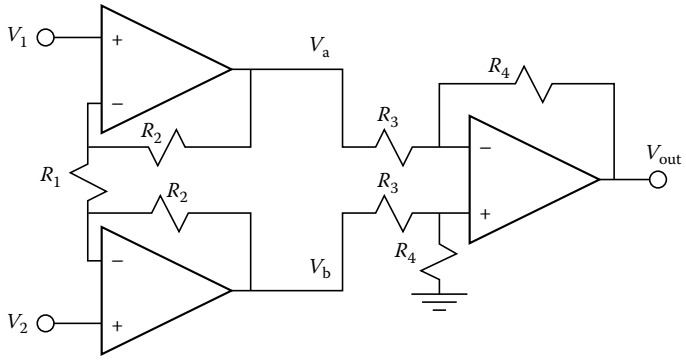

FIGURE 16.10 Instrumentation amplifier.

16.1.3.7 Instrumentation Amplifiers

The differential amplifier depicted in Figure 16.9b is useful for detecting weak signals in a noisy environment. Unfortunately, its input resistance is only $2R_1$. To circumvent this problem, V_1 and V_2 can be buffered using two unity gain buffers. A better solution is to use the instrumentation amplifier illustrated in Figure 16.10. This circuit combines two circuits of the type shown previously in Figure 16.9a and the differential amplifer in Figure 16.9b. Based on Equation 16.15, the voltage at V_a will be

$$V_a = \left(1 + \frac{R_2}{R_1}\right) V_1 - \frac{R_2}{R_1} V_2 \tag{16.17}$$

and the voltage at V_b will be

$$V_b = \left(1 + \frac{R_2}{R_1}\right) V_2 - \frac{R_2}{R_1} V_1 \tag{16.18}$$

With V_a and V_b applied to the differential amplifier, the instrumentation amplifier's output voltage will be

$$V_{out} = \frac{R_2}{R_1}(V_b - V_a) \tag{16.19}$$

Due to the op-amp's ideally zero output resistance, the differential amplifier's low input resistance does not load the other two circuits. Hence, by substituting Equations 16.17 and 16.18 for V_a and V_b, respectively, the output voltage can be expressed as

$$V_{out} = \left[1 + \frac{2R_2}{R_1}\right] \frac{R_4}{R_3}(V_2 - V_1) \tag{16.20}$$

which allows the difference between V_1 and V_2 to be either amplified or attenuated without loading the signal sources. Only one R_1 exists; therefore, it can be made variable to allow for an easily adjustable gain. Due to their usefulness, instrumentation amplifiers are available in a single package from many manufacturers.

This last circuit illustrates the two primary characteristics of op-amps when used in a closed-loop negative feedback configuration. First, a virtual short exists between the op-amp's input terminals

allowing a high impedance source to set the potential of a circuit node. Second, the op-amp's low output resistance allows op-amp circuits to be connected together without altering their individual transfer functions. These two characteristics greatly simplify the analysis and design of circuits containing many op-amps.

16.1.4 Comparators

If the op-amp is not used in a closed-loop, its output will be either high or low, depending on the polarity of the voltage between its inputs. This appears to make op-amps suitable for comparing two closely spaced signal levels. In practice, it is usually better to use a circuit called a comparator for this application. Comparators are similar to op-amps but have been specifically designed to operate in an open-loop circuit.

The basic comparator compares the voltage levels at its two inputs. If the voltage at the positive input, in^+, exceeds that at the negative input, in^-, the comparator will generate a logic high. If the voltage at in^- exceeds that at in^+, a logic low will be produced. Often, complementary outputs are also provided. The logic high and low levels are set either by the manufacturer or by the user. Typically, the logic levels are compatible with common logic families such as TTL, CMOS, or ECL.

The comparator's primary objective is to provide the correct output level as fast as possible while op-amps are usually used in a closed-loop configuration. To ensure closed-loop stability, most op-amps require some form of compensation (see Section 16.2 and [3]), which reduces their speed and bandwidth. On the other hand, comparators are specifically designed for open-loop operation thereby, making them better suited for high-speed comparisons.

The comparator is usually used as a threshold comparator and often has added hysteresis. When used as a threshold detector, a reference level is applied to one input and the signal is applied to the other input. The choice of inputs determines the output's polarity. Circuits of this type are commonly employed as level detectors and in analog-to-digital converters (see Chapter 20).

In many cases, the input signal contains noise that causes the comparator's output to oscillate as the signal passes the threshold level. To avoid this problem, the use of positive feedback, as depicted in Figure 16.11a, is used to generate hysteresis, as depicted in Figure 16.11b. The resistor R_3 is included to reduce the effects of the comparator's bias currents (see Section 16.2.5). For this circuit, the level that causes the output to go low, V_{INL}, is

$$V_{INL} = V_{REF} + (V_{REF} - V_{OH})/K \tag{16.21}$$

where

V_{OH} is the output-high level

K is the ratio of the resistors depicted in Figure 16.11b

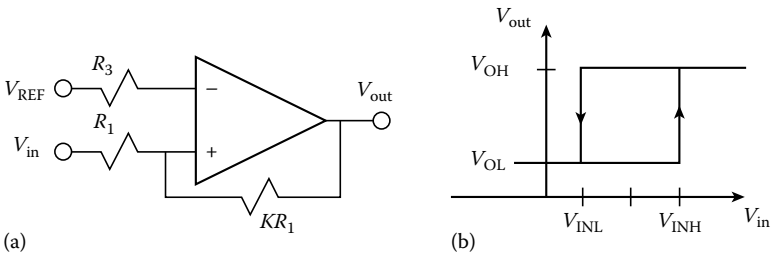

FIGURE 16.11 (a) A comparator with hysteresis and (b) its input–output relationship.

The level that causes the output to go high, V_{INH}, is

$$V_{INH} = V_{REF} + (V_{REF} - V_{OL})/K \tag{16.22}$$

where V_{OL} is the output-low level. By adjusting the ratio K, the amount of noise immunity can be adjusted.

16.1.5 Other Op-Amp Configurations

As mentioned in Section 16.1, the ideal op-amp can be implemented in any of four possible configurations: a voltage amplifier, a current amplifier, a transimpedance amplifier, and a transconductance amplifier. When used in a closed-loop configuration with negative feedback, all four of the ideal op-amps behave the same. In particular, the virtual short circuit between the two inputs remains and the output is unaffected by loading. Consequently, op-amps of all four types exist. Due to practical limitations, some configurations are better suited than others for particular applications.

To illustrate that the ideal op-amp's configuration does not affect the performance of an op-amp circuit, the inverting op-amp circuit in Figure 16.12 has been implemented with a current op-amp. The ideal current op-amp displays zero resistance between its input terminals. The output, which is a current source, has an infinite output resistance. Hence, the current op-amp is the dual of the voltage op-amp. The circuit's output voltage can be found by summing the currents at the op-amp's input. Since there is a physical short between the two input terminals, the current through R_1 will be

$$I_1 = \frac{V_{in}}{R_1} \tag{16.23}$$

while the current through R_2 will be

$$I_2 = \frac{V_{out}}{R_2} \tag{16.24}$$

and due to the op-amp's current gain, A_i, the op-amp's input current will be

$$i_i = \frac{V_{out}}{A_i R_2} \tag{16.25}$$

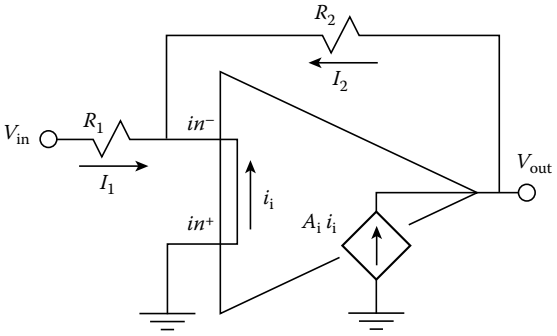

FIGURE 16.12 Inverting amplifier configuration implemented with a current op-amp.

The sum of Equations 16.23 through 16.25 must equal zero. Therefore,

$$\frac{V_{out}}{V_{in}} = -\frac{R_2}{R_1}\left[\frac{1}{1 + 1/A_i}\right] \tag{16.26}$$

which for $A_i = \infty$ results in the same gain as that produced by the inverting configuration implemented with an ideal voltage op-amp. More important, the current through R_1 equals the current through R_2 and the op-amp's input current goes to zero. Hence, even with the physical short between the op-amp's inputs, only a virtual short exists in the closed-loop circuit because no current flows between the

two terminals. At the output, the infinite gain of the ideal current op-amp ensures that the output stays at the value indicated by Equation 16.26 even if a load is added to the output. Consequently, the ideal op-amp's closed-loop behavior is preserved independent of the op amp's configuration.

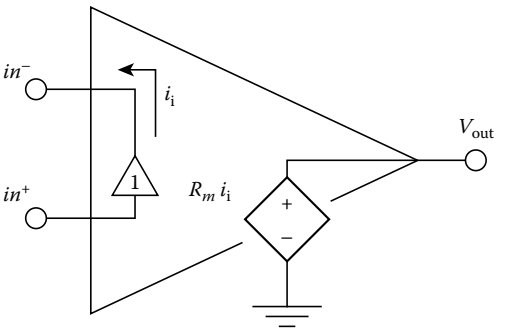

FIGURE 16.13 Practical transimpedance op-amp.

16.1.5.1 Current Op-Amps

Ideally, the current op-amp acts as a current- controlled current source with an infinite current gain. In practical current op-amps, the gain is relatively low. Therefore, the assumption of an infinite gain is unrealistic for most applications. The primary purpose of current op-amps is to boost the output current of a voltage op-amp (see Section 16.2).

16.1.5.2 Transimpedance Op-Amps

The ideal transimpedance op-amp is a current-controlled voltage source with an infinite transimpedance gain. Op amps of this type are commonly referred to as current feedback op-amps. Practical implementations of transimpedance op-amps typically display a much higher speed than most voltage op-amps (see Section 16.3 and [4]). Due to practical considerations, transimpedance op-amps typically have a unity gain buffer between the noninverting and inverting input terminals as illustrated in Figure 16.13.

The added buffer has no effect on the ideal closed-loop performance, but it does increase the input resistance of the noninverting input for practical circuits.

16.1.5.3 Transconductance Op-Amps

The ideal transconductance op-amp is a voltage-controlled current source with an infinite transconductance gain. Practical transconductance op-amps are usually implemented in MOS technologies [5]. MOSFET's themselves are voltage-controlled current sources. Because a practical transimpedance op-amp has a less that infinite output resistance, it is not suited for driving resistive loads. This does not pose a problem because most transimpedance op-amps are used in switched-capacitor circuits, where they are used to drive capacitive loads.

16.1.6 Summary

The ideal op-amp is a high gain circuit element. When used in an open-loop configuration, the op-amp can be used to compare closely spaced signal levels. It is generally much more useful when negative feedback is applied to control its output. With negative feedback, the differential voltage at its input approaches zero and the current between its input approaches zero. This makes it particularly useful for controlling the voltage or current in a circuit without drawing power from the controlling source. The ideal op-amp model, although only approximated in practical op-amps, is very useful for quickly analyzing and understanding the operation of larger circuits. Once the circuit's behavior is understood, the effects of the op-amp's nonidealities can be considered.

16.2 Nonideal Operational Amplifier

Practical op-amps differ significantly from the ideal op-amp. These differences limit the signal levels and range of impedances that can be used in op-amp circuits. Fortunately, the nonidealities are only significant in certain applications. For these applications, circuit design precautions often reduce the effects of the nonidealities to acceptable levels. Alternatively, higher performance op-amps can be used. The op-amp's dominant nonidealities, how they affect various applications, and techniques to compensate for their detrimental effects are discussed in the following sections.

16.2.1 Finite Differential Gain

The op-amp's most critical nonideality is its finite gain. Unlike the infinite gain of the ideal op-amp, the gain of a practical op-amp is typically large at dc and decreases at high frequencies. Most op-amps are internally compensated for a frequency dependent gain of the form

$$\frac{v_o}{v_i} = \frac{A_O}{1 + j\omega(A_O/\omega_t)} \tag{16.27}$$

where
A_O is the dc differential open-loop gain
ω is the frequency
ω_t is the op-amp's unity gain frequency

Unity gain frequencies are typically in the MHz range. At low frequencies, the op-amp's gain simply becomes A_O. At high frequencies, the op-amp's gain can be approximated as

$$\frac{v_o}{v_i} = \frac{\omega_t}{j\omega} \tag{16.28}$$

Further details on the amp's high-frequency behavior will be discussed in Section 16.3. The dc gain, A_O, is typically quite large, hence it is usually expressed in decibels (dB). A_O ranges from 40 dB for high-speed op-amps to 120 dB for high-precision op-amps. General-purpose op-amps usually have differential gains in the 100 dB region. Because A_O is subject to wide variations, manufacturers usually specify a minimum and typical value.

The op-amp's finite A_O reduces the closed-loop gain of most op-amp circuits. To illustrate the problem, the noninverting and inverting amplifiers shown in Figure 16.14 can be analyzed assuming a finite op-amp gain. The finite gain results in a nonzero differential voltage at the op-amp's input:

$$v_d = \frac{v_o}{A_O} \tag{16.29}$$

Consequently, the voltage at the inverting input is not equal to that at the noninverting input. Hence, the voltage across R_1 and the current through it is changed. By equating the current in R_1 and R_2, it is seen that the noninverting amplifier's gain is reduced to

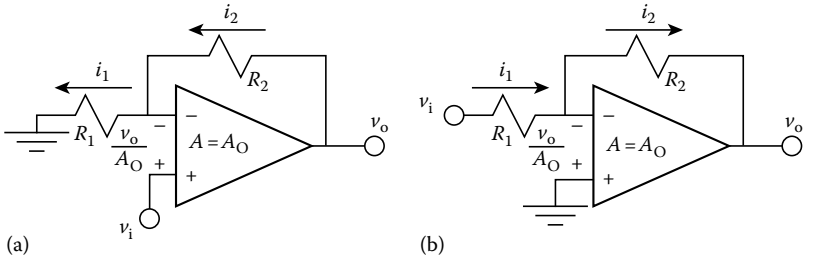

FIGURE 16.14 Analysis of the noninverting (a) and inverting (b) configurations for an op-amp with finite gain A_O.

$$\frac{v_o}{v_i} = \frac{1 + R_2/R_1}{1 + (1 + R_2/R_1)/A_O} \tag{16.30}$$

while the inverting amplifier's gain is reduced to

$$\frac{v_o}{v_i} = \frac{-R_2/R_1}{1 + (1 + R_2/R_1)/A_O} \tag{16.31}$$

For large values of A_O, Equations 16.30 and 16.31 reduce to the gains that would be obtained with an ideal op-amp (i.e., $v_o/v_i = 1 + R_2/R_1$ and $v_o/v_i = -R_2/R_1$, respectively).

It is only when A_O and the desired closed-loop gain become comparable that the op-amp's finite gain leads to a significant reduction in the closed-loop gain. To illustrate this problem, the gain deviation for the noninverting amplifier versus $(1 + R_2/R_1)/A_O$ is plotted in Figure 16.15. Because A_O is subject to wide variations, only gains that are at least 100× lower than A_O should be used to ensure a well-controlled gain. Consequently, the op-amp's finite open-loop differential gain places an upper limit on the closed-loop gain that can be provided accurately.

16.2.2 Output Saturation

Although op-amps can provide high gains, the op-amp's maximum output voltage and current are limited. The maximum output voltage is limited by the op-amp's supply voltages, while the maximum output current is usually limited by the op-amp's allowable power dissipation.

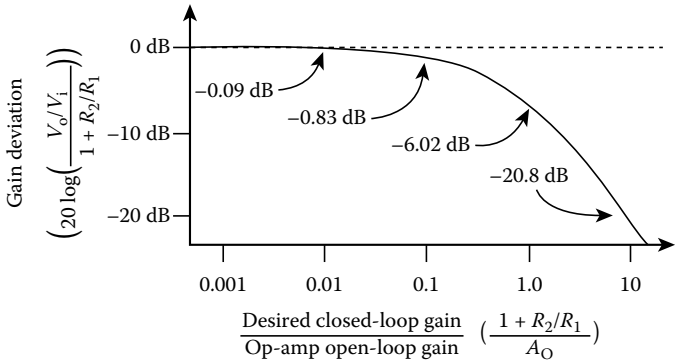

FIGURE 16.15 Gain deviation for the noninverting configuration caused by a finite A_O.

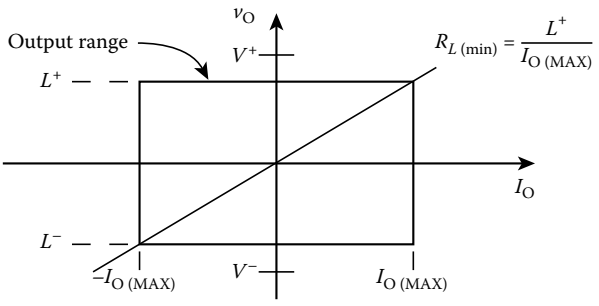

FIGURE 16.16 Voltage and current limitations on the op-amp's output signal swing.

The op-amp, similar to any electronic amplifier, requires a dc power supply. Most op-amps require a positive, V^+, and a negative, V^-, power supply. Because V^+ and V^- are typically the same size and of opposite polarity, they are referred to as dual or split supplies. Usually, the op-amp has no connection to ground. The supply voltage typically ranges from ±5 to ±18 V, with ±15 V being the most common. Special-purpose op-amps include low-voltage/low-power op-amps for use with lower supply voltages, high-voltage op-amps for use with supply voltages beyond ±18 V and single supply op-amps for use with a single supply.

Regardless of the op-amp type, the maximum L^+ and minimum L^- output voltages cannot exceed the supply voltages. Typically, the output saturates within 1–3 V of the supplies as shown in Figure 16.16. Low-voltage op-amps often feature a ''rail-to-rail'' output swing that allows the output signal to extend to both V^+ and V^-. Due to the op-amp's limited output swing, the input signal must be kept small enough to avoid distortion caused by clipping the output signal.

The second limitation on the op-amp's output signal is the op-amp's maximum output current specification. This limitation is determined by the maximum allowed power dissipation of the op-amp. If the power dissipation limit is exceeded, the resulting temperature rise can damage the device. The worst-case power dissipation usually occurs when the op-amp has a load resistance of zero (i.e., the output is shorted to ground). In this situation, the full supply voltage appears across the op-amp's output stage and the power dissipation is

$$P_{\text{Disp}} = V^+ I_O + P_Q \tag{16.32}$$

P_Q is the op-amp's quiescent power dissipation and usually much smaller than $V^+ I_O$. Hence, to avoid an excessive temperature rise, I_O must be limited to a safe value, $I_{O(MAX)}$. Many op-amps are designed with short-circuit protection that limits $I_{O(MAX)}$ to a safe level. For general-purpose op-amps, $I_{O(MAX)}$ is in the 20 mA range.

The limitations imposed by the combination of L^+, L^-, and $I_{O(MAX)}$ are illustrated in Figure 16.16. For loads below $R_{L(min)}$:

$$R_{L(\text{min})} = \frac{L^+}{I_{O(MAX)}} \tag{16.33}$$

the op-amp's output swing will be limited by the op-amp's current-limiting circuitry. For large values of R_L, the signal swing will be limited by the op-amp's maximum and minimum output voltages. Therefore, to ensure that the signal peaks are not clipped, the equivalent load resistance seen by the op-amp must be greater than $R_{L(min)}$ and the amplifier's input signal must be small enough to ensure the output voltage will not exceed either L^+ or L^-.

16.2.3 Offset Voltage

For an ideal op-amp, a zero differential input voltage produces a zero output voltage. For a practical op-amp, as illustrated in Figure 16.17, a zero differential input voltage will, in general, produce a nonzero

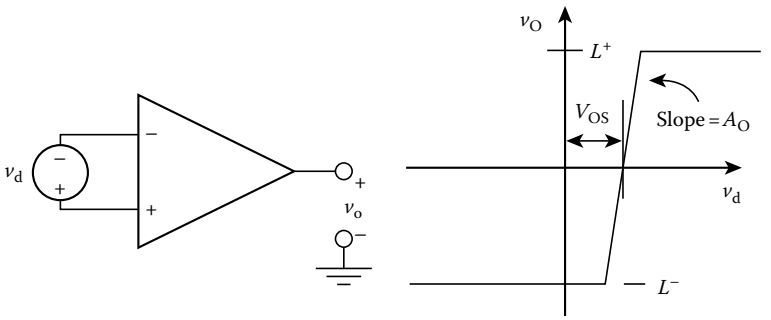

FIGURE 16.17 Transfer function of a practical op-amp illustrating A_O, L^+, L^-, and V_{OS}.

output. Due to the op-amp's high gain, the output will usually saturate at either L^+ or L^- if no feedback is applied. To obtain a zero output voltage, a nonzero input voltage, defined as the input offset voltage, V_{OS}, must be applied between the input terminals.

V_{OS} is generally quite small. It arises from small mismatches in the devices used in the op-amp's input stage and circuit asymmetries. General-purpose op-amps have offset voltages in the 0.1–10 mV range. Typically, op-amps with FET input devices will have higher offset voltages than op-amps with bipolar input devices. If a very low V_{OS} is required, precision and low offset voltage op-amps are available with offset voltages in the μV range. The offset voltage is not constant, it is subject to drift with time and changes in temperature. Consequently, its effects will be evident in most circuits.

To analyze the effect of V_{OS}, a voltage source of unknown polarity, equal to V_{OS}, is connected to one of the inputs of an ideal op-amp. Then, using superposition, the circuit's output voltage due to V_{OS} and the input voltage can be determined. Because superposition applies, the effect of V_{OS} on both the inverting and noninverting configurations is identical. As illustrated in Figure 16.18a, in which a practical op-amp has been replaced with an ideal op-amp in series with V_{OS}, and v_i set to zero, the output v_o, due to V_{OS} alone (i.e., the output offset voltage) is

$$v_o = V_{OS}\left(\frac{1 + R_2}{R_1}\right) \tag{16.34}$$

where it is evident that large dc gains result in a large output offset voltage. If dc gain is not required, a capacitor can be placed in series with R_1 to reduce the dc gain to unity. The resulting output offset voltage then becomes V_{OS}. Another group of circuits affected by V_{OS} are integrating circuits such as the one in Figure 16.18b. If R_f is not included, V_{OS} causes a dc current V_{OS}/R_1 to flow through R_1 and be integrated

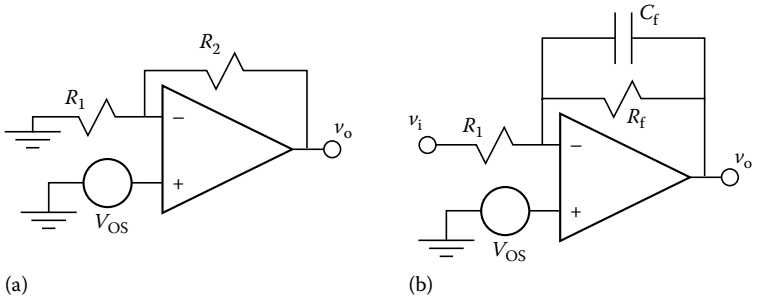

FIGURE 16.18 Some circuits affected by the op-amps offset voltage. (a) The inverting and noninverting configurations. (b) Integrator circuits.

on C_f, thereby causing the output voltage to saturate. Adding R_f limits the dc gain and hence, limits the output offset voltage.

In situations where the smallest possible V_{OS} is required, low V_{OS} op-amps can be used. Alternatively, many op-amps are provided with one or two terminals to which an offset nulling circuit can be attached. The op-amp's V_{OS} can then be trimmed to zero. Because the trimming can only be done for one temperature, V_{OS} will still drift due to temperature and time and hence will limit the circuit's dc accuracy.

16.2.4 Finite Common-Mode Rejection Ratio and Power-Supply Rejection Ratio

If an op-amp's inputs are shorted together, as depicted in Figure 16.19, variations in any one of the three voltages; v_{cm}, the common-mode input voltage, V^+, the positive supply voltage, or V^-, the negative supply voltage, should not affect the output voltage. Nevertheless, if all three voltages are changed by the same amount, it is evident that the output voltage must also change by the same amount [3]. Hence, the op-amp's output voltage will be affected by changes in v_{cm}, V^+ and V^-. The relationship between changes in v_{cm} and v_o is usually characterized by the common-mode rejection ratio (CMRR). The effects of changes in the positive and negative supplies on v_o are usually referred to as the power-supply rejection ratios, $PSRR^+$ and $PSRR^-$, respectively.

16.2.4.1 Common-Mode Rejection Ratio

The op-amp has two input terminals, therefore, two signal types exist: differential signals and common-mode signals. Referring to Figure 16.19, the differential signal v_d is the difference between the two input voltages, v_{in}^+ and v_{in}^-:

$$v_d = v_{in}^+ - v_{in}^- \tag{16.35}$$

while the common-mode signal v_{cm} is their average:

$$v_{cm} = \frac{(v_{in}^+ + v_{in}^-)}{2} \tag{16.36}$$

Ideally, the op-amp rejects (i.e., does not respond to) common-mode signals. For practical op-amps, changes in v_{cm} lead to changes in v_o, resulting in a common-mode gain A_{cm}:

$$A_{cm} = \frac{v_o}{v_{cm}} \tag{16.37}$$

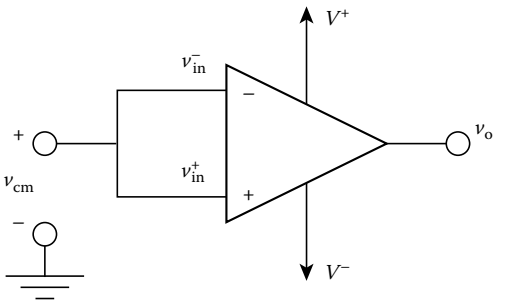

FIGURE 16.19 Op amp with its various input voltages.

Over a specified range, known as the common-mode range, A_{cm} is relatively small. Beyond the common-mode range, A_{cm} rises rapidly and the op-amp ceases to function properly. Typically, the common-mode range does not extend to either the positive or negative supply. Single-supply op-amps, however, are usually designed to have a common-mode range that extends down to and often slightly below the lower supply. Within the common-mode range, A_{cm} is usually specified by the CMRR

$$\text{CMRR} = \frac{A_o}{A_{cm}} \tag{16.38}$$

The CMRR is usually expressed in dB

$$\text{CMRR} = 20\log\left|\frac{A_o}{A_{cm}}\right| \tag{16.39}$$

and ranges from 60 to over 120 dB. An alternate interpretation of the CMRR is the ratio of a change in v_{cm} to the resulting change in the op-amp's V_{OS}.

$$\text{CMRR} = \frac{V_{cm}}{V_{OS}} \tag{16.40}$$

The two interpretations of CMRR are equivalent.

A finite CMRR affects those circuits for which a sizable v_{cm} is applied to the op-amp. Hence, the inverting configuration, with a virtual ground at its input, is unaffected by the common-mode gain. On the other hand, circuits such as the noninverting configuration and the differential configuration in Figure 16.20, have a nonzero v_{cm} and hence display common-mode problems.

The effects of a common-mode signal can be determined as follows. Because a finite CMRR can be interpreted as a change in the op-amp's V_{OS}, due to the presence of a v_{cm}, the V_{OS} due to the nonzero v_{cm} and the finite CMRR can be found as

$$V_{OS} = \frac{v_{cm}}{\text{CMRR}} \tag{16.41}$$

Then, the effect of the resulting V_{OS} can be found by analyzing the op-amp assuming the common-mode gain is zero. For example, the noninverting circuit in Figure 16.20a, has a v_{cm} approximately equal to v_i, which leads to an equivalent V_{OS} of

$$V_{OS} = \frac{v_i}{\text{CMRR}} \tag{16.42}$$

and a total output voltage of

$$v_o = v_i\left(\frac{1+1}{\text{CMRR}}\right)\left(\frac{1+R_2}{R_1}\right) \tag{16.43}$$

Consequently, the CMRR leads to a gain error. For the differential configuration in Figure 16.20b, a finite CMRR leads to an output voltage of the form

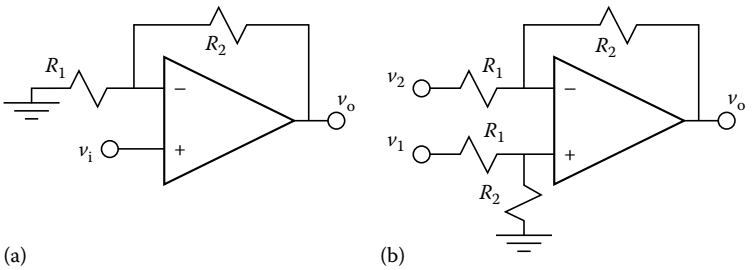

FIGURE 16.20 Some op-amp circuits affected by a finite CMRR. (a) The noninverting configuration. (b) The differential configuration.

$$v_o = \frac{R_2}{R_1}(v_1 - v_2) + \frac{R_2}{R_1}\frac{v_1}{\text{CMRR}} \tag{16.44}$$

where if $(v_1 + v_2)/2 \gg v_1 - v_2$, v_i will be approximately equal to the signal's common-mode voltage and it can be seen that the differential amplifier responds to both the differential and common-mode components of the signal. Consequently, the op-amp's CMRR can lead to problems if both of the op-amp's terminal potentials vary with the input signal.

16.2.4.2 Power-Supply Rejection Ratio

Ideally, changing either or both of an op-amp's power supplies should not affect the op-amp's performance. Practical op-amps though display a power-supply dependent gain and at higher frequencies, power-supply fluctuations are coupled into the op-amp's signal path, leading to variations in the output voltage. These problems can be characterized as an equivalent gain, A_{V+} and A_{V-} from V^+ and V^- terminals, respectively, to the output. Alternatively, the variation can be characterized as a power-supply dependent variation in the op-amp's equivalent input offset voltage. Because the op-amp is only supposed to amplify differential signals applied to its input, and reject signals applied to the power supplies, it is desirable to have $A_O \gg A_{V+}$ and $A_O \gg A_{V-}$. To measure this performance, the PSRRs are used

$$\text{PSRR}^+ = \frac{A_O}{A_{V+}} \tag{16.45}$$

$$\text{PSRR}^- = \frac{A_O}{A_{V-}} \tag{16.46}$$

Usually, the PSRRs are expressed in dB

$$\text{PSRR}^+ = 20\log\left|\frac{A_O}{A_{V+}}\right| \tag{16.47}$$

$$\text{PSRR}^- = 20\log\left|\frac{A_O}{A_{V-}}\right| \tag{16.48}$$

PSRRs of 60–100 dB are common at dc. At higher frequencies, the PSRR decreases.

A noninfinite PSRR may pose a problem if there are variations in the power-supply voltages. Such variations can arise from either the ripple voltage of the supply itself or from large variations in the current being drawn from the supply. To reduce unwanted variations in the op-amp's output voltage, either an op-amp with a better PSRR can be selected or power-supply decoupling capacitors can be used. If decoupling capacitors are used, they should be placed as close as possible to the op-amp's power-supply terminals.

16.2.4.3 Finite Input Impedance and Nonzero Output Impedance

Unlike the ideal op-amp, practical op-amps exhibit a finite input impedance and a nonzero output impedance. The input impedance is composed of a differential and a common-mode component as illustrated in Figure 16.21. R_{id} and C_{id} represent the equivalent resistance and capacitance seen between the op-amp's two input terminals. R_{icm} and C_{icm} represent the total resistance and capacitance to ground that would be seen by a common-mode signal applied to both input terminals. R_{id} ranges from 100 kΩ to over 100 MΩ. The higher differential input resistances are found in op-amps employing FET input stages. R_{icm} is typically two orders of magnitude higher than R_{id}. The input capacitances are generally in the picofarad range. The output resistance R_o is usually in the 50–100 Ω range. Generally, the use of

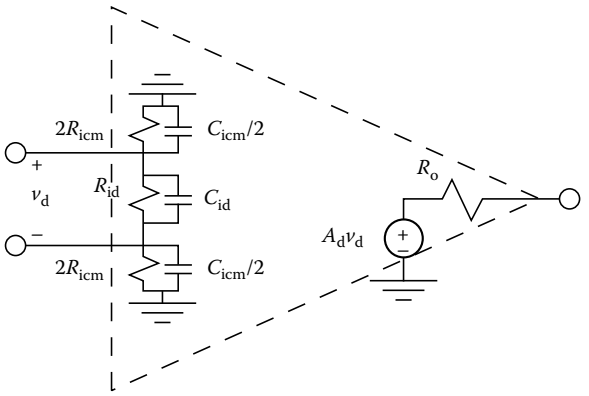

FIGURE 16.21 Input and output impedance of practical op-amp.

negative feedback reduces the effects of these impedances to levels where they can be neglected. Nevertheless, problems can arise in some applications.

The noninverting configuration is often used as a buffering amplifier due to its high input resistance. At low frequencies, the op-amp's input capacitances can be neglected and the negative feedback provided by the op-amp's high gain keeps the voltage across and the current through R_{id} negligible. Hence, the effective input resistance is approximately $2R_{icm}$. At high frequencies, C_{id} shorts the input and the op-amp's decreasing gain causes the voltage across and hence, the current through R_{id} to increase resulting in a significantly decreased input impedance.

Most op-amps employ shunt sampling negative feedback, so the op-amp's effective output resistance is reduced. Hence, even relatively high values of R_o can be tolerated in most circuits. Nevertheless if the circuit is used to drive a capacitive load, problems can arise. Because the op-amp's gain decreases at higher frequencies (see Section 16.2.1), the amount of negative feedback also decreases leading to an output impedance that appears inductive (i.e., increases with frequency). This can be found by analyzing the output impedance of the circuit in Figure 16.22a. Approximating the op-amp's gain as (see Section 16.2.1)

$$A = \frac{w_t}{jw} \tag{16.49}$$

and assuming that $R_o \ll R_1 + R_2$, the output impedance becomes

$$Z_{out} \approx R_o \parallel jwL_{eff} \tag{16.50}$$

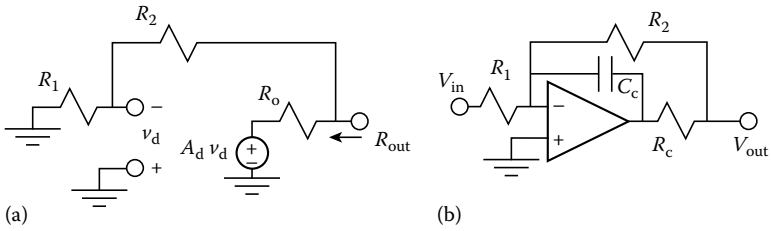

FIGURE 16.22 (a) Determining R_{out} for the inverting and noninverting configurations and (b) compensating for large capacitive loads.

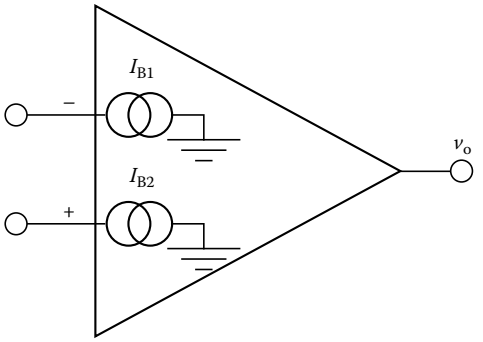

FIGURE 16.23 Op-amp showing its input bias currents.

where

$$L_{\text{eff}} = \frac{R_o}{w_t}\left(\frac{R_1 + R_2}{R_1}\right) \tag{16.51}$$

Consequently, if the circuit drives a large capacitor, it may become unstable due to the presence of L_{eff}. To reduce this problem, a compensation network as illustrated in Figure 16.22b is commonly used.

16.2.5 Input Bias Currents

When operating, current flows in each of the op-amp's input leads as depicted in Figure 16.23. These input currrents, which are due to the internal structure of the op-amp, give rise to errors in many circuits and prevent the practical realization of some circuit configurations. Because these currents cannot be avoided, they should be considered when designing op-amp circuits.

The input currents are determined by the devices used to implement the amplifier's input stage. If BJTs are used, their base currents determine the input currents. If FETs are used, the input currents are due to the gate leakage current. In either case, the average of the two input currents, I_{B1} and I_{B2}, is referred to as the input bias current, I_B:

$$I_B = \frac{(I_{B1} + I_{B2})}{2} \tag{16.52}$$

where I_{B1} and I_{B2} are the input currents that cause the op-amp's output to go to zero with a zero common-mode input voltage. I_B can range from 0.1 pA to 1 μA, which is much higher than would be expected based on the amplifier's finite input resistance alone. Typically, op-amps with FET inputs display a much lower I_B than their bipolar counterparts. Due to mismatches, I_{B1} and I_{B2} are rarely equal. Their difference, referred to as the input offset current, I_{OS}, is defined as

$$I_{OS} = |I_{B1} - I_{B2}| \tag{16.53}$$

I_{OS} is typically an order of magnitude lower than I_B. Therefore, in all but the most critical applications, I_{OS} can be neglected.

The effects of nonzero bias currents on both the inverting and noninverting configurations are illustrated in Figure 16.24a. If I_B is not compensated for, both op-amp configurations will display an output voltage of

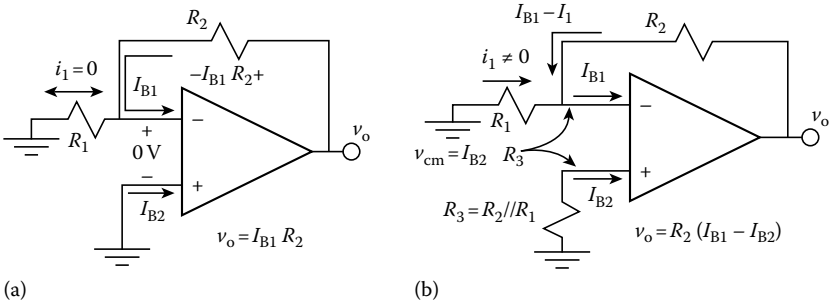

FIGURE 16.24 Analysis of the inverting and noninverting configurations with nonzero I_B. (a) Without bias current compensation and (b) with bias current compensation.

$$v_o = I_{B1}R_2 \tag{16.54}$$

This voltage can be reduced either by reducing R_2 or by selecting an op-amp with lower bias currents. Alternatively, a resistor R_3 equal to the parallel equivalent of R_2 and R_1 can be included in the positive terminal's lead, as illustrated in Figure 16.24b. This added resistor causes the voltage at the op-amp's input to be equal to

$$v_{cm} = -I_{B2}R_1 \parallel R_2 \tag{16.55}$$

which, if two bias currents are equal ($I_{OS} = 0$), causes v_o to be zero. For the practical case of a nonzero offset current, v_o becomes

$$v_o = I_{OS}R_2 \tag{16.56}$$

Because I_{OS} is usually much lower than I_B, the error is greatly reduced. It is important to note that I_B is a dc current. Hence, R_3 should be equal to the equivalent dc resistance seen by the op-amp's negative terminal.

All op-amps require an I_B for proper operation, therefore, a dc path between each input terminal and ground must be provided. For example, the ac coupled buffer of Figure 16.25a requires the addition of R_i to provide a path for I_{B2}. Unfortunately, R_i decreases the buffer's input resistance. In Figure 16.25b, the difference between I_{B1} and $I_{B2}R_3/R_1$ will flow to C_f, quickly leading to saturation of op-amp's output at either L^+ or L^-. By adding R_f, a dc path for the difference current is provided. Unfortunately, R_f makes the integrator nonideal at low frequencies. Consequently, the op-amp's bias currents restrict the dc accuracy and the frequency range of applications for op-amp circuits.

16.2.6 Electrical Noise

Similar to any electronic component, op-amps generate noise that can degrade the system's signal-to-noise ratio (SNR). The amplifier's noise is characterized by the equivalent noise sources in Figure 16.26a. $\overline{e_n}$ is the equivalent input noise voltage density and is expressed in $nV/\sqrt{Hz}$. $\overline{i_{n1}}$ and $\overline{i_{n2}}$ are the equivalent input noise current density and are expressed in $pA/\sqrt{Hz}$. Usually, $\overline{i_{n1}}$ and $\overline{i_{n2}}$ have the same magnitude and are both referred to as $\overline{i_n}$. The typical behavior of $\overline{e_n}$ and $\overline{i_n}$ are illustrated in Figure 16.26b. At higher frequencies, e_n and i_n are independent of frequency (i.e., white noise). In this range, values of $\overline{e_n}$ and $\overline{i_n}$ range from 50 $nV/\sqrt{Hz}$ and $0.6pA/\sqrt{Hz}$, respectively, for general-purpose op-amps to $2nV/\sqrt{Hz}$ and $10fA/\sqrt{Hz}$ for ultra-low-noise op-amps. At low frequencies, op-amps display noise that increases

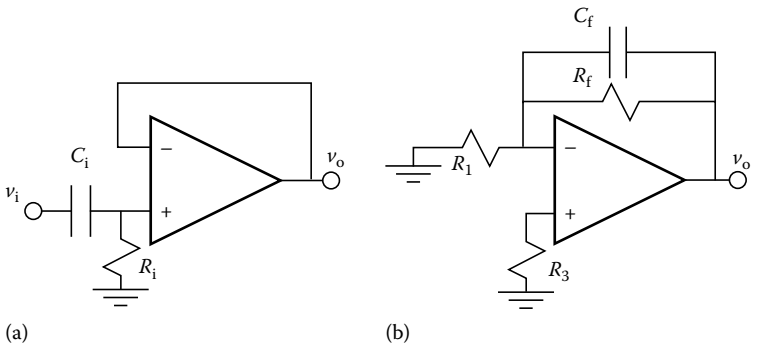

FIGURE 16.25 Some op-amp circuits affected by the op-amp's bias current. (a) The ac coupled buffer. (b) The inverting integrator.

$\overline{i_{n2}}$	$\overline{i_{n2}}\,R_S\,(1+R_2/R_1)$
$\overline{e_n}$	$\overline{e_n}\,(1+R_2/R_1)$
$\overline{e_{rs}}$	$\overline{e_{rs}}\,(1+R_2/R_1)$

FIGURE 16.27 Op-amp circuit showing its noise sources.

with decreasing frequency (i.e., $1/f$ noise). To specify the low frequency noise, a plot such as the one in Figure 16.26b may be provided. In some cases, only the noise corner frequency f_c (see Figure 16.26b) may be specified.

To determine the effects of the op-amp's noise, the circuit in Figure 16.26 can be used. The noise sources are generally uncorrelated, so the total noise is the square root of the sum of the square of each noise source acting independently. Therefore, the first step is to identify all the noise sources, as illustrated in Figure 16.27. Each resistor may be modeled as a noiseless resistor in series with a noise voltage density of

$$\overline{e_r} = \sqrt{4kTR}\Big/\sqrt{\text{Hz}} \tag{16.57}$$

where

k is the Boltzmann constant
T is the absolute temperature

Each noise source then gives rise to the output values shown in the table (see Figure 16.27). The designer is free to choose R_1 and R_2, so the noise sources $\overline{e_n}$, $\overline{e_{rs}}$, and $\overline{i_{n2}}$ typically determine the circuit's total output noise voltage. The total rms white-noise voltage at the output is

$$\overline{v_{\text{output}}} = \sqrt{\frac{\pi}{2}\text{BW}}\sqrt{\overline{e_n^2}\left(1+\frac{R_2}{R_1}\right)^2+\overline{e_{rs}^2}\left(1+\frac{R_2}{R_1}\right)^2+\overline{i_{n2}^2}R_S\left(1+\frac{R_2}{R_1}\right)^2} \tag{16.58}$$

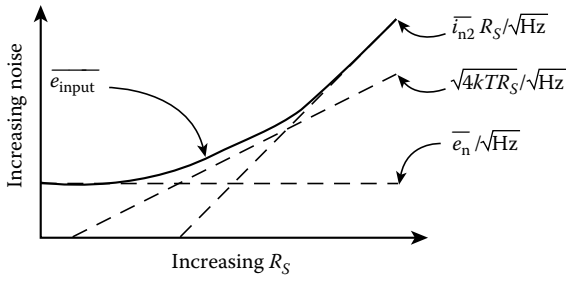

FIGURE 16.28 Effect of R_S on the total noise for the circuit of Figure 16.26a.

where BW is the op-amp's closed-loop bandwidth (see Section 16.3). The factor $\pi/2$ converts the closed-loop bandwidth to the noise equivalent bandwidth, assuming the op-amp is characterized by a single pole. The equivalent voltage white-noise density at the input is

$$\overline{e_{input}} = \sqrt{\overline{e_n^2} + 4kTR_S + \overline{i_{n2}^2}R_S^2}\Big/\sqrt{Hz} \tag{16.59}$$

The relative importance of each of these three factors depends on the value of R_S as shown in Figure 16.28. For low values of R_S, $\overline{e_n}$ dominates. At high values of R_S, $\overline{i_{n2}}$ dominates. In the middle region, R_S dominates if $\sqrt{4kt} > \sqrt{i_n e_n}$.

Two measures are used to specify the circuit's noise performance: the SNR and the noise figure (NF). The SNR is the ratio of the signal power to the total noise power, which assuming only white noise is present, can be expressed as

$$SNR = 20\log\left|\frac{v_s}{\overline{e_{input}}\sqrt{(\pi BW)/2}}\right| \tag{16.60}$$

The second measure, NF, expresses the increase in noise due to the amplifier over that due to the source resistance alone:

$$NF = 10\log\left|\frac{\overline{e_n^2} + \overline{e_{rs}^2} + \overline{i_{n1}^2 R_S^2}}{\overline{e_{rs}^2}}\right| \tag{16.61}$$

Although a low NF is desirable, it is usually more important to minimize the total noise to achieve the highest possible SNR.

16.2.7 Summary

Practical op-amps suffer from a wide range of nonidealities. The dominant effect of these nonidealities is to limit the range of applications for which an op-amp can be used. Problems such as the offset voltage, the CMRR, the bias currents, and the electrical noise will limit the accuracy of op-amp circuits. The op-amp's finite gain and saturation levels will limit the maximum controllable gain of an op-amp circuit. Factors such as the op-amp's saturation limits and its input and output impedances will limit the range of impedances that can be buffered by or driven by an op-amp. In many cases, circuit techniques or special-purpose op-amps can be used to reduce the detrimental effects of the op-amp's nonidealities.

16.3 Frequency- and Time-Domain Considerations

One of the most important limitations of practical op-amps is gain roll-off with frequency. This limitation affects both the frequency-domain and the time-domain behavior of circuits built around op-amps. We have linear effects, such as finite small-signal bandwidth and nonzero rise time, and nonlinear effects, such as slew-rate (SR) limiting and finite full-power bandwidth (FPBW). Additional effects are the settling time and intermodulation distortion. We discuss these limitations both for voltage-mode and current-mode op-amps [1].

16.3.1 Voltage-Mode Op-Amps

Conventional op-amps, the most popular representative of which is without doubt the 741 type, are voltage-mode amplifiers because in order to produce an output they require an input imbalance of the voltage type. Consequently, when a negative feedback loop is created around the op-amp, the signal returned to the input must be in the form of a voltage.

16.3.2 Block Diagram

Shown in Figure 16.29 is a simplified circuit diagram [2] that can be used to describe a wide variety of practical voltage-mode op-amps, including the popular 741. As illustrated in block-diagram form in Figure 16.30, the circuit is made up of three stages.

The *input stage* consists of transistors Q_1 through Q_4, whose function is to sense any imbalance between the inverting and noninverting input voltages V_n and V_p, and convert it to a single-ended output current I_{o1}. This stage is also designed to provide high input impedance and draw negligible input currents.

Q_1 and Q_2 form a differential pair whose task is to split the bias current I_A into two currents I_1 and I_2 in amounts controlled by the imbalance between V_n and V_p. If this imbalance is sufficiently small, we can write $I_1 - I_2 = g_{m1}(V_p - V_n)$, where g_{m1} is the transconductance of Q_1 and Q_2.

Ignoring transistor base currents, we have $I_3 = I_1$. In response to current I_3, Q_3 develops a base–emitter voltage drop that is then applied to Q_4, forcing the latter to draw the same amount of current as the former, or $I_4 = I_3$. For obvious reasons, Q_3 and Q_4 are said to form a current mirror. Summing currents, we obtain $I_{o1} = I_2 - I_4 = I_2 - I_3 = I_2 - I_1$, or

$$I_{o1} = -g_{m1}(V_p - V_n) = -g_{m1}V_d \tag{16.62}$$

where $V_d = V_p - V_n$ is called the differential input voltage.

The *intermediate stage* consists of Darlington pair $Q_5 - Q_6$ and frequency-compensation capacitance C_c. Its function is to provide additional gain as well as to introduce a dominant pole in the open-loop

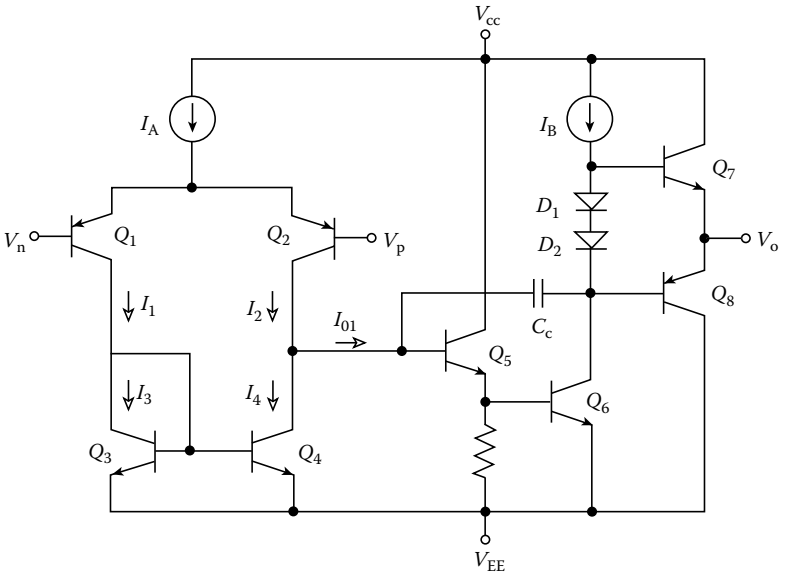

FIGURE 16.29 Simplified circuit diagram of a voltage-mode op-amp.

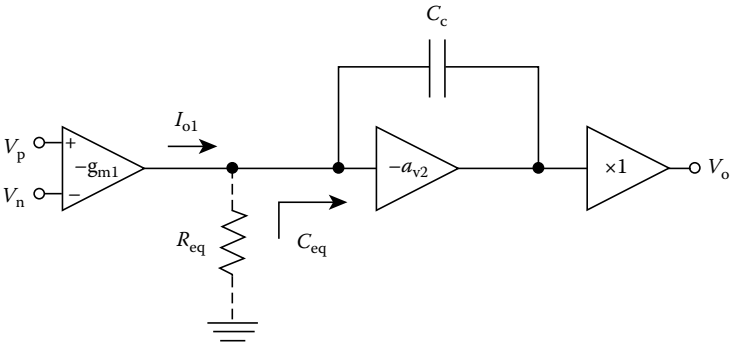

FIGURE 16.30 Voltage-mode op-amp block diagram.

response of the amplifier. Denoting the net equivalent resistance and capacitance between the input node of this stage and ground as R_{eq} and C_{eq}, the pole frequency is

$$f_{OL} = \frac{1}{2\pi R_{eq} C_{eq}} \tag{16.63}$$

By the Miller effect we have $C_{eq} = (1 + a_{v2})C_c$, where $-a_{v2}$ is the voltage gain of the Darlington pair.

The *output stage* consists of emitter–followers Q_7 and Q_8, and biasing diodes D_1–D_2. Though the voltage gain of this stage is only unity, its current gain can be fairly high, indicating that this stage acts as a power amplifier. Its function is also to provide a low output impedance. Q_7 and Q_8 are referred to as a push–pull pair because in the presence of an output load, Q_7 sources (or pushes) current to the load, and Q_8 sinks (or pulls) current from the load.

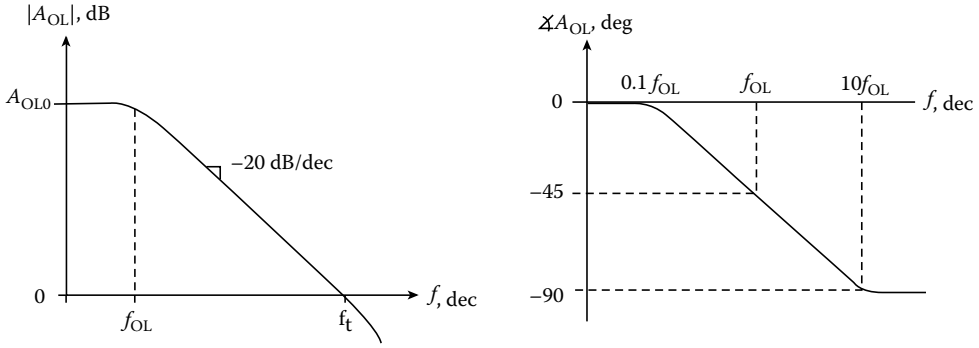

FIGURE 16.31 Frequency plots of the open-loop gain.

The small-signal transfer characteristic of the op-amp is

$$V_o = A_{OL}(jf)V_d \tag{16.64}$$

where $A_{OL}(jf)$, called the *open-loop voltage gain*, is a complex function of frequency f, and $j = \sqrt{-1}$ is the imaginary unit. With dominant pole compensation, this function can be approximated as

$$A_{OL}(jf) = \frac{A_{OL0}}{1 + jf/f_{OL}} \tag{16.65}$$

where A_{OL0} and f_{OL} are, respectively, the *dc value* and *bandwidth* of $A_{OL}(jf)$. For the circuit shown, $A_{OL0} = g_{m1}R_{eq}a_{v2}$. As an example, the popular 741 op-amp has $A_{OL0} \simeq 2 \times 10^5$ V/V and $f_{OL} \simeq 5$ Hz. Figure 16.31 shows the Bode plots of $A_{OL}(jf)$. We make the following observations.

1. For $f \ll f_{OL}$ we have $|A_{OL}(jf)| \simeq A_{OL0}$ and $\measuredangle A_{OL}(jf) \simeq 0°$ indicating an approximately constant gain and negligible delay.
2. For $f = f_{OL}$ we have $|A_{OL}(jf)| = A_{OL0}/\sqrt{2}$ and $\measuredangle A_{OL}(jf) = -45°$. Rewriting as $|A_{OL}(jf)|_{dB} = 20 \log_{10}|A_{OL}(jf)| = |A_{OL0}|_{dB} - 3$ dB explains why f_{OL} is also referred to as the -3 dB frequency or the half-power frequency of the open-loop response.
3. For $f \gg f_{OL}$ gain rolls off with frequency at a constant rate of -20 dB/dec, and it can be approximated as $|A_{OL}(jf)| \simeq A_{OL0}/(f/f_{OL})$ and $\measuredangle A_{OL}(jf) \simeq -90°$ Rewriting as

$$|A_{OL}(jf)| \times f \simeq A_{OL0} \times f_{OL} = f_t \tag{16.66}$$

indicates that in the roll-off region the op-amp exhibits a constant gain–bandwidth product (constant GBP). Increasing frequency by a given amount causes gain to decrease by the same amount. The frequency $f_t = A_{OL0}f_{OL}$ at which gain drops to 0 dB is aptly called the transition frequency. For the 741 op-amp, $f_t = 2 \times 10^5 \times 5 = 1$ MHz.

16.3.2.1 Closed-Loop Frequency Response

Figure 16.32 shows a simplified model of the voltage-mode op-amp, along with external circuitry to create the popular noninverting configuration. The resistors sample V_o and feed the voltage

$$V_n = \frac{R_1}{R_1 + R_2} V_o = \beta V_o \tag{16.67}$$

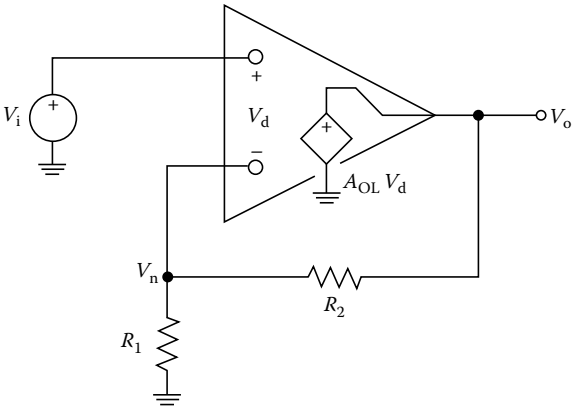

FIGURE 16.32 The noninverting configuration.

back to the inverting input. The parameter

$$\beta = \frac{R_1}{R_1 + R_2} = \frac{1}{1 + R_2/R_1} \tag{16.68}$$

representing the fraction of the output being fed back to the input is called the feedback factor. By inspection,

$$V_o = A_{OL}(jf)V_d = A_{OL}(jf)(V_i - \beta V_o) \tag{16.69}$$

In negative-feedback parlance $V_d = V_i - \beta V_o$ is referred to as the error signal. Collecting and solving for the ratio V_o/V_i yields, after minor algebraic manipulations,

$$A_{CL}(jf) = \frac{V_o}{V_i} = \left(1 + \frac{R_2}{R_1}\right)\frac{1}{1 + 1/T(jf)} \tag{16.70}$$

where $A_{CL}(jf)$ is called the closed-loop gain, and

$$T(jf) = A_{OL}(jf)\beta = \frac{A_{OL}(jf)}{1 + R_2/R_1} \tag{16.71}$$

is called the loop gain. This designation stems from the fact that a voltage propagating clockwise around the loop is first magnified by $A_{OL}(jf)$, and then attenuated by β, thus experiencing an overall gain of $T(jf) = A_{OL}(jf)\beta$.

By Equation 16.70 we have

$$\lim_{T\to\infty} A_{CL} = 1 + \frac{R_2}{R_1} \tag{16.72}$$

a value aptly called ideal closed-loop gain. Clearly, T provides a measure of how close A_{CL} is to ideal: the larger the T, the better. To ensure a substantial loop gain for a range of closed-loop gains, op-amp manufacturers strive to make A_{OL} as large as possible. Consequently, V_d will assume extremely small values since $V_d = V_o/A_{OL}$. In the limit $A_{OL} \to \infty$ we obtain $V_d \to 0$, that is, $V_n \to V_p$. This provides the

basis for the familiar ideal voltage-mode op-amp rule: When operated with negative feedback, an op-amp will provide whatever output is needed to drive its error signal V_d to zero or, equivalently, to force V_n to track V_p.

Substituting Equation 16.65 into Equation 16.71 and then into Equation 16.70, and exploiting the fact that $\beta A_{OL0} \gg 1$, we obtain, after minor algebra,

$$A_{CL}(jf) = \frac{A_{CL0}}{1 + jf/f_{CL}} \tag{16.73}$$

where

$$A_{CL0} = 1 + \frac{R_2}{R_1} = \frac{1}{\beta} \tag{16.74}$$

is the closed-loop dc gain, and

$$f_{CL} = \beta f_t = \frac{f_t}{A_{CL0}} \tag{16.75}$$

is the closed-loop small-signal bandwidth. The quantity $1/\beta$ is also called the dc noise gain because this is the gain with which the amplifier will magnify any dc noise present right at its input pins, such as the input offset voltage V_{OS}.

Equation 16.75 indicates a gain–bandwidth trade-off. As we raise the R_2/R_1 ratio to increase A_{CL0}, we also decrease f_{CL} in the process. Moreover, by Equation 16.71, $T(jf)$ is also decreased, thus leading to a greater departure of $A_{CL}(jf)$ from the ideal.

The above concepts can be visualized graphically as follows. By Equation 16.70 we can write $|T|_{dB} = 20 \log_{10}|T| = 20 \log_{10}|A_{OL}| - 20 \log_{10}(1/\beta)$, or

$$|T|_{dB} = |A_{OL}|_{dB} - |1/\beta|_{dB} \tag{16.76}$$

indicating that the loop gain can be found graphically as the difference between the decibel plot of the open-loop gain and that of the noise gain. This is illustrated in Figure 16.33. The frequency at which the two curves meet is aptly called the crossover frequency. It is readily seen that at this frequency we

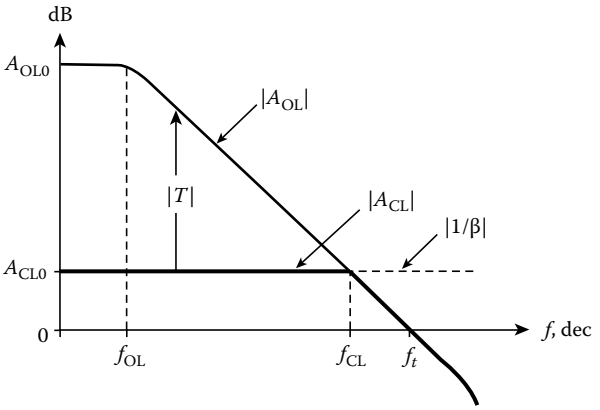

FIGURE 16.33 Graphical interpretation of the loop gain.

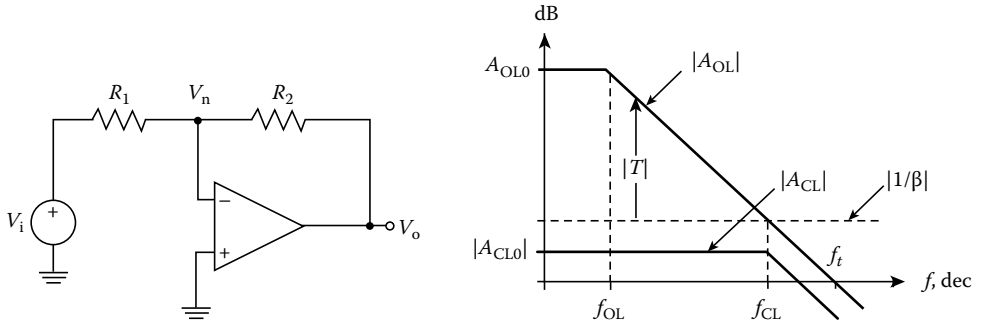

FIGURE 16.34 The inverting configuration.

have $T = 1\angle -90^\circ = -j$, so $|A_{CL}| = A_{CL0}/|1 + j| = A_{CL0}/\sqrt{2}$, by Equations 16.70 and 16.74. Consequently, the crossover frequency represents the -3 dB frequency of $A_{CL}(jf)$, that is, f_{CL}.

We now see that increasing A_{CL0} reduces T and causes the cross-point to move up the $|A_{OL}|$ curve, thus decreasing f_{CL}. The circuit with the widest bandwidth and the highest loop gain is also the one with the lowest closed-loop gain. This is the familiar voltage follower, obtained by letting $R_1 = \infty$ and $R_2 = 0$. Then, by Equations 16.74 and 16.75 we have $A_{CL0} = 1$ and $f_{CL} = f_t$.

Let us now turn to another important configuration, namely, the popular inverting amplifier of Figure 16.34. Since $V_p = 0$, it follows that $V_d = -V_n$. Applying the superposition priniciple we have

$$V_d = -\frac{R_2}{R_1 + R_2} V_i - \frac{R_1}{R_1 + R_2} V_o = \frac{-R_2}{R_1 + R_2} V_i - \beta V_o \tag{16.77}$$

indicating that the feedback factor $\beta = R_1/(R_1+R_2)$ is the same as for the noninverting configuration. Substituting into Equation 16.64, we find the closed-loop gain as

$$A_{CL}(jf) = \frac{V_o}{V_i} = \left(-\frac{R_2}{R_1}\right) \frac{1}{1 + 1/T(jf)} \tag{16.78}$$

Moreover, proceeding as for noninverting configuration, we get

$$A_{CL}(jf) = \frac{A_{CL0}}{1 + if/f_{CL}} \tag{16.79}$$

where

$$A_{CL0} = -\frac{R_2}{R_1} \tag{16.80}$$

is the closed-loop dc gain, and

$$f_{CL} = \beta f_t \tag{16.81}$$

is the closed-loop small-signal bandwidth. We can again find this bandwidth as the intercept of the $|A_{OL}|_{dB}$ and $|1/\beta|_{dB}$ curves. However, since we now have $|A_{CL0}| < |1/\beta|$, it follows that the $|A_{CL}|_{dB}$ curve will be shifted downward, as explicitly shown in Figure 16.34.

Before concluding, we wish to point out that open-loop gain roll-off affects not only the closed-loop gain, but also the closed-loop input and output impedances. Interested readers can find additional information in the literature [3].

16.3.2.2 Closed-Loop Transient Response

To fully characterize the dynamic behavior of an op-amp circuit we also need to know its transient response. This response is usually specified for the case of the op-amp operating as a unity-gain voltage follower. As we know, its small-signal transfer characteristic is $V_o = V_i/(1 + jf/f_t)$. This is formally similar to that of an ordinary *RC* circuit. Subjecting a voltage follower to a step of suitably small amplitude V_m, as shown in Figure 16.35, will cause an exponential output transition with the time constant

$$\tau = \frac{1}{2\pi f_t} \tag{16.82}$$

The rise time t_r, defined as the time it takes for V_o to swing from 10% to 90% of V_m, provides a measure of how rapidly the transition takes place. One can readily see that $t_r = \tau \ln 9 \simeq 2.2\tau$. For the 741 op-amp we have $\tau = 1/(2\pi \times 10^6) \simeq 159$ ns, and $t_r \simeq 350$ ns.

The rate at which V_o changes with time is highest at the beginning of the exponential transition, when its value is V_m/τ. Increasing the step magnitude, V_m increases this initial rate, until a point is reached beyond which the rate saturates at a constant value called the slew rate (SR). The transition is now a ramp, rather than an exponential. Figure 16.36 shows the SR limited response to a pulse.

SR limiting stems from the limited ability of the internal circuitry to charge or discharge the compensation capacitance C_c. To understand this effect, refer to Figure 16.37. As long as the input

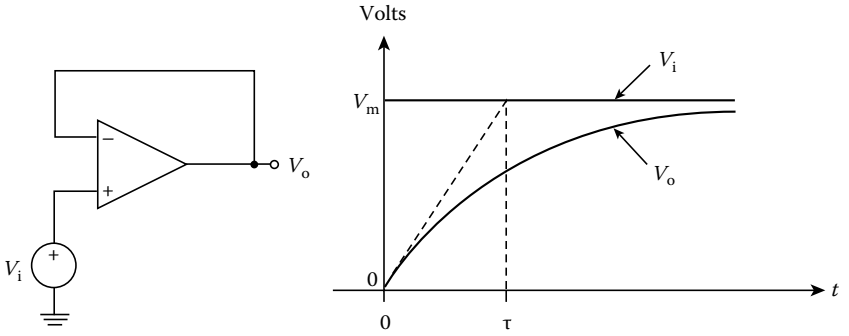

FIGURE 16.35 Voltage follower and its small-signal step response.

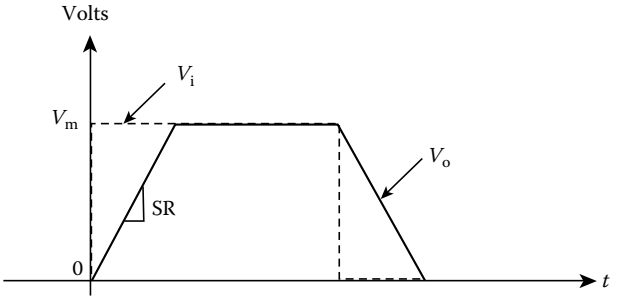

FIGURE 16.36 Large-signal response of the voltage follower.

imbalance V_d is sufficiently small, Equation 16.62 still holds and the step response is exponential. However, for large values of V_d, I_{o1} is no longer linearly proportional to V_d, but saturates at $\pm I_A$, where I_A is the input-stage bias current depicted in Figure 16.29. Turning now to Figure 16.30 and observing that the second stage acts as an integrator, we can state that the maximum rate at which C_c can be charged or discharged is $(dV_o/dt)_{max} = I_A/C_c$. This is precisely the SR,

$$SR = \frac{I_A}{C_c} \tag{16.83}$$

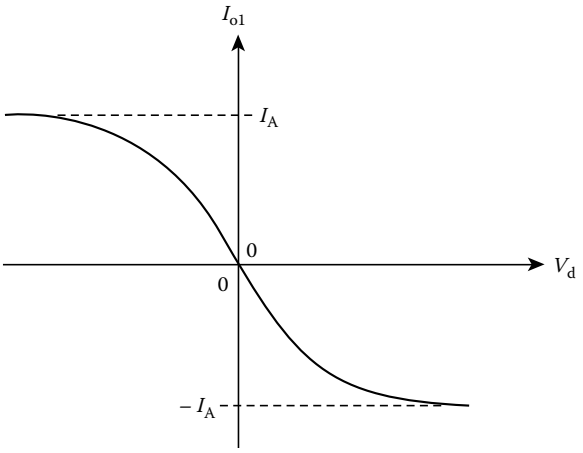

FIGURE 16.37 Actual transfer characteristic of the first stage.

The 741 op-amp has typically $I_A = 20$ μA and $C = 30$ pF, so $SR = 10 \times 10^{-6}/(30 \times 10^{-12}) = 0.67$ V/μs. To respond to a 10 V input step a 741 follower will take approximately $10/0.67 = 15$ μs.

The step magnitude corresponding to the onset of SR limiting in such that $V_m/\tau = SR$, or $V_m = SR \times \tau = SR/(2\pi f_t)$. For the 741 op-amp, $V_m = 0.67 \times 10^6/(2\pi \times 10^6) = 106$ mV. This means that as long as the input step is less than 106 mV, a 741 follower will respond with an exponential transition governed by $\tau \simeq 159$ ns. For a greater input step, however, the output will slew at a constant rate of 0.67 V/μs, and it will do so until it comes within 106 mV of the final value, after which it will complete the transition in exponential fashion.

In certain applications it is important to know the settling time t_s, defined as the time it takes for the output to settle within a specified band around its final value, usually for a full-scale output transition. It is apparent that SR limiting plays an important role in the settling-time characteristic of a circuit.

SR limiting affects also the FPBW, defined as the maximum frequency at which the circuit still yields an undistorted full-power output. Letting $V_o = V_m \sin 2\pi ft$, we have $(dV_o/dt)_{max} = (2\pi f V_m \cos 2\pi ft)_{max} = 2\pi f V_m$. Equating it to the SR and solving for f, whose value is the FPBW, we get

$$FPBW = \frac{SR}{2\pi V_m} \tag{16.84}$$

For instance, for $V_m = 10$ V, the 741 op-amp has $FPBW = SR/(20\pi) = 10.6$ kHz. Figure 16.38 shows the distorted response of a voltage follower to a full-power input with a frequency higher than the FPBW.

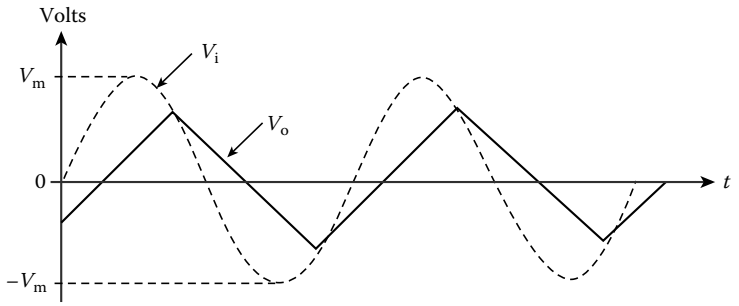

FIGURE 16.38 Distortion when the FPBW is exceeded.

From Equations 16.63 and 16.83, it is apparent that the primary cause of frequency and SR limitations is the capacitance C_c. Why not eliminate C_c altogether? Without C_c the open-loop response would exhibit a much wider bandwidth, but also a much greater phase lag because of the various poles introduced by the transistors making up the op-amp. We are interested in the situation at the crossover frequency, where $|T| = 1$. Should the phase shift at this frequency reach $-180°$, we would have $T = 1\angle -180° = -1$ which, after substitution into Equation 16.70, would yield $|A_{CL}| \rightarrow (1 + R_2/R_1)/(1 - 1) \rightarrow \infty$! The physical meaning of an infinite closed-loop gain is that the circuit would be capable of sustaining a nonzero output with a vanishingly small external input. But, this is the recipe for sustained oscillation! It is precisely to avoid this possibility that the manufacturer incorporates the frequency-compensation capacitance C_c.

As mentioned, C_c causes gain to roll-off, so that by the time the frequency of $-180°$ phase lag is reached, $|A_{OL}|$ has already dropped well below 0 dB, making it impossible for the circuits of Figures 16.32, 16.34, and 16.35 to achieve $T = -1$ at the crossover frequency, regardless of the values of R_1 and R_2. This requires that the dominant-pole frequency be suitably low, and thus, by Equation 16.63, that C_{eq} be suitably large. To avoid the need to manufacture impractically large on-chip capacitances, it is customary to start out with a realistic value, such as 30 pF for the 741 op-amp, and then exploit the multiplicative action of the Miller effect to raise it to the desired equivalent value.

The hardest configuration to compensate is the unity-gain voltage follower because its crossover frequency is the closest to the frequency region of additional phase lag stemming from the higher-order poles of the op-amp. This is why this particular configuration is usually chosen for the specification of the transient response.

16.3.2.3 SPICE Simulation

Op amp dynamics can readily be simulated via SPICE using the op-amp macromodels available from the manufacturers. Shown in Figure 16.39 is the SPICE circuit used to display the frequency and transient responses of the 741 op-amp. The curves of Figure 16.40 are obtained by displaying the dB curves of $|a| = |V_o/(V_p - V_n)| = |V_o/V_n|$ and $|A| = |V_o/V_i|$. The curves of Figures 16.41 and 16.42 display, respectively, the small-signal and the large-signal responses to an input step. The former is dominated by exponential transients, the latter by SR-limited ramps. Note how in either case the inverting input node itself exhibits a transient before becoming a virtual ground once the circuit reaches its steady state.

16.3.3 Current-Mode Op-Amps

Current-mode op-amps exploit a special circuit topology [4], along with high-speed complementary bipolar processes, to achieve much faster dynamics than their voltage-mode amplifier counterparts. The

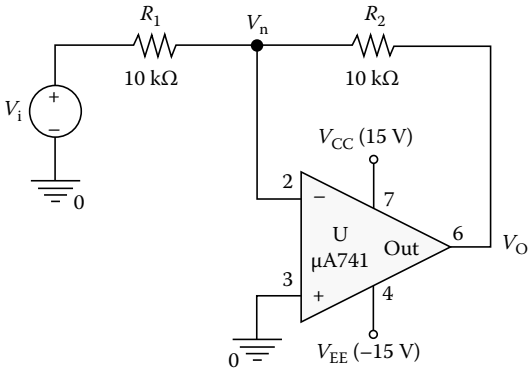

FIGURE 16.39 SPICE circuit to simulate the dynamics of the 741 op-amp.

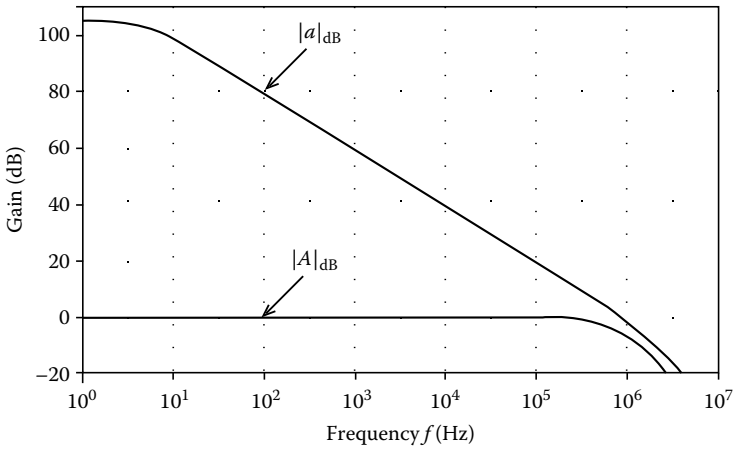

FIGURE 16.40 Open-loop and closed-loop responses of the circuit of Figure 16.39.

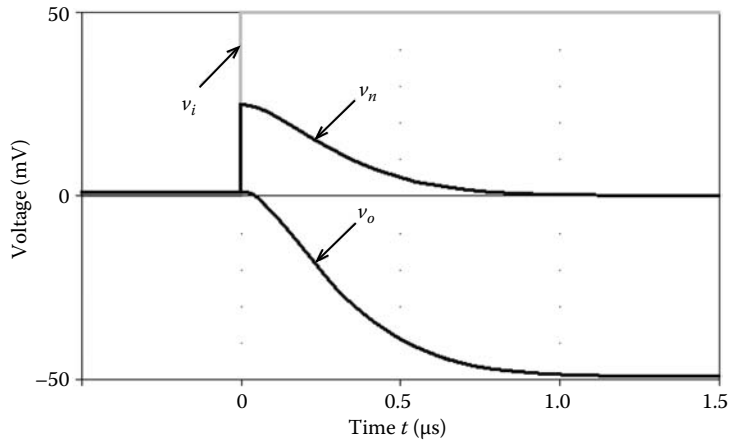

FIGURE 16.41 Small-signal transient response of the 741 op-amp.

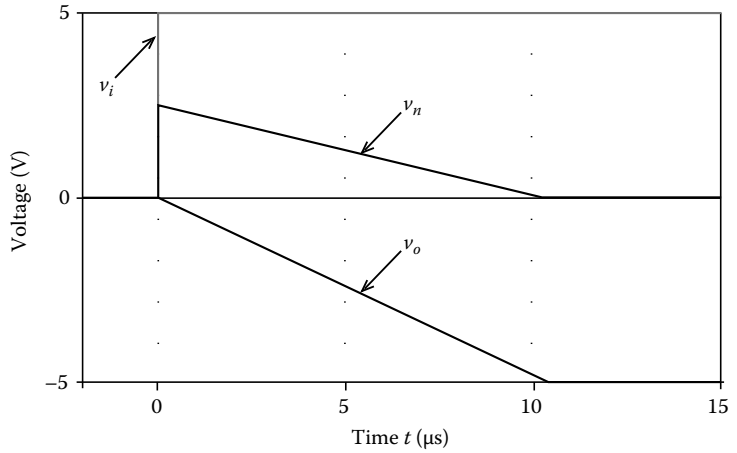

FIGURE 16.42 Large-signal transient response of the 741 op-amp.

name stems from the fact that these amplifiers respond to an input imbalance of the current type, and the signal propagating around the feedback loop is thus in the form of a current rather than a voltage.

16.3.3.1 Block Diagram

Figure 16.43 shows the simplified circuit diagram of a current-mode op-amp. Referring also to Figure 16.44, we identify three functional blocks.

1. The first functional block is a unity-grain input buffer, consisting of transistors Q_1 through Q_4. Q_1 and Q_2 form a low output-impedance push–pull stage, while Q_3 and Q_4 provide V_{BE} compensation as well as a Darlington function to raise the input impedance. This buffer forces V_n to follow V_p, very much like a voltage-mode op-amp does via negative feedback.
   When the op-amp is embedded in a circuit, current can easily flow in or out of its low-impedance inverting input-pin, though we shall see that in the steady-state (nonslewing) condition this current approaches zero. The function of the buffer is to sense this current, denoted as I_n, and produce an imbalance

$$I_1 - I_2 = I_n \tag{16.85}$$

   between the push–pull transistor currents I_1 and I_2.
2. The second block is a pair of current mirrors $Q_5 - Q_6$ and $Q_7 - Q_8$, which reflect currents I_1 and I_2 and sum them at a common junction node. The current into this node thus equals I_n, as shown.
3. Finally, a unity-gain output buffer, consisting of transistors Q_9 through Q_{12}, buffers the summing node voltage to the outside and provides a low output impedance for the overall op-amp.

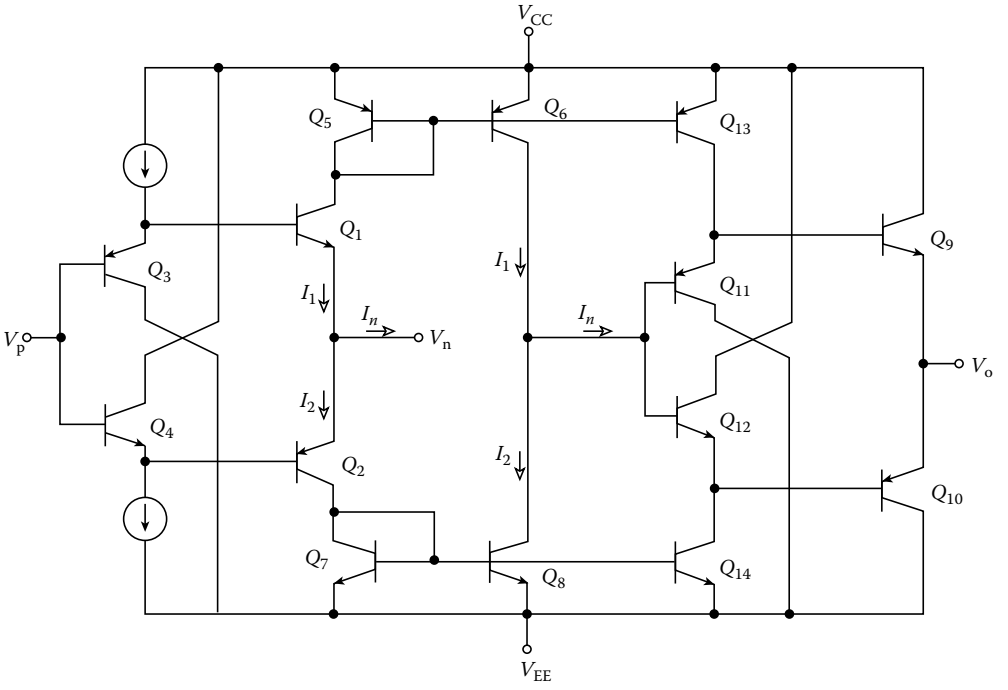

FIGURE 16.43 Simplified circuit diagram of a current-mode op-amp.

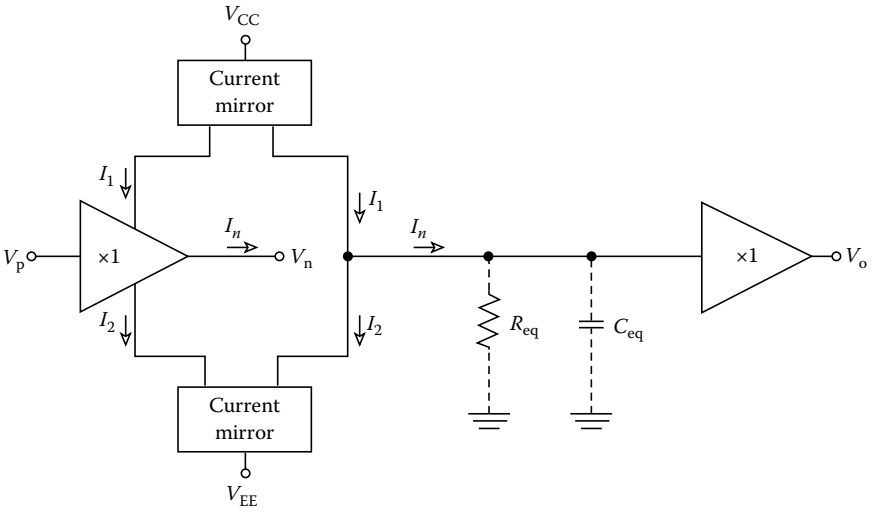

FIGURE 16.44 Current-mode op-amp block diagram.

Denoting the net equivalent resistance and capacitance of the summing node toward ground as R_{eq} and C_{eq}, we can write

$$V_o = Z_{OL}(jf)I_n \tag{16.86}$$

where $Z_{OL}(jf)$, called the *open-loop transimpedance gain*, is the impedance due to the parallel combination of R_{eq} and C_{eq}. This impedance can be expressed as

$$Z_{OL}(jf) = \frac{Z_{OL0}}{1 + jf/f_{OL}} \tag{16.87}$$

where $Z_{OL0} = R_{eq}$, and

$$f_{OL} = \frac{1}{2\pi R_{eq} C_{eq}} \tag{16.88}$$

As an example in Figure 16.44, the CLC401 current-mode op-amp (National Semiconductor Co.) has $Z_{OL0} \simeq 710$ kΩ, $f_{CL} \simeq 350$ kHz, and $C_{eq} = 1(2\pi R_{eq} f_{OL}) \simeq 0.64$ pF.

We observe a formal similarity with voltage-mode op-amps, except that now the error signal I_n is a current rather than a voltage, and the gain $Z_{OL}(jf)$ is in V/A rather than in V/V. For this reason, current-mode op-amps are also referred to as transimpedance op-amps. Than gain $Z_{OL}(jf)$ is approximately constant from dc to f_{OL}, after which it rolls off with frequency at a constant rate of −1 dec/dec.

16.3.3.2 Closed-Loop Characteristics

Figure 16.45 shows a simplified model of the current-mode op-amp, along with an external feedback network to configure it as a noninverting amplifier. Any attempt to unbalance the inputs will cause the input buffer to source (or sink) an imbalance current I_n to the external network. By Equation 16.86, this imbalance causes V_o to swing in the positive (or negative) direction until the original imbalance current is neutralized via the negative-feedback loop.

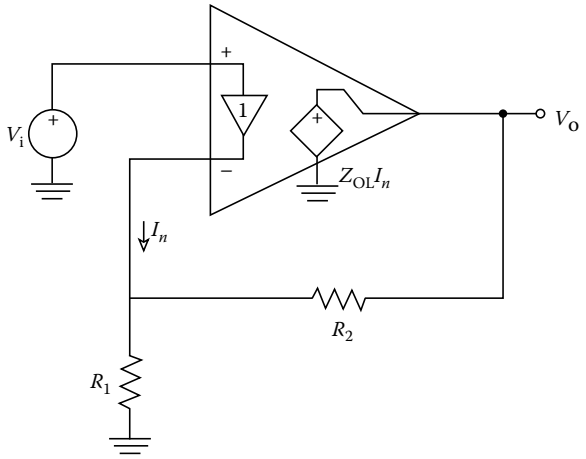

FIGURE 16.45 Noninverting configuration.

Exploiting the fact that the input buffer keeps $V_n = V_p = V_i$, we can apply the superposition principle and write

$$I_n = \frac{V_i}{R_1 \parallel R_2} - \frac{V_o}{R_2} = \frac{V_i}{R_1 \parallel R_2} - \beta V_o \tag{16.89}$$

Clearly, the feedback signal V_o/R_2 is now a current, and the feedback factor

$$\beta = \frac{1}{R_2} \tag{16.90}$$

is now in A/V. Substituting into Equation 16.86 and collecting, we get

$$A_{CL}(jf) = \frac{V_o}{V_i} = \left(1 + \frac{R_2}{R_1}\right) \frac{1}{1 + 1/T(jf)} \tag{16.91}$$

where $A_{CL}(jf)$ is the closed-loop gain of the circuit, and

$$T(jf) = Z_{OL}(jf)\beta = \frac{Z_{OL}(jf)}{R_2} \tag{16.92}$$

is the loop gain. This designation is due again to the fact that a current propagating clockwise around the loop is first multipled by $Z_{OL}(jf)$ to be converted to a voltage, and divided by R_2 to be converted back to a current, thus experiencing an overall gain of $T(jf) = Z_{OL}(jf)/R_2$.

To make $A_{CL}(jf)$ approach the ideal value $1 + R_2/R_1$, it is desirable that $T(jf)$ be as large as possible. To ensure a substantial loop gain over a range of closed-loop gains, manufacturers strive to maximize $Z_{OL}(jf)$ relative to R_2. Consequently, since $I_n = V_o/Z_{OL}$, the inverting input-pin current will be very small, even though this is a low-impedance node because of the input buffer. In the limit $Z_{OL} \to \infty$ we obtain $I_n \to 0$, indicating that a current-mode op-amp will ideally provide whatever output is needed to drive I_n to zero. Thus, the familiar op-amp conditions $V_n \to V_p$, $I_n \to 0$, and $I_p \to 0$ hold also for current-mode op-amps, though for different reasons than their voltage-mode counterparts.

16.3.3.3 Current-Mode Op-Amp Dynamics

Substituting Equation 16.87 into Equation 16.92 and then into Equation 16.91, and exploiting the fact that $Z_{OL0}/R_2 \gg 1$, we obtain

$$A_{CL}(jf) = \frac{A_{CL0}}{1 + jf/f_t} \tag{16.93}$$

where

$$A_{CL0} = 1 + \frac{R_2}{R_1} \tag{16.94}$$

is the closed-loop dc gain, and

$$f_t = \frac{Z_{OL0} f_{OL}}{R_2} = \frac{1}{2\pi R_2 C_{eq}} \tag{16.95}$$

is the closed-loop bandwidth. With R_2 in the kΩ range and C_{eq} in the pF range, f_t is typically in range of 10^8 Hz.

We can again visualize $|T|$ and f_t graphically by noting that if we define $|T|_{dec} = \log_{10}|T|$, then we have, by Equation 16.92, $|T|_{dec} = \log_{10}|Z_{OL}(jf)| - \log_{10}|R_2|$, or

$$|T|_{dec} = |Z_{OL}(jf)|_{dec} - |R_2|_{dec} \tag{16.96}$$

As shown in Figure 16.46, we can visualize the loop gain as the difference between the decade plot of $|Z_{OL}(jf)|$ and that of $|R_2|$, with the latter now acting as the noise gain. Since at the crossover frequency we have $T = 1\ \angle -90° = -j$, Equations 16.91 and 16.94 yield $|A_{CL}| = A_{CL0}/\sqrt{2}$. Consequently, the crossover frequency represents the −3 dB frequency of $A_{CL}(jf)$, that is, f_t.

We are now ready to make two important observations.

1. Equation 16.95 shows that for a given amplifier the closed-loop bandwidth depends only on R_2. We can thus use R_2 to select the bandwidth f_t via Equation 16.95, and R_1 to select the dc gain A_{OL0} via Equation 16.94. The ability to set gain independently of bandwidth, along with the absence of gain-bandwidth trade-off, constitutes the first major advantage of current-mode over voltage-mode op-amps, see Figure 16.47.

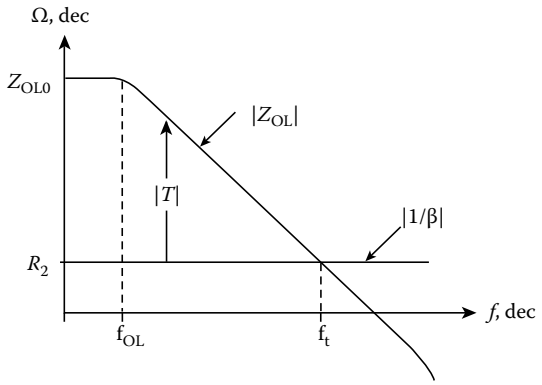

FIGURE 16.46 Graphical interpretation of the loop gain.

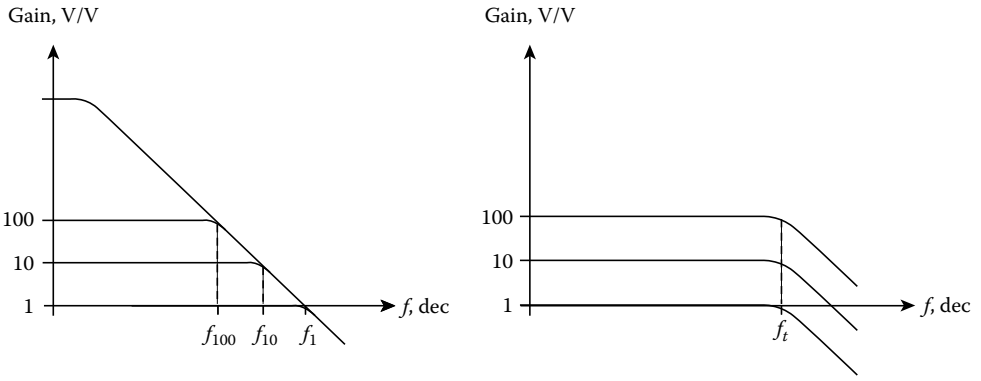

FIGURE 16.47 Comparing the gain–bandwidth characteristics of voltage-mode (left) and current-mode (right) op amps.

2. The other major advantage of current-mode op-amps is the absence of SR limiting. To justify, suppose we apply an input step $V_i = V_m$ to the circuit of Figure 16.45. Referring also to Figure 16.44, we note that the resulting current imbalance I_n yields an output V_o such that $I_n = C_{eq}dV_o/dt + V_o/R_{eq}$. Substituting into Equation 16.89, rearranging, and exploiting the fact that $R_2/Z_{OL0} \ll 1$, we get

$$R_2 C_{eq} \frac{dV_o}{dt} + V_o = A_{OL0} V_m \tag{16.97}$$

indicating an *exponential* output transient regardless of V_m. The time constant governing the transient is

$$T = R_2 C_{eq} \tag{16.98}$$

and is set by R_2, regardless of A_{CL0}. For instance, a CLC401 op-amp with $R_2 = 1.5$ kΩ has $\tau = R_2 C_{eq} = 1.5 \times 10^3 \times 0.64 \times 10^{-12} \simeq 1$ ns. The rise time is $t_r = 2.2\tau \simeq 2.2$ ns, and the settling time within 0.1% of the final value is $t_s \simeq 7\tau \simeq 7$ ns, in reasonable agreement with the data-sheet values $t_r = 2.5$ ns and $t_s = 10$ ns.

16.3.3.4 Higher-Order Effects

The above analysis indicates that once R_2 has been set, the dynamics are unaffected by the closed-loop gain setting. In practice it is found that bandwidth and rise time do vary with gain somewhat, though not as drastically as for voltage-mode op-amps. The main cause is the nonzero output resistance R_n of the input buffer, whose effect is to alter the loop gain and, hence, the closed-loop dynamics. Referring to Figure 16.48, we again use the superposition principle and write

$$I_n = \frac{V_i}{R_n + R_1 \parallel R_2} - \beta V_o \tag{16.99}$$

where the feedback factor is found using the current divider formula and Ohm's law,

$$\beta = \frac{R_1}{R_1 + R_n} \times \frac{1}{R_2 + (R_n \parallel R_1)} = \frac{1}{R_2 + A_{CL0} R_n} \tag{16.100}$$

Comparing with Equation 16.90, we observe that the effect of R_n is to replace R_2 with $R_2 + A_{CL0}R_n$. The $|1/\beta|$ curve of Figure 16.46 will thus be shifted upward, leading to a decrease in the crossover frequency,

which we shall now denote as f_{CL}. This frequency is obtained by letting $R_2 \rightarrow (R_2 + A_{CL0}R_n)$ in Equation 16.95,

$$f_{CL} = \frac{Z_{OL0}f_{OL}}{R_2 + A_{CL0}R_n} = \frac{1}{2\pi(R_2 + A_{CL0}R_n)C_{eq}} \qquad (16.101)$$

As an example, suppose an op-amp has $R_n = 50\ \Omega$, $R_2 = 1.5\ \text{k}\Omega$, and $f_t = 100$ MHz. Then, Equation 16.101 yields $f_{CL} = f_t/(1 + A_{CL0}R_n/R_2) = 10^8/(1 + A_{CL0}/30)$. The bandwidths corresponding to $A_{CL0} = 1$ V/V, 10 V/V, and 100 V/V are, respectively, $f_1 = 96.8$ MHz, $f_{10} = 75.0$ MHz, and $f_{100} = 23.1$ MHz, and are shown in Figure 16.49. The corresponding rise times are, respectively, $t_1 = 3.6$ ns, $t_{10} = 4.7$ ns, and $t_{100} = 15.2$ ns. We note that the above bandwidth reductions still compare favorably with voltage-mode op-amps, where the reduction factors would be, respectively, 1, 10, and 100.

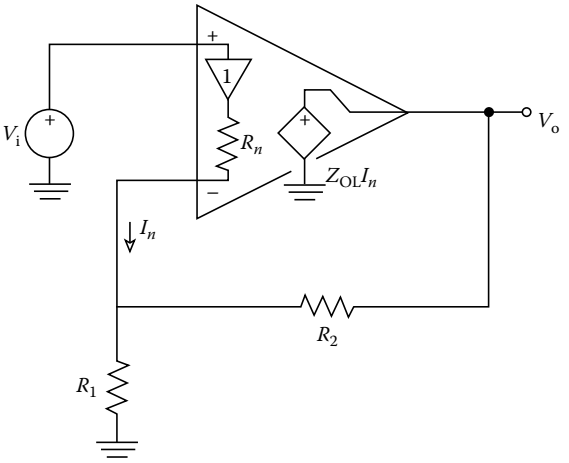

FIGURE 16.48 Investigating the effect of R_n.

The values of R_1 and R_2 can be predistorted to compensate for the bandwidth reduction. Using Equation 16.101 we find R_2 for a given bandwidth f_{CL} and dc gain A_{CL0},

$$R_2 = \frac{Z_{OL0}f_{OL}}{f_{CL}} - A_{CL0}R_n \qquad (16.102)$$

and using Equation 16.94 we find R_1 for the given dc gain A_{CL0},

$$R_1 = \frac{R_2}{A_{CL0} - 1} \qquad (16.103)$$

As an example, suppose an op-amp with $Z_{OL0}f_{OL} = 1.5 \times 10^{11}\ \Omega \times \text{Hz}$ and $R_n = 50\ \Omega$ is to be configured for $A_{CL0} = 10$ V/V and $f_{CL} = 100$ MHz. Then, using Equations 16.102 and 16.103 we find $R_2 = 1.5 \times 10^{11}/10^8 - 10 \times 50 = 1\ \text{k}\Omega$, and $R_1 = 10^3/(10 - 1) = 111\ \Omega$.

Though our analysis has focused on the noninverting configuration, we can readily extend our line of reasoning to other circuits such as the popular inverting configuration. The latter is obtained by

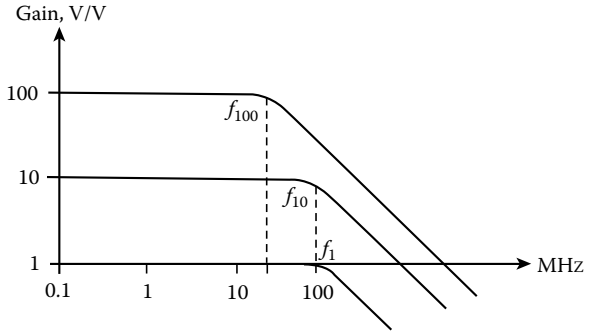

FIGURE 16.49 Bandwidth reduction for different gain settings.

grounding the noninverting input of Figure 16.48, and applying the source V_i via the bottom lead of R_1. The bandwidth is still as in Equation 16.101, but the dc gain is now $-R_2/R_1$. Interested readers can consult the literature [1,5] for additional current-mode op-amp circuits as well as application hints.

We conclude by pointing out that current-mode op-amps, though exhibiting much faster dynamics than their voltage-mode counterparts, in general suffer from poorer input offset voltage and input bias current characteristics. Moreover, having much wider bandwidths, they tend to be noisier. There is no question that the circuit designer must carefully weigh both advantages and disadvantages before deciding which amplifier type is best suited to the application at hand.

17.1 Introduction

As the operating frequency of communication channels for both video and wireless increases, there is an ever-increasing demand for high-frequency (HF) amplifiers. Furthermore, the quest for single-chip integration has led to a whole new generation of amplifiers predominantly geared toward CMOS VLSI. In this chapter, we will focus on the design of high-frequency amplifiers for potential applications in the front-end of video, optical, and RF systems. Figure 17.1 shows, for example, the architecture of a typical mobile phone transceiver front-end. With channel frequencies approaching the 2 GHz range, coupled with demands for reduced chip size and power consumption, there is an increasing quest for VLSI at microwave frequencies. The shrinking feature size of CMOS has facilitated the design of complex analog circuits and systems in the 1–2 GHz range, where more traditional low-frequency lumped circuit techniques are now becoming feasible. Since the amplifier is the core component in such systems,

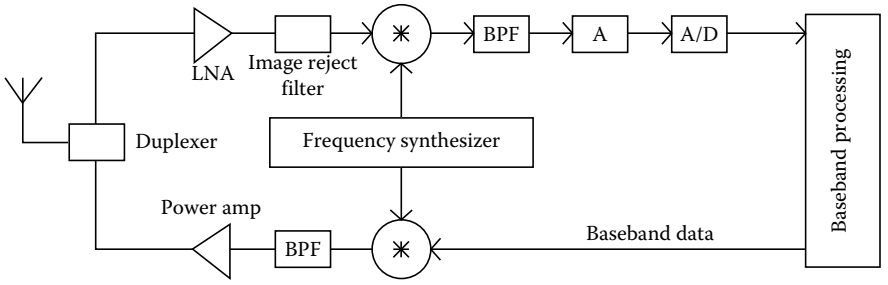

FIGURE 17.1 Generic wireless transceiver architecture.

there has been an abundance of circuit design methodologies for high-speed, low-voltage, low-noise, and low-distortion operation.

This chapter will present various amplifier designs that aim to satisfy these demanding requirements. In particular, we will review, and in some cases present new ideas for power amps, LNAs, and transconductance cells, which form core building blocks for systems such as Figure 17.1. Section 17.2 begins by reviewing the concept of current feedback, and shows how this concept can be employed in the development of low-voltage, high-speed, constant-bandwidth CMOS amplifiers. The next two sections of the chapter focus on amplifiers for wireless receiver applications, investigating performance requirements and design strategies for optical receiver amplifiers (Section 17.3) and HF low-noise amplifiers (LNAs) (Section 17.4). Section 17.5 considers the design of amplifiers for the transmitter side, and in particular the design and feasibility of Class E power amps are discussed. Finally, Section 17.6 reviews a very recent low-distortion amplifier design strategy termed ''log-domain,'' which has shown enormous potential for HF, low-distortion tunable filters.

17.2 Current Feedback Op-Amp

17.2.1 Current Feedback Op-Amp Basics

The operational amplifier (op-amp) is one of the fundamental building blocks of analog circuit design [1,2]. High-performance signal processing functions such as amplifiers, filters, oscillators, etc. can be readily implemented with the availability of high-speed, low-distortion op-amps. In the last decade, the development of complementary bipolar technology has enabled the implementation of single-chip video op-amps [3–7]. The emergence of op-amps with nontraditional topologies, such as the current feedback op-amp (CFOA), has improved the speed of these devices even further [8–11]. CFOA structures are well known for their ability to overcome (to a first-order approximation) the gain-bandwidth trade-off and slew rate limitation that characterizes traditional voltage feedback op-amps (VFOAs) [12].

Figure 17.2 shows a simple macromodel of a CFOA, along with a simplified circuit diagram of the basic architecture. The topology of the CFOA differs from the conventional VFOA in two respects. First, the input stage of a CFOA is a unity-gain voltage buffer connected between the inputs of the op-amp. Its function is to force V_n to follow V_p, very much like a conventional VFOA does via negative feedback. In the case of the CFOA, because of the low output impedance of the buffer, current can flow in or out of the inverting input, although in normal operation (with negative feedback) this current is extremely small. Secondly, a CFOA provides a high open-loop transimpedance gain $Z(j\omega)$, rather than open-loop voltage gain as with a VFOA. This is shown in Figure 17.2, where a current-controlled current source senses the current I_{INV} delivered by the buffer to the external feedback network, and copies this current to a high impedance $Z(j\omega)$. The voltage conveyed to the output is given by Equation 17.1:

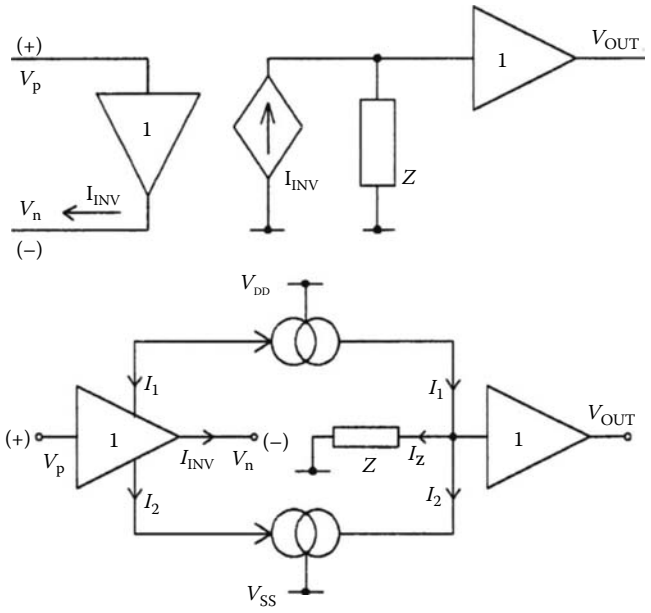

FIGURE 17.2 CFOA macromodel.

$$V_{OUT} = Z(j\omega) \cdot I_{INV} \Rightarrow \frac{V_{OUT}}{I_{INV}}(j\omega) = Z(j\omega) \tag{17.1}$$

When the negative feedback loop is closed, any voltage imbalance between the two inputs due to some external agent will cause the input voltage buffer to deliver an error current I_{INV} to the external network. This error current $I_{INV} = I_1 - I_2 = I_Z$ is then conveyed by the current mirrors to the impedance Z, resulting in an ouput voltage as given by Equation 17.1. The application of negative feedback ensures that V_{OUT} will move in the direction that reduces the error current I_{INV} and equalizes the input voltages.

We can approximate the open-loop dynamics of the CFOA as a single pole response. Assuming that the total impedance $Z(j\omega)$ at the gain node is the combination of the output resistance of the current mirrors R_o in parallel with a compensation capacitor C, we can write:

$$Z(j\omega) = \frac{R_o}{1 + j\omega R_o C} = \frac{R_o}{1 + j\frac{\omega}{\omega_o}} \tag{17.2}$$

where $\omega_o = 1/R_o C$ represents the frequency where the open-loop transimpedance gain is 3 dB down from its low frequency value R_o. In general, R_o is designed to be very high in value.

Referring to the noninverting amplifier configuration shown in Figure 17.3:

$$I_{INV} = \frac{V_{IN}}{R_G} - \frac{V_{OUT} - V_{IN}}{R_F} = \frac{V_{IN}}{R_G // R_F} - \frac{V_{OUT}}{R_F} \tag{17.3}$$

Substituting Equation 17.1 into Equation 17.3 yields the following expression for the closed-loop gain:

$$A_{CL}(j\omega) = \left(1 + \frac{R_F}{R_G}\right) \cdot \frac{Z(j\omega)}{R_F + Z(j\omega)} = \left(1 + \frac{R_F}{R_G}\right) \cdot \frac{1}{1 + \frac{R_F}{Z(j\omega)}} \tag{17.4}$$

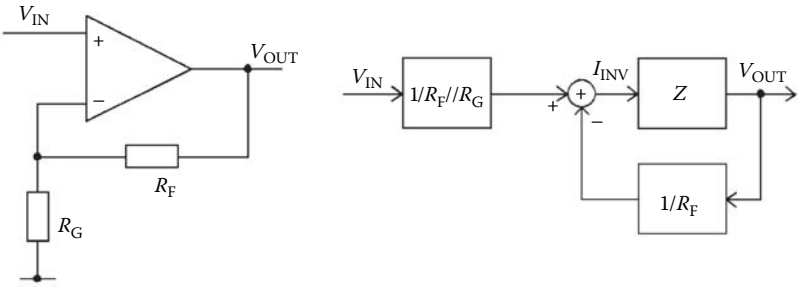

FIGURE 17.3 CFOA noninverting amplifier configuration.

Combining Equations 17.2 and 17.4, and assuming that the low frequency value of the open-loop transimpedance is much higher than the feedback resistor ($R_o \gg R_F$) gives:

$$A_{CL}(j\omega) = \left(1 + \frac{R_F}{R_G}\right) \cdot \frac{1}{1 + j\frac{R_F \cdot \omega}{R_o \cdot \omega_o}} = \frac{A_{Vo}}{1 + j\frac{\omega}{\omega_\alpha}} \tag{17.5}$$

Referring to Equation 17.5, the closed-loop gain $A_{Vo} = 1 + R_F/R_G$, while the closed-loop −3 dB frequency ω_α is given by

$$\omega_\alpha = \frac{R_o}{R_F} \cdot \omega_o \tag{17.6}$$

Equation 17.6 indicates that the closed-loop bandwidth does not depend on the closed-loop gain as in the case of a conventional VFOA, but is determined by the feedback resistor R_F. Explaining this intuitively, the current available to charge the compensation capacitor at the gain node is determined by the value of the feedback resistor R_F and not R_o, provided that $R_o \gg R_F$. So, once the bandwidth of the amplifier is set via R_F, the gain can be independently varied by changing R_G. The ability to control the gain independently of bandwidth constitutes a major advantage of CFOAs over conventional VFOAs.

The other major advantage of the CFOA compared to the VFOA is the inherent absence of slew rate limiting. For the circuit of Figure 17.3, assume that the input buffer is very fast and thus a change in voltage at the noninverting input is instantaneously converted to the inverting input. When a step ΔV_{IN} is applied to the noninverting input, the buffer output current can be derived as

$$I_{INV} = \frac{V_{IN} - V_{OUT}}{R_F} + \frac{V_{IN}}{R_G} \tag{17.7}$$

Equation 17.7 indicates that the current available to charge/discharge the compensation capacitor is proportional to the input step regardless of its size, that is, there is no upper limit. The rate of change of the output voltage is thus

$$\frac{dV_{OUT}}{dt} = \frac{I_{INV}}{C} \Rightarrow V_{OUT}(t) = \Delta V_{IN} \cdot \left(1 + \frac{R_F}{R_G}\right) \cdot (1 - e^{-t/R_f \cdot C}) \tag{17.8}$$

Equation 17.8 indicates an exponential output transition with time constant $\tau = R_F \cdot C$. Similar to the small-signal frequency response, the large-signal transient response is governed by R_F alone, regardless of the magnitude of the closed-loop gain. The absence of slew rate limiting allows for faster settling times and eliminates slew rate-related nonlinearities.

In most practical bipolar realizations, Darlington-pair transistors are used in the input stage to reduce input bias currents, which makes the op-amp somewhat noisier and increases the input offset voltage. This is not necessary in CMOS realizations due to the inherently high MOSFET input impedance. However, in a closed-loop CFOA, R_G should be much larger than the output impedance of the buffer. In bipolar realizations, it is fairly simple to obtain a buffer with low output resistance, but this becomes more of a problem in CMOS due to the inherently lower gain of MOSFET devices. As a result, R_G typically needs to be higher in a CMOS CFOA than in a bipolar realization, and consequently, R_F needs to be increased above the value required for optimum HF performance. Additionally, the fact that the input buffer is not in the feedback loop imposes linearity limitations on the structure, especially if the impedance at the gain node is not very high. Regardless of these problems, CFOAs exhibit excellent HF characteristics and are increasingly popular in video and communications applications [13].

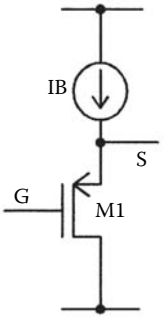

FIGURE 17.4 Simple PMOS source follower.

The following sections outline the development of a novel low output impedance CMOS buffer, which is then employed in a CMOS CFOA to reduce the minimum allowable value of R_G.

17.2.2 CMOS Compound Device

A simple PMOS source follower is shown in Figure 17.4. The output impedance seen looking into the source of M1 is approximately $Z_{out} = 1/g_m$, where g_m is the small-signal transconductance of M1. To increase g_m, the drain current of M1 could be increased, which leads to an increased power dissipation. Alternatively, the dimensions of M1 can be increased, resulting in additional parasitic capacitance and hence an inferior frequency response. Figure 17.5 shows a configuration that achieves a higher transconductance than the simple follower of Figure 17.3 for the same bias current [11]. The current of M2 is fed back to M1 through the a:1 current mirror. This configuration can be viewed as a compound transistor whose gate is the gate of M1 and whose source is the source of M2. The impedance looking into the compound source can be approximated as $Z_{out} = (g_{m1} - a \cdot g_{m2})/(g_{m1} \cdot g_{m2})$, where g_{m1} and g_{m2} represent the small-signal transconductance of M1 and M2, respectively. The output impedance can be made small by setting the current mirror transfer ratio $a = g_{m1}/g_{m2}$.

The p-compound device is practically implemented as in Figure 17.6. In order to obtain a linear voltage transfer function from node 1 to 2, the gate-source voltages of M1 and M3 must cancel. The current mirror (M4–M2) acts as an NMOS–PMOS gate-source voltage matching circuit [14] and compensates for the difference in the gate-source voltages of M1 and M3, which would normally appear as an output offset. DC analysis, assuming a square law model for the MOSFETs, shows that the output voltage exactly follows the input voltage. However, in practice, channel length modulation and body effects preclude exact cancellation [15].

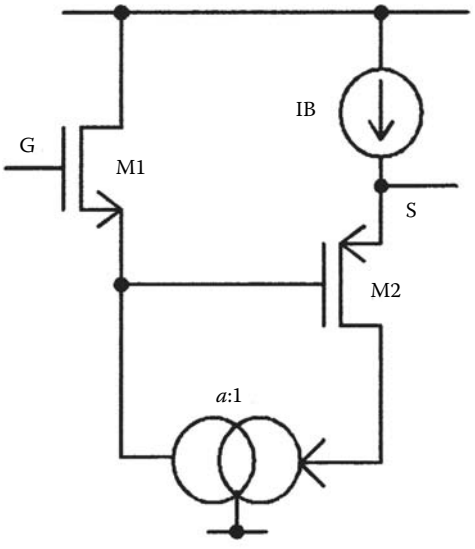

FIGURE 17.5 Compound MOS device.

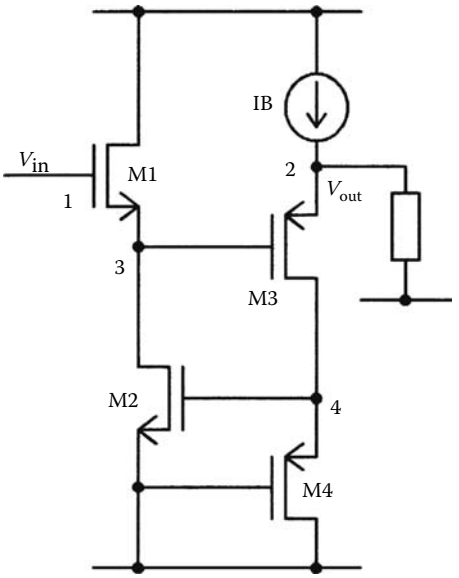

FIGURE 17.6 Actual p-compound device implementation.

17.2.3 Buffer and CFOA Implementation

The CFOA op-amp shown in Figure 17.7 has been implemented in a single-well 0.6 μm digital CMOS process [11]; the corresponding layout plot is shown in Figure 17.8. The chip has an area of 280 μm by 330 μm and a power dissipation of 12 mW. The amplifier comprises two voltage followers (input and output) connected by cascoded current mirrors to enhance the gain node impedance. A compensation capacitor ($C_c = 0.5$ pF) at the gain node ensures adequate phase margin and thus closed-loop stability. The voltage followers have been implemented with two compound transistors, p-type and n-type, in a push–pull arrangement. Two such compound transistors in the output stage are shown shaded in Figure 17.7. The input voltage follower of the CFOA was initially tested open-loop, and measured results are summarized in Table 17.1. The load is set to 10 kΩ/10 pF, except where mentioned otherwise, 10 kΩ being a limit imposed by overall power dissipation of the chip. Intermodulation distortion was

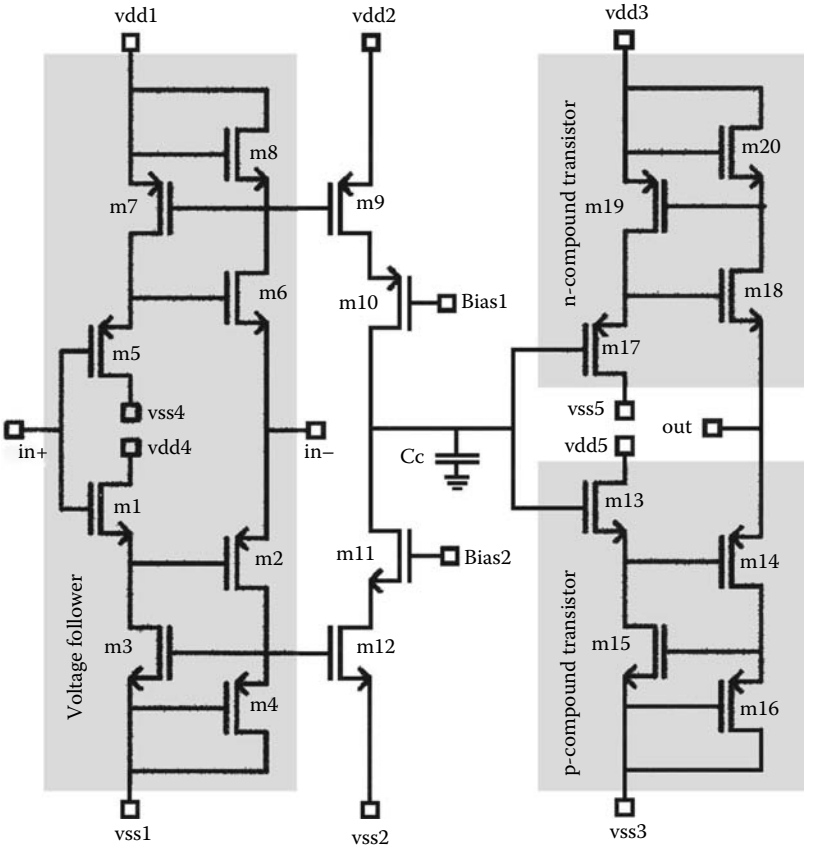

FIGURE 17.7 CFOA schematic.

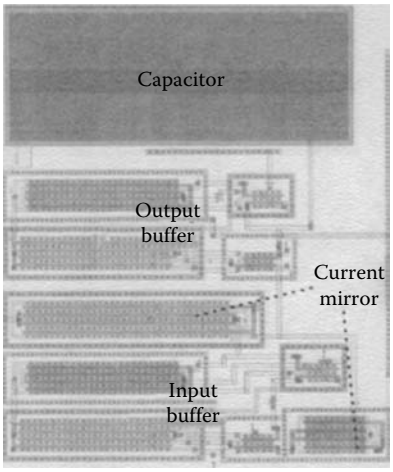

FIGURE 17.8 CFOA layout plot.

measured with 2 tons separated by 200 kHz. The measured output impedance of the buffer is given in Figure 17.9. It remains below 80 Ω up to a frequency of about 60 MHz, when it enters an inductive region. A maximum impedance of 140 Ω is reached around 160 MHz. Beyond this frequency, the output impedance is dominated by parasitic capacitances. The inductive behavior is characteristic of the use of feedback to reduce output impedance, and can cause stability problems when driving capacitive loads. Small-signal analysis (summarized in Table 17.2) predicts a double zero in the output impedance [15].

Making factor G in Table 17.2 small will reduce the output impedance, but also moves the double zero to lower frequencies and intensifies the inductive behavior. The principal trade-off in this configuration is between output impedance magnitude and inductive behavior. In practice, the output impedance can be reduced by a factor of 3 while still maintaining good stability when driving capacitive loads. Figure 17.10 shows the measured frequency response of the buffer. Given the low power dissipation, excellent slew rates have been achieved (Table 17.2).

After the characterization of the input buffer stage, the entire CFOA was tested to confirm the suitability of the compound transistors for the implementation of more complex building blocks. Open-loop transimpedance measurements are shown in Figure 17.11. The bandwidth of the amplifier was measured at gain settings of 1, 2, 5, and 10 in a noninverting configuration, and the feedback resistor was trimmed to achieve maximum bandwidth at each gain setting separately. CFOA measurements are summarized in Table 17.3, loading conditions are again 10 kΩ/10 pF.

Figure 17.12 shows the measured frequency response for various gain settings. The bandwidth remains constant at 110 MHz for gains of 1, 2, and 5, consistent with the expected behavior of a CFOA. The bandwidth falls to 42 MHz for a gain of 10 due to the finite output impedance of the input buffer stage which series as the CFOA inverting input. Figure 17.13 illustrates the step response of the CFOA driving a 10 kΩ/10 pF load at a voltage gain of 2. It can be seen that the inductive behavior of the buffers has little effect on the step response. Finally, distortion measurements were carried out for the entire CFOA for gain settings 2, 5, and 10 and are summarized in Table 17.3. HD2 levels can be further improved by employing a double-balanced topology. A distortion spectrum is shown in Figure 17.14; the onset of HD3 is due to clipping at the test conditions.

TABLE 17.1 Voltage Buffer Performance

Power Supply	5 V	Dissipation	5 mW
DC gain (no load)	−3.3 dB	Bandwidth	140 MHz
Output impedance	75 Ω	Min. load resistance	10 kΩ
HD2 ($V_{in} = 200$ mV$_{rms}$)	1 MHz	−50 dB	
	10 MHz	−49 dB	
	20 MHz	−45 dB	
IM3 ($V_{in} = 200$ mV$_{rms}$)	20 MHz, $\Delta f = 200$ kHz	−53 dB	
Slew rate	(Load = 10 pF)	+130 V/μs	−72 V/μs
Input-referred noise	10 nV$\sqrt{\text{Hz}}$		

Note: Load = 10 kΩ/10 pF, except for slew rate measurement.

TABLE 17.2 Voltage Transfer Function and Output Impedance of Compound Device

$Z_{out} = \dfrac{G}{(g_{m1} + g_{ds1} + g_{ds2}) \cdot (g_{m3} + g_{ds3}) \cdot (g_{m4} + g_{ds4})}$
$\dfrac{V_{out}}{V_{in}} = \dfrac{g_{m1} \cdot g_{m3} \cdot (g_{m4} + g_{ds4})}{(g_{m1} + g_{ds1} + g_{ds2}) \cdot (g_{m3} + g_{ds3}) \cdot (g_{m4} + g_{ds4}) + g_L \cdot G}$
$G = (g_{m1} + g_{ds1} + g_{ds2}) \cdot (g_{m4} + g_{ds4} + g_{ds3}) - g_{m2} \cdot g_{m3}$

17.3 RF Low-Noise Amplifiers

This section reviews the important performance criteria demanded of the front-end amplifier in a wireless communication receiver. The design of CMOS LNAs for front-end wireless communication receiver applications is then addressed. Section 17.4 considers the related topic of LNAs for optical receiver front-ends.

17.3.1 Specifications

The front-end amplifier in a wireless receiver must satisfy demanding requirements in terms of noise, gain, impedance matching, and linearity.

17.3.1.1 Noise

Since the incoming signal is usually weak, the front-end circuits of the receiver must possess very low noise characteristics so that the original signal can be recovered. Provided that the gain of the front-end amplifier is sufficient so as to suppress noise from the subsequent stages, the receiver noise performance is determined predominantly by the front-end amplifier. Hence, the front-end amplifier should be an LNA.

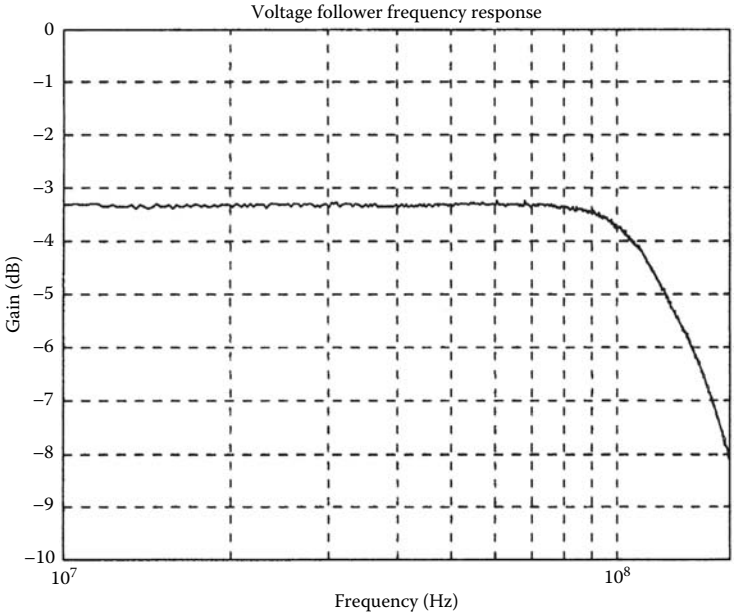

FIGURE 17.10 Measured buffer frequency response.

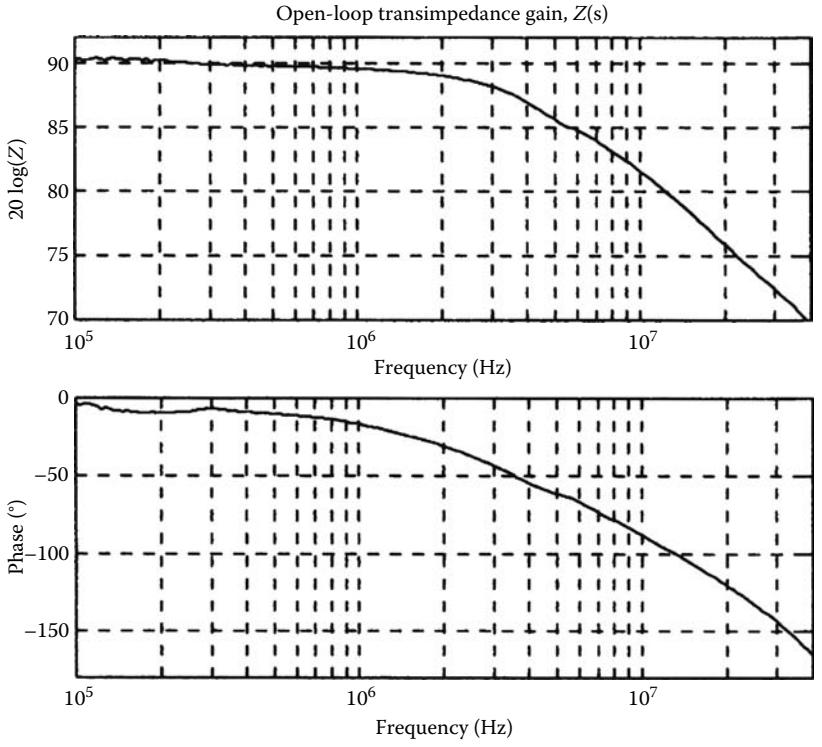

FIGURE 17.11 Measured CFOA open-loop transimpedance gain.

TABLE 17.3 CFOA Measurement Summary

Power Supply	5 V	Power Dissipation	12 mW
Gain	Bandwidth (MHz)		
1	117		
2	118		
5	113		
10	42		
Frequency	**Input (mV rms)**	**Gain**	**HD2 (dB)**
1 MHz	140	2	−51
	40	5	−50
	10	10	−49
10 MHz	80	2	−42
	40	5	−42
	13	10	−43

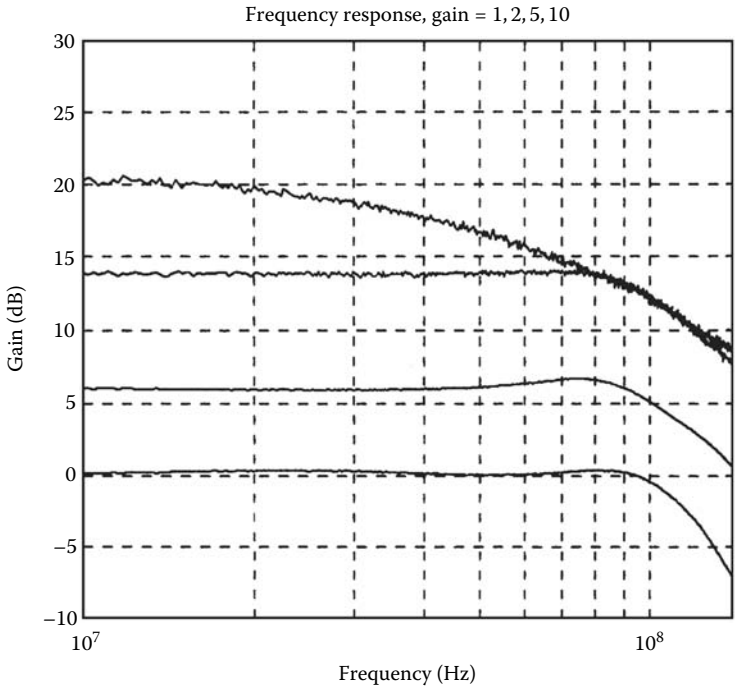

FIGURE 17.12 Measured CFOA closed-loop frequency response.

17.3.1.2 Gain

The voltage gain of the LNA must be high enough to ensure that noise contributions from the following stages can be safely neglected. As an example, Figure 17.15 shows the first three stages in a generic front-end receiver, where the gain and output-referred noise of each stage are represented by G_i and N_i ($i = 1, 2, 3$), respectively. The total noise at the third stage output is given by

$$N_{\text{out}} = N_{\text{in}}G_1G_2G_3 + N_1G_2G_3 + N_2G_3 + N_3 \tag{17.9}$$

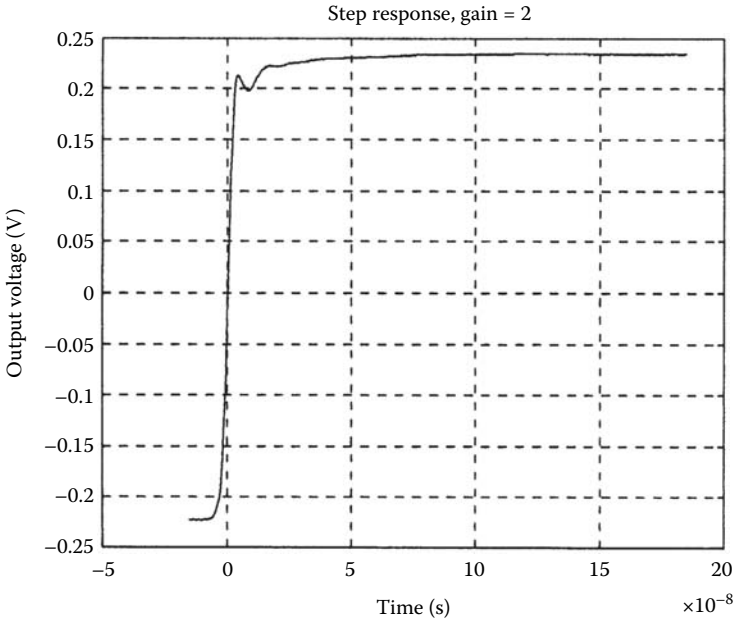

FIGURE 17.13 Measured CFOA step response.

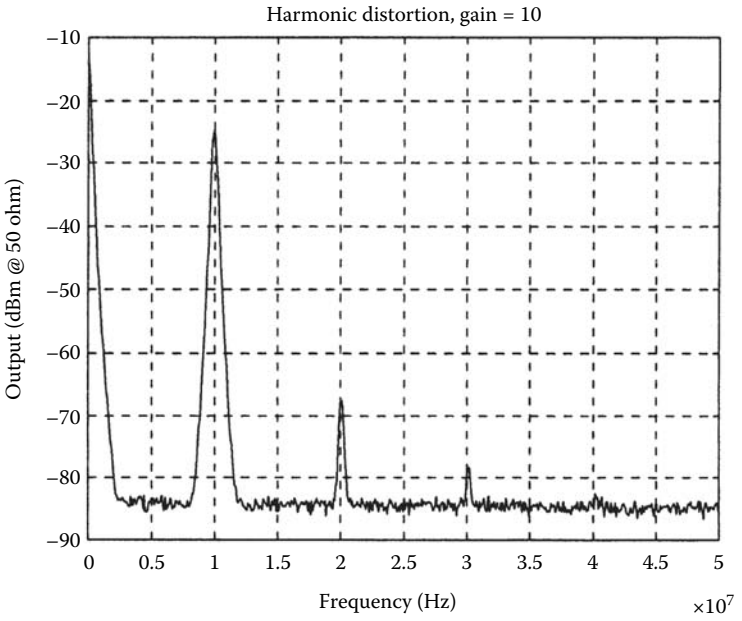

FIGURE 17.14 CFOA harmonic distortion measurements.

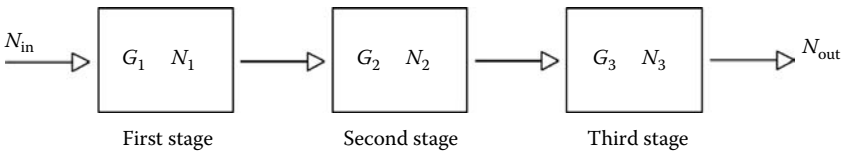

FIGURE 17.15 Three-stage building block with gain G_i and noise N_i per stage.

This output noise (N_{out}) can be referred to the input to derive an equivalent input noise (N_{eq}):

$$N_{eq} = \frac{N_{out}}{\text{Gain}} = \frac{N_{out}}{G_1 G_2 G_3} = N_{in} + \frac{N_1}{G_1} + \frac{N_2}{G_1 G_2} + \frac{N_3}{G_1 G_2 G_3} \tag{17.10}$$

According to Equation 23.10, the gain of the first stage should be high in order to reduce noise contributions from subsequent stages. However, if the gain is too high, a large input signal may saturate the subsequent stages, yielding intermodulation products which corrupt the desired signal. Thus, optimization is inevitable.

17.3.1.3 Input Impedance Matching

The input impedance of the LNA must be matched to the antenna impedance over the frequency range of interest, in order to transfer the maximum available power to the receiver.

17.3.1.4 Linearity

Unwanted signals at frequencies fairly near the frequency band of interest may reach the LNA with signal strengths many times higher than that of the wanted signal. The LNA must be sufficiently linear to prevent these out-of-band signals from generating intermodulation products within the wanted frequency band, and thus degrading the reception of the desired signal. Since third-order mixing products are usually dominant, the linearity of the LNA is related to the "third-order intercept point" (IP3), which is defined as the input power level that results in equal power levels for the output fundamental frequency component and the third-order intermodulation components. The dynamic range (DR) of a wireless receiver is limited at the lower bound by noise and at the upper band by nonlinearity.

17.3.2 CMOS Common-Source LNA: Simplified Analysis

17.3.2.1 Input Impedance Matching by Source Degeneration

For maximum power transfer, the input impedance of the LNA must be matched to the source resistance, which is normally 50 Ω. Impedance-matching circuits consist of reactive components and therefore are (ideally) lossless and noiseless. Figure 17.16 shows the small-signal equivalent circuit of a common-source (CS) LNA input stage with impedance-matching circuit, where the gate-drain capacitance C_{gd} is

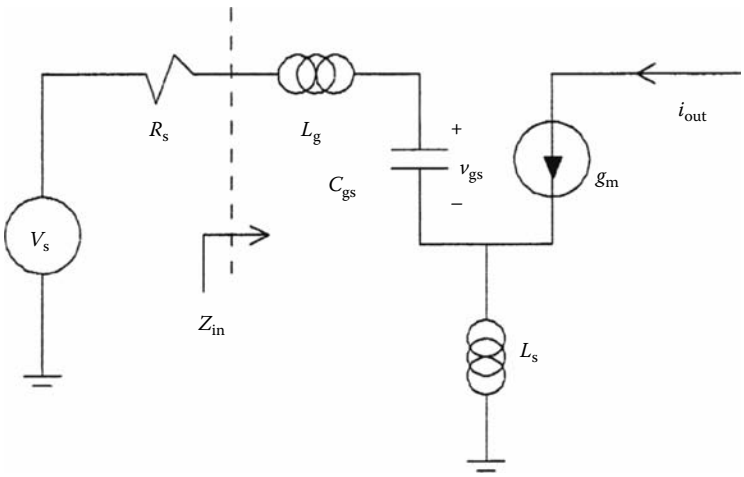

FIGURE 17.16 Simplified small-signal equivalent circuit of the CS stage.

assumed to have negligible effect and is thus neglected [16,17]. The input impedance of this CS input stage is given by

$$Z_{in} = j\omega(L_g + L_s) + \frac{1}{j\omega C_{gs}} + \frac{g_m}{C_{gs}} L_s \tag{17.11}$$

Thus, for matching, the two conditions below must be satisfied:

$$\text{(i) } \omega_o^2 = \frac{1}{(L_g + L_s)C_{gs}} \quad \text{and} \quad \text{(ii) } \frac{g_m}{C_{gs}} L_s = R_s \tag{17.12}$$

17.3.2.2 Noise Figure of CS Input Stage

Two main noise sources exist in a CS input stage as shown in Figure 17.17; thermal noise from the source resistor R_s (denoted $\overline{v_{Rs}^2}$) and channel thermal noise from the input transistor (denoted $\overline{i_d^2}$). The output noise current due to $\overline{v_{Rs}^2}$ can be determined from Figure 17.17 as

$$\overline{i_{nout1}^2} = \frac{g_m^2 \overline{v_{Rs}^2}}{\omega^2 (g_m L_s + R_s C_{gs})^2} = \frac{g_m^2}{4\omega^2 R_s^2 C_{gs}^2} \overline{v_{Rs}^2} \tag{17.13}$$

while the output noise current due to $\overline{i_d^2}$ can be evaluated as

$$\overline{i_{nout2}} = \frac{\overline{i_d}}{\left(1 + \frac{g_m L_s}{R_s C_{gs}}\right)} = \frac{1}{2}\overline{i_d} \quad \therefore \ \overline{i_{nout2}^2} = \frac{1}{4}\overline{i_d^2} \tag{17.14}$$

From Equations 17.13 and 17.14, the noise figure (NF) of the CS input stage is determined as

$$NF = 1 + \frac{\overline{i_{nout2}^2}}{i_{nout1}^2} = 1 + \Gamma\left(\frac{\omega_o^2 R_s C_{gs}^2}{g_m}\right) = 1 + \Gamma\left(\frac{L_s}{L_s + L_g}\right) \tag{17.15}$$

In practice, any inductor (especially a fully integrated inductor) has an associated resistance that will contribute thermal noise, degrading the NF in Equation 17.15.

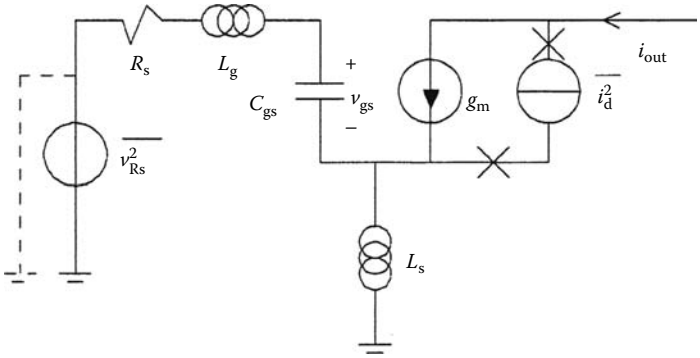

FIGURE 17.17 Simplified noise equivalent circuit of the CS stage. $\overline{V_{Rs}^2} = 4kT_{Rs}$; $\overline{id^2} = KT\Gamma g_{dc}$.

17.3.2.3 Voltage Amplifier with Inductive Load

Referring to Figure 17.15, the small-signal current output is given by

$$i_{\text{out}} = \frac{g_{\text{m}} v_{\text{s}}}{[1 - \omega^2 C_{\text{gs}}(L_{\text{g}} + L_{\text{s}})] + j\omega(g_{\text{m}} L_{\text{s}} + R_{\text{s}} C_{\text{gs}})} \tag{17.16}$$

For an inductive load (L_1) with a series internal resistance r_{L1}, the output voltage is thus

$$v_{\text{out}} = -i_{\text{out}}(r_{\text{L1}} + j\omega L_1) = \frac{-(r_{\text{L1}} + j\omega L_1) g_{\text{m}} v_{\text{s}}}{[1 - \omega^2 C_{\text{gs}}(L_{\text{g}} + L_{\text{s}})] + j\omega(g_{\text{m}} L_{\text{s}} + R_{\text{s}} C_{\text{gs}})} \tag{17.17}$$

Assuming that the input is impedance matched, the voltage gain at the output is given by

$$\left|\frac{v_{\text{out}}}{v_{\text{s}}}\right| = \frac{\sqrt{(r_{\text{L1}})^2 + (\omega_{\text{o}})^2 (L_1)^2}}{2\omega_{\text{o}} L_{\text{s}}} = \frac{r_{\text{L1}}}{2\omega_{\text{o}} L_{\text{s}}} \sqrt{1 + \left(\frac{\omega_{\text{o}} L_1}{r_{\text{L1}}}\right)^2} \cong \frac{1}{2}\omega_{\text{o}} \left(\frac{L_1}{L_{\text{s}}}\right)\left(\frac{L_1}{r_{\text{L1}}}\right) \tag{17.18}$$

17.3.3 CMOS Common-Source LNA: Effect of C_{gd}

In the analysis so far, the gate-drain capacitance (C_{gd}) has been assumed to be negligible. However, at very high frequencies, this component cannot be neglected. Figure 17.18 shows the modified input stage of a CS LNA including C_{gd} and an input ac-coupling capacitance C_{in}. Small-signal analysis shows that the input impedance is now given by

$$Z_{\text{in}} = \frac{g_{\text{m}} L_{\text{s}}}{C_{\text{gs}} + C_{\text{gd}}\left[j\omega L_{\text{s}} g_{\text{m}} + \frac{g_{\text{m}}(1 - \omega^2 L_{\text{s}} C_{\text{gd}})}{\frac{1}{Z_{\text{L}}} + j\omega C_{\text{gd}}}\right]} \tag{17.19}$$

Equation 17.19 exhibits resonance frequencies that occur when

$$1 - \omega^2 L_{\text{s}} C_{\text{gs}} = 0 \quad \text{and} \quad 1 - \omega^2 L_{\text{g}} C_{\text{in}} = 0 \tag{17.20}$$

Equation 17.19 indicates that the input impedance matching is degraded by the load Z_L when C_{gd} is included in the analysis.

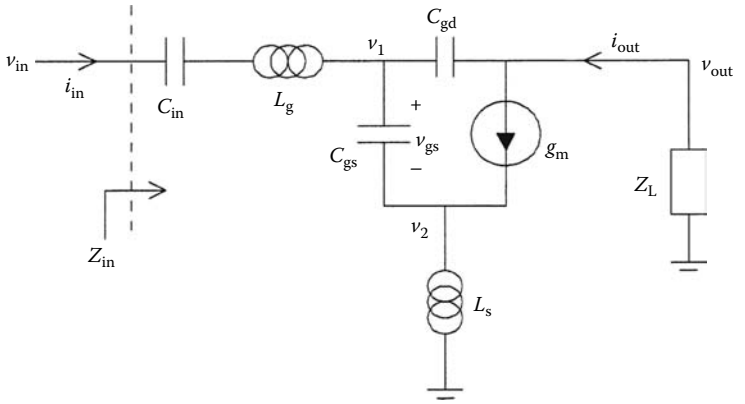

FIGURE 17.18 Noise equivalent circuit of the CS stage, including effects of C_{gd}.

17.3.3.1 Input Impedance with Capacitive Load

If the load Z_L is purely capacitive, that is,

$$Z_L = \frac{1}{j\omega C_L} \tag{17.21}$$

then the input impedance can be easily matched to the source resistor R_s. Substituting Equation 17.21 for Z_L, the bracketed term in the denominator of Equation 17.19 becomes

$$d_1 = j\omega L_s g_m + \frac{g_m(1-\omega^2 L_s C_{gd})}{j\omega(C_{gd}+C_L)} = 0 \tag{17.22}$$

under the condition that

$$1 - \omega^2 L_s(2C_{gd} + C_L) = 0 \tag{17.23}$$

The three conditions in Equations 17.20 and 17.23 should be met to ensure input impedance matching. However, in practice, we are unlikely to be in the situation of using a load capacitor.

17.3.3.2 Input Impedance with Inductive Load

If $Z_L = j\omega L_L$, the CS LNA input impedance is given by

$$Z_{in} = \frac{g_m L_s}{C_{gs} + j\omega C_{gd} g_m \left[L_s + L_L\left(\frac{1-\omega^2 L_s C_{gd}}{1-\omega^2 L_L C_{gd}}\right)\right]} \tag{17.24}$$

In order to match to a purely resistive input, the value of the reactive term in Equation 17.24 must be negligible, which is difficult to achieve.

17.3.4 Cascode CS LNA

17.3.4.1 Input Matching

As outlined in the paragraph above, the gate-drain capacitance (C_{gd}) degrades the input impedance matching and therefore reduces the power transfer efficiency. In order to reduce the effect of C_{gd}, a cascoded structure can be used [18–20]. Figure 17.19 shows a cascode CS LNA. Since the voltage gain from the gate to the drain of M1 is unity, the gate-drain capacitance (C_{gd1}) no longer sees the full input–output voltage swing which greatly improves the input–output isolation. The input impedance can be approximated by Equation 17.11, thus allowing a simple matching circuit to be employed [18].

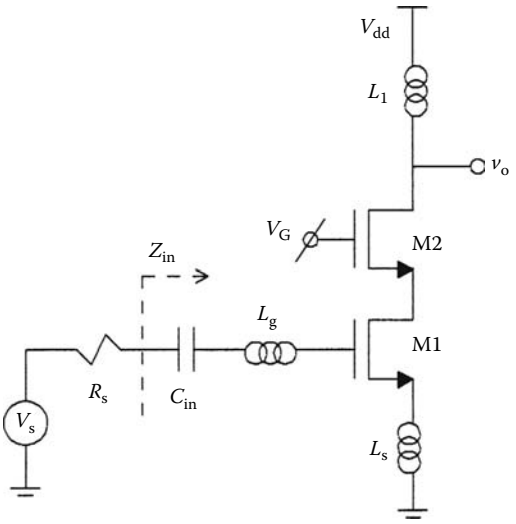

FIGURE 17.19 Cascode CS LNA.

17.3.4.2 Voltage Gain

Figure 17.20 shows the small-signal equivalent circuit of the cascode CS LNA. Assuming that input is fully matched to the source, the voltage gain of the amplifier is given by

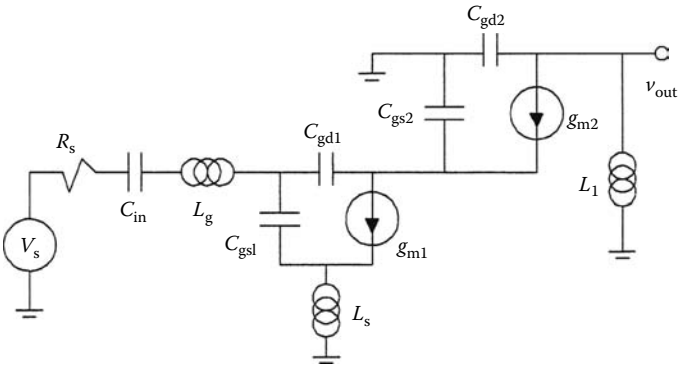

FIGURE 17.20 Equivalent circuit of cascode CS LNA.

$$\frac{v_{out}}{v_s} = -\frac{1}{2}\left(\frac{j\omega L_1}{1-\omega^2 L_1 C_{gd2}}\right)\left(\frac{g_{m2}}{g_{m2}+j\omega C_{gs2}}\right)\left[\frac{g_{m1}}{(1-\omega^2 L_s C_{gs1})+j\omega L_s g_{m1}}\right] \tag{17.25}$$

At the resonant frequency, the voltage gain is given by

$$\frac{v_{out}}{v_s}(\omega_o) = -\frac{1}{2}\left(\frac{L_1}{L_s}\right)\left(\frac{1}{1-\omega_o^2 L_1 C_{gd2}}\right)\times\frac{1}{1+j\omega_o\left(\frac{C_{gs1}}{g_{m2}}\right)} \approx -\frac{1}{2}\left(\frac{L_1}{L_s}\right)\times\frac{1}{1+j\left(\frac{\omega_o}{\omega_T}\right)} \tag{17.26}$$

From Equation 17.26, the voltage gain is dependent on the ratio of the load and source inductance values. Therefore, high gain accuracy can be achieved since this ratio is largely process independent.

17.3.4.3 Noise Figure

Figure 17.21 shows an equivalent circuit of the cascode CS LNA for noise calculations. Three main noise sources can be identified: the thermal noise voltage from R_s, and the channel thermal noise currents from M1 and M2. Assuming that the input impedance is matched to the sources, the output noise current due to $\overline{v_{Rs}^2}$ can be derived as

$$\overline{i_{out1}} = \frac{1}{2j\omega_o L_s(1-\omega_o^2 L_1 C_{gd2})}\left(\frac{g_{m2}}{g_{m2}+j\omega_o C_{gs2}}\right)\overline{v_{Rs}} \tag{17.27}$$

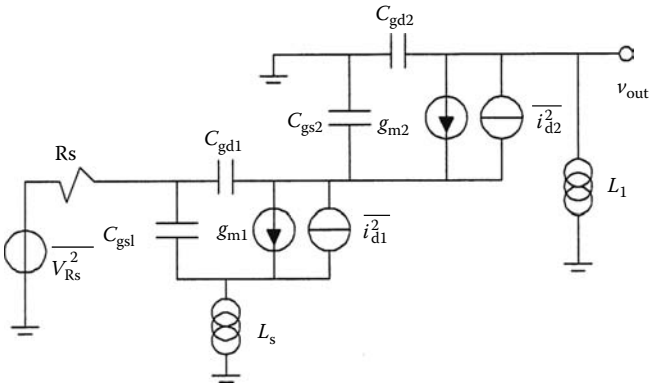

FIGURE 17.21 Noise equivalent circuit of cascode CS LNA.

The output noise current contribution due to $\overline{i_{d1}^2}$ of M1 is given by

$$\overline{i_{out2}} = \frac{1}{2(1-\omega_o^2 L_1 C_{gd2})}\left(\frac{g_{m2}}{g_{m2}+j\omega_o C_{ds2}}\right)\overline{i_{d1}} \tag{17.28}$$

The output noise current due to $\overline{i_{d2}^2}$ of M2 is given by

$$\overline{i_{out3}} = \frac{j\omega_o C_{gs2}}{(1-\omega_o^2 L_1 C_{gd2})(g_{m2}+j\omega_o C_{gs2})}\overline{i_{d2}} \tag{17.29}$$

The NF of the cascode CS LNA can thus be derived as

$$\mathrm{NF} = 1 + \frac{\overline{i_{out2}^2}}{\overline{i_{out1}^2}} + \frac{\overline{i_{out3}^2}}{\overline{i_{out1}^2}} = 1 + \Gamma\left(1 + \frac{4\omega_o^2 C_{gs2}^2}{g_{m1}g_{m2}}\right) \tag{17.30}$$

In order to improve the NF, the transconductance values (g_m) of M1 and M2 should be increased. Since the gate-source capacitance (C_{gs2}) of M2 is directly proportional to the gate width, the gate width of M2 cannot be enlarged to increase the transconductance. Instead, this increase should be realized by increasing the gate bias voltage.

17.4 Optical Low-Noise Preamplifiers

Figure 17.22 shows a simple schematic diagram of an optical receiver, consisting of a photodetector, a preamplifier, a wide-band voltage amplifier, and a predetection filter. Since the front-end transimpedance preamplifier is critical in determining the overall receiver performance, it should possess a wide bandwidth so as not to distort the received signal, high gain to reject noise from subsequent stages, low noise to achieve high sensitivity, wide DR, and low intersymbol interference (ISI).

17.4.1 Front-End Noise Sources

Receiver noise is dominated by two main noise sources: the detector (PIN photodiode) noise and the amplifier noise. Figure 17.23 illustrates the noise equivalent circuit of the optical receiver.

17.4.1.1 PIN Photodiode Noise

The noise generated by a PIN photodiode arises mainly from three shot noise contributions: quantum noise $S_q(f)$, thermally generated dark-current shot noise $S_D(f)$, and surface leakage-current shot noise $S_L(f)$. Other noise sources in a PIN photodiode, such as series resistor noise, are negligible in comparison. The quantum noise $S_q(f)$, also called signal-dependent shot noise, is produced by the light-generating

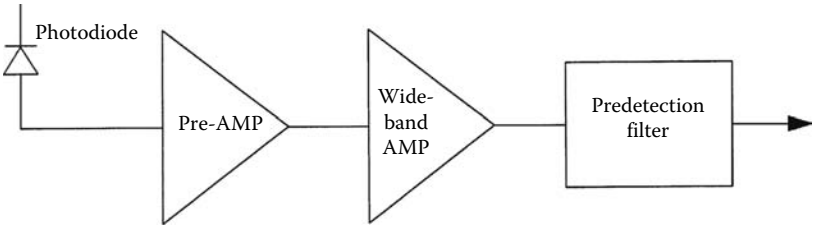

FIGURE 17.22 Front-end optical receiver.

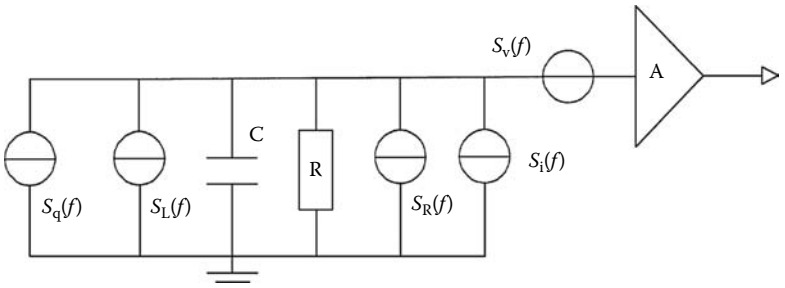

FIGURE 17.23 Noise equivalent circuit of the front-end optical receiver.

nature of photonic detection and has a spectral density $S_q(f) = 2qI_{pd}\Delta f$, where I_{pd} is the mean signal current arising from the Poisson statistics. The dark-current shot noise $S_D(f)$ arises in the photodiode bulk material. Even when there is no incident optical power, a small reverse leakage current still flows, resulting in shot noise with a spectral density $S_D(f) = 2qI_{DB}\Delta f$, where I_{DB} is the mean thermally generated dark current. The leakage shot noise $S_L(f)$ occurs because of surface effects around the active region, and is described by $S_L(f) = 2qI_{SL}\Delta f$, where I_{SL} is the mean surface leakage current.

17.4.1.2 Amplifier Noise

For a simple noise analysis, the pre- and postamplifiers in Figure 17.22 are merged to a single amplifier with a transfer function of $A_v(\omega)$. The input impedance of the amplifier is modeled as a parallel combination of R_{in} and C_{in}.

If the photodiode noise is negligibly small, the amplifier noise will dominate the whole receiver noise performance, as can be inferred from Figure 17.23. The equivalent noise current and voltage spectral densities of the amplifier are represented as S_i (A^2/Hz) and S_v (V^2/Hz), respectively.

17.4.1.3 Resistor Noise

The thermal noise generated by a resistor is directly proportional to the absolute temperature T and is represented by a series noise voltage generator or by a shunt noise current generator [21] of value:

$$\overline{v_R^2} = 4kTR\Delta f \quad \text{or} \quad \overline{i_R^2} = 4kT\frac{1}{R}\Delta f \tag{17.31}$$

where

k is Boltzmann's constant

R is the resistance

17.4.2 Receiver Performance Criteria

17.4.2.1 Equivalent Input Noise Current $\overline{\langle i_{eq}^2 \rangle}$

The transfer function from the current input to the amplifier output voltage is given by

$$Z_T(\omega) = \frac{V_{out}}{I_{pd}} = Z_{in}A_v(\omega) = \frac{R_{in}}{1j\omega R_{in}(C_{pd} + C_{in})}A_v(\omega) \tag{17.32}$$

where

C_{pd} is the photodiode capacitance

R_{in} and C_{in} are the input resistance and capacitance of the amplifier, respectively

Assuming that the photodiode noise contributions are negligible and that the amplifier noise sources are uncorrelated, the equivalent input noise current spectral density can be derived from Figure 17.23 as

$$S_{\text{eq}}(f) = S_i + \frac{S_v}{[Z_{\text{in}}]^2} = S_i + S_v\left[\frac{1}{R_{\text{in}}^2} + (2\pi f)^2(C_{\text{pd}} + C_{\text{in}})^2\right] \tag{17.33}$$

The total mean-square noise output voltage $\langle\overline{v_{\text{no}}^2}\rangle$ is calculated by combining Equations 17.32 and 17.33 as follows:

$$\langle\overline{v_{\text{no}}^2}\rangle = \int_0^\infty S_{\text{eq}}(f)|Z_{\text{T}}(f)|^2\,\text{d}f \tag{17.34}$$

This total noise voltage can be referred to the input of the amplifier by dividing it by the squared dc gain $|Z_{\text{T}}(0)|^2$ of the receiver, to give an equivalent input mean-square noise current:

$$\begin{aligned}\left\langle\overline{i_{\text{eq}}^2}\right\rangle &= \frac{\langle\overline{v_{\text{no}}^2}\rangle}{|Z_{\text{T}}(0)|^2} = \left(S_i + \frac{S_v}{R_{\text{in}}^2}\right)\int_0^\infty \frac{|Z_{\text{T}}(f)|^2}{|Z_{\text{T}}(0)|^2}\,\text{d}f + S_v[2\pi(C_{\text{pd}} + C_{\text{in}})]^2\int_0^\infty f^2\frac{|Z_{\text{T}}(f)|^2}{|Z_{\text{T}}(0)|^2}\,\text{d}f \\ &= \left(S_i + \frac{S_v}{R_{\text{in}}^2}\right)I_2B + [2\pi(C_{\text{pd}} + C_{\text{in}})]^2 I_3B^3S_v\end{aligned} \tag{17.35}$$

where

B is the operating bit-rate

$I_2(=0.56)$ and $I_3(=0.083)$ are the Personick second and third integrals, respectively, as given in Ref. [22]

According to Morikuni et al. [23], the Personick integral in Equation 17.35 is correct only if a receiver produces a raised-cosine output response from a rectangular input signal at the cut-off bit-rate above which the frequency response of the receiver is zero. However, the Personick integration method is generally preferred when comparing the noise (or sensitivity) performance of different amplifiers.

17.4.2.2 Optical Sensitivity

Optical sensitivity is defined as the minimum received optical power incident on a perfectly efficient photodiode connected to the amplifier, such that the presence of the amplifier noise corrupts on average only 1 bit per 10^9 bits of incoming data. Therefore, a detected power greater than the sensitivity level guarantees system operation at the desired performance. The optical sensitivity is predicted theoretically by calculating the equivalent input noise spectral density of the receiver, and is calculated [24] via Equation 17.36:

$$S = 10\log_{10}\left(Q\frac{hc}{q\lambda}\sqrt{\left\langle i_{\text{eq}}^2\right\rangle}\cdot\frac{1}{1\text{mW}}\right)(\text{dBm}) \tag{17.36}$$

where

h is Planck's constant

c is the speed of light

q is the electronic charge

λ (μm) is the wavelength of light in an optical fiber

$Q = \sqrt{\text{SNR}}$, where SNR represents the required signal-to-noise ratio (SNR)

The value of Q should be 6 for a bit error rate (BER) of 10^{-9}, and 7.04 for a BER of 10^{-12}. The relation between Q and BER is given by

$$\text{BER} = \frac{\exp(-Q^2/2)}{\sqrt{2\pi}Q} \tag{17.37}$$

Since the number of photogenerated electrons in a single bit is very large (more than 10^4) for optoelectronic integrated receivers [25], Gaussian statistics of the above BER equation can be used to describe the detection probability in PIN photodiodes.

17.4.2.3 SNR at the Photodiode Terminal [22]

Among the photodiode noise sources, quantum noise is generally dominant and can be estimated as

$$\left\langle \overline{i_n^2} \right\rangle_q = 2qI_{\text{pd}}B_{\text{eq}} \tag{17.38}$$

where

I_{pd} is the mean signal current
B_{eq} is the equivalent noise bandwidth

The SNR referred to the photodiode terminal is thus given by

$$\text{SNR} = \frac{I_{\text{pd}}^2}{\left\langle \overline{i_{\text{n}}^2} \right\rangle_{\text{pd}} + \frac{4kTB_{\text{eq}}}{R_{\text{B}}} + \left\langle \overline{i_{\text{eq}}^2} \right\rangle_{\text{amp}}} \tag{17.39}$$

where all noise contributions due to the amplifier are represented by the equivalent noise current $\left\langle \overline{i_{\text{eq}}^2} \right\rangle_{\text{amp}}$. It is often convenient to combine the noise contributions from the amplifier and the photodiode with the thermal noise from the bias resistor, by defining an NF:

$$\left\langle \overline{i_{\text{n}}^2} \right\rangle_{\text{pd}} + \frac{4kTB_{\text{eq}}}{R_{\text{B}}} + \left\langle \overline{i_{\text{eq}}^2} \right\rangle_{\text{amp}} = \frac{4kTB_{\text{eq}}\text{NF}}{R_{\text{B}}} \tag{17.40}$$

The SNR at the photodiode input is thus given by

$$\text{SNR} \cong \frac{I_{\text{pd}}^2 R_{\text{B}}}{4kTB_{\text{eq}}\text{NF}} \tag{17.41}$$

17.4.2.4 Intersymbol Interference

When a pulse passes through a band-limited channel, it gradually disperses. When the channel bandwidth is close to the signal bandwidth, the expanded rise and fall times of the pulse signal will cause successive pulses to overlap, deteriorating the system performance and giving higher error rates. This pulse overlapping is known as ISI. Even with raised signal power levels, the error performance cannot be improved [26].

In digital optical communication systems, sampling at the output must occur at the point of maximum signal in order to achieve the minimum error rate. The output pulse shape should therefore be chosen to maximize the pulse amplitude at the sampling instant and give a zero at other sampling points; that is, at multiples of $1/B$, where B is the data-rate. Although the best choice for this purpose is the sinc-function

pulse, in practice a raised-cosine spectrum pulse is used instead. This is because the sinc-function pulse is very sensitive to changes in the input pulse shape and variations in component values, and because it is impossible to generate an ideal sinc-function.

17.4.2.5 Dynamic Range

The DR of an optical receiver quantifies the range of detected power levels within which correct system operation is guaranteed. DR is conventionally defined as the difference between the minimum input power (which determines sensitivity) and the maximum input power (limited by overload level). Above the overload level, the bit-error-rate (BER) rises due to the distortion of the received signal.

17.4.3 Transimpedance (TZ) Amplifiers

High-impedance (HZ) amplifiers are effectively open-loop architectures, and exhibit a high gain but a relatively low bandwidth. The frequency response is similar to that of an integrator, and thus HZ amplifiers require an output equalizer to extend their frequency capabilities. In contrast, the transimpedance (TZ) configuration exploits resistive negative feedback, providing an inherently wider bandwidth and eliminating the need for an output equalizer. In addition, the use of negative feedback provides a relatively low input resistance and thus the architecture is less sensitive to the photodiode parameters. In a TZ amplifier, the photodiode bias resistor R_B can be omitted, since bias current is now supplied through the feedback resistor.

In addition to wider bandwidth, TZ amplifiers offer a larger DR because the transimpedance gain is determined by a linear feedback resistor, and not by a non-linear open-loop amplifier as is the case for HZ amplifiers. The DR of TZ amplifiers is set by the maximum voltage swing available at the amplifier output, provided no integration of the received signal occurs at the front end. Since the TZ output stage is a voltage buffer, the voltage swing at the output can be increased with high current operation. The improvement in DR in comparison to the HZ architecture is approximately equal to the ratio of open-loop to closed-loop gain [27]. Conclusively, the TZ configuration offers the better performance compromise compared to the HZ topology, and hence this architecture is preferred in optical receiver applications.

A schematic diagram of a TZ amplifier with PIN photodiode is shown in Figure 17.24. With an open-loop, high-gain amplifier and a feedback resistor, the closed-loop transfer function of the TZ amplifier is given by

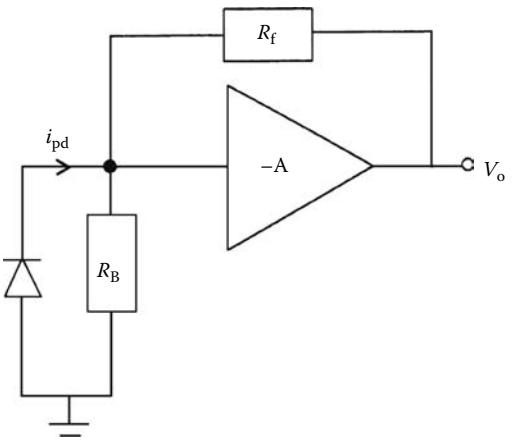

FIGURE 17.24 Schematic diagram of a transimpedance amplifier with photodiode.

$$Z_T(s) = \frac{-R_f}{\left(\frac{1+A}{A}\right) + sR_f\left[\frac{C_{in}+(1+A)C_f}{A}\right]} \cong \frac{R_f}{1 + sR_f\left(\frac{C_{in}}{A} + C_f\right)} \tag{17.42}$$

where

A is the open-loop mid-band gain of the amplifier which is assumed to be greater than unity
R_f is the feedback resistance
C_{in} is the total input capacitance of the amplifier including the photodiode and the parasitic capacitance
C_f represents the stray feedback capacitance

The −3 dB bandwidth of the TZ amplifier is approximately given by

$$f_{-3d} = \frac{(1+A)}{2\pi R_f C_T} \tag{17.43}$$

where C_T is the total input capacitance including the photodiode capacitance. The TZ amplifier can thus have wider bandwidth by increasing the open-loop gain, although the open-loop gain cannot be increased indefinitely without stability problems.

However, a trade-off between low noise and wide bandwidth exists, since the equivalent input noise current spectral density of TZ amplifier is given by

$$S_{eq}(f) = \frac{4kT}{R_f} + \frac{4kT}{R_B} + S_i(f) + S_v(f)\left[\left(\frac{1}{R_f} + \frac{1}{R_B}\right)^2 + (2\pi f)^2(C_{pd} + C_{in})^2\right] \tag{17.44}$$

where C_{in} is the input capacitance of the input transistor. Increasing the value of R_f reduces the noise current in Equation 17.44 but also shrinks the bandwidth in Equation 17.43. This conflict can be mitigated by making A in Equation 17.43 as large as the closed-loop stability allows [28]. However, the feedback resistance R_f cannot be increased indefinitely due to the DR requirements of the amplifier, since too large a feedback resistance causes the amplifier to be overloaded at high signal levels. This overloading can be avoided by using automatic gain control (AGC) circuitry, which automatically reduces the transimpedance gain in discrete steps to keep the peak output signal constant [27].

The upper limit of R_f is set by the peak amplitude of the input signal. Since the dc transimpedance gain is approximately equal to the feedback resistance R_f, the output voltage is given by $I_{pd} \times R_f$, where I_{pd} is the signal photocurrent. If this output voltage exceeds the maximum voltage swing at the output, the amplifier will be saturated and the output will be distorted, yielding bit errors. The minimum value of R_f is determined by the output signal level at which the performance of the receiver is degraded due to noise and offsets. For typical fiber-optic communication systems, the input signal power is unknown, and may vary from just above the noise floor to a large value enough to generate 0.5 mA at the detector diode [29].

The TZ configuration has some disadvantages over HZ amplifiers. The power consumption is fairly high, partly due to the broadband operation provided by negative feedback. A propagation delay exists in the closed-loop of the feedback amplifier that may reduce the phase margin of the amplifier and cause peaking in the frequency response. Additionally, any stray feedback capacitance C_f will further deteriorate the ac performance.

Among three types of TZ configuration in CMOS technology (common-source, common-drain, and common-gate TZ amplifiers), the common-gate configuration has potentially the highest bandwidth due to its inherently lower input resistance. Using a common-gate input configuration, the resulting amplifier bandwidth can be made independent of the photodiode capacitance (which is usually the limiting factor in achieving GHz preamplifier designs). Recently, a novel common-gate TZ amplifier has been demonstrated, which shows superior performance compared to various other configurations [30,31].

17.4.4 Layout for HF Operation

Wideband high-gain amplifiers have isolation problems irrespective of the choice of technology. Couplings from output to input, from the power supply rails, and from the substrate are all possible. Therefore, careful layout is necessary, and special attention must be given to stray capacitance, both on the integrated circuit and associated with the package [32].

17.4.4.1 Input/Output Isolation

For stable operation, a high level of isolation between I/O is necessary. Three main factors degrade the I/O isolation [33,34]: (1) capacitive coupling between I/O signal paths through the air and through the substrate; (2) feedback through the dc power supply rails and ground-line inductance; and (3) the package cavity resonance since at the cavity resonant frequency, the coupling between I/O can become very large.

In order to reduce the unwanted coupling (or to provide good isolation, typically more than 60 dB) between I/O, the I/O pads should be laid out to be diagonally opposite to each other on the chip with a thin ''left-to-right'' geometry between I/O. The small input signal enters on the left-hand side of the chip, while the large output signal exits on the far right-hand side. This helps to isolate the sensitive input stages from the larger signal output stages [35,36].

The use of fine line-widths and shielding are effective techniques to reduce coupling through the air. Substrate coupling can be reduced by shielding and by using a thin and low-dielectric substrate. Akazawa et al. [33] suggest a structure for effective isolation: a coaxial-like signal-line for high shielding, and a very thin dielectric dc feed-line structure for low characteristic impedance.

17.4.4.2 Reduction of Feedback through the Power Supply Rails

Careful attention should be given to the layout of power supply rails for stable operation and gain flatness. Power lines are generally inductive; thus, on-chip capacitive decoupling is necessary to reduce the HF power line impedance. However, a resonance between these inductive and capacitive components may occur at frequencies as low as several hundred megahertz, causing a serious dip in the gain–frequency response and an upward peaking in the isolation-frequency characteristics. One way to reduce this resonance is to add a series damping resistor to the power supply line, making the Q factor of the LC resonance small. Additionally, the power supply line should be widened to reduce the characteristic impedance/inductance. In practice, if the characteristic impedance is as small as several ohms, the dip and peaking do not occur, even without resistive termination [33].

Resonance also occurs between the IC pad capacitance (C_{pd}) and the bond-wire inductance (L_{bond}). This resonance frequency is typically above 2 GHz in miniature RF packages. Also in layout, the power supply rails of each IC chip stage should be split from the other stages in order to reduce the parasitic feedback (or coupling effect through wire-bonding inductance), which causes oscillation [34]. This helps to minimize crosstalk through power supply rail. The IC is powered through several pads and each pad is individually bonded to the power supply line.

17.4.4.3 I/O Pads

The bond pads on the critical signal path (e.g., input pad and output pads) should be made as small as possible to minimize the pad-to-substrate capacitance [35]. A floating n-well placed underneath the pad will further reduce the pad capacitance since the well capacitance will appear in series with the pad capacitance. This floating well also prevents the pad metal from spiking into the substrate.

17.4.4.4 High-Frequency (HF) Ground

The best possible HF grounds to the sources of the driver devices (and hence the minimization of interstage crosstalk) can be obtained by separate bonding of each source pad of the driver MOSFETs to the ground plane that is very close to the chip [36]. A typical bond-wire has a self-inductance of a few nH,

which can cause serious peaking within the bandwidth of amplifiers or even instability. By using multiple bond-wires in parallel, the ground-line inductance can be reduced to less than 1 nH.

17.4.4.5 Flip-Chip Connection

In noisy environments, the noise-insensitive benefits of optical fibers may be lost at the receiver connection between the photodiode and the preamplifier. Therefore, proper shielding, or the integration of both components onto the same substrate, is necessary to prevent this problem. However, proper shielding is costly, while integration restricts the design to GaAs technologies.

As an alternative, the flip-chip interconnection technique using solder bumps has been used [37,38]. Small solder bumps minimize the parasitics due to the short interconnection lengths and avoid damages by mechanical stress. Also, it needs relatively low-temperature bonding and hence further reduces damage to the devices. Easy alignment and precise positioning of the bonding can be obtained by a self-alignment effect. Loose chip alignment is sufficient because the surface tension of the molten solder during reflow produces precise self-alignment of the pads [34]. Solder bumps are fabricated onto the photodiode junction area to reduce parasitic inductance between the photodiode and the preamplifier.

17.5 Fundamentals of RF Power Amplifier Design

17.5.1 PA Requirements

An important functional block in wireless communication transceivers is the power amplifier (PA). The transceiver PA takes as input the modulated signal to be transmitted, and amplifies this to the power level required to drive the antenna. Because the levels of power required to transmit the signal reliably are often fairly high, the PA is one of the major sources of power consumption in the transceiver. In many systems, power consumption may not be a major concern, as long as the signal can be transmitted with adequate power. For battery-powered systems, however, the limited amount of available energy means that the power consumed by all devices must be minimized so as to extend the transmit time. Therefore, power efficiency is one of the most important factors when evaluating the performance of a wireless system.

The basic requirement for a PA is the ability to work at low supply voltages as well as high operating frequencies, and the design becomes especially difficult due to the trade-offs between supply voltage, output power, distortion, and power efficiency that can be made. Moreover, since the PA deals with large signals, small-signal analysis methods cannot be applied directly. As a result, both the analysis and the design of PAs are challenging tasks.

This section will first present a study of various configurations employed in the design of state-of-the-art nonlinear RF PAs. Practical considerations toward achieving full integration of PAs in CMOS technology will also be highlighted.

17.5.2 Power Amplifier Classification

PAs currently employed for wireless communication applications can be classified into two categories: linear PAs and nonlinear PAs. For linear PAs, the output signal is controlled by the amplitude, frequency, and phase of the input signal. Conversely, for nonlinear PAs, the output signal is only controlled by the frequency of input signal.

Conventionally, linear PAs can be classified as Class A, Class B, or Class AB. These PAs produce a magnified replica of the input signal voltage or current waveform, and are typically used where accurate reproduction of both the envelope and the phase of the signal is required. However, either poor power efficiency or large distortion prevents them from being extensively employed in wireless communications.

Many applications do not require linear RF amplification. Gaussian minimum shift keying (GMSK) [39], the modulation scheme used in the European standard for mobile communications (GSM), is an

example of constant envelope modulation. In this case, the system can make use of the greater efficiency and simplicity offered by nonlinear PAs. The increased efficiency of nonlinear PAs, such as Class C, Class D, and Class E, results from techniques that reduce the average collector voltage–current product (i.e., power dissipation) in the switching device. Theoretically, these switching-mode PAs have 100% power efficiency since, ideally, there is no power loss in the switching device.

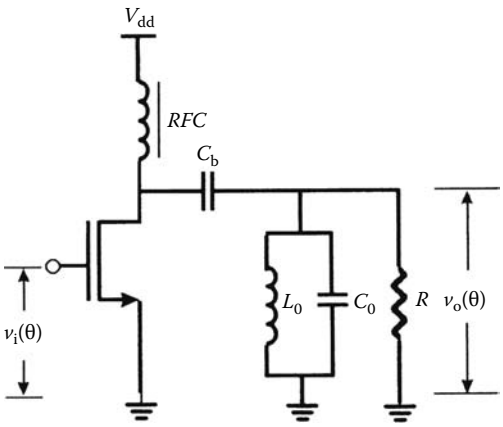

FIGURE 17.25 Single-ended Class A PA.

17.5.2.1 Linear Power Amplifiers

17.5.2.1.1 Class A

The basic structure of the Class A PA is shown in Figure 17.25 [40]. For Class A amplification, the conduction angle of the device is 360°, that is, the transistor is in its active region for the entire input cycle. The serious shortcoming with Class A PAs is their inherently poor power efficiency, since the transistor is always dissipating power. The efficiency of a single-ended Class A PA is ideally limited to 50%. However, in practice, few designs can reach this ideal efficiency due to additional power loss in the passive components. In an inductorless configuration, the efficiency is only about 25% [41].

17.5.2.1.2 Class B

A PA is defined as Class B when the conduction angle for each transistor of a push–pull pair is 180° during any one cycle. Figure 17.26 shows an inductorless Class B PA. Since each transistor only conducts for half of the cycle, the output suffers crossover distortion due to the finite threshold voltage of each transistor. When no signal is applied, there is no current flowing; as a result, any current through either device flows directly to the load, thereby maximizing the efficiency. The ideal efficiency can reach 78% [41], allowing this architecture to be of use in applications where linearity is not the main concern.

17.5.2.1.3 Class AB

The basic idea of Class AB amplification is to preserve the Class B push–pull configuration while improving the linearity by biasing each device slightly above threshold. The implementation of Class AB PAs is similar to Class B configurations. By allowing the two devices to conduct current for a short period, the output voltage waveform during the crossover period can be smoothed, which thus reduces the crossover distortion of the output signal.

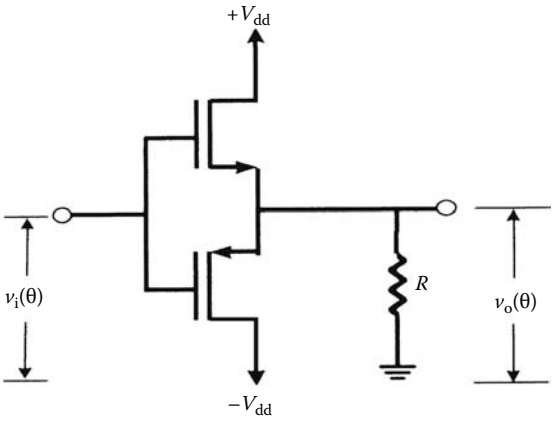

FIGURE 17.26 Inductorless Class B PA.

17.5.2.2 Nonlinear Power Amplifiers

17.5.2.2.1 Class C

A Class C PA is the most popular nonlinear PA used in the RF band. The conduction angle is less than 180° since the switching transistor is biased on the verge of conduction. A portion of the input signal will make the transistor operate in the amplifying region, and thus the drain current of the transistor is a pulsed signal.

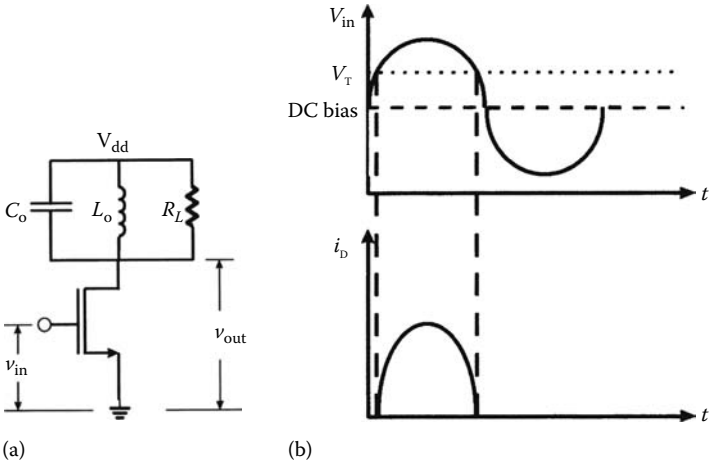

FIGURE 17.27 (a) Class C PA and (b) Class C waveforms.

Figure 17.27a and b shows the basic configuration of a Class C PA and its corresponding waveforms; clearly, the input and output voltages are not linearly related.

The efficiency of an ideal Class C amplifier is 100% since at any point in time, either the voltage or the current waveforms are zero. In practice, this ideal situation cannot be achieved, and the power efficiency should be maximized by reducing the power loss in the transistor. That is, minimize the current through the transistor when the voltage across the output is high, and minimize the voltage across the output when the current flows through the device.

17.5.2.2.2 Class D

A Class D amplifier employs a pair of transistors and a tuned output circuit, where the transistors are driven to act as a two-pole switch and the output circuit is tuned to the switching frequency. The theoretical power efficiency is 100%. Figure 17.28 shows the voltage-switching configuration of a Class D amplifier. The input signals of transistors Q_1 and Q_2 are out of phase, and consequently when Q_1 is on, Q_2 is off, and vice versa. Since the load network is a tuned circuit, we can assume that it provides little

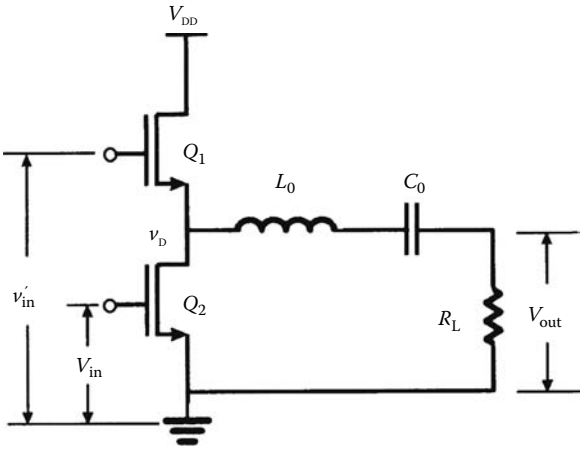

FIGURE 17.28 Class D PA.

impedance to the operating frequency of the voltage v_d and high impedance to other harmonics. Since v_d is a square wave, its Fourier expansion is given by

$$v_d(\omega t) = V_{dc}\left[\frac{1}{2} + \frac{2}{\pi}\sin(\omega t) + \frac{2}{3\pi}\sin(3\omega t)\ldots\right] \tag{17.45}$$

The impedance of the RLC series load at resonance is equal to R_L, and thus the current is given by

$$i_L(\omega t) = \frac{2V_{dc}}{\pi R_L}\sin(\omega t) \tag{17.46}$$

Each of the devices carries the current during one half of the switching cycle. Therefore, the output power is given by

$$P_o = \frac{2}{\pi^2}\frac{V_{dc}^2}{R_L} \tag{17.47}$$

Design efforts should focus on reducing the switching loss of both transistors as well as generating the input driving signals.

17.5.2.2.3 Class E

The idea behind the Class E PA is to employ nonoverlapping output voltage and output current waveforms. Several criteria for optimizing the performance can be found in Ref. [42]. Following these guidelines, Class E PAs have high power efficiency, simplicity, and relatively high tolerance to circuit variations [43]. Since there is no power loss in the transistor as well as in the other passive components, the ideal power efficiency is 100%. Figure 17.29 shows a Class E PA, and the corresponding waveforms are given in Figure 17.30.

The Class E waveforms indicate that the transistor should be completely off before the voltage across it changes, and that the device should be completely on before it starts to allow current to flow through it. Refs. [44,45] demonstrate practical Class E operation at RF frequencies using a GaAs process.

17.5.3 Practical Considerations for RF Power Amplifiers

More recently, single-chip solutions for RF transceivers have become a goal for modern wireless communications due to potential savings in power, size, and cost. CMOS must clearly be the technology

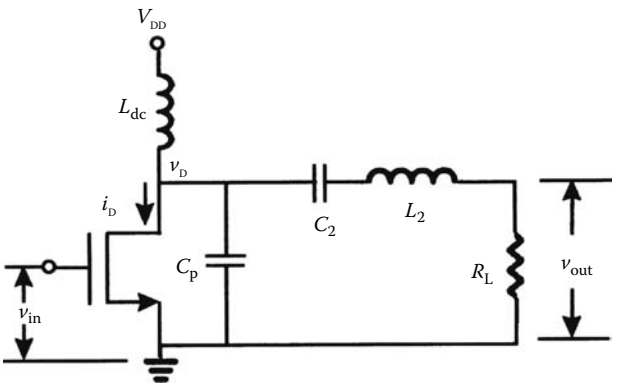

FIGURE 17.29 Class E PA.

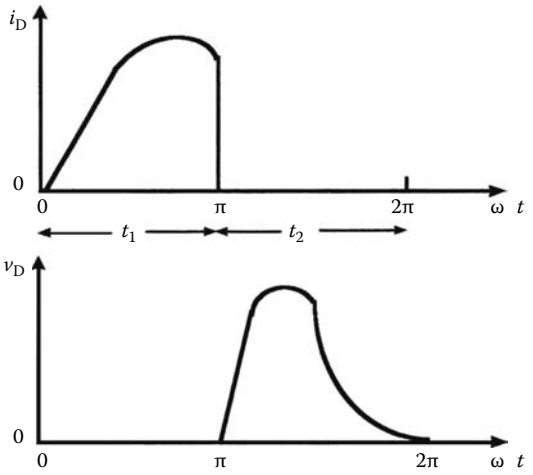

FIGURE 17.30 Waveforms of Class E operation.

of choice for a single-chip transceiver due to the large amount of digital baseband processing required. However, the PA design presents a bottleneck toward full integration, since CMOS PAs are still not available. The requirements of low supply voltage, gigahertz-band operation, and high output power make the implementation of CMOS PAs very demanding. The proposal of ''microcell'' communications may lead to a relaxed demand for output power levels that can be met by designs such as that described in Ref. [46], where a CMOS Class C PA has demonstrated up to 50% power efficiency with 20 mW output power.

Nonlinear PAs seem to be popular for modern wireless communications due to their inherent high power efficiency. Since significant power losses occur in the passive inductors as well as the switching devices, the availability of on-chip, low-loss passive inductors is important. The implementation of CMOS on-chip spiral inductors has therefore become an active research topic [47].

Due to the poor spectral efficiency of a constant envelope modulation scheme, the high power efficiency benefit of nonlinear PAs is eliminated. A recently proposed linear transmitter using a nonlinear PA may prove to be an alternative solution [48]. The development of high mobility devices such as SiGe HBTs has led to the design of PAs demonstrating output power levels up to 23 dBm at 1.9 GHz with power-added efficiency of 37% [49]. Practical PA designs require that much attention be paid to issues of package and harmonic terminations. Power losses in the matching networks must be absolutely minimized, and trade-offs between power-added efficiency and linearity are usually achieved through impedance matching. Although GaAs processes provide low-loss impedance matching structures on the semi-insulating substrate, good shielding techniques for CMOS may prove to be another alternative.

17.5.4 Conclusions

Although linear PAs provide conventional ''easy-design'' characteristics and linearity for modulation schemes such as $\pi/4$-DQPSK, modern wireless transceivers are more likely to employ nonlinear PAs due to their much higher power efficiency. As the development of high-quality on-chip passive components makes progress, the trend toward full integration of the PA is becoming increasingly plausible.

The rapid development of CMOS technology seems to be the most promising choice for PA integration, and vast improvements in frequency performance have been gained through device scaling. These improvements are expected to continue as silicon CMOS technologies scale further, driven by the

demand for high-performance microprocessors. The further development of high mobility devices such as SiGe HBTs may finally see GaAs MOSFETs being replaced by wireless communication applications, since SiGe technology is compatible with CMOS.

17.6 Applications of High-Q Resonators in IF-Sampling Receiver Architectures

Transconductance-C (gm-C) filters are currently the most popular design approach for realizing continuous-time filters in the intermediate frequency range in telecommunications systems. This section will consider the special application area of high-Q resonators for receiver architectures employing IF sampling.

17.6.1 IF Sampling

A design approach for contemporary receiver architectures that is currently gaining popularity is IF digitization, whereby low-frequency operations such as second mixing and filtering can be performed more efficiently in the digital domain. A typical architecture is shown in Figure 17.31. The IF signal is digitized, multiplied with the quadrature phases of a digital sinusoid, and lowpass filtered to yield the quadrature baseband signals. Since processing takes place in the digital domain, I/Q mismatch problems are eliminated. The principal issue in this approach, however, is the performance required from the A/D converter (ADC). Noise referred to the input of the ADC must be very low so that selectivity remains high. At the same time, the linearity of the ADC must be high to minimize corruption of the wanted signal through intermodulation effects. Both the above requirements should be achieved at an input bandwidth commensurate with the value of the IF frequency, and at an acceptable power budget.

Oversampling has become popular in recent years because it avoids many of the difficulties encountered with conventional methods for A/D and D/A conversion. Conventional converters are often difficult to implement in fine-line, very large-scale integration (VLSI) technology, because they require precise analog components and are very sensitive to noise and interference. In contrast, oversampling converters trade off resolution in time for resolution in amplitude, in such a way that the imprecise nature of the analog circuits can be tolerated. At the same time, they make extensive use of digital signal processing power, taking advantage of the fact that fine-line VLSI is better suited for providing fast digital circuits than for providing precise analog circuits. Therefore, IF-digitization techniques utilizing oversampling Sigma-Delta modulators are very well suited to modern submicron CMOS technologies, and their potential has made them the subject of active research.

Most Delta-Sigma modulators are implemented with discrete-time circuits, switched-capacitor (SC) implementations being by far the most common. This is mainly due to the ease with which monolithic SC filters can be designed, as well as the high linearity which they offer. The demand for high-speed $\Sigma\Delta$ oversampling ADCs, especially for converting bandpass signals, makes it necessary to look for a

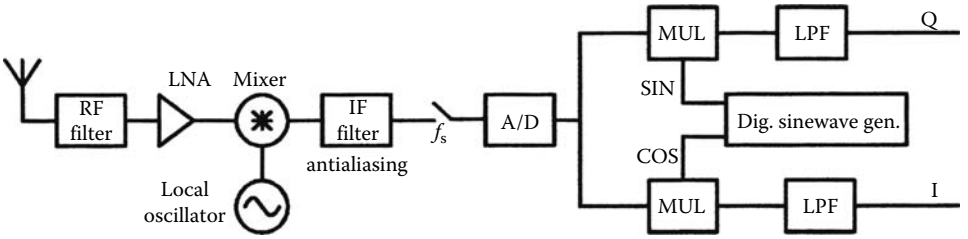

FIGURE 17.31 IF-sampling receiver.

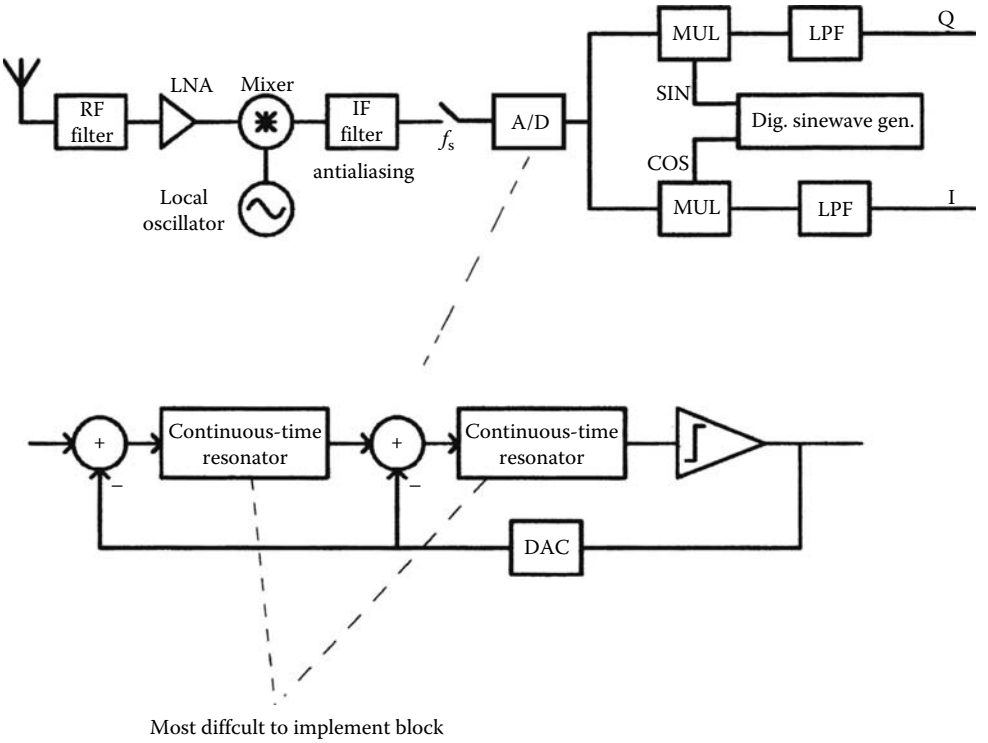

FIGURE 17.32 Continuous-time ΣΔ A/D in IF-sampling receiver.

technique that is faster than SC. This demand has stimulated researchers to develop a method for designing continuous-time ΣΔ ADCs (not checked with MS to identify that there is an missing symbol). Although continuous-time modulators are not easy to integrate, they possess a key advantage over their discrete-time counterparts. The sampling operation takes place inside the modulator loop, making it is possible to "noise-shape" the errors introduced by sampling, and provide a certain amount of anti-aliasing filtering at no cost. On the other hand, they are sensitive to memory effects in the DACs and are very sensitive to jitter. They must also process continuous-time signals with high linearity. In communications applications, meeting the latter requirement is complicated by the fact that the signals are located at very high frequencies.

As shown in Figure 17.32, integrated bandpass implementations of continuous-time modulators require integrated continuous-time resonators to provide the noise shaping function. The gm-C approach of realizing continuous-time resonators offers advantages of complete system integration and total design freedom. However, the design of CMOS high-Q high-linearity resonators at the tens of megahertz is very challenging. Since the linearity of the modulator is limited by the linearity of the resonators utilized, the continuous-time resonator is considered to be the most demanding analog subblock of a bandpass continuous-time Sigma-Delta modulator. Typical specifications for a gm-C resonator used to provide the noise-shaping function in a ΣΔ modulator in a mobile receiver (see Figure 17.32) are summarized in Table 17.4.

17.6.2 Linear Region Transconductor Implementation

The implementation of fully integrated, high-selectivity filters operating at tens to hundreds of megahertz provides benefits for wireless transceiver design, including chip area economy and cost reduction. The main disadvantages of on-chip active filter implementations when compared to off-chip passives include

TABLE 17.4 Fully Integrated Continuous-Time Resonator Specifications

Resonator Specifications	
Center frequency	50 MHz
Quality factor	50
SFDR	>30 dB
Power dissipation	Minimal

increased power dissipation, deterioration in the available DR with increasing Q, and Q and resonant frequency integrity (because of process variations, temperature drifts, and aging, automatic tuning is often unavoidable, especially in high-Q applications). The transconductor-capacitor (gm-C) technique is a popular technique for implementing high-speed continuous-time filters and is widely used in many industrial applications [52]. Because gm-C filters are based on integrators built from an open-loop transconductance amplifier driving a capacitor, they are typically very fast but have limited linear DR. Linearization techniques that reduce distortion levels can be used, but often lead to a compromise between speed, DR, and power consumption.

As an example of the trade-offs in design, consider the transconductor shown in Figure 17.33. This design consists of a main transconductor cell (M1, M2, M3, M4, M10, M11, and M14) with a negative resistance load (M5, M6, M7, M8, M9, M12, and M13). Transistors M1 and M2 are biased in the triode region of operation using cascode devices M3 and M4 and determine the transconductance gain of the cell. In the triode region of operation, the drain current versus terminal voltage relation can be approximated (for simple hand calculations) as $I_D = K[2(V_{GS} - V_T)V_{DS} - V_{DS}^2]$, where K and V_T are the transconductance parameter and the threshold voltage, respectively. Assuming that V_{DS} is constant for both M1 and M2, both the differential mode and the common-mode transconductance gains can be derived as $G_{DM} = G_{CM} = 2KV_{DS}$, which can thus be tuned by varying V_{DS}.

The high value of common-mode transconductance is undesirable since it may result in regenerative feedback loops in high-order filters. To improve the CMRR transistor and avoid the formation of such loops, M10 is used to bias the transconductor, thus transforming it from a pseudo differential to a fully differential transconductor [53]. Transistors M11 and M14 constitute a floating voltage source, thus maintaining a constant drain-source voltage for M1 and M2.

The nonlinearities in the voltage-to-current transfer of this stage are mainly due to three effects. The first is the finite impedance levels at the sources of the cascode devices, which cause a signal-dependent variation of the corresponding drain-source voltages of M1 and M2. A fast floating voltage source and large

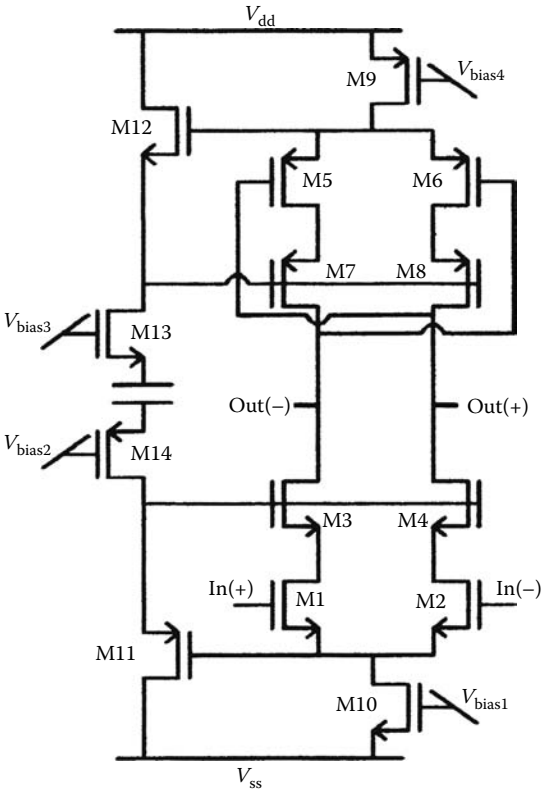

FIGURE 17.33 Triode region transconductor.

cascode transistors therefore need to be used to minimize this nonlinearity. The second cause of nonlinearity is the variation of carrier mobility μ of the input devices M1 and M2 with $V_{GS} - V_T$, which becomes more apparent when short-channel devices are used ($K = \mu \cdot C_{ox} \cdot W/2 \cdot L$) . A simple first-order model for transverse-field mobility degradation is given by $\mu = \mu_0/(1 + \theta \cdot (V_{GS} - V_T))$, where μ_0 and θ are the zero-field mobility and the mobility reduction parameter, respectively. Using this model, the third-order distortion can be determined by a Maclaurin series expansion as $\theta^2/4(1 + \theta(V_{CM} - V_T))$ [54]. This expression cannot be regarded as exact, although it is useful to obtain insight. Furthermore, it is valid only at low frequencies, where reactive effects can be ignored and the coefficients of the Maclaurin series expansion are frequency independent. At high frequencies or when very low values of distortion are predicted by the Maclaurin series method, a generalized power series method (Volterra series) must be employed [55,56]. Finally, a further cause of nonlinearity is a mismatch between M1 and M2, which can be minimized by good layout. A detailed linearity analysis of this transconductance stage is presented in Ref. [15].

To provide a load for the main transconductor cell, a similar cell implemented by p-devices is used. The gates of the linear devices M5 and M6 are now cross-coupled with the drains of the cascode devices M7 and M8. In this way, weak positive feedback is introduced. The differential-mode output resistance can now become negative and is tuned by the V_{DS} of M5 and M6 (M12 and M13 form a floating voltage source), while the common-mode output resistance attains a small value.

When connected to the output of the main transconductor cell as shown in Figure 17.33, the cross-coupled p-cell forms a high-ohmic load for differential signals and a low-ohmic load for common-mode signals, resulting in a controlled common-mode voltage at the output [54,57]. CMRR can be increased even further using M10, as described previously. Transistor M9 is biased in the triode region of operation and is used to compensate the offset common-mode voltage at the output.

The key performance parameter of an integrator is the phase shift at its unity-gain frequency. Deviations from the ideal $-90°$ phase include phase lead due to finite dc gain and phase lag due to HF parasitic poles. In the transconductor design of Figure 17.33, dc gain is traded for phase accuracy, thus compensating the phase lag introduced by the parasitic poles. The reduction in dc gain for increased phase accuracy is not a major problem for bandpass filter applications, since phase accuracy at the center frequency is extremely important while dc gain has to be adequate to ensure that attenuation specifications are met at frequencies below the passband.

From simulation results using parameters from a 0.8 μm CMOS process, with the transconductor unity-gain frequency set at 50 MHz, third-order intermodulation components were observed at -78 dB with respect to the fundamental signals (two input signals at 49.9 and 50.1 MHz were applied, each at 50 mVpp).

17.6.3 gm-C Bandpass Biquad

17.6.3.1 Filter Implementation

The implementation of on-chip high-Q resonant circuits presents a difficult challenge. Integrated passive inductors have generally poor quality factors, which limits the Q of any resonant network in which they are employed. For applications in the hundreds of megahertz to a few gigahertz, one approach is to implement the resonant circuit using low-Q passive on-chip inductors with additional Q-enhancing circuitry. However, for lower frequencies (tens of megahertz), on-chip inductors occupy a huge area and this approach is not attractive.

As disscussed above, an alternative method is to use active circuitry to eliminate the need for inductors. gm-C-based implementations are attractive due to their high-speed potential and good tunability. A bandpass biquadratic section based upon the transconductor of Figure 17.33 is shown in Figure 17.34. The transfer function of Figure 17.34 is given by

$$\frac{V_o}{V_i} = \frac{g_{mi} \cdot R_o}{(R_o \cdot C)^2} \cdot \frac{(1 + s \cdot R_o \cdot C)}{\left\{ s^2 + s\frac{2 \cdot R_o + g_m^2 \cdot R_o^2 \cdot R}{R_o^2 \cdot C} + \frac{1 + g_m^2 \cdot R_o^2}{R_o^2 \cdot C^2} \right\}} \tag{17.48}$$

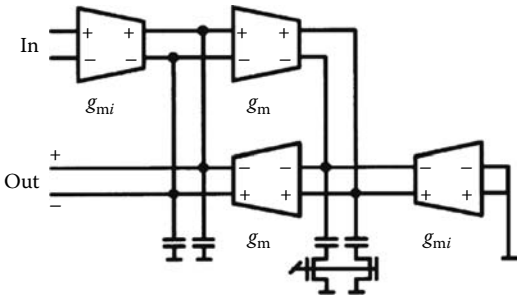

FIGURE 17.34 Biquad bandpass.

R_o represents the total resistance at the nodes due to the finite output resistance of the transconductors. R represents the effective resistance of the linear region transistors in the transconductor (see Figure 17.33), and is used here to introduce damping and control the Q. From Equation 17.48, it can be shown that $\omega_o \approx g_m/C$, $Q \approx g_m \cdot R_o/(2 + R_o \cdot R \cdot g_m^2)$, $Q_{max} = Q|_{r=0} = (g_m \cdot R_o)/2$ and $A_o = g_{mi} \supseteq Q$. Thus, g_m is used to set the central frequency, R is used to control the Q, and g_{mi} controls the bandpass gain A_o. A dummy g_{mi} is used to provide symmetry and thus better stability due to process variations, temperature, and aging.

One of the main problems when implementing high-Q HF resonators is maintaining the stability of the center frequency ω_o and the quality factor Q. This problem calls for very careful layout and the implementation of an automatic tuning system. Another fundamental limitation regarding available DR occurs: namely, that the DR of high-Q gm-C filters has been found to be inversely proportional to the filter Q [57]. The maximum DR is given by

$$\mathrm{DR} = \frac{V_{max}^2}{V_{noise}^2} = \frac{V_{max}^2 \cdot C}{4 \cdot k \cdot T \cdot \xi \cdot Q} \tag{17.49}$$

where

V_{max} is the maximum rms voltage across the filter capacitors
C is the total capacitance
k is Boltzman's constant
T is the absolute temperature
ξ is the noise factor of the active circuitry ($\xi = 1$ corresponds to output noise equal to the thermal noise of a resistor of value $R = 1/g_m$, where g_m is the transconductor value used in the filter)

In practice, the DR achieved will be less than this maximum value due to the amplification of both noise and intermodulation components around the resonant frequency. This is a fundamental limitation, and the only solution is to design the transconductors for low noise and high linearity. The linearity performance in narrowband systems is characterized by the spurious-free dynamic range (SFDR). SFDR is defined as the SNR when the power of the third-order intermodulation products equals the noise power. As shown in Ref. [15], the SFDR of the resonator in Figure 17.34 is given by

$$\mathrm{SFDR} = \frac{1}{2(k \cdot T)^{2/3}} \left(\frac{3 \cdot V_{o,peak}^2 \cdot C}{4 \cdot \xi \cdot IM_{3,int}} \right)^{2/3} \frac{1}{Q^2} \tag{17.50}$$

where $IM_{3,int}$ is the third-order intermodulation point of the integrator used to implement the resonator. The SFDR of the resonator thus deteriorates by 6 dB if the quality factor is doubled, assuming that the output swing remains the same. In contrast, implementing a resonant circuit using low-Q passive on-chip

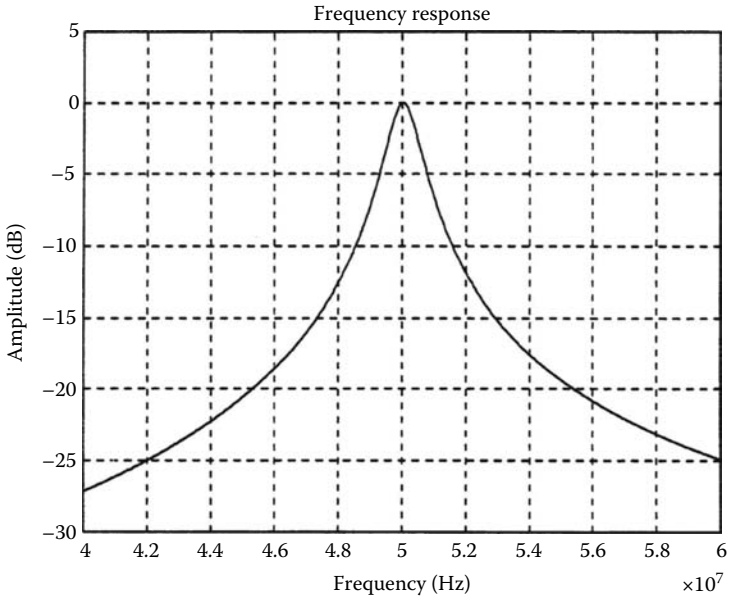

FIGURE 17.35 Simulated bandpass frequency response.

inductors with additional Q-enhancing circuitry leads to a DR amplified by a factor Q_o, where Q_o is the quality factor of the on-chip inductor itself [59]. However, as stated above, for frequencies in the tens of megahertz, on-chip inductors occupy a huge area and thus the Q_o improvement in DR is not high enough to justify the area increase.

17.6.3.2 Simulation Results

To confirm operation, the filter shown in Figure 17.34 has been simulated in HSPICE using process parameters from a commercial 0.8 μm CMOS process. Figure 17.35 shows the simulated frequency and phase response of the filter for a center frequency of 50 MHz and a quality factor of 50. Figure 17.36 shows the simulated output of the filter when the input consists of 2 tons at 49.9 and 50.1 MHz, respectively, each at 40 mVpp. At this level of input signal, the third-order intermodulation components were found to be at the same level as the noise. Thus, the predicted SFDR is about 34 dB with $Q = 50$. Table 17.5 summarizes the simulation results.

17.7 Log-Domain Processing

17.7.1 Instantaneous Companding

The concept of *instantaneous companding* is an emerging area of interest within the field of analog integrated circuit design. Currently, the main area of application for this technique is the implementation of continuous-time, fully integrated filters with wide DR, HF potential, and wide tunability.

With the drive toward lower supply voltages and higher operating frequencies, traditional analog integrated circuit design methodologies are proving inadequate. Conventional techniques to linearize inherently nonlinear devices require an overhead in terms of increased power consumption or reduced operating speed. Recently, the use of companding, originally developed for audio transmission, has been proposed as an elegant solution to the problem of maintaining DR and HF operation under low supply

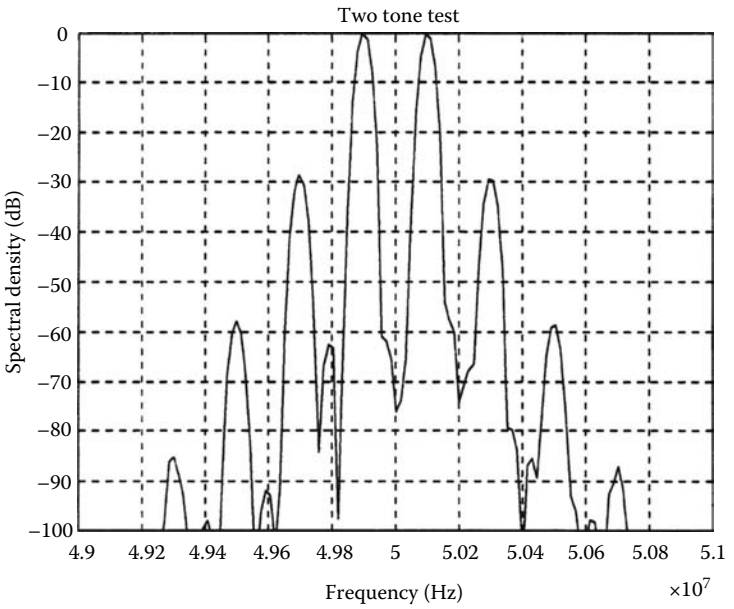

FIGURE 17.36 Simulated two-tone intermodulation test.

TABLE 17.5 Simulation Results

Power dissipation (supply voltage = 5 V)	12.5 mW
Common-mode output offset	<1 mV
Center frequency	50 MHz
Quality factor	50
Output noise voltage (integrated over the band from 40 to 60 MHz with $Q = 50$)	500 μV_{rms}
Output signal voltage (so that intermodulation components are at the same level as the noise, $Q = 50$)	25.2 mV_{rms}
SFDR ($Q = 50$)	34 dB

voltage [50]. In this approach, nonlinear amplifiers are used to compress the DR of the input signal to ensure, for example, that signal levels always remain above a certain noise threshold but below levels that may cause overload. The overall system must thus adapt its operation to ensure that input–output linearity is maintained as the instantaneous signal level alters. Although the system is input–output linear, signals internal to the system are inherently nonlinear. Companding has traditionally been realized in two ways—syllabic and instantaneous—depending on how the system adapts in response to the changing input signal level. In *syllabic* companding, the level of compression (and expansion) is a nonlinear function of a slowly varying property of the signal (e.g., envelope or power). In contrast, *instantaneous* companding adapts the compression and expansion ratios instantaneously with the changing input signal amplitude.

Perhaps the best-known recent example of this approach is the log-domain technique, where the exponential I–V characteristics of bipolar junction transistors (BJTs) are directly exploited to implement

input–output linear filters. Since the large signal device equations are utilized, there is no need for small-signal operation or local linearization techniques, and the resulting circuits have the potential for wide DR and HF operation under low power supply voltages. Log-domain circuits are generally implemented using BJTs and capacitors only and thus are inherently suitable for integration. The filter parameters are easily tunable, which makes them robust. In addition, the design procedure is systematic, which suggests that these desirable features can be reproduced for different system implementations. Section 17.7.2 provides an introduction to the synthesis of log-domain filters and highlights various performance issues. Interested readers are advised to consult Refs. [61–76] for a more detailed treatment of the subject.

17.7.2 Log-Domain Filter Synthesis

The synthesis of log-domain filters using state-space transformations was originally proposed by Frey [62]. As an example of this methodology, consider a biquad filter with the following transfer function:

$$Y(s) = \frac{s\omega_o U_1(s) + \omega_o^2 U_2(s)}{s^2 + (\omega_o/Q)s + \omega_o^2} \tag{17.51}$$

Thus, using u_1 as input gives a bandpass response at the output y, while using u_2 as input gives a lowpass response. This system can also be described by the following state space equations:

$$\begin{aligned} \dot{x}_1 &= -(\omega_o/Q)x_1 - \omega_o x_2 + \omega_o u_1 \\ \dot{x}_2 &= -\omega_o x_1 - \omega_o u_2 \\ y &= x_1 \end{aligned} \tag{17.52}$$

where a ''dot'' denotes differentiation in time. To transform these linear state equations into nonlinear nodal equations that can be directly implemented using bipolar transistors, the following exponential transformations are defined:

$$\begin{aligned} x_1 &= I_S \exp\left(\frac{V_1}{V_t}\right) \quad & u_1 &= \left(\frac{I_S^2}{I_o}\right) \exp\left(\frac{V_{in1}}{V_t}\right) \\ x_2 &= I_o \exp\left(\frac{V_2}{V_t}\right) \quad & u_2 &= I_S \exp\left(\frac{V_{in2}}{V_t}\right) \end{aligned} \tag{17.53}$$

These transformations map the linear state variables to currents flowing through bipolar transistors (BJTs) biased in the active region. I_S represents the BJT reverse saturation current, while V_t is the thermal voltage. Substituting these transformations into the state (Equation 17.52) gives

$$\begin{aligned} C\dot{V}_1 &= -\frac{I_o}{Q} - \frac{I_o^2}{I_S} \exp\left(\frac{V_2 - V_1}{V_t}\right) + I_S \exp\left(\frac{V_{o1} - V_1}{V_t}\right) \\ C\dot{V}_2 &= I_S \exp\left(\frac{V_1 - V_2}{V_t}\right) - I_S \exp\left(\frac{V_{o2} - V_2}{V_t}\right) \\ y &= I_S \exp\left(\frac{V_1}{V_t}\right) \end{aligned} \tag{17.54}$$

In Equation 17.54, a tuning current $I_o = C\omega_o V_t$ is defined, where C is a scaling factor which represents a capacitance. The linear state space equations have thus been transformed into a set of nonlinear nodal equations, and the task for the designer is now to realize a circuit architecture that will implement these

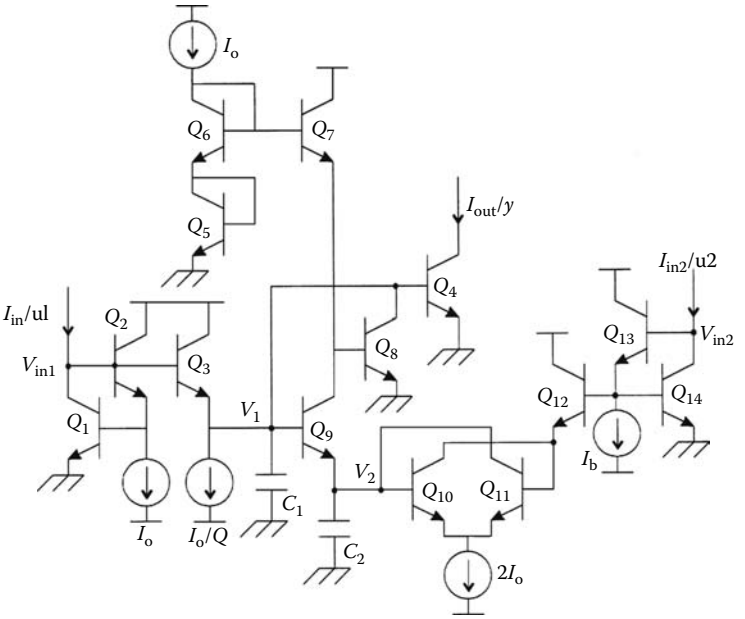

FIGURE 17.37 A log-domain biquadratic filter. A lowpass response is obtained by applying a signal at I_{u2} and keeping I_{u1} constant, while a bandpass response is obtained by applying a signal at I_{u1} and keeping I_{u2} constant.

nonlinear equations. Considering the first two equations in Equation 17.54, the terms on the LHS can be implemented as currents flowing through grounded capacitors of value C connected at nodes V_1 and V_2, respectively. The expressions on the RHS can be implemented by constant current sources in conjunction with appropriately biased bipolar transistors to realize the exponential terms. The third equation in Equation 17.54 indicates that the output y can be obtained as the collector current of a bipolar transistor biased with a base–emitter voltage V_1.

Figure 17.37 shows a possible circuit implementation, which is derived using Gilbert's translinear circuit principle [63]. The detailed circuit implementation is described in more detail in Ref. [62]. The center frequency of this filter is given by $\omega_o = (I_o/CV_t)$ and can thus be tuned by varying the value of the bias current I_o.

17.7.3 Performance Aspects

17.7.3.1 Tuning Range

Both the quiescent bias current I_o and capacitance value C can be varied to alter the filter response. However, the allowable capacitor values are generally limited to within a certain range. On the lower side, C must not become smaller than the parasitic device capacitance. The base–emitter diffusion capacitance of the transistors is particularly important, since this is generally the largest device capacitance (up to the picofarad range) and is also nonlinear. In addition, as the value of C decreases, it becomes more difficult to match the capacitance values. The silicon area available limits the maximum value of C; for example, in a typical technology, a 50 pF poly–poly capacitor consumes 100×1000 μm of silicon area.

The range of allowable currents in a modern BJT is, in principle, fairly large (several decades); however, at very low and very high current levels, the current gain (β) is degraded. For HF operation, particular attention must be paid to the actual f_t of the transistors, which is given by [6]

$$f_t = \frac{g_m}{2\pi(C_\pi + C_\mu)} = \frac{g_m}{2\pi(C_d + C_{je} + C_{jc})} \tag{17.55}$$

where

C_{je} and C_{jc} represent the emitter and collector junction capacitance, respectively, and are only a weak function of the collector bias current

C_d represents the base–emitter diffusion capacitance and is proportional to the instantaneous collector current; $C_d = (\tau_f I_c/V_t)$, where τ_f is the effective base transit time

g_m represents the device transconductance, which is again dependent on the collector current; $g_m = (I_c/V_t)$

At high current levels, the diffusion capacitance is much larger than the junction capacitance, and thus:

$$f_t = \frac{g_m}{2\pi C_d} = \frac{1}{2\pi\tau_f} \tag{17.56}$$

At lower current levels, C_d and g_m decrease, whereas C_{je} and C_{jc} remain constant and f_t is reduced:

$$f_t = \frac{g_m}{2\pi(C_{je} + C_{jc})} \tag{17.57}$$

At very high current levels, f_t again reduces due to the effects of high-level injection.

17.7.3.2 Finite Current Gain

To verify the performance of the biquad filter, the circuit of Figure 17.37 was simulated using HSPICE with transistor parameters from a typical bipolar process. Transient (large signal) simulations were carried out to confirm the circuit operation, and the lowpass characteristic (input at I_{u2}) is found to be very close to the ideal response. However, with an input signal applied at I_{u1} to obtain a bandpass response, the filter performance clearly deviates from the ideal characteristic as shown in Figure 17.38. At low frequencies, the stop-band attenuation is only 25 dB. Resimulating the circuit with ideal transistor models gives the required ideal bandpass characteristic as shown in Figure 17.38; and by reintroducing the transistor parameters one at a time, the cause of the problem is found to be the finite current gain (β) of the bipolar transistors.

To increase the effective β, each transistor can be replaced by a Darlington pair, as shown in Figure 17.39. This combination acts as a bipolar transistor with $\beta = \beta_a\beta_b + \beta_a + \beta_b \approx \beta^2$. Simulating the bandpass response of the circuit with Darlington pairs results in improved stop-band attenuation as shown in Figure 17.40, where the dc attenuation $H(0)$ is now approximately -50 dB. A disadvantage, however, is that a higher supply voltage is now required, since the effective base–emitter voltage V_{be} of the Darlington pair is double that of a single device. In addition, the current in device Q_a of Figure 17.39 is now β times smaller than the design current I_o, resulting in a much lower f_t for this device.

An alternative method to improve the bandpass characteristic is described below. The (nonideal) transfer function from the bandpass input I_{u1} is described by

$$H_1(s) = \frac{I_{out}(s)}{I_{u1}(s)} = \frac{\omega_o(s + \omega_z)}{s^2 + (\omega_o/Q)s + \omega_o^2} \tag{17.58}$$

ω_z is a parasitic zero, which describes the low-frequency "flattening-out" of the bandpass characteristic. The transfer function from the second input I_{u2} is a lowpass response:

$$H_2(s) = \frac{I_{out}(s)}{I_{u2}(s)} = \frac{\omega_o^2}{s^2 + (\omega_o/Q)s + \omega_o^2} \tag{17.59}$$

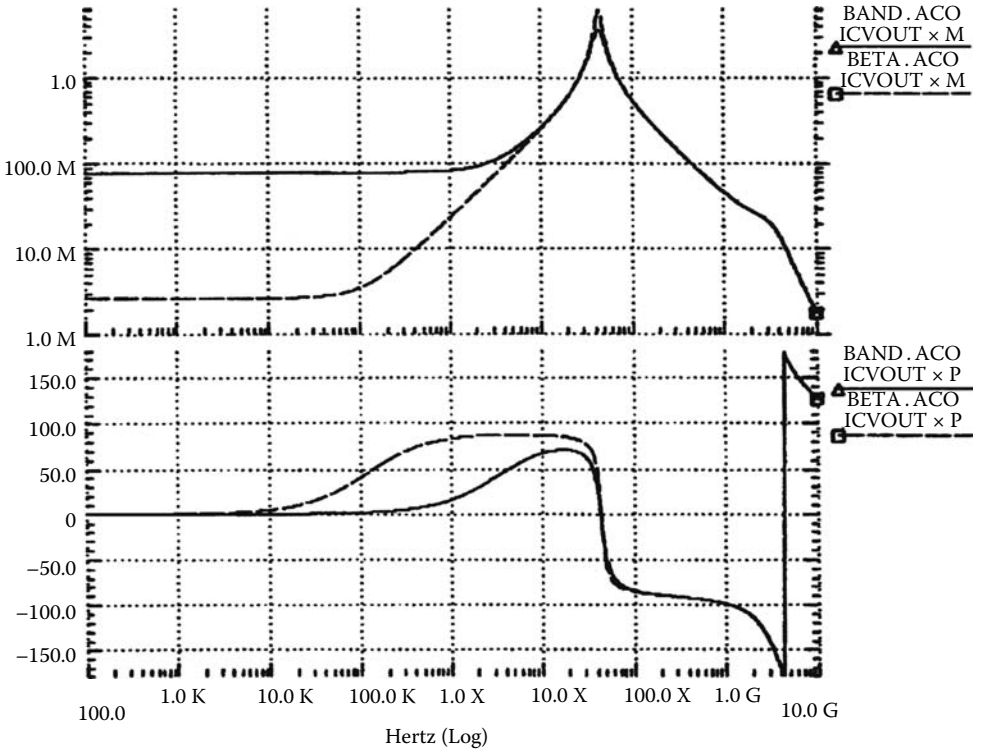

FIGURE 17.38 Bandpass response of the biquad of Figure 17.37. Notice the poor low-frequency stop-band attenuation (approx. 25 dB) if real transistor models are used (solid line), versus the much better stop-band attenuation with β set to 1000 (dashed line).

By applying a scaled version of the input signal I_{u1} to the lowpass input I_{u2}, the unwanted zero ω_z can thus be compensated. Setting $I_{u2} = -(\omega_z/\omega_o)\, I_{u1}$

$$I_{\text{out}}(s) = \frac{\omega_o(s+\omega_z)I_{u1}(s) + \omega_o^2\left(-\frac{\omega_z}{\omega_o}I_{u1}(s)\right)}{s^2 + (\omega_o/Q)s + \omega_o^2} = \frac{\omega_o s}{s^2 + (\omega_o/Q)s + \omega_o^2} I_{u1}(s) \tag{17.60}$$

This idea is confirmed by simulation as shown in Figure 17.40. However, in practice, since this technique is very sensitive to the exact factor by which the input signal is scaled, active on-chip tuning would be required.

17.7.3.3 Frequency Performance

The log-domain filter operates in current mode, and all nodes within the circuit have an impedance of the order of $1/g_m$. Thus, any parasitic poles or zeros within the circuit are of the order of g_m/C_p, where C_p represents the parasitic capacitance at the given node. Typically, the parasitic capacitors are dominated by base–emitter diffusion capacitance Cπ, and the parasitic poles are situated close to the f_t of the technology. This underscores the potential of the log-domain technique for HF

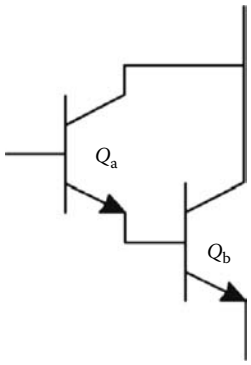

FIGURE 17.39 Darlington pair.

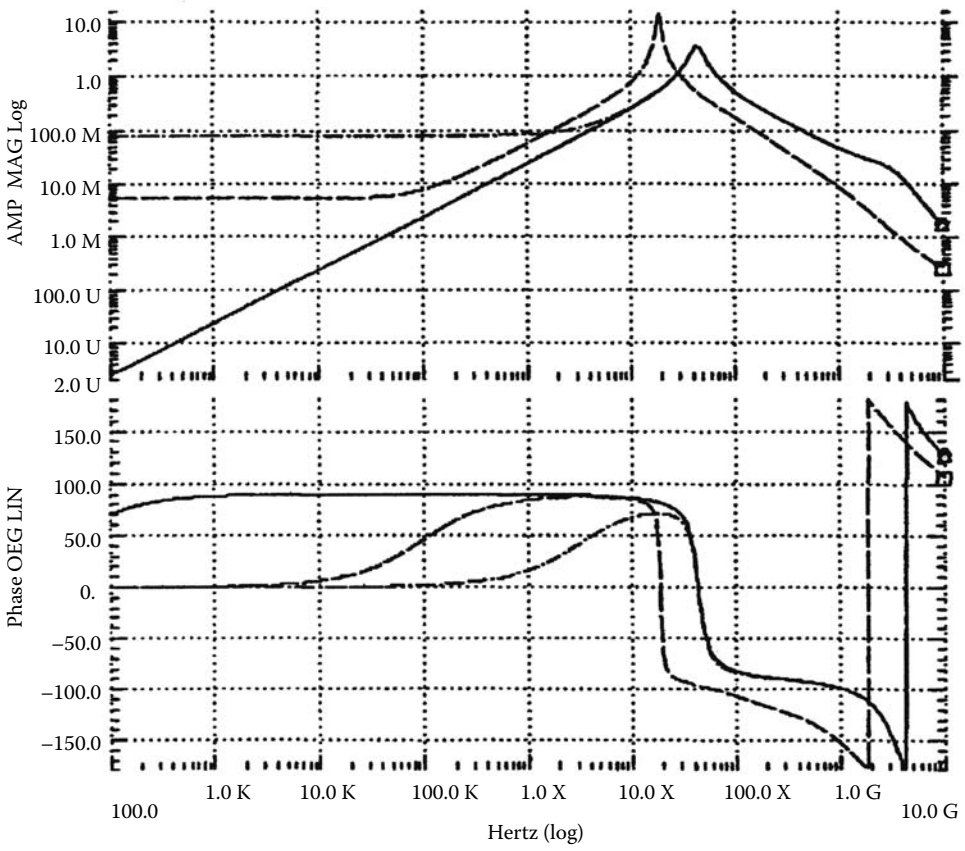

FIGURE 17.40 Possible solutions for the effect of finite β. The "dashed-dotted" line is the original response with a stop-band attenuation of only 25 dB. The dashed line (−50 dB) is the result of replacing all BJTs by Darlington pairs. The solid line is the result of feeding a fraction of the input signal to the second (i.e., lowpass) input.

operation. In practice, as with all HF circuits, careful design and layout are required to achieve the maximum frequency potential [75,76].

17.7.4 Basic Log-Domain Integrator

Section 17.7.3 has outlined some of the limitations of practical log-domain circuits that result from intrinsic device parasitics. This section analyzes these nonidealities in more detail by considering the simplest log-domain circuit, a first-order lowpass filter (lossy integrator).

A log-domain first-order lowpass filter is shown in Figure 17.41. Referring to this circuit, and assuming an ideal exponential characteristic for each BJT, the following set of equations can be written (assuming matched components and neglecting the effect of base currents):

$$\begin{aligned} I_{\text{in}} &= I_{\text{S}} \exp\left(\frac{V_{\text{in}}}{V_{\text{t}}}\right) \quad I_{\text{out}} = I_{\text{S}} \exp\left(\frac{V_{\text{out}}}{V_{\text{t}}}\right) \\ V_{\text{out}} &= V_{\text{c}} + V_{\text{t}} \ln\left(\frac{I_{\text{o}}}{I_{\text{S}}}\right) \quad I_{\text{o}} + C\frac{\text{d}V_{\text{c}}}{\text{d}t} = I_{\text{S}} \exp\left(\frac{V_{\text{in}} - V_{\text{c}}}{V_{\text{t}}}\right) \end{aligned} \tag{17.61}$$

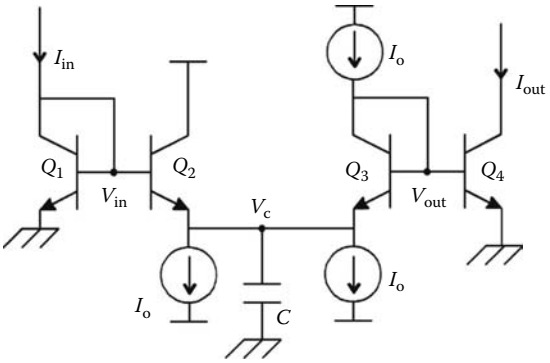

FIGURE 17.41 A first-order lowpass filter (lossy integrator).

Combining these equations results in the following linear first-order differential equation:

$$\left(\frac{CV_t}{I_o}\right)\frac{dI_{out}}{dt} + I_{out} = I_{in} \tag{17.62}$$

Taking the Laplace transform produces the following linear transfer function:

$$\frac{I_{out}(s)}{I_{in}(s)} = \frac{I_o}{I_o + sCV_t} \tag{17.63}$$

Equation 17.63 describes a first-order lowpass circuit with −3 dB frequency $f_c = I_o/2\pi CV_t$. This transfer function has been derived assuming an ideal exponential BJT characteristic; however, in practice, device nonidealities will introduce deviations from this ideal exponential characteristic, resulting in transfer function errors and distortion. This is similar to the case of ''conventional'' linear system design, where any deviation from the ideal linear building block response will contribute to output distortion. A brief discussion of the performance limitations of log-domain filters due to device nonidealities is given below; further discussion of distortion and performance limitations can be found in Refs. [65,66].

17.7.4.1 Effects of Finite Current Gain

Assuming all transistors have equal β, Equation 17.62 is modified to the following nonlinear differential equation (neglecting terms with β^2 or higher in the denominator):

$$\left(\frac{CV_t}{I_o}\right)\frac{dI_{out}}{dt}\left(1 + \frac{I_o}{I_{out}(1+\beta)}\right) + I_{out}\left(1 + \frac{I_{out}}{\beta I_o}\right) + \frac{2I_o}{1+\beta} = I_{in}\left(1 + \frac{I_{in}}{\beta}\right) \tag{17.64}$$

An analytical solution to Equation 17.64 is difficult to obtain; thus, a qualitative discussion is given. At low frequencies, neglecting the differential terms, finite β causes a dc gain error and quadratic (even-order) distortion. At high frequencies, the differential term is modified, depending on the values of I_{out} and β; therefore, scalar error and modulation of the 3 dB frequency are expected. In practice, the effects of finite β are further complicated due to its dependence on frequency and device collector current.

17.7.4.2 Component Mismatch

Emitter area mismatches cause variations in the saturation current I_S between transistors. Taking the emitter area into account, Equation 17.62 can be rewritten as

$$\left(\frac{CV_t}{I_o}\right)\frac{dI_{out}}{dt} + I_{out} = \lambda I_{in} \tag{17.65}$$

where $\lambda = (I_{S3}I_{S4}/I_{S1}I_{S2}) = (A_3A_4/A_1A_2)$. It is clear from Equation 17.65 that area mismatches introduce only a change in the proportionality constant or dc gain of the integrator, and do not have any effect on the linearity or time constant of the integrator. The gain error can be compensated by easily adjusting one of the dc bias currents; thus, I_s mismatches do not seem to be a significant problem.

17.7.4.3 Ohmic Resistance

Ohmic resistances include the base and emitter diffusion resistance, and the resistance of interconnects and contact interfaces. For simplicity, all these resistances can be referred to the base as an equivalent ohmic base resistance r_b. The device collector current can thus be defined as

$$I_c = I_S \exp\left(\frac{V_{be} - I_b r_b}{V_t}\right) = I_S \exp\left(\frac{V_{be}}{V_t}\right) \exp\left(-\alpha I_c\right) \tag{17.66}$$

where

V_{be} is the applied (extrinsic) base–emitter voltage
$\alpha = r_b/\beta V_t$

When the first-order filter of Figure 17.41 is analyzed using the expression given in Equation 17.66, a modified differential equation is obtained (assuming all base resistances are equal):

$$\left(\frac{CV_t}{I_o}\right)\frac{d[I_{out}e^{\alpha I_{out}}]}{dt} + I_{out}e^{\alpha I_{out}} = (e^{\partial\alpha I_o})I_{in}e^{\alpha I_{in}}e^{\left(-\alpha\frac{CV_t}{I_o}\frac{dI_{out}}{dt}(1+\alpha I_{out})\right)} \tag{17.67}$$

The term $\partial\alpha$ represents the difference between two α values and will be close to zero if all base resistances are assumed equal, and thus can be neglected. At frequencies well below ω_o, the time derivative in the exponent can also be neglected to give

$$\left(\frac{CV_t}{I_o}\right)\frac{d[I_{out}\exp(\alpha I_{out})]}{dt} + I_{out}\exp(\alpha I_{out}) = I_{in}\exp(\alpha I_{in}) \tag{17.68}$$

Expanding the differential term in Equation 17.68:

$$I_{out}\exp(\alpha I_{out}) + \tau\frac{dI_{out}}{dt}\exp(\alpha I_{out}) + \tau\alpha I_{out}\frac{dI_{out}}{dt}\exp(\alpha I_{out}) = I_{in}\exp(\alpha I_{in}) \tag{17.69}$$

Equation 17.69 is clearly no longer linear; and thus, distortion products will be present at the output. To quantify this distortion, we apply as an input signal $I_{in} = A\exp(j\omega t)$, and expect as output:

$$I_{out} = B\exp j(\omega w + \theta) + c\exp j(2\omega t + \phi) + D\exp j(3\omega t + \psi) \tag{17.70}$$

Expanding the exponential terms in Equation 17.69 by the first few terms of their series expansion:

$$\exp(x) = 1 + x + \frac{x^2}{2} + \frac{x^3}{6} \tag{17.71}$$

and identifying the terms in $\exp(j\omega t)$, $\exp(2j\omega t)$, etc. results in

$$B\exp j\theta = \frac{A}{1+s\tau} \quad C\exp j\phi = \alpha A^2 p(\tau) \quad D\exp j\psi = \alpha^2 A^3 q(s\tau) \tag{17.72}$$

The expression for B is (as expected) the first-order transfer function of the system. The expressions for C and D give the second and third harmonic terms:

$$\mathrm{HD}_2 = \frac{|C \exp j\phi|}{|\mathrm{A}|} \quad \mathrm{HD}_3 = \frac{|D \exp j\psi|}{|\mathrm{A}|} \tag{17.73}$$

$p(s\tau)$ and $q(s\tau)$ are rational functions in $s\tau$; thus, the output distortion is frequency dependent. Distortion is low at low frequencies, and peaks around the cut-off frequency ($s\tau = 1$), where $p = 0.25$ and $q = 2$. The maximum distortion levels can be approximated as

$$\begin{aligned} \mathrm{HD}_{2(\max)} &= 0.25\alpha A = 0.25 \frac{r_\mathrm{b}}{\beta V_\mathrm{t}} I_\mathrm{in} \\ \mathrm{HD}_{3(\max)} &= 2(\alpha A)^2 = 2\left(\frac{r_\mathrm{b}}{\beta V_\mathrm{t}}\right)^2 I_\mathrm{in}^2 \end{aligned} \tag{17.74}$$

These expressions demonstrate that when the voltage drop across the base resistance becomes comparable to V_t, there is significant distortion. This analysis also predicts that the distortion is larger at frequencies closer to the cut-off frequency, which is confirmed by circuit simulation.

In practice, the base resistance can be minimized by good layout (multiple base contacts), or by connecting several transistors in parallel. The latter, however, decreases the current through each transistor, which may lead to a decrease in f_t. It should be noted that, from a technological point of view, a high f_t and a low r_b are opposing goals. To achieve a high f_t, the base should be as shallow as possible, reducing base transit time. At the same time, however, a shallow base increases the silicon (intrinsic) base resistance.

17.7.4.4 Early Effect

The early effect (base-width modulation) causes the collector current to vary with the collector–emitter and base–collector voltages. Considering the variation of collector–emitter voltage, the collector current can be written as $I_\mathrm{c} = (1 + V_\mathrm{ce}/V_\mathrm{A}) \exp(V_\mathrm{be}/V_\mathrm{t})$, where V_A is the forward-biased early voltage. An analysis of the circuit of Figure 17.41 shows that the early effect introduces a scalar error to the dc gain as in the case of emitter area (I_S) mismatch. In practice, the base-width modulation of the devices also introduces distortion because V_ce and V_bc are signal dependent. However, since voltage swings in current-mode circuits are minimized, this is not believed to be a major source of distortion.

17.7.4.5 Frequency Limitations

Each bipolar transistor has various intrinsic capacitors, the most important being C_μ (base–collector junction capacitance), C_cs (collector–substrate junction capacitance), and C_π (the sum of the base–emitter junction capacitance and the base–emitter diffusion capacitance). The junction capacitors depend only slightly on the operating point, while the base–emitter diffusion capacitance is proportional to the bias current, as given by $C_\mathrm{d} = \tau_\mathrm{f} I_\mathrm{c}/V_\mathrm{t}$. To determine the position of the parasitic poles and zeros, Figure 17.41 should be analyzed using large-signal device models. Unfortunately, the complexity of the resulting expressions renders this approach impractical even for the simplest log-domain circuits. To gain an intuitive understanding of the HF limitations of the circuit, a small-signal analysis can be performed. Although log-domain circuits are capable of large-signal operation, this small-signal approach is justified to some extent since small signals can be considered ''special case'' of large signals. If the circuit fails to operate correctly for small signals, then it will almost certainly fail in large-signal operation (unfortunately, the opposite does not hold; if a circuit operates correctly for small signals, it does not necessarily work well for large signals). Analyzing the circuit of Figure 17.41, replacing each transistor by a

small-signal (hybrid-π) equivalent model (comprising g_m, r_b, r_π, C_π, C_μ) [64], results in the following expression:

$$\frac{I_{out}}{I_{in}} = \left(\frac{g_{m4}}{g_{m1}}\right)\frac{1+\tau_z s}{(1+\tau_{p1}s)(1+\tau_{p2}s)} \tag{17.75}$$

τ_{p1} is the time constant of the first (dominant) pole, given by

$$\tau_{p1} = \frac{C}{g_{m2}} + (C_{\mu4}+C_{\pi4})\left(r_{b4}+\frac{1}{g_{m2}}+\frac{1}{g_{m3}}\right)+\frac{C_{\pi1}}{g_{m1}}+\frac{C_{\pi2}}{g_{m2}} + \frac{C_{\pi3}}{g_{m3}} + C_{\mu1}r_{b1} + C_{\mu2}r_{b2} + C_{\mu3}r_{b3} \tag{17.76}$$

Ideally, this pole location should depend only on the design capacitance C, and not on the device parasitics. Therefore, $C_\mu\ r_b$, $C_\pi/g_m \ll C/g_{m2}$. Since $1/C_\mu r_b$ is typically much greater than f_t, this first constraint does not form a limit. The value of C_π/g_m depends on the operating point. For large currents, C_π is dominated by diffusion capacitance C_d so that $C_\pi/g_m = 1/f_t$. For smaller currents, g_m decreases while C_π becomes dominated by junction capacitance C_{je}, so that $C_\pi/g_m \gg 1/f_t$. Thus, it would seem that the usable cut-off frequency of the basic log-domain first-order filter is limited by the actual f_t of the transistors. The second pole time constant τ_{p2} (assuming that $\tau_{p1} = C/g_{m2}$) is

$$\tau_{p2} = (C_{\mu4}+C_{\pi4})\left(r_{b4}+\frac{1}{g_{m3}}\right)+(C_{\mu2}+C_{\pi2})\left(r_{b2}+\frac{1}{g_{m1}}\right)+\frac{C_{\pi1}+C_{cs1}}{g_{m1}} + \frac{C_{\pi13}+C_{cs3}}{g_{m3}} + C_{\mu1}r_{b1} + C_{\mu4}r_{b4} \tag{17.77}$$

This corresponds approximately to the f_t of the transistors, although Equation 17.77 shows that the collector–substrate capacitance also contributes toward limiting the maximum operating frequency. The zero time constant τ_z is given by

$$\tau_z = (C_{\pi1}+C_{\mu1})r_{b1} + \frac{C_{\pi2}}{g_{m2}} + \frac{C_{\pi4}}{g_{m4}} + C_{\mu4}r_{b4} \tag{17.78}$$

This is of the same order of magnitude as the second pole. This means that the first zero and the second pole will be close together, and will compensate to a certain degree. However, in reality, there are more poles and zeros than Equation 17.75 would suggest, and it is likely that others will also occur around the actual f_t of the transistors.

17.7.4.6 Noise

Noise in companding and log-domain circuits is discussed in some detail in Refs. [68–70], and a complete treatment is beyond the scope of this discussion. For linear (noncompanding) circuits, noise is generally assumed to be independent of signal level, and the SNR will increase with increasing input signal level. This is not true for log-domain systems. At small input signal levels, the noise value can be assumed approximately constant, and an increase in signal level will give an increase in SNR. At high signal levels, the instantaneous value of noise will increase, and thus the SNR levels out at a constant value. This can be considered as an intermodulation of signal and noise power. For the Class A circuits discussed above, the peak signal level is limited by the dc bias current. In this case, the large-signal noise is found to be of the same order of magnitude as the quiescent noise level, and thus a linear approximation is generally acceptable (this is not the case for Class AB circuits).

17.7.5 Synthesis of Higher-Order Log-Domain Filters

The state-space synthesis technique outlined above proves difficult if implementation of high-order filters is required, since it becomes difficult to define and manipulate a large set of state equations. One solution is to use the signal flow graph (SFG) synthesis method proposed by Perry and Roberts [71] to simulate LC ladder filters using log-domain building blocks. The interested reader is also referred to Refs. [72–74], which present modular and transistor-level synthesis techniques that can be easily extended to higher-order filters.

18.1 Electrical Circuit

An electrical circuit or electrical network is an array of interconnected elements wired so as to be capable of conducting current. As discussed earlier, the fundamental two-terminal elements of an electrical circuit are the resistor, capacitor, inductor, voltage source, and current source. The circuit schematic symbols of these elements, together with the algebraic symbols used to denote their respective general values, shown in Figure 18.1.

As suggested in Figure 18.1, the value of a resistor is known as its resistance, R, and its dimensional units are ohms. The case of a wire used to interconnect the terminals of two electrical elements corresponds to the special case of a resistor whose resistance is ideally zero ohms; that is, $R = 0$. For the capacitor in Figure 18.1b, the capacitance, C, has units of farads, and from Figure 18.1c, the value of an inductor is its inductance, L, the dimensions of which are henries. In the case of the voltage sources depicted in Figure 18.1d, a constant, time-invariant source of voltage, or battery, is distinguished from a voltage source that varies with time. The latter type of voltage source is often referred to as a time-varying signal or simply, a signal. In either case, the value of the battery voltage, E, and the time-varying signal, $v(t)$, is in units of volts. Finally, the current source of Figure 18.1e has a value, I, in units of amperes, which is typically abbreviated as amps.

Elements having three, four, or more than four terminals can also appear in practical electrical networks. The discrete component bipolar junction transistor (BJT), which is schematically portrayed in Figure 18.2a, is an example of a three-terminal element, in which the three terminals are the collector, base, and emitter. On the other hand, the monolithic metal-oxide-semiconductor field-effect transistor (MOSFET) depicted in Figure 18.2b has four terminals: drain, gate, source, and bulk substrate.

Multiterminal elements appearing in circuits identified for systematic mathematical analyses are routinely represented, or modeled, by equivalent subcircuits formed of only interconnected two-terminal elements. Such a representation is always possible, provided that the list of two-terminal elements itemized in Figure 18.1 is appended by an additional type of two-terminal element known as the controlled source, or dependent generator. Two of the four types of controlled sources are voltage sources and two are current sources. In Figure 18.3a, the dependent generator is a voltage-controlled

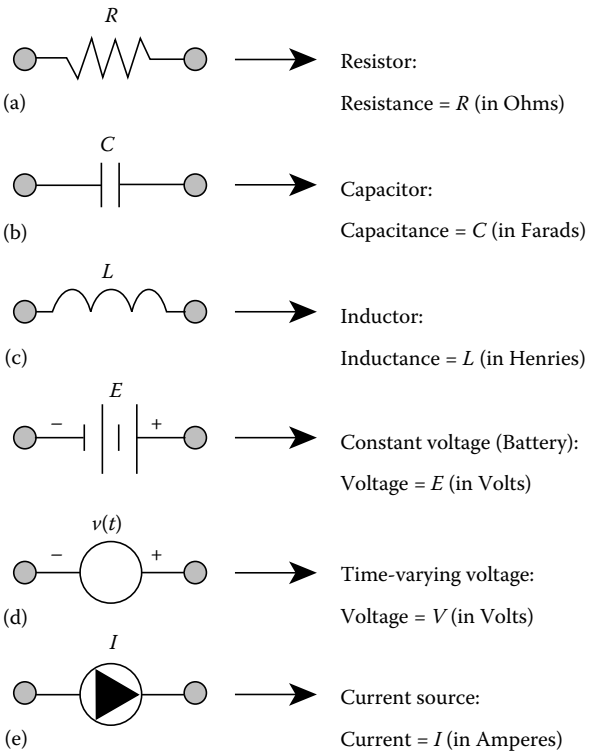

FIGURE 18.1 Circuit schematic symbol and corresponding value notation for (a) resistor, (b) capacitor, (c) inductor, (d) voltage source, and (e) current source. Note that a constant voltage source, or battery, is distinguished from a voltage source that varies with time.

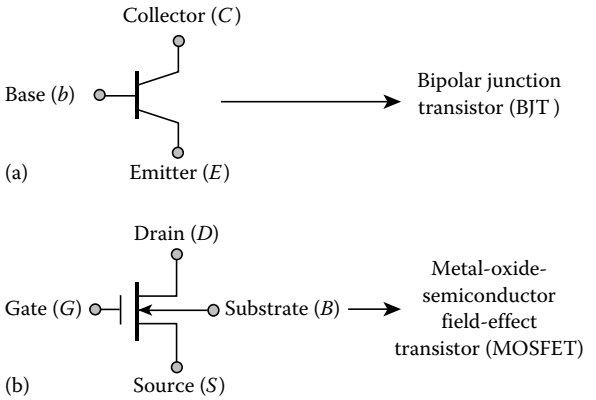

FIGURE 18.2 Circuit schematic symbol for (a) discrete component BJT and (b) MOSFET.

voltage source (VCVS) in that the voltage, $v_o(t)$, developed from terminal 3 to terminal 4 is a function of, and is therefore dependent on, the voltage, $v_i(t)$, established elsewhere in the considered network from terminal 1 to terminal 2. The controlled voltage, $v_o(t)$, as well as the controlling voltage, $v_i(t)$, can be constant or time-varying. Regardless of the time-domain nature of these two voltage, the value of $v_o(t)$ is

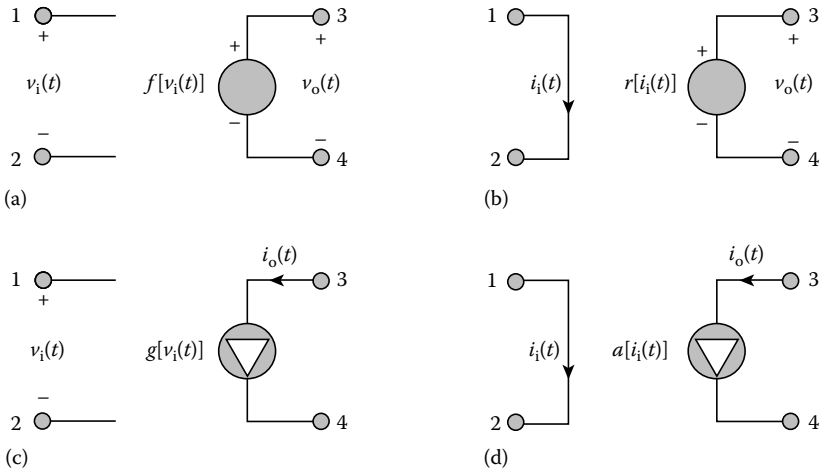

FIGURE 18.3 Circuit schematic symbol for (a) VCVS, (b) CCVS, (c) VCCS, and (d) CCCS.

not an independent number. Instead, its value is determined by $v_i(t)$ in accordance with a prescribed functional relationship, for example,

$$v_o(t) = f[v_i(t)] \tag{18.1}$$

If the function, $f(\cdot)$, is linearly related to its argument, Equation 18.1 collapses to the form

$$v_o(t) = f_\mu v_i(t) \tag{18.2}$$

where f_μ is a constant, independent of either $v_o(t)$ or $v_i(t)$. When the function on the right-hand side of Equation 18.1 is linear, the subject VCVS becomes known as a linear voltage-controlled voltage source.

The second type of controlled voltage source is the current-controlled voltage source (CCVS) depicted in Figure 18.3b. In this dependent generator, the controlled voltage, $v_o(t)$, developed from terminal 3 to terminal 4 is a function of the controlling current, $i_i(t)$, flowing elsewhere in the network between terminals 1 and 2, as indicated. In this case, the generalized functional dependence of $v_o(t)$ on $i_i(t)$ is expressible as

$$v_o(t) = r[i_i(t)] \tag{18.3}$$

which reduces to

$$v_o(t) = r_m i_i(t) \tag{18.4}$$

when $r(\cdot)$ is a linear function of its argument.

The two types of dependent current sources are diagrammed symbolically in Figure 18.3c and d. Figure 18.3c depicts a voltage-controlled current source (VCCS), for which the controlled current $i_o(t)$, flowing in the electrical path from terminal 3 to terminal 4, is determined by the controlling voltage, $v_i(t)$, established across terminals 1 and 2. Therefore, the controlled current can be written as

$$i_o(t) = g[v_i(t)] \tag{18.5}$$

In the current-controlled current source (CCCS) of Figure 18.3d

$$i_o(t) = a[i_i(t)] \tag{18.6}$$

where the controlled current, $i_o(t)$, flowing from terminal 3 to terminal 4 is a function of the controlling current, $i_i(t)$, flowing elsewhere in the circuit from terminal 1 to terminal 2. As is the case with the two controlled voltage sources studied earlier, the preceding two equations collapse to the linear relationships

$$i_o(t) = g_m v_i(t) \tag{18.7}$$

and

$$i_o(t) = a_\alpha i_i(t) \tag{18.8}$$

when $g(\cdot)$ and $a(\cdot)$, respectively, are linear functions of their arguments.

The immediate implication of the controlled source concept is that the definition for an electrical circuit given at the beginning of this section can be revised to read "an electrical circuit or electrical network is an array of interconnected two-terminal elements wired in such a way as to be capable of conducting current." Implicit in this revised definition is the understanding that the two-terminal elements allowed in an electrical circuit are the resistor, capacitor, inductor, voltage source, current source, and any of the four possible types of dependent generators.

In, an attempt to reinforce the engineering utility of the foregoing definition, consider the voltage-mode operational amplifier, or op-amp, whose circuit schematic symbol is submitted in Figure 18.4a. Observe that the op-amp is a five-terminal element. Two terminals, labeled 1 and 2, are provided to receive input signals that derive either from external signal sources or from the output terminals of subcircuits that feedback a designable fraction of the output signal established between terminal 3 and the system ground. Battery voltages, identified as E_{CC} and E_{BB} in the figure, are applied to the remaining two op-amp terminals (terminals 4 and 5) with respect to ground to bias or activate the op-amp for its intended application. When E_{CC} and E_{BB} are selected to ensure that the subject op-amp behaves as a linear circuit element, the voltages, E_{CC} and E_{BB}, along with the corresponding terminals at which they are incident, are inconsequential. In this event the op-amp of Figure 18.4a can be modeled by the electrical circuit appearing in Figure 18.4b, which exploits a linear VCVS. Thus, the voltage amplifier of Figure 18.4c, which interconnects two batteries, a signal source voltage, three resistors, a capacitor, and an op-amp, can be represented by the network given in Figure 18.4d. Note that the latter configuration uses only two terminal elements, one of which is a VCVS.

18.1.1 Current and Current Polarity

The concept of an electrical current is implicit to the definition of an electrical circuit in that a circuit is said to be an array of two-terminal elements that are connected in such a way as to permit the condition of current. Current flow through an element that is capable of current conduction requires that the net charge observed at any elemental cross-section change with time. Equivalently, a net nonzero charge, $q(t)$, must be transferred over finite time across any cross-sectional area of the element. The current, $i(t)$, that actually flows is the time rate of change of this transferred charge:

$$i(t) = \frac{dq(t)}{dt} \tag{18.9}$$

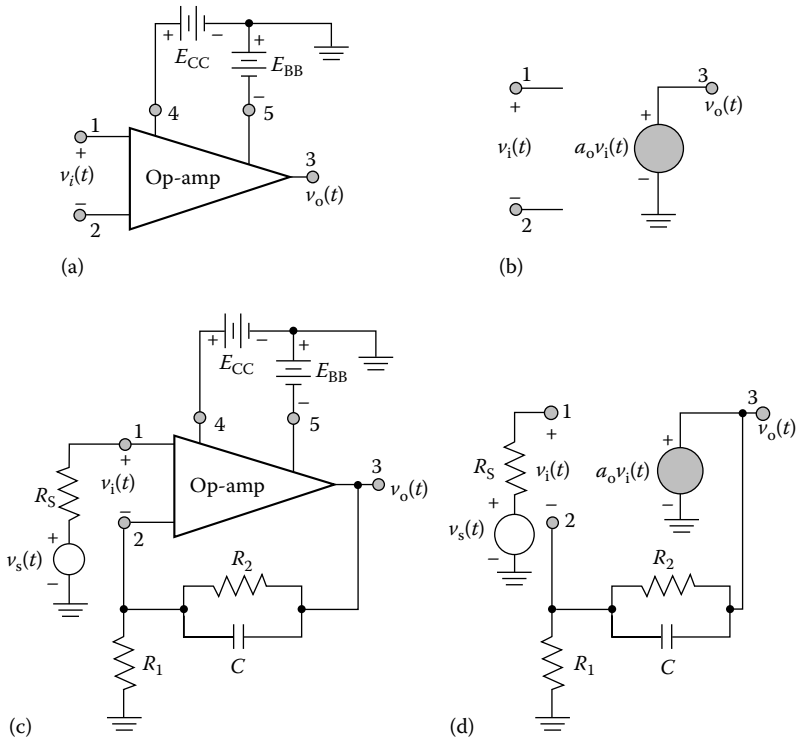

FIGURE 18.4 (a) Circuit schematic symbol for a voltage-mode operational amplifier. (b) First-order linear model of the op-amp. (c) A voltage amplifier realized with the op-amp functioning as the gain element. (d) Equivalent circuit of the voltage amplifier in (c).

where

MKS unit of charge is the coulomb
time t is measured in seconds
resultant current is measured in units of amperes

Note that zero current does not necessarily imply a lack of charge at a given cross-section of a conductive element. Instead, zero current implies only that the subject charge is not changing with time, that is, the charge is not moving through the elemental cross-section.

Electrical charge can be negative, as in the case of electrons transported through a cross-section of a conductive element such as aluminum or copper. A single electron has a charge of $-(1.6021 \times 10^{-19})$ C. Thus, Equation 18.9 implies a need to transport an average of (6.242×10^{18}) electrons in 1 s through a cross-section of aluminum if the aluminum element is to conduct a constant current of 1 A. Charge can also be positive, as in the case of holes transported through a cross-section of a semiconductor such as germanium or silicon. Hole transport in a semiconductor is actually electron transport at an energy level that is smaller than the energy required to effect electron transport in that semiconductor. To first order, therefore, the electrical charge of a hole is the negative of the charge of an electron, which implies that the charge of a hole is $+(1.602 \times 10^{-19})$ C.

A positive charge, $q(t)$, transported from the left of the cross-section to the right of the cross-section in the element abstracted in Figure 18.5a gives rise to a positive current, $i(t)$, which also flows from left to right across the indicated cross-section. Assume that, prior to the transport of such charge, the volumes to the left and to the right of the cross-section are electrically neutral, that is, these volumes have zero

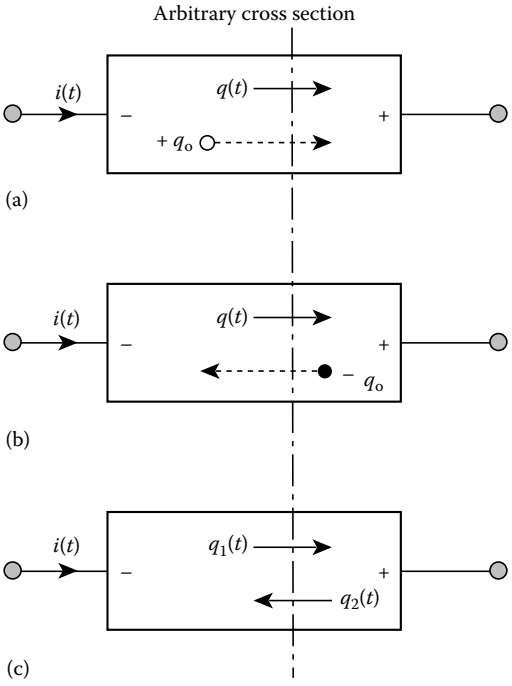

FIGURE 18.5 (a) Transport of a positive charge from the left-hand side to the right-hand side of an arbitrary cross-section of a conductive element. (b) Transport of a negative charge from the right-hand side to the left-hand side of an arbitrary cross-section of a conductive element. (c) Transport of positive or negative charges from either side to the other side of an arbitrary cross-section of a conductive element.

initial net charge. Then, the transport of a positive charge, q_0, from the left side to the right side of the element charges the right side to $+1q_0$ and the left side to $-1q_0$.

Alternatively, suppose a negative charge in the amount of $-q_0$ is transported from the right side of the element to its left side, as suggested in Figure 18.5b. Then, the left side charges to $-q_0$, and the right side charges to $+q_0$, which is identical to the electrostatic condition incurred by the transport of a positive charge in the amount of q_0 from left- to right-hand sides. As a result, the transport of a net negative charge from right to left produces a positive current, $i(t)$, flowing from left to right, just as positive charge transported from left- to right-hand sides induces a current flow from left to right.

Assume, as portrayed in Figure 18.5c, that a positive or a negative charge, say, $q_1(t)$, is transported from the left side of the indicated cross-section to the right side. Simultaneously, a positive or a negative charge in the amount of $q_2(t)$ is directed through the cross-section from right to left. If $i_1(t)$ is the current arising from the transport of the charge $q_1(t)$, and if $i_2(t)$ denotes the current corresponding to the transport of the charge, $q_2(t)$, the net effective current $i_e(t)$, flowing from the left side of the cross-section to the right side of the cross-section is

$$i_e(t) = \frac{d}{dt}[q_1(t) - q_2(t)] = i_1(t) - i_2(t) \tag{18.10}$$

where the charge difference, $[q_1(t) - q_2(t)]$, represents the net charge transported from left to right. Observe that if $q_1(t) + q_2(t)$, the net effective current is zero, even though conceivably large numbers of charges are transported back and forth across the junction.

18.1.2 Energy and Voltage

The preceding section highlights the fundamental physical fact that the flow of current through a conductive electrical element mandates that a net charge be transported over finite time across any arbitrary cross-section of that element. The electrical effect of this charge transport is a net positive charge induced on one side of the element in question and a net negative charge (equal in magnitude to the aforementioned positive charge) mirrored on the other side of the element. This ramification conflicts with the observable electrical properties of an element in equilibrium. In particular, an element sitting in free space, without any electrical connection to a source of energy, is necessarily in equilibrium in the sense that the net positive charge in any volume of the element is precisely counteracted by an equal amount of charge of opposite sign in said volume. Thus, if none of the elements abstracted in Figure 18.5 is connected to an external source of energy, it is physically impossible to achieve the indicated electrical charge differential that materializes across an arbitrary cross-section of the element when charge is transferred from one side of the cross-section to the other.

The energy commensurate with sustaining current flow through an electrical element derives from the application of a voltage, $v(t)$, across the element in question. Equivalently, the application of electrical energy to an element manifests itself as a voltage developed across the terminals of an element to which energy is supplied. The amount of applied voltage, $v(t)$, required to sustain the flow of current, $i(t)$, as diagrammed in Figure 18.6a, is precisely the voltage required to offset the electrostatic implications of the differential charge induced across the element through which $i(t)$ flows. This is to say that without the connection of the voltage, $v(t)$, to the element in Figure 18.6a, the element cannot be in equilibrium. With $v(t)$ connected, equilibrium for the entire system comprised of element and voltage source is reestablished by allowing for the conduction of the current, $i(t)$.

Instead of viewing the delivery of energy to an electrical element as the ramification of a voltage source applied to the element, the energy delivery may be interpreted as the upshot of a current source used to excite the element, as depicted in Figure 18.6b. This interpretation follows from the fact that energy must be applied in an amount that effects charge transport at a desired time rate of change. It follows that the application of a current source in the amount of the desired current is necessarily in one-to-one

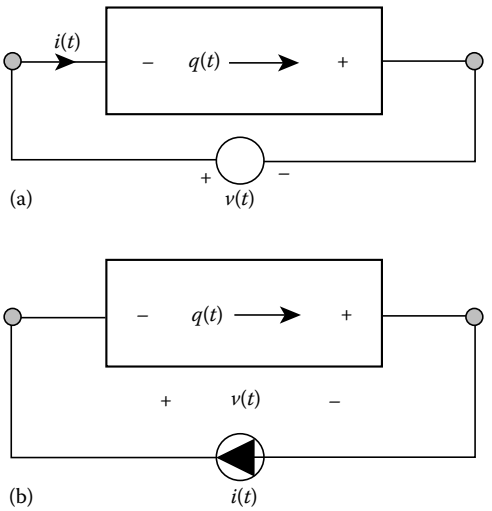

FIGURE 18.6 (a) The application of energy in the form of a voltage applied to an element that is made to conduct a specified current. The applied voltage, $v(t)$, causes the current, $i(t)$, to flow. (b) The application of energy in the form of a current applied to an element that is made to establish a specified terminal voltage. The applied current, $i(t)$, causes the voltage, $v(t)$, to be developed across the terminals of the electrical element.

correspondence with the voltage required to offset the charge differential manifested by the charge transport that yields the subject current. To be sure, a voltage source is a physical entity, while current source is not, but the mathematical modeling of energy delivery to an electrical element can nonetheless be accomplished through either a voltage source or a current source.

In Figure 18.6, the terminal voltage, $v(t)$, corresponding to the energy, $w(t)$, required to transfer an amount of charge, $q(t)$, across an arbitrary cross-section of the element is

$$v(t) = \frac{dw(t)}{dq(t)} \tag{18.11}$$

where

$v(t)$ is in units of volts when $q(t)$ is expressed in coulombs
$w(t)$ is specified in joules

Thus, if 1 J of applied energy results in the transport of 1 C of charge through an element, the elemental terminal voltage manifested by the 1 J of applied energy is 1 V.

It should be understood that the derivative on the right-hand side of Equation 18.11, and thus the terminal voltage demanded of an element that is transporting a certain amount of charge through its cross-section, is a function of the properties of the type of material from which the element undergoing study is fabricated. For example, an insulator such as paper, air, or silicon dioxide is ideally incapable of current conduction and hence, intrinsic charge transport. Thus, $q(t)$ is essentially zero in an insulator and by Equation 18.11, an infinitely large terminal voltage is required for even the smallest possible current. In a conductor such as aluminum, iron, or copper, large amounts of charge can be transported for very small applied energies. Accordingly, the requisite terminal voltage for even very large currents approaches zero in ideal conductors. The electrical properties of semiconductors such as germanium, silicon, and gallium arsenide lie between the extremes of those for an insulator and a conductor. In particular, semiconductor elements behave as insulators when their terminals are subjected to small voltages, while progressively larger terminal voltages render the electrical behavior of semiconductors akin to conductors. This conditional conductive property of a semiconductor explains why semiconductor devices and circuits generally must be biased to appropriate voltage levels before these devices and circuits can function in accordance with their requirements.

18.1.3 Power

The foregoing material underscores the fact that the flow of current through a two-terminal element, or more generally, through any two terminals of an electrical network, requires that charge be transported over time across any cross-section of that element or network. In turn, such charge transport requires that energy be supplied to the network, usually through the application of an external voltage source. The time rate of change of this applied energy is the power delivered by the external voltage or current source to the network in question. If $p(t)$ denotes this power in units of watts

$$p(t) = \frac{dw(t)}{dq} \tag{18.12}$$

where, of course, $w(t)$ is the energy supplied to the network in joules. By rewriting Equation 18.12 in the form

$$p(t) = \frac{dw(t)}{dq(t)} \frac{dq(t)}{dt} \tag{18.13}$$

and applying Equations 18.9 and 18.11, the power supplied to the two terminals of an element or a network becomes the more expedient relationship

$$p(t) = v(t)i(t) \tag{18.14}$$

Equation 18.14 expresses the power delivered to an element as a simple product of the voltage applied across the terminals of the element and the resultant current conducted by that element. However, care must be exercised with respect to relative voltage and current polarity, when applying Equation 18.14 to practical circuits.

To the foregoing end, it is useful to revisit the simple abstraction of Figure 18.6a, which is redrawn as the slightly modified form in Figure 18.7. In this circuit, a signal source voltage, $v_s(t)$, is applied across the two terminals, 1 and 2, of an element, which responds by conducting a current $i(t)$, from terminal 1 to terminal 2 and developing a corresponding terminal voltage $v(t)$, as illustrated. If the wires (zero resistance conductors, as might be approximated by either aluminum or copper interconnects) that connect the signal source to the element are ideal, the voltage, $v(t)$, is identical to $v_s(t)$. Moreover, because the current is manifested by the application of the signal source, which thereby establishes a closed electrical path for current conduction, the element current, $i(t)$, is necessarily the same as the current, $i_s(t)$, that flows through $v_s(t)$.

If attention is focused on only the element in Figure 18.7, it is natural to presume that the current conducted by the element actually flows from terminal 1 to terminal 2 when (as shown) the voltage developed across the element is positive at terminal 1 with respect to terminal 2. This assertion may be rationalized qualitatively by noting that the positive voltage nature at terminal 1 acts to repel positive charges from terminal 1 to terminal 2, where the negative nature of the developed voltage, $v(t)$, tends to attract the repulsed positive charges. Similarly, the positive nature of the voltage at terminal 1 serves to attract negative charges from terminal 2, where the negative nature of $v(t)$ tends to repel such negative charges. Because current flows in the direction of transported positive charge and opposite to the direction of transported negative charge, either interpretation gives rise to an elemental current, $i(t)$, which flows from terminal 1 to terminal 2. In general, if current is indicated as flowing from the "high" (+) voltage terminal to the "low" (−) voltage terminal of an element, the current conducted by the element and the voltage developed across the element to cause this flow of current are said to be in associated reference polarity. When the element current, $i(t)$, and the corresponding element voltage, $v(t)$, as exploited in the defining power relationship of Equation 18.14, are in associated reference polarity, the resulting computed power is a positive number and is said to represent the power delivered to the element. In contrast, $v(t)$ and $i(t)$ are said to be in disassociated reference polarity when $i(t)$ flows from the "low" voltage terminal of the element to its "high" voltage terminal. In this case the voltage-current product in Equation 18.14 is a negative number. Instead of stating that the resulting negative power is delivered to the element, it is more meaningful to assert that the computed negative power is a positive power that is generated by the element in question.

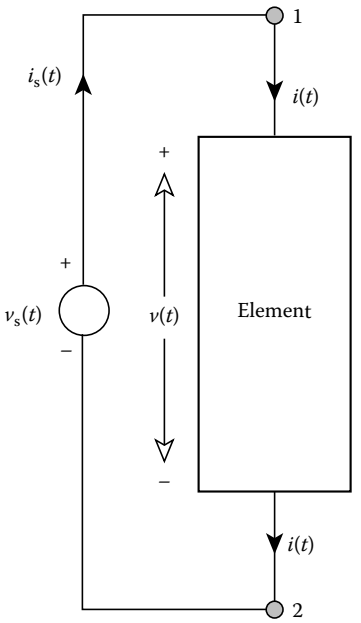

FIGURE 18.7 Circuit used to illustrate power calculations and the associated reference polarity convention.

At first glance, it may appear as though the latter polarity disassociation between element voltage and current variables is an impossible circumstance. Not only is polarity disassociation possible, it is absolutely necessary if electrical circuits are to subscribe to the fundamental principle of conversation of power. This

principle states that the net power dissipated by a circuit must be identical to the net power supplied to that circuit. A confirmation of this basic principle derives from a further consideration of the topology in Figure 18.7. The electrical variables, $v(t)$ and $i(t)$, pertinent to the element delineated in this circuit, are in associated reference polarity. Accordingly, the power, $p_e(t)$, dissipated by this element is positive and given by Equation 18.14:

$$p_e(t) = v(t)i(t) \tag{18.15}$$

However, the voltage and current variables, $v_s(t)$ and $i_s(t)$, relative to the signal source voltage are in disassociated polarity. It follows that the power, $p_s(t)$, delivered to the signal source is

$$p_s(t) = -v_s(t)i_s(t) \tag{18.16}$$

Because, as stated previously, $v_s(t) = v(t)$ and $i_s(t) = i(t)$, for the circuit at hand, Equation 18.16 can be written as

$$p_s(t) = -v(t)i(t) \tag{18.17}$$

The last result implies that the

$$\text{power delivered by the signal source} = +v(t)i(t) \equiv p_e(t) \tag{18.18}$$

that is, the power delivered to the element by the signal source is equal to the power dissipated by the element.

An alternative statement to conservation of power, as applied to the circuit in Figure 18.7 derives from combining Equations 18.15 and 18.17 to arrive at

$$p_s(t) + p_e(t) = 0 \tag{18.19}$$

The foregoing result may be generalized to the case of a more complex circuit comprised of an electrical interconnection of N elements, some of which may be voltage and current sources. Let the voltage across the kth element by $v_k(t)$, and let the current flowing through this kth element, in associated reference polarity with $v_k(t)$, be $i_k(t)$. Then, the power, $p_k(t)$, delivered to the kth electrical element is $v_k(t)\ i_k(t)$. By conservation of power,

$$\sum_{k=1}^{N} p_k(t) = \sum_{k=1}^{N} v_k(t) = i_k(t) = 0 \tag{18.20}$$

The satisfaction of the expression requires that at least one of the $p_k(t)$ be negative, or equivalently, at least one of the N elements embedded in the circuit at hand must be a source of energy.

18.2 Circuit Classifications

It was pointed out earlier that the relationship between the current that is made to flow through an electrical element and the applied energy, and thus voltage, that is required to sustain such current flow is dictated by the material from which the subject element is fabricated. The element material and the associated manufacturing methods exploited to realize a particular type of circuit element determine the mathematical nature between the voltage applied across the terminals of the element and the resultant

current flowing through the element. To this end, electrical elements and circuits in which they are embedded are generally codified as linear or nonlinear, active or passive, time-varying or time-invariant, and lumped or distributed.

18.2.1 Linear vs. Nonlinear

A linear two-terminal circuit element is one for which the voltage developed across, and the current flowing through, are related to one another by a linear algebraic or a linear integro-differential equation. If the relationship between terminal voltage and corresponding current is nonlinear, the element is said to be nonlinear. A linear circuit contains only linear circuit elements, while a circuit is said to be nonlinear if a least one of its embedded electrical elements is nonlinear.

All practical circuit elements, and thus all practical electrical networks, are inherently nonlinear. However, over suitably restricted ranges of applied voltages and corresponding currents, the volt–ampere characteristics of these elements and networks emulate idealized linear relationships. In the design of an electronic linear signal processor, such as an amplifier, an implicit engineering task is the implementation of biasing subcircuits that constrain the voltages and currents of internal semiconductor elements to ranges that ensure linear elemental behavior over all possible operating conditions.

The voltage–current relationship for the linear resistor offered in Figure 18.8a is

$$v(t) = Ri(t) \tag{18.21}$$

where the voltage, $v(t)$, appearing across the terminals of the resistor and the resultant current, $i(t)$, conducted by the resistor are in associated reference polarity. The resistance, R, is independent of either $v(t)$ or $i(t)$. From Equation 18.14, the dissipated resistor power, which is mainfested in the form of heat is

$$p_r(t) = i^2(t)R = \frac{v^2(t)}{R} \tag{18.22}$$

The linear capacitor and the linear inductor, with schematic symbols that appear, respectively, in Figure 18.8b and c, store energy as opposed to dissipating power. Their volt–ampere equations are the linear relationships

$$i(t) = C\frac{dv(t)}{dt} \tag{18.23}$$

for the capacitor, whereas for the inductor in Figure 18.8c,

$$v(t) = L\frac{di(t)}{dt} \tag{18.24}$$

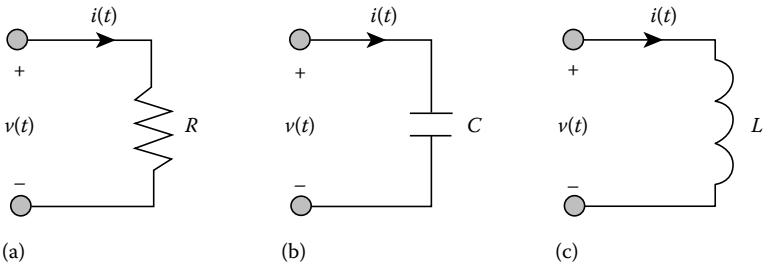

FIGURE 18.8 Circuit schematic symbol and corresponding voltage and current notation for (a) linear resistor, (b) linear capacitor, and (c) linear inductor.

Observe from Equations 18.23 and 18.14 that the power, $p_c(t)$, delivered to the linear capacitor is

$$p_c(t) = v(t)i(t) = Cv(t)\frac{dv(t)}{dt} \tag{18.25}$$

From Equation 18.12, this power is related to the energy, for example, $w_c(t)$, stored in the form of charge deposited on the plates of the capacitor by

$$Cv(t)dv(t) = dw_c(t) \tag{18.26}$$

It follows that the energy delivered to, and hence stored in, the capacitor from time $t = 0$ to time t is

$$w_c(t) = \frac{1}{2}Cv^2(t) \tag{18.27}$$

It should be noted that this stored energy, like the energy associated with a signal source or a battery voltage, is available to supply power to other elements in the network in which the capacitor is embedded. For example, if very little current is conducted by the capacitor in question, Equation 18.23 implies that the voltage across the capacitor is essentially constant. However, an element whose terminal voltage is a constant and in which energy is stored and therefore available for use behaves as a battery.

If the preceding analysis is repeated for the inductor of Figure 18.8c, it can be shown that the energy, $w_l(t)$, stored in the inductive element form time $t = 0$ to time t is

$$w_l(t) = \frac{1}{2}Li^2(t) \tag{18.28}$$

Although an energized capacitor conducting almost zero current functions as a voltage source, an energized inductor supporting almost zero terminal voltage emulates a constant current source.

18.2.2 Active vs. Passive

An electrical element or network is said to be passive if the power delivered to it, defined in accordance with Equation 18.14, is positive. This definition exploits the requirement that the terminal voltage, $v(t)$, and the element current $i(t)$, appearing in Equation 18.14 be in associated reference polarity. In contrast, an element or network to which the delivered power is negative is said to be active, that is, an active element or network generates power instead of dissipating it.

Conventional two-terminal resistors, capacitors, and inductors are passive elements. It follows that networks formed of interconnected two-terminal resistors, capacitors, and inductors are passive networks. Two-terminal voltage and current sources generally behave as active elements. However, when more than one source of externally applied energy is present in an electrical network, it is possible for one more of these sources to behave as passive elements. Comments similar to those made in conjunction with two-terminal voltage and current sources apply equally well to each of the four possible dependent generators. Accordingly, multiterminal configurations, whose models exploit dependent sources, can behave as either passive or active networks.

18.2.3 Time-Varying vs. Time-Invariant

The elements of a circuit are defined electrically by an identifying parameter, such as resistance, capacitance, inductance, and the gain factors associated with dependent voltage or current sources. An

element whose identifying parameter changes as a function of time is said to be a time-varying element. If said parameter is a constant over time, the element in question is time-invariant. A network containing at least one time-varying electrical element it is said to be a time-varying network. Otherwise, the network is time-invariant. Excluded from the list of elements whose electrical character establishes the time variance or time invariance of a considered network are externally applied voltage and current sources. Thus, for example, a network with internal elements that are exclusively time-invariant resistors, capacitors, inductors, and dependent sources, but which is excited by a sinusoidal signal source, is nonetheless a time-invariant network.

Although some circuits, and particularly electromechanical networks, are purposely designed to exhibit time-varying volt–ampere characteristics, parametric time variance is generally viewed as a parasitic phenomena in the majority of practical circuits. Unfortunately, a degree of parametric time variance is unavoidable in even those circuits that are specifically designed to achieve input–output response properties that closely approximate time-invariant characteristics. For example, the best of network elements exhibit a slow aging phenomenon that shifts the values of its intrinsic physical parameters. The upshot of these shifts is electrical circuits where overall performance deteriorates with time.

18.2.4 Lumped vs. Distributed

Electrons in conventional conductive elements are not transported instantaneously across elemental cross sections, but their transport velocities are very high. In fact, these velocities approach the speed of light, say c, which is (3×10^8) m/s or about 982 ft./μs. Electrons and holes in semiconductors are transported at somewhat slower speeds, but generally no less than an order of magnitude or so smaller than the speed of light. The time required to transport charge from one terminal of a two-terminal electrical element to its other terminal, compared with the time required to propagate energy uniformly through the element, determines whether an element is lumped or distributed. In particular, if the time required to transport charge through an element is significantly smaller than the time required to propagate the energy through the element that is required to incur such charge transport, the element in question is said to be lumped. On the other hand, if the charge transport time is comparable to the energy propagation time, the element is said to be distributed.

The concept of a lumped, as opposed to a distributed, circuit element can be qualitatively understood through a reconsideration of the circuit provided in Figure 18.7. As argued, the indicated element current, $i(t)$, is identical to the indicated source current, $i_s(t)$. This equality implies that $i(t)$, is effectively circulating around the loop that is electrically formed by the interconnection of the signal source voltage, $v_s(t)$, to the element. Equivalently, the subject equality implies that $i(t)$ is entering terminal 1 of the element and simultaneously is exiting at terminal 2, as illustrated. Assuming that the element at hand is not a semiconductor, the current, $i(t)$, arises from the transport of electrons through the element in a direction opposite to that of the indicated polarity of $i(t)$. Specifically, electrons must be transported from terminal 2, at the bottom of the element, to terminal 1, at the top of the element, and in turn the requisite amount of energy must be applied in the immediate neighborhoods of both terminals. The implication of presuming that the element at hand is lumped is that $i(t)$ is entering terminal 1 at precisely the same time that it is leaving terminal 2. Such a situation is clearly impossible, for it mandates that electrons be transported through the entire length of the element in zero time. However, given that electrons are transported at a nominal velocity of 982 ft./μs, a very small physical elemental length renders the approximation of zero electron transport time reasonable. For example, if the element is $\frac{1}{2}$ in. long (a typical size for an off-the-shelf resistor), the average transport time for electrons in this unit is only about 42.4 ps. As long as the period of the applied excitation, $v_s(t)$, is significantly larger than 42.4 ps, the electron transport time is significantly smaller than the time commensurate with the propagation of this energy through the entire element. A period of 42.4 ps corresponds to a signal whose frequency of approximately 23.6 GHz. Thus, a $\frac{1}{2}$ in. resistive element excited by a signal whose frequency is significantly smaller than 23.6 GHz can be viewed as a lumped circuit element.

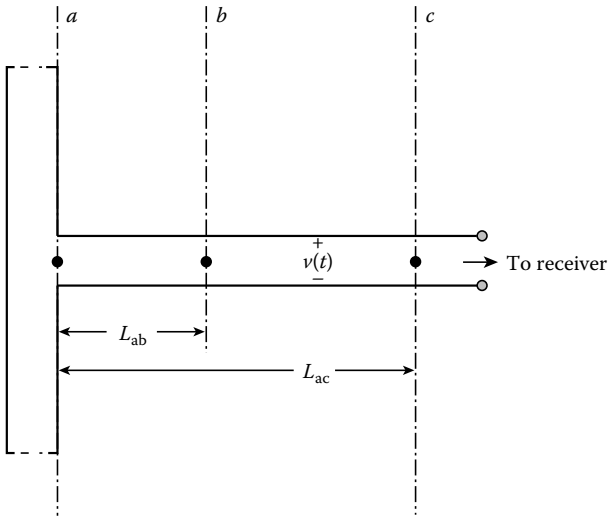

FIGURE 18.9 Schematic abstraction of a dipole antenna for an FM receiver application.

In the vast majority of electrical and electronic networks it is difficult not to satisfy the lumped circuit approximation. Nevertheless, several practical electrical systems cannot be viewed as lumped entities. For example, consider the lead-in wire that connects the antenna input terminals of a frequency-modulated (FM) radio receiver to an antenna, as diagrammed in Figure 18.9. Let the signal voltage, $v_a(t)$, across the lead-in wires at point "a" be the sinusoid

$$v_a(t) = V_M \cos(\omega t) \tag{18.29}$$

where

V_M represents the amplitude of the signal
ω is its frequency in units of radians per second

Consider the case in which $\omega = 2\pi(103.5 \times 10^6)$ rad/s, which is a carrier frequency lying within the commercial FM broadcast band. This high signal frequency makes the length of antenna lead-in wire critically important for proper signal reception.

In an attempt to verify the preceding contention, let the voltage developed across the lead-in lines at point "b" in Figure 18.9 be denoted as $v_b(t)$, and let point "b" be 1 ft. displaced from point "a"; that is, $L_{ab} = 1$ ft. The time, τ_{ab} required to transport electrons over the indicated length, L_{ab}, is

$$\tau_{ab} = \frac{L_{ab}}{c} = 1.018 \text{ ns} \tag{18.30}$$

Thus, assuming an idealized line in the sense of zero effective resistance, capacitance, and inductance, the signal, $v_b(t)$, at point "b" is seen as the signal appearing at "a," delayed by approximately 1.02 ns. It follows that

$$v_b(t) = V_M \cos[\omega(t - \tau_{ab})] = V_M \cos(\omega t - 0.662) \tag{18.31}$$

where the phase angle associated with $v_b(t)$ is 0.662 rad, or almost 38°. Obviously, the signal established at point "b" is a significantly phase-shifted version of the signal presumed at point "a."

An FM receiver can effectively retrieve the signal voltage, $v_a(t)$, by detecting a phase-inverted version of $v_a(t)$ at its input terminals. To this end, it is of interest to determine the length, L_{ac}, such that the signal, $v_c(t)$, established at point "c" in Figure 18.9 is

$$v_c(t) = V_M \cos(\omega t - \pi) \tag{18.32}$$

The required phase shift of 180°, or π radians, corresponds to a time delay, τ_{ac}, of

$$\tau_{ac} = \frac{\pi}{\omega} = 4.831 \text{ ns} \tag{18.33}$$

In turn, a time delay of τ_{ac} implies a required line length, L_{ac} of

$$L_{ac} = c\tau_{ac} = 4.744 \text{ ft.} \tag{18.34}$$

A parenthetically important point is the observation that the carrier frequency of 103.5 MHz corresponds to a wavelength, λ, of

$$\lambda = \frac{2\pi c}{\omega} = 9.489 \text{ ft.} \tag{18.35}$$

Accordingly, the lead-in length computed in Equation 18.34 is $\lambda/2$; that is, a half-wavelength.

19.1 Kirchhoff's Voltage and Current Laws

Circuit analysis, like Euclidean geometry, can be treated as a mathematical system, that is, the entire theory can be constructed upon a foundation consisting of a few fundamental concepts and several axioms relating these concepts. As it happens, important advantages accrue from this approach—it is not simply a desire for mathematical rigor, but a pragmatic need for simplification that prompts us to adopt such a mathematical attitude.

The basic concepts are conductor, element, time, voltage, and current. Conductor and element are axiomatic, thus, they cannot be defined, only explained. A conductor is the idealization of a piece of copper wire; an element is a region of space penetrated by two conductors of finite length termed leads and pronounced ''leeds.'' The ends of these leads are called terminals and are often drawn with small circles as in Figure 19.1.

Conductors and elements are the basic objects of circuit theory; we will take time, voltage, and current as the basic variables. The time variable is measured with a clock (or, in more picturesque language, a chronometer). Its unit is the second, s. Thus, we will say that time, like voltage and current, is defined operationally, that is, by means of a measuring instrument and a procedure for measurement. Our view of reality in this context is consonant with that branch of philosophy termed operationalism [1].

Voltage is measured with an instrument called a voltmeter, as illustrated in Figure 19.2. In Figure 19.2, a voltmeter consists of a readout device and two long, flexible conductors terminated in points called probes that can be held against other conductors, thereby making electrical contact with them. These conductors are usually covered with an insulating material. One is often colored red and the other black. The one colored red defines the positive polarity of voltage, and the other the negative polarity. Thus, voltage is always measured between two conductors. If these two conductors are element leads, the voltage is that across the corresponding element. Figure 19.3 is the symbolic description of such a measurement;

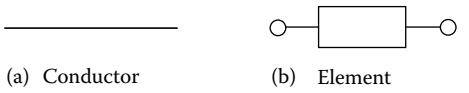

FIGURE 19.1 Conductors and elements.

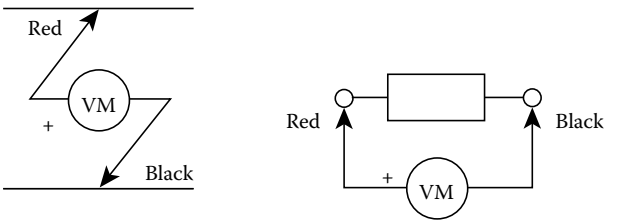

FIGURE 19.2 Operational definition of voltage.

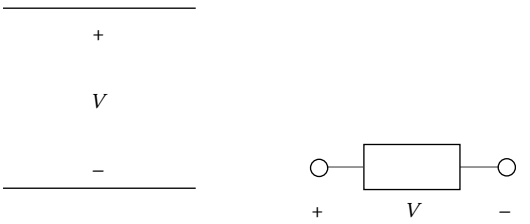

FIGURE 19.3 Symbolic description of the voltage measurement.

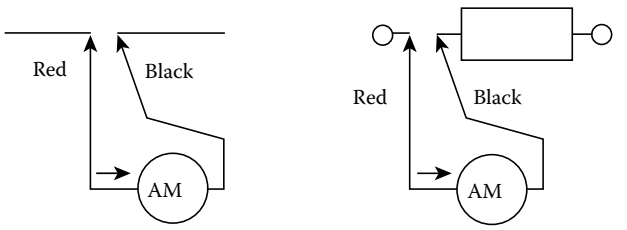

FIGURE 19.4 Operational definition of current.

the variable v, along with the corresponding plus and minus signs, means exactly the experimental procedure depicted in Figure 19.2, neither more nor less. The outcome of the measurement, incidentally, can be either positive or negative. Thus, a reading of $v = -12$ V, for example, has meaning only when viewed within the context of the measurement. If the meter leads are simply reversed after the measurement just described, a reading of $v' = +12$ V will result. The latter, however, is a different variable; hence, we have changed the symbol to v'. The V after the numerical value is the unit of voltage, the volt, V.

Although voltage is measured across an element (or between conductors), current is measured through a conductor or element. Figure 19.4 provides an operational definition of current. One cuts the conductor or element lead and touches one meter lead against one terminal thus formed and the other against the second. A shorthand symbol for the meter connection is an arrow close to one lead of the ammeter. This arrow, along with the meter reading, defines the current. We show the shorthand symbol for a current in Figure 19.5. The reference arrow and the symbol i are shorthand for the complete measurement in Figure 19.4—merely this and nothing more. The variable i can be either positive or negative; for example, one possible

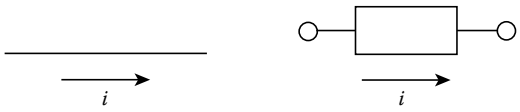

FIGURE 19.5 Symbolic representation of a current measurement.

TABLE 19.1 Summary of the Basic Concepts of Circuit Theory

Objects	Variables			
Conductor	Element	Time	Voltage	Current
—	—	Seconds, s	Volt, V	Ampere, A

outcome of the measurement might be $i = -5$ A. The A signifies the unit of current, the ampere. If the red and black leads in Figure 19.4 were reversed, the reading sign would change.

Table 19.1 provides a summary of the basic concepts of circuit theory: the two basic objects and the three fundamental variables. Notice that we are a bit at variance with the SI system here because although time and current are considered fundamental in that system, voltage is not. Our approach simplifies things, however, for one does not require any of the other SI units or dimensions. All other quantities are derived. For instance, charge is the integral of current and its unit is the ampere-second, or the coulomb, C. Power is the product of voltage and current. Its unit is the watt, W. Energy is the integral power, and has the unit of the watt-second, or joule, J. In this manner one avoids the necessity of introducing mechanical concepts, such as mechanical work, as being the product of force and distance.

In the applications of circuit theory, of course, one has need of the other concepts of physics. If one is to use circuit analysis to determine the efficiency of an electric motor, for example, the concept of mechanical work is necessary. However—and this is the main point of our approach—the introduction of such concepts is not essential in the analysis of a circuit itself. This idea is tied in to the concept of modeling. The basic catalog of elements used here does not include such things as temperature effects or radiation of electromagnetic energy. Furthermore, a ''real'' element such as resistor is not ''pure.'' A real resistor is more accurately modeled, for many purposes, as a resistor plus series inductance and shunt capacitance. The point is this: In order to adequately model the ''real world'' one must often use complicated combinations of the basic elements. Additionally, to incorporate the influence of variables such as temperature, one must assume that certain parameters (such as resistance or capacitance) are functions of that variable. It is the determination of the more complicated model or the functional relationship of a given parameter to, for example, temperatures that fall within the realm of the practitioner. Such ideas were discussed more fully in Chapter 18. Circuit analysis merely provides the tools for analyzing the end result.

The radiation of electromagnetic energy is, on the other hand, a quite different aspect of circuit theory. As will be seen, circuit analysis falls within a regime in which such behavior can be neglected. Thus, the theory of circuit analysis we will expound has a limited range of application: to low frequencies or, what is the same in the light of Fourier analysis, to waveforms that do not vary too rapidly.

We are now in a position to state two basic axioms, which we will assume all circuits obey:

Axiom 1: The behavior of an element is completely determined by its v–i characteristic, which can be determined by tests made on the element in isolation from the other elements in the circuit in which it is connected.

Axiom 2: The behavior of a circuit is independent of the size or the shape or the orientation of its elements, the conductors that interconnect them, and the element leads.

At this point, we loosely consider a circuit to be any collection of elements and conductors, although we will sharpen our definition a bit later. Axiom 1 means that we can run tests on an element in the laboratory, then wire it into a circuit and have the assurance that it will not exhibit any new and different behavior. Axiom 2 means that it is only the topology of a circuit that matters, not the way the circuit is stretched or bent or rearranged, so long as we do not change the listing of which element leads are connected to which others or to which conductors. Another way of saying this is that the circuit graph, described in Chapter 7, give all the necessary information about the way a circuit is wired.

The remaining two axioms are somewhat more involved and require some discussion of circuit topology. Consider, for a moment, the collection of elements in Figure 19.6. We labeled each element with a letter to distinguish it from the others. First, notice the two solid dots. We refer to them as joints. The idea is that they represent ''solder joints,'' where the ends of two or more leads or conductors were connected. If only two ends are connected we do not show the joints explicitly; where three or more are connected, however, they are drawn. We temporarily (as a test) erase all of the element bodies and replace them with open space. The result is given in Figure 19.7. We refer to each of the interconnected ''islands'' of a conductor as a node. This example circuit has six nodes, and we labeled them with the numbers one through six for identification purposes.

Axiom 3 (Kirchhoff's current law): The charge on a node or in an element is identically zero at all instants of time.

Kirchhoff's current law (KCL) is not usually phrased in quite this manner. Thus, let us consider the closed (or ''Gaussian'') surface S in Figure 19.8. We assume that it is penetrated only by conductors. The elements, of course, are there; we simply do not show them so that we can concentrate on the conductors. We have arbitrarily defined the currents in the conductors penetrating S. Now, recalling that charge is the time integral of the current and thus has the same direction as the current from which it is derived, one can phrase Axiom 3 as follows:

$$\sum_{S} q_{\text{in}} = q_{\text{enclosed}} = 0 \tag{19.1}$$

at each instant of time. This equation is simply one form of conservation of charge. Because current is the time derivative of voltage, one can also state that

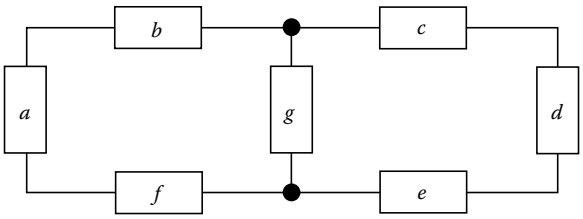

FIGURE 19.6 Example circuit.

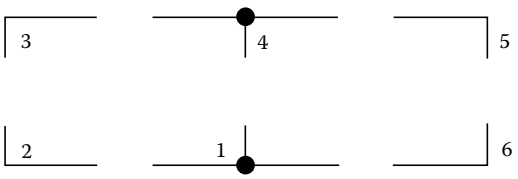

FIGURE 19.7 Nodes of the example circuit.

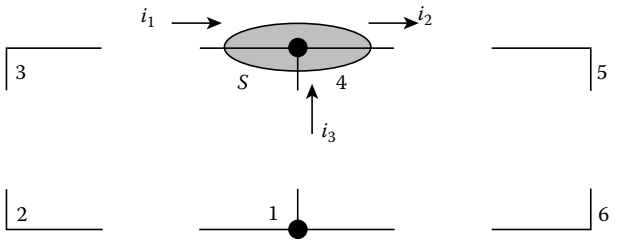

FIGURE 19.8 Illustration of KCL.

$$\sum_S i_{\text{in}} = 0 \tag{19.2}$$

at each and every time instant. This last equation is the usual phrasing of KCL. The subscript "in" means that a current reference pointed inward is to be considered positive; by default, therefore, a current with its reference pointed outward is to have a negative sign affixed. This sign is in addition to any negative sign that might be present in the value of each variable. For node 4 in Figure 19.8, KCL in its current form, therefore, reads

$$i_1 - i_2 + i_3 = 0 \tag{19.3}$$

Two other ways of expressing KCL (in current form) are

$$\sum_S i_{\text{out}} = 0 \tag{19.4}$$

and

$$\sum_S i_{\text{in}} = \sum_S i_{\text{out}} \tag{19.5}$$

The equivalent charge forms are also clearly valid. We emphasize the latter to a greater extent than is usual in the classical treatment because of the current interest in charge distribution and transfer circuits.

The Gaussian surface used to express KCL is not constrained to enclose only conductors. It can enclose elements as well, although it still can be penetrated by only conductors (which can be element leads). Thus, consider Figure 19.9, which illustrates the same circuit with which we have been working. Now, however, the elements are given and the Gaussian surface encloses three elements, as well as conductors carrying the currents previously defined. Because these currents are not carried in the conductors

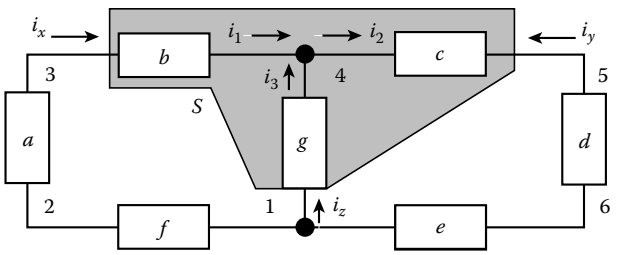

FIGURE 19.9 KCL for a more general surface.

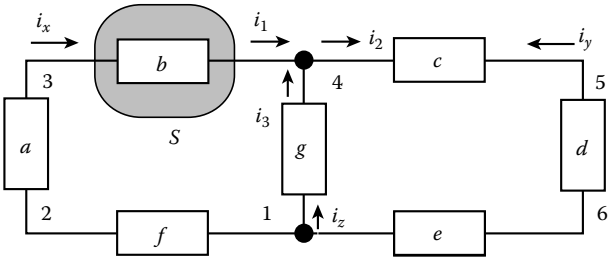

FIGURE 19.10 KCL for a single element.

penetrating the surface under consideration, they do not enter into KCL for that surface. Instead, KCL becomes

$$i_x + i_y + i_z = 0 \tag{19.6}$$

As a special case let us look once more at the preceding figure, but use a different surface, one enclosing only the element *b*. This is depicted in Figure 19.10. If we refer to Axiom 3, which notes that charge cannot accumulate inside an element, and apply charge conservation, we find that

$$i_x = i_1 \tag{19.7}$$

This states that the current into any element in one of its leads is the same as the current leaving in the other lead. In addition, we see that KCL for nodes and KCL for elements (both of which are implied by Axiom 3) imply that KCL holds for any general closed surface penetrated only by conductors such as the one used in connection with Figure 19.9.

In order to phrase our last axiom, we must discuss circuit topology a bit more, and we will continue to use the circuit just considered previously. We define a path to be an ordered sequence of elements having the property that any two consecutive elements in the sequence share a common node. Thus, referring for convenience back to Figure 19.10, we see that {*f*, *a*, *b*} is a path. The elements *f* and *a* share node 2 and *a* and *b* share node 3. One lead of the last element in a path is connected to a node that is not shared with the preceding element. Such a node is called the terminal node of the path. Similarly, one lead of the first element in the sequence is connected to a node that is not shared with the preceding element.* It is called the initial node of the path. Thus, in the example just cited, node 1 is the initial node and node 4 is the final node. Thus, a direction is associated with a path, and we can indicate it diagrammatically by means of an arrow on the circuit. This is illustrated in Figure 19.11 for the path $P_1 = \{f, a, b\}$ and $P_2 = \{g, c, d, e\}$.

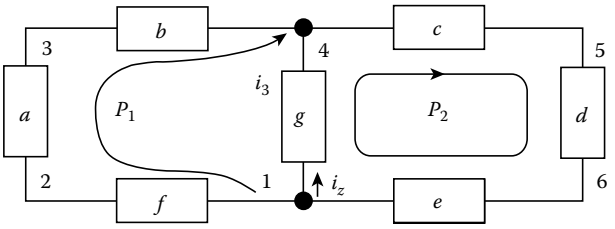

FIGURE 19.11 Circuit paths.

* We assume that no element has its two leads connected together and that more than two elements are in the path in this definition.

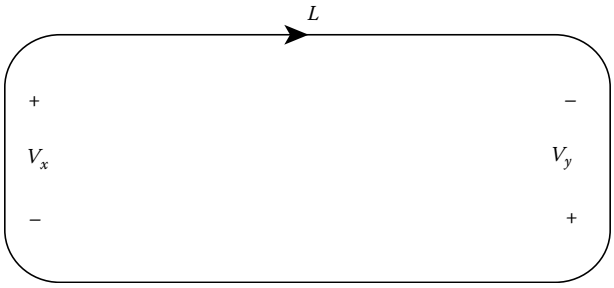

FIGURE 19.12 Voltage rise and drop.

If the initial node is identical to the terminal node, then the corresponding path is called a loop. An example is $\{f, a, b, g\}$. The patch P_2 is a loop. An alternate definition of a loop is as a collection of branches having the property that each node connected to a patch branch is connected to precisely two path branches, that is, it has degree two relative to the path branches.

We can define the voltage across each element in our circuit in exactly two ways, corresponding to the choices of which lead is designated plus and which is designated minus. Figure 19.12 presents two voltages and a loop L in a highly stylized manner. We have purposely not drawn the circuit itself so that we can concentrate on the essentials in our discussion. If the path enters the given element on the lead carrying the minus and exits on the one carrying the positive, its voltage will be called a voltage rise; however, if it enters on the positive and exits on the minus, the voltage will be called a voltage drop. If the signs of a voltage are reversed and a negative sign is affixed to the voltage variable, the value of that variable remains unchanged; thus, note that a negative rise is a drop, and vice versa.

We are now in a position to state our fourth and final axiom:

Axiom 4 (Kirchhoff's voltage law): The sum of the voltage rises around any loop is identically zero at all instants of time.

We refer to this law as Kirchhoff's voltage law (KVL) for the sake of economy of space. Just as KCL was phrased in terms of charge, KVL could just as well be phrased in terms of flux linkage. Flux linkage is the time integral of voltage, so it can be said that the sum of the flux linkages around a loop is zero. In voltage form, we write

$$\sum_{\text{loop}} v_{\text{rises}} = 0 \tag{19.8}$$

We observed that a negative rise is a drop, so

$$\sum_{\text{loop}} v_{\text{drops}} = 0 \tag{19.9}$$

or

$$\sum_{\text{loop}} v_{\text{rises}} = \sum_{\text{loop}} v_{\text{drops}} \tag{19.10}$$

Thus, in Figure 19.13, we could write (should we choose to use the form of Equation 19.8)

$$v_x - v_y - v_a + v_b = 0 \tag{19.11}$$

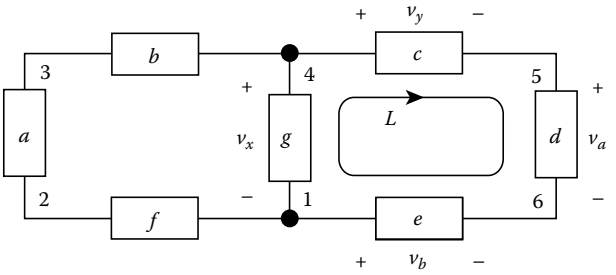

FIGURE 19.13 Illustration of KVL.

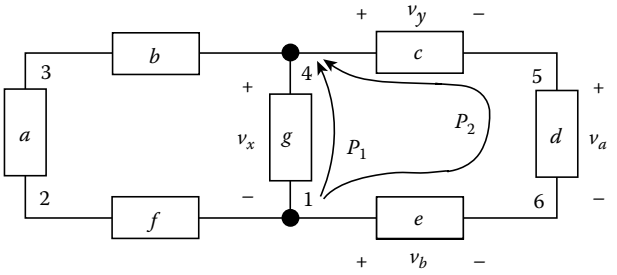

FIGURE 19.14 Path form of KVL.

Clearly, one can rearrange KVL into many different algebraic forms that are equivalent to those just stated; one form, however, is more useful in circuit computations than many others. It is known as the path form of KVL. To better appreciate this form, review Figure 19.13. This time, however, the paths are defined a bit differently. As illustrated in Figure 19.14, we consider two paths, P_1 and P_2, having the same initial and terminal nodes, 1 and 4, respectively.* We can rearrange Equation 19.11 into the form

$$v_x = -v_b + v_a + v_y \tag{19.12}$$

This form is often useful for finding one unknown voltage in terms of known voltages along some given path. In general, if P_1 and P_2 are two paths having the same initial and final nodes,

$$\sum_{P_1} v_{\text{rises}} = \sum_{P_2} v_{\text{rises}} = 0 \tag{19.13}$$

Be careful to distinguish this equation from Equation 19.10. In the present case two paths are involved; in the former we find only a single loop, and drops are located on one side of the equation and rises on the other. One might call the path form the ''all roads lead to Rome'' form.

We covered four basic axioms, and these are all that are needed to construct a mathematical theory of circuit analysis. The first axiom is often referred to by means of the phrase ''lumped circuit analysis,'' for we assume that all the physics of a given element are internal to that element and are of no concern to us; we are only interested in the v–i characteristic. That is, we are treating all the elements as lumps of matter that interact with the other elements in a circuit by means of the voltage and current at their leads.

* If one defines the negative of a path as a listing of the same elements as the original path in the reverse order and summation of two paths as a concatenation of the two listings, one sees that $P_1 - P_2 = L$, the loop in Figure 19.13.

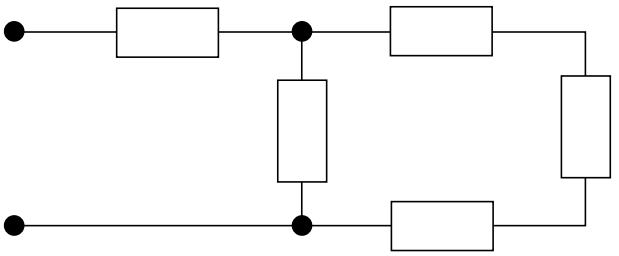

FIGURE 19.15 Noncircuit.

The second axiom says that the physical construction is irrelevant and that the interconnections are completely described by means of the circuit graph. KCL is an expression of conservation of charge, plus the assumption that neither conductors nor elements can maintain a net charge. In this connection, observe that a capacitor maintains a charge separation internally, but it is a separation of two charges of opposite sign; thus, the total algebraic charge within it is zero. Finally, KVL is an expression of conservation of flux linkage. If $\mathrm{l}(t) = \int_{-\infty}^{t} v(\alpha)\mathrm{d}\alpha$ is the flux linkage, then one can write* (using one form of KVL)

$$\sum_{\text{loop}} \lambda_{\text{rises}}^{(t)} = 0 \tag{19.14}$$

In the theory of electromagnetics, one finds that this equation does not hold exactly; in fact, the right-hand side is equal to the negative of the derivative of the magnetic flux contained within the loop (this is the Faraday–Lenz law). If, however, the time variation of all signals in the circuit are slow, then the right-hand side is approximately zero and KVL can be assumed to hold. A similar result holds also for KCL. For extremely short instants of time, a conductor can support an unbalanced charge. One finds, however, that the ''relaxation'' time of such unbalanced charge is quite short in comparison with the time variations of interest in the circuits considered in this text.

Finally, we tie up a loose end left hanging at the beginning of this section. We consider a circuit to be, not just any collection of elements that are interconnected, but a collection having the property that each element is contained in at least one loop. Thus, the circuit in Figure 19.15 is not a circuit; instead, it must be treated as a subcircuit, that is, as part of a larger circuit in which it is to be imbedded.

The remainder of this section develops the application of the axioms presented here to the analysis of circuits. The reader is referred to Refs. [2–4] for a more detailed treatment.

19.1.1 Nodal Analysis

Nodal analysis of electric circuits, although using all four of the fundamental axioms presented in the introduction, concentrates upon KCL explicitly. KVL is also satisfied automatically in view of the way the basic equations are formulated. This effective method uses the concept of a node voltage. Figure 19.16 illustrates the concept. Observe a voltmeter, with its black probe attached to a single node, called the reference node, which remains fixed during the course of the investigation. In the case shown node 1 is the reference node. The red probe is shown being touched to node 4; therefore, we call the resulting voltage v_4. The subscript denotes the node and the result is always assumed to have its positive reference

* One might anticipate a constant on the right side of Equation 19.14; however, a closer investigation reveals that it is more realistic and pragmatic to assume that all signals are one-sided and that all elements are causal. This implies that the constant is zero. Two-sided signals only arise legitimately within the context of steady-state behavior of stable circuits and systems.

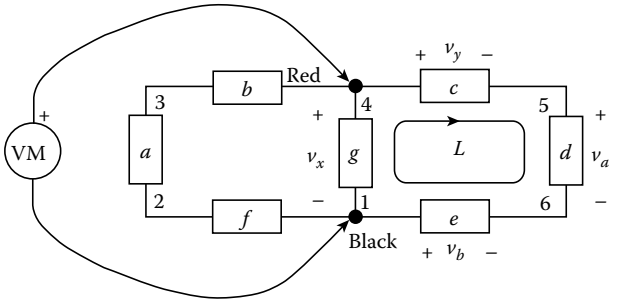

FIGURE 19.16 Node voltages.

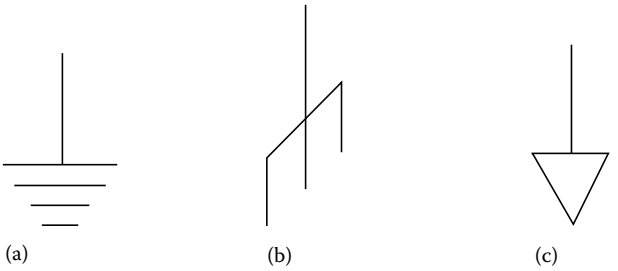

FIGURE 19.17 Reference node symbols.

on the given node. In the present instance v_4 is identical to the element voltage because element g (across which v_g is defined) is connected between node 4 and the reference node. Note that the voltage of such an element is always either the node voltage or its negative, depending upon the reference polarities of its associated element voltage. If we were to touch the red probe to node 5, however, no element voltage would have this relationship to the resulting node voltage v_5 because no elements are connected directly between nodes 5 and 1.

The concept of reference node is used so often that a special symbol is used for it (see Figure 19.17a); alternate symbols often seen on circuit diagrams are shown in the figure as well. Often one hears the terms ''ground'' or ''ground reference'' used. This is commonly accepted argot for the reference node; however, one should be aware that a safety issue is involved in the process of grounding a circuit or appliance. In such cases, sometimes one symbol specifically means ''earth ground'' and one or more other symbols are used for such things as ''signal ground'' or ''floating ground,'' although the last term is something of an oxymoron. Here, we use the terms ''reference'' or ''reference node.'' The reference symbol is quite often used to simplify the drawing of a circuit. The circuit in Figure 19.16, for instance, can be redrawn as in Figure 19.18; circuit operation will be unaffected. Note that all four of the reference symbols refer to a single node, node 1, although they are shown separated from one another. In fact, the circuit is not changed electrically if one bends the elements around and thereby separates the ground symbols even more, as we have done in Figure 19.19. Notice that the loop L shown in the original figure, Figure 19.16, remains a loop, as in Figures 19.18 and 19.19. Redrawing a circuit using ground reference symbols does not alter the circuit topology, the circuit graph.

Suppose the red probe were moved to node 5. As described previously, no element is directly connected between nodes 5 and 1; hence, node voltage v_5 is not an element voltage. However, the element voltages and the node voltages are directly related in a one-to-one fashion. To see how, look at Figure 19.20. This figure shows a ''floating element,'' e, which is connected between two nodes, k and j,

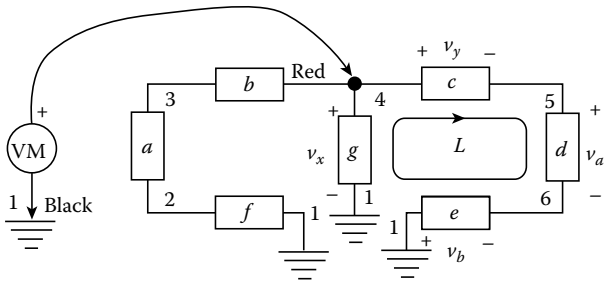

FIGURE 19.18 Alternate drawing.

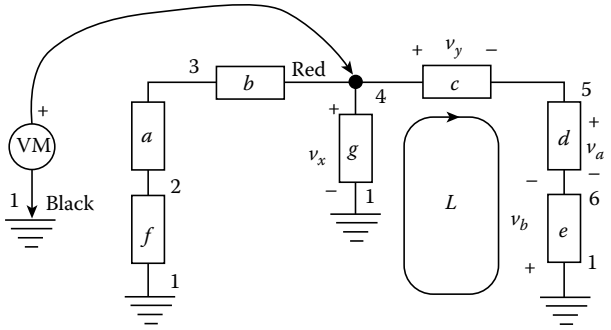

FIGURE 19.19 Equivalent drawing.

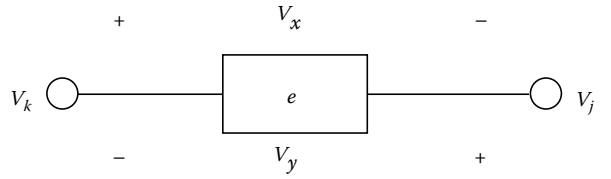

FIGURE 19.20 Floating element and its voltage.

neither of which is the reference node. It is vital here to remember that all node voltages are assumed to have their positive reference polarities on the nodes themselves and their negative reference on the reference node. Now, we can define the element voltage in either of two possible ways, as illustrated in the figure. KVL (the simplest form perhaps being the path form) shows at once that

$$v_x = v_k - v_j \tag{19.15}$$

and

$$v_y = v_j - v_k \tag{19.16}$$

An easy mnemonic for this result is the following:

$$v_{\text{floating element}} = v_+ - v_- \tag{19.17}$$

where v_+ is the node voltage of the node to which the element lead associated with the positive reference for the element voltage is connected, and v_- is the node voltage of the node to which the lead carrying the negative reference for the element voltage is connected. We refer to an element that is not floating, by the way, as being "grounded."

It is easy to see that a circuit having N nodes has $N-1$ node voltages; further, if one uses Equation 19.17, any element voltage can be expressed in terms of these $N-1$ node voltages. Then, for any invertible element,* one can determine the element current. The nodal analysis method uses this fact and considers the node voltages to be the unknown variables.

To illustrate the method, first consider a resistive circuit that contains only resistors and/or independent sources. Furthermore, we initially limit our investigation to circuits whose only independent sources (if any) are current sources. Such a circuit is depicted in Figure 19.21. Because nodal analysis relies upon the node voltages as unknowns, one must first select an arbitrary node for the reference. For circuits that contain voltage sources, one can achieve some simplification for hand analysis by choosing the reference wisely; however, if current sources are the only type of independent source present, one can choose it arbitrarily. As it happens, physical intuition is almost always better served if one chooses the bottom node. Such is done here and the circuit is redrawn using reference symbols as in Figure 19.22. Here, we have arbitrarily assigned node voltages to the $N-1=2$ nonreference nodes. In performing these two steps, we have "prepared the circuit for nodal analysis." The next step involves writing one KCL equation at each of the nonreference nodes. As it happens, the resulting equations are nice and compact if the form

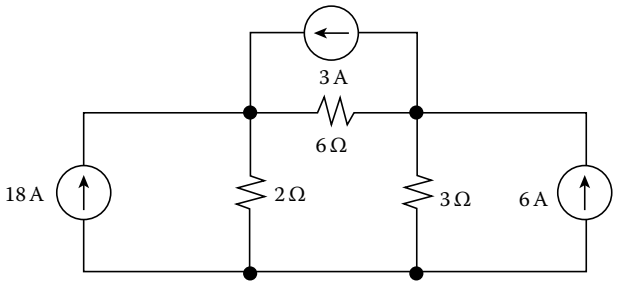

FIGURE 19.21 Example circuit.

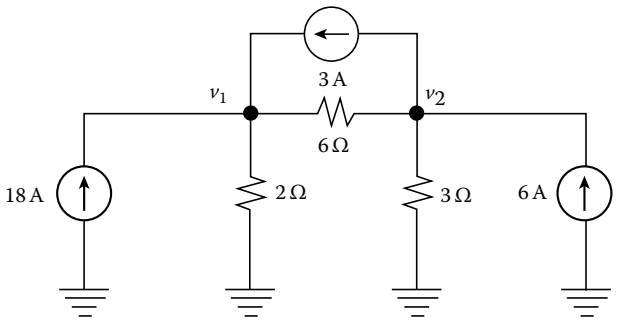

FIGURE 19.22 Example circuit prepared for nodal analysis.

* For instance, resistors, capacitors, and inductors are invertible in the sense that one can determine their element currents if their element voltages are known.

$$\sum_{\text{node}} i_{\text{out}}(R's) = \sum_{\text{node}} i_{\text{in}}(I - \text{Sources}) \tag{19.18}$$

is used. Here, we mean that the currents leaving a node through the resistors must sum up to be equal to the current being supplied to that node from current sources. Because these two types of elements are exhaustive for the circuits we are considering, this form is exactly equivalent to the other forms presented in the introduction. Furthermore, for a current leaving a node through a resistor, the floating element KVL result in Equation 19.17 is used along with Ohm's law:

$$\sum_{j=1}^{N-1} \frac{v_k - v_j}{R_{kj}} = \sum_{q=1}^{M_k} i_{\text{sq}}(\text{node } k). \tag{19.19}$$

In this equation for node k, R_{kj} is the resistance between nodes k and j (or the equivalent resistance of the parallel combination if more than one are found), i_{sq} is the value of the qth current source connected to node k (positive if its reference is toward node k), and M_k is the number of such sources. Clearly, one can simply omit the $j = k$ term on the left side because $v_k - v_k = 0$.

The nodal equations for our example circuit are

$$\frac{v_1}{2} + \frac{v_1 - v_2}{6} = 18 + 3 \tag{19.20}$$

and

$$\frac{v_2 - v_1}{6} + \frac{v_2}{3} = 6 - 3 \tag{19.21}$$

Notice, by the way, that we are using units of A, Ω, and V. It is a simple matter to show that KVL, KCL, and Ohm's law remain invariant if we use the consistent units of mA, kΩ, and V. The latter is often a more practical system of units for filter design work. In the present case the matrix form of these equations is

$$\begin{bmatrix} \frac{2}{3} & -\frac{1}{6} \\ -\frac{1}{6} & \frac{1}{2} \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} = \begin{bmatrix} 21 \\ 3 \end{bmatrix} \tag{19.22}$$

It can be verified easily that the solution is $v_1 = 36$ V and $v_2 = 18$ V. To see that one can compute the value of any desired variable from these two voltages, consider the problem of determining the current i_6 (let us call it) through the horizontal 6 Ω resistor from right to left. One can simply use the equation

$$i_6 = \frac{v_2 - v_1}{6} = \frac{18 - 36}{6} = -3 \text{ A} \tag{19.23}$$

The previous procedure works for essentially all circuits encountered in practice. If the coefficient matrix on the left in Equation 19.22 (which will always be symmetric for circuits of the type we are considering) is nonsingular, a solution is always possible. It is surprisingly difficult, however, to determine conditions on the circuit under which solutions do not exist, although this is discussed at greater length in a later section.

Suppose, now, that our circuit to be solved contains one or more independent voltage sources in addition to resistors and/or current sources. This constrains the node voltages because a given voltage source value must be equal to the difference between two node voltages if it is floating and to a node

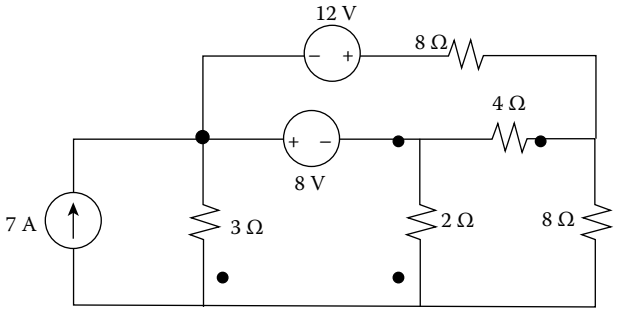

FIGURE 19.23 Example circuit.

voltage or its negative if it is grounded. One might expect that this complicates matters, but fortunately the converse is true.

To explore this more fully, examine the example circuit in Figure 19.23. The algorithm just presented will not work as is because it relies upon balancing the current between resistors and current sources. Thus, it seems that we must account in some fashion for the currents in the voltage sources. In fact, we do not, as the following analysis shows. The key step in our reasoning is this: the analysis procedure should not depend upon the values of the independent circuit variables, that is, on the values of the currents in the current sources and voltages across the voltage sources. This is almost inherent in the definition of an independent source, for it can be adjusted to any value whatsoever. What we are assuming in addition to this is simply that we would not write one given set of equations for a specific set of source values, then change to another set of equations when these values are altered. Thus, let us test the circuit by temporarily deactivating all the independent sources (i.e., by making their values zero). Recalling that a deactivated voltage source is equivalent to a short circuit and a deactivated current source to an open circuit, we have the resulting configuration of Figure 19.24. The resulting nodes are shaded for convenience. Note carefully, however, that the nodes in the circuit under test are not the same as those in the original circuit, although they are related. Notice that, for the circuit under test, all the resistor voltages would be determined by the node voltages as expected; however, the number of nodes has been reduced by one for each voltage source. Hence, we suspect that the required number of KCL equations N_{ne} (and the number of independent node voltages) is

$$N_{ne} = N - 1 - N_v \tag{19.24}$$

where N_v is the number of voltage sources. In the example circuit one can easily compute this required number to be $5 - 1 - 2 = 2$. This is compatible with the fact that clearly three nodes ($3 - 1 = 2$ nonreference nodes) are clearly found in Figure 19.24.

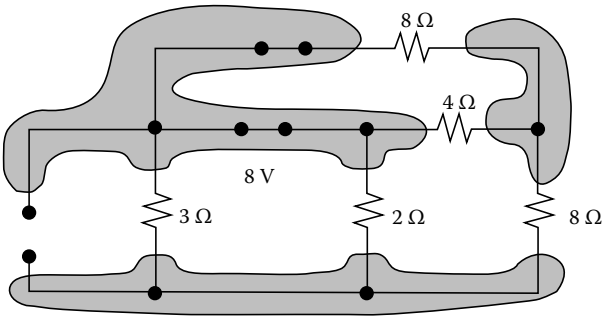

FIGURE 19.24 Example circuit deactivated.

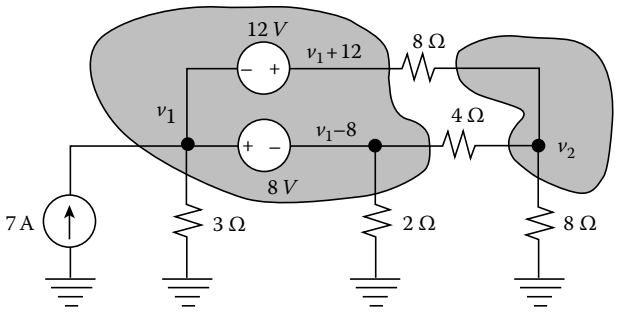

FIGURE 19.25 Example circuit prepared for nodal analysis.

It should also be rather clear that there is only one independent voltage within each of the shaded regions shown in Figure 19.24. We can use KVL to express any other in terms of that one. For example, in Figure 19.25 we have redrawn our example circuit with the bottom node arbitrarily chosen as the reference. We have also arbitrarily chosen a node voltage within the top left surface as the unknown v_1. Note how we have used KVL (the path form, again, is perhaps the most effective) to determine the node voltages of all the other nodes within the top left surface. Any set of connected conductors, leads, and voltage sources to which only one independent voltage can be assigned is called a generalized node. If that generalized node does not include the reference node, it is termed a supernode. The node within the shaded surface at the top left in Figure 19.25, however, has no voltage sources; hence, it is called an essential node.

As pointed out earlier, the equations that one writes should not depend upon the values of the independent sources. If one were to reduce all the independent sources to zero, each generalized node would reduce to a single node; hence, only one equation should be written for each supernode. One equation should be written for essential node also; it is unaffected by deactivation of the independent sources. Observe that deactivation of the current sources does not reduce the number of nodes in a circuit.

Writing one KCL equation for the supernode and one for the essential node in Figure 19.25 results in

$$\frac{v_1}{3}+\frac{v_1-8}{2}+\frac{v_1-8-v_2}{4}+\frac{v_1+12-v_2}{8}=7 \tag{19.25}$$

and

$$\frac{v_2}{8}+\frac{v_2-(v_1-8)}{4}+\frac{v_2-(v_1+12)}{8}=0 \tag{19.26}$$

In matrix form, one has

$$\begin{bmatrix} \frac{29}{24} & -\frac{3}{8} \\ -\frac{3}{8} & \frac{1}{2} \end{bmatrix}\begin{bmatrix} v_1 \\ v_2 \end{bmatrix}=\begin{bmatrix} \frac{23}{2} \\ -\frac{1}{2} \end{bmatrix} \tag{19.27}$$

The solution is $v_1=12$ V and $v_2=8$ V. Notice once again that the coefficient matrix on the left-hand side is symmetric. This actually follows from our earlier observation about this property for circuits containing only current sources and resistors because the voltage sources only introduce knowns into the nodal equations, thus modifying the right-hand side of Equation 19.27.

The general form for nodal equations in any circuit containing only independent sources and resistors, based upon our foregoing development, is

$$A\bar{v}_n=F_v\bar{v}_s+F_I\bar{i}_s \tag{19.28}$$

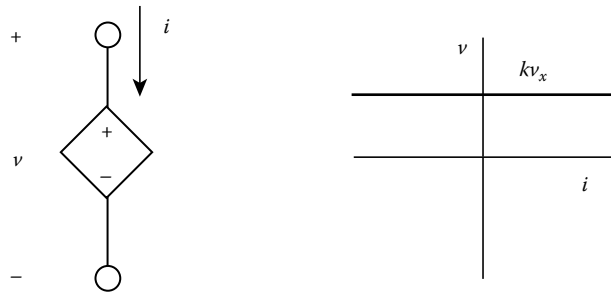

FIGURE 19.26 Dependent source.

where

A is a symmetric square matrix of constant coefficients
F_v and F_I are rectangular matrices of constants
$\bar{v}_n$ is the column matrix of independent mode voltages

The vectors $\bar{v}_s$ and $\bar{i}_s$ are column matrices of independent source values. Clearly, if A is a nonsingular matrix, Equation 19.28 can be solved for the node voltages. Then, using KVL and/or Ohm's law, one can solve for any element current or voltage desired. Equally clearly, if a solution exists, it is a multilinear function of the independent source values.*

Now suppose that the circuit under consideration contains one or more dependent sources. Recall that the two-terminal characteristics of such elements are indistinguishable from those of the corresponding independent sources except for the fact that their value depends upon some other circuit variable. For instance, in Figure 19.26 a voltage-controlled voltage source (VCVS) is shown. Its v–i characteristic is identical to that of an independent source except for the fact that its voltage (the controlled variable) is a constant multiple† of another circuit variable (the controlling variable), in this case another voltage. This fact will be relied upon to develop a modification to the nodal analysis procedure.

We will adopt the following attitude: We will imagine that the dependent relationship, kv_x in Figure 19.26, is a label pasted to the surface of the source in much the same way that a battery is labeled with its voltage. We will imagine ourselves to take a small piece of opaque masking tape and apply it over this label; we will call this process taping the dependent source. This means that we are—temporarily—treating it as an independent source. The usual nodal analysis procedure is then followed, which results in Equation 19.28. Then, we imagine ourselves to remove the tape from the dependent source(s) and note that the relationship is linear, with the controlling variables as the independent ones and the controlled variables the dependent ones. We next express the controlling variables—and thereby the controlled ones as well—in terms of the node voltages using KVL, KCL, and Ohm's law. The resulting relationships have the forms

$$\bar{v}_c = B'\bar{v}_n + C'\bar{y}_{si} + D'\bar{i}_{si} \tag{19.29}$$

and

$$\bar{i}_c = B''\bar{v}_n + C''\bar{v}_{si} + D''\bar{i}_{si} \tag{19.30}$$

* That is, it is a linear function of the vector consisting of all of the independent source values.
† Thus, one should actually refer to such a device as a linear dependent source.

Here, the subscript i refers to the fact that the corresponding sources are the independent ones. Noting that $\bar{v}_c$ and $\bar{i}_c$ appear on the right-hand side of Equation 19.28 because they are source values, one can use the last two results to express the vectors of all source voltages and all source currents in that equation in the form

$$\bar{v}_c = B'''\bar{v}_{si} + C'''\bar{i}_{si} + D'''\bar{v}_n \tag{19.31}$$

and

$$\bar{i}_c = B''''\bar{v}_{si} + C''''\bar{i}_{si} + D''''\bar{v}_n \tag{19.32}$$

Finally, using the last two equations in Equation 19.28, one has

$$A\bar{v}_n = F'_v\bar{v}_s + F'_I\bar{i}_s + B\bar{v}_n \tag{19.33}$$

Now,

$$(A - B)\bar{v}_n = F'_v\bar{v}_s + F'_I\bar{i}_s \tag{19.34}$$

This equation can be solved for the node voltages, provided that $A - B$ is nonsingular. This is even more problematic than for the case without dependent sources because the matrix B is a function of the gain coefficients of the dependent sources; for some set of such values the solution might exist and for others it might not. In any event if $A - B$ is nonsingular, one obtains once more a response that is linear with respect to the vector of independent source values.

Figure 19.27 shows a rather complex example circuit with dependent sources. As pointed out earlier, there are often reasons for preferring one reference node to another. Here, notice that if we choose one of the nodes to which a voltage source is attached it is not necessary to write a nodal equation for the nonreference node because, when the circuit is tested by deactivation of all the sources, the node disappears into the ground reference; thus, it is part of a generalized node including the reference called a nonessential node. For this circuit, choose the node at the bottom of the 2 V independent source. The resulting circuit, prepared for nodal analysis, is shown in Figure 19.28. Surfaces have been drawn around both generalized nodes and the one essential node and they have been shaded for emphasis. Note that we have chosen one node voltage within the one supernode arbitrarily and have expressed the other node

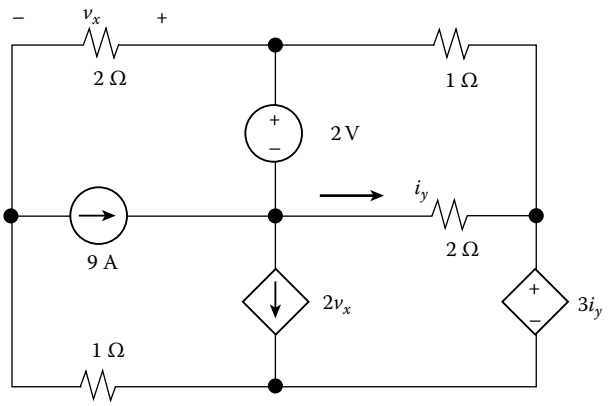

FIGURE 19.27 Example circuit.

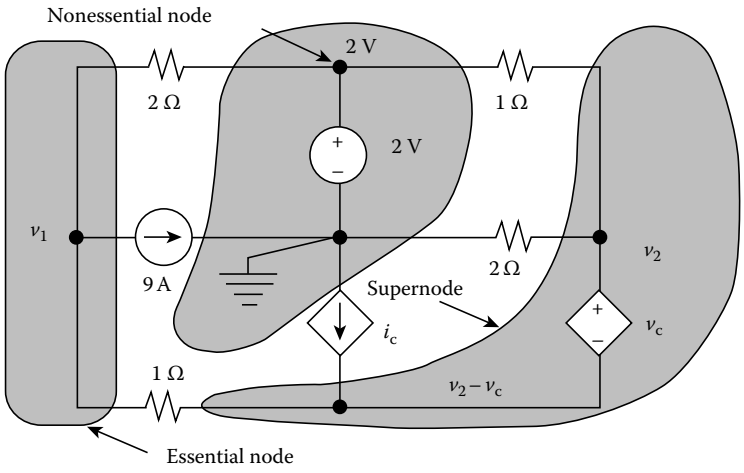

FIGURE 19.28 Example circuit prepared for nodal analysis.

voltage within that supernode in terms of the first and the voltage source value; furthermore, we have taped both dependent sources and written in the known value at the one nonessential node.

The nodal equations for the supernode and for the essential node are

$$\frac{v_1 - 2}{2} + \frac{v_1 - (v_2 - v_c)}{1} = -9 \quad \text{(essential node)} \tag{19.35}$$

and

$$\frac{v_2}{2} + \frac{v_2 - 2}{1} + \frac{v_2 - v_c - v_1}{1} = i_c \quad \text{(supernode)} \tag{19.36}$$

Now, the two dependent sources are untaped and their values expressed in terms of the unknown node voltages and known values using KVL, KCL, and Ohm's law. This results in (referring to the original circuit for the definitions)

$$v_c = -\frac{3}{2} v_2 \tag{19.37}$$

and

$$i_c = 4 - 2v_2 \tag{19.38}$$

Solving these four equations simultaneously gives $v_1 = -2$ V and $v_2 = 2$ V.

If the circuit under consideration contains op-amps, one can first replace each op amp by a VCVS, using the above procedure, and then allow the voltage gain to go to infinity. This is a bit unwieldy, so one often models the op-amp in a different way as a circuit element called a nullor. This is explored in more detail elsewhere in the book and is not discussed here.

Thus far, this chapter has considered only nondynamic circuits whose independent sources were all constants (DC). If these independent sources are assumed to possess time-varying waveforms, no essential modification ensues. The only difference is that each node voltage, and hence each circuit variable, becomes a time-varying function. If the circuit considered contains capacitors and/or inductors,

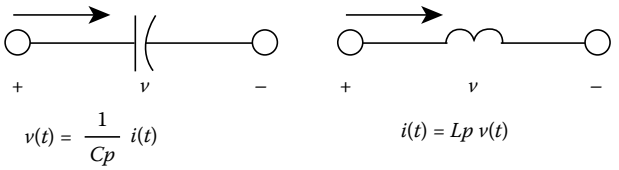

FIGURE 19.29 Dynamic element relationships.

however, the nodal equations are no longer algebraic; they become differential equations. The method developed above remains applicable, however. We will now show why.

Capacitors and inductors have the *v–i* relationships given in Figure 19.29. The symbols p and $1/p$ are referred to as operators, differential operators, or Heaviside operators. The last term is in honor of Oliver Heaviside, who first used them in circuit analysis. They are defined by

$$p = \frac{d}{\mathrm{d}t} \tag{19.39}$$

$$\frac{1}{p} = \int_{-\infty}^{t} (\,)\mathrm{d}a \tag{19.40}$$

The notation suggests that they are inverses of each other, and this is true; however, one must suitably restrict the signal space in order for this to hold. The most realistic assumption is that the signal space consists of all piecewise continuous functions whose derivatives of all orders exist except on a countable set of points that does not have any finite points of accumulation—plus all generalized derivatives of such functions. In fact, Laurent Schwartz, on the first page of the preface of his important work on the theory of distributions, acknowledges that this work was motivated by that of Heaviside. Thus, we will simply assume that all derivatives of all orders of any waveform under consideration exists in a generalized function sense. Higher order differentiation and integration operators are defined in power notation, as expected:

$$p^n = p \cdot p \cdots p = \frac{\mathrm{d}^n}{\mathrm{d}t^n} \tag{19.41}$$

and

$$\frac{1}{p^n} = \frac{1}{p} \cdot \frac{1}{p} \cdots \frac{1}{p} = \int_{-\infty}^{t} \int_{-\infty}^{b} \cdots \int_{-\infty}^{g} (\,)\mathrm{d}a \tag{19.42}$$

Another fact of the preceding issue often escapes notice, however. Look at any arbitrary function in the above-mentioned signal set, compute its running integral, and differentiate it. This action results in

$$p\left[\frac{1}{p}x(t)\right] = \frac{d}{\mathrm{d}t} \int_{-\infty}^{t} x(\alpha)\mathrm{d}\alpha = x(t) \tag{19.43}$$

In fact, it is precisely this property that characterizes the set of all generalized functions. It is closed under differentiation. However, suppose the computation is done in the reverse order:

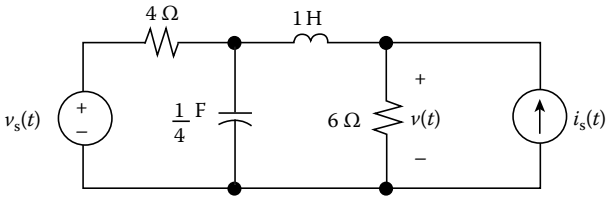

FIGURE 19.30 Example circuit.

$$\frac{1}{p}[px(t)] = \int_{-\infty}^{t} x'(a)\mathrm{d}a = x(t) = x(t) - x(\infty) \tag{19.44}$$

We have assumed here that the fundamental theorem of calculus holds. This is permissible within the framework of generalized functions, provided that the waveform $x(t)$ has a value in the conventional sense at time t. The problem with the previous result is that one does not regain $x(t)$. If it is assumed, however, that $x(t)$ is one sided, that is, $x(t)$ is identically zero for sufficiently large negative values of (t), $x(t)$ will be regained and p and $1/p$ will be inverses of one another. Thus, in the following, we will assume that all independent waveforms are one-sided. We will, in fact, interpret this as meaning that they are all zero for $t < 0$. We will also assume that all circuit elements possess one property in addition to their defining v–i relationship, namely, that they are causal. Thus, all waveforms in any circuit under consideration will be zero for $t \leq 0$ and the previous two operators are inverses of one another. The only physically reasonable situation in which two-sided waveforms can occur is that of a stable circuit operating in the steady state, which we recognize as being an approximate mode of behavior derived from the previous considerations in the limit as time becomes large.

Referring to Figure 19.29 once more, we define

$$Z_c(p) = \frac{1}{Cp} \tag{19.45}$$

$$Z_L(p) = Lp \tag{19.46}$$

to be the impedance operators (or operator impedances) for the capacitor and the inductor, respectively. With our one-sidedness causality assumptions, we can manipulate these qualities just as we would manipulate algebraic functions of a real or complex variable.

The analysis of a dynamic circuit is illustrated by Figure 19.30. The circuit is shown prepared for nodal analysis, with the reference node at the bottom of the circuit and the dynamic elements expressed in terms of their impedance operators, in Figure 19.31. Note that if the circuit were to contain dependent sources, we would have taped them at this step. The nodal equations at the two essential nodes are

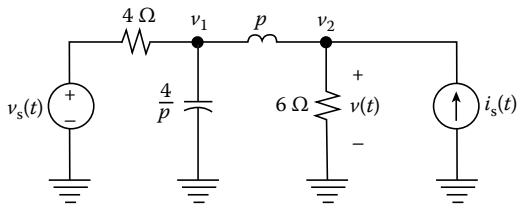

FIGURE 19.31 Example circuit prepared for nodal analysis.

$$\frac{v_1 - v_2}{4} + \frac{v_1}{4/p} + \frac{v_1 - v_2}{p} = 0 \tag{19.47}$$

and

$$\frac{v_2}{6} + \frac{v_2 - v_1}{p} = i_s \tag{19.48}$$

In matrix form, merely rationalizing and collecting terms,

$$\begin{bmatrix} \frac{1}{4} + \frac{p}{4} + \frac{1}{p} & -\frac{1}{p} \\ -\frac{1}{p} & \frac{1}{6} + \frac{1}{p} \end{bmatrix} \begin{bmatrix} v_1(t) \\ v_2(t) \end{bmatrix} = \begin{bmatrix} \frac{1}{4} v_s(t) \\ i_s(t) \end{bmatrix} \tag{19.49}$$

Notice that the coefficient matrix is once again symmetric because no dependent sources exist. Multiplying the first row of each side by $4p$ and the second by $6p$, thus clearing fractions, one obtains

$$\begin{bmatrix} p^2 + p + 4 & -4 \\ -6 & p + 6 \end{bmatrix} \begin{bmatrix} v_1(t) \\ v_2(t) \end{bmatrix} = \begin{bmatrix} p v_s(t) \\ 6 p i_s(t) \end{bmatrix} \tag{19.50}$$

Now, multiply both sides by the inverse of the 2×2 coefficient matrix to get

$$\begin{bmatrix} v_1(t) \\ v_2(t) \end{bmatrix} = \frac{1}{p(p^2 + 7p + 10)} \begin{bmatrix} p + 6 & 4 \\ 6 & p^2 + p + 4 \end{bmatrix} \begin{bmatrix} p v_s(t) \\ 6 p i_s(t) \end{bmatrix} \tag{19.51}$$

Multiplying the two matrices on the right and canceling the common p factor (legitimate under our assumptions), we finally have

$$v(t) = v_2(t) = \frac{6 v_s(t) + 6(p^2 + p + 4) i_s(t)}{p^2 + 7p + 10} \tag{19.52}$$

We can, on the one hand, consider the result of our nodal analysis process to be a differential equation which we obtain by cross-multiplication:

$$\left[p^2 + 7p + 10\right] v(t) = 6 v_s(t) + 6\left(p^2 + p + 4\right) i_s(t) \tag{19.53}$$

In conventional notation, using the distributive properties of the p operators, one has

$$\frac{d^2 v(t)}{dt^2} + 7\frac{dv(t)}{dt} + 10 v(t) = 6 v_s(t) + 6\frac{d^2 i_s(t)}{dt^2} + 6\frac{di_s(t)}{dt} + 24 i_s(t) \tag{19.54}$$

On the other hand, it is possible to interpret Equation 19.52 directly as a solution operator equation. We simply note that the denominator factors, then do a partial fraction expansion to get

$$\begin{aligned} v(t) &= \frac{6}{(p+2)(p+5)} v_s(t) + \frac{6(p^2 + p + 4)}{(p+2)(p+5)} i_s(t) \\ &= \frac{2}{p+2} v_s(t) - \frac{2}{p+2} v_s(t) + 6 i_s(t) + \frac{2}{p+2} i_s(t) - \frac{8}{p+2} i_s(t) \end{aligned} \tag{19.55}$$

Thus, we have expressed the two second-order operators in terms of operators of order one. It is quite easy to show that the first-order operator has the following simple form:

$$\frac{1}{p+a}x(t) = e^{-at}\frac{1}{p}[e^{at}x(t)] \tag{19.56}$$

Using this result, one can quickly show that the impulse and step responses of the first-order operator are

$$h(t) = \frac{1}{p+a}\delta(t) = e^{-at}u(t) \tag{19.57}$$

and

$$s(t) = \frac{1}{p+a}u(t) = [1 - e^{-at}]u(t) \tag{19.58}$$

respectively. Thus, if $i_s(t) = \delta(t)$ and $v_s(t) = u(t)$, one has

$$v(t) = 6\delta(t) + \frac{1}{5}\left[3 + 5e^{-2t} - 38e^{-5t}\right]u(t) \tag{19.59}$$

References [5,6] demonstrate that all the usual algebraic results valid for the Laplace transform are also valid for Heaviside operators.

19.1.2 Mesh Analysis

The central concept in nodal analysis is, of course, the node. The central idea in the method we will discuss here is the loop. Just as KCL formed the primary set of equations for nodal analysis, KVL will serve a similar function here. We will begin with the idea of a mesh. A mesh is a special kind of loop in a planar circuit (one that can be drawn on a plane) a loop that does not contain any other loop inside it. If one reflects on this definition a bit, one will see that it depends upon how the circuit is drawn. Figure 19.32 illustrates the idea of a mesh. The nodes have been numbered and the elements labeled with letters for clarity. The circuit graph in Figure 19.32 abstracts all of the information about how the elements are connected, but does not show them explicitly. The lines represent the elements and the solid dots represent the nodes. If we apply the definition given in the introduction to this section, we can

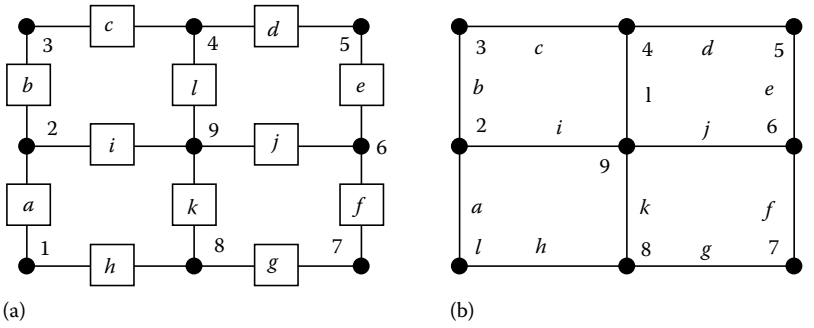

FIGURE 19.32 Circuit (a) and its graph (b).

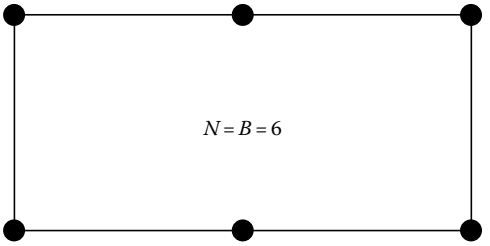

FIGURE 19.33 One-mesh (series) circuit.

quickly verify that {*h*, *a*, *i*, *k*} is a loop. It is a simple loop because each of its elements share only one node with any of the other path elements. It is a mesh because no other loops are inside it.

It is an important fact that the number of meshes in a circuit is given by

$$N_{\text{me}} = B - N + 1 \tag{19.60}$$

where

B is the number of branches (elements)
N is the number of nodes

To see this, just look at the simple one-mesh graph in Figure 19.33. The number of branches is the same as the number of nodes for such a graph (or circuit). Imagine constructing the graph by placing an element on a planar surface, thereby forming two nodes with the one element. $B - N + 1 = 1 - 2 + 1 = 0$ in this case, and no meshes exist. Now, add another element by connecting one of its leads to one of the leads of the first element. Now, $B - N + 1 = 2 - 3 + 1 = 0$. This can be done indefinitely (or until you tire). At this point, connect one lead of the last element to the free lead of the one immediately preceding and the other lead of the last element to a node already placed. N nodes and $N - 1$ branches will have been put down, and exactly one mesh will have been formed. Thus, it is true that $B - N + 1 = N - (N - 1) + 1 = 1$ mesh and the formula is verified. Now connect a new element to one of the old nodes; the result is that one new element and one new node have been added. A glance at the formula verifies that it remains valid. Again, continue indefinitely, and then connect one new element and no new nodes by connecting the free lead of the last element with one of the nodes in the original one-loop circuit. Clearly, the number of added branches exceeds the number of added nodes by one; once again, the formula is verified. Figure 19.34 shows the new circuit. For the graph shown in the figure, $B = 13$ and $N = 12$, so $B - N + 1 = 2$, as expected. Induction generalizes the result, and Equation 19.60 has been proved.

We now define a fictitious set of currents circulating around the meshes of a circuit. Figure 19.35 illustrates this idea with a circuit graph. All mesh currents are assumed to be circulating in a clockwise

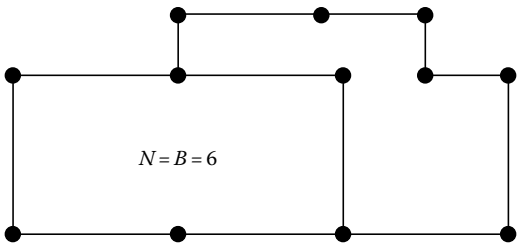

FIGURE 19.34 Two-mesh (series) circuit.

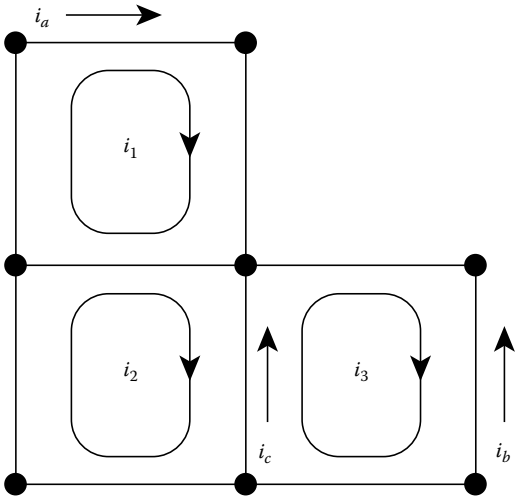

FIGURE 19.35 Mesh currents.

direction, although this is not necessary. We see that i_1 is the only current flowing in the branch in which the element current i_a is defined, therefore, $i_a = i_1$; similarly, i_3 is the only mesh current flowing in the element carrying element current i_b, but the two are defined in opposite directions. Thus, one sees that $i_b = -i_3$. The third element where the current is indicated, however, is seen to carry two mesh currents in opposite directions. Hence, its element current is $i_c = i_3 - i_2$. In general, an element that is shared between two meshes has an element current which is the algebraic sum or difference* of the two adjacent mesh currents.

We used the term ''fictitious'' in our definition of mesh current. In the last example, however, we see that it is possible to make a physical measurement of each mesh current because each flows in an element that is not shared with any other mesh. Thus, one need only insert an ammeter in that element to measure the associated mesh current. Circuits exist, however, in which one or more mesh currents are impossible to measure. Figure 19.36 plots the graph of such a circuit. Each of the meshes is assumed to be carrying a mesh current, although only one has been drawn explicitly, i_k. As readily observed, each of the other mesh currents appears in a nonshared branch. For the mesh where the current is shown, however, it is impossible to find an element or a conductor carrying only that current. For this reason, i_k is merely a fiction, though a useful one.

It is easy to see that mesh currents automatically satisfy KCL because they form a complete loop. Observe the stylized picture in Figure 19.37, which shows three meshes represented for simplicity as small, closed ovals. M_1 lies entirely within the arbitrary closed surface S; thus, its current does not appear in KCL for that surface. M_2 lies entirely outside S, so the same thing is true for its current. Finally, we note that, regardless of the shape of S, M_3 penetrates it an even number of times. Thus, its current will appear in KCL for S an even number of times, and half of its appearances will carry a positive sign and half a negative sign. Thus, we have shown that any mesh current automatically satisfies KCL for any closed surface.

Because KCL is automatically satisfied, we must turn to KVL for the solution of a network in terms of its mesh currents. Figure 19.38 is an example circuit. Just as we assumed at the outset of Section 19.1.1 that any circuit under consideration contained only resistors and current sources, we will assume at first that any circuit under consideration contains only resistors and voltage sources. The one shown in Figure 19.38 has this property.

* Always the difference if all mesh currents are defined in the same direction: clockwise or counterclockwise.

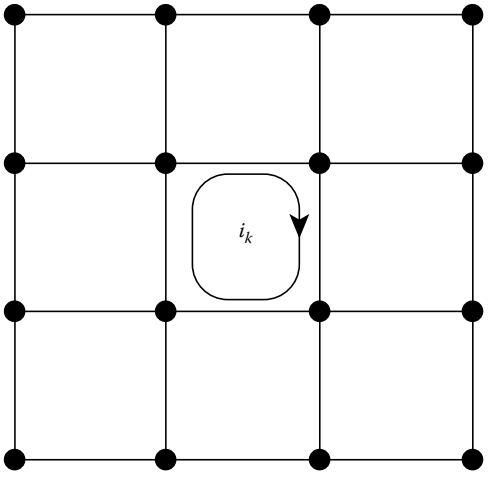

FIGURE 19.36 Fictitious mesh current.

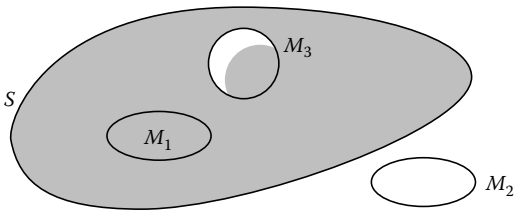

FIGURE 19.37 Illustration of KCL for mesh currents.

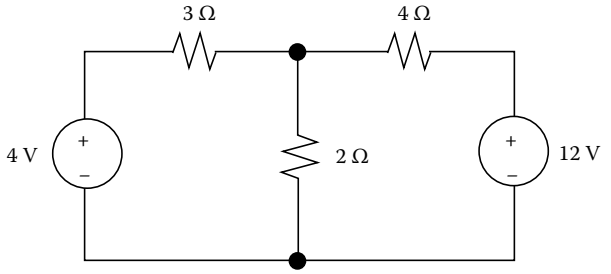

FIGURE 19.38 Example circuit.

The first step is to identify the meshes and assign a mesh current to each. Identification of the meshes is easy, and this is the primary reason for its effectiveness in hand analysis of circuits. The mesh currents can be assigned in arbitrary directions, but for circuits of the sort considered here, it is more convenient to assign them all in the same direction, as in Figure 19.39. Writing one KVL equation for each mesh results in

$$3i_1 + 2(i_1 - i_2) = 4 \tag{19.61}$$

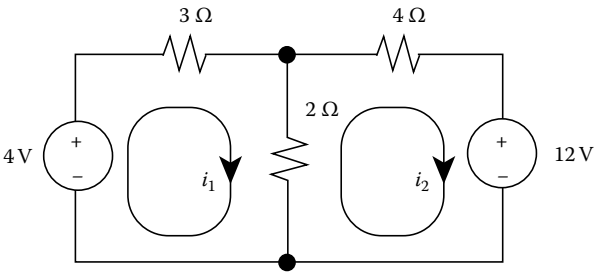

FIGURE 19.39 Example circuit prepared for mesh analysis.

and

$$2(i_2 - i_1) + 4i_2 = -12 \tag{19.62}$$

In matrix form,

$$\begin{bmatrix} 5 & -2 \\ -2 & 6 \end{bmatrix} \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} 4 \\ -12 \end{bmatrix} \tag{19.63}$$

The solution is $i_1 = 0$ A and $i_2 = 2$ A. The same procedure holds for any planar circuit of an arbitrary number of meshes.

Suppose, now, that the circuit being considered has one or more current sources, such as the one in Figure 19.40. The meshes are readily determined; one need only to look for the ''window panes,'' as meshes have been called. The only problem is this: When we write our mesh equations, what values do we use for the voltages across the current sources? These voltages are not known.

Thus, we could ascribe their voltages as unknowns, but this would lead to a hybrid form of analysis in which the unknowns are both element voltages and mesh currents; however, a more straightforward way is available. Consider this question: should the variables we use or the loops around which we decide to write KVL change if we alter the values of any of the independent sources? The answer, of course, is no. Thus, let us test the circuit by deactivating it, that is, by reducing all sources to zero. Recalling that a zero-valued voltage source is a short circuit and a zero-valued current source is an open circuit, we obtain the test circuit in Figure 19.41.

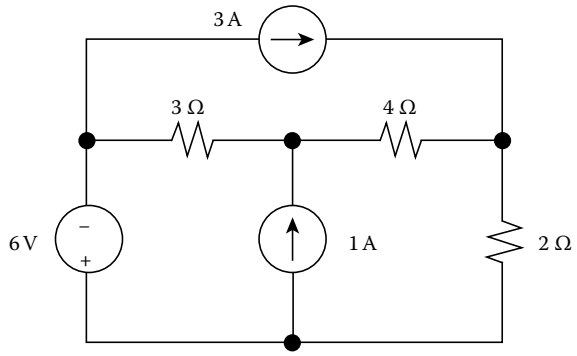

FIGURE 19.40 Example with current sources.

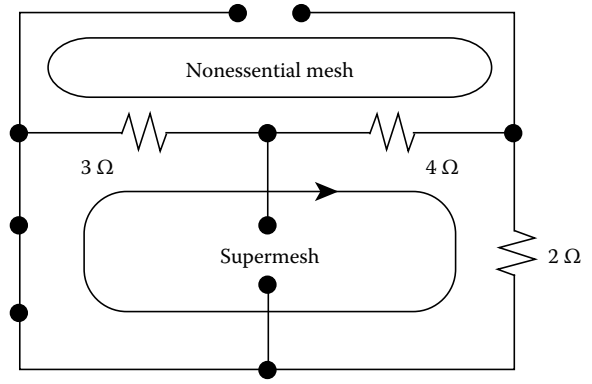

FIGURE 19.41 Deactivated current.

Notice what has happened. The two bottom meshes merge, thus forming one larger mesh in the deactivated circuit. The top mesh disappears (as a mesh or loop). For this reason, we refer to the former as a supermesh and the latter as a nonessential mesh. Observe also that it was the deactivation of the current sources that altered the topology; in fact, deactivation of the voltage sources has no effect on the mesh structure at all. Thus, we see that only one KVL equation is required to solve the deactivated circuit. (Reactivation of the source(s) is necessary, otherwise all voltage and currents will have zero values.) The conclusion relative to our example circuit is this: To solve the original circuit in terms of mesh currents, only one equation (KVL around the supermesh) is necessary.

The original circuit, with its three mesh currents arbitrarily defined, is redrawn in Figure 19.42. Notice that the isolated (nonshared) current source in the top (nonessential) mesh defines the associated mesh current as having the same value as the source itself. On the other hand, the 1 A current source shared by the bottom two meshes introduces a more general constraint: the difference between the two mesh currents must be the same as the source current. This constraint has been used to label the mesh current in the right-hand mesh with a value such that it, minus the left-hand mesh current, is equal to the source current. The nice feature of this approach is that one can clearly see which mesh currents are unknown and which are dependent upon the unknowns. Exactly one independent mesh current is always associated with a supermesh. Recalling our test circuit in Figure 19.41, we see that we need to write only one KVL equation around the supermesh. It is

$$3(i-3)+4(i+1-3)+2(i+1)=-6 \tag{19.64}$$

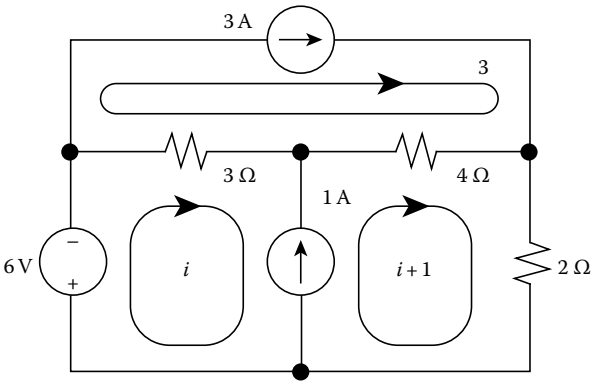

FIGURE 19.42 Assigning the mesh currents.

or

$$9i - 9 - 8 + 2 = -6 \tag{19.65}$$

The solution is $i = 1$ A. From this, one can compute the mesh current on the bottom right to be $i + 1 = 2$ A and the one in the top loop is already known to be 3 A. With these known mesh currents, we can solve for any circuit variable desired.

The development of mesh analysis seems at first glance to be the complete analog of nodal. This is not quite the case, however, because nodal will work for nonplanar circuits, while mesh works only for planar circuits; furthermore, no global reference exists for mesh currents as it does for node voltages.

Analyzing the problem, we observe that each current source, when deactivated, reduces the number of meshes by one. (A given element can be shared only by two meshes). Combining this fact with Equation 19.60, we see that the required number of mesh equations is

$$N_{\text{me}} = B - N + 1 - N_{\text{I}}, \tag{19.66}$$

where

B is the number of branches
N is the number of nodes
N_{I} is the number of current sources

Note that mesh analysis is undertaken for circuits containing dependent sources in exactly the same manner as in nodal analysis, that is, by first taping the dependent sources, writing the mesh equations as above, and then untaping the dependent sources and expressing their controlled variables in terms of the unknown mesh currents. Figure 19.43 shows an example of such a circuit; in fact, it is the same figure investigated with nodal analysis in the preceding section.

The first step is to tape the dependent sources, thus placing them on the same footing as their more independent relatives. Then the circuit is tested for complexity by deactivating it as shown in Figure 19.44. All element labels have been removed merely to avoid obscuring the ideas being discussed. We see one supermesh, one essential mesh, and no nonessential mesh. Therefore, two KVL equations must be written in the original circuit, which is shown with the dependent sources taped in Figure 19.45. Notice that only two unknowns exist, and also that the dependent sources have been taped. For the moment, we have turned them into independent sources (albeit with unknown values).

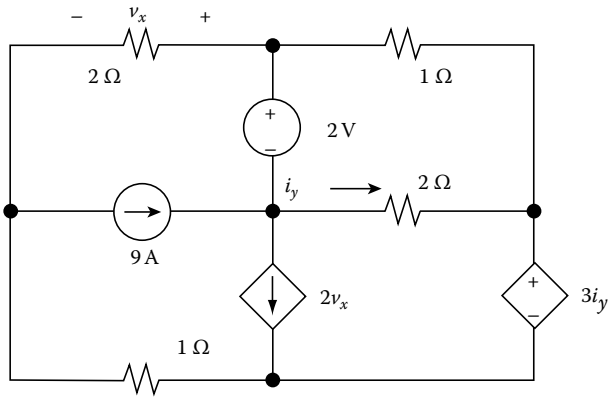

FIGURE 19.43 Example circuit.

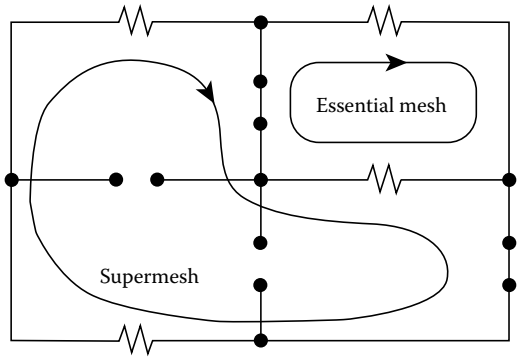

FIGURE 19.44 Testing the example circuit.

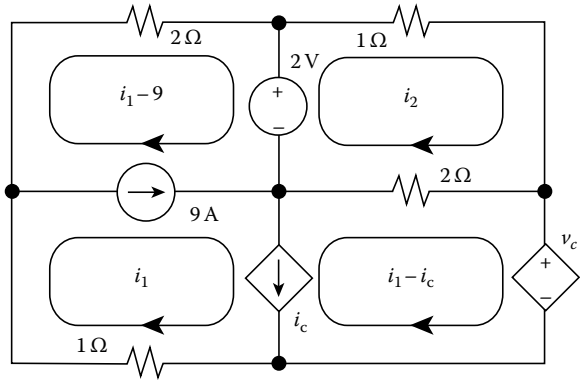

FIGURE 19.45 Example circuit prepared for mesh analysis.

We are now in a position to write KVL equations:

$$2(i_1 - 9) + 2(i_1 - i_c - i_2) + 1i_1 = -2 - v_c \quad \text{(supermesh)} \tag{19.67}$$

and

$$1i_2 + 2(i_2 - i_1 + i_c) = 2 \quad \text{(essential mesh)} \tag{19.68}$$

Observe that i_c and v_c are not known quantities, as would be the case where they are the values of independent sources. Thus, at this point, we must untape the dependent sources and express their values in terms of the mesh currents. We find that

$$i_c = 2v_x = 2x2x(-i_1 + 9) = -4i_1 + 36 \tag{19.69}$$

and

$$v_c = 3i_y = 3(i_1 - i_c - i_2) = 15i_1 - 3i_2 + 36 \tag{19.70}$$

Inserting the last two results in Equations 19.67 and 19.68 results in the matrix equation

$$\begin{bmatrix} 28 & -5 \\ -10 & 3 \end{bmatrix} \begin{bmatrix} i_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} 196 \\ -70 \end{bmatrix} \tag{19.71}$$

The coefficient matrix is no longer symmetric now that dependent sources have been introduced. (This is also the case with nodal analysis. The example treating this same circuit is found in Section 19.1.3 and should be checked to verify this point.) However, the solution is found, as usual, to be $i_1 = 7$ A and $i_2 = 0$ A.

A careful consideration of what we have done up to this point reveals that the mesh equations can be written in the form

$$A\bar{i}_M = B\bar{i}_s + C\bar{v}_s \tag{19.72}$$

In this general formulation, A is a square $n_M \times n_M$ matrix, where M is the number of meshes, and B and C are rectangular matrices whose dimensions depend upon the number of independent voltage and current sources, respectively. The variables $\bar{v}_s$ and $\bar{i}_s$ are the column matrices of independent voltage and current source values, respectively. A is symmetric if the circuit contains only resistors and independent sources. As was the case for nodal analysis, the elucidation of conditions under which the A matrix is nonsingular is difficult. Certainly, it can be singular for circuits with dependent sources; surprisingly, circuits also exist with only resistors and independent sources for which A is singular as well.

Finally, the mesh analysis procedure for circuits with dynamic elements should be clear. The algebraic process closely follows that for nodal analysis. For this reason, that topic is not discussed here.

19.1.3 Fundamental Cutset-Loop Circuit Analysis

As effective as nodal and mesh analysis are in treating circuits by hand, particular circuits exist for which they fail. Consider, for example, the circuit in Figure 19.46. If we were to blindly perform nodal analysis on this circuit, we would perhaps prepare it for analysis as shown in Figure 19.47. We have three nonreference nodes, hence, we have three nodal equations:

$$\frac{v_1}{2} = 2 \tag{19.73}$$

$$\frac{v_2 - v_3}{2} = 2 \tag{19.74}$$

$$\frac{v_3 - v_2}{2} = -2 \tag{19.75}$$

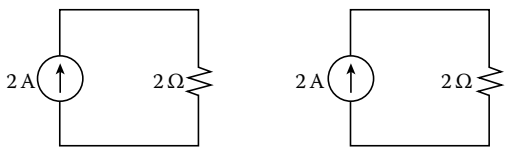

FIGURE 19.46 Example circuit.

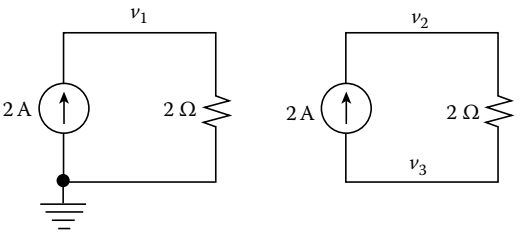

FIGURE 19.47 Example circuit prepared for nodal analysis.

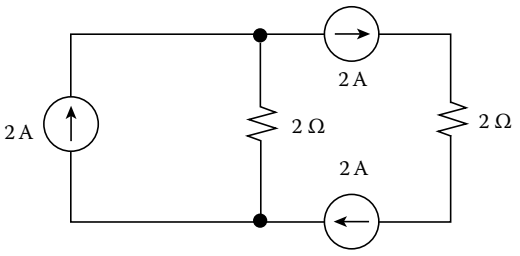

FIGURE 19.48 Another example circuit.

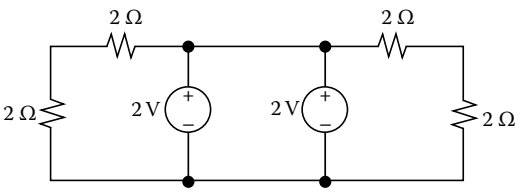

FIGURE 19.49 Another example of a singular circuit.

The third equation is simply the negative of the second; hence, the set of equations is linearly dependent and does not have a unique solution. The reason is quite obvious: the circuit is not connected.* It actually consists of two circuits considered as one. Therefore, one should actually select two reference nodes rather than one. A bit of reasoning along this line indicates that the number of nodal equations should be

$$N_{ne} = N - 1 - P \tag{19.76}$$

where P is the number of separate parts, and hence the number of reference nodes required.

Another way nodal analysis can fail is not quite as obvious. Figure 19.48 illustrates the situation. In this case, we have a cutset of current sources. Therefore, in reality, at least one of the current sources cannot be independent for it must have the same value as the other in the cutset. We will leave the writing of the nodal equations as an exercise for the reader. They are, however, linearly dependent. The problem here clearly becomes evident if one deactivates the circuit, because the resulting test circuit is not connected.

Analogous problems can occur with mesh analysis, as the circuit in Figure 19.49 demonstrates. We find a loop of voltage sources and, when the circuit is deactivated, one mesh disappears. Again, it is left as an exercise for the reader to write the mesh equations and show that they are linearly independent (the coefficients of all currents in the KVL equation for the central mesh are zero).

One might question the practically of such circuits because clearly no one would design such networks to perform a useful function. In the computer automation of circuit analysis, however, dynamic elements are often modeled over a small time increment in terms of independent sources, and singular behavior can result. Furthermore, one would like to be able to include more general elements than R, L, C, and voltage and current sources. For such reasons, a general method that does not fail is desirable. We develop this method next. It is related to the modified nodal analysis technique that is described elsewhere in the book.

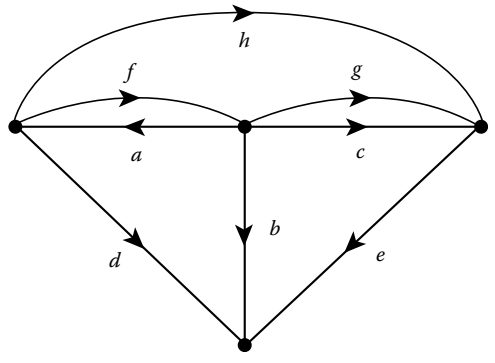

FIGURE 19.50 Example of a circuit graph.

To develop this technique, we will examine the graph of a specific circuit: the one in Figure 19.50. Graph theory is covered elsewhere in the book, but salient points will be reviewed here [7,8]. The graph, of course, is not concerned at all with the v–i characteristics of the elements themselves—only with

* A circuit is connected if at least one path exists between each pair of nodes.

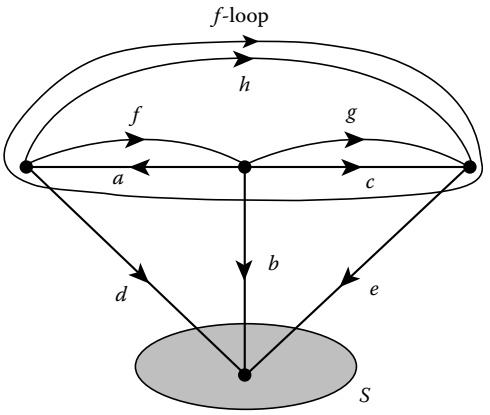

FIGURE 19.51 Fundamental cutsets and loops.

how they are interconnected. The lines (or edges or branches) represent the elements and the dots represent the nodes. The arrows represent the assumed references for voltage and current, the positive voltage at the "upstream" end of the arrow and the current reference in the direction of the arrow. We also recall the definition of a tree: for a connected graph of N nodes, a tree is any subset of edges of the graph that connects all the nodes, but which contains no loops. Such a tree is shown by means of the darkened edges in the figure: a, b, and c. The complement of a tree is called a cotree. Thus, edges d, e, f, g, and h form a cotree in Figure 19.50. If a graph consists of separate parts (that is, it is not connected), then one calls a subset of edges that connects all N nodes, but forms no loops, a forest. The complement of a forest is a coforest. The analysis method presented here is applicable to either connected or nonconnected circuits. However, we will use the terms for a graph that is connected for ease of comprehension; one should go through a parallel development for nonconnected circuits to assure oneself that the generalization holds.

Each edge contained in a tree is called a twig, and each edge contained in a cotree is called a link. (Remember that the set of all nodes in a connected graph is split into exactly two sets of nodes, each of which is individually connected by twigs, when a tree edge is removed). The set of links having one of its nodes in one set and another in the second, together with the associated twig defining the two sets of nodes, is called a fundamental cutset, of f-cutset. If all links associated with a given tree are removed, then the links replaced one at a time, it can be seen that each link defines a loop called a fundamental loop or f-loop. Figure 19.51 is a fundamental cutset and a fundamental loop for the graph shown in Figure 19.50. The closed surface S is placed around one of the two sets of nodes so defined (in this case consisting of a single node) and is penetrated by the edges in the cutset b, d, and e. A natural orientation of the cutset is provided by the direction of the defining twig, in this case edge b. Thus, a positive sign is assigned to b; then, any link in the fundamental cutset with a direction relative to S agrees with that of the twig receives a positive sign, and each with a direction that is opposite receives a negative sign. Similarly, the fundamental loop is given a positive sense by the direction of the defining link, in the case edge h. It is assigned a positive sign; then, each twig in the f-loop is given a positive sign if its direction coincides in the loop with the defining link, and a negative sign if it does not.

The positive and negative signs just defined can be used to write one KCL equation for each f-cutset and one KVL equation for each f-loop, as follows. Consider the example graph with which we are working. The f-cutsets are $\{d, b, e\}$, $\{d, a, f, h\}$, and $\{e, c, g, h\}$. In general, $N-1$ f-cutsets are associated with each tree—exactly the same as the number of twigs in the tree. Using surfaces similar to S in Figure 19.51 for each of the f-cutsets, we have the following set of KCL equations:

$$i_a - i_d - i_f - i_h = 0 \tag{19.77}$$

$$i_b + i_d + i_e = 0 \tag{19.78}$$

$$i_c - i_e + i_g + i_h = 0 \tag{19.79}$$

In matrix form, these equations become

$$\begin{bmatrix} 1 & 0 & 0 & -1 & 0 & -1 & 0 & -1 \\ 0 & 1 & 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & -1 & 0 & 1 & 1 \end{bmatrix} \begin{bmatrix} i_a \\ i_b \\ i_c \\ i_d \\ i_e \\ i_f \\ i_g \\ i_h \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \tag{19.80}$$

The coefficient matrix consists of zeroes, and positive and negative ones. It is called the *f*-cutset matrix. Each row corresponds to the KCL equation for one of the *f*-cutsets, and has a zero entry for each edge not in that cutset, $a+1$ for any edge in the cutset with the same orientation as the defining twig, and $a-1$ for each edge in the cutset whose orientation is opposite to the defining twig, and $a-1$ for each edge in the cutset whose orientation is opposite to the defining twig. One often labels the rows and columns,

$$Q = \begin{matrix} a \\ b \\ c \end{matrix} \begin{bmatrix} a & b & c & d & e & f & g & h \\ 1 & 0 & 0 & -1 & 0 & -1 & 0 & -1 \\ 0 & 1 & 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & -1 & 0 & 1 & 1 \end{bmatrix} \tag{19.81}$$

to emphasize the relation between the matrix and the graph. Thus, the first row corresponds to KCL for the *f*-cutset defined by twig *a*, the second to that defined by twig *b*, and the last to the cutset defined by twig *c*. The columns correspond to each of the edges in the graph, with the twigs occupying the first $N-1$ columns in the same order as that in which they appear in the rows. Notice that a unit matrix of order $N-1 \times N-1$ is located in the leftmost $N-1$ columns. Furthermore, Q has dimensions $(N-1) \times B$, where B is the number of branches (edges). Clearly, Q has maximum rank because of the leading unit matrix. More succinctly, one writes KCL in terms of the *f*-cutset matrix as

$$Q\bar{i} = [U \dot{:} H]\bar{i} = 0 \tag{19.82}$$

where $\bar{i}$ is the column matrix of all the branch currents. Here, the structure of Q appears explicitly with the unit matrix in the first $N-1$ columns and, for our example,

$$H = \begin{bmatrix} -1 & 0 & -1 & 0 & -1 \\ 1 & 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 1 & 1 \end{bmatrix} \tag{19.83}$$

In general, H will have dimensions $(N-1) \times (b-N+1)$.

Each of the links, all $B-N+1$ of them, have an associated KVL equation. In our example, using the same order for these links and equations that occurs in the KCL equations,

$$\begin{bmatrix} 1 & -1 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & -1 & 1 & 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & -1 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} v_a \\ v_b \\ v_c \\ v_d \\ v_e \\ v_f \\ v_g \\ v_h \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \tag{19.84}$$

We have one row for each link and, therefore, one for each *f*-loop. If a given edge is in the given loop, $a+1$ is in the corresponding column if its direction agrees with that of the defining link, and $a-1$ if it disagrees. Notice that a unit matrix of dimensions $(B-N+1)\times(B-N+1)$ is located in the last $B-N+1$ columns. Even more important, observe that the matrix in the first $N-1$ columns has a familiar form; in fact, it is $-H'$, the negative transpose of the matrix in Equation 19.83.

This is no accident. In fact, the entries in this matrix are strictly due to twigs in the tree. Focus on a given twig and a given link. The twig defines two twig-connected sets of nodes, as mentioned above. If the given link has both its terminal nodes in only one of these sets, the given twig voltage does not appear in the KVL equation for that *f*-loop. If, on the other hand, one of the link nodes is in one of those sets and the other in the alternate set, the given twig voltage will appear in the KVL equation for the given link, with $a+1$ multiplier if the directions of the twig agree relative to the *f*-loop and $a-1$ if they do not. However, a little thought shows that the same result holds for the *f*-cutset equation defined by the twig, except that the signs are reversed. If the link and twig directions agree for the *f*-loop, they disagree for the *f*-cutset, and vice versa. Thus, we can write KVL for the *f*-loops, in general, as

$$B_f\bar{v} = [-H'\vdots U]\bar{v} = 0 \tag{19.85}$$

where

B_f is called the fundamental loop matrix

$\bar{v}$ is the column matrix of all branch voltages

Suppose that we partition the branch voltages and branch currents according to whether they are associated with twigs or links. Thus, we write

$$\bar{v} = \left[\bar{v}_T'\bar{v}_C'\right]' \tag{19.86}$$

and

$$\bar{i} = \left[\bar{i}_T'\bar{i}_C'\right]' \tag{19.87}$$

We use transpose notation to conserve space, and the subscripts T and C represent tree and cotree voltages and currents, respectively. We cannot use Equations 19.82 and 19.85 to write the composite circuit variable vector as

$$\bar{u} = \begin{bmatrix}\bar{v}\\ \bar{i}\end{bmatrix} = \begin{bmatrix} U & 0\\ H' & 0\\ 0 & -H\\ 0 & U\end{bmatrix}\begin{bmatrix}\bar{v}_T\\ \bar{i}_C\end{bmatrix} \tag{19.88}$$

The coefficient matrix is of dimensions $2B\times B$ and has rank B because of the two unit matrices. What we have accomplished is a direct sum decomposition of the $2B$-dimensional vector space consisting of all circuit variables in terms of the $N-1$ dimensional vector space of tree voltages and the $B-N+1$ dimensional vector space of link currents. Furthermore, the tree voltages and link currents form a basis for the vector space of all circuit variables.

We have discussed topology enough for our purposes. We now treat the elements. We are looking for a generalized method of circuit analysis that will succeed, not only for circuits containing *R*, *L*, *C*, and source elements, but ideal transformers, gyrators, nullators, and norators (among others) as well. Thus, we turn to a discussion of elements [9].

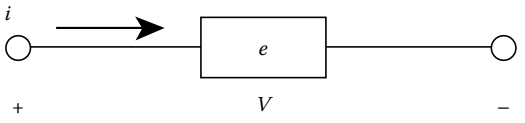

FIGURE 19.52 Two-terminal element.

Consider elements having two terminals only, as shown in Figure 19.52. The most general assumption we can make, assuming that we are ruling out "nonlinear" elements, is that the *v–i* characteristic of each such element be affine, that is, it is defined by an operator equation of the form

$$\begin{bmatrix} a & b \\ 0 & c \end{bmatrix} \begin{bmatrix} v \\ i \end{bmatrix} = \begin{bmatrix} f(t) \\ g(t) \end{bmatrix} \tag{19.89}$$

where the parameters a, b, and c are operators. It is more classical to assume a scalar form of this equation; that is, with c and $g(t)$ both zero. In a series of papers in the 1960s, however, Carlin and Youla, Belevitch, and Tellegen [10–12] proposed that the *v–i* characteristic be interpreted as a multidimensional relationship. Among other things to come out of the approach was the definition of the nullator and the norator. Now, assuming that this defining characteristic is indeed multidimensional, we see at once that it is not necessary to consider operator matrices of a dimension larger than 2×2. There must be two columns because there are only two scalar terminal variables. If more than two rows were found, the additional equations would be either redundant or inconsistent, depending upon whether row reductions resulted in additional rows of all zeroes or in an inconsistent equation. Finally, the (2, 1) element in the operator matrix clearly can be chosen to be zero as shown, because otherwise it could be reduced to zero with elementary row operations. That is, one could, unless $a = 0$; but here, an exchange of rows produces the desired result shown. Note that any or all of a, b, and c can be the zero operator.

We pause here to remark that a and b can be rather general operators. If they are differential, or Heaviside, operators, (that is, they are real, rational functions of p), a theory of lumped circuits (differential systems) is obtained. On the other hand, they could be rational functions of the delay operator E.* In this case, one would obtain the theory of distributed (transmission line) circuits. Then, if a common delay parameter is used, one obtains a theory of commensurate transmission line circuits; if not, an incommensurate theory results. If the parameters are functions of both p and d, a mixed theory results. We will assume here that a, b, and c are rational functions of p.

Let us suppose that c is the zero operator and that $g(t) = 0$ is the second equality resulting from the stipulation of existence (consistency). This gives the affine scalar relationship

$$av + bi = f(t) \tag{19.90}$$

Special cases are now examined. For instance, if $b = 0$ and $a \neq 0$, one has

$$v(t) = f(t)/a = v_s(t) \tag{19.91}$$

This, of course, is the *v–i* characteristic for an independent voltage source. If, on the other hand, $a = 0$ and $b \neq 0$, one has

$$i(t) = f(t)/b = i_s(t) \tag{19.92}$$

This is an ideal current source. If, in addition $f(t)$ is identically zero, one obtains a short circuit and an open circuit, respectively. These results are shown in Figure 19.53. Now suppose that a and b are both zero. Then, $f(t)$ must be identically zero as well; otherwise, the element does not exist. In this case any arbitrary voltage and current are possible. The resulting element, a "singular one" to be sure, is called a norator. Its symbol is shown in Figure 19.54.

* $Ex(t) = x(t - T)$ for all t and all waveforms $x(t)$.

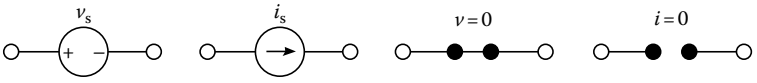

FIGURE 19.53 Conventional two-terminal elements.

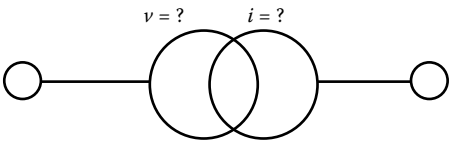

FIGURE 19.54 Norator.

Remaining with the same general case, that is, with $c = 0$ and $g(t) = 0$, we ask what element results if we also assume that neither a nor b are zero, but that $f(t)$ is identically zero. We can solve for either the voltage or the current. In either case, one obtains a passive element, as shown in Figure 19.55. If $-b/a$ is constant, a resistor will result; if $-b/a$ is a constant times the differential operator p, an inductor will result; and if $-b/a$ is reciprocal in p, a capacitor will result. In case the ratio is a more complicated function of p, one would consider the two-terminal object to be a subcircuit, that is, a two-terminal object decomposable into other elements, with $-b/a$ being the driving point impedance operator.

One can, in fact, derive the Thévenin and Norton equivalents from these considerations. Staying with the general case of c and $g(t)$ both zero, but allowing $f(t)$ to be nonzero, we first assume that $a \neq 0$. Then, we obtain

$$v(t) = \frac{f(t)}{a} - \frac{b}{a} i(t) = v_{oc}(t) + Z_{eq}(p) i(t) \tag{19.93}$$

which represents the Thévenin equivalent subcircuit shown in Figure 19.56a. Alternately, if $b \neq 0$ we can write

$$i(t) = \frac{f(t)}{b} - \frac{a}{b} i(t) = i_{sc}(t) + Y_{eq}(p) v(t) \tag{19.94}$$

The latter equation is descriptive of the Norton equivalent shown in Figure 19.56b. The basic assumption is that the two-terminal object has a v–i characteristic (i.e., an affine relationship); if this object contains only elements characterized by affine relationships having a rank property to be given later, one can use the analysis method being presented here to prove that this assumption is true. At this point,

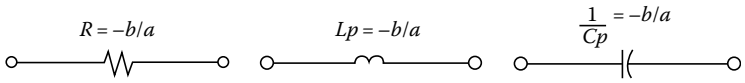

FIGURE 19.55 Passive elements.

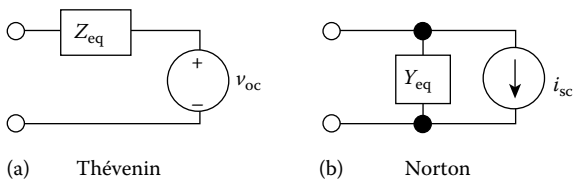

FIGURE 19.56 Two general equivalent subcircuits.

however, we are merely assembling a catalog of elements, so we assume that the two-terminal object is, indeed, a single element (it cannot be decomposed farther).

We have only one other case to consider: that in which c is a nonzero operator. If this is the situation and if, in addition, $a \neq 0$ as well, one can solve Equation 19.90 by inverting the coefficient matrix to obtain

$$\begin{bmatrix} v \\ i \end{bmatrix} = \begin{bmatrix} 1/c & -b/ac \\ 0 & 1/a \end{bmatrix} \begin{bmatrix} f(t) \\ g(t) \end{bmatrix} = \begin{bmatrix} v_s(t) \\ i_s(t) \end{bmatrix} \tag{19.95}$$

Therefore, the voltage and current are independently specified. First, suppose that both $v_s(t)$ and $i_s(t)$ are identically zero. Then, one has $v(t) = 0$ and $i(t) = 0$ for t. The associated element is called a nullator, and has the symbol shown in Figure 19.57a. Finally, if $v_s(t)$ and $i_s(t)$ are nonzero, one can sketch the equivalent subcircuit as in Figure 19.57b.

At this point, we have an exhaustive catalog of two-terminal circuit elements: the independent voltage and current sources, the resistor, the inductor, the capacitor, the norator, and the nullator. We would like to include more complex elements with more than two terminals as well. Figure 19.58a shows a three-terminal element and Figure 19.58b shows a two-port element. For the former, we see at once that only two voltages and two currents can be independently specified because KVL gives the voltage between the left and right terminals in terms of the two shown, while KCL gives the current in the third lead. As for the latter, it is a basic assumption that only the two-port voltages and the two-port currents are required to specify its operation. In fact, one assumes that the currents coming out of the bottom leads are identical to those going into the top leads. We also assume that the v–i characteristic is independent of the voltages between terminals in different ports. Each of the ports will be an edge in the circuit graph that results when such elements are interconnected.

Because four variables are associated with a three-terminal or two-port element, the dimensionality of the resulting vector space is four; thus, we assume that the describing v–i characteristic is

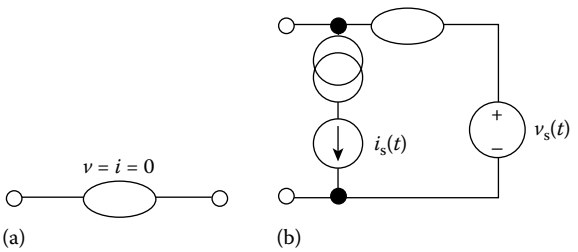

FIGURE 19.57 Nullator element (a) and an equivalent subcircuit (b).

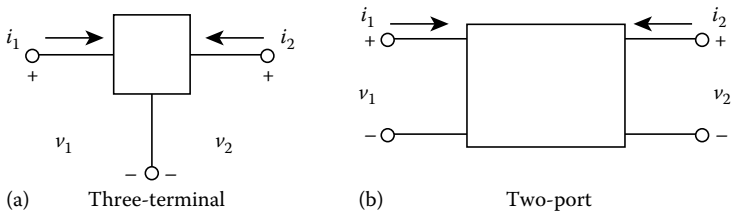

FIGURE 19.58 Three-terminal (a) and two-port elements (b).

$$\begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} \\ 0 & a_{22} & a_{23} & a_{24} \\ 0 & 0 & a_{33} & a_{34} \\ 0 & 0 & 0 & a_{44} \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ i_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} f_1(f) \\ f_2(f) \\ f_3(f) \\ f_4(f) \end{bmatrix} \tag{19.96}$$

We justify this form exactly as for the case of two-terminal elements. We will not exhaustively catalog all of the possible three-terminal/two-port elements for reasons of space; however, note that the usual case is that in which $a_{ij} = 0$ for $i \geq 3$. In this case one must insist that $f_3(t) = f_4(t) = 0$; then one has the 2×2 system of equations

$$\begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} \\ 0 & a_{22} & a_{23} & a_{24} \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ i_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} f_1(t) \\ f_2(t) \end{bmatrix} \tag{19.97}$$

If the two forcing functions on the right are not identically zero, a number of different two-port equivalent circuits can be generated—generalized Thévenin and Norton equivalents. If both of these forcing functions are identically zero and if at least one 2×2 submatrix of the coefficient operator matrix on the left side is nonsingular, one can derive a hybrid matrix and a hybrid parameter equivalent circuit. Specialized versions are the impedance parameters, the admittance parameters, and the transmission or chain parameters. Furthermore, one can accommodate controlled sources, transformers, gyrators, and all of the other known two-port elements.

To present just one example, assume that the operator Equation 19.97 has the form

$$\begin{bmatrix} n & -1 & 0 & 0 \\ 0 & 0 & -1 & n \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ i_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \tag{19.98}$$

The parameter n, assumed to be a real scalar multiplier, is called the turns ratio, and the element is the ideal transformer. The VCVS obeys

$$\begin{bmatrix} \mu & -1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ i_1 \\ i_2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \tag{19.99}$$

Thus, i_1 is identically zero and $v_2 = \mu v_1$. The quantity μ is the voltage gain.

Similarly, for each element with any number of ports,* we can write

$$A_0 \bar{v} + B_0 \bar{i} = \bar{C}_0 \tag{19.100}$$

where the voltage and current vectors are the terminal variables of the element. We can then represent the element equations for any circuit in the same form by forming A_0 and B_0 as quasidiagonal matrices,

* A two-terminal element is a one-port device.

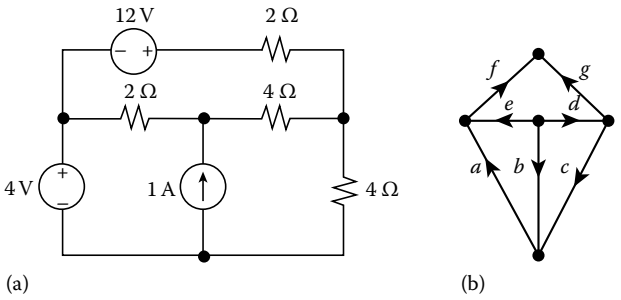

FIGURE 19.59 Example circuit (a) and its graph (b).

each of whose diagonal terms is the corresponding A_0 or B_0 for a given element, and stacking up the individual $\bar{C}_0$ column matrices to form the overall matrix. We then rewrite Equation 19.100 in the form

$$[A_0 B_0]\begin{bmatrix}\bar{v}\\ \bar{i}\end{bmatrix} = \bar{C} \tag{19.101}$$

where the voltage and current vectors are each $B \times 1$ column matrices of the individual element voltages and currents. We make the assumption that the matrix $[A\ B]$, which is of dimension $B \times 2B$ is of maximum rank b. This is the only assumption required for the procedure to be outlined to succeed, as will later be demonstrated.

An example will clarify things. Figure 19.59 is an example circuit. The correspondence between the edge labels and the circuit elements is obvious; that is, for instance, a is the 4 V voltage source and its voltage is -4 V (minus, because of the definition of positive voltage on edge a in the graph). We have shown a tree on the graph. The f-cutset matrix is

$$Q = \begin{matrix}b\\ d\\ e\\ f\end{matrix}\begin{bmatrix} b & d & e & f & a & c & g\\ 1 & 0 & 0 & 0 & -1 & 1 & 0\\ 0 & 1 & 0 & 0 & 0 & -1 & -1\\ 0 & 0 & 1 & 0 & 1 & 0 & 1\\ 0 & 0 & 0 & 1 & 0 & 0 & 1 \end{bmatrix} = [U \vdots H] \tag{19.102}$$

Thus,

$$H = \begin{bmatrix} -1 & 1 & 0\\ 0 & -1 & -1\\ 1 & 0 & 1\\ 0 & 0 & 1 \end{bmatrix} \tag{19.103}$$

Although we could construct it from the Q matrix, we can just as easily read off the f-loop matrix from the graph:

$$B = \begin{matrix}a\\ c\\ g\end{matrix}\begin{bmatrix} b & d & e & f & a & c & g\\ 1 & 0 & -1 & 0 & 1 & 0 & 0\\ -1 & 1 & 0 & 0 & 0 & 1 & 0\\ 0 & 1 & -1 & -1 & 0 & 0 & 1 \end{bmatrix} = [-H' \vdots U] \tag{19.104}$$

The element constraint equations are

$$\begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & -4 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & -2 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & -4 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & -2 \end{bmatrix} \begin{bmatrix} v_b \\ v_d \\ v_e \\ v_f \\ v_a \\ v_c \\ v_g \\ i_b \\ i_d \\ i_e \\ i_f \\ i_a \\ i_c \\ i_g \end{bmatrix} = \begin{bmatrix} -1 \\ 0 \\ 0 \\ -12 \\ 4 \\ 0 \\ 0 \end{bmatrix} \tag{19.105}$$

In this case, both A_0 and B_0 are diagonal because all the elements are of the two-terminal variety.

The vector of all circuit variables is now expressed in terms of the basis in Equation 19.88, the tree voltages and link currents. We then have

$$[AB]\begin{bmatrix} \bar{v} \\ \bar{i} \end{bmatrix} = [AB]\begin{bmatrix} U & 0 \\ H' & 0 \\ 0 & -H \\ 0 & U \end{bmatrix}\begin{bmatrix} \bar{v}_{\mathrm{T}} \\ \bar{i}_{\mathrm{C}} \end{bmatrix}$$

$$= \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & -4 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & -2 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & -4 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & -2 \end{bmatrix}$$

$$\times \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ -1 & 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & -1 & 0 & -1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} v_b \\ v_d \\ v_e \\ v_f \\ v_a \\ i_c \\ i_g \end{bmatrix} = \begin{bmatrix} -1 \\ 0 \\ 0 \\ -12 \\ 4 \\ 0 \\ 0 \end{bmatrix} \tag{19.106}$$

After multiplying the two matrices, we have a more compact matrix

$$\begin{bmatrix} 0 & 0 & 0 & 0 & 1 & -1 & 0 \\ 0 & 1 & 0 & 0 & 0 & -4 & -4 \\ 0 & 0 & 1 & 0 & 2 & 0 & 2 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ -1 & 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & -1 & 0 & 0 & 0 & -4 & 0 \\ 0 & -1 & 1 & 1 & 0 & 0 & -2 \end{bmatrix} \begin{bmatrix} v_b \\ v_d \\ v_e \\ v_f \\ v_a \\ i_c \\ i_g \end{bmatrix} = \begin{bmatrix} -1 \\ 0 \\ 0 \\ -12 \\ 4 \\ 0 \\ 0 \end{bmatrix} \tag{19.107}$$

We leave it to the reader to show that the solution is given by (in transpose notation):

$$\begin{bmatrix} v_b & v_d & v_e & v_f & i_a & i_c & i_g \end{bmatrix}' = [0 \quad -4 \quad 4 \quad -12 \quad 0 \quad 1 \quad -2] \tag{19.108}$$

In general, one must solve the matrix equation

$$[A \; B] = \begin{bmatrix} U & 0 \\ H' & 0 \\ 0 & -H \\ 0 & U \end{bmatrix} \begin{bmatrix} \bar{v}_T \\ \bar{i}_C \end{bmatrix} = C \tag{19.109}$$

where H is the nonunit submatrix in the f-cutset matrix and C_0 is the $B \times 1$ column matrix of constants (or independent functions of time). Here is the crucial result: $[A_0 \; B_0]$ has dimensions $B \times 2B$; if it has rank B, then the product of it with the next matrix, which also has rank B, will be square (of dimensions $B \times B$) and of rank B by Sylvester's inequality [13]. In this case, the resulting coefficient matrix will be invertible, and a solution is possible.

The procedure just described, although involving more computation than, for example, nodal analysis, is general. If one solves for all element currents and voltages for a general circuit, however, one must anticipate additional complexity. Furthermore, the method outlined is algorithmic and can be computer automated. The element constraint matrices A_0 and B_0 consist of stylized submatrices corresponding to each type of element. These are referred to as ''stamps'' in the modified nodal technique described elsewhere in this volume, and the preceding method is quite similar. The major difference is that is uses node voltage as a basis for the branch voltage space of a circuit instead of the tree voltages described previously.

19.2 Network Theorems

Marwan A. Simaan

In Section 19.1, we learned how to determine currents and voltages in a resistive circuit. Methods have been developed, which are based on applying KVL and KCL, to derive a set of mesh or node equations which, when solved, will yield mesh currents or node voltages, respectively. Frequently, and especially if the circuit is complex with many elements, the application of these methods may be considerably simplified if the circuit itself is simplified. For example, we may wish to replace a portion of the circuit consisting of resistors and sources by an equivalent circuit that has fewer elements in order to write fewer mesh or node equations.

In this context, we introduce three important and related theorems known as the superposition, the Thévenin and the Norton theorems. The superposition theorem shows how to solve for a variable in a circuit that has many independent sources, by solving simpler circuits, each excited by only one source. The Thévenin and Norton theorems can be used to replace a portion of a circuit at any two terminals by an equivalent circuit which consists of a voltage source in series with a resistor (i.e., a nonideal voltage source) or a current source in parallel with a resistor (i.e., a nonideal current source). Another important result derived in this section concerns the calculation of power dissipated in a load resistor connected to a circuit. This result is known as the maximum power transfer theorem, and is frequently used in circuit design problems. Finally, a result known as the reciprocity theorem is also discussed.

An important property of linear resistive circuits is the type of relationship that exists between any variable in the circuit and the independent sources. For linear resistive circuits the solution for a voltage or current variable can always be expressed as a linear combination of the independent sources. Let us elaborate on what we mean by this statement through an example.

Consider the circuit in Figure 19.60 and assume that we are interested in the voltage v across R_2. We can solve for v by first applying KCL at node a to get the equation

$$-\frac{v - v_1}{R_1} + \beta i_x + i_1 - \frac{v}{R_2} = 0 \tag{19.110}$$

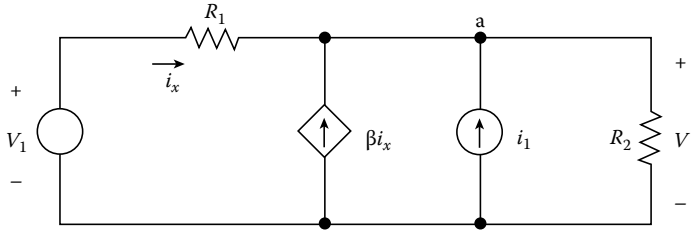

FIGURE 19.60 Example of a linear circuit.

and then by making use of the fact that

$$i_x = \frac{v_1 - v}{R_1} \tag{19.111}$$

This gives

$$v = \frac{(1+\beta)R_2}{R_1 + (1+\beta)R_2} v_1 + \frac{R_1 R_2}{R_1 + (1+\beta)R_2} i_1 \tag{19.112}$$

Here, the voltage v is a linear combination of the independent sources v_1 and i_1.

The preceding observation indeed applies to every linear circuit. In general, if we let y denote a voltage across, or a current in, any element in a linear circuit and if we let $\{x_1, x_2, \ldots, x_N\}$ denote the independent voltage and current sources in that circuit (assuming there is a total of N such sources), then we can write

$$y = \sum_{k=1}^{N} a_k x_k \tag{19.113}$$

where $a_1, a_2, \ldots, a_N$ are constants which depend on the circuit parameters. Thus, in the circuit of Figure 19.60, every current or voltage variable can be expressed as a linear combination of the form

$$y = a_1 V_1 + a_2 i_1$$

where a_1 and a_2 are constants that depend on R_1, R_2, and β. For the voltage v across R_2, this relationship is given by expression (Equation 19.112).

Mathematically, the relationship between y and $\{x_1, x_2, \ldots, x_N\}$ expressed in Equation 19.113 is said to be linear because it satisfies the following two conditions:

1. The *superposition condition*, which requires that

$$\begin{aligned} \text{if} \quad & \hat{y} = \sum_{k=1}^{N} a_k \hat{x}_k \\ \text{and} \quad & \tilde{y} = \sum_{k=1}^{N} a_k \tilde{x}_k \\ \text{then} \quad & \hat{y} + \tilde{y} = \sum_{k=1}^{N} a_k (\hat{x}_k + \tilde{x}_k) \end{aligned}$$

2. The homogeneity condition, which requires that

$$\begin{aligned} \text{if} \quad & \hat{y} = \sum_{k=1}^{N} a_k \hat{x}_k \\ \text{then} \quad & c\hat{y}(t) = \sum_{k=1}^{N} a_k \{c\hat{x}_k\} \end{aligned}$$

for any constant c.

Example 19.1 illustrates how these two conditions are satisfied for the circuit of Figure 19.60.

Example 19.1

For the circuit of Figure 19.60, let $R_1 = 2\ \Omega$, $R_2 = 1\ \Omega$, and $\beta = 2$. Show that the expression for v in terms of v_1 and i_1 satisfies the superposition and homogeneity conditions.

Substituting the values of R_1, R_2, and β in Equation 19.112, the expression for v becomes

$$v = \frac{3}{5}v_1 + \frac{2}{5}i_1 \tag{19.114}$$

To check the superposition property, let $v_1 = \hat{v}_1$ and $i_1 = \hat{i}_1$. Then, the voltage $\hat{v}$ across R_2 is

$$\hat{v} = \frac{3}{5}\hat{v}_1 + \frac{2}{5}\hat{i}_1$$

Similarly, let $V_1 = \tilde{V}_1$ and $i_1 = \tilde{i}_1$. Then, the voltage $\tilde{V}$ across R_2 is

$$\tilde{v} = \frac{3}{5}\tilde{v}_1 + \frac{2}{5}\tilde{i}_1$$

Now, assume that $V_1 = \hat{V}_1 + \tilde{V}_1$ and that $i_1 = \hat{i}_1 + \tilde{i}_1$. Then, according to Equation 19.114 the corresponding voltage V across R_2 is

$$\begin{aligned} V &= \frac{3}{5}\left(\hat{V}_1 + \tilde{V}_1\right) + \frac{2}{5}\left(\hat{i}_1 + \tilde{i}_1\right) \\ &= \left(\frac{3}{5}\hat{V}_1 + \frac{2}{5}\hat{i}_1\right) + \left(\frac{3}{5}\tilde{V}_1 + \frac{2}{5}\tilde{i}_1\right) \\ &= \hat{V} + \tilde{V} \end{aligned}$$

Hence, the superposition condition is satisfied.

To check the homogeneity condition, let $V_1 = c\hat{V}_1$ and $i_1 = c\hat{i}_1$, where c is an arbitrary constant. Then, according to Equation 19.114 the corresponding voltage v across R_2 is

$$\begin{aligned} V &= \frac{3}{5}\left(c\hat{V}_1\right) + \frac{2}{5}\left(c\hat{i}_1\right) \\ &= c\left(\frac{3}{5}\hat{V}_1 + \frac{3}{5}\hat{i}_1\right) \\ &= c\hat{V} \end{aligned}$$

The homogeneity condition is also satisfied.

19.2.1 Superposition Theorem

Let us reexamine expression (Equation 19.112) for the voltage v in the circuit of Figure 19.60. To be more specific, let us use this expression to calculate the voltage across R_2 for the two circuits shown in Figure 19.61a and b, respectively. Observe that the first circuit is obtained from the original circuit by deactivating the current source (i.e., setting $i_1 = 0$) and leaving the voltage source to act alone. The second is obtained by deactivating the voltage source (i.e., setting $V_1 = 0$) and leaving the current source to act alone. If we label the voltages across R_2 in these two circuits as v_a and v_b, respectively, then

$$v_a = v\Big|_{\substack{\text{when} \\ i_1 = 0}} = \frac{(1+\beta)R_2}{R_1 + (1+\beta)R_2}v_1$$

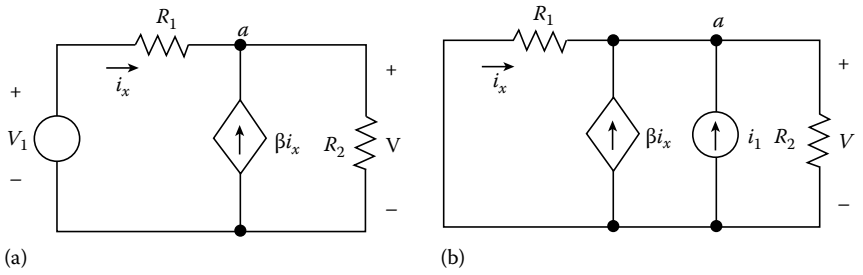

FIGURE 19.61 Circuit of Figure 19.60 with (a) the current source deactivated and with (b) the voltage source deactivated.

and

$$v_b = v\Big|_{\substack{\text{when}\\ v_1=0}} = \frac{R_1 R_2}{R_1 + (1+\beta)R_2} i_1$$

In other words, expression (Equation 19.112), which was used to derive the above two expressions, can itself be written as

$$v = v\Big|_{\substack{\text{when}\\ i_1=0}} + v\Big|_{\substack{\text{when}\\ v_1=0}}$$

or

$$v = v_a + v_b$$

Thus, we conclude that the voltage across R_2 in Figure 19.60 is actually equal to the sum of two voltages across R_2 due to two independent sources in the circuit acting individually.

The preceding result is in fact a direct consequence of the linearity property

$$y = a_1 x_1 + a_2 x_2 + \cdots + a_N x_N$$

expressed in Equation 19.113. Note that, from this expression, we can write

$$\begin{aligned}
a_1 x_1 &= y\big|_{\text{when } x_1 \neq 0, x_2 = 0, x_3 = 0, \ldots, x_N = 0},\\
a_2 x_2 &= y\big|_{\text{when } x_1 = 0, x_2 \neq 0, x_3 = 0, \ldots, x_N = 0},\\
&\vdots \quad\quad \vdots\\
a_N x_N &= y\big|_{\text{when } x_1 = 0, x_2 = 0, x_3 = 0, \ldots, x_N \neq 0}
\end{aligned}$$

This means Equation 19.113 can be rewritten as

$$\begin{aligned}
y = {} & y\big|_{\text{when } x_1 \neq 0, x_2 = 0, x_3 = 0, \ldots, x_N = 0}\\
& + y\big|_{\text{when } x_1 = 0, x_2 \neq 0, x_3 = 0, \ldots, x_N = 0}\\
& \quad \vdots \quad\quad \vdots\\
& + y\big|_{\text{when } x_1 = 0, x_2 = 0, x_3 = 0, \ldots, x_N \neq 0}
\end{aligned}$$

The following theorem, known as the superposition theorem, is therefore directly implied from the previous expression:

> The voltage across any element (or current through any element) in a linear circuit may be calculated by adding algebraically the individual voltages across that element (or currents through that element) due to each independent source acting alone with all other independent sources deactivated.

In this statement, the word deactivated is used to imply that the source is set to zero. In this context, we refer to a deactivated current source as one that is replaced by an open circuit and a deactivated voltage source as one that is replaced by a short circuit. Note that the action of deactivating a source refers only to independent sources. Example 19.2 illustrates how the superposition theorem can be used to solve for a variable in a circuit with more than one independent source.

Example 19.2

For the circuit shown in Figure 19.62, apply superposition to calculate the current *I* in the 4 Ω resistor.

Because we are interested in calculating *I* using the superposition theorem, we need to consider the two circuits shown in Figure 19.63a and b. The first is obtained by deactivating the current source and the second is obtained by deactivating the voltage source. Let I_a be the current in the 4 Ω resistor in the first circuit and I_b be the current in the same resistor in the second. Then, by superposition

$$I = I_a + I_b$$

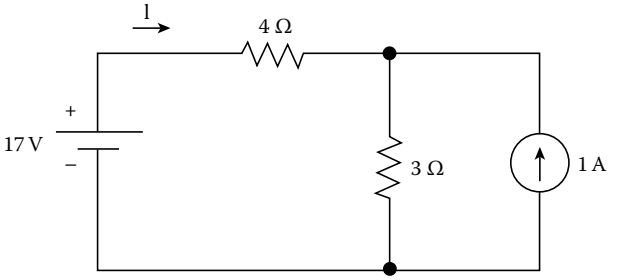

FIGURE 19.62 Circuit for Example 19.2.

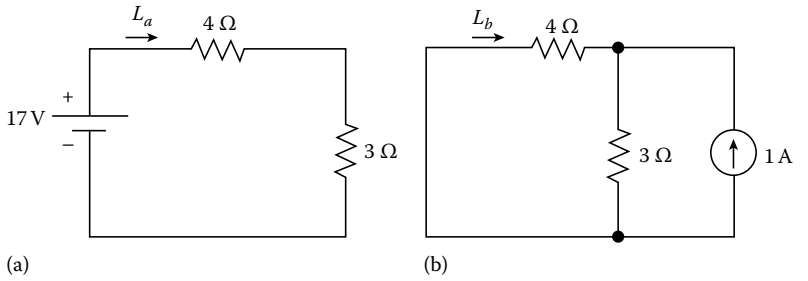

FIGURE 19.63 Circuit for Example 19.2 with (a) the current source deactivated and with (b) the voltage source deactivated.

We can solve for I_a and I_b independently as follows. From Figure 19.63a:

$$I_a = \frac{17}{7}\text{A}$$

and from Figure 19.63b, applying the current divider rule,

$$I_b = -1 \cdot \frac{3}{7}\text{A}$$

Thus,

$$\begin{aligned} I &= \frac{17}{7} - \frac{3}{7} \\ &= 2\text{A} \end{aligned}$$

19.2.2 Thévenin Theorem

In the discussion on the superposition theorem, we interpreted Equation 19.112 for the voltage V in the circuit of Figure 19.60 as a superposition of two terms. Let us now examine a different interpretation of this expression.

Suppose we factor the common term in expression (Equation 19.112), so that it can be written as

$$v = \frac{(1+\beta)R_2}{R_1 + (1+\beta)R_2}\left\{v_1 + \frac{R_1}{1+\beta}i_1\right\} \tag{19.115a}$$

or

$$v = \frac{R_2}{(R_1/(1+\beta)) + R_2}\left\{v_1 + \left(\frac{R_1}{1+\beta}\right)i_1\right\} \tag{19.115b}$$

Now, suppose we define

$$v_0 = v_1 + \frac{R_1}{1+\beta}i_1 \tag{19.116}$$

and

$$R_0 = \frac{R_1}{1+\beta} \tag{19.117}$$

Then, we can write Equation 19.112 in the simple form

$$v = \frac{R_2}{R_0 + R_2}v_0 \tag{19.118}$$

This expression can be interpreted as a voltage divider equation for a two-resistor circuit as shown in Figure 19.64. This circuit has a voltage source v_0 in series with two resistors R_0 and R_2. When this circuit

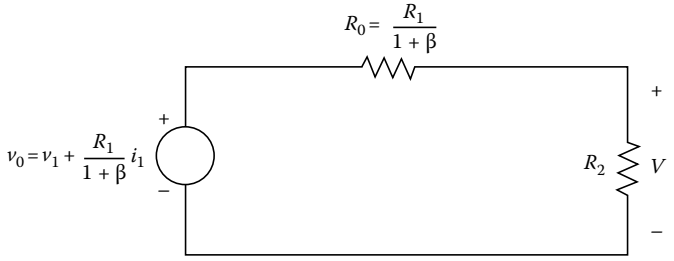

FIGURE 19.64 Voltage divider circuit representing Equation 19.118.

is compared with Figure 19.60, the combination of voltage source v_0 in series with R_0 can be interpreted as an equivalent replacement of all the elements in the circuit connected to R_2. That is, we could remove that portion of the circuit of Figure 19.60 consisting of v_1, R_1, βi_x, and i_1 and replace it with the voltage source v_0 in series with the resistor R_0.

The fact that a portion of a circuit can be replaced by an equivalent circuit consisting of a voltage source in series with a resistor is actually a direct result of the linearity property, and hence is true for linear circuits in general. It is known as Thévenin's theorem* and is stated as follows:

> Any portion of a linear circuit between two terminals a and b can be replaced by an equivalent circuit consisting of a voltage source V_{th} in series with a resistor R_{th}. The voltage V_{th} is determined as the open circuit voltage at terminals $a-b$. The resistor R_{th} is equal to the input resistance at terminals $a-b$ with all the independent sources deactivated.

The various steps involved in the derivation of the Thévenin equivalent circuit are illustrated in Figure 19.65. The Thévenin voltage v_{th} is determined by solving for the voltage at terminals $a-b$ when open circuited, and the Thévenin resistance R_{th} is determined by calculating the input resistance of the circuit at terminals $a-b$ when all the independent sources have been deactivated. Examples 19.3 and 19.4 illustrate the application of this important theorem.

Example 19.3

For the circuit in Figure 19.66, determine the Thévenin equivalent of the portion of the circuit to the left of terminals $a-b$; use it to calculate the current I in the 2 Ω resistor.

First, we determine V_{th} from the circuit of Figure 19.67a. Note that because terminals $a-b$ are open circuited the current in the branch containing the 2 Ω resistor and 9 V source is equal to 3 A in the direction shown. Applying KCL at the upper node of the 1 Ω resistor, we can calculate the current in this resistor to be $3 + 2 = 5$ A as shown. Writing a KVL equation around the inner loop (counterclockwise at terminal b) we have

$$V_{\text{th}} + 9 - (2 \times 3) - (1 \times 5) = 0$$

which yields

$$V_{\text{th}} = 2 \text{ V}$$

* For an interesting, brief discussion on the history of Thévenin's theorem, see an article by James E. Brittain, in *IEEE Spectrum*, p. 42, March 1990.

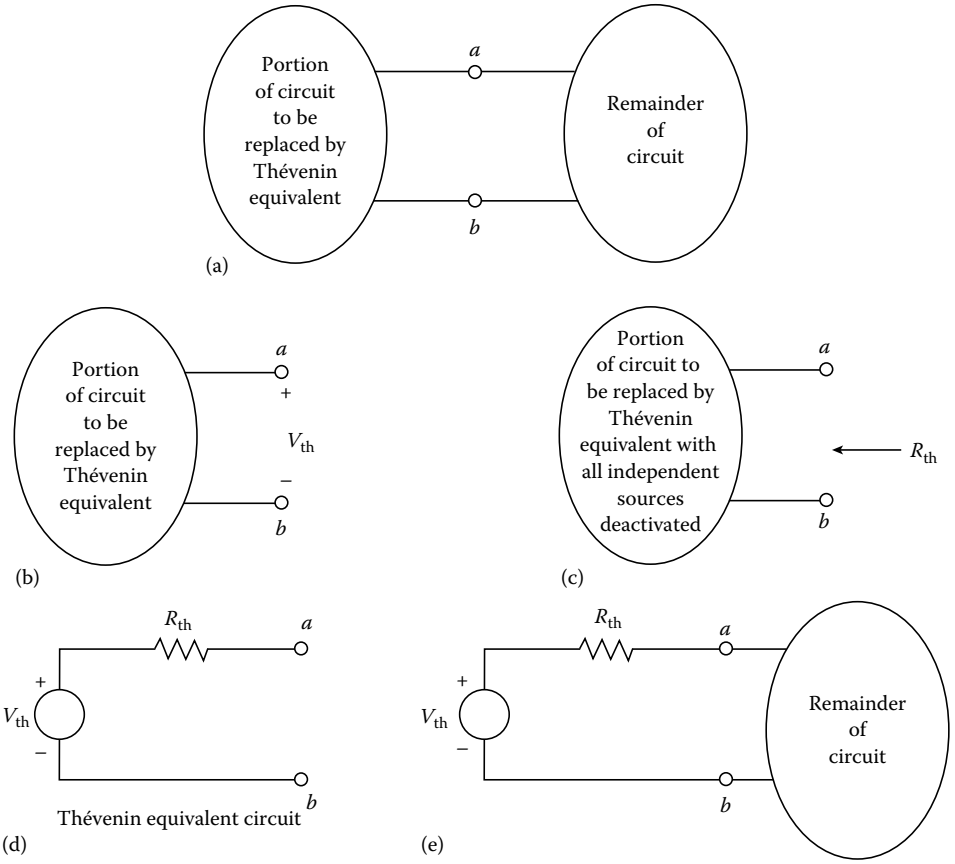

FIGURE 19.65 Steps in determining the Thévenin equivalent circuit.

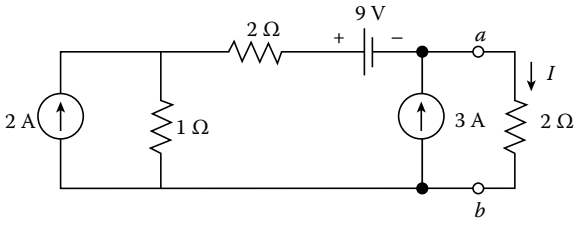

FIGURE 19.66 Circuit for Example 19.3.

Now, for R_{th} the three sources are deactivated to obtain the circuit shown in Figure 19.67b. From this circuit, it is clear that

$$R_{th} = 3\ \Omega$$

The circuit obtained by replacing the portion to the left of terminals $a-b$ with its Thévenin equivalent is shown in Figure 19.67c. The current I is now easily computed as

$$I = \frac{2}{2+3} = 0.4\ \text{A}$$

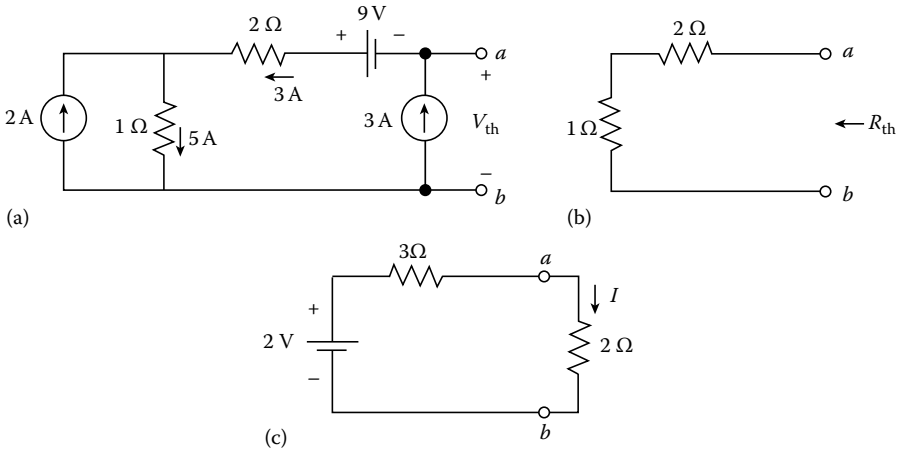

FIGURE 19.67 (a) Calculation of V_{th}, (b) calculation of R_{th}, and (c) the equivalent circuit for Example 19.3.

Example 19.4

For the circuit shown in Figure 19.60, determine the Thévenin equivalent circuit for the portion of the circuit to the left of resistor R_2.

In deriving Equation 19.118 from 19.110, we actually already determined the Thévenin equivalent for the portion of the circuit to the left of R_2. This was shown in Figure 19.64. Of course, this procedure is not the most efficient way to determine the Thévenin equivalent. Let us now illustrate how the equivalent circuit is obtained using the procedure described in Thévenin's theorem. First, we determine v_{th} from the circuit of Figure 19.68a with R_2 removed and terminals $a-b$ left open. Applying KCL at node a, we have

$$i_x + \beta i_x + i_1 = 0$$

or

$$i_x = -\frac{i_1}{1+\beta}$$

Hence,

$$\begin{aligned} v_{th} &= v_1 - R_1 i_x \\ &= v_1 + \frac{R_1}{1+\beta} i_1 \end{aligned}$$

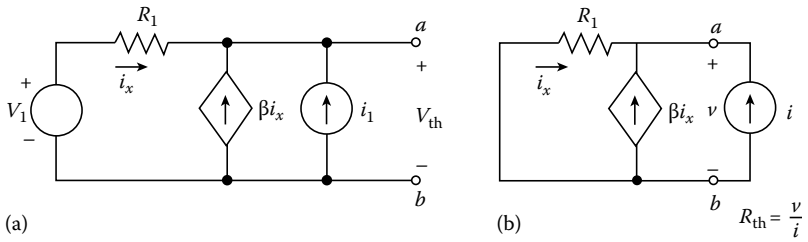

FIGURE 19.68 Calculation of (a) V_{th} and (b) R_{th} for the circuit of Figure 19.60 (Example 19.4).

As for R_{th}, we need to consider the circuit shown in Figure 19.68b, in which the two independent sources were deactivated. Because of the presence of the dependent source βi_x, we determine R_{th} by exciting the circuit with an external source. Let us use a current source i for this purpose and determine the voltage v across it as shown in Figure 19.68b. We stress that i is an arbitrary and completely independent source and is in no way related to i_1, which was deactivated. Applying KCL at node a, we have

$$i_x + \beta i_x + i = 0$$

or

$$i_x = -\frac{1}{1+\beta} i$$

Also, applying Ohm's law to R_1,

$$v = -R_1 i_x$$

or

$$v = \frac{R_1}{1+\beta} i$$

Hence,

$$R_{th} = \frac{v}{i} = \frac{R_1}{1+\beta}$$

Note that v_{th} and R_{th} determined previously are the same as v_0 and R_0 of Equations 19.116 and 19.117.

19.2.3 Norton Theorem

Instead of a voltage source in series with a resistor, it is possible to replace a portion of a circuit by an equivalent current source in parallel with a resistor. This result is formally known as Norton's theorem and is stated as follows:

> Any portion of linear circuit between two terminals a and b can be replaced by an equivalent circuit consisting of a current source i_n in parallel with a resistor R_n. The current i_n is determined as the current that flows from a to b in a short circuit at terminals $a-b$. The resistor R_n is equal to the input resistance at terminals $a-b$ with all the independent sources deactivated.

As in the case of Thévenin's, the preceding theorem provides a procedure for determining the "Norton" current source and "Norton" resistance in the Norton equivalent circuit. The various steps in this procedure are illustrated in Figure 19.69. The Norton current is determined by solving for the current in a short circuit at terminals $a-b$ and the Norton resistance is determined by calculating the input resistance to the circuit at terminals $a-b$ when all independent sources have been deactivated. The Norton's equivalent of a portion of a circuit is, in effect, a nonideal current source representation of that portion. It should be noted that the procedure to determine R_n is exactly the same as that for R_{th}. In other words,

$$R_n = R_{th}$$

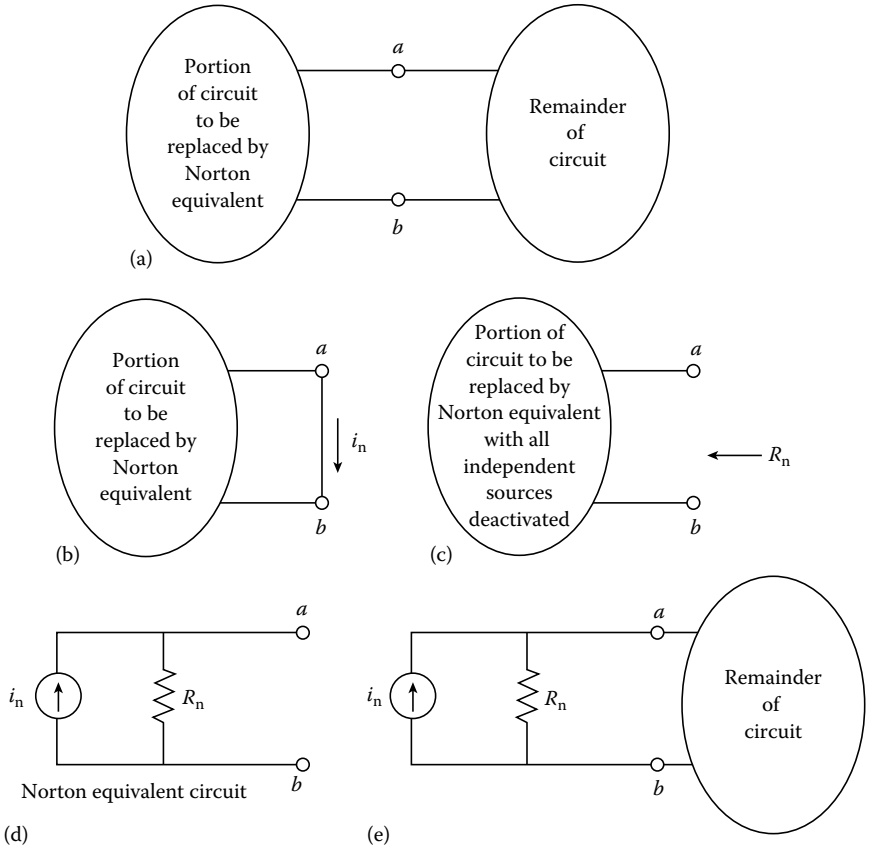

FIGURE 19.69 Steps in determining the Norton equivalent circuit.

Also, if we compare Thévenin's and Norton's equivalent circuits, we see that these are indeed related by the voltage–current source transformation rule discussed earlier in this chapter. Each circuit is a source transformation of the other. For this reason, the Thévenin and Norton equivalent circuits are often referred to as dual circuits, and the two resistance R_{th} and R_n are frequently referred to as the source resistance and denoted by R_s. Clearly, v_{th} and i_n are related by

$$v_{th} = R_s i_n$$

Example 19.5

For the circuit shown in Figure 19.70, determine the Norton equivalent circuit at terminals *a*–*b*.

We determine Norton's current I_n by placing a short circuit between *a* and *b*, as shown in Figure 19.71a, and solving for the current in it with a reference direction going from *a* to *b*. For this circuit, we could use the mesh equation method. In matrix form, the mesh equations are

$$\begin{bmatrix} 8 & -4 \\ -4 & 7 \end{bmatrix} \cdot \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} 10 \\ 5 \end{bmatrix}$$

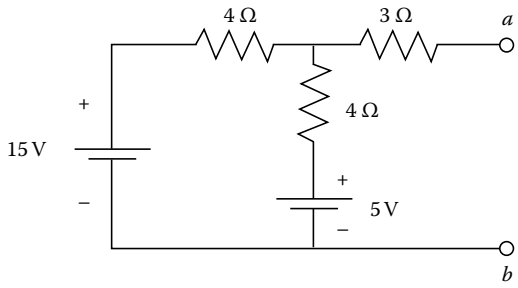

FIGURE 19.70 Circuit for Example 19.5.

and the solution for the mesh currents is

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \frac{1}{56-16}\begin{bmatrix} 7 & 4 \\ 4 & 8 \end{bmatrix} \cdot \begin{bmatrix} 10 \\ 5 \end{bmatrix}$$

From this, we extract I_n as

$$I_n = I_2 = \frac{40+40}{40} = 2 \text{ A}$$

Norton's resistance R_n is determined by deactivating the two voltage sources, as shown in Figure 19.71b, and calculating the input resistance at terminals $a-b$. Clearly,

$$R_n = (4 \parallel 4) + 3 = 5 \ \Omega$$

Thus, the Norton equivalent for the circuit of Figure 19.70 is shown in Figure 19.71c.

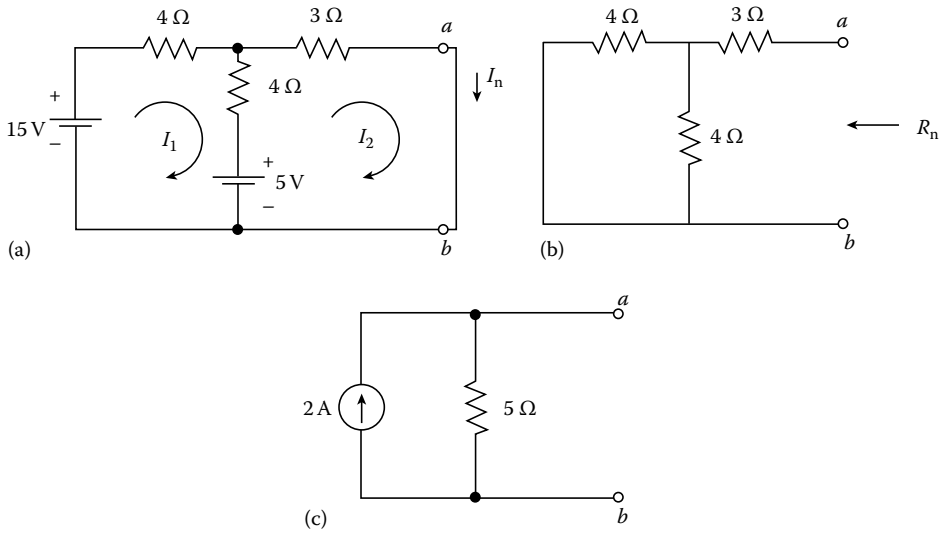

FIGURE 19.71 (a) Calculation of I_n, (b) calculation of R_n and (c) Norton's equivalent for the circuit of Example 19.5.

Example 19.6

For the circuit shown in Figure 19.72 determine the Norton equivalent circuit at terminals *a*–*b* and use it to calculate the current and power dissipated in *R*.

With a short circuit placed at terminals *a*–*b*, as shown in Figure 19.73a, the voltage $V_x = 0$. Hence, the dependent source in this circuit is equal to zero. This means that the 8 A current source has the 9 and 3 Ω resistors in parallel across it, and I_n is the current in the 3 Ω resistor. Using the current divider rule we have

$$I_n = 8\frac{9}{12} = 6 \text{ A}$$

Now, deactivating the independent source to determine R_n, we excite the circuit with a voltage source V at terminals *a*–*b*. Let I be the current in this source as shown in Figure 19.73b. Applying KCL at node a yields the current in the 3 Ω resistor to be $I - (V/4)$ from right to left. Applying KVL around the outer loop and making use of the fact that in this circuit $V_x = V$, we get

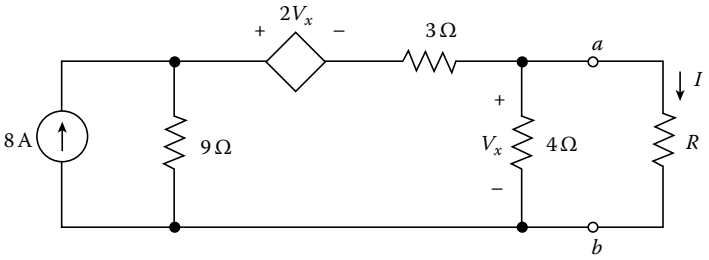

FIGURE 19.72 Circuit for Example 19.6.

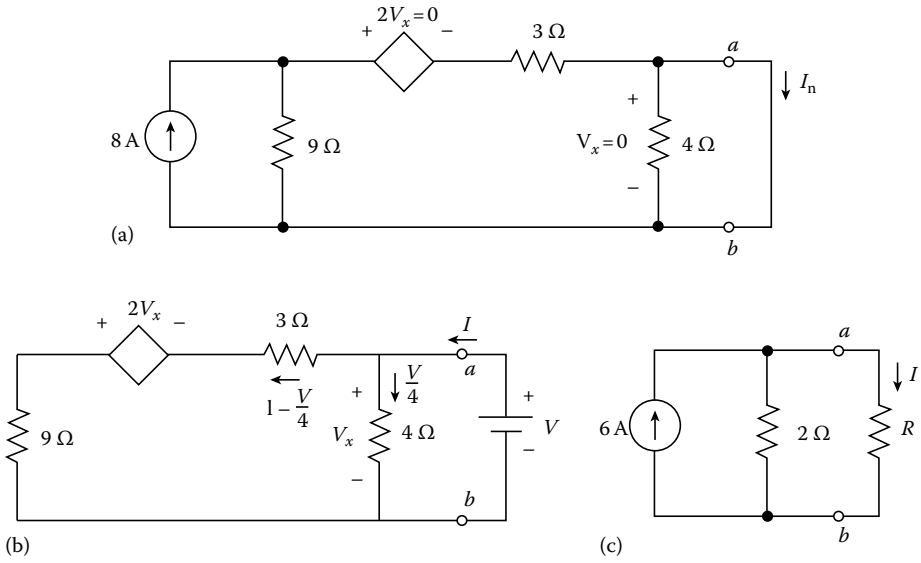

FIGURE 19.73 (a) Calculation of I_n, (b) calculation of R_n, and (c) Norton's equivalent for the circuit of Example 19.6.

$$V - 3\left(I - \frac{V}{4}\right) + 2V - 9\left(I - \frac{V}{4}\right) = 0$$

Solution of this equation yields

$$R_{\mathrm{n}} = \frac{V}{I} = 2\ \Omega$$

The Norton equivalent of the portion of the circuit to the left of terminals $a-b$, connected to the resistor R is shown in Figure 19.73c. Applying the current divider rule gives

$$\begin{aligned} I &= 6\frac{2}{2+R} \\ &= \frac{12}{2+R}\,\mathrm{A} \end{aligned}$$

and the power dissipated in R is

$$\begin{aligned} P &= RI^2 \\ P &= \frac{144R}{(2+R)^2}\,\mathrm{W} \end{aligned} \tag{19.119}$$

19.2.4 Maximum Power Transfer Theorem

In Example 19.6, we replaced the entire circuit connected to the resistor R at terminals $a-b$ by its Norton equivalent in order to calculate the power P dissipated in R. Because R did not have a fixed value, we determined an expression for P in terms of R. Suppose we are now interested in examining how P varies as a function of R. A plot of P versus R as given by Equation 19.119 is given in Figure 19.74.

The first noticeable characteristic of this plot is that it has a maximum. Naturally, we would be interested in the value of R that results in maximum power delivered to it. This information is directly available from the plot in Figure 19.74. To maximize P the value of R should be 2 Ω and the maximum power is $P_{\mathrm{max}} = 18$ W. That is, 18 W is the most that this circuit can deliver at terminals $a-b$, and that occurs when $R = 2\ \Omega$. Any other value of R will result in less power delivered to it.

The problem of finding the value of a load resistor R_{L} such that maximum power is delivered to it is obviously an important circuit design problem. Because it is possible to reduce any linear circuit connected to R_{L} into either its Thévenin or Norton equivalent, as illustrated in Figure 19.75, the problem becomes quite simple. We need to consider only either the circuit of Figure 19.75b or that of Figure 19.75c. Let us first consider the circuit that uses the Thévenin equivalent. In this case, the power P delivered to R_{L} is given by

$$P = \left(\frac{v_{\mathrm{th}}}{R_{\mathrm{th}} + R_{\mathrm{L}}}\right)^2 R_{\mathrm{L}} \tag{19.120}$$

In general, we may not always be able to plot P vs. R_{L}, as we did earlier, therefore, we need to maximize P mathematically. We do this by solving the necessary condition

$$\frac{\mathrm{d}P}{\mathrm{d}R_{\mathrm{L}}} = 0 \tag{19.121}$$

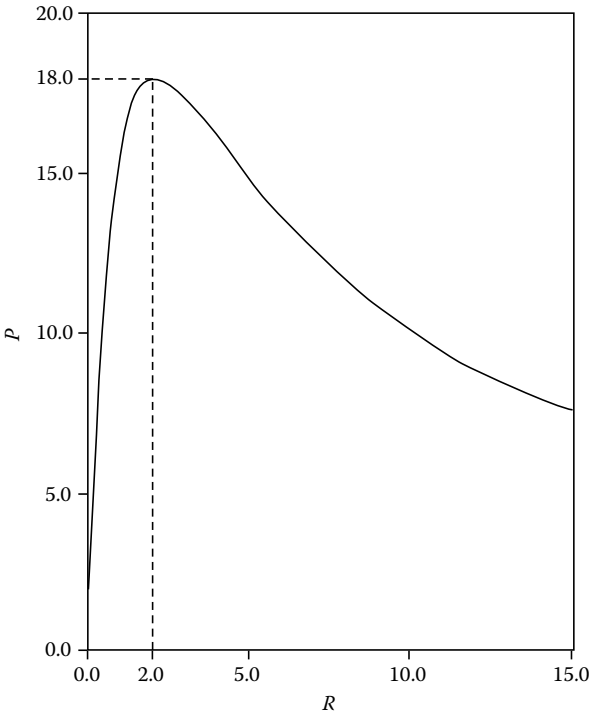

FIGURE 19.74 Plot of P vs. R for the circuit of Example 19.6.

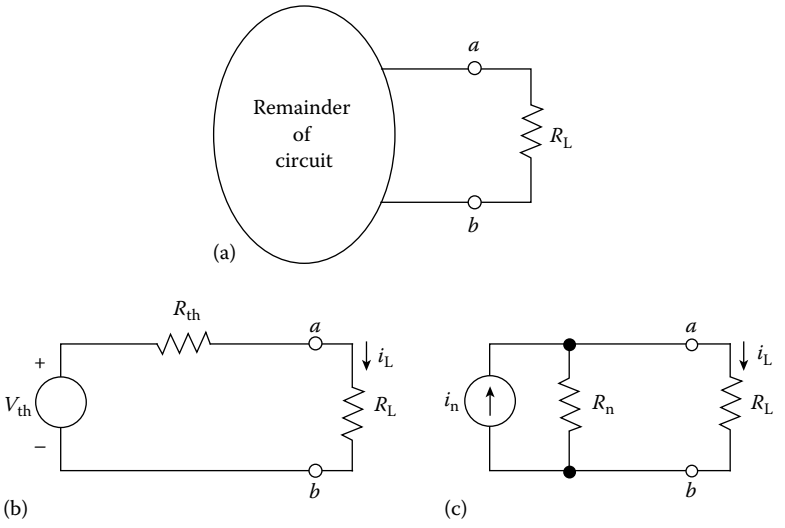

FIGURE 19.75 (a) A load resistance R_L in a circuit. (b) R_L with the remainder of the circuit reduced to a Thévenin equivalent. (c) R_L with the remainder of the circuit reduced to a Norton equivalent.

for R_L. To guarantee that R_L maximizes P, it must also satisfy the sufficiency condition

$$\left.\frac{d^2P}{dR_L^2}\right|_{R_L} < 0 \tag{19.122}$$

Thus, applying these conditions to Equation 19.120, we have

$$\begin{aligned}\frac{dP}{dR_L} &= v_{th}^2\left[\frac{(R_{th}+R_L)^2 - 2R_L(R_{th}+R_L)}{(R_{th}+R_L)^4}\right],\\ &= v_{th}^2\frac{(R_{th}-R_L)}{(R_{th}+R_L)^3}\end{aligned} \tag{19.123}$$

Equating the right-hand side of Equation 19.123 to zero and solving for R_L yields

$$R_L = R_{th}$$

The sufficiency condition (Equation 19.122) yields

$$\frac{d^2P}{dR_L^2} = v_{th}^2\frac{2R_{th}-4R_L}{(R_{th}+R_L)^4}$$

When R_L is replaced with R_{th}, we get

$$\left.\frac{d^2P}{dR_L^2}\right|_{R_L=R_{th}} = -\frac{v_{th}^2}{8R_{th}^3} < 0$$

Thus, $R_L = R_{th}$ satisfies both conditions (Equations 19.121 and 19.122), and hence is the maximizing value. This result is often referred to as the "maximum power transfer theorem." It says

> The maximum power that can be transferred to a load resistance R_L by a circuit represented by its Thévenin equivalent is attained when R_L is equal to R_{th}.

The corresponding value of P_{max} is obtained from Equation 19.120 as

$$P_{max} = \frac{v_{th}^2}{4R_{th}} \tag{19.124}$$

In the case of Norton's equivalent circuit of Figure 19.75b, a similar derivation can be carried out. The power P delivered to R_L is given by

$$P = \left(\frac{R_n i_n}{R_n + R_L}\right)^2 R_L \tag{19.125}$$

This expression has exactly the same form as Equation 19.120. Consequently, its maximum is achieved when

$$R_L = R_n$$

and the corresponding maximum power is

$$P_{\max} = \frac{R_n i_n^2}{4} \tag{19.126}$$

This leads to the following alternate statement of the maximum power transfer theorem:

> The maximum power that can be transferred to a load resistance R_L by a circuit represented by its Norton equivalent is attained when R_L is equal to R_n.

Example 19.7

Consider the circuit of Example 19.3 in Figure 19.66. Determine the value of a load resistor R_L connected in place of the 2 Ω resistor at terminals $a-b$ in order to achieve maximum power transfer to the load.

Solution

The Thévenin equivalent for the circuit of Figure 19.66 already was determined and is shown in Figure 19.67c. Using the results of the maximum power transfer theorem, we should have

$$R_L = 3\Omega$$

The corresponding value of maximum power is

$$P_{\max} = \frac{2^2}{4 \times 3} = \frac{1}{3}\text{W}$$

19.2.5 Reciprocity Theorem

The reciprocity theorem is an important result that applies to circuits consisting of linear resistors and one independent source (either a current source or a voltage source). It does not apply to nonlinear circuits, and, in general, it does not apply to circuits containing dependent sources. The reciprocity theorem is stated as follows:

The ratio of a voltage (or current) response in one part of the circuit to the current (or voltage) source is the same if the locations of the response and the source are interchanged.

It is important to note that the reciprocity theorem applies only to circuits in which the source and response are voltage and current or current and voltage, respectively. It does not apply to circuits in which the source and response are of the same type (i.e., voltage and voltage or current and current).

Example 19.8

Verify the reciprocity theorem for the circuit shown in Figure 19.76a.

Solution

If we interchange the location of the 40 V voltage source and current response I, we obtain the circuit shown in Figure 19.76b. The reciprocity theorem implies that I should be the same in both circuits.

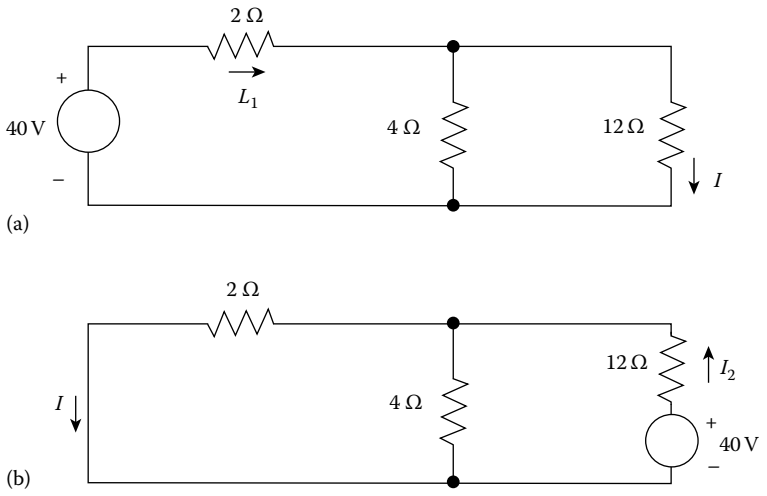

FIGURE 19.76 (a) Circuit for Example 19.8. (b) Circuit with location of voltage source and current response interchanged.

For the circuit in Figure 19.76a, the current I_1 in the 2 Ω resistor is equal to

$$\begin{aligned} I_1 &= \frac{40}{2 + 4 \parallel 12} \\ &= \frac{40}{2 + 3} \\ &= 8\,\text{A} \end{aligned}$$

and the response I can be easily determined, using the current divider rule, as

$$\begin{aligned} I &= 8 \times \frac{4}{4 + 12} \\ &= 2\,\text{A} \end{aligned}$$

For the circuit in Figure 19.76b, the current I_2 in the 12 Ω resistor is equal to

$$\begin{aligned} I_2 &= \frac{40}{12 + 2 \parallel 4} \\ &= \frac{40}{12 + \frac{4}{3}} \\ &= 3\,\text{A} \end{aligned}$$

and the response I can be determined easily, using the current divider rule, as

$$\begin{aligned} I &= 3 \times \frac{4}{2 + 4} \\ &= 2\,\text{A} \end{aligned}$$

Thus, the reciprocity theorem is satisfied.

20.1 Introduction

Frequently, it is useful to decompose a large circuit into subcircuits and to consider the subcircuits separately. Subcircuits are connected to other subcircuits using terminals or ports. Terminal and port representations of a subcircuit describe how that subcircuit will act when connected to other subcircuits [1,2]. Terminal and port representations do not provide the details of mesh or node equations because these details are not required to describe how a subcircuit interacts with other subcircuits.

In this chapter, terminal and port representations of circuits are described. Particular attention is given to the distinction between terminals and ports. Applications show the usefulness of terminal and port representations.

20.2 Terminal Representations

Figure 20.1 illustrates a subcircuit that can be connected to other subcircuits using terminals. The subcircuit is shown symbolically on the left and an example is shown on the right. Nodes *a*, *b*, *c*, and *d* are terminals and may be used to connect this circuit to other circuits. Node *e* is internal to the circuit and is not a terminal. The terminal voltages V_a, V_b, V_c, and V_d are node voltages with respect to an arbitrary reference node. The terminal currents I_a, I_b, I_c, and I_d describe currents that will exist when this subcircuit is connected to other subcircuits. Terminal representations show how the terminal voltages and currents are related. Several equivalent representations are possible, depending on which of the terminal currents and voltages are selected as independent variables.

A terminal representation of the example network in Figure 20.1 can be obtained by writing a node equation for the network. A simpler procedure is available for passive networks, i.e., networks consisting entirely of resistors, capacitors, and inductors. Because the circuit in Figure 20.1 is a passive circuit, the simpler procedure will be used to write terminal equations to represent this circuit.

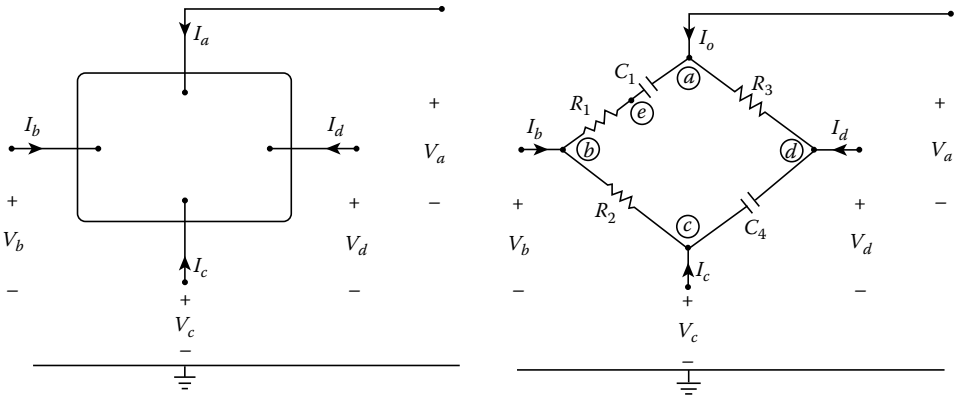

FIGURE 20.1 Four-terminal network.

The nodal admittance matrix of the example circuit will have five rows and five columns. The rows, and also the columns, of this matrix will correspond to the five nodes of the circuit in the order *a*, *b*, *c*, *d*, and *e*. For example, the fourth row of the nodal admittance matrix corresponds to node *d* and the third column corresponds to node *c*. Let y_{ij} denote the admittance of a branch of the network which is incident with nodes *i* and *j* and let Y_{ij} denote the element of the nodal admittance matrix that is in row *i* and column *j*. Then,

$$Y_{ii} = \sum_{\substack{\text{all branches} \\ \text{incident to node } i}} y_{ij} \tag{20.1}$$

i.e., the diagonal element of the nodal admittance matrix in row *i* and column *i* is equal to the sum of the admittances of all branches in the circuit that are incident with node *i*. The off-diagonal elements of the nodal admittance matrix are given by

$$Y_{ij} = -\sum_{\substack{\text{all branches incident} \\ \text{to both nodes } i \text{ and } j}} y_{ij} \tag{20.2}$$

The example circuit is represented by the node equation

$$\begin{pmatrix} I_a \\ I_b \\ I_c \\ I_d \\ 0 \end{pmatrix} = \begin{pmatrix} C_1 s + \dfrac{1}{R_3} & 0 & 0 & -\dfrac{1}{R_3} & -C_1 s \\ 0 & \dfrac{1}{R_1} + \dfrac{1}{R_2} & -\dfrac{1}{R_2} & 0 & -\dfrac{1}{R_1} \\ 0 & -\dfrac{1}{R_2} & C_4 s + \dfrac{1}{R_2} & -C_4 s & 0 \\ -\dfrac{1}{R_3} & 0 & -C_4 s & C_4 s + \dfrac{1}{R_3} & 0 \\ -C_1 s & -\dfrac{1}{R_1} & 0 & 0 & C_1 s + \dfrac{1}{R_1} \end{pmatrix} \begin{pmatrix} V_a \\ V_b \\ V_c \\ V_d \\ V_e \end{pmatrix} \tag{20.3}$$

Suppose that $C_1 = 1$ F, $C_4 = 2$ F, $R_1 = 1/2\ \Omega$, $R_2 = 1/4\ \Omega$, and $R_3 = 1\ \Omega$. Then,

$$\begin{pmatrix} I_a \\ I_b \\ I_c \\ I_d \\ 0 \end{pmatrix} = \begin{pmatrix} s+1 & 0 & 0 & -1 & -1s \\ 0 & 6 & -4 & 0 & -2 \\ 0 & -4 & 2s+4 & -2s & 0 \\ -1 & 0 & -2s & 2s+1 & 0 \\ -s & -2 & 0 & 0 & s+2 \end{pmatrix} \begin{pmatrix} V_a \\ V_b \\ V_c \\ V_d \\ V_e \end{pmatrix}$$

No external current I_e exists because node e is not a terminal. Row 5 of this equation, corresponding to node e, can be solved for V_e and then V_e can be eliminated. Doing so results in

$$\begin{pmatrix} I_a \\ I_b \\ I_c \\ I_d \end{pmatrix} = \begin{pmatrix} \dfrac{3s+2}{s+2} & -\dfrac{2s}{s+2} & 0 & -1 \\ -\dfrac{2s}{s+2} & \dfrac{6s+8}{s+2} & -4 & 0 \\ 0 & -4 & 2s+4 & -2s \\ -1 & 0 & -2s & 2s+1 \end{pmatrix} \begin{pmatrix} V_a \\ V_b \\ V_c \\ V_d \end{pmatrix} \tag{20.4}$$

The terminal voltages were selected to be the independent variables and the entries in the matrix are admittances. Because none of the nodes of the subcircuit was chosen to be the reference node, the rows and columns of the matrix both sum to zero. This matrix is called an indefinite admittance matrix. Because it is singular, Equation 20.4 cannot be solved directly. To see the utility of Equation 20.4, consider Figure 20.2. Here, the four-terminal network has been connected to a voltage source and an amplifier and node c has been grounded. This external circuitry restricts the terminal currents and voltages of the four-terminal network. In particular,

$$V_b = V_s, \quad I_a = 0, \quad V_c = 0, \quad I_d = 0, \quad \text{and} \quad V_o = KV_d \tag{20.5}$$

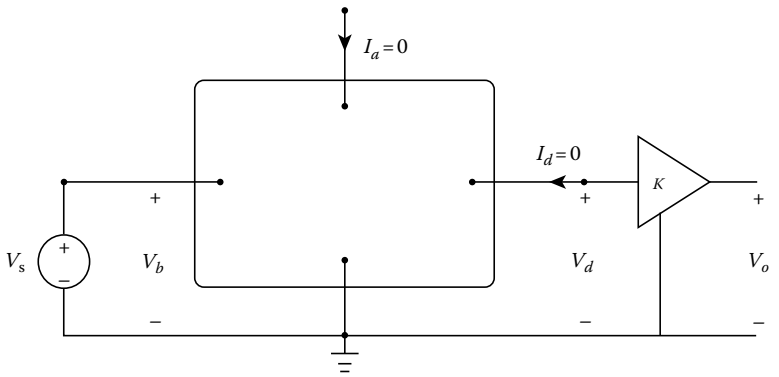

FIGURE 20.2 First application of the four-terminal network.

Under these conditions, Equation 20.4 becomes

$$\begin{pmatrix} 0 \\ I_b \\ I_c \\ 0 \end{pmatrix} = \begin{pmatrix} \frac{3s+2}{s+2} & -\frac{2s}{s+2} & 0 & -1 \\ -\frac{2s}{s+2} & \frac{6s+8}{s+2} & -4 & 0 \\ 0 & -4 & 2s+4 & -2s \\ -1 & 0 & -2s & 2s+1 \end{pmatrix} \begin{pmatrix} V_a \\ V_s \\ 0 \\ \frac{V_o}{K} \end{pmatrix} \tag{20.6}$$

Because I_b and I_c are not of interest, the second and third rows of this equation can be ignored. The first and fourth rows can be solved to obtain the transfer function of this circuit

$$\frac{V_o(s)}{V_s(s)} = \frac{K}{3(s+1)} \tag{20.7}$$

Next, consider Figure 20.3. The four-terminal network is used in a second, different application. In this case,

$$I_a + I_b = -\frac{V_b}{R_b}, \quad V_c = V_s, \quad V_a = V_b, \quad I_d = 0, \quad \text{and} \quad V_d = V_o \tag{20.8}$$

Because $V_a = V_b$, the first two columns of Equation 20.4 can be added together, replacing V_a by V_b. Also, it is convenient to add the first two rows together to obtain $I_a + I_b$. Then, Equation 20.4 reduces to

$$\begin{pmatrix} -\frac{V_b}{R_b} \\ I_c \\ 0 \end{pmatrix} = \begin{pmatrix} 5 & -4 & -1 \\ -4 & 2s+4 & -2s \\ -1 & -2s & 2s+1 \end{pmatrix} \begin{pmatrix} V_b \\ V_s \\ V_o \end{pmatrix} \tag{20.9}$$

Because I_c is not of interest, the second row of this equation can be ignored. The first and third rows of this equation can be solved to obtain the transfer function

$$\frac{V_o(s)}{V_s(s)} = \frac{(10R_b + 2)s + 4R_b}{(10R_b + 2)s + 4R_b + 1} \tag{20.10}$$

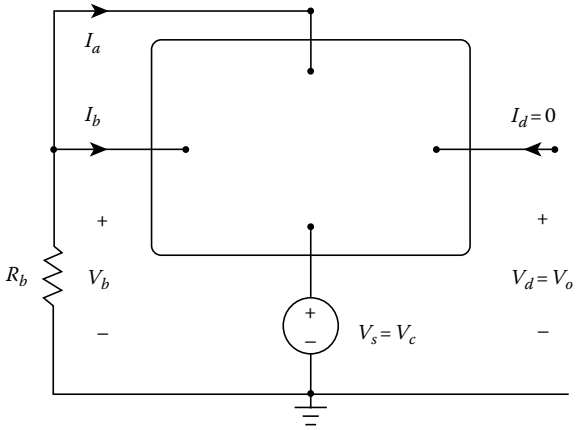

FIGURE 20.3 Second application of the four-terminal network.

These examples illustrate the utility of the terminal equations. In these examples, the problem of analyzing a network was divided into two parts. First, the terminal equation was obtained from the node equation by eliminating the rows and columns corresponding to nodes that are not terminals. Second, the terminal equation is combined with equations describing the external circuitry connected to the four-terminal network. When the external circuit is changed, only the second step must be redone. The advantage of representing a subnetwork by terminal equations is greater when

1. The subnetwork has many nodes that are not terminals.
2. The subnetwork is expected to be a component of many different networks.

20.3 Port Representations

A port consists of two terminals with the restriction that the terminal currents have the same magnitude but opposite sign. Figure 20.4 shows a two-port network. In this case, the two-port network was constructed from the four-terminal network by pairing terminals a and b to form port 1 and pairing terminals d and c to form port 2. The restrictions

$$I_1 = I_a = -I_b \quad \text{and} \quad I_2 = I_d = -I_c \tag{20.11}$$

must be satisfied in order for these two pairs of terminals to be ports.

The behavior of the two-port network is described using four variables. These variables are the port voltages V_1 and V_2 and the port currents I_1 and I_2. Several equivalent representations are possible, depending on which two of the port currents and voltages are selected as independent variables. The left column of Table 20.1 shows the two-port representations corresponding to four of the possible choices of independent variables. These representations are equivalent, and the right column of Table 20.1 shows how one representation can be obtained from another.

In row 1 of Table 20.1, the port voltages are selected to be the independent variables. In this case, the two-port circuit is represented by an equation of the form

$$\begin{pmatrix} I_1 \\ I_2 \end{pmatrix} = \begin{pmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \end{pmatrix} \tag{20.12}$$

The elements of the matrix in this equation have units of admittance. They are denoted using the letter y to suggest admittance and are called the "y parameters" or the "admittance parameters" of the two-port network.

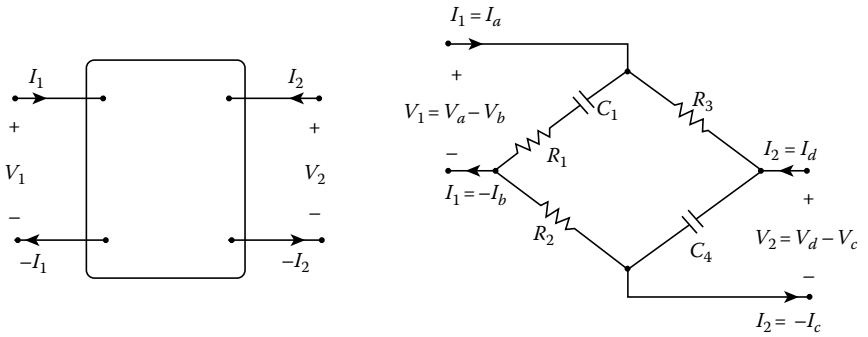

FIGURE 20.4 Two-port network.

TABLE 20.1 Relationships between Two-Port Representations

$\begin{pmatrix} I_1 \\ I_2 \end{pmatrix} = \begin{pmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \end{pmatrix}$ $\lvert Y \rvert = y_{11}y_{22} - y_{12}y_{21}$	$\begin{pmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{pmatrix} = \begin{pmatrix} \frac{z_{22}}{\lvert Z \rvert} & -\frac{z_{12}}{\lvert Z \rvert} \\ -\frac{z_{21}}{\lvert Z \rvert} & \frac{z_{11}}{\lvert Z \rvert} \end{pmatrix} = \begin{pmatrix} \frac{1}{h_{11}} & -\frac{h_{12}}{h_{11}} \\ \frac{h_{21}}{h_{11}} & \frac{\lvert H \rvert}{h_{11}} \end{pmatrix} = \begin{pmatrix} \frac{D}{B} & -\frac{\lvert T \rvert}{B} \\ -\frac{1}{B} & \frac{A}{B} \end{pmatrix}$
$\begin{pmatrix} V_1 \\ V_2 \end{pmatrix} = \begin{pmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{pmatrix} \begin{pmatrix} I_1 \\ I_2 \end{pmatrix}$ $\lvert Z \rvert = z_{11}z_{22} - z_{12}z_{21}$	$\begin{pmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{pmatrix} = \begin{pmatrix} \frac{y_{22}}{\lvert Y \rvert} & -\frac{y_{12}}{\lvert Y \rvert} \\ -\frac{y_{21}}{\lvert Y \rvert} & \frac{y_{11}}{\lvert Y \rvert} \end{pmatrix} = \begin{pmatrix} \frac{\lvert H \rvert}{h_{22}} & \frac{h_{12}}{h_{22}} \\ -\frac{h_{21}}{h_{22}} & \frac{1}{h_{22}} \end{pmatrix} = \begin{pmatrix} \frac{A}{C} & -\frac{\lvert T \rvert}{C} \\ \frac{1}{C} & \frac{D}{C} \end{pmatrix}$
$\begin{pmatrix} V_1 \\ I_2 \end{pmatrix} = \begin{pmatrix} h_{11} & h_{12} \\ h_{21} & h_{22} \end{pmatrix} \begin{pmatrix} I_1 \\ V_2 \end{pmatrix}$ $\lvert H \rvert = h_{11}h_{22} - h_{12}h_{21}$	$\begin{pmatrix} h_{11} & h_{12} \\ h_{21} & h_{22} \end{pmatrix} = \begin{pmatrix} \frac{1}{y_{11}} & -\frac{y_{12}}{y_{11}} \\ \frac{y_{21}}{y_{11}} & \frac{\lvert Y \rvert}{y_{11}} \end{pmatrix} = \begin{pmatrix} \frac{\lvert Z \rvert}{z_{22}} & \frac{z_{12}}{z_{22}} \\ -\frac{z_{21}}{z_{22}} & \frac{1}{z_{22}} \end{pmatrix} = \begin{pmatrix} \frac{B}{D} & \frac{\lvert T \rvert}{D} \\ -\frac{1}{D} & \frac{C}{D} \end{pmatrix}$
$\begin{pmatrix} V_1 \\ I_1 \end{pmatrix} = \begin{pmatrix} A & B \\ C & D \end{pmatrix} \begin{pmatrix} V_2 \\ -I_2 \end{pmatrix}$ $\lvert T \rvert = AD - BC$	$\begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} -\frac{y_{22}}{y_{21}} & -\frac{1}{y_{21}} \\ -\frac{\lvert Y \rvert}{y_{21}} & -\frac{y_{11}}{y_{21}} \end{pmatrix} = \begin{pmatrix} \frac{z_{11}}{z_{21}} & \frac{\lvert Z \rvert}{z_{21}} \\ \frac{1}{z_{21}} & \frac{z_{22}}{z_{21}} \end{pmatrix} = \begin{pmatrix} -\frac{\lvert H \rvert}{h_{21}} & -\frac{h_{11}}{h_{21}} \\ -\frac{h_{22}}{h_{21}} & -\frac{1}{h_{21}} \end{pmatrix}$

In row 2 of Table 20.1, the port currents are selected to be the independent variables. Now the elements of the matrix have units of impedance. They are denoted using the letter z to suggest impedance and are called the "z parameters" or the "impedance parameters" of the two-port network.

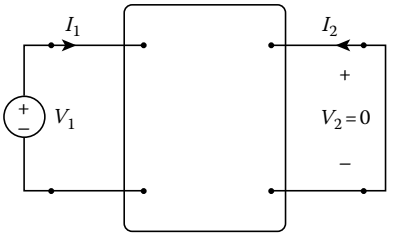
In row 3 of Table 20.1, I_1 and V_2 are the independent variables. The elements of the matrix do not have the same units. In this sense, this is a hybrid matrix. They are denoted using the letter h to suggest hybrid and are called the "h parameters" or the "hybrid parameters" of the two-port network. Hybrid parameters are frequently used to represent bipolar transistors.

In the last row of Table 20.1, the independent signals are V_2 and $-I_2$. In this case, the two-port parameters are called "transmission parameters" or "*ABCD* parameters." They are convenient when two-port networks are connected in cascade.

Next, consider the problem of calculating or measuring the parameters of a two-port circuit. Equation 20.12 suggests a procedure for calculating the y parameters of a two-port circuit. The first row of Equation 20.12 is

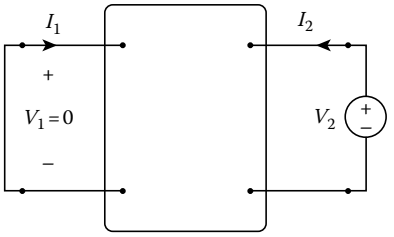
$$I_1 = y_{11}V_1 + y_{12}V_2 \tag{20.13}$$

Setting $V_1 = 0$ leads to



$$y_{12} = \frac{I_1}{V_2} \quad \text{when} \quad V_1 = 0 \tag{20.14}$$

This equation describes a procedure that can be used to measure or calculate y_{12}. A short circuit is connected to port 1 to set $V_1 = 0$. A voltage source having voltage V_2 is connected across port 2 and the current, I_1, in the short circuit is calculated. Finally, y_{12} is calculated as the ratio of I_1 to V_2.



Similar procedures can be used to calculate any of the y, z, h, or transmission parameters. Table 20.2 tabulates these procedures.

As an example of how Table 20.2 can be used, consider calculating the y parameters of the two-port circuit shown in Figure 20.3. (Recall that $C_1 = 1$ F, $C_4 = 2$ F, $R_1 = 1/2\ \Omega$, $R_2 = 1/4\ \Omega$, and $R_3 = 1\ \Omega$.) According to Table 20.2, two cases will have to be considered. In the first, a voltage source is connected

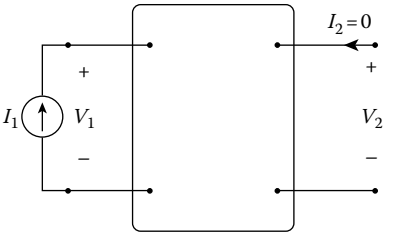


TABLE 20.2 Calculation of Two-Port Parameters

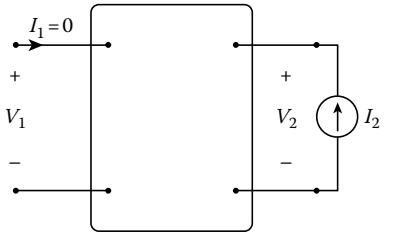
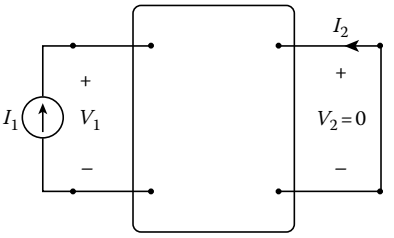
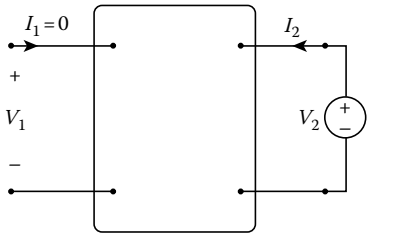


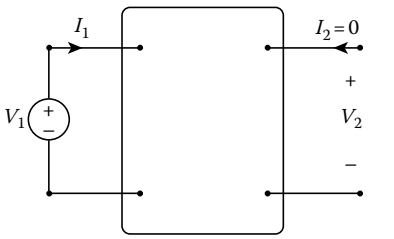
$y_{11} = \frac{I_1}{V_1}$ and $y_{21} = \frac{I_2}{V_1}$ when $V_2 = 0$



$y_{12} = \frac{I_1}{V_2}$ and $y_{22} = \frac{I_2}{V_2}$ when $V_1 = 0$

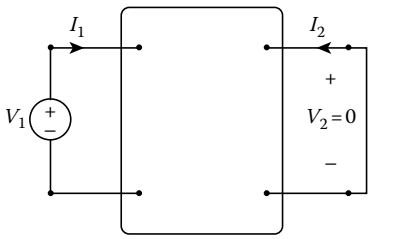


$z_{11} = \frac{V_1}{I_1}$ and $z_{21} = \frac{V_2}{I_1}$ when $I_2 = 0$



$z_{12} = \frac{V_1}{I_2}$ and $y_{22} = \frac{V_2}{I_1}$ when $I_1 = 0$

$h_{11} = \frac{V_1}{I_1}$ and $h_{21} = \frac{I_2}{I_1}$ when $V_2 = 0$



$h_{12} = \frac{V_1}{V_2}$ and $h_{22} = \frac{I_2}{V_2}$ when $I_1 = 0$

$A = \frac{V_1}{V_2}$ when $I_2 = 0$

$C = \frac{I_1}{V_2}$ when $I_2 = 0$

$B = \frac{V_1}{-I_2}$ when $V_2 = 0$

$D = \frac{I_1}{-I_2}$ when $V_2 = 0$

to port 1 and a short circuit is connected to port 2. In the second, a short circuit is connected across port 1 and a voltage source is connected to port 2. The resulting circuits are shown in Figure 20.5. In Figure 20.5a

$$I_1 = \frac{V_1}{R_1 + \frac{1}{C_1 s}} + \frac{V_1}{R_2 + R_3} = \frac{14s + 8}{5s + 10} V_1 = y_{11} V_1 \tag{20.15}$$

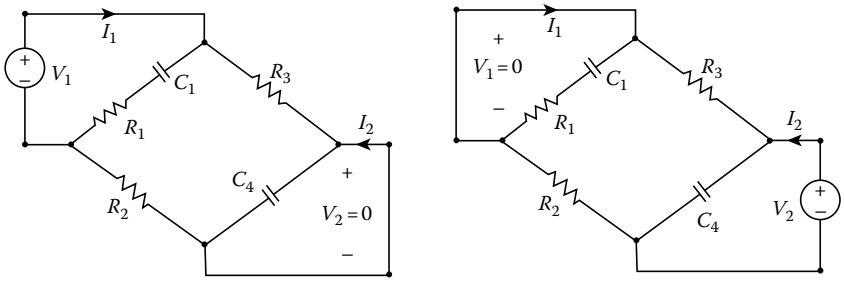


FIGURE 20.5 Test circuits used to calculate the *y* parameters of the example circuit.

and

$$I_2 = -\frac{V_1}{R_2 + R_3} = -\frac{4}{5}V_1 = y_{21}V_1 \tag{20.16}$$

In Figure 20.5b

$$I_1 = -\frac{V_2}{R_2 + R_3} = -\frac{4}{5}V_2 = y_{12}V_2 \tag{20.17}$$

and

$$I_2 = \frac{V_2}{\frac{1}{C_4 s}} + \frac{V_2}{R_2 + R_3} = \frac{10s + 4}{5}V_2 = y_{22}V_2 \tag{20.18}$$

Finally, the two-port network is represented by

$$\begin{pmatrix} I_1 \\ I_2 \end{pmatrix} = \begin{pmatrix} \dfrac{14s + 8}{5s + 10} & -\frac{4}{5} \\ -\frac{4}{5} & \dfrac{10s + 4}{5} \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \end{pmatrix} \tag{20.19}$$

To continue the example, row 3 of Table 20.1 illustrates how to convert these admittance parameters to hybrid parameters. From Table 20.1,

$$|Y| = \frac{14s + 8}{5s + 10}\left[\frac{10s + 4}{5}\right] - \left(-\frac{4}{5}\right)\left(-\frac{4}{5}\right) = \frac{28s^2 + 24s}{5(s + 2)} \tag{20.20}$$

$$h_{11} = \frac{1}{y_{11}} = \frac{5s + 10}{14s + 8} \tag{20.21}$$

$$h_{12} = -\frac{y_{12}}{y_{11}} = \frac{2s + 4}{7s + 4} \tag{20.22}$$

$$h_{21} = \frac{y_{21}}{y_{11}} = -\frac{2s + 4}{7s + 4} \tag{20.23}$$

$$h_{22} = \frac{|Y|}{y_{11}} = \frac{(14s + 12)s}{7s + 4} \tag{20.24}$$

To complete the example, notice that Table 20.2 shows how to calculate the hybrid parameters directly from the circuit. According to Table 20.2, h_{22} is calculated by connecting an open circuit across port 1 and a voltage source having voltage V_2 across port 2. The resulting circuit is depicted in Figure 20.6. Now, h_{22} is determined from Figure 20.6b by calculating the port current I_2.

$$I_2 = \frac{V_2}{R_1 + R_2 + R_3 + \frac{1}{C_1 s}} + \frac{V_2}{\frac{1}{C_4 s}} = \frac{14s^2 + 12s}{7s + 4} V_2 = h_{22} V_2 \tag{20.25}$$

Of course, this is the same expression as was calculated earlier from the y parameters of the circuit.

Next, consider the problem of analyzing a circuit consisting of a two-port network and some external circuitry. Figure 20.7 depicts such a circuit. The currents in the resistors R_s and R_L are given by

$$I_1 = \frac{V_s - V_1}{R_s} \quad \text{and} \quad I_2 = -\frac{V_2}{R_L} \tag{20.26}$$

Suppose the two-port network used in Figure 20.7 is the circuit shown in Figure 20.4 and represented by y parameters in Equation 20.19. Combining the previous expressions for I_1 and I_2 with Equation 20.19 yields

$$\begin{pmatrix} \frac{V_s}{R_s} \\ 0 \end{pmatrix} = \begin{pmatrix} \frac{14s+8}{5s+10} + \frac{1}{R_s} & -\frac{4}{5} \\ -\frac{4}{5} & \frac{10s+4}{5} + \frac{1}{R_L} \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \end{pmatrix} \tag{20.27}$$

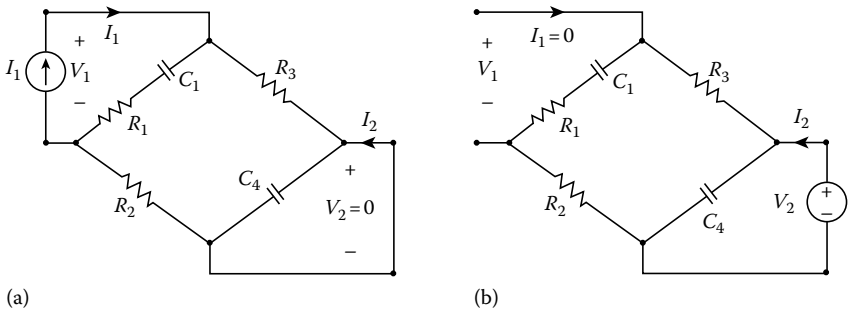

FIGURE 20.6 Test circuits used to calculate the h parameters of the example circuit.

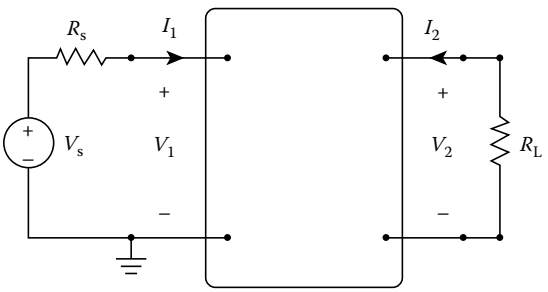

FIGURE 20.7 Application of the two-port network.

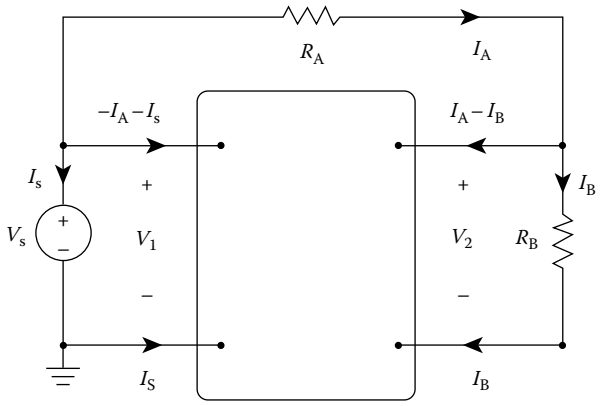

FIGURE 20.8 Incorrect application of the two-port representation.

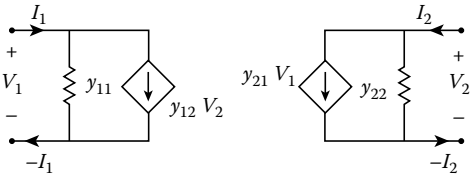

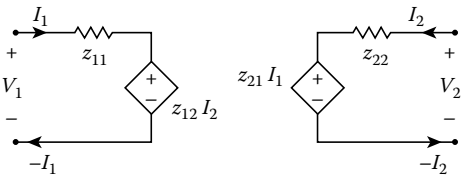

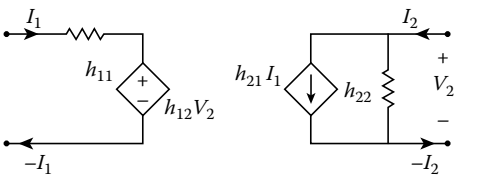

This equation can then be solved, e.g., using Cramer's rule, for the transfer function

$$\frac{V_2}{V_s}(s) = \frac{-\left(-\frac{4}{5}\right)\left(\frac{1}{R_s}\right)}{\left(\frac{14s+8}{5s+10} + \frac{1}{R_s}\right)\left(\frac{10s+4}{5} + \frac{1}{R_L}\right) - \left(-\frac{4}{5}\right)^2} = \frac{4(s+2)R_L}{(28s^2+24s)R_L R_s + (10s+4)(s+2)R_L + (14s+8)R_s + 5(s+2)} \tag{20.28}$$

Next consider Figure 20.8. This circuit illustrates a caution regarding use of the port convention. The use of ports assumes that the currents in the terminals comprising a port are equal in magnitude and opposite in sign. This assumption is not satisfied in Figure 20.8 so port equations cannot be used to represent the four-terminal network.

Table 20.3 presents three circuit models for two-port networks. These three models are based on *y*, *z*, and *h* parameters, respectively. Such models are useful when analyzing circuits that contain subcircuits

TABLE 20.3 Models of Two-Port Networks

$\begin{pmatrix} I_1 \\ I_2 \end{pmatrix} = \begin{pmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \end{pmatrix}$	
$\begin{pmatrix} V_1 \\ V_2 \end{pmatrix} = \begin{pmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{pmatrix} \begin{pmatrix} I_1 \\ I_2 \end{pmatrix}$	
$\begin{pmatrix} V_1 \\ V_2 \end{pmatrix} = \begin{pmatrix} h_{11} & h_{12} \\ h_{21} & h_{22} \end{pmatrix} \begin{pmatrix} I_1 \\ I_2 \end{pmatrix}$	

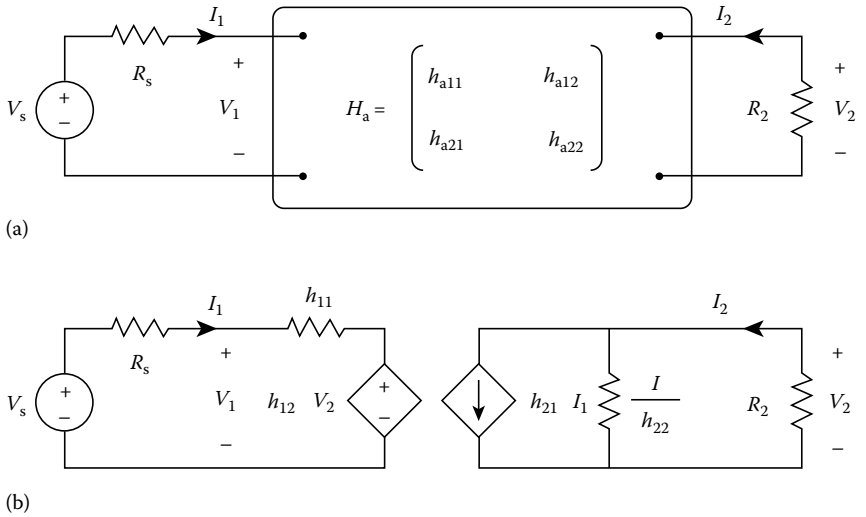

FIGURE 20.9 Application of the circuit model associated with *H* parameters.

that are represented by port parameters. As an example, consider the circuit shown in Figure 20.9a. This circuit contains a two-port network represented by *h* parameters. In Figure 20.9b the two-port network has been replaced by the model corresponding to *h* parameters. Analysis of Figure 20.9b yields

$$\begin{aligned} V_s &= (R_s + h_{11})I_1 + h_{12}V_2 \\ V_2 &= h_{21}\frac{-R_2}{R_2h_{22}+1}I_1 \end{aligned} \tag{20.29}$$

After some algebra,

$$\frac{V_2}{V_s} = \frac{h_{21}R_2}{h_{12}h_{21}R_2 - (h_{11}+R_2)(h_{22}R_2+1)} \tag{20.30}$$

The circuits in Figure 20.9a and b are equivalent, so this is the voltage gain of the circuit in Figure 20.9a.

H parameters are frequently used to describe bipolar transistors. Table 20.4 shows the popular methods for converting this three terminal device into a two-port network. The three configurations shown in Table 20.4 are called "common emitter," "common collector," and "common base" to indicate which terminal is common to both ports. Table 20.4 also presents the notation that is commonly used to name the *h* parameters when they are used to represent a transistor.

For example, h_{fe} is the forward gain when the transistor is connected in the common emitter configuration. Comparing with Table 20.3, it can be observed that $h_{fe} = h_{21}$.

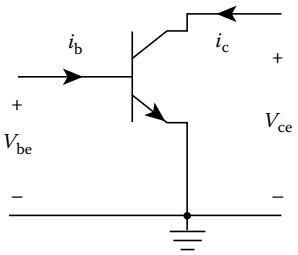

Figure 20.10 depicts a popular model of a bipolar transistor. Suppose the *h* parameters are calculated for the common emitter configuration. The result is

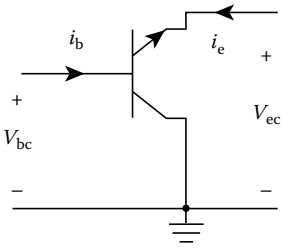
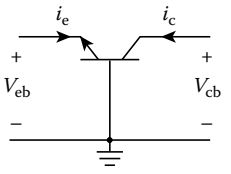
$$\begin{pmatrix} h_{ie} & h_{re} \\ h_{fe} & h_{oe} \end{pmatrix} = \begin{pmatrix} r_\pi & 0 \\ \beta & r_0 \end{pmatrix} \tag{20.31}$$

This calculation makes a connection between the parameters of the circuit model of the transistor and the *h* parameters used to describe the transistor, e.g., $h_{fe} = \beta$.



Figures 20.11 through 20.13 illustrate some common interconnections of two-port networks. In Figure 20.11, the two-port networks labeled A and B are connected in cascade. As illustrated in Figure 20.11, the

TABLE 20.4 Using *H* Parameters to Specify Bipolar Transistors



Common emitter

$$\begin{pmatrix} v_{be} \\ i_c \end{pmatrix} = \begin{pmatrix} h_{ie} & h_{re} \\ h_{fe} & h_{oe} \end{pmatrix} \begin{pmatrix} i_b \\ v_{ce} \end{pmatrix}$$

Common collector

$$\begin{pmatrix} v_{bc} \\ i_e \end{pmatrix} = \begin{pmatrix} h_{ic} & h_{rc} \\ h_{fc} & h_{oc} \end{pmatrix} \begin{pmatrix} i_b \\ v_{ec} \end{pmatrix}$$

Common base

$$\begin{pmatrix} v_{eb} \\ i_c \end{pmatrix} = \begin{pmatrix} h_{ib} & h_{rc} \\ h_{fb} & h_{oc} \end{pmatrix} \begin{pmatrix} i_b \\ v_{cb} \end{pmatrix}$$

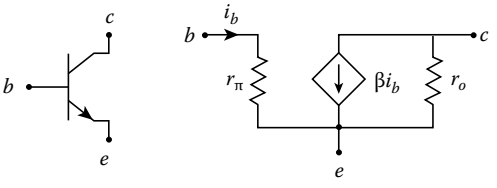
Note: i, input impedance or admittance; o, output impedance or admittance; f, forward gain; r, reverse gain; e, common emitter; b, common base; c, common collector.

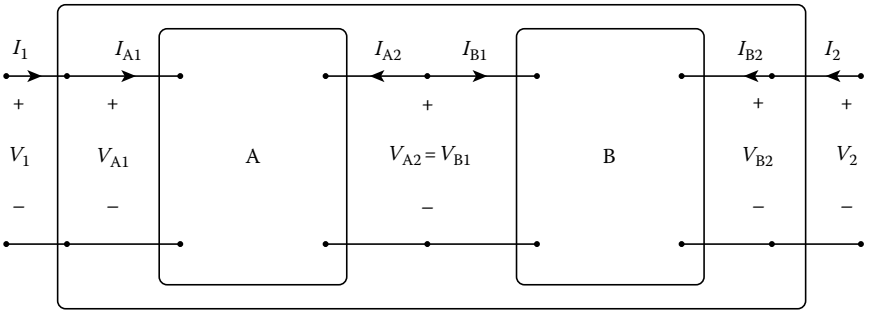
transmission matrix of the composite network is given by the product of the transmission matrices of the subnetworks. This simple relationship makes it convenient to use transmission parameters to represent a composite network that consists of the cascade of two subnetworks.

In Figure 20.12, the two-port networks labeled A and B are connected in parallel. As shown in Figure 20.12, the admittance matrix of the composite network is given by the sum of the admittance matrices of the subnetworks. This simple relationship makes it convenient to use admittance parameters to represent a composite network that consists of parallel subnetworks.

In Figure 20.13, the two-port networks labeled A and B are connected in series. As illustrated in Figure 20.13, the impedance matrix of the composite network is given by the sum of the impedance matrices of the subnetworks. This simple relationship makes it convenient to use impedance parameters to represent a composite network that consists of series subnetworks.

Figure 20.14 is a circuit that consists of three two-port networks. Two-port parameters representing the entire network can be calculated from the two-port parameters of the subnetworks. Let *c* denote the two-port network consisting of network *b* connected in parallel with network *a*. Represent network *c* with *y* parameters by converting the *h* parameters





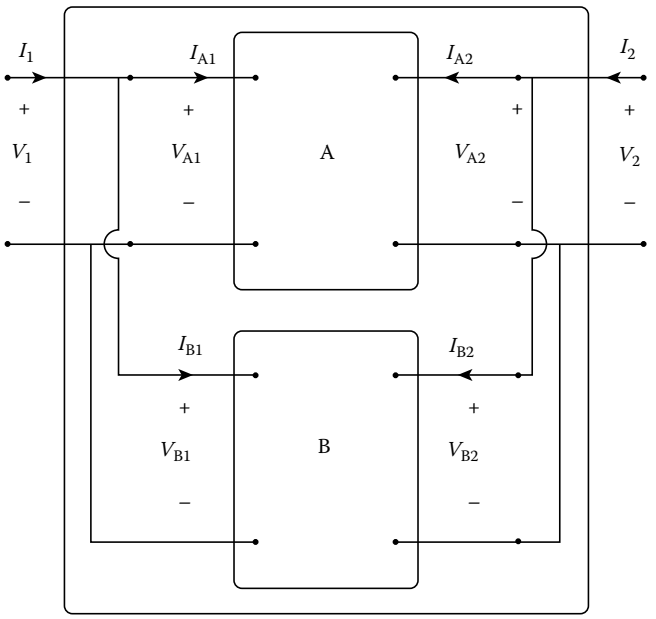


FIGURE 20.10 Hybrid pi model of a transistor.

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix} = \begin{pmatrix} A_a & B_a \\ C_a & D_a \end{pmatrix} \begin{pmatrix} A_b & B_b \\ C_b & D_b \end{pmatrix}$$

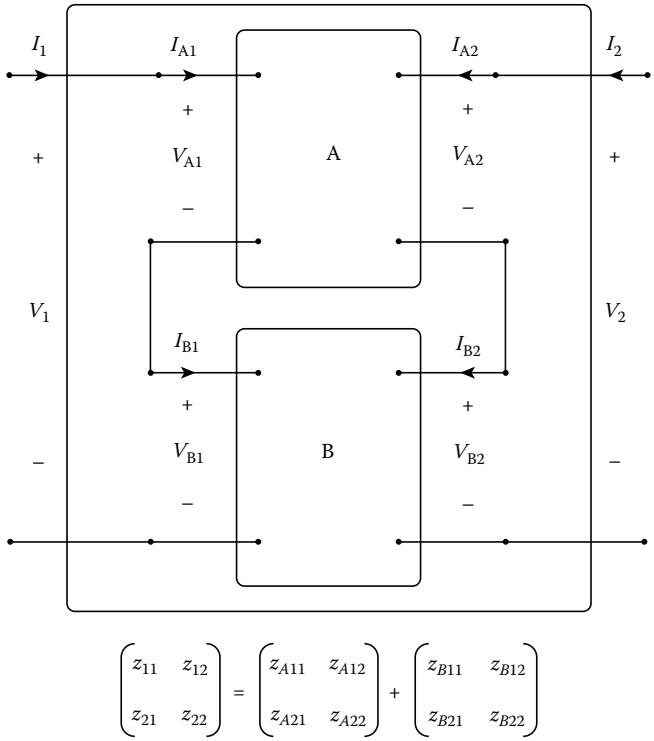

FIGURE 20.13 Series connection of two-port networks.

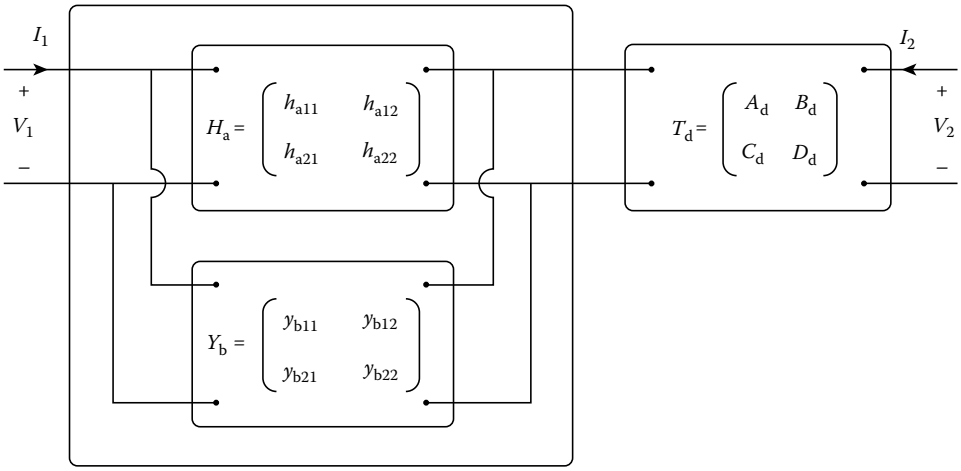

FIGURE 20.14 Circuit consisting of three two-port networks.

Next, network *c* is connected in cascade with network *d*. Represent network *d* with transmission parameters by converting the *y* parameters representing network *c* to transmission parameters and multiplying these transmissions parameters by the transmission parameters representing network *d*.

$$T = \begin{pmatrix} -\dfrac{y_{c22}}{y_{c21}} & -\dfrac{1}{y_{c21}} \\ -\dfrac{|Y_c|}{y_{c21}} & -\dfrac{y_{c11}}{y_{c21}} \end{pmatrix} \begin{pmatrix} A_d & B_d \\ C_d & D_d \end{pmatrix} \triangleq \begin{pmatrix} A & B \\ C & D \end{pmatrix} \tag{20.33}$$

Finally, the circuit in Figure 20.14 is represented by

$$\begin{pmatrix} V_1 \\ I_1 \end{pmatrix} = \begin{pmatrix} A & B \\ C & D \end{pmatrix} \begin{pmatrix} V_2 \\ -I_2 \end{pmatrix} \tag{20.34}$$

20.4 Port Representations and Feedback Systems

Port representations of networks can be used to decompose a network into subnetworks. In this section, the decomposition will be done in such a way as to establish a connection between the network and a feedback system represented by the block diagram shown in Figure 20.15. Having established this connection, the theory of feedback systems can be applied to the network. Here, the problem of determining the relative stability of the network will be considered.

The theory of feedback systems [4] can be used to determine relative stability such as the one shown in Figure 20.15. The transfer function of this system is

$$T(\omega) = D(\omega) + \frac{C_1(\omega)A(\omega)C_2(\omega)}{1 + A(\omega)\beta(\omega)} \tag{20.35}$$

The phase and gain margins are parameters of a system that are used to measure relative stability. These parameters can be calculated from $A(\omega)$ and $\beta(\omega)$. To calculate the phase margin, first identify ω_m as the frequency at which

$$\begin{aligned} |A(\omega_m)||\beta(\omega_m)| = 1 &\Rightarrow |A(\omega_m)| = \frac{1}{|\beta(\omega_m)|} \\ &\Rightarrow 20\log_{10}|A(\omega_m)| = -20\log_{10}|\beta(\omega_m)| \end{aligned} \tag{20.36}$$

The phase margin is then given by

$$\begin{aligned} \phi_m &= 180^\circ + \angle(A(\omega_m)\,\beta(\omega_m)) \\ &= 180^\circ + (\angle A(\omega_m) + \angle\beta(\omega_m)) \end{aligned} \tag{20.37}$$

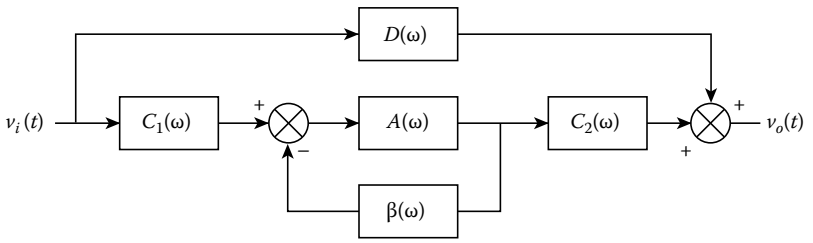

FIGURE 20.15 Feedback system.

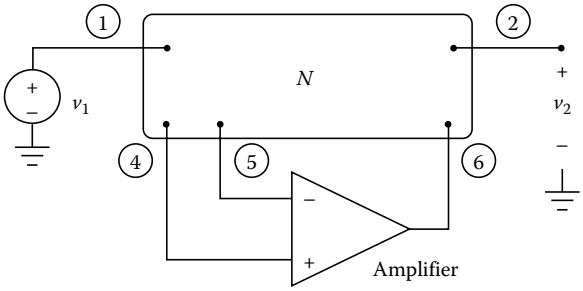

FIGURE 20.16 Identifying the network *N*.

The gain margin is calculated similarly. First, identify ω_p as the frequency at which

$$180^\circ = \angle\big(A(\omega_p)\beta(\omega_p)\big) \tag{20.38}$$

The gain margin is given by

$$\text{GM} = \frac{1}{|A(\omega_p)||\beta(\omega_p)|} \tag{20.39}$$

Next, consider an active circuit which can be represented as shown in Figure 20.16. For convenience, it is assumed that the input and output of the circuit are both node voltages. An amplifier has been selected and separated from the rest of the circuit. The rest of the circuit has been denoted as *N*.

Suppose that the amplifier is a voltage-controlled voltage source (VCVS), e.g., an inverting or a noninverting amplifier or an op-amp. Replacing the VCVS by a simple model yields the circuit shown in Figure 20.17. (The VCVS model accounts for input and output resistance and frequency-dependent gain.) Figure 20.17 shows how to identify the network *N*β which consists of the network *N* from Figure 20.16 together with the input and output resistances of the VCVS. The network *N*β has been called the "Beta Network" [5].

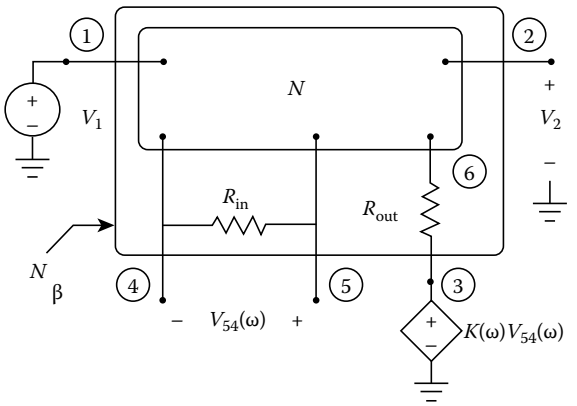

FIGURE 20.17 Identifying the Beta Network, *N*β.

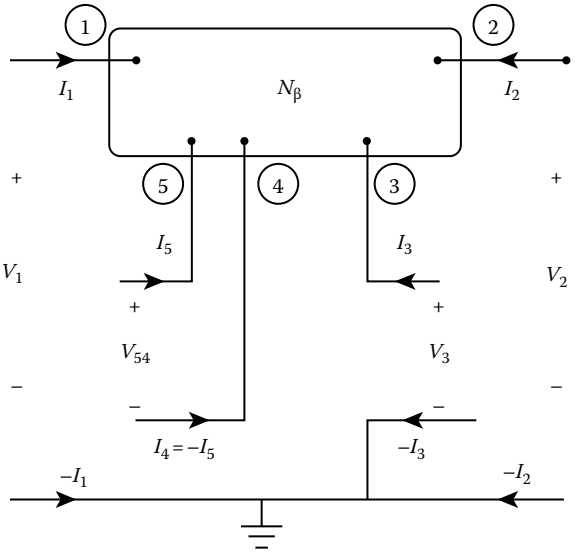

FIGURE 20.18 Identifying the ports of the Beta Network.

Figure 20.18 illustrates a way of grouping the terminals of the five-terminal network $N\beta$ to obtain a four-port network. This four-port network can be represented by the hybrid equation

$$\begin{pmatrix} I_1 \\ V_2 \\ I_3 \\ V_{54} \end{pmatrix} = \begin{pmatrix} H_{11} & H_{12} & H_{13} & H_{14} \\ H_{21} & H_{22} & H_{23} & H_{24} \\ H_{31} & H_{32} & H_{33} & H_{34} \\ H_{41} & H_{42} & H_{43} & H_{44} \end{pmatrix} \begin{pmatrix} V_1 \\ I_2 \\ V_3 \\ I_5 \end{pmatrix} \tag{20.40}$$

Because I_1 and I_3 are not of interest, the first and third rows of this equation can be set aside. Then setting I_2 and I_5 equal to zero yields

$$\begin{pmatrix} V_2 \\ V_{54} \end{pmatrix} = \begin{pmatrix} H_{21} & H_{23} \\ H_{41} & H_{43} \end{pmatrix} \begin{pmatrix} V_1 \\ V_3 \end{pmatrix} \tag{20.41}$$

where, for example,

$$H_{43}(\omega) = \frac{V_{54}(\omega)}{V_3(\omega)} \quad \text{when} \quad V_1(\omega) = 0 \tag{20.42}$$

and $H_{21}(\omega)$, $H_{23}(\omega)$, and $H_{41}(\omega)$ are defined similarly.

The amplifier model requires that

$$V_3(\omega) = K(\omega)V_{54}(\omega) \tag{20.43}$$

Combining these equations yields

$$T(\omega) = \frac{V_2(\omega)}{V_1(\omega)} = H_{21}(\omega) + \frac{K(\omega)H_{23}(\omega)H_{41}(\omega)}{1 - K(\omega)H_{43}(\omega)} \tag{20.44}$$

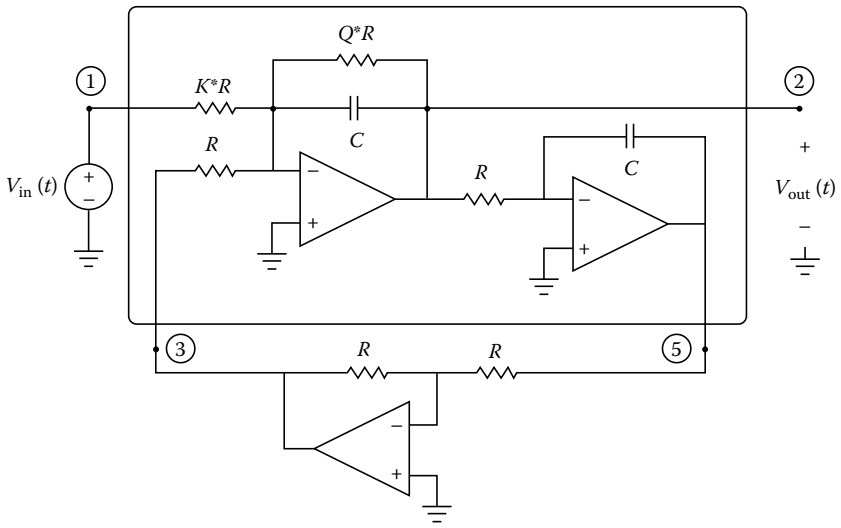

FIGURE 20.19 Tow–Thomas biquad.

Comparing this equation with the transfer function of the feedback system yields

$$\begin{aligned} A(\omega) &= -K(\omega) \\ \beta(\omega) &= H_{43}(\omega) \\ C_1(\omega) &= H_{23}(\omega) \\ C_2(\omega) &= H_{41}(\omega) \\ D(\omega) &= H_{21}(\omega) \end{aligned} \tag{20.45}$$

These equations establish a correspondence between the feedback system in Figure 20.15 and the active circuit in Figure 20.16. This correspondence can be used to identify $A(s)$ and $\beta(s)$ corresponding to a particular circuit. Once $A(s)$ and $\beta(s)$ are known, the phase or gain margin can be calculated.

Figure 20.19 shows a Tow–Thomas bandpass biquad [3]. When the op-amps are ideal devices the transfer function of this circuit is

$$T(s) = \frac{V_{in}(s)}{V_{out}(s)} = \frac{-\frac{1}{KRC}s}{s^2 + \frac{s}{QRC} + \frac{1}{R^2C^2}} \tag{20.46}$$

Figure 20.20 illustrates circuits that can be used to identify $A(s)$ and $\beta(s)$.

$$\begin{aligned} A(s) &= -1 \\ \beta(s) &= \frac{Q}{QR^2C^2s^2 + RCs} \end{aligned} \tag{20.47}$$

Next,

$$1 = |A(\omega_m)||\beta(\omega_m)| \Rightarrow (RC\omega_m)^2 = \frac{\frac{1}{Q^2} \pm \sqrt{\frac{1}{Q^4} + 4}}{2} \tag{20.48}$$

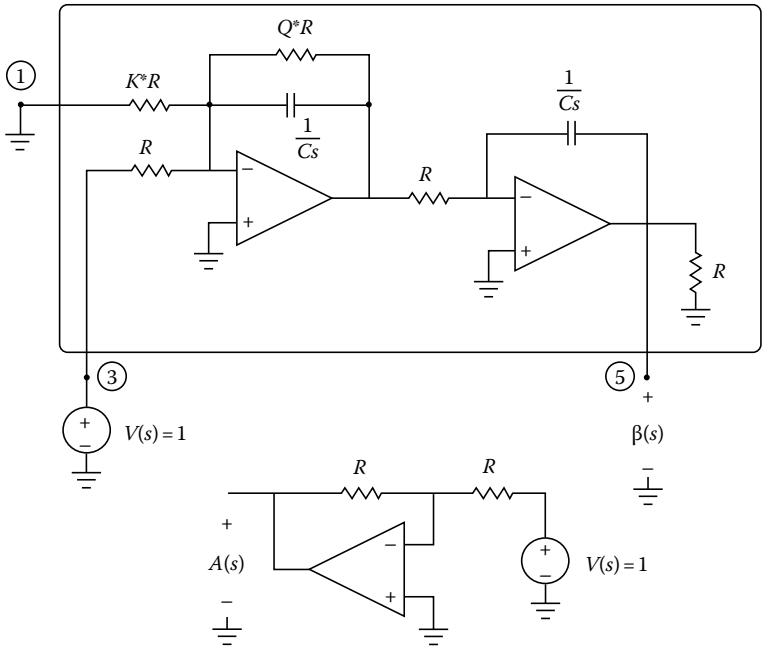

FIGURE 20.20 Calculating $A(s)$ and $\beta(s)$ for the Tow–Thomas biquad.

The phase margin is given by

$$\begin{aligned}\phi_m &= 180^\circ + \angle A(\omega_m) + \angle\beta(\omega_m)\\ &= 180^\circ + 180^\circ - \tan^{-1}\frac{-1}{QRC\omega_m}\\ &= \tan^{-1}\frac{1}{QRC\omega_m}\end{aligned} \tag{20.49}$$

When Q is large,

$$\omega_m \approx \frac{1}{RC} \Rightarrow \phi_m \approx \tan^{-1}\frac{1}{Q} \tag{20.50}$$

When the op-amps are not ideal, it is not practical to calculate the phase margin by hand. With computer-aided analysis, accurate amplifier models, such as macromodels, can easily be incorporated into this analysis [5].

20.5 Conclusions

It is frequently useful to decompose a large circuit into subcircuits. These subcircuits are connected together at ports and terminals. Port and terminal parameters describe how the subcircuits interact with other subcircuits but do not describe the inner workings of the subcircuit itself.

This chapter has presented procedures for determining port and terminal parameters and for analyzing networks consisting of subcircuits which are represented by port or terminal parameters. Port equations were used to establish a connection between electronic circuits and feedback systems.

21.1 Formulation of Signal Flow Graphs for Linear Networks

Any lumped network obeys three basic laws: Kirchhoff's voltage law (KVL), Kirchhoff's current law (KCL), and the elements' laws (branch characteristics). For filter applications, we write the frequency-domain instead of the time-domain network equations. Three general methods for writing network equations are described in Chapter 19. They are the node equations, loop equations, and hybrid equations. This section outlines another method, the signal flow graph (SFG) method of characterizing a linear network. The basic definitions of terms and theorems related to SFGs are presented in Section 8.4. The concepts of tree, cotree, loop, and cutset, required for the present discussion, are introduced in Chapter 7. Note that the terms loop, tree, and cotree refer to directed circuit, spanning tree, and cospanning tree defined in Chapter 7.

Consider first the construction of SFGs for linear networks without controlled sources. For all practical networks, the independent voltage sources (E) contain no loops, and the independent current sources (J) contain no cutsets. Under these conditions, it is always possible to select a tree T, such that all voltage sources are included in the tree and all current sources are included in the cotree. The network branches are divided into four sets (each set may be empty) indicated by subscripts as follows:

E: independent voltage sources
J: independent current sources
Z: passive branches in the tree, characterized by impedances
Y: passive branches in the cotree, characterized by admittances

A step-by-step procedure for constructing an SFG is given below.

Procedure 1 (for linear networks without controlled sources)

Step 1: Apply KVL to express each V_Y (voltage of a passive branch in the cotree) in terms of V_E and V_Z.

Step 2: Apply KCL to express each I_Z (current of a passive branch in the tree) in terms of I_J and I_Y.

Step 3: For each passive tree branch, consider its voltage as the product of impedance and current, i.e., $V_Z = Z_Z I_Z$.

Step 4: For each passive cotree branch, consider its current as the product of admittance and voltage, i.e., $I_Y = Y_Y V_Y$.

Example 21.1

Construct a SFG for the low-pass filter network shown in Figure 21.1a, and use Mason's formula to find the voltage gain function $H(s) = V_o(s)/V_i(s)$.

Solution

The graph associated with the network is shown in Figure 21.1b in which the branch numbers and reference directions (passive sign convention) have been assigned. The complexity of the SFG depends on the choice of the tree. In the case of a ladder network, a good tree to use is a star tree which has all tree branches connected to a common node. For the present network, we choose the tree to be $T = \{1, 2, 3, 4\}$, shown in heavy lines in Figure 21.1b.

Step 1 yields: $V_5 = V_i - V_2$, $V_6 = V_2 - V_3$, $V_7 = V_3 - V_4$

Step 2 yields: $I_2 = I_5 - I_6$, $I_3 = I_6 - I_7$, $I_4 = I_7$

$$V_2 = \frac{1}{0.31s} I_2$$

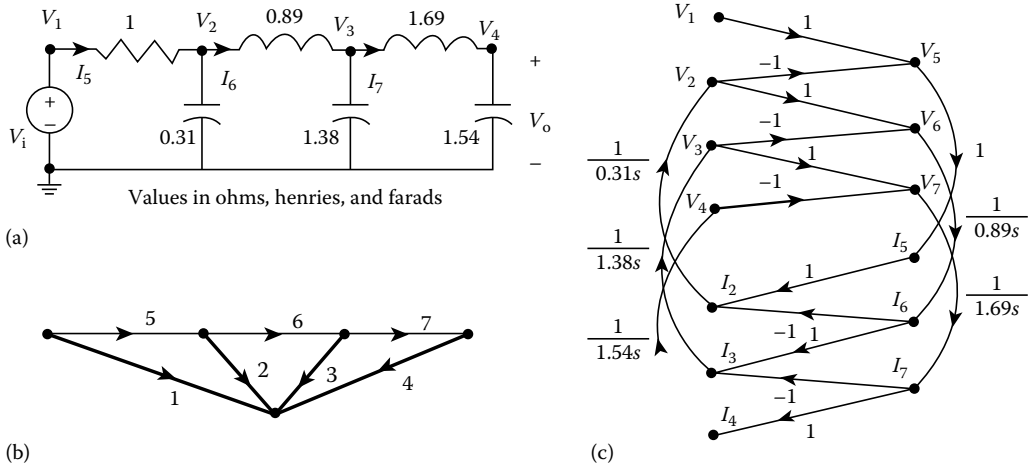

FIGURE 21.1 (a) A low-pass filter network. (b) Directed graph for the network and a chosen tree. (c) SFG based on the chosen tree.

$$\textbf{Step 3 yields: } V_3 = \frac{1}{1.38s} I_3$$
$$V_4 = \frac{1}{1.54s} I_4$$
$$I_5 = V_5$$
$$\textbf{Step 4 yields: } I_6 = \frac{1}{0.89s} V_6$$
$$I_7 = \frac{1}{1.69s} V_7$$

The SFG of Figure 21.1c displays all the preceding relationships.

Applying Mason's gain formula to the SFG of Figure 21.1c, we find

$$H(s) = \frac{V_o}{V_i} = \frac{V_4}{V_1} = \frac{1}{s^5 + 3.24s^4 + 5.24s^3 + 5.24s^2 + 3.24s + 1}$$

Next, consider linear networks containing controlled sources. All four types of controlled sources may be present. Our strategy is to utilize procedure 1 described previously with some preanalysis manipulations. The following is a step-by-step procedure.

Procedure 2 (for linear networks containing controlled sources)

Step 1: Temporarily replace each controlled voltage source by an independent voltage source, and each controlled current source by an independent current source, while retaining their original reference directions. The resultant network has no controlled sources.

Step 2: Construct the SFG for the network obtained in step 1 using procedure 1.

Step 3: Express the desired outputs and all controlling variables, if they are not present in the SFG, in terms of the quantities already present in the SFG.

Step 4: Reinstate the constraints of all controlled sources.

Example 21.2

Construct an SFG for the amplifier circuit depicted in Figure 21.2a.

Solution

We first replace the controlled voltage source μV_g by an independent voltage source V_x. A tree is chosen to be (V_s, R_a, V_x). The result of step 1 of procedure 2 is depicted in Figure 21.2b where dashed lines indicate cotree branches.

For the links R_b and R_c, we have $I_b = G_b V_b = G_b\ (V_s - V_a + V_x)$, and $I_c = G_c V_c = -G_c V_x$. For the tree branch R_a we have $V_a = R_a I_a = R_b I_b$. The result of step 2 of procedure 2 is depicted in Figure 21.2c. Note that the simple relationships $V_b = (V_s - V_a + V_x)$, $V_c = -V_x$ and $I_a = I_b$ have been used to eliminate the variables V_b, V_c and I_a. As a result, these variables do not appear in Figure 21.2c.

The desired output is $V_o = -V_x$ and the controlling voltage is $V_g = V_s - V_a$. After expressing these relationships in the SFG, step 3 of procedure 2 results in Figure 21.2d.

Finally, we reinstate the constraint of the controlled source, namely, $V_x = \mu V_g$. The result of step 4 of Procedure 21.2, in Figure 21.2e, is the desired SFG.

21.2 Synthesis of Active Filters Based on Signal Flow Graph Associated with a Passive Filter Circuit

The preceding section demonstrates that the equations governing a linear network can be described by an SFG in which the branch weights (or transmittances) are either real constants or simple expressions of the form K_s or K/s. All the cause–effect relationships displayed in such an SFG can, in turn, be

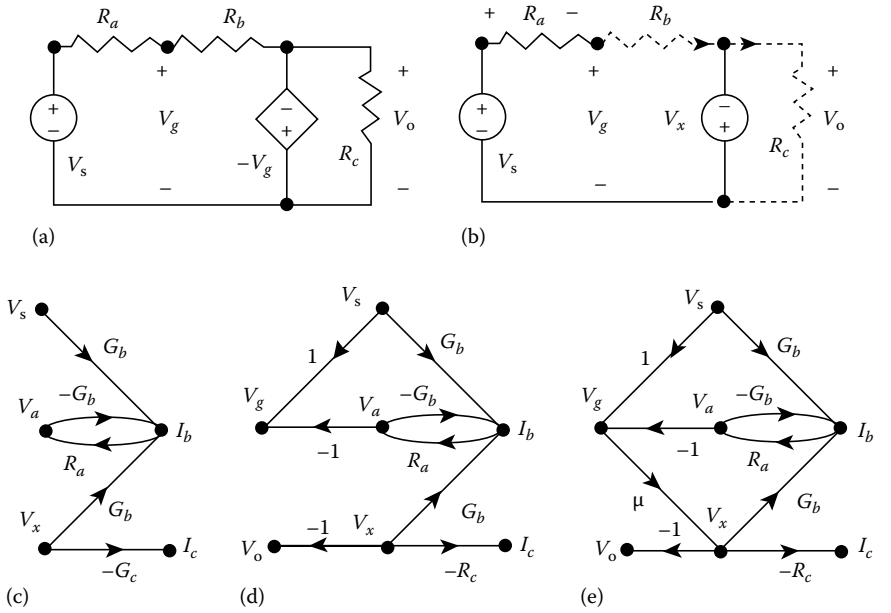

FIGURE 21.2 (a) A linear active network. (b) Result of step 1, Procedure 21.2. (c) Result of step 2, Procedure 21.2. (d) Result of step 3, Procedure 21.2. (e) The desired SFG.

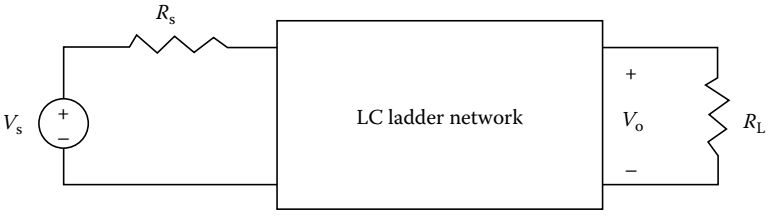

FIGURE 21.3 A doubly terminated passive filter.

implemented with resistors, capacitors, and ideal operational amplifiers. The inductors are not needed in the implementation. Whatever frequency response prevailing in the original linear circuit appears exactly in the RC-op-amp circuit.

In active filter synthesis, the method described in Section 21.1 is applied to a passive filter in the form of an *LC* (inductor–capacitor) ladder network terminated in a resistance at both ends as illustrated in Figure 21.3. The reason is that this type of filter, with $R_s = R_L$, has been proved to have the best sensitivity property [1, p. 196]. By this, we mean that the frequency response is least sensitive with respect to the changes in element values, when compared to other types of filter circuits. Because magnitude scaling (i.e., multiplying all impedances in the network by a factor K_m) does not affect the voltage gain function, we always normalize the prototype passive filter network so that the source resistance becomes 1 Ω. The advantage of this normalization will become evident in several examples given in this section.

The SFG illustrated in Figure 21.1c has many branches crossing each other. For a ladder network, with a proper choice of the tree and a rearrangement of the SFG nodes, all crossings can be eliminated. To achieve this, we first label a general ladder network as shown in Figure 21.4.

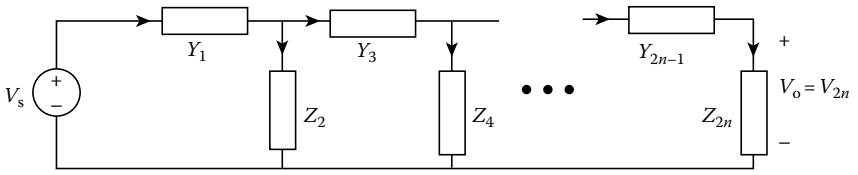

FIGURE 21.4 A general ladder network.

The following conventions are used in the labels of Figure 21.4:

1. All series branches are numbered odd and characterized by their admittances.
2. All shunt branches are numbered even and characterized by their impedances.
3. A single arrow is used to indicate the reference directions of both the voltage and the current of each network branch. Passive sign convention is used.
4. If the *LC* ladder in Figure 21.4 has a series element at the source end, then Y_1 represents that element in series with R_s.
5. If the *LC* ladder in Figure 21.4 has a shunt element at the load end, then Z_{2n} represents that element in parallel with R_L.

For constructing the SFG, choose a tree to consist of the voltage source and all shunt branches. The SFG for the circuit may be constructed using procedure 1 of Section 21.1. First, list the equations obtained in each step.

Step 1: $V_1 = V_s - V_2,\ V_3 = V_2 - V_4, \ldots,\ V_{2n-1} = V_{2n-2} - V_{2n}$
Step 2: $I_2 = I_1 - I_3,\ I_4 = I_3 - I_5, \ldots,\ I_{2n} = I_{2n-1}$
Step 3: $V_2 = Z_2 I_2,\ V_4 = Z_4 I_4, \ldots,\ V_{2n} = Z_{2n} I_{2n}$
Step 4: $I_1 = Y_1 V_1,\ I_3 = Y_3 V_3, \ldots,\ I_{2n-1} = Y_{2n-1} V_{2n-1}$

These relationships are represented by the SFG in Figure 21.5 for the case of a four-element ladder network. Note that the SFG graph nodes have been arranged in such a way that there are no branch crossings. The pattern displayed in this SFG suggests the children's game of "leapfrog." Consequently, an active filter synthesis based on the SFG of Figure 21.5 is called a leapfrog realization. The transmittance of each SFG branch indicates the type of mathematical operation performed. For example, $1/s$ means integration and is implemented by an op-amp integrator. Likewise, $1/(s+a)$ is implemented by a lossy op-amp integrator. It is well known that inverting integrators and inverting summers can be designed with singled-ended op-amps (i.e., the noninverting input terminal of each op-amp is grounded), [2–5]. Noninverting integrators and noninverting summers can also be designed, but require differential-input op-amps and more complex circuitry. Therefore, there is an advantage in using the inverting types. To this end, we multiply all Z's and Y's in Figure 21.5 by -1, with the result shown in Figure 21.6. Note that in Figure 21.6 we have removed the labels of internal SFG nodes because they are of no consequence in determining the transfer function. The transfer function V_o/V_s is the same for both Figures 21.5 and 21.6. This is quite obvious from Mason's gain formula, as all path weights and loop weights are not affected by

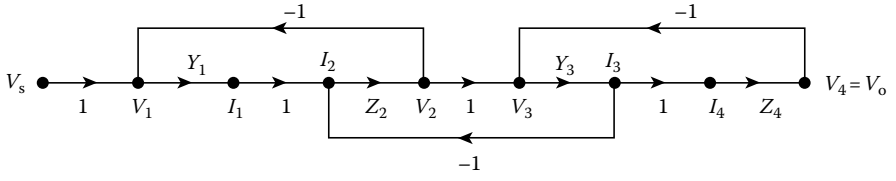

FIGURE 21.5 SFG for a four-element ladder network.

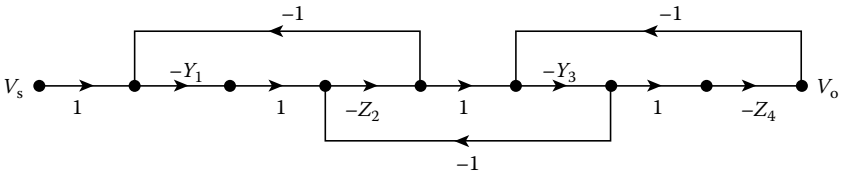

FIGURE 21.6 Inverting integrators are used in this modified SFG.

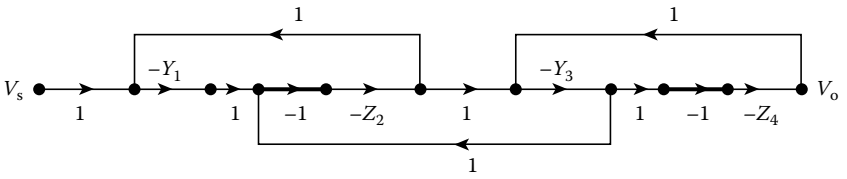

FIGURE 21.7 Modification to reduce the number of inverting amplifiers.

the modification. A branch transmittance of -1 indicates an inverting amplifier. In the interest of reducing the total number of op-amps used, we want to reduce the number of branches in the SFG that have weight -1. This can be achieved by inserting branches weighted -1 in some strategic places. Each insertion will lead to the change of the signs of one or two feedback branches. The rules are (a) inserting a branch weighted -1 in a forward path segment shared by two feedback loops changes the signs of the two feedback branch weights; (b) inserting a branch weighted -1 in a forward path segment belonging to one feedback loop only changes the signs of that feedback branch weight. Figure 21.6 is modified this way and the result is shown in Figure 21.7. The inserted branches are shown in heavy lines.

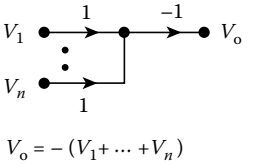
Comparing Figure 21.6 with Figure 21.7, we see that there is no change in path weights and loop weights. Therefore, Mason's gain formula assures that both SFG have the same transfer function. For a six-element ladder network, three branches weighted -1 must be inserted. This leads to a sign change of the single forward path weight in the SFG, and the output node variable now becomes $-V_o$. For filter applications this change of sign in the transfer function is acceptable as we are concerned mainly with the magnitude response.

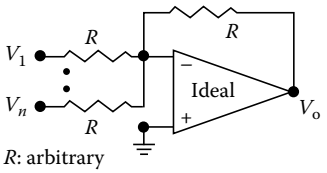
An implementation of the SFG of Figure 21.7 may be accomplished easily by referring to Table 21.1 and picking the component op-amp circuits for realizing the SFG transmittances -1, $-Y_1$, $-Z_2$, etc. Figure 21.7 dictates how these component op-amp circuits are interconnected to produce the desired voltage gain function. An example will illustrate the procedure.

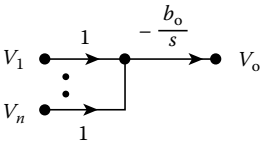
Example 21.3

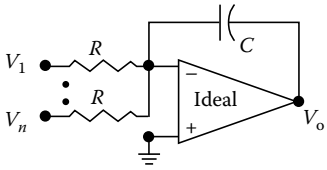
Figure 21.8 shows a normalized Butterworth fourth-order, low-pass filter, where the 1 Ω source resistance has been included in Y_1, and the 1 Ω load resistance included in Z_4.

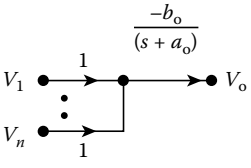
The leapfrog-type SFG for this circuit, after suitable modifications, is shown in Figure 21.7, where

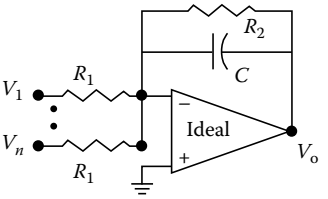












$$-Y_1 = -\frac{1}{0.7654s + 1}$$

$$-Z_2 = -\frac{1}{1.848s}$$

$$-Y_3 = -\frac{1}{1.848s}$$

$$-Z_4 = -\frac{1}{0.7654s + 1}$$

TABLE 21.1 Component Op-Amp Circuits for Synthesizing Active Low-Pass Filters by the Leapfrog Technique

(1)	 $V_o = -(V_1 + \cdots + V_n)$	Inverting summer  *R*: arbitrary
(2)	 $V_o = -\frac{b_o}{s}(V_1 + \cdots + V_n)$	Inverting summing integrator  *C*: arbitrary, $R = \frac{1}{b_o C}$
(3)	 $V_o = \frac{-b_o}{(s + a_o)}(V_1 + \cdots + V_n)$	Inverting summing lossy integrator  *C*: arbitrary, $R_1 = \frac{1}{b_o C}$, $R_2 = \frac{1}{a_o C}$

Note: Each component RC-op-amp circuit in the right column may be magnitude-scaled by an arbitrary factor.

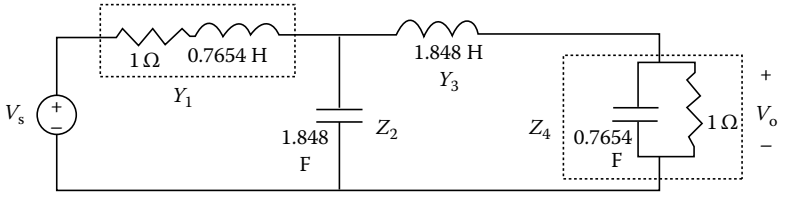


FIGURE 21.8 A fourth-order, Butterworth low-pass filter.

The SFG branch transmittance $-Z_2$ and $-Y_3$ are realized using item (2) of Table 21.1, while $-Y_1$ and $-Z_4$ use item (3). The two SFG branches with weight -1 in Figure 21.7 require item (1). The SFG branches with weight 1 merely indicate how to feed the inputs to each component network. No additional op-amps are needed for such SFG branches. Thus, a total of six op-amps are required. The interconnection of these component circuits is described by Figure 21.7. The complete circuit is shown in Figure 21.9. One-farad capacitances have been used in the circuit. Recall that the original passive low-pass filter has a 3 dB frequency of 1 rad/s. By suitable magnitude scaling and frequency scaling, all element values in the active filter of Figure 21.9 can be made practical. For example, if the 3 dB frequency

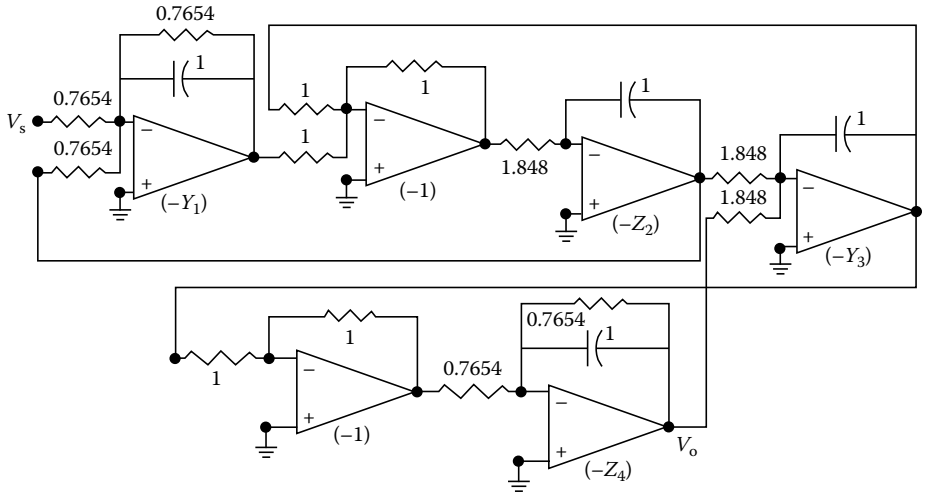

FIGURE 21.9 Leapfrog realization of passive filter of Figure 21.8. For the normalized case of $\omega_{3\ dB} = 1$ rad/s, values are in Ω and F. For a practical case of $\omega_{3\ dB} = 10^6$ rad/s, values are in kΩ and nF.

is changed to 10^6 rad/s, then the capacitances in Figure 21.9 are divided by 10^6. We may arbitrarily magnitude scale the resultant circuit by a factor of 10^3. Then, all resistances are multiplied by 10^3 and all capacitances are further divided by 10^3. The final circuit is still the one shown in Figure 21.9, but with resistances in kΩ and capacitance in nF. The parenthetical quantity beside each op-amp indicates the type of transfer function it produces.

If a doubly terminated passive filter has a shunt reactance at the source end and a series reactance the load end, then its dual network has a series reactance at the source end and a shunt reactance at the load end. The voltage gain functions of the original network and its dual differ at most by a multiplying constant. We can apply the method to the dual network.

For doubly terminated Butterworth and Chebyshev low-pass filters of odd orders, the passive filter either has series reactances or shunt reactances at both ends. The next example shows the additional SFG manipulations needed to construct the RC-op-amp circuit.

Example 21.4

Obtain a leapfrog realization of the third-order Butterworth low-pass filter shown in Figure 21.10a.

Solution

The network is again a four-element ladder network with a modified SFG in terms of the series admittances and shunt impedances as depicted in Figure 21.6. Note that the 1 Ω source resistance alone constitutes the element Y_1. Inserting a branch weighted -1 in front of $-Y_3$ changes the weights of two feedback branches from -1 to 1, and the output from V_o to $-V_o$. Figure 21.10b gives the result. Next, apply the node absorption rule to remove nodes V_A and V_B in Figure 21.10b. The result is Figure 21.10c.

Finally, we recognize that the left-most branch weight -1 is not contained in any loop weights, and appears in the single forward path weight. Therefore, if this branch weight is changed from -1 to 1, the output will be changed from $-V_o$ to V_o. When this change is made, and all specific branch weights are used, the final SFG is given in Figure 21.10d. The circuit implementation is now a simple matter of

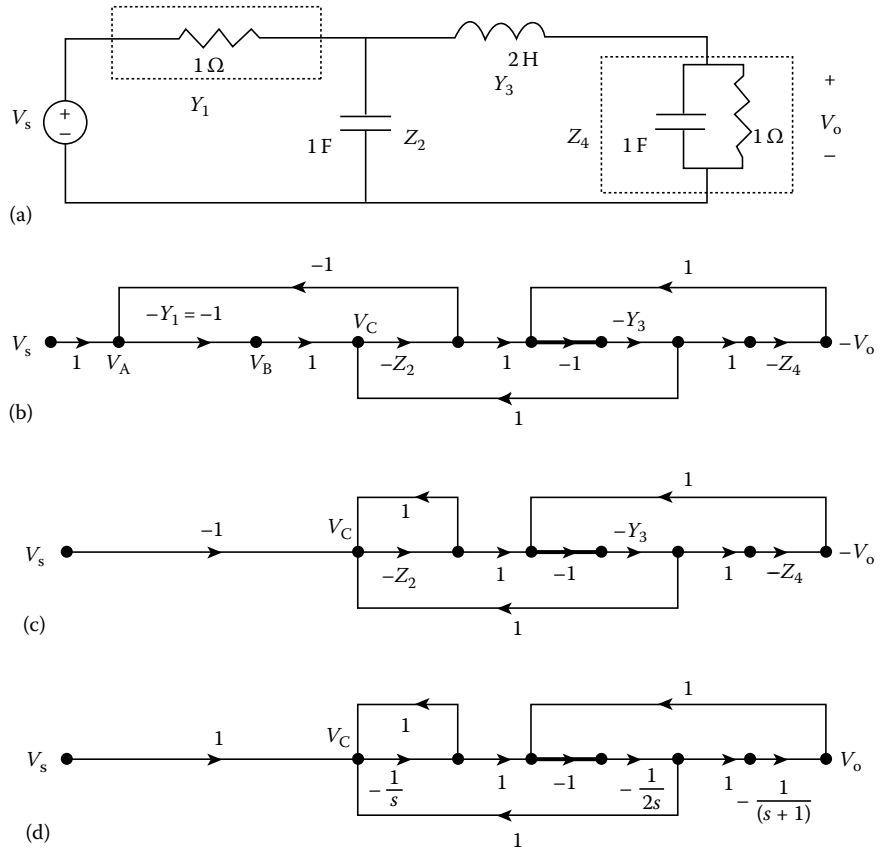

FIGURE 21.10 Leapfrog realization of a third-order, Butterworth low-pass filter. (a) The passive prototype. (b) Leapfrog SFG simulation. (c) Absorption of SFG nodes. (d) Final SFG for active filter realization.

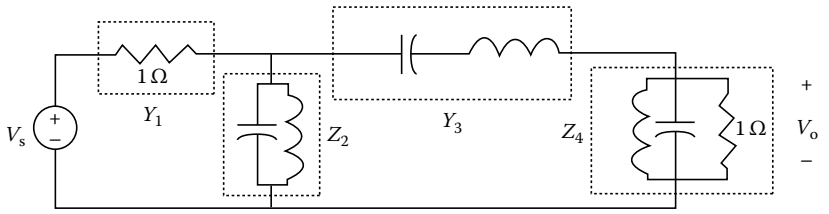

FIGURE 21.11 A bandpass passive filter derived from the circuit of Figure 21.10a.

picking component networks from Table 21.1 and connecting them as in Figure 21.10d. A total of four op-amps are required, one each for the branch transmittance $-1/s$, $-1/(2s)$, $-1/(s+1)$, and -1.

Passive bandpass filters may be derived from low-pass filters using the frequency transformation technique described in Chapter 3 of *Passive, Active and Digital Filters*. The configuration of a bandpass filter derived from the third-order Butterworth filter of Figure 21.10a is given in Figure 21.11.

The impedance and admittance functions Z_2, Y_3, and Z_4 are of the form

$$\frac{s}{a_2 s^2 + a_1 s + a_0}$$

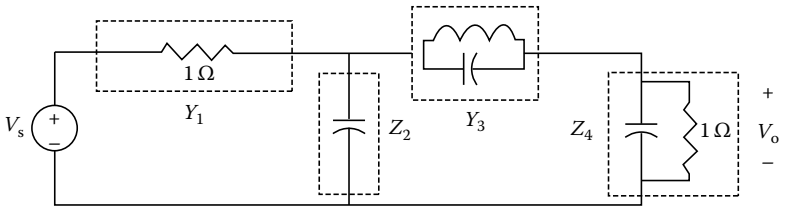

FIGURE 21.12 Network configuration of a doubly terminated filter having a third-order, elliptic or inverse Chebyshev low-pass response.

The SFG thus contains quadratic branch transmittances. Several single op-amp realizations of the quadratic transmittances are discussed in Chapter 14 of *Passive, Active and Digital Filters*, while some multiple op-amp realizations are presented in the next section. The interconnection of the component networks, however, is completely specified by an SFG similar to Figure 21.7 or Figure 21.10d. Complete design examples of this type of bandpass active filter may be found in many books [2–5].

The previous example shows the application of the leapfrog technique to low-pass and bandpass filters of the Butterworth or Chebyshev types. The technique, when applied to a low-pass filter having an elliptic response or an inverse Chebyshev response will require the use of some differentiators. The configuration of a third order low-pass elliptic filter or inverse Chebyshev filter is depicted in Figure 21.12. Notice that Y_3 has the expression

$$Y_3 = a_2 s + \frac{a_0}{s} = \frac{a_2 s^2 + a_0}{s}$$

The term $a_2 s$ in the voltage gain function of the component network clearly indicates the need of a differentiator. An example of such a design may be found in Ref. [1, pp. 382–385].

As a final point in the leapfrog technique, consider the problem of impedance normalization. In all the previous examples, the passive prototype filter has equal terminations and has been magnitude-scaled so that $R_s = R_L = 1$. Situations occur where the passive filter has unequal terminations. For example, the passive filter may have $R_s = 100\ \Omega$ and $R_L = 400\ \Omega$ in a four-element ladder network in Figure 21.8. Three possibilities will be considered.

1. No impedance normalization is done on the passive filter. Then,

$$-Y_1 = -\frac{1}{L_1 s + 100}$$
$$-Z_4 = -\frac{1}{C_4 s + \frac{1}{400}}$$

   From Table 21.1, the lossy integrator realizing $-Y_1$ has a resistance ratio of 100, and the resistance ratio for the $-Z_4$ circuit is 400. Such a large ratio is undesirable.
2. An impedance normalization is done with $R_o = 100\ \Omega$ so that R_s becomes 1 and R_L becomes 4. Then

$$-Y_1 = -\frac{1}{L_1 s + 1}$$
$$-Z_4 = -\frac{1}{C_4 s + \frac{1}{4}}$$

   The resistance ratio in the lossy integrator now becomes 1 for the $-Y_1$ circuit, and 4 for the $-Z_4$ circuit—an obvious improvement over the nonnormalized case.

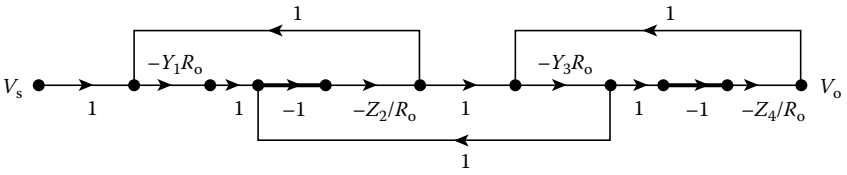

FIGURE 21.13 Result of normalization of the SFG of Figure 21.7.

3. An impedance normalization is done with $R_o = \sqrt{R_s R_L} = 200$. Then $R_s = 0.5$, $R_L = 2$, and

$$-Y_1 = -\frac{1}{L_1 s + 0.5}$$
$$-Z_4 = -\frac{1}{C_4 s + 0.5}$$

The resistance ratio in the lossy integrator is now 2 for both the $-Y_1$ circuit and the $-Z_4$ circuit—a further improvement over case (2) using $R_o = R_s$.

The conclusion is that, in the interest of reducing the spread of resistance values, the best choice of R_o for normalizing the passive filter is $R_o = \sqrt{R_s R_L}$. For the case of equal terminations, this choice leads to $R_s = R_L = 1$.

Instead of starting with a normalized passive filter, one can also construct a leapfrog-type SFG based on the unnormalized passive filter. For a four-element ladder network, the result is given in Figure 21.7. We now perform the following SFG manipulation, which has the same effect as the impedance normalization of the passive filter: Select a normalization resistance, R_o and divide all Z's in the SFG by R_o, and multiply all Y's by R_o. The resultant SFG is given in Figure 21.13.

It is easy to see that the SFG in both Figures 21.7 and 21.13 have the same loop weights and single forward path weight. Therefore, the voltage gain function remains unchanged with the normalization process. One advantage of using the normalized SFG is that the branch transmittances $Y_k R_o$ and Z_k/R_o are dimensionless, and truly represent voltage gain function of component op-amp circuits [2, p. 288].

21.3 Synthesis of Active Filters Based on Signal Flow Graph Associated with a Filter Transfer Function

The preceding section describes one application of the SFG in the synthesis of active filters. The starting point is a passive filter in the form of a doubly terminated *LC* ladder network. In this section, we describe another way of using the SFG technique to synthesize an active filter. The starting point in this case is a filter transfer function instead of a passive network.

Let the transfer voltage ratio function of a filter be

$$\frac{V_o}{V_i} = H(s) = \frac{b_m s^m + b_{m-1} s^{m-1} + \cdots + b_1 s + b_0}{s^n + a_{n-1} s^{n-1} + \cdots + a_1 s + a_0}, \quad m \le n \tag{21.1}$$

In Chapters 2 and 3 of *Passive, Active, and Digital Filters*, it is demonstrated that, by properly selecting the coefficient a's and b's, all types of filter characteristics can be obtained: low-pass, high-pass, bandpass, band elimination, and all-pass. We assume that these coefficients have been determined. Our problem is how to realize the transfer function using SFG theory and RC-op-amp circuits.

Recall Mason's gain formula of an SFG described in Section 8.4. For the present application, we impose two constraints on the SFG:

1. No second-order or higher-order loops are present. In other words, all loops in the SFG touch each other.
2. Every forward path from the source node to the output node touches all loops.

For such a special kind of SFG, Mason's gain formula reduces to

$$\frac{V_o}{V_i} = H(s) = \frac{\sum P_k}{1 - (L_1 + L_2 + \cdots + L_n)} \tag{21.2}$$

where

L_n is the nth loop weight

P_k is the kth forward path weight

Summations are over all forward paths and all loops

Our strategy is to manipulate Equation 21.1 into the form of Equation 21.2, and then construct an SFG to have the desired loops and paths, meeting constraints (1) and (2). Integrators are preferred over differentiators in actual circuit implementation, therefore, we want $1/s$ instead of s to appear as the SFG branch transmittances. This suggests the division of both the numerator and denominator of Equation 21.1 by s^n, the highest degree term in the denominator.

The result is

$$\begin{aligned}\frac{V_o}{V_i} &= H(s) \\ &= \frac{b_m\left(\frac{1}{s}\right)^{n-m} + b_{m-1}s^{n-m+1} + \cdots + b_1\left(\frac{1}{s}\right)^{n-1} + b_0\left(\frac{1}{s}\right)^n}{1 + a_{n-1}\left(\frac{1}{s}\right) + \cdots + a_1\left(\frac{1}{s}\right)^{n-1} + a_0\left(\frac{1}{s}\right)^n}, \quad m \le n\end{aligned} \tag{21.3}$$

Comparing Equation 21.3 with Equation 21.2, we can identify the loop weights

$$\begin{aligned} L_1 &= -a_{n-1}(1/s) \\ L_2 &= -a_{n-2}(1/s)^2 \\ &\cdots \\ L_n &= -a_0(1/s)^n \end{aligned} \tag{21.4}$$

and the forward path weights

$$b_m\left(\frac{1}{s}\right)^{n-m},\ b_{m-1}\left(\frac{1}{s}\right)^{n-m+1},\ \ldots\ b_1\left(\frac{1}{s}\right)^{n-1},\ b_0\left(\frac{1}{s}\right)^n \tag{21.5}$$

Many SFGs may be constructed to have such loop and path weights, and the touching properties stated previously in (1) and (2). Two simple ones are given in Figure 21.14a and b for the case $n = m = 3$. The extension to higher-order transfer functions is obvious. In control theory, the system represented by Figure 21.14a is said to be of the controllable canonical form, and Figure 21.14b the observable canonical form. In a filter application, we need not be concerned about the controllability and observability of the system. The terms are used here merely for the purpose of circuit identification. Our major concern here is how to implement the SFG by an RC-op-amp circuit.

An SFG branch having transmittance $1/s$ indicates an integrator. If the terminating node of the $1/s$ branch has no other incoming branches (as in Figure 21.14a), then that node variable represents the output of the integrator. On the other hand, if $1/s$ is the transmittance of only one of several incoming branches incident at the node V_k (as in Figure 21.14b), then V_k is not the output of an integrator. In order

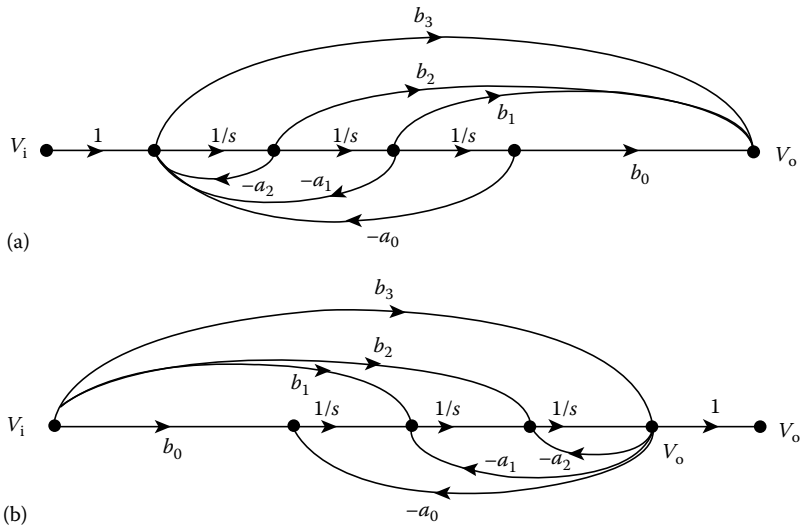

FIGURE 21.14 Two simple SFGs having a gain function given by Equation 21.3. (a) Controllable canonical form. (b) Observable canonical form.

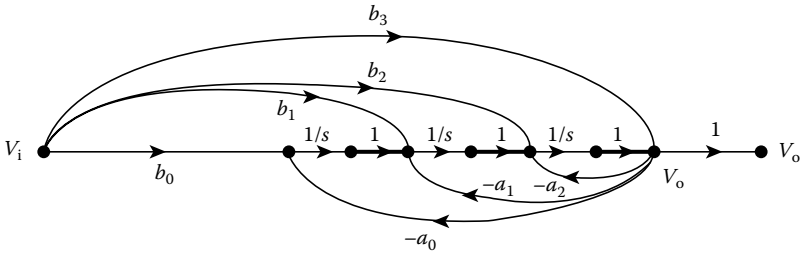

FIGURE 21.15 Insertion of dummy branches to identify integrator outputs.

to identify the integrator outputs clearly for the purpose of circuit interconnection, we insert some dummy branches with weight 1 in series with the branches weighted $1/s$. When this is done to Figure 21.14b, the result is Figure 21.15 with the inserted dummy branches shown in heavy lines. An SFG branch with weight $-1/s$ represents an inverting integrator. As pointed out in Section 21.2, the circuitry of an inverting integrator is simpler than that of a noninverting integrator. To have an implementation utilizing inverting integrators, we replace all SFG branch weights $1/s$ in Figure 21.14 by $-1/s$. In order to maintain the original path and loop weights, the signs of some feedback branches and forward path branches must be changed accordingly. When this is done, Figures 21.14a and 21.15 become those shown in Figure 21.16a and b, respectively. Our next goal is to implement these SFGs by RC-op-amp circuits. Because SFGs of the kind described in this section are widely used in the study of linear systems by the state variable approach, the active filters based such SFGs are called state variable filters [6].

Example 21.5

Synthesize a state variable active filter to have a third order Butterworth low-pass response having 3 dB frequency $\omega_o = 10^6$ rad/s. All op-amps used are single-ended.

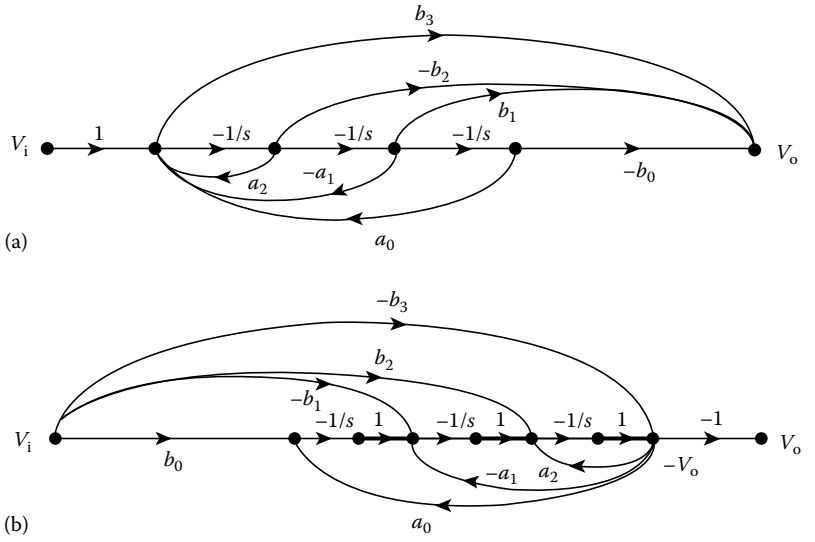

FIGURE 21.16 Simulation of $H(s)$ by an SFG containing inverting integrators.

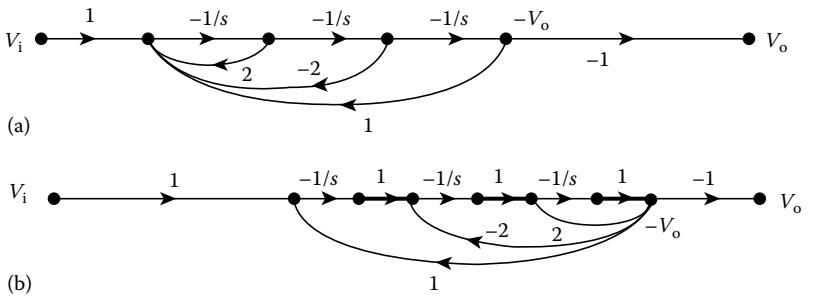
Solution

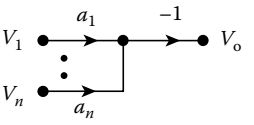
As usual in filter synthesis, we first construct the filter for the normalized case, i.e., $\omega_o = 1$ rad/s, and then perform frequency scaling to obtain the required filter. From Chapter 2 of *Passive, Active, and Digital Filters*, the normalized voltage gain function of the filter is

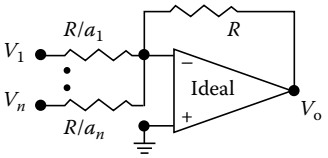
$$H(s) = \frac{V_o}{V_i} = \frac{1}{s^3 + 2s^2 + 2s + 1} \tag{21.6}$$

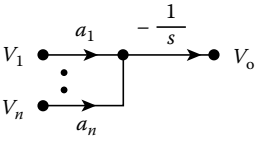
and the two SFGs in Figure 21.16 become those depicted in Figure 21.17.

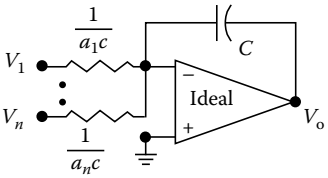
Because we are concerned with the magnitude response only, $-V_o$ instead of V_o can be accepted as the desired output. Therefore, in Figure 21.17, the rightmost SFG branch with gain (-1) need not be implemented. The implementation of the SFG as RC-op-amp circuits is now just a matter of looking up Table 21.2, selecting proper component networks and connecting them as specified by Figure 21.17. The results are given in Figure 21.18a and b. These circuits, with element values in ohms and farads,

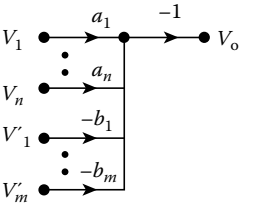












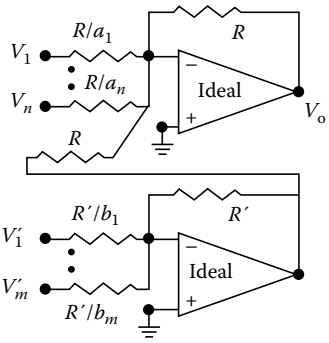


FIGURE 21.17 Two SFG representations of Equation 21.6.

TABLE 21.2 Single-Ended Op-Amp Circuits for Implementing State Variable Active Filters

	SFG	RC-op-amp circuit
(1)		Inverting scaled summer 
	$V_o = -(a_1V_1 + \cdots + a_nV_n)$	R: arbitrary
(2)		Inverting scaled summing integrator

	$V_o = -(a_1V_1 + \cdots + a_nV_n) + (b_1V'_1 + \cdots + b_mV_n)$	R and R': arbitrary

realize the normalized transfer function having $\omega_c = 1$ rad/s. To meet the original specification of $\omega_c = 10^6$ rad/s, we frequency-scale the circuits by a factor 10^6 (i.e., divide all capacitances by 10^6). To have practical resistance values, we further magnitude-scale the circuits by a factor of, say, 1000. The resistances are multiplied by 1000, and the capacitances are further divided by 1000. The final circuits are still given by Figure 21.18, but now with element values in kΩ and nF.

In Example 21.5, both realizations require four op-amps. In general, for an nth order transfer function given by Equation 21.1 with all coefficients nonzero, a synthesis based on Figure 21.16a (controllable canonical form) requires $n + 3$ single-ended op-amps. The breakdown is as follows (refer to Figure 21.16a):

n inverting scaled integrators (item 2, Table 21.2) for the n SFG branches with weight $-1/s$
Two op-amps for the bipolarity summer (item 3, Table 21.2) to obtain V_o
One inverting scaled summer (item 1, Table 21.2) to invert and add up signals from branches with weights $-a_1$, $-a_3$, etc., before applying to the left-most integrator

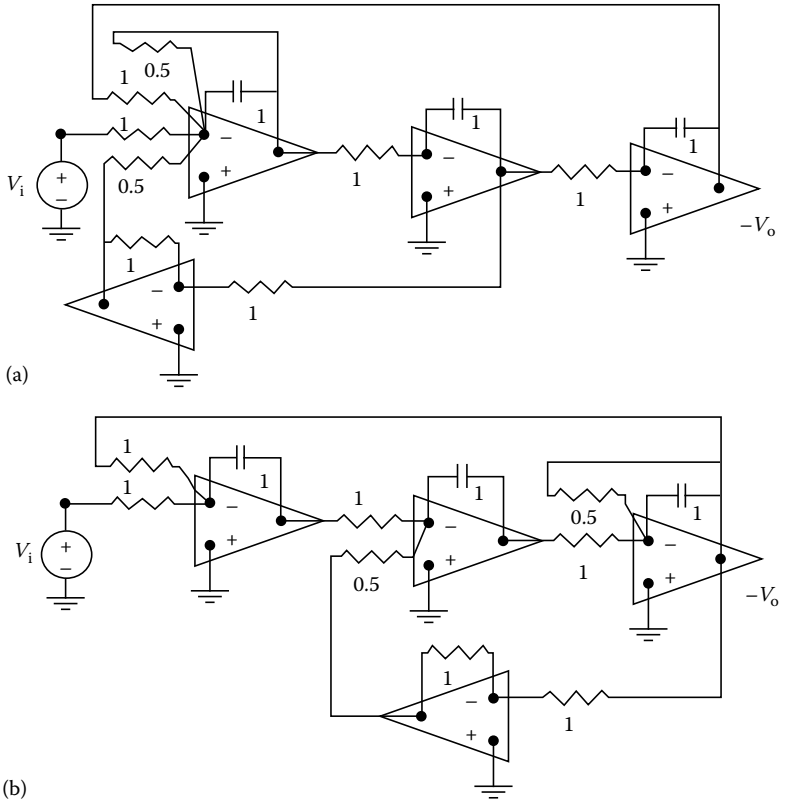

FIGURE 21.18 Two op-amp circuit realizations of $H(s)$ given by Equation 21.6.

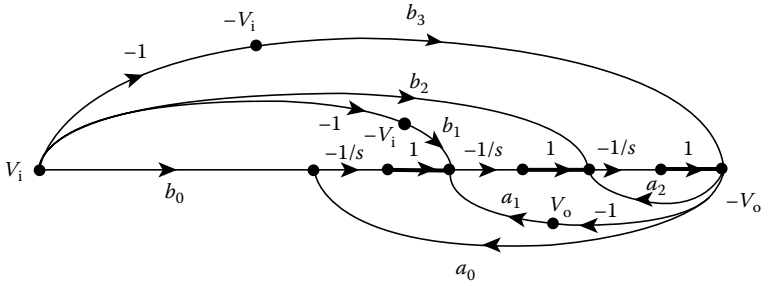

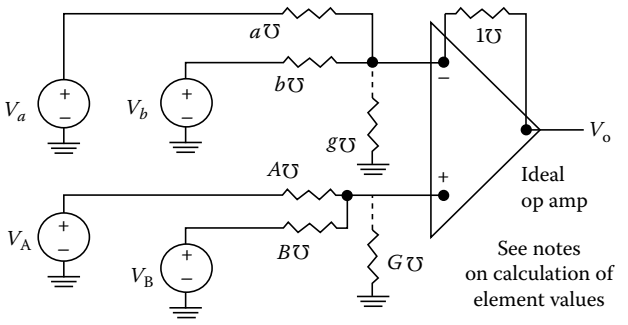

FIGURE 21.19 Modification of Figure 21.16b to use all positive a's and b's.

On the other hand, a synthesis based on Figure 21.16b (observable canonical form) requires only $n+2$ single-ended op-amps. To see this, we redraw Figure 21.16b as Figure 21.19 by inserting branches with weight -1, and making all literal coefficients positive. The breakdown is as follows (referring to Figure 21.19, extended to nth order $H(s)$):

n inverting scaled integrators (item 2, Table 21.2) for the n SFG branches with weight $-1/s$
One inverting amplifier at the input end to provide $-V_i$
One inverting amplifier at the output end to make available both V_o and $-V_o$

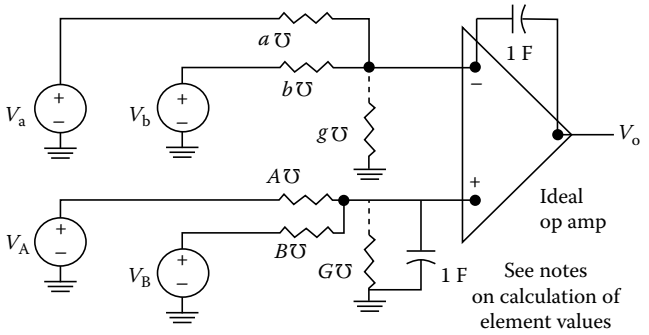

TABLE 21.3 Differential-Input Op-Amp Circuit

(1) Bi-polarity scaled summer $V_o = -(aV_a + bV_b) + (AV_A + BV_B)$

(2) Bi-polarity scaled summing integrator

$V_o = \frac{1}{s}[-(aV_a + bV_b) + (AV_A + BV_B)$

Note: Calculation of element values in Table 21.3 [7].

(i) The initial design uses 1 Ω resistance or 1 F capacitance as the feedback element.

(ii) Either the g mho conductance or the G mho conductance (not both) is connected.

Choose the values of g or G such that the sum of all conductances connected to the inverting input terminal equals the sum of all conductances connected to the noninverting input terminal.

(iii) Starting with the initial design, one may magnitude-scale all elements connected to the inverting input terminal by one factor, and all elements connected to the noninverting input terminal by the same or a different factor.

The number of op-amps can be reduced if the restriction of using single-ended op-amp is removed. Table 21.3 describes several differential-input op-amp circuits suitable for use in the state variable active filters.

If differential-input op-amps are used, then the number of op-amps required for the realization of Equation 21.1 (with $m = n$) is reduced to $(n+1)$ for Figure 21.16a and n for Figure 21.16b. The breakdowns are as follows:

For the controllable canonical form SFG of Figure 21.16a:

$n-1$ inverting integrators (item 2, Table 21.2 with one input) for the n SFG branches with weight $-1/s$, except the leftmost

One bipolarity-scaled summing integrator (item 2, Table 21.3) for the leftmost SFG branch with weight $-1/s$

One bipolarity-scaled summer (item 1, Table 21.3) to obtain V_o

For the observable canonical form SFG of Figure 21.16b:

n bipolarity scaled summing integrator (item 2, Table 21.3), one for each SFG branch with weight $-1/s$

To construct the op-amp circuit, one refers to the SFG of Figure 21.14 and obtains the expression relating the output of each op-amp to the outputs of other op-amps. After that is done, refer to Table 21.3, pick the appropriate component circuits, and connect them as specified by the SFG. The next example outlines the procedure of utilizing differential-input type op-amps to reduce the total number of op-amps to $(n+1)$ or n.

Example 21.6

Design a state-variable active low-pass filter to meet the following requirements: magnitude response is of the inverse Chebyshev type

$$\alpha_{max} = 0.5\,\text{dB}, \quad \alpha_{min} = 20\,\text{dB}, \quad \alpha(\omega_s) = \alpha_{min}$$
$$\omega_p = 333.33\,\text{rad/s}, \quad \omega_s = 1000\,\text{rad/s}$$

Solution

Using the method described in Chapter 3 of *Passive, Active, and Digital Filters*, the normalized transfer function (i.e., $\omega_s = 1$ rad/s) is found to be

$$H(s) = \frac{V_o}{V_i} = \frac{K(s^2 + 1.33333)}{s^3 + 1.40534s^2 + 0.94200s + 0.40196} \tag{21.7}$$

The SFGs for this $H(s)$ are simply obtained from Figure 21.16 by removing the two branches having weights b_3 and b_1.The results are shown in Figure 21.20a for the case $K = 1$, and in Figure 21.20b for the case $K = -1$. A four op-amp circuit for the normalized $H(s)$ may be constructed in accordance with the SFG of Figure 21.20a. The component op-amp circuits are selected from Tables 21.2 and 21.3 in the following manner:

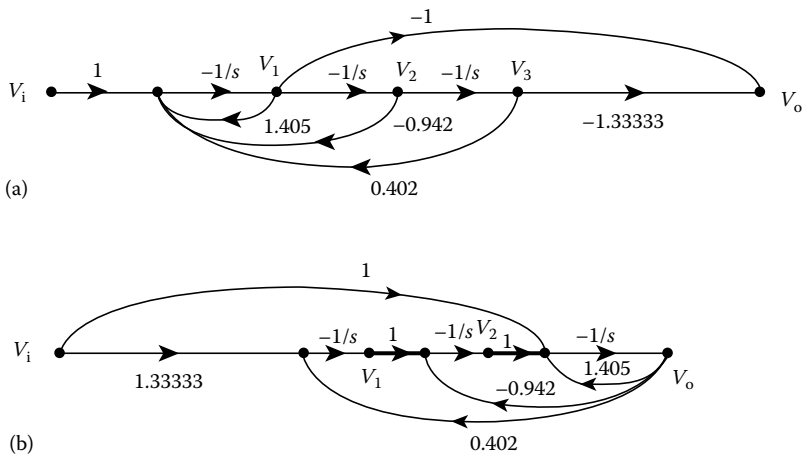

FIGURE 21.20 Two SFGs realizing the transfer function of Equation 21.7.

Relationship from SFG	component op-amp circuit
$V_1 = -\frac{1}{s}(V_i + 1.405V_1 + 0.402V_3 - 0.942V_2)$	item 2, Table 21.3
$V_2 = -\frac{1}{s}V_1$	item 2, Table 21.2
$V_3 = -\frac{1}{s}V_2$	item 2, Table 21.2
$V_o = -V_1 - 1.33333\ V_3$	item 1, Table 21.2

After connecting these four-component op-amp circuits as described in Figure 21.20a, and frequency-scaling the whole circuit by 1000, and magnitude-scaling by 1000, the final op-amp circuit meeting the low-pass filter specifications is shown in Figure 21.21a.

In a similar manner, a three-op-amp circuit for the normalized $H(s)$ may be constructed in accordance with the SFG of Figure 21.20b. The final op-amp circuit meeting the lowpass filter specifications is shown in Figure 21.21b. Both circuits in Figure 21.21 achieve a gain constant $|K| = 1$ in Equation 21.7. Should a different value of $|K| = 1/\alpha$ be desired, it is only necessary to multiply the values of all resistors connected to the input V_i by α.

When the method of this section is applied to a second order transfer function, the resultant op-amp circuit is called a "state variable biquad." Biquads and first order op-amp circuits are used as the basic building blocks in the synthesis of a general nth order transfer function by the "cascade" approach. Single op-amp biquads are discussed in Section II of *Passive, Active, and Digital Filters*. Depending on the SFGs chosen and the types of op-amps allowed (single-ended or differential-input), a state variable biquad may require from two to five op-amps. Some special but useful state variable biquads are listed in Table 21.4 for reference purposes.

All the SFGs used in the previous examples are of the two types (controllable and observable canonical forms) illustrated in Figure 21.16; however, many other possible SFGs produce the same transfer function. For example, a third-order, low-pass Butterworth or Chebyshev filter has an all-pole transfer function.

$$H(s) = \frac{V_o}{V_i} = \frac{K}{s^3 + a_2 s^2 + a_1 s + a_0} \tag{21.8}$$

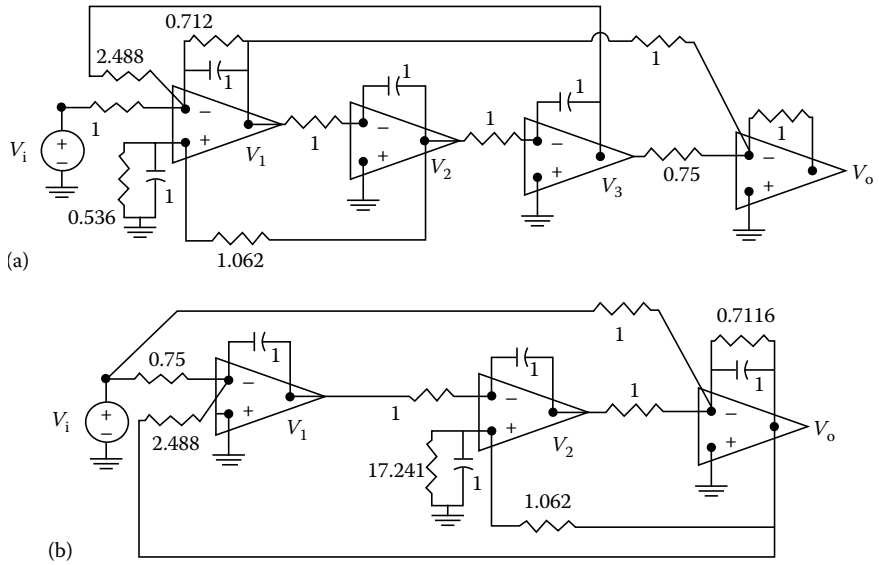

FIGURE 21.21 Two realizations of the third-order, inverse Chebyshev low-pass filter of Example 21.6. Element values are in kΩ and μF.

Either R_1 or R_2 is connected. See notes in Table 21.3 for the determination of their values.

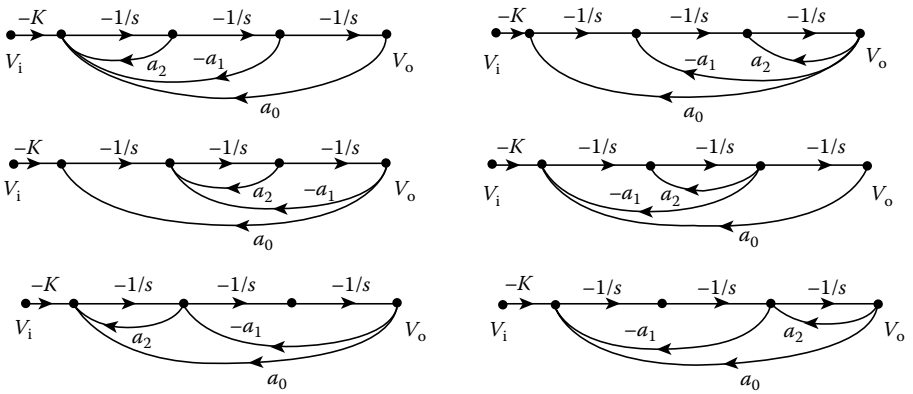

FIGURE 21.22 Six SFGs realizing a third-order, all-pole transfer function.

A total of six SFGs may be constructed in accordance with Equation 21.2 to produce the desired $H(s)$. These are illustrated in Figure 21.22. Among these, six SFGs only two have been chosen for consideration in this section.

Similarly, for a fourth-order, low-pass Butterworth or Chebyshev filter, a total of 20 SFGs may be constructed. The reader should consult Refs. [8,9] for details.

22.1 Network Functions

Jiri Vlach

22.1.1 Definition of Network Functions

Network functions can be defined if the following constraints are satisfied:

1. Network is linear.
2. It is analyzed in the frequency domain using the Laplace transform.
3. All initial voltages and currents are zero (zero state conditions).

This chapter demonstrates how the various functions can be derived, but first we introduce some explanations and definitions. If we analyze any linear network, we can take as output any nodal voltage, or a difference of any two nodal voltages; denote such as output voltage by V_{out}. We can also take as the output a current through any element of the network; we call it output current, I_{out}. If the network is excited by a voltage source, E, then we can also calculate the current delivered into the network by this source; this is the input current, I_{in}. If the network is excited by a current source, J, then the voltage across the current source is the input voltage, V_{in}.

Suppose that we analyze the network and keep the letter E or J in our derivations. Then, we can define the following network functions:

$$\begin{aligned}
&\text{Voltage transfer function,} && T_{\mathrm{v}} = \frac{V_{\mathrm{out}}}{E}\\
&\text{Input admittance,} && Y_{\mathrm{in}} = \frac{I_{\mathrm{in}}}{E}\\
&\text{Transfer admittance,} && Y_{\mathrm{tr}} = \frac{I_{\mathrm{out}}}{E}\\
&\text{Current transfer function,} && T_{\mathrm{i}} = \frac{I_{\mathrm{out}}}{J}\\
&\text{Input impedance,} && Z_{\mathrm{in}} = \frac{V_{\mathrm{in}}}{J}\\
&\text{Transfer impedance,} && Z_{\mathrm{tr}} = \frac{V_{\mathrm{out}}}{J}
\end{aligned} \tag{22.1}$$

Output impedance or output admittance are also used, but the concept is equivalent to the input impedance or admittance. The only difference is that, for calculations, the source is placed temporarily at a point from which the output normally will be taken. In the Laplace transform, it is common to use capital letters, V for voltages and I for currents. We also deal with impedances, Z, and admittances, Y. Their relationships are

$$V = ZI, \quad I = YV$$

The impedance of a capacitor is $Z_{\mathrm{C}} = 1/sC$, the impedance of an inductor is $Z_{\mathrm{L}} = sL$, and the impedance of a resistor is R. The inverse of these values are admittances: $Y_{\mathrm{C}} = sC$, $Y_{\mathrm{L}} = 1/sL$, and the admittance of a resistor is $G = 1/R$.

To demonstrate the derivations of the above functions two examples are used. Consider the network in Figure 22.1, with input delivered by the voltage source, E. By Kirchhoff's current law (KCL), the sum of currents flowing away from node 1 must be zero:

$$(G_1 + sC_1 + G_2)V_1 - G_2V_2 - EG_1 = 0$$

Similarly, the sum of currents flowing away from node 2 is

$$-V_1G_2 + (G_2 + sC_2 + G_3)V_2 = 0$$

The independent source is denoted by the letter E, and is assumed to be known. In mathematics, we transfer known quantities to the right. Doing so and collecting the equations into one matrix equation results in

$$\begin{bmatrix} G_1 + G_2 + sC_1 & -G_2 \\ -G_2 & G_2 + G_3 + sC_2 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} EG_1 \\ 0 \end{bmatrix}$$

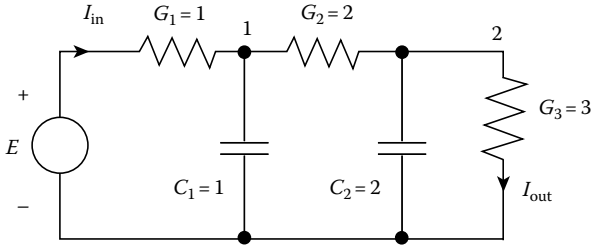

FIGURE 22.1 Network used to illustrate the derivations of network functions.

If numerical values from the figure are used, this system simplifies to

$$\begin{bmatrix} s+3 & -2 \\ -2 & 2s+5 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} E \\ 0 \end{bmatrix}$$

or

$$\boldsymbol{YV} = \boldsymbol{E}$$

Any method can be used to solve this system, but for the sake of explanation it is advantageous to use Cramer's rule. First, find the determinant of the matrix,

$$D = 2s^2 + 11s + 11$$

To obtain the solution for the variable $V_1(V_2)$, replace the first (second) column of $\boldsymbol{Y}$ by the right-hand side and calculate the determinant of such a modified matrix. Denoting such a determinant by the letter N with an appropriate subscript, evaluate

$$N_1 = \begin{vmatrix} E & -2 \\ 0 & 2s+5 \end{vmatrix} = (2s+5)E$$

Then,

$$V_1 = \frac{N_1}{D} = \frac{2s+5}{2s^2+11s+11}E$$

Now, divide the equation by E, which results in the voltage transfer function

$$T_{\mathrm{v}} = \frac{V_1}{E} = \frac{2s+5}{2s^2+11s+11}$$

To find the nodal voltage V_2, replace the second column by the elements of the vector on the right-hand side:

$$N_2 = \begin{vmatrix} s+3 & E \\ -2 & 0 \end{vmatrix} = 2E$$

The voltage is

$$V_2 = \frac{N_2}{D} = \frac{2}{2s^2+11s+11}E$$

and another voltage transfer function of the same network is

$$T_{\mathrm{v}} = \frac{V_2}{E} = \frac{2}{2s^2+11s+11}$$

Note that many network functions can be defined for any network. For instance, we may wish to calculate the currents I_{in} or I_{out}, marked in Figure 22.1. Because the voltages are already known, they are used: For the output current $I_{out} = G_3 V_2$ and divided by E

$$Y_{tr} = \frac{I_{out}}{E} = \frac{3V_2}{E} = \frac{6}{2s^2 + 11s + 11}$$

The input current $I_{in} = E - G_1 V_1 = E - V_1 = E(2s^2 + 9s + 6)/(2s^2 + 11s + 11)$ and dividing by E

$$Y_{in} = \frac{I_{in}}{E} = \frac{2s^2 + 9s + 6}{2s^2 + 11s + 11}$$

In order to define the other possible network functions, we must use a current source, J, as in Figure 22.2, where we also take the current through the inductor as an output variable. This method of formulating the network equations is called modified nodal. The sum of currents flowing away from node 1 is

$$(G_1 + sC_1)V_1 + I_L - J = 0$$

from node 2 it is

$$G_2 V_2 - I_L = 0$$

and the properties of the inductor are expressed by the additional equation

$$V_1 - V_2 - sLI_L = 0$$

Inserting numerical values and collecting in matrix form:

$$\begin{bmatrix} s+1 & 0 & 1 \\ 0 & 2 & -1 \\ 1 & -1 & -s \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ I_L \end{bmatrix} = \begin{bmatrix} J \\ 0 \\ 0 \end{bmatrix}$$

The determinant of the system is

$$D = -(2s^2 + 3s + 3)$$

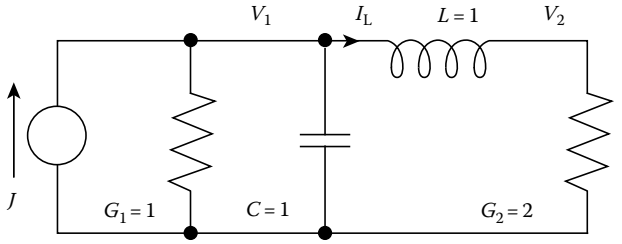

FIGURE 22.2 Network used to calculate other possible network functions.

To solve for V_1, we replace the first column by the right-hand side and evaluate the determinant

$$N_1 = \begin{vmatrix} J & 0 & 1 \\ 0 & 2 & -1 \\ 0 & -1 & -s \end{vmatrix} = -(2s+1)J$$

Then, $V_1 = N_1/D$ and dividing by J we obtain the network function

$$Z_{\text{tr}} = \frac{V_1}{J} = \frac{2s+1}{2s^2+3s+3}$$

To obtain the inductor current, evaluate the determinant of a matrix in which the third column is replaced by the right-hand side: $N_3 = -2J$. Then, $I_{\text{L}} = N_3/D$ and

$$T_{\text{i}} = \frac{I_{\text{L}}}{J} = \frac{2}{s^2+3s+3}$$

In general,

$$F = \frac{\text{Output variable}}{E \text{ or } J} = \frac{\text{Numerator polynomial}}{\text{Denominator polynomial}} \tag{22.2}$$

Any method that may be used to formulate the equations will lead to the same result. One example shows this is true. Reconsider the network in Figure 22.2, but use the admittance of the inductor, $Y_{\text{L}} = 1/sL$, and do not consider the current through the inductor. In such a case, the nodal equations are

$$\left\{1 + s + \frac{1}{s}\right\} V_1 - \frac{1}{s} V_2 = J$$
$$-\frac{1}{s} V_1 + \left\{\frac{1}{s} + 2\right\} V_2 = 0$$

We can proceed in two ways:

1. We can multiply each equation by s and thus remove the fractions. This provides the system equation

$$\begin{bmatrix} s^2+s+1 & -1 \\ -1 & 2s+1 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} sJ \\ 0 \end{bmatrix}$$

   The determinant of this matrix is $D = 2s^3 + 3s^2 + 3s$. To calculate V_1, find $N_1 = s(2s+1)J$. Their ratio is the same as before because one s in the numerator can be canceled against the denominator.
2. If we do not remove the fractions and go ahead with the solution, we have the matrix equation

$$\begin{bmatrix} s+1+1/s & -1/s \\ -1/s & 1/s+2 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} J \\ 0 \end{bmatrix}$$

   The determinant is $D = 2s + 3 + 3/s$ and the numerator for V_1 is $N_1 = (1/s+2)J$. Taking their ratio

$$V_1 = \frac{(1/s+2)J}{2s+3+3/s} = \frac{2s+1}{2s^2+3s+3} J$$

   which is the same result as before.

We conclude that it does not matter which method is used to formulate the equations. The result is always a ratio of two polynomials in the variable s.

Many additional conclusions can be drawn from these examples. The most important result so far is that all network functions of any given network have the same denominator. It was easy to discover this property because we used Cramer's rule, with its evaluation by the ratio of two determinants. It should be mentioned at this point that we may have network functions in which some terms of the numerator can cancel against the same terms of the denominator. Such a cancellation represents a mathematical simplification which does not change the validity of the above statement.

Occasionally, the network may have more than one source. In such cases, we apply the superposition principle of linear networks. The contribution to the output can be calculated separately for each source and the results added. All that must be done is to correctly remove those sources which are not considered at the moment. All unused independent voltage sources must be replaced by short circuits. All unused independent current sources are replaced by open circuits (removed from the network). Although we did not use dependent sources in our examples, it is necessary to stress that such removal must not take place for dependent sources.

Network functions can be used to find responses to any given input signal. First, multiply the network function by E or J; this will give the expression for the output. Afterward, the letter E or J is replaced by the Laplace transform of the signal. For instance, if the signal is a unit step, then the source is replaced by $1/s$. If it is cost ωt, then the source is replaced by the Laplace transform, $s/(s^2 + \omega^2)$, and so on.

In the Laplace transform, one special signal exists, the Dirac impulse, commonly denoted by $\delta(t)$. It can be represented as a rectangular pulse having width T and height $1/T$. The area of the pulse is always 1, even if we go to lim $T \to 0$, which is the Dirac impulse. Its Laplace transform is 1. Because multiplication by 1 does not change the network function, we conclude that any network function is also the Laplace transform of the network response to the Dirac impulse.

A word of caution: In the network function always divide by the independent voltage (current) source. We cannot take two analysis results, for instance V_1 and V_2, derived for Figure 22.1, and take their ratio. This will not be a network function.

22.1.2 Poles and Zeros

Networks with lumped elements have network functions which are always ratios of two polynomials with real coefficients. For some applications the polynomials may be expressed as functions of some (or all) elements, but the principle is unchanged.

Because we have a ratio of two polynomials, the network function can be written in two forms:

$$F = \frac{\sum_{i=0}^{M} a_i s^i}{\sum_{i=0}^{N} b_i s^i} = K \frac{\prod_{i=1}^{M} (s - z_i)}{\prod_{i=1}^{N} (s - p_i)} \tag{22.3}$$

The middle form is what we obtain from analyses similar to those in the examples. Algebraically, a polynomial of order N has exactly N roots. This leads to the form on the right. The multiplicative constant, K, is the ratio

$$K = \frac{a_M}{b_N}$$

and is obtained by dividing each polynomial by the coefficient of its highest power.

It is easy to find roots of a first- and second-order polynomial because formulas are available, but in all other cases iterative methods and a computer are utilized. However, even without actually finding the roots, we can draw a number of important conclusions.

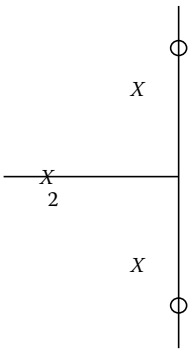

FIGURE 22.3 Network function with two complex conjugate zeros on the imaginary axis, two complex conjugate poles, and one double real pole.

If the highest power of the polynomial is odd, then at least one real root will exist. The other roots may be either real or complex, but if they are complex, then they always appear in complex conjugate pairs. The roots of the numerator are called zeros, and those of the denominator are called poles. We denote the zeros by

$$z_i = a_i + jb_i$$

where $j = \sqrt{-1}$. Either a or b may be zero. For the poles, we have similarly

$$p_i = c_i + jd_i$$

The polynomial also may have multiple roots. For instance, the polynomial $P(s) = (s+1)^2(s+2)^3$ has a double root at $s = -1$ and a triple root at $s = -2$. The positions of the poles and zeros, with the constant K, completely define the network function and also all network properties. The positions can be plotted in a complex plane, the zeros indicated by small circles and poles by crosses. A multiple pole (zero) is indicated by a number appearing at the cross (circle). Figure 22.3 shows a network function with two complex conjugate zeros on the imaginary axis, two complex conjugate poles, and one double real pole.

As derived previously, all network functions of any given network have the same poles. Their positions depend only on the structure of the network and are independent of the signal or where the signal is applied. Because of this fundamental property, the poles are also called natural frequencies of the network. The zeros depend on the place at which we attach the source and also on the point where we take the output.

It is possible to have networks in which a pole is in exactly the same position as a zero; mathematically, such terms cancel. Figure 22.4 is an example. Writing the sum of currents at nodes 1, 2, and 3, we obtain

$$\begin{aligned}(2s+2)V_1 - (s+3)V_3 &= sE\\ (2s+2)V_2 - V_3 &= E\\ -sV_1 - V_2 + (s+3)V_3 &= 0\end{aligned}$$

and in matrix form

$$\begin{bmatrix} 2s+2 & 0 & -(s+3) \\ 0 & 2s+2 & -1 \\ -s & -1 & s+3 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ V_3 \end{bmatrix} = \begin{bmatrix} sE \\ E \\ 0 \end{bmatrix}$$

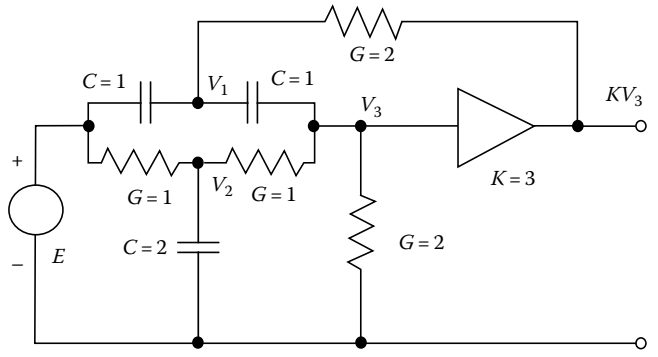

FIGURE 22.4 Network in which a pole is in exactly the same position as a zero.

By carefully evaluating the determinant we discover that we can keep the term $(2s+2)$ separate and get $D=(2s+2)(s^2+2s+5)$. Replacing the third column by the right-hand side, we calculate the numerator $N_3=(2s+2)(s^2+1)E$. Because the output is KV_3, the voltage transfer function is

$$T_{\mathrm{v}}=\frac{3(2s+2)(s^2+1)}{(2s+2)(s^2+2s+5)}$$

Mathematically, the term $(2s+2)$ cancels and the network function is sometimes written as

$$T_{\mathrm{v}}=\frac{3(s^2+1)}{s^2+2s+5}$$

Such cancellation makes the denominator different from other network functions that we might derive for the same network, but it is not a correct way to describe the properties of the network. The cancellation gives the impression that we have a second-order network, while it is actually a third-order network.

22.1.3 Network Stability

Stability of the network depends entirely on the positions of its poles. The following is a list of the conditions in order for the network to be stable, with subsequent explanation of the reasons:

1. Network is stable if all its poles are in the left half of the complex plane.
2. Network is unstable if at least one of its poles is in the right-half plane.
3. Network is marginally stable if all its poles are simple and exactly on the imaginary axis.
4. Network is unstable if it has all poles on the imaginary axis, but at least one of them has multiplicity two or more.

Courses on mathematics teach the process of decomposing a rational function into partial fractions. We show an example with one simple real pole and a pair of simple complex conjugate poles,

$$F(s)=\frac{3s^2+8s+6}{(s+1)(s^2+2s+2)}=\frac{1}{s+1}+\frac{1+j}{s+1+j}+\frac{1-j}{s+1-j}$$

The poles are $p_1=-1$ and $p_{2,3}=-1\pm j$, all with negative real parts and all lying in the left-half plane. Partial fraction decomposition is on the right of the preceding equation. It is always true, for any lumped network, that the decomposition for a real pole has a real constant in the numerator. Complex poles always appear in complex conjugate pairs and the decomposition constants, if complex, also are complex conjugate. Once such a decomposition is available, tables can be used to invert the functions into time domain. The decomposition may be quite a laborious process, however, only a few types of terms need be considered for lumped networks. All are collected in Table 22.1. Each time domain expression is multiplied by unit step, $u(t)$, which is zero for $t<0$ and is one for $t\geq 0$. Such multiplication correctly expresses the fact that the time functions start at $t=0$.

Formula one in Table 22.1 shows that a real, single pole in the left-half plane will lead to a time-domain function which decreases as e^{-ct}. This response is called stable. If $c=0$, then the response becomes $u(t)$. Should the pole be in the right-half plane, the exponent will be positive and e^{ct} will grow rapidly and without bound. This network is said to be unstable.

Formula two shows what happens if the pole is real, with multiplicity n. If it is in the left-half plane, then t^{n-1} is a growing function, but e^{-ct} decreases faster, and for large t the result tends to zero. The function is still stable.

TABLE 22.1 Laplace Transform Pairs

Formula	Laplace Domain	Time Domain
1	$\frac{K}{s+c}$	$Ke^{-ct}u(t)$
2	$\frac{K}{(s+c)^n}$	$K\frac{t^{n-1}}{(n-1)!}e^{-ct}u(t)$
3	$\frac{A+jB}{s+c+jd}+\frac{A-jB}{s+c-jd}$	$2e^{-ct}(A\cos dt+B\sin dt)u(t)$
4	$\frac{A+jB}{(s+c+jd)^n}+\frac{A-jB}{(s+c-jd)^n}$	$\frac{2t^{n-1}}{(n-1)!}e^{-ct}(A\cos dt+B\sin dt)u(t)$

Formula three considers the case of two simple complex conjugate poles. Their real parts influence the exponent, and the imaginary parts contribute to oscillations. If the real part is negative, the oscillations will be damped, the response will become zero for large t, and the network will be stable. If the real part is zero, then the oscillations continue indefinitely with constant amplitude. For the positive real part, the network becomes unstable.

Formula four considers a pair of multiple complex conjugate poles. As long as the real part is negative, the oscillations will decrease with time and the network will be stable. If a real part is zero or positive, the network is unstable because the oscillations will grow.

22.1.4 Initial and Final Value Theorems

Finding the poles and evaluating the time domain response is a complicated process, which normally requires the use of a computer. It is, therefore, advisable to use all possible steps that may provide information about the network behavior without actually finding the full time-domain response.

Two Laplace transform theorems help in finding how the network behaves at $t=0$ and at $t\to\infty$. Both theorems are derived from the Laplace transform formula for differentiation,

$$\int_{0^-}^{\infty} f'(t)e^{-st}\,dt = sF(s)-f(0^-) \tag{22.4}$$

where 0^- indicates that we are considering the instant just before the signal is applied. If we let $s\to 0$, then $e^0=1$, and the integral of the derivative becomes the function itself. Inserting the integrating limits we get

$$f(\infty)-f(0^-)=\lim_{s\to 0}[sF(s)-f(0^-)]$$

Canceling $f(0^-)$ on both sides, we arrive at the "final value theorem"

$$\lim_{t\to\infty} f(t)=\lim_{s\to 0} sF(s) \tag{22.5}$$

Another possibility is to let $s\to\infty$; then e^{-st} in Equation 22.4 will be zero and the whole left side becomes zero. This can be written as

$$0=\lim_{s\to\infty}[sF(s)-f(0^-)]$$

and because $f(0^-)$ is nothing but the limit of $f(t)$ for $t \to 0^-$, we obtain the initial value theorem

$$\lim_{t\to 0} f(t) = \lim_{s\to\infty} sF(s) \tag{22.6}$$

Note the similarity of the two theorems; we will apply them to the function used in Section 22.1.3. Consider

$$sF(s) = \frac{3s^3 + 8s^2 + 6s}{s^3 + 3s^2 + 4s + 2}$$

If we take any large value of s, the highest powers will dominate and in limit, for $s \to \infty$, we get 3. This is the value of the time-domain response at $t = 0$. The limit for $s = 0$ is zero, and from the final value theorem we know that $f(t)$ will be zero for $t \to \infty$.

To extract still more information, use the example collected in Table 22.2. Scrolling down the table, each Laplace domain function is s times that above it. Each multiplication by s means differentiation in the time domain, as follows from Equation 22.4. Scrolling down the second column of Table 22.2, each function is the derivative of that above it. To apply the limiting theorems, take the Laplace domain formula, which is one level lower, and insert the limits. The limiting is also shown and is confirmed by inserting either $t = 0$ or $t \to \infty$ into the time functions.

Although the two theorems are useful, the final value theorem is valid only if the function is stable. Consider the unstable function with two poles in the right-half plane

$$F_1(s) = \frac{1}{(s+1)(s-1+j)(s-1-j)} = \frac{1}{s^3 - s^2 + 2}$$

Its time-domain response is

$$f_1(t) = \frac{1}{5}[e^{-t} + e^{+t}(2\sin^t - \cos^t)]u(t)$$

and the term e^{+t} will cause the function to grow for large t. If the final value theorem is applied, we consider

$$sF_1(s) = \frac{s}{s^3 + s^2 + 2}$$

Inserting $s = 0$, the theorem predicts that the time function will approach zero for large t. This is disappointing, but some additional simple rules can be applied. The function is unstable if some coefficients of the denominator are missing, or if the denominator coefficients do not all have the

TABLE 22.2 Additional Laplace Transform Pairs

Laplace Domain $D = s^3 + 3s^2 + 4s + 2$	Time Domain	$s \to \infty$ $t = 0$	$s = 0$ $t \to \infty$
$F(s) = 1/D$	$f(t) = e^{-t}(1 - \cos t)u(t)$	0	0
$G(s) = sF(s) = s/D$	$g(t) = f'(t) = e^{-t}(-1 + \cos t + \sin t)u(t)$	0	0
$H(s) = s^2F(s) = s^2/D$	$h(t) = f''(t) = e^{-t}(1 - 2\sin t)u(t)$	1	0
$K(s) = s^3/D$	$k(t) = f'''(t) = \delta(t) + e^{-t}(2\sin t - 2\cos t - 1)u(t)$	$\delta(t)$	0

same sign (all + or all −). Such situations are easily detected, but if all coefficients have the same sign, nothing can be said about stability. Additional theorems exist (e.g., Hurwitz theorem), but if in doubt, it is probably simplest to go to the computer and find the poles.

22.2 Advanced Network Analysis Concepts

John Choma, Jr.

22.2.1 Introduction

The systematic analysis of an electrical or electronic network entails formulating and solving the relevant Kirchhoff equations of equilibrium. The analysis is conducted to acquire a theoretically sound understanding of circuit responses. Such an understanding minimally delineates the dynamical effects of topology, controllable circuit branch variables, and observable parameters for active devices embedded in the circuit. It also illuminates circuit node and branch impedances to which the relevant responses of the circuit undergoing investigation are especially sensitive. Unfortunately, the complexity of modern networks, and particularly integrated analog electronic circuits, often inhibits the mathematical tractability that underpins an engineering understanding of circuit behavior. It is therefore not surprising that when mathematical analyses accompany a computer-assisted circuit design venture, the subcircuits identified for manual study are simplified representations of the corresponding subcircuits in the draft design solution. Unless care is exercised, these approximations can mask a satisfying understanding, and they can even lead to erroneous results.

Analytical and modeling approximations notwithstanding, the key to assimilating a satisfying understanding of the electrical characteristics of complex circuits is appropriate studies of simpler partitions of these circuits. To this end, Kron [1,2] has provided, and others have explained and reinforced [3–5], an elegant theory that allows the circuit response solutions of these network partitions to be coalesced so that the desired response of the interconnected circuit is reconstructed exactly. Aside from formalizing an analytical mechanism for studying complicated circuits in terms of the solutions gleaned for more manageable subcircuits of the composite network [6], Kron's work allows for a computationally efficient study of feedback network responses. The theory also allows for the investigation of the sensitivity of overall network performance with respect to both small and large parametric changes [7]. In view of the exclusive focus on linear circuits in this section, it is worth interjecting that a form of Kron's partitioning theory is also applicable to certain classes of nonlinear circuits [8].

22.2.2 Fundamental Network Analysis Concepts

The derivation of Kron's formula, as well as the development of a general methodology for applying Kron's partitioning mechanism to the analyses of complex circuits, requires a fundamental understanding of the classical techniques exploited in the analysis of linear networks. Such an understanding begins by considering the $(n+1)$ node, b branch linear network abstracted in Figure 22.5a. The input port, which is defined by the node pair, 1–2, is excited by a signal source whose Thévenin voltage is V_S and whose Thévenin impedance is Z_S. In response to this excitation, a load voltage, V_L, is developed across a load impedance, Z_L, which shunts the output port consisting of the node pair, 3–4. Two other nodes, nodes m and p, are explicitly delineated for future reference. In response to the applied signal source, the voltage across the input port is V_I, while the voltage established across the node pair, m–p is V_k. In addition, the reference, or ground, node is labeled node 0. Either node 2, node 4, or both of these nodes can be incident with the ground node; that is, the signal source and/or the load impedance can be terminated to the network ground. The diagram in Figure 22.5b is identical to

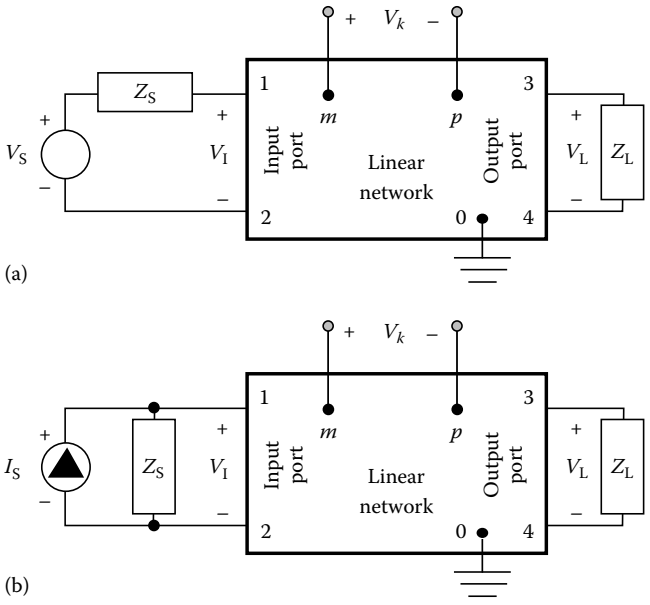

FIGURE 22.5 (a) Generalized linear network driven by a voltage source. (b) The network of (a), but with the signal excitation represented by its Norton equivalent circuit.

that of Figure 22.5a except for the fact that the applied signal source is represented by its Norton equivalent circuit, where the Norton signal current, I_S, is

$$I_S = \frac{V_S}{Z_S} \tag{22.7}$$

Assuming that a nodal admittance matrix exists for the linear $(n+1)$ node network at hand, the n equilibrium Kirchhoff's current law (KCL) equations can be expressed as the matrix relationship

$$\mathbf{J} = \mathbf{YE} \tag{22.8}$$

where

J is an n-vector whose ith entry
J_i is an independent current flowing into the ith circuit node
E is an n-vector of node voltages such that its ith entry
E_i is an ith node voltage referenced to network ground
Y is a square matrix of order n, is the nodal admittance matrix of the circuit

If **Y** is nonsingular, the node voltages follow as

$$\mathbf{E} = \mathbf{Y}^{-1}\mathbf{J} \tag{22.9}$$

Note that Equation 22.9 is useful symbolically, but not necessarily computationally. In particular, Equation 22.9 shows that the n node voltages of the $(n+1)$ node, b branch network of Figure 22.5 can be straightforwardly computed in terms of the known independent current source vector and the parameters embedded in the network nodal admittance matrix. In an actual analytical environment, however, the nodal admittance matrix is rarely formulated and inverted. Instead, some or all of the n

node voltages of interest are determined merely by algebraically manipulating and solving either the n independent KCL equations or the $(b-n)$ independent Kirchhoff's voltage law (KVL) equations that are required to establish the equilibrium conditions of the subject network.

If the n vector, **E**, is indeed evaluated, all n independent node voltages are known, because

$$\mathbf{E}^{\mathrm{T}} = [E_1, E_2, E_3, \ldots, E_m, \ldots, E_p, \ldots, E_n] \tag{22.10}$$

where the superscript T indicates the operation of matrix transposition. In general, E_i, for $i = 1, 2, \ldots, n$, is the voltage developed at node i with respect to ground. It follows that the voltage between any two nodes derives directly from the network solution inferred by Equation 22.9. For example, the input port voltage, V_{I}, is $(E_1 - E_2)$, the output port voltage, V_{L}, is $(E_3 - E_4)$, and the voltage, V_k, from node m to node p is $V_k = (E_m - E_p)$.

The calculation of the voltage appearing between any two circuit nodes can be formalized with the help of the generalized network diagrammed in Figure 22.6 and through the introduction of the connection vector concept. In particular, let $\mathbf{A}_{ij}$ denotes the $(n \times 1)$ connection vector for the port defined by the node pair, i–j. Moreover, let the voltage, V, at node i be taken as positive with respect to node j, and allow a current, I (which may be zero), to flow into node i and out of node j, as indicated in the diagram. Then, the elements of the connection vector, $\mathbf{A}_{ij}$, are all zero except for $a+1$ in its ith row and $a-1$ in its jth row. If node j is the reference node, all elements of $\mathbf{A}_{ij}$, which in the case can be written simply as $\mathbf{A}_i$, are zero except for the ith row element, which remains $+1$. Thus, $\mathbf{A}_{ij}$ has the form

$$\mathbf{A}_{ij}^{\mathrm{T}} = \begin{bmatrix} 0 & 0 & \cdots & \underset{\substack{\downarrow \\ i\text{th column}}}{+1} & \cdots & \underset{\substack{\uparrow \\ j\text{th column}}}{-1} & \cdots & \underset{\substack{\downarrow \\ n\text{th column}}}{0} \end{bmatrix} \tag{22.11}$$

For the special case in which a circuit branch element interconnects every pair of circuit nodes, $\mathbf{A}_{ij}$ is the appropriate column of the node to branch incidence matrix, which is a rectangular matrix of order $(n \times b)$, for the $(n+1)$ node, b branch network at hand [9].

Returning to the calculation of V_{I}, V_{L}, and V_k, it follows from Equations 22.9 through 22.11 that

$$V_{\mathrm{I}} = E_1 - E_2 = \mathbf{A}_{12}^{\mathrm{T}}\mathbf{E} = \mathbf{A}_{12}^{\mathrm{T}}\mathbf{Y}^{-1}\mathbf{J} \tag{22.12}$$

$$V_{\mathrm{L}} = E_3 - E_4 = \mathbf{A}_{34}^{\mathrm{T}}\mathbf{E} = \mathbf{A}_{34}^{\mathrm{T}}\mathbf{Y}^{-1}\mathbf{J} \tag{22.13}$$

and

$$V_k = E_m - E_p = \mathbf{A}_{mp}^{\mathrm{T}}\mathbf{E} = \mathbf{A}_{mp}^{\mathrm{T}}\mathbf{Y}^{1}\mathbf{J} \tag{22.14}$$

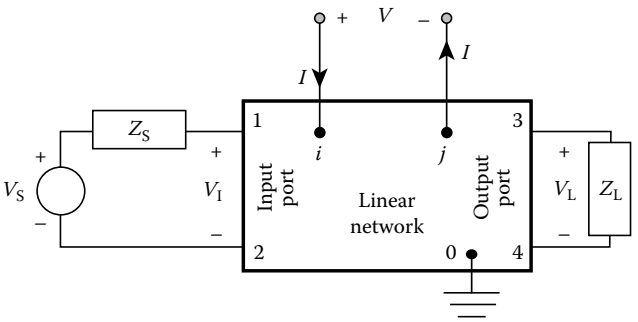

FIGURE 22.6 Generalized network diagram used to define the connection vector concept.

Assuming that I_S is the only independent source of excitation in the network of Figure 22.5

$$\mathbf{J} = \mathrm{A}_{12} I_S \tag{22.15}$$

which is the mathematical equivalent of the observation that the Norton source current, I_S, is entering node 1 of the network and leaving node 2. Accordingly,

$$V_I = \left(\mathbf{A}_{12}^T \mathbf{Y}^{-1} \mathbf{A}_{12}\right) I_S \tag{22.16}$$

$$V_L = \left(\mathbf{A}_{34}^T \mathbf{Y}^{-1} \mathbf{A}_{12}\right) I_S \tag{22.17}$$

and

$$V_k = \left(\mathbf{A}_{mp}^T \mathbf{Y}^{-1} \mathbf{A}_{12}\right) I_S \tag{22.18}$$

Several noteworthy features are implicit to the foregoing three relationships. First, each of the three parenthesized matrix products on the right-hand sides of the equations is a scalar. This observation follows from the facts that a transposed connection vector is a row matrix of order $(1 \times n)$, the inverse nodal admittance matrix is an n-square, and a connection vector is an n-vector. Second, these scalar products represent transimpedances from the input port to the port at which the voltage of interest is extracted. In the case of Equation 22.16, the ratio, $V_I\, I_S$, is actually the impedance, Z_{SS}, seen by the Norton current, I_S; that is,

$$Z_{SS} \triangleq \frac{V_S}{I_S} = \left(\mathbf{A}_{12}^T \mathbf{Y}^{-1} \mathbf{A}_{12}\right) \tag{22.19}$$

where, as asserted previously, I_S is presumed to be the only source of energy applied to the network undergoing study. Similarly,

$$Z_{LS} \triangleq \frac{V_L}{I_S} = \left(\mathbf{A}_{34}^T \mathbf{Y}^{-1} \mathbf{A}_{12}\right) \tag{22.20}$$

is the transimpedance from the input port to the output port, while

$$Z_{kS} \triangleq \frac{V_k}{I_S} = \left(\mathbf{A}_{mp}^T \mathbf{Y}^{-1} \mathbf{A}_{12}\right) \tag{22.21}$$

is the transimpedance from the input port to the port defined by the node pair, m–p.

The impedance in Equation 22.19 and the transimpedances given by Equations 22.20 and 22.21 are cast as explicit algebraic functions of the inverse of the network nodal admittance matrix. However, similar to the node voltages in Equations 22.19 and 22.10, network transimpedances are rarely calculated manually through an actual delineation and inversion of the nodal admittance matrix. Instead, they usually derive from a straightforward analysis of the considered network, subject to the proviso that all excitations applied to the subject network, save for the single test current source, are reduced to zero. For example, in the abstraction shown in Figure 22.7, the transimpedance, Z_{ij}, from any port j to any port i is

$$Z_{ij} \triangleq \left.\frac{V_{\text{test}}}{I_{\text{test}}}\right|_{\text{all independent sources} = 0} \tag{22.22}$$

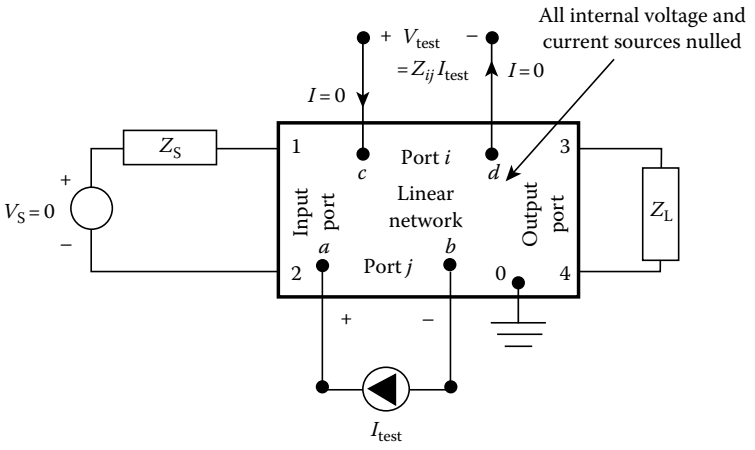

FIGURE 22.7 An illustration of a practical manual technique for computing the transimpedance between any port j to any port i of a linear network.

For the case of $j = i$, this transimpedance becomes the effective impedance seen at port i by the test current source. In view of the preceding discussion, and the node pairs indicated in Figure 22.7, the transimpedance (or impedance) quantity that derives from Equation 22.22 is identical to the matrix relationship

$$Z_{ij} = \left(\mathbf{A}_{cd}^{\mathrm{T}} \mathbf{Y}^{-1} \mathbf{A}_{ab}\right) \tag{22.23}$$

The last result highlights the fact that all network transimpedances are directly related to the inverse of the nodal admittance matrix. Hence, these transimpedances are inversely proportional to the determinant, $\Delta Y(s)$, of the admittance matrix, $\mathbf{Y}$. It follows that the poles of all transimpedances and effective port impedances are the roots of the characteristic polynomial

$$\det(\mathbf{Y}) \triangleq \Delta Y(s) = 0 \tag{22.24}$$

Note from Equations 22.7, 22.17, and 22.20 that the voltage gain of the considered linear network is

$$\frac{V_{\mathrm{L}}}{V_{\mathrm{S}}} = \frac{Z_{\mathrm{LS}}}{Z_{\mathrm{S}}} \tag{22.25}$$

Thus, if the source impedance in Figure 22.5 is a real number, $Z_S = R_S$, the roots of Equation 22.24 also comprise the poles of the voltage transfer function and, indeed, of the linear network.

22.2.3 Kron's Formula

Assume now that the network depicted in Figure 22.5 has been analyzed in the sense that all network node voltages developed in response to the signal source have been determined. Assume further that subsequent to this analysis, an impedance, Z_k, appended to nodes m and p, as shown in Figure 22.8. In addition to causing a current, I, to flow into node m and out of node p, this additional branch element is likely to perturb the values of all of the originally computed circuit node and circuit branch voltages. The matrix, $\mathbf{E}'$, of new node voltages can be evaluated for the modified topology in Figure 22.8 by determining the new nodal admittance matrix $\mathbf{Y}'$, and the reapplying Equation 22.9. The tedium associated with a

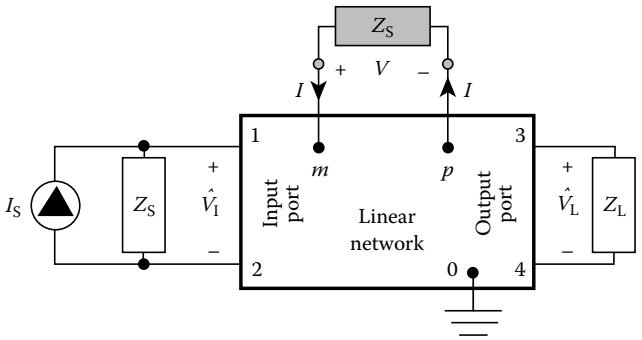

FIGURE 22.8 The inclusion of an impedance, Z_k, between nodes m And p, subsequent to the analysis of the network in Figure 22.5.

second network analysis, along with the inefficiency of discarding the results of a study performed on a network whose topology differs only modestly from that of the original configuration, can be circumvented through the use of Kron's theorem. As illuminated next, this theorem derives from a methodical application of such classical concepts as the theories of superposition, substitution, and Thévenin. In addition to providing a computationally efficient mechanism for determining $\mathbf{E}'$, Kron's technique allows for a direct comparison of $\mathbf{E}'$ to the matrix, $\mathbf{E}$, of original node voltages. It therefore allows for a convenient response sensitivity analysis with respect to the appended branch element.

It is appropriate to interject that the problem postulated previously possesses more than mere academic interest. It is, in fact, a problem that is commonly encountered, for example, in the analysis of electronic circuits. In order to linearize these circuits around specified quiescent operating points, it is necessary to supplant the utilized active devices by small signal equivalent circuits. Such models are invariably simplified, often through the tacit neglect of presumably noncritical branch elements, to mitigate analytical complexity and tedium. Thus, while the circuit properly identified for investigation might be of the topological form appearing in Figure 22.8, the circuit actually subjected to manual circuit analysis is likely the reduced structure depicted in Figure 22.5; that is, the ostensibly noncritical impedance, Z_k is removed in the interest of analytical tractability. Questions naturally arise in regard to the degree of error incurred by the invoked circuit simplification. Kron's method, as developed next, answers these questions in terms of the results already deduced for the approximate network and without requiring explicit analytic results for the ''exact'' network.

The process of evaluating the perturbation on network node voltages incurred by the action of shunting nodes m and p in the circuit of Figure 22.5 by the impedance Z_k begins by determining the Thévenin equivalent circuit that drives the appended branch. To this end, Z_k is removed in the diagram of Figure 22.8, thereby collapsing the network to Figure 22.5a. The relevant Thévenin voltage, V_{th}, at the node pair, mp, is, in fact, V_k, as defined by Equation 22.18. Recalling Equation 22.21, this voltage is

$$V_{\text{th}} \equiv V_k = \left(\mathbf{A}_{mp}^{\text{T}}\mathbf{Y}^{-1}\mathbf{A}_{12}\right)I_{\text{S}} = Z_{k\text{S}}I_{\text{S}} \tag{22.26}$$

The corresponding Thévenin impedance, Z_{th}, derives from a study of the test configuration of Figure 22.9, in which the independent source current, I_{S}, is nulled, the impedance, Z_k, in Figure 22.8 is replaced by a test current of value I_{test}, and the ratio of the resultant port voltage, V_{test}, to I_{test} is understood to be the desired Thévenin impedance. For this configuration, the network nodal admittance matrix, $\mathbf{Y}$, is unchanged, but the independent network current vector, $\mathbf{J}$, becomes $\text{A}_{mp}\,I_{\text{test}}$. Thus, the resultant n-vector, $\mathbf{E}''$, of nodal voltages is

$$\mathbf{E}'' = \mathbf{Y}^{-1}\mathbf{A}_{mp}I_{\text{test}} \tag{22.27}$$

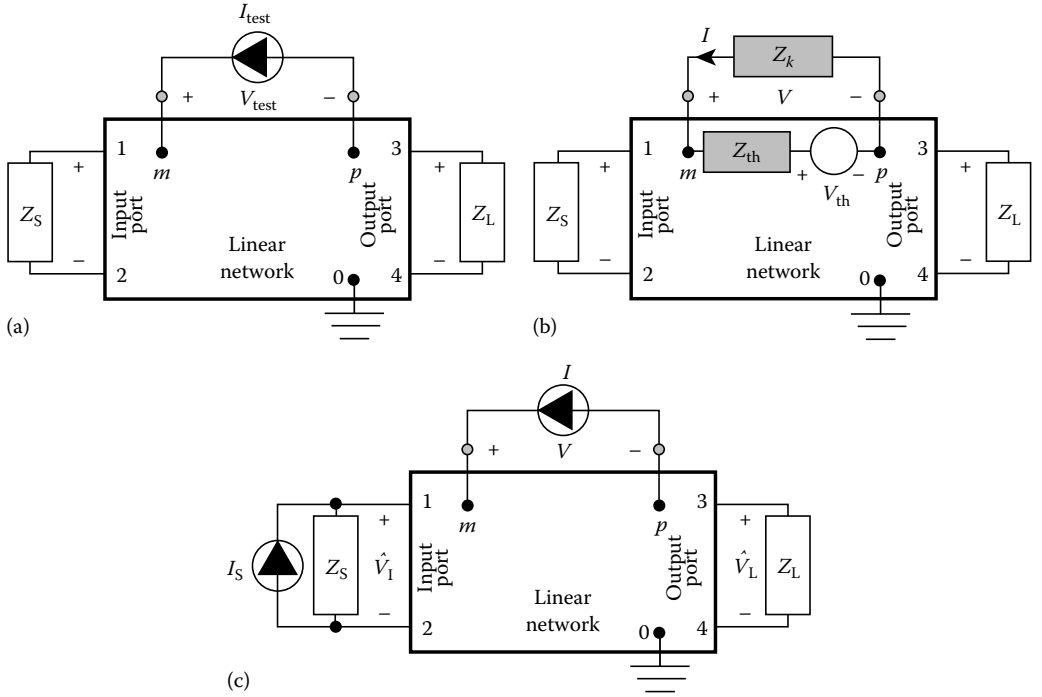

FIGURE 22.9 (a) Circuit diagram for evaluating the Thévenin impedance seen by the appended impedance Z_k. (b) Circuit diagram used to compute the current, I, conducted by Z_k. (c) The application of the substitution theorem with respect to Z_k.

and by Equation 22.8, the voltage, V_{test}, is

$$V_{\text{test}} = \left(\mathbf{A}_{mp}^{\text{T}}\mathbf{Y}^{-1}\mathbf{A}_{mp}\right)I_{\text{test}} \tag{22.28}$$

It follows that the requisite Thévenin impedance, Z_{th}, is

$$Z_{\text{th}} = \frac{V_{\text{test}}}{I_{\text{test}}} = \left(\mathbf{A}_{mp}^{\text{T}}\mathbf{Y}^{-1}\mathbf{A}_{mp}\right) \tag{22.29}$$

Insofar as the appended impedance, Z_k, is concerned, the network in Figure 22.8 behaves in accordance with the circuit abstraction of Figure 22.9. The current, I, conducted by Z_k is, without approximation,

$$I = -\frac{V_{\text{th}}}{Z_{\text{th}} + Z_{\text{k}}} = -\left(\frac{Z_{k\text{S}}}{Z_{\text{th}} + Z_k}\right)I_{\text{S}} \tag{22.30}$$

where Equation 22.26 has been used, and Z_{th} is understood to be given by Equation 22.29. However, by the substitution theorem, the impedance, Z_k in Figure 22.8 can be supplanted by an independent current source of value I, as suggested in Figure 22.9c. Specifically, this substitution of the impedance of interest with a current source with a value that is dictated by Equation 22.30 guarantees that the n-vector of node voltages for the modified circuit in Figure 22.9c is identical to the n-vector, E', of node voltages for the topology given in Figure 22.8.

The circuit of Figure 22.9c now has two independent excitations: the original current sources, I_S, and the current, I, substituted for the appended impedance, Z_k. Accordingly, the current source vector for the subject circuit superimposes two current components and is given by

$$\mathbf{J} = \mathbf{A}_{12} I_S + \mathbf{A}_{mp} I = \mathbf{A}_{12} I_S - \mathbf{A}_{mp} \left(\frac{Z_{kS}}{Z_{th} + Z_k} \right) I_S \tag{22.31}$$

The corresponding vector of node voltages is, by Equation 22.9,

$$\mathbf{E}' = \mathbf{Y}^{-1} \left[\mathbf{A}_{12} - \mathbf{A}_{mp} \left(\frac{Z_{kS}}{Z_{th} + Z_k} \right) \right] I_S \tag{22.32}$$

If analytical attention focuses on the general output voltage, $\hat{V}_{ij}$, developed between nodes i and j in the circuit of Figure 22.8,

$$\hat{V}_{ij} = \mathbf{A}_{ij}^{T} \mathbf{E}' \tag{22.33}$$

where

$$\hat{V}_{ij} = \left[\left(\mathbf{A}_{ij}^{T} \mathbf{Y}^{-1} \mathbf{A}_{12} \right) - \left(\mathbf{A}_{ij}^{T} \mathbf{Y}^{-1} \mathbf{A}_{mp} \right) \left(\frac{Z_{kS}}{Z_{th}} + Z_k \right) \right] I_S \tag{22.34}$$

The result in Equation 22.34 is one of many possible versions of Kron's formula. It states that when an impedance, Z_k, is appended between nodes m and p of a linear network whose nodal admittance matrix is $\mathbf{Y}$, the perturbed voltage established between any two nodes, i and j, can be determined as a function of the parameters indigenous to the original network (prior to the inclusion of Z_k). In particular, the evaluation is executed on the original network (with Z_k absent) and exploits the original nodal admittance matrix, $\mathbf{Y}$, the original transimpedance, Z_{kS}, between the input port and the port to which Z_k is ultimately appended, and the Thévenin impedance, Z_{th}, is observed when looking into the terminal pair to which Z_k is connected.

22.2.4 Engineering Application of Kron's Formula

The engineering utility of Kron's formula, Equation 22.34, is best demonstrated by examining the voltage transfer function of the network in Figure 22.8 in terms of the companion gain for the network depicted in Figure 22.5a. Using Equation 22.7 and noting that the perturbed output voltage is developed from node 3 to node 4, the perturbed voltage gain, $\hat{A}_v$, is

$$\hat{A}_v \triangleq \frac{\hat{V}_L}{V_S} = \frac{\mathbf{A}_{34}^{T} \mathbf{Y}^{-1} \mathbf{A}_{12}}{Z_S} - \left(\frac{\mathbf{A}_{34}^{T} \mathbf{Y}^{-1} \mathbf{A}_{mp}}{Z_S} \right) \left(\frac{Z_{kS}}{Z_{th} + Z_k} \right) \tag{22.35}$$

The first matrix product on the right-hand side of this relationship represents the transimpedance, Z_{LS}, from the input port to the output port of the original network, as given by Equation 22.20. Moreover, the resultant impedance ratio, Z_{LS}/Z_S, is the voltage gain, A_v, of the original ($Z_k = \infty$) network, as delineated in Equation 22.25. The second matrix product symbolizes the transimpedance, Z_{Lk}, from the port to which the appended impedance, Z_k, is connected to the output port; that is,

$$Z_{Lk} = \mathbf{A}_{34}^{T} \mathbf{Y}^{-1} \mathbf{A}_{mp} \tag{22.36}$$

Assuming $A_v \neq 0$, Equation 22.35 can then be reduced to

$$\hat{A}_v = A_v\left[1 - \left(\frac{Z_{Lk}}{Z_{LS}}\right)\left(\frac{Z_{kS}}{Z_{th} + Z_k}\right)\right] \tag{22.37}$$

This result expresses the perturbed voltage gain as a function of the original voltage gain, A_v, the input to output transimpedance, Z_{LS}, the transimpedance, Z_{kS}, from the input port to the port at which Z_k is appended, and Z_{Lk}, the transimpedance from the port to which Z_k is incident to the output port. Observe that when the appended impedance is infinitely large, the perturbed gain reduces to the original voltage gain, as expected.

In an actual analytical situation, however, all of the transimpedances indicated in Equation 22.37 need not be calculated. In order to demonstrate this contention, rewrite Equation 22.37 in the form

$$\hat{A}_v = A_v\left[\frac{1 + Y_k(Z_{th} - (Z_{Lk}Z_{kS}/Z_{LS}))}{1 + Y_k Z_{th}}\right] \tag{22.38}$$

where

$$Y_k = \frac{1}{Z_k} \tag{22.39}$$

is the admittance of the appended impedance, Z_k. Now consider the test structure of Figure 22.10a, which is the modified circuit shown in Figure 22.8, but with the appended branch supplanted by a test current source, I_{test}. With two sources, I_S and I_{test}, activating the network, superposition yields a resultant output port voltage, V_{LL}, of

$$V_{LL} = Z_{LS}I_S + Z_{Lk}I_{test} \tag{22.40}$$

and a test port voltage, V_{test}, of

$$V_{test} = Z_{kS}I_S - Z_{kk}I_{test} \tag{22.41}$$

For $I_S = 0$, the network in Figure 22.10a reduces to the configuration in Figure 22.9a, and Equation 22.41 delivers $V_{test}/I_{test} = Z_{kk}$. It follows that the impedance parameter, Z_{kk}, is the Thévenin impedance seen by

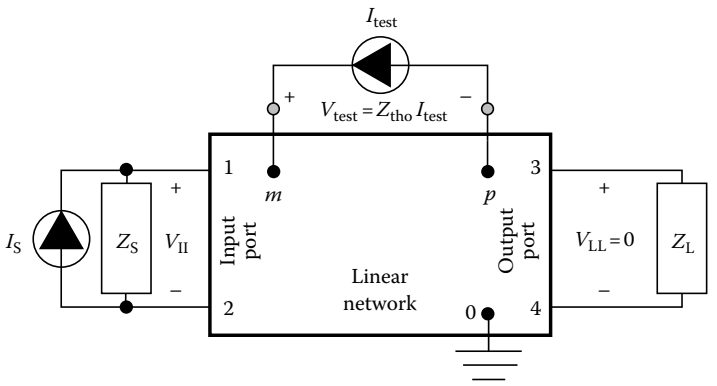

FIGURE 22.10 Network diagram pertinent to the computation of the null Thévenin impedance seen by the impedance appended to the node pair, *m*–*p*.

Z_k, as determined in conjunction with an analytical consideration of Figure 22.5a; that is, Equation 22.41 is equivalent to the expression

$$V_{\text{test}} = Z_{k\text{S}} I_{\text{S}} + Z_{\text{th}} I_{\text{test}} \tag{22.42}$$

Consider the case, suggested in Figure 22.10, in which the output port voltage, V_{LL}, is constrained to zero for any and all values of the load impedance, Z_{L}. From Equation 22.40, this case requires a source excitation that satisfies

$$I_{\text{S}} = -\left(\frac{Z_{\text{L}k}}{Z_{\text{LS}}}\right) I_{\text{test}} \tag{22.43}$$

If this result is substituted into Equation 22.42, the ratio, $V_{\text{test}}/I_{\text{test}}$, is found to be

$$\frac{V_{\text{test}}}{I_{\text{test}}} = Z_{\text{th}} - \frac{Z_{\text{L}k} Z_{k\text{S}}}{Z_{\text{LS}}} \tag{22.44}$$

which mirrors the parenthesized numerator term on the right-hand side of Equation 22.38. The ratio in Equation 22.44 might rightfully be termed a null Thévenin impedance, Z_{tho}, seen by Z_k, in the sense that it is indeed the Thévenin impedance witnessed by Z_k, but under the special circumstance of a nonzero source excitation selected to null the output response variable of the network undergoing investigation. Thus, in Figure 22.10,

$$\left.\frac{V_{\text{test}}}{\text{I}_{\text{test}}}\right|_{\substack{\text{Source}\neq 0 \\ \text{Output}=0}} \triangleq Z_{\text{tho}} = Z_{\text{th}} - \frac{Z_{\text{L}k} Z_{k\text{S}}}{Z_{\text{LS}}} \tag{22.45}$$

Equation 22.38 now reduces to the simpler result

$$\hat{A}_{\text{v}} = A_{\text{v}} \left(\frac{1 - Y_k Z_{\text{tho}}}{1 + Y_k Z_{\text{th}}}\right) = A_{\text{v}} \left(\frac{1 + (Z_{\text{tho}}/Z_k)}{1 + (Z_{\text{th}}/Z_k)}\right) \tag{22.46}$$

Equation 22.46 is both computationally useful and philosophically important. From a computational viewpoint, it allows for an efficient evaluation of the voltage transfer function of a linear network, perturbed by the addition of an impedance element between two extant nodes of the network, in terms of the voltage gain of the original, unperturbed circuit. As expected, this original voltage gain, A_{v}, is the voltage gain of the perturbed network for the special case of a perturbing impedance where the admittance is zero (or whose impedance value is infinitely large). Only two other parameters are required to complete the evaluation of the perturbed gain. The first is the Thévenin impedance, Z_{th}, seen by the appended impedance element. This Thévenin impedance is calculated traditionally by nulling all independent sources applied to the subject network. The second parameter is the null Thévenin impedance, Z_{tho}, which is the value of Z_{th} for the special circumstance of a test current source and independent source excitations selected to constrain the output response variable to zero. Once Z_{tho} and Z_{th} are determined, the degree to which the voltage transfer function is dependent on the appended impedance is easily determined. For example, the per-unit change in gain owing to the addition of Z_k between nodes m and p in the network of Figure 22.8 is

$$\frac{\Delta A_{\text{v}}}{A_{\text{v}}} = \frac{\hat{A}_{\text{v}} - A_{\text{v}}}{A_{\text{v}}} = \frac{Z_{\text{tho}} - Z_{\text{th}}}{Z_k + Z_{\text{th}}} \tag{22.47}$$

it is important to note that the transfer function sensitivity implied by Equation 22.47 imposes no *a priori* restrictions on the value of Z_k. In particular, Z_k can assume any value from that of a short circuit to that of the opposite extreme of an open circuit.

From a philosophical perspective, when analytical attention focuses explicitly on feedback circuits, Equation 22.46 can be derived from signal flow theory [10,11] and is actually Bode's classical gain equation [12]. In the context of Bode's theory Y_k is referred to as a reference parameter, or a critical parameter, of the feedback circuit. The product, Y_kZ_{th}, is termed the return ratio with respect to the critical parameter, while the product Y_kZ_{tho}, is identified as the null return ratio with respect to the critical parameter. Finally, when Equation 22.46 is applied as Bode's equation, the transfer function, A_v is termed the null transfer function, in the sense that it is the actual transfer function of the network at hand, under the special case of a critical parameter constrained to zero.

Example 22.1

In an attempt to demonstrate the engineering utility of the foregoing theoretical disclosures, consider the problem of determining the voltage gain of the common emitter amplifier—a schematic diagram is offered in Figure 22.11a. Without detracting from the primary intent of this example, the schematic diagram at hand has been simplified in that requisite biasing subcircuitry is not shown. Assuming that the bipolar junction transistor embedded in the amplifier operates in its linear regime, the pertinent small signal equivalent circuit is the topology depicted in Figure 22.11b.

Assume that the amplifier source resistance, R_S, is 600 Ω and that the load resistance, R_K, is 10 kΩ. Assume further that the model parameters for the transistor are as follows: r_b (internal emitter resistance) = 2.5 Ω, r_0 (forward early resistance) = 18 kΩ, β (forward short circuit current gain) = 90, and r_c (internal collector resistance) = 70 Ω. Determine the voltage gain of the amplifier and the effect exerted on the gain by neglecting the early resistance, R_0.

Solution

1. Analytical simplicity traditionally dictates the tacit neglect of the forward Early resistance, r_0. This commonly invoked approximation reduces the model given in Figure 22.11b to the equivalent circuit in Figure 22.12a. By inspection of the latter diagram, the approximate gain of the common emitter voltage is

$$A_v = \frac{V_O}{V_S} = -\frac{\beta R_L}{R_S + r_b + r_\pi + (\beta + 1)r_e} = -388.3 \text{ v/v}$$

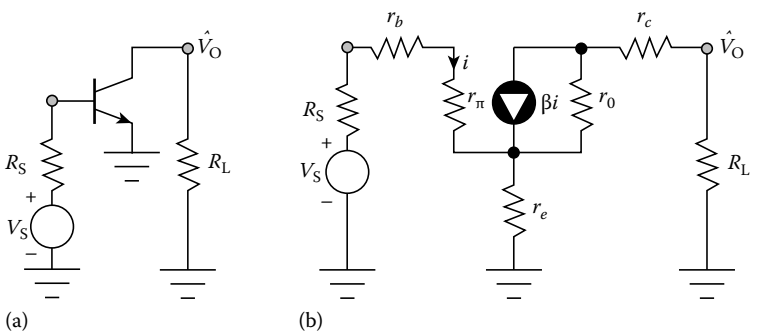

FIGURE 22.11 (a) Simplified schematic diagram of a common emitter amplifier. (b) The small signal equivalent circuit of the common emitter amplifier.

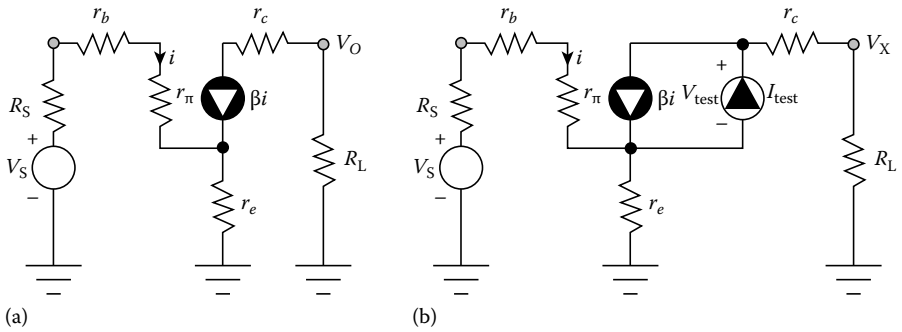

FIGURE 22.12 (a) The approximate small signal equivalent circuit of the common emitter amplifier in Figure 22.11a. The approximation entails the tacit neglect of the forward Early resistance, r_0. (b) The test equivalent circuit used to compute the Thévenin and the null Thévenin resistances seen by r_0 in (a).

2. In order to determine the impact that r_0 has on this voltage gain, r_0 is removed from the equivalent circuit and replaced by a test current source, I_{test}, as depicted in Figure 22.12b. With the independent input voltage, V_S, set to zero, the Thévenin resistance seen by r_0, which is the ratio, V_{test}/I_{test}, is easily shown to be

$$R_{th} = r_e \left\| \left(\frac{R_S + r_b + r_n}{\beta + 1} \right) + \frac{r_c + R_L}{1 + \dfrac{\beta r_e}{R_S + r_b + r_\pi + r_e}} = 9.10 \text{ k}\Omega \right.$$

On the other hand, if V_X is constrained to zero, no current flows through the load resistance branch, and therefore, I_{test} is necessarily βi. This condition gives a null Thévenin resistance of

$$R_{tho} = -\frac{r_e}{\beta} = -27.78 \times 10^{-3} \ \Omega$$

3. With $A_v = -388.3$ v/v, $Z_k = r_0 = 18$ kΩ, $Z_{th} = R_{th} = 9.10$ kΩ, and $Z_{tho} = R_{tho} = -27.78 \times 10^{-3}$ Ω, Equation 22.46 produces a corrected voltage gain of

$$\hat{A}_v = A_v \left(\frac{1 + \dfrac{R_{tho}}{r_0}}{1 + \dfrac{R_{th}}{r_0}} \right) = -258.0 \text{ v/v}$$

From Equation 22.47, the presence of r_0, as opposed to its absence, decreases the voltage gain of the subject amplifier by almost 34%.

Example 22.2

As a second example, consider the series-shunt feedback amplifier whose schematic diagram, neglecting requisite biasing circuitry, appears in Figure 22.13a. The analysis of this circuit is simplified by the removal of the connection of the feedback resistance, R_F, at the emitter of transistor Q_1, as shown in Figure 22.13b. If the voltage gain of the simplified topology is denoted as A_v, the voltage gain of the closed loop configuration in Figure 22.13a derives from Equation 22.46, provided that the impedance, Z_k, between the indicated node pair, m–p, is taken as a short circuit; that is, $Z_k = 0$.

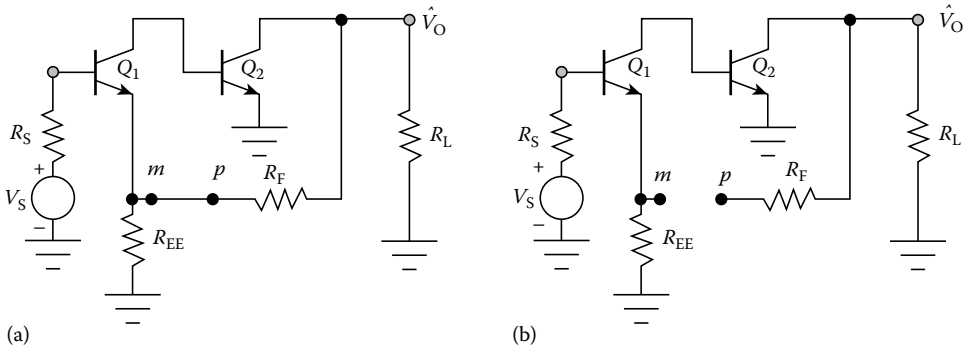

FIGURE 22.13 (a) Simplified schematic diagram of a series-shunt feedback bipolar junction transistor amplifier. The biasing subcircuitry is not shown. (b) The amplifier in (a), but with the feedback resistance connection to the emitter of transistor Q_1 removed.

Assume that the amplifier source resistance, R_S, is 300 Ω, the load resistance, R_L, is 3.5 kΩ, the feedback resistance, R_F, is 1.5 kΩ, and the emitter degeneration resistance, R_{EE}, is 100 Ω. The transistor model invoked for small signal analysis is identical to that used in the preceding example, save for the proviso that the Early resistance, r_0, is ignored herewith. Both transistors are presumed to have identical small signal model parameters as follows: $r_b = 90\ \Omega$, $r_\pi = 1.4$ kΩ, $r_e = 2.5\ \Omega$, $\beta = 90$, and $r_c = 70\ \Omega$. Use Kron's theorem to determine the voltage gain of the closed loop series-shunt feedback amplifier.

Solution

1. The voltage gain of the pertinent equivalent circuit in Figure 22.14 is straightforwardly derived as

$$A_v = \frac{V_O}{V_S} = \frac{\beta^2 R_L}{R_S + r_b + r_\pi + (\beta + 1)(r_e + R_{EE})} = 2550 \text{ v/v}$$

   Observe that the feedback resistance, R_F, does not enter into this calculation because of its disconnection at the emitter of transistor Q_1. Furthermore, the internal collector resistance, r_c, is inconsequential for both transistor stages because the neglect of the forward Early resistance, r_0, places r_c in series with a controlled current source.
2. The Thévenin resistance, R_{th}, seen by the ultimately appended short circuit between nodes m and p is now calculated through use of the model in Figure 22.14b. For this calculation, the signal voltage, V_S, is reduced to zero. With $V_S = 0$,

$$\frac{i_1}{i_{test}} = -\frac{R_{EE}}{R_S + r_b + r_\pi + (\beta + 1)(r_e + R_{EE})}$$

   Noting that $i_2 = -\beta i_1$, KVL yields

$$V_{test} = (R_{EE} + R_L + R_F)I_{test} + \left[(\beta + 1)R_{EE} - \beta^2 R_L\right] i_1$$

   Using the preceding result, introducing the resistance variable, R_X, such that

$$R_X \triangleq r_e + \frac{R_S + r_b + r_\pi}{\beta + 1} = 22.17\ \Omega$$

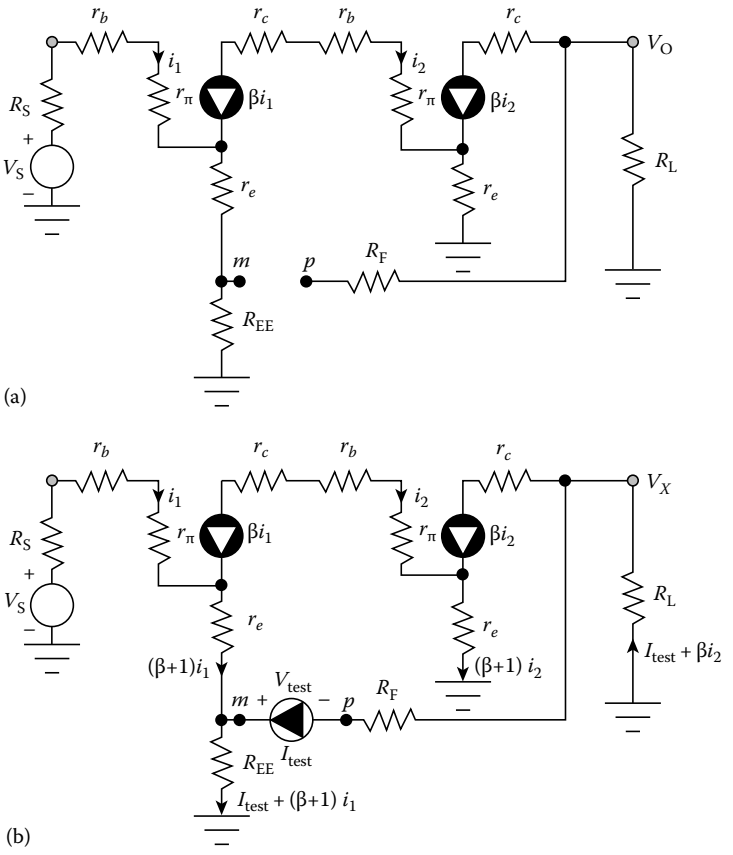

FIGURE 22.14 (a) Small signal equivalent circuit of the feedback amplifier in Figure 22.13b. This circuit is used to compute the voltage gain with the feedback resistance disconnected at the emitter of transistor Q_1. (b) The small signal model used to compute the Thévenin and the null Thévenin resistances seen by the short circuit that is ultimately appended to the node pair, m–p, in Figure 22.13b.

and letting

$$\alpha \triangleq \frac{\beta}{\beta + 1} = 0.989$$

R_{th}, which is the ratio V_{test}/I_{test}, is found to be

$$R_{th} = R_F + (R_{EE}|R_X)\left(1 + \frac{\alpha\beta R_{EE}}{R_{EE} + R_X}\right)R_L = 260.0\ \text{k}\Omega$$

3. For the evaluation of null Thévenin resistance, R_{tho}, the output voltage variable, V_X, in Figure 22.14b is nulled, thereby forcing the current relationship, $I_{test} = -\beta i_2 = +\beta^2 i_1$. Accordingly,

$$R_{tho} = R_F + \left(1 + \frac{1}{\alpha\beta}\right)R_{EE} = 1601\ \Omega$$

4. With $Z_k = 0$, $Z_{th} = R_{th} = 260$ kΩ, and $Z_{tho} = R_{tho} = 1601$ Ω, Equation 22.46 provides, after reconnection of the feedback element, an amplifier gain of

$$\hat{A}_v = A_v\left(\frac{R_{tho}}{R_{th}}\right) = 15.70 \text{ v/v}$$

It is interesting to note that, if the transistors utilized in the feedback amplifier have very large β, which is tantamount to very small R_X and $a \approx 1$, the voltage gain with the feedback element disconnected is

$$a_v \approx \frac{\beta R_L}{R_{EE}}$$

Moreover,

$$R_{th} \approx \beta R_L$$

and

$$R_{tho} \approx R_F + R_{EE}$$

It follows from Equation 22.46 that the approximate voltage gain, subsequent to the reconnection of the feedback resistance, R_F, to the emitter of transistor Q_1 is

$$\hat{A}_v = A_v\left(\frac{R_{tho}}{R_{th}}\right) \approx \left(\frac{\beta R_L}{R_{EE}}\right)\left(\frac{R_F + R_{EE}}{\beta R_L}\right) = 1 + \frac{R_F}{R_{EE}} = 16 \text{ v/v}$$

which is within 2% of the accurately estimated voltage gain.

22.2.5 Generalization of Kron's Formula

The Kron–Bode equation in Equation 22.46 was derived expressly for investigating the voltage transfer function of a linear network to which an impedance element is appended between two network nodes. This equation also can be adapted to the problem of determining the explicit dependence of any type of transfer relationship on any parameter within any linear network.

To this end, consider any linear network, such as the generalization shown in Figure 22.15, whose, load impedance is Z_L and whose source impedance is Z_S. Identify a critical network parameter, say P, to which the dependence on, and sensitivity to, the overall transfer performance of the network undergoing study

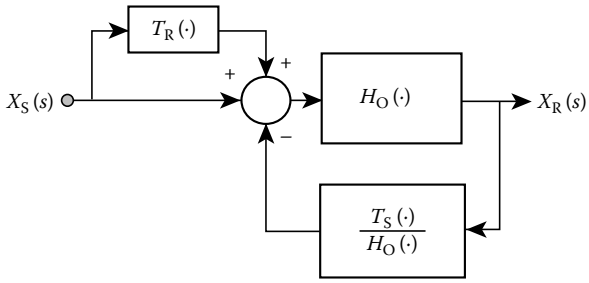

FIGURE 22.15 Generalized block diagram nodel of the I–O transfer characteristics of a linear network.

is of particular interest. This parameter can be, for example, a circuit branch impedance or an active element gain factor where numerical values cannot be determined accurately or controlled adequately in view of potentially unacceptable manufacturing tolerances or device fabrication uncertainties. Let the transfer function of interest be

$$H(P, Z_S, Z_L) = \frac{X_R(s)}{X_S(s)} \tag{22.48}$$

where

$X_R(s)$ denotes the transform of the voltage or current response variable
$X_S(s)$ is the transform of the voltage or current input variable

The functional notation, $H(P, Z_S, Z_L)$, underscores the observation that the transfer function of the liner network is likely to be dependent on the critical parameter, P, the source impedance, Z_S, and the load impedance, Z_L. The corresponding extension of the Kron–Bode relationship is

$$H(P, Z_S, Z_L) = \frac{X_R(s)}{X_S(s)} = H(0, Z_S, Z_L)\left[\frac{1 + PQ_R(Z_S, Z_L)}{1 + PQ_S(Z_S, Z_L)}\right] \tag{22.49}$$

where $H(0, Z_S, Z_L)$, termed the null gain or zero parameter gain, signifies the value of the network transfer function, $H(P, Z_S, Z_L)$, when P is set to zero. This null gain must be finite and nonzero. With reference to the appended impedance formulation in Equation 22.46, observe that the critical parameter, P, is Y_k, the admittance of the appended impedance element, while $H(0, Z_S, Z_L)$ is the gain, A_v, of the network, under the condition of an absent impedance element ($Y_k = 0$).

The product, $PQ_S(Z_S, Z_L)$, is termed the return ratio with respect to parameter P, $T_S(P, Z_S, Z_L)$, and the product, $PQ_R(Z_S, Z_L)$, is referred to as the null return ratio with respect to P, $T_R(P, Z_S, Z_L)$, that is,

$$T_R(P, Z_S, Z_L) \triangleq PQ_R(Z_S, Z_L) \tag{22.50a}$$

$$T_S(P, Z_S, Z_L) \triangleq PQ_S(Z_S, Z_L) \tag{22.50b}$$

It is to be understood that both $Q_S(Z_S, Z_L)$ and $Q_R(Z_S, Z_L)$ are independent of the critical parameter, P. With reference once again to Equation 22.46, note that $Q_S(Z_S, Z_L)$ is the Thévenin impedance seen by the appended admittance, Y_k, while $Q_S(Z_S, Z_L)$ is the null Thévenin impedance facing Y_k.

Equation 22.49 can now be rewritten as

$$H(P, Z_S, Z_L) = \frac{X_R(s)}{X_S(s)} = H(0, Z_S, Z_L)\left[\frac{1 + T_R(P, Z_S, Z_L)}{1 + T_S(P, Z_S, Z_L)}\right] \tag{22.51}$$

Alternatively,

$$H(P, Z_S, Z_L) = \frac{X_R(s)}{X_S(s)} = H(0, Z_S, Z_L)\left[\frac{F_R(P, Z_S, Z_L)}{F_S(P, Z_S, Z_L)}\right] \tag{22.52}$$

where

$$F_S(P, Z_S, Z_L) \triangleq 1 + T_S(P, Z_S, Z_L) \tag{22.53a}$$

$$F_R(P, Z_S Z_L) \triangleq 1 + T_R(P, Z_S, Z_L) \tag{22.53b}$$

respectively, denote the return difference with respect to P and the null return difference with respect to P.

An initial appreciation of the engineering significance of the zero parameter gain, $H(0, Z_S, Z_L) + H_0(\cdot)$, the return ratio, $T_S(P, Z_S, Z_L) + T_S(\cdot)$, and the null return ratio, $T_R(P, Z_S, Z_L) + T_R(\cdot)$, is gleaned by using Equation 22.51 to write

$$X_R(s) = H_0(\cdot)[1 + T_R(\cdot)]X_S(s) - T_S(\cdot)X_R(s) \tag{22.54}$$

In view of the generality of the Kron–Bode formula, this algebraic manipulation of Equation 22.51 implies that the dynamical input/output transfer relationship of all linear networks can be symbolically represented by the block diagram offered in Figure 22.15. This block diagram makes clear that because $T_S(\cdot)$ and $T_R(\cdot)$ are zero for $P = 0$, $H_0(\cdot)$ is the gain afforded by the network as a result of input–output electrical paths that exclude the parameter, P. The diagram also suggests that $T_S(\cdot)$ is a measure of the amount of feedback incurred by parameter P around that part of the circuit that excludes parameter P. Finally, the diagram at hand implies that $T_R(\cdot)$ is a measure of the amount of feedforward incurred by parameter P. In particular, if feedback is removed, two paths remain for the transmission of a signal from the input port to the output port of a linear network. One of these paths, the transmittance of which is measured by $H_0(\cdot)$, is direct and entails the processing of the input signal by that part of the circuit that excludes P. The other nonfeedback path has an effective transmittance of $T_R(\cdot)\, H_0(\cdot)$. The latter path is the feedforward path in the sense that signal is processed through a signal path that is divorced from feedback and is not a result of direct source coupling through the topological part of the network that excludes parameter P.

22.2.6 Return Ratio Calculations

In the generalized transfer relationship of Equation 22.49, the critical parameter, P, can assume one of only six possible forms: circuit branch admittance, circuit branch impedance, transimpedance, transadmittance, gain associated with a current-controlled current source (CCCS), and gain associated with a voltage-controlled voltage source (VCVS) [13]. The methodology underlying the computation of the return ratio and the null return ratio with respect to each of these critical parameter possibilities is given below. The case of $P = Y_k$, a circuit branch admittance, was investigated in the context of Kron's partitioning theorem. Nevertheless, it is reinvestigated next for the purpose of establishing an analytical common denominator for return ratio calculations with respect to the five other reference parameter possibilities.

22.2.6.1 Circuit Branch Admittance

Consider the network abstraction of Figure 22.16a, which identifies a branch admittance, Y_k, as a critical parameter for analysis; that is, $P = Y_k$ in Equation 22.49. The input excitation can be either a voltage source, or a current source and is therefore indicated as a general transformed input variable, $X_S(s)$. Similarly, the output or response variable can be either a voltage or a current, thereby encouraging the generalized transformed response notation, $X_R(s)$. The source and load impedances (or admittances) are absorbed into the network. In order to evaluate the zero parameter gain, $H(0, Z_S, Z_L)$, Y_k is set to zero by removing it from the network. An analysis is then conducted to determine the ratio $X_R(s)/X_S(s)$, of output to input variables, as suggested in Figure 22.16b.

As demonstrated for the case of $P = Y_k$, a circuit branch admittance, the function, $Q_S(Z_S, Z_L)$, in Equation 22.49 is the Thévenin impedance, Z_{th}, facing Y_k. This impedance is computed by determining the ratio, V_x/I_x, with the signal source, $X_S(s)$, nulled, as indicated in Figure 22.16c. Note in Figure 22.16a, that the volt–ampere relationship of the branch housing Y_k is $I_k = Y_k V_k$, where the direction of the branch current, I_k, coincides with the direction of the test current source, I_x, used in the determination of Z_{th}.

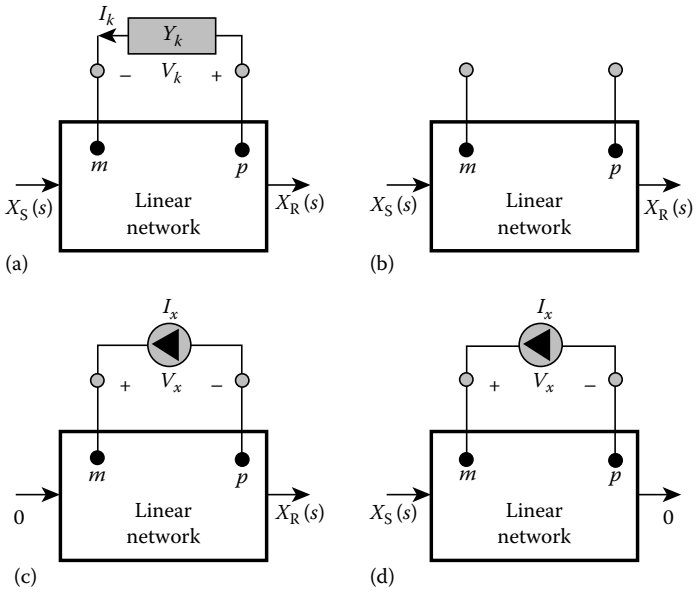

FIGURE 22.16 (a) Linear circuit for which the identified critical parameter is a branch admittance, Y_k. (b) The ratio, $X_R(s)/X_S(s)$, is the zero parameter gain $H(0, Z_S, Z_L)$. (c) The ratio, V_x/I_x, is the function $Q_S(Z_S, Z_L)$, in Equation 22.49. (d) The ratio, V_x/I_x, is the function, $Q_R(Z_S, Z_L)$, in Equation 22.49.

A comparison Figure 22.16c and alludes to the methodology of replacing the admittance branch by a source of excitation (a current source) where the electrical nature is identical to the dependent electrical variable (a current, I_k) of the branch volt–ampere characteristic. Note that the polarity of the voltage, V_x, used in the determination of the test ratio, V_x/I_x, is opposite to that of the original branch voltage V_k. This is to say that although I_k and V_k are in associated reference polarity in Figure 22.16a, I_x and V_x in the test cell of Figure 22.16c are in disassociated polarity.

The computation of the function, $Q_R(Z_S, Z_L)$, in Equation 22.49 mirrors the computation of $Q_S(Z_S, Z_L)$, except for the fact that instead of setting the source excitation to zero, the output response, $X_R(s)$, is nulled. The source excitation, $X_S(s)$, remains at some computationally unimportant nonzero value, such that its effects, when superimposed over those of the test current, I_x, forces $X_R(s)$ to zero. The situation at hand is diagrammed in Figure 22.16d.

Example 22.3

Return to the series-shunt feedback amplifier of Figure 22.29a. Evaluate the voltage gain of the circuit, but, take the conductance, G_F, of the feedback resistance, R_F, as the critical parameter. The circuit and device model parameters remain the same as in Example 22.2: $R_S = 300\ \Omega$, $R_L = 3.5\ k\Omega$, $R_F = 1.5\ k\Omega$, $R_{EE} = 100\ \Omega$, $r_b = 90\ \Omega$, $r_\pi = 1.4\ k\Omega$, $r_e = 2.5\ \Omega$, $\beta = 90$, and $r_c = 70\ \Omega$.

Solution

1. The zero parameter voltage gain, A_{vo}, of the subject amplifier is the voltage gain of the circuit with $G_F = 0$. But $G_F = 0$ amounts to a removal of the feedback resistance, R_F. Such removal is electrically equivalent to open circuiting the indicated node pair, *m–p*, as diagrammed in the small signal

model of Figure 22.14a. Thus, A_{vo} is identical to the gain, computed in Step (1) of Example 22.2. In particular,

$$A_{vo} = \frac{\beta^2 R_L}{R_S + r_b + r_\pi + (\beta + 1)(r_e + R_{EE})} = 2550 \text{ v/v}$$

2. The model pertinent to computing the functions, $Q_S(Z_S, Z_L)$, and $Q_R(Z_S, Z_L)$, is offered in Figure 22.17. Note that the test current source, I_x, which replaces the critical conductance element, G_F, and the resultant test response voltage, V_x, are in disassociated reference polarity. As in Example 22.2, let

$$R_X \triangleq r_e + \frac{R_S + r_b + r_\pi}{\beta + 1} = 22.17$$

and

$$\alpha \triangleq \frac{\beta}{\beta + 1} = 0.989$$

Then, with $V_S = 0$, and writing $Q_S(Z_S, Z_L)$ as $Q_S(R_S, R_L)$ because of the lack of energy storage elements in the circuit undergoing study,

$$Q_S(R_S, R_L) = \left.\frac{V_x}{I_x}\right|_{V_S=0} = R_{EE} \parallel R_X + \left(1 + \frac{\alpha\beta R_{EE}}{R_{EE} + R_X}\right) R_L' = 258.5 \text{ k}\Omega$$

On the other hand,

$$Q_R(R_S, R_L) = \left.\frac{V_x}{I_x}\right|_{V_O=0} = \left(1 + \frac{1}{\alpha\beta}\right) R_{EE} = 101.1 \ \Omega$$

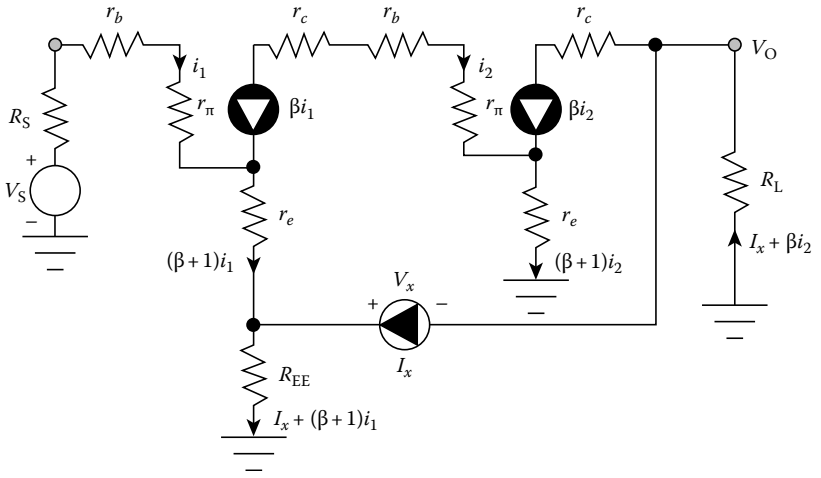

FIGURE 22.17 Circuit used to computer the return ratio and the null return ratio with respect to the conductance, G_F, in the series-shunt feedback amplifier of Figure 22.13a.

3. Substituting the preceding results into Equation 22.49, and recalling that $G_F = 1/R_F$, the voltage gain of the series-shunt feedback amplifier is found to be

$$A_v = \frac{V_O}{V_S} = A_{vo}\left[\frac{1 + \dfrac{Q_R(R_S, R_L)}{R_F}}{1 + \dfrac{Q_S(R_S, R_L)}{R_F}}\right] = 15.7 \text{ v/v}$$

which is the gain result deduced previously.

22.2.6.2 Circuit Branch Impedance

In the circuit of Figure 22.18a, a branch impedance, Z_k, is selected as a critical parameter for analysis; that is $P = Z_k$ in Equation 22.49. The zero parameter gain, $H(0, Z_S, Z_L)$, is evaluated by replacing Z_k with a short circuit, as suggested in Figure 22.18b.

The volt–ampere characteristic equation of the critical impedance branch is $V_k = Z_k I_k$, where, of course, the branch voltage, V_k, and the branch current, I_k, are in associated reference polarity. Because the dependent variable in this volt–ampere expression is a branch voltage, the return and null return ratios are calculated by replacing the subject branch impedance by a test voltage source, V_x. As suggested in Figure 22.18c, the ratio, I_x/V_x, under the condition of nulled independent sources, gives the function $Q_S(Z_S, Z_L)$ in Equation 22.49. On the other hand, and as depicted in Figure 22.18d, the ratio I_x/V_x, with a nulled response, yields $Q_R(Z_S, Z_L)$. Observe that in the present situation, the functions, $Q_S(Z_S, Z_L)$ and $Q_R(Z_S, Z_L)$ are, respectively, the Thévenin and the null Thévenin admittances facing the branch impedance, Z_k.

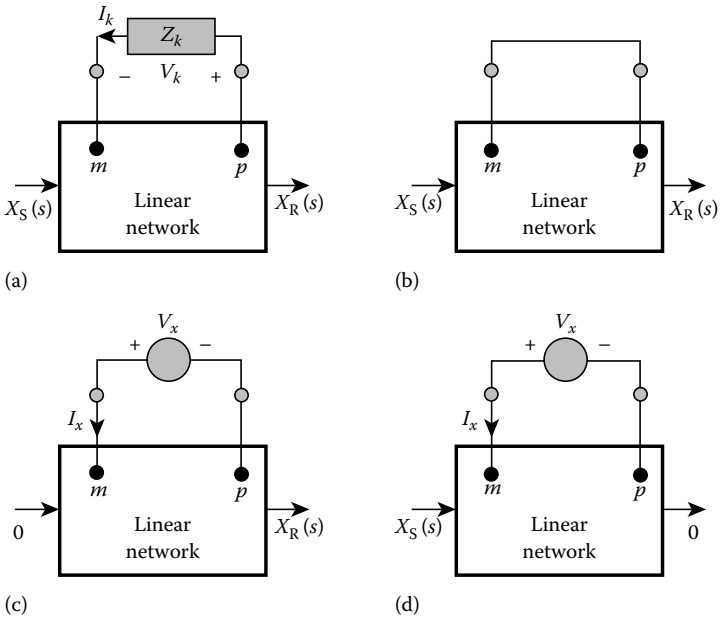

FIGURE 22.18 (a) Linear circuit for which the identified critical parameter is a branch impedance, Z_k. (b) The ratio, $X_R(s)/X_S(s)$, is the zero parameter gain, $H(0, Z_S, Z_L)$. (c) The ratio, I_x/V_x, is the function, $Q_S(Z_S, Z_L)$, in Equation 22.49. (d) The ratio, I_x/V_x, is the function, $Q_R(Z_S, Z_L)$, in Equation 22.49.

22.2.6.3 Circuit Transimpedance

In the circuit of Figure 22.19a, a circuit transimpedance, Z_t, is selected as a critical parameter for analysis; that is, $P = Z_t$ in Equation 22.49. The zero parameter gain, $H(0, Z_S, Z_L)$, is evaluated by replacing the current-controlled voltage source (CCVS) by a short circuit, as shown in Figure 22.19b.

The volt–ampere characteristic equation of the critical transimpedance branch is $V_k = Z_t I_k$, where I_k is the controlling current for the controlled source branch. Because the dependent variable in this volt–ampere expression is a branch voltage, the return and null return ratios are calculated by replacing the CCVS with a test voltage source, V_x. However, as indicated in Figures 22.19c and d, the polarity of V_x mirrors that of the voltage, V_k, developed across the controlled branch. With I_x taken as a current flowing in the controlling branch in a direction opposite to the polarity of the original controlling current, I_k, the ratio, I_x/V_x, under the condition of nulled independent sources, gives the function, $Q_S(Z_S, Z_L)$ in Equation 22.49. On the other hand, and as depicted in Figure 22.19d, the ratio, I_x/V_x, with a nulled response, yields $Q_R(Z_S, Z_L)$.

22.2.6.4 Circuit Transadmittance

In the network of Figure 22.20a, a circuit transadmittance, Y_t, is selected as the critical parameter. The zero parameter gain, $H(0, Z_S, Z_L)$, is evaluated by replacing the voltage-controlled current source (VCCS) with an open circuit, as shown in Figure 22.20b.

The volt–ampere characteristic question of the critical transadmittance branch is $I_k = Y_t V_k$, where V_k is the controlling voltage for the VCCS. Because the dependent variable in this volt–ampere expression is a branch current, the return and null return ratios are calculated by replacing the VCCS with a test current source, I_x, where, as indicated in Figures 22.20c and d, the polarity of I_x mirrors that of the current, I_k, flowing through the controlled branch. With V_x taken as a voltage developed across the controlling branch in a direction opposite to the polarity of the original controlling voltage, V_k, the ratio, V_x/I_x, under

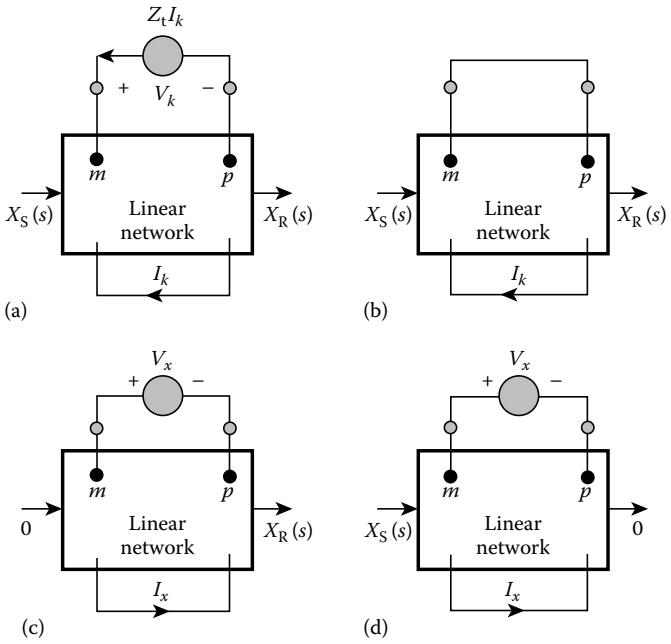

FIGURE 22.19 (a) Linear circuit for which the identified critical parameter is a circuit transimpedance, Z_t. (b) The ratio, $X_R(s)/X_S(s)$, is the zero parameter gain, $H(0, Z_S, Z_L)$. (c) The ratio, I_x/V_x, is the function, $Q_S(Z_S, Z_L)$, in Equation 22.49. (d) The ratio, I_x/V_x, is the function, $Q_R(Z_S, Z_L)$, in Equation 22.49.

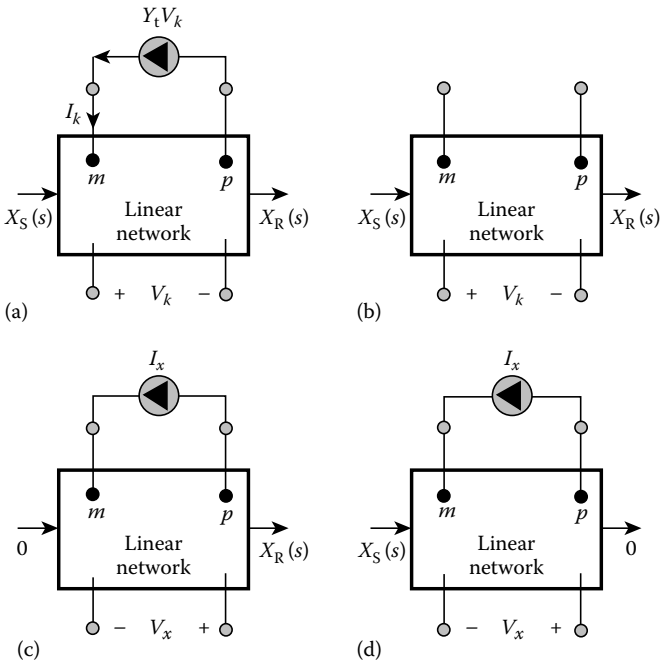

FIGURE 22.20 (a) Linear circuit for which the identified critical parameter is a circuit transadmittance, Y_t, (b) The ratio, $X_R(s)/X_S(s)$, is the zero parameter gain, $H(0, Z_S, Z_L)$. (c) The ratio, V_x/I_x, is the function $Q_S(Z_S, Z_L)$, in Equation 22.49. (d) The ratio, V_x/I_x, is the function $Q_R(Z_S, Z_L)$, in Equation 22.49.

the condition of nulled independent sources, gives the function, $Q_S(Z_S, Z_L)$ in Equation 22.43. On the other hand, and as offered in Figure 22.20d, the ratio, V_x/I_x, under the condition of a nulled response, yields $Q_R(Z_S, Z_L)$.

Example 22.4

The circuit in Figure 22.21a is a low-frequency, small-signal model of a voltage feedback amplifier. With the transconductance, g_m, selected as the reference parameter of interest, derive a general expression for the voltage gain, $A_v = V_O/V_S$. Approximate the final result for the special case of very large g_m.

Solution

1. The zero parameter voltage gain, A_{vo}, derives from an analysis of the circuit structure given in Figure 22.21b. The diagram differs from Figure 22.21a in that the current conducted by the controlled source branch has been nulled by open circuiting said branch. By inspection of the subject model,

$$A_{vo} = \frac{R_L}{R_L + R_F + R_S}$$

2. The diagram given in Figure 22.21c is appropriate to the computation of the return ratio, $T_S(g_m, Z_S, Z_L) = g_m Q_S(R_S, R_L)$ with respect to the critical transconductance, g_m. A comparison of the model at hand with the diagram in Figure 22.21a confirms that the controlled source, $g_m V$, is replaced by an independent current source, I_x, which flows in a direction identical to that of the controlled source

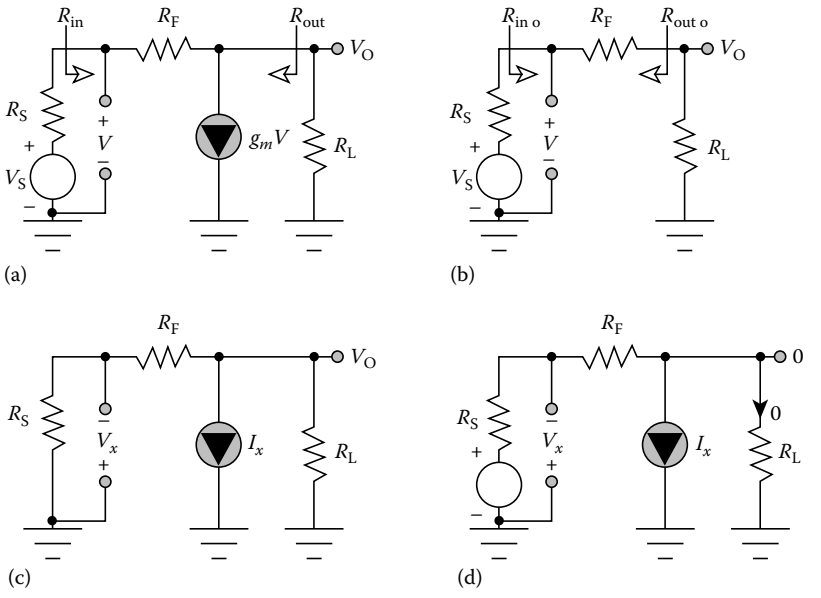

FIGURE 22.21 (a) The low-frequency, small-signal model of a voltage feedback amplifier. (b) The circuit used to evaluate the zero parameter ($g_m = 0$) gain. (c) The circuit used to evaluate the return ratio with respect to g_m. (d) The circuit used to computer the null return ratio with respect to g_m.

it supplants. The ratio, V_x/I_x, is to be computed, where V_x is developed, antiphase to V, across the branch that supports the original controlling voltage for the VCCS. A straightforward analysis produces

$$Q_S(R_S, R_L) = \frac{V_x}{I_x}\left(\frac{R_L}{R_L + R_F + R_S}\right)R_S \equiv A_{vo}R_S$$

3. The null return ratio, $T_R(g_m, Z_S, Z_L) = g_m Q_R(R_S, R_L)$, with respect to g_m is obtained from an analysis of the circuit in Figure 22.21d. Observe a nulled output voltage, with zero current flow through the load resistance, R_L. Observe further that the signal source voltage is nonzero. The specific value of this source voltage is not crucial, and is therefore not delineated. An analysis reveals

$$Q_R(R_S, R_L) = \frac{V_x}{I_x} = -R_F$$

4. Using Equation 22.49, the voltage gain of the circuit undergoing study is found to be

$$A_v = \frac{V_O}{V_S} = A_{vo}\left[\frac{1 + g_m(-R_F)}{1 + g_m R_S A_{vo}}\right]$$

which, for large g_m, reduces to

$$A_v \approx -\frac{R_F}{R_S}$$

22.2.6.5 Gain of a Current-Controlled Current Source

For the network in Figure 22.22a, the reference parameter is α_k, the gain associated with a CCCS. The zero parameter gain, $H(0, Z_S, Z_L)$, is evaluated by replacing this CCCS with an open circuit, as depicted in Figure 22.22b.

The volt–ampere characteristic equation of the branch in which the reference parameter is embedded is $I_k = \alpha_k I_j$, where I_j is the controlling current for the CCCS. Because the dependent variable in this volt-ampere characteristic is a branch current, the return and null return ratios are calculated by replacing the CCCS with a test current source, I_x. As indicated in Figure 22.22c and d, the polarity for I_x mirrors that of the current, I_k, flowing through the controlled branch. Let I_y be the resultant current conducted by the controlling branch, and let this current flow a direction opposite to the polarity of the original controlling current. Then, the current ratio, I_y/I_x, computed under the condition of nulled independent sources, is the function, $Q_S(Z_S, Z_L)$ in Equation 22.49. Similarly, and as suggested in Figure 22.22d, the ratio, I_y/I_x, under the condition of a nulled response, yields $Q_R(Z_S, Z_L)$.

22.2.6.6 Gain of a Voltage-Controlled Voltage Source

In the network of Figure 22.23a, the selected reference parameter is μ_k, the gain corresponding to a VCVS. The zero parameter gain, $H(0, Z_S, Z_L)$, is evaluated by replacing this VCVS with a short circuit, as per Figure 22.23b.

The volt–ampere characteristic equation of the dependent generator branch is $V_k = \mu_k V_j$, where V_j is the controlling voltage for the VCVS. Because the dependent variable in this volt–ampere expression is a branch voltage, the return and null return ratios are calculated by replacing the VCVS with a test voltage source, V_x, where as indicated in Figure 22.23c and d, the polarity of V_x is identical to that of the voltage,

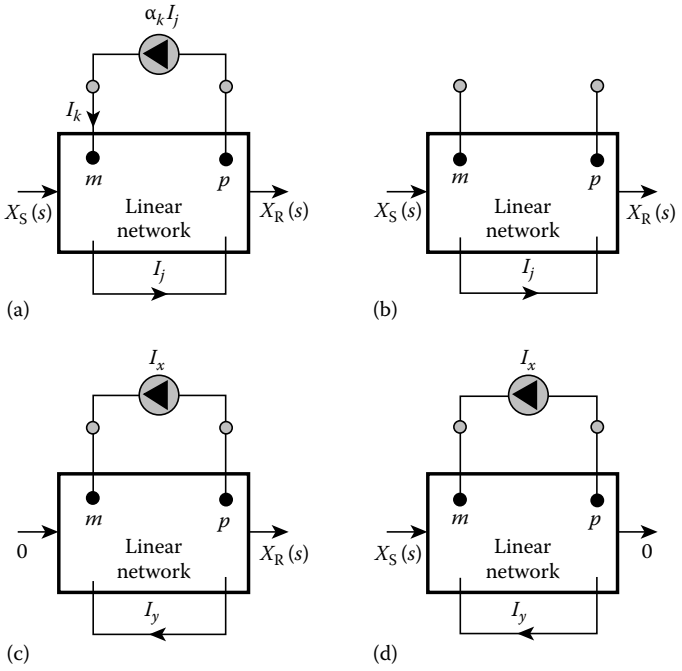

FIGURE 22.22 (a) Linear circuit for which the identified critical parameter is the current gain α_k associated with a CCCS. (b) The ratio, $X_R(s)/X_S(s)$, is the zero parameter gain, $H(0, Z_S, Z_L)$. (c) The ratio, I_y/I_x, is the function, $Q_S(Z_S, Z_L)$, in Equation 22.49. (d) The ratio, I_y/I_x, is the function, $Q_R(Z_S, Z_L)$, in Equation 22.49.

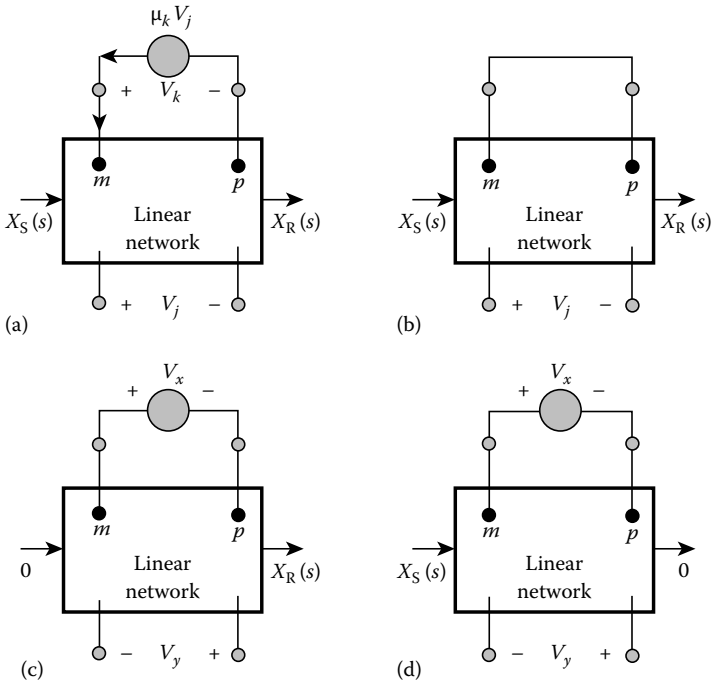

FIGURE 22.23 (a) Linear circuit for which the identified critical parameter is the voltage gain, μ_{k1} associated with a VCVS. (b) The ratio, $X_R(s)/X_S(s)$, is the zero parameter gain, $H(0, Z_S, Z_L)$. (c) The ratio, V_y/V_x, is the function $Q_S(Z_S, Z_L)$, in Equation 22.49. (d) The ratio, V_y/V_x, is the function, $Q_R(Z_S, Z_L)$, in Equation 22.49.

V_k, developed across the controlled branch. Let V_y be the resultant voltage established across the controlling branch, and let the polarity of this voltage be in a direction opposite to that of the original controlling voltage. Then, the voltage ratio, V_y/V_x, computed under the condition of nulled independent sources, is the function, $Q_S(Z_S, Z_L)$, in Equation 22.49. As suggested in Figure 22.23d, the voltage ratio, V_y/V_x, under the condition of a nulled response, yields $Q_R(Z_S, Z_L)$.

22.2.7 Evaluation of Driving Point Impedances

Having formulated generalized techniques for computing the return ratio and the null return ratio with respect to any of the six possible types of critical circuit parameters, the application of Equation 22.49 is established as a powerful and computationally expedient vehicle for evaluating any transfer function of any linear network. The only restriction limiting the utility of Equation 22.49 is that parameter P must be selected in such a way as to ensure that the zero parameter transfer function is finite and nonzero.

Equation 22.49 is commonly used to evaluate the voltage gain, current gain, transimpedance gain, or transadmittance gain of feedback and other types of complex circuitry. However, the expression is equally well suited to determining the driving point input impedance seen by the source impedance, as well as the driving point output impedance seen by the terminating load impedance. In fact, once the return ratios relevant to the gain of interest are found, these I–O impedances can be determined with minimal additional analysis.

Without loss of generality, the foregoing contention is explicitly demonstrated in conjunction with a transimpedance amplifier whose reference parameter is selected to be a branch impedance, Z_k. To this end, consider the circuit abstracted in Figure 22.24, for which the driving point input impedance, Z_{in}, is

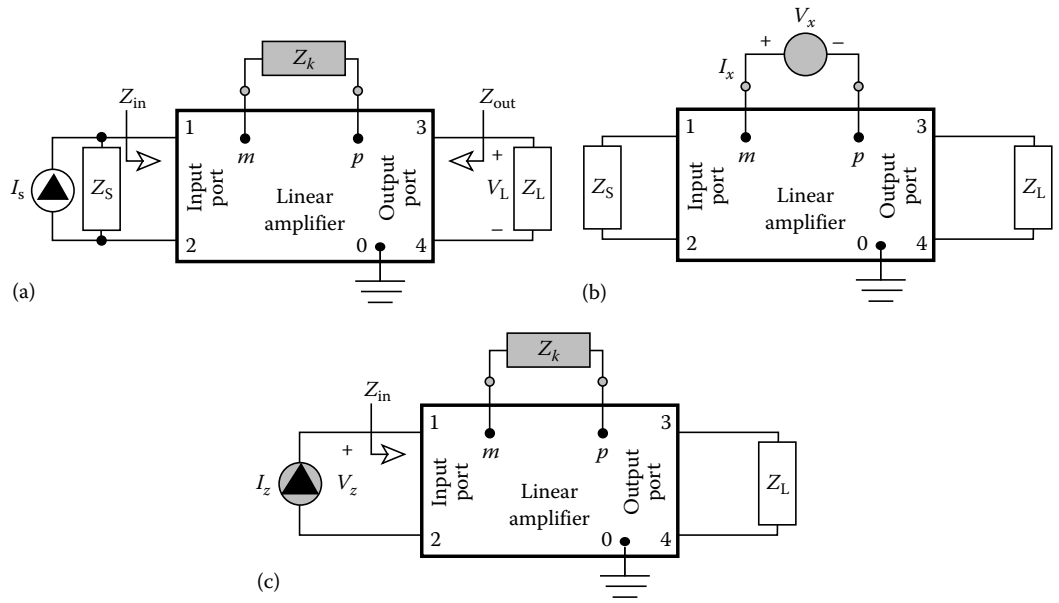

FIGURE 22.24 (a) A liner amplifier for which the input impedance is to be determined. (b) The circuit used for calculating the return ratio with respect to Z_k. (c) The circuit used for calculating the driving point input impedance.

to be determined. The input excitation is a current, I_S, and in response to this input, a signal voltage, V_L, is developed across the load impedance, Z_L. Using Equation 22.49, the I–O transimpedance, $Z_T(Z_k, Z_S, Z_L)$, is

$$Z_T(Z_k, Z_S, Z_L) = \frac{V_L(s)}{I_S(s)} = Z_T(0, Z_S, Z_L)\left[\frac{1 + Z_k Q_R(Z_S, Z_L)}{1 + Z_k Q_S(Z_S, Z_L)}\right] \tag{22.55}$$

where

$Z_T(0, Z_S, Z_L)$ is the circuit transimpedance for $Z_k = 0$, $Z_k Q_R(Z_S, Z_L)$ is the null return ratio with respect to Z_k

$Z_k Q_S(Z_S, Z_L)$ is the return ratio with respect to Z_k

For future reference, the circuit appropriate to the calculation of the function, $Q_S(Z_S, Z_L)$, is drawn in Figure 22.24b.

The input impedance derives from an analytical consideration of the cell depicted in Figure 22.24c, in which the Norton representation of the signal source has been supplanted by a test current source of value I_z. Note that the load impedance remains as the terminating element for the output port. The transfer relationship of interest is the ratio, V_z/I_z, which is the desired driving point input impedance, Z_{in}. Taking care to choose Z_k, the reference parameter for the gain enumeration, as the reference parameter for the input impedance determination, Equation 22.49 gives

$$Z_{in} = \frac{V_z}{I_z} = Z_{in\ o}\left[\frac{1 + Z_k Q_{RR}(Z_S, Z_L)}{1 + Z_k Q_{SS}(Z_S, Z_L)}\right] \tag{22.56}$$

In this expression, $Z_{in\ o}$ generally derives straightforwardly because it is the $Z_k = 0$ value of Z_{in}; that is, Z_{in} is evaluated for the special case of a nulled reference parameter. Such a null in the present situation is

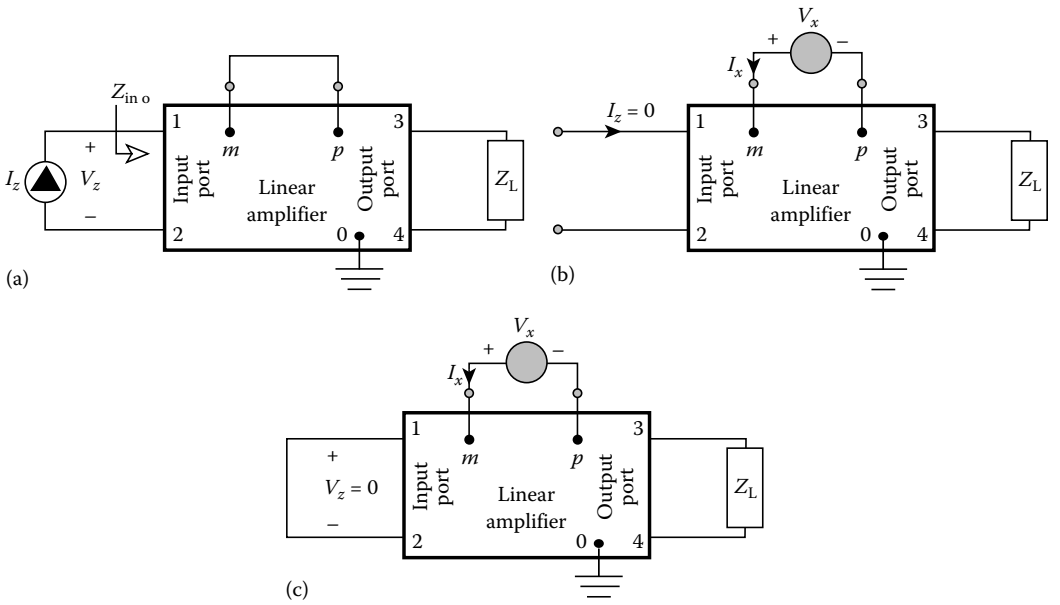

FIGURE 22.25 (a) The circuit used to evaluate the zero parameter driving point input impedance. (b) The computation, relative to input impedance, of the return ratio with respect to Z_k. (c) The computation, relative to input impedance, of the null return ratio with respect to Z_k.

equivalent to short-circuiting Z_k, as indicated in Figure 22.25a. The function, $Q_{SS}(Z_S, Z_L)$, is the delineated.

I_x/V_x ratio, for the case of a source excitation (I_z in the present case) set to zero. The pertinent circuit diagram is the structure in Figure 22.25b. This last circuit differs from the circuit, shown in Figure 22.24b, exploited to find $Q_S(Z_S, Z_L)$ in the gain relationship of Equation 22.50 in only one way: Z_S has been removed, and thus, effectively, Z_S has been set to an infinitely large value. It follows that

$$Q_{SS}(Z_S, Z_L) \equiv Q_S(\infty, Z_L) \tag{22.57}$$

In other words, a circuit analysis aimed toward determining $Q_{SS}(Z_S, Z_L)$ is unnecessary. Instead, $Q_{SS}(Z_S, Z_L)$ is found by evaluating $Q_S(Z_S, Z_L)$, which is already known from the gain analysis, at $Z_S = \infty$.

To evaluate $Q_{RR}(Z_S, Z_L)$, the foregoing I_x/V_x ratio is calculated for the case of zero response. In the present situation the response is the voltage, V_z, and accordingly, the appropriate circuit is depicted in Figure 22.25c. However, a comparison of the circuit at hand with the structure in Figure 22.24, which is exploited to evaluate the return ratio in the gain equation, indicates that it differs only in that Z_S is now constrained to zero to ensure $V_z = 0$. It is therefore apparent that in Equation 22.56

$$Q_{RR}(Z_S, Z_L) \equiv Q_S(0, Z_L) \tag{22.58}$$

Equation 22.56 is now expressible as

$$Z_{in} = \frac{V_z}{I_z} = Z_{in\,o}\left[\frac{1 + Z_k Q_S(0, Z_L)}{1 + Z_k Q_S(\infty, Z_L)}\right] \tag{22.59}$$

which is occasionally referred to as Blackman's formula [14].

Analogous considerations at the output port in the circuit of Figure 22.24a dictate a driving point output impedance, Z_{out}, of

$$Z_{out} = Z_{out\,o}\left[\frac{1 + Z_k Q_S(Z_S, 0)}{1 + Z_k Q_S(Z_S, \infty)}\right] \tag{22.60}$$

where, similar to $Z_{in\,o}$, $Z_{out\,o}$, the $Z_k = 0$ value of Z_{out}, must be finite and nonzero. Although the preceding two relationships were derived for the case in which the selected reference parameter is a branch impedance, both expressions are applicable for any reference parameter, P. In general,

$$Z_{in} = Z_{in\,o}\left[\frac{1 + PQ_S(0, Z_L)}{1 + PQ_S(\infty, Z_L)}\right] \tag{22.61a}$$

$$Z_{out} = Z_{out\,o}\left[\frac{1 + PQ_S(Z_S, 0)}{1 + PQ_S(Z_S, \infty)}\right] \tag{22.61b}$$

Example 22.5

Use the pertinent results of Example 22.4 to derive expression for the driving point input resistance, R_{in}, and the driving point output resistance, R_{out}, of the feedback amplifier in Figure 22.21a.

Solution

1. With g_m set to zero, an inspection of the circuit diagram in Figure 22.21b delivers

$$R_{in\,o} = R_F + R_L$$
$$R_{out\,o} = R_F + R_S$$

2. From the second step in the solution to Example 22.4, the function, $Q_S(R_S, R_L)$, to which the return ratio, $T_S(g_m, R_S, R_L)$ is directly proportional, was found to be

$$Q_S(R_S, R_L) = \left(\frac{R_L}{R_L + R_F + R_S}\right) R_S$$

It follows that

$$Q_S(0, R_L) = 0$$
$$Q_S(\infty, R_L) = R_L$$

Moreover,

$$Q_S(R_S, 0) = 0$$
$$Q_S(R_S, \infty) = R_S$$

3. Equations 22.61a and b resultantly yield

$$R_{in} = R_{in\,o}\left[\frac{1 + g_m Q_S(0, Z_L)}{1 + g_m Q_S(\infty, Z_L)}\right] = \frac{R_R + R_L}{1 + g_m R_L}$$

for the driving point input resistance and

$$R_{\text{out}} = R_{\text{out o}}\left[\frac{1 + g_m Q_S(R_S, 0)}{1 + g_m Q_S(R_S, \infty)}\right] = \frac{R_F + R_S}{1 + g_m R_S}$$

for the driving point output resistance.

22.2.8 Sensitivity Analysis

Yet another advantage of the Kron–Bode formula is its amenability to evaluating the impact exerted on a circuit transfer relationship by potentially large fluctuations in the reference parameter P. This convenience stems from the fact that parameter P is isolated in Equation 22.49; that is, $H(0, Z_S, Z_L)$, $Q_R(Z_S, Z_L)$, and (Z_S, Z_L) are each independent of P. A quantification of this impact is achieved by exploiting the sensitivity function,

$$S_P^H \triangleq \frac{\Delta H/H}{\Delta P/P} \tag{22.62}$$

which compares the per unit change in transfer function, $\Delta H/H$, resulting from a specified per unit change $\Delta P/P$ in a critical parameter. In particular, the notation in this definition is such that if H designates the transfer characteristic, $H(P_0, Z_S, Z_L)$, at the nominal parameter setting, $P = P_0$, $(H + \Delta H)$ signifies the perturbed characteristic, $H(P_0 + \Delta P, Z_S, Z_L)$ where P_0 is altered by an amount ΔP_0. Using Equation 22.49 and dropping the functional notation in Equations 22.53a and 22.53b, it can be demonstrated that

$$S_P^H \triangleq \frac{F_R - F_S}{F_R\left[F_S + (F_S - 1)\left(\dfrac{\Delta P}{P_0}\right)\right]} \tag{22.63}$$

where F_S and F_R are understood to be evaluated at the nominal parameter setting, $P = P_0$. It should be emphasized that unlike a more traditional sensitivity analysis, such as that predicated on the adjoint network [15], Equation 22.63 is easy to use manually and does not rely on an *a priori* assumption of small parametric changes.

23.1 Introduction

Network analysis is based on formulation of the relevant equations and on their solutions. Various approaches are possible. If we wish to get as much theoretical information as possible, we may resort to hand analysis and keep the elements as variables (literal parameters). In such cases, it is an absolute necessity to use a method that leads to the smallest possible number of equations. If we plan to use a computer, then we can accept methods which lead to larger systems, but the methods must be relatively easy to program. The purpose of this chapter is to give an overview of the various possibilities and point out advantages and disadvantages. Many more details are available in Refs. [1,2].

Section 23.2 is a summary of the nodal and mesh formulations. We review them because they are the best ones for analysis of small networks. Tableau formulation, given in Section 23.3, is very general, but requires special solution routines, probably not available to the reader. Section 23.4 describes the best method for computerized solutions; it is used in many commercial simulators. If nonlinear elements are involved, then iterative solution methods must be used; an introduction on how to deal with nonlinear elements is given in Section 23.5. Finally, Section 23.6 presents a method that is suitable for hand solutions of active networks and which automatically leads to the smallest system of equations.

23.2 Nodal and Mesh Formulations

Classical methods use two types of network equations formulation: the nodal and the mesh. The first one is based on Kirchhoff's current law (KCL): the sum of currents flowing away from a node is equal to zero. The mesh method is based on Kirchhoff's voltage law (KVL): the sum of voltages around any loop is equal to zero.

For simple problems, both methods are about equivalent, but nodal formulation is more general. The mesh formulation is suitable only for planar networks: It must be possible to draw the network without

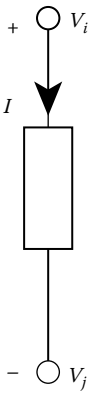

FIGURE 23.1 Definition of positive current direction with respect to the voltage across the element.

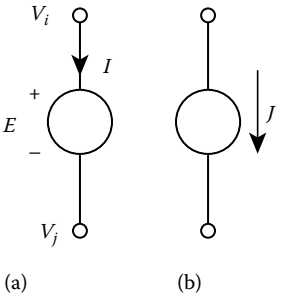

FIGURE 23.2 (a) Direction of positive current through an independent voltage source. (b) Direction of the current through an independent current source.

any element crossing over any other element. Many practical networks are planar, but it is not always easy to see that it is actually the case.

We first introduce some definitions. A positive current flows from a terminal with a higher potential to a terminal with a lower potential. This is sketched on the two-terminal element in Figure 23.1. If we use this definition, then the product of the current and of the voltage across the element, $V_i - V_j$, expresses the power consumed by the element. If the current flows in opposite direction, then the element is delivering power.

We will use the previous definition of a positive current for all elements of the network, irrespective of what their role eventually may be. Thus, a positive current through an independent voltage source will flow from the more positive terminal to the less positive terminal, as sketched in Figure 23.2a. The current flowing through an independent current source is indicated on its symbol, Figure 23.2b, but the voltage across it is not defined; it depends on the network.

The nodal formulation uses the principle that the sum of currents at any node must be equal to zero at any instant of time. To apply this rule in an efficient way, we realize that before we solve the equations, we do not know which way the currents will actually flow. All we know is that if a node is more positive than all the other nodes, then all currents must flow away from this node.

In nodal formulation, the unknowns are nodal voltages and the equations express the sum of currents flowing away from the node. To write the equations we use element admittances: in Laplace transform $Y_C = sC$ for a capacitor, $Y_L = 1/sL$ for an inductor, and $Y_G = G = 1/R$ for a resistor. It is advantageous to use G, because we thus avoid fractions in the equations.

We demonstrate how to set up the equations by considering the network in Figure 23.3. The nodal voltages are denoted V_1 and V_2 and ground (the lower line) is considered to be at zero potential. We do

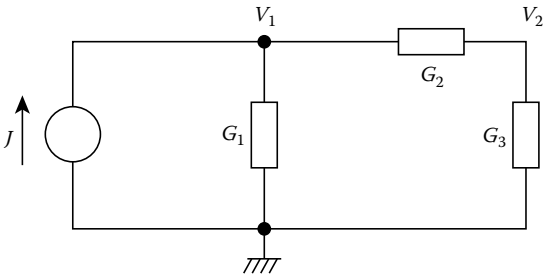

FIGURE 23.3 Example for nodal formulation.

not know which of these nodes is more positive, but we can assume that any node we consider at a given moment is the most positive one. This assumption has the consequence that all currents must flow away from this node. For the given network, the current through G_1 will flow down and its value will be $I_{G_1} = G_1 V_1$, current through G_2 will flow from left to right and will be $I_{G_2} = G_2(V_1 - V_2)$. Current from the independent current source flows into the node and thus must be subtracted. Together, the sum of the currents at node 1 will be zero:

$$G_1 V_1 + G_2(V_1 - V_2) - J = 0$$

Moving to the second node, we still do not know which node is more positive, but we can still make the assumption that now it is this node that is the most positive one. If we make such an assumption, then all currents must flow away from this node: The current through G_3 will be $I_{G_3} = G_3 V_2$ and will flow down, the current through G_2 will flow from right to left and will be $I_{G_2} = G_2(V_1 - V_2)$. In this expression, the first voltage within the parentheses must be the assumed higher potential. This is expressed by the equation

$$G_3 V_2 + G_2(V_2 - V_1) = 0$$

It is advantageous to put the equations into matrix form, with the known independent source transferred to the right side:

$$\begin{bmatrix} G_1 + G_2 & -G_2 \\ -G_2 & G_2 + G_3 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} \begin{bmatrix} J \\ 0 \end{bmatrix}$$

The preceding steps were simple because we selected elements that can be handled by this formulation. Unfortunately, many practical elements are not expressed in terms of currents. For instance, a voltage source connected between nodes i and j, with its positive reference on node i, is described by the equation

$$V_i - V_j = E$$

A positive current does flow through such an element from i to j, but is not available in its defining equation. In fact, all voltage sources, independent or dependent, will create this problem. Another element which cannot be handled directly is a short circuit. It is described by the equation

$$V_i - V_j = 0$$

and current is not a part of its definition.

We can always use transformations by applying various theorems such as the Thévenin and Norton transformations or source splitting, and eventually arrive at a network in which all elements have voltage as the independent variable. Such transformations are practical for hand analysis, but are not advantageous for computerized solutions. This is the reason why other formulations have been invented.

Consider next the mesh equations where we use the KVL and impedances of the elements: $Z_L = sL$ for the inductor, $Z_C = 1/sC$ for the capacitor, and R for the resistor. In this formulation, we sum the voltages across the elements in a given closed loop. Because this method is suitable for planar networks only, we usually use the concept or circulating mesh currents, indicated on the network in Figure 23.4. The currents I_1 and I_2 create voltage drops across the resistors. When considering the first mesh, we take the current I_1 as a positive one. The voltage across R_1 is $V_{R_1} = R_1 I_1$. The voltage across R_2 is $V_{R_2} = R_2(I_1 - I_2)$ and the voltage source contributes a value E to the equation. According to our earlier definition, a positive current flows from plus to minus, but I_1 actually goes in the opposite direction through the voltage source. Thus, the voltage across E must be taken with a negative sign and the sum of voltages around the first mesh is

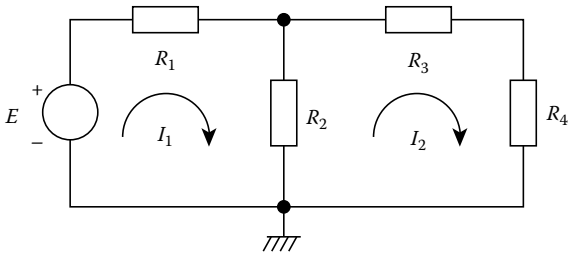

FIGURE 23.4 Example for mesh formulation.

$$R_1 I_1 + R_2(I_1 - I_2) - E = 0$$

When we move to the second mesh, we consider the current I_2 as positive and the sum of voltage drops around the second mesh is

$$R_2(I_2 - I_1) + R_3 I_2 + R_4 I_2 = 0$$

The equations can be collected into one matrix equation

$$\begin{bmatrix} R_1 + R_2 & -R_2 \\ -R_2 & R_2 + R_3 + R_4 \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} \begin{bmatrix} E \\ 0 \end{bmatrix}$$

Each of these fundamental formulations has its problems.

In nodal formulation, we can deal directly with the following elements:
- Current source, J
- Conductance, $G = 1/R$
- Capacitor admittance, sC
- Voltage controlled current source, VC
- Inductor admittance, $1/sL$

In mesh formulation, we can deal directly with the elements:
- Voltage source, E
- Resistor, R
- Inductor impedance, sL
- Current controlled voltage source, CV
- Capacitor impedance, $1/sC$.

All other elements create problems and must be dealt with by the Thévenin and Norton theorems and/or source splitting.

As an example, we take the network in Figure 23.5a. It is directly suitable for mesh formulation, but we demonstrate both. For simplicity, all resistors have unit values.

The mesh formulation, with the indicated circulating currents I_1 and I_2, leads to the equations

$$\begin{aligned} (R_1 + R_2)I_1 - R_2 I_2 &= E \\ -R_2 I_1 + (R_2 + R_3)I_2 + 3I_1 &= 0 \end{aligned}$$

Inserting numerical values

$$\begin{aligned} 2I_1 - I_2 &= E \\ 2I_1 + 2I_2 &= 0 \end{aligned}$$

The solution is $I_1 = E/3$, $I_2 = -E/3$ and $V_1 = R_2(I_1 - I_2) = 2E/3$.

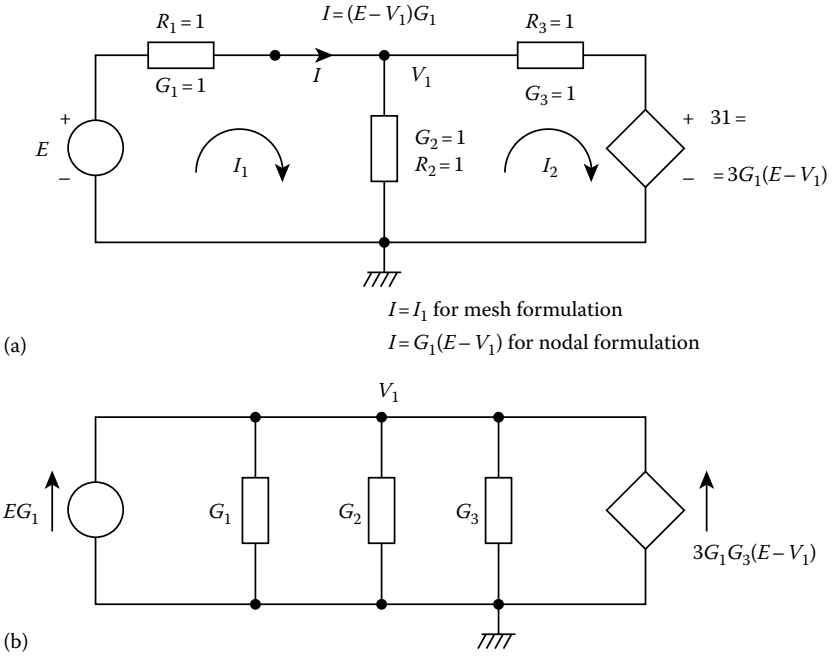

FIGURE 23.5 (a) Example of a network suitable for mesh formulation. (b) Modification of the network in Figure 23.5a to be suitable for nodal formulation.

To use nodal formulation, we must apply several transformation steps. First, we must express the controlling currents as $I = G_1(E - V_1) = E - V_1$ and replace I in the definition of the current controlled voltage source. This has been done in the figure. Afterward, applying Thévenin–Norton transformation we change the voltage sources, in series with resistors, into current sources, in parallel with the same resistors. We get the network in Figure 23.5b. It has only one node for which the balance of current is

$$(G_1 + G_2 + G_3)V_1 - EG_1 - 3G_1G_3(E - V_1) = 0$$

Inserting numerical values and solving, we get the same V_1 as previously.

If we have a mixture of elements, such transformations will always be lengthy, will require redrawings, and can lead to errors. To reduce the chance of such errors to a minimum, in computer applications we need formulations that avoid transformations and use descriptions of the elements as they are given. This is done in both the tableau and nodal formulations, the subjects of the following sections.

Although the nodal and mesh formulations are not always easy to apply, we must stress that they are the best ones for hand solutions. They may require several steps of transformations and redrawings, but ultimately they lead to the smallest possible systems of equations.

23.3 Graphs and Tableau Formulation

Tableau is the most general formulation because the solution simultaneously provides the voltages across all elements, the currents through all elements, and all nodal voltages. The difficulty is that tableau leads to such large systems of equations that complicated sparse matrix solvers are an absolute necessity. Most readers will not have access to such routines, therefore, we will explain its properties only to the extent necessary for understanding. We advise the reader not to use it.

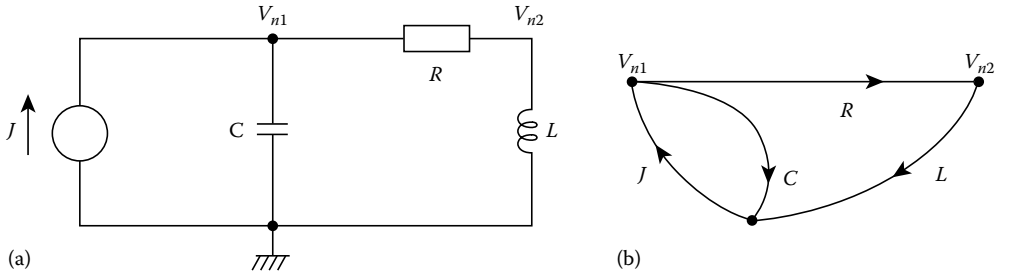

FIGURE 23.6 (a) A simple network and (b) its graph.

Tableau formulation needs for its construction the concept of graphs and the concept of the incidence matrix. Consider the network in Figure 23.6a. A graph of the network replaces each element by a line. We will use oriented graphs, with arrows, because they can be identified with the flow of currents. In all passive elements, the current can flow in any direction and the orientation of the graph is entirely our choice. We do not have such freedom when we consider sources. The direction of the current through the current source is given by the arrow marked at its symbol and we use the same direction in the graph. For the voltage source, the direction of the graph will be from plus to minus, in agreement with our previous explanations. Each node is marked by the node voltage and the line representing the element is given the name of the element. Following these rules, we have constructed the graph in Figure 23.6b. Because the directions of the arrows are the assumed directions of currents, we can write KCL for the two nodes: positive direction is away from the node, negative is into the node. The sums of currents for the nodes are

$$\begin{aligned} -I_{\mathrm{J}} + I_{\mathrm{C}} + I_{\mathrm{R}} &= 0 \\ -I_{\mathrm{R}} + I_{\mathrm{L}} &= 0 \end{aligned}$$

This can also be summarized in one matrix equation

$$\begin{bmatrix} -1 & 1 & 1 & 0 \\ 0 & 0 & -1 & 1 \end{bmatrix} \begin{bmatrix} I_{\mathrm{J}} \\ I_{\mathrm{C}} \\ I_{\mathrm{R}} \\ I_{\mathrm{L}} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

or

$$\mathbf{AI} = 0 \tag{23.1}$$

The matrix **A** is called the incidence matrix. It has as many rows as there are ungrounded nodes, and as many columns as the number of elements. Note that $+1$ in any given row indicates that we expect the current to flow away from the node, -1 means the opposite.

Still more information can be extracted from this matrix. Denote the nodal voltages by subscripts n in V_{n1} and V_{n2}, as done in Figure 23.6. The voltages across the elements will have as subscripts the names of the elements. We can write the following set of equations which couple the voltages across the elements with the nodal voltages:

$$\begin{aligned} V_{\mathrm{J}} &= -V_{n1} \\ V_{\mathrm{C}} &= V_{n1} \end{aligned}$$

$$V_{\mathrm{R}} = V_{n1} - V_{n2}$$
$$V_{\mathrm{L}} = V_{n2}$$

In matrix form, this is equivalent to

$$\begin{bmatrix} V_{\mathrm{J}} \\ V_{\mathrm{C}} \\ V_{\mathrm{R}} \\ V_{\mathrm{L}} \end{bmatrix} = \begin{bmatrix} -1 & 0 \\ 1 & 0 \\ 1 & -1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} V_{n1} \\ V_{n2} \end{bmatrix}$$

The matrix is the transpose of the incidence matrix and we can generalize

$$\mathbf{V}_{\mathrm{el}} - \mathbf{A}^{I}\mathbf{V}_{n} = 0 \tag{23.2}$$

Complete formulation needs expressions that couple the element currents and the element voltages. Writing them in the same sequence as for the graph, and using Laplace transformation, we have

$$I_{\mathrm{J}} = J$$
$$I_{\mathrm{C}} = sCV_{\mathrm{C}}$$
$$V_{\mathrm{R}} = RI_{\mathrm{R}}$$
$$V_{\mathrm{L}} = sLI_{\mathrm{L}}$$

For matrix notation, we need an expression that, with a proper choice of entries, will cover all possible elements. Such an expression is

$$YV_{\mathrm{el}} + ZI_{\mathrm{el}} = W$$

For instance, if we consider the current source, we set $Y = 0$, $Z = 1$ and $W = J$, which gives the preceding equation. Similar choices can be made for the other elements.

The KCL equation, $\mathbf{AI} = \mathbf{0}$, the KVL equation, $\mathbf{V}_{\mathrm{el}} - \mathbf{A}^{\mathrm{T}}\mathbf{V}_{n} = \mathbf{0}$, and the previous equation $\mathbf{YV}_{\mathrm{el}} + \mathbf{ZI}_{\mathrm{el}} = \mathbf{W}$ are collected in one matrix equation. Any sequence can be used; we have chosen

$$\begin{aligned} \mathbf{V}_{\mathrm{el}} - \mathbf{A}^{\mathrm{T}}\mathbf{V}_{n} &= 0 \\ \mathbf{YV}_{\mathrm{el}} + \mathbf{ZI}_{\mathrm{el}} &= \mathbf{W} \\ \mathbf{AI}_{\mathrm{el}} &= 0 \end{aligned} \tag{23.3}$$

and in matrix form

$$\begin{bmatrix} \mathbf{1} & \mathbf{0} & -\mathbf{A}^{\mathrm{T}} \\ \mathbf{Y} & \mathbf{Z} & \mathbf{0} \\ \mathbf{0} & \mathbf{A} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{V}_{\mathrm{el}} \\ \mathbf{I}_{\mathrm{el}} \\ \mathbf{V}_{n} \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{W} \\ \mathbf{0} \end{bmatrix} \tag{23.4}$$

Once the incidence matrix is available, writing this matrix equation is actually quite simple. First determine its size: it will be twice the number of elements plus the number of nodes. For our example, it will be 10. The system equation is in Figure 23.7 where all zero entries were omitted to clearly show the structure. In the top partition is a unit matrix and the negative of the transpose of the **A** matrix. In the bottom partition is the incidence matrix, **A**. The middle portion is filled, element by element, using

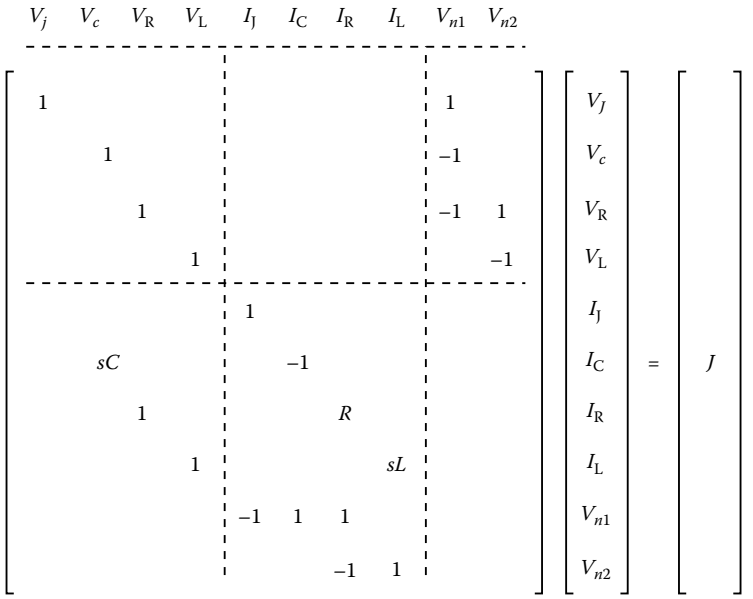

FIGURE 23.7 Tableau formulation for the network in Figure 23.6.

the previous element equation. For better understanding, it is a good idea to write the variables above the matrix, as shown, because each column of the matrix is multiplied by the variable which appears above it.

We have used this simple example to point out the main difficulty of the tableau formulation: the system becomes very large. In nodal formulation, this problem would lead to only two equations. However, the tableau system matrix has many zeros and is said to be sparse. Sparse systems are always solved by special routines which, roughly speaking, do not store the zeros and do not operate on them. Such codes are quite difficult to write, and in tableau we have the additional difficulty that the matrix has a complicated structure. We discussed this formulation more as a warning instead of a recommendation. Unless a suitable sparse matrix solver is already available, this formulation should be avoided.

23.4 Modified Nodal Formulation

Modified nodal formulation is an extension of the nodal formulation and is the method of choice for computerized analysis. It is used in most commercial simulators, and we will explain it in considerable detail.

When nodal formulation is taught in schools, inductors are usually taken as admittances, $Y_L = 1/sL$. This is fine, as long as we work by hand and derive the network function. For instance, nodal equations for the network in Figure 23.8 would be written in the form

$$\left(G_1 + sC_1 + \frac{1}{sL}\right)V_1 - \frac{1}{sL}V_2 = J$$
$$-\frac{1}{sL}V_1 + \left(G_2 + sC_2 + \frac{1}{sL}\right)V_2 = 0$$

However, this creates a problem for computerized solutions. Multiplication by s represents differentiation in the Laplace transform and $1/s$ represents integration. As a result, the two equations are actually a set of two integro-differential equations, and we do not normally have methods to solve them directly in such a

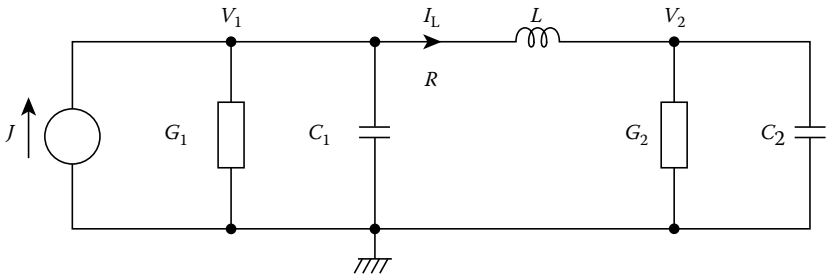

FIGURE 23.8 Example for modified nodal formulation.

form. In all computerized methods, we use integration of systems of first-order differential equations and the preceding equations cannot be arranged into such a form. What we need is a method which will keep all frequency-dependent elements in the form sC or sL, with the variable s in the numerator. Such possibility exists if we take into account a new variable, the current through the inductor. Writing KCL for the two nodes of Figure 23.8

$$(G_1 + sC_1)V_1 + I_L = J$$
$$(G_2 + sC_2)V_2 - I_L = 0$$

We now have two equations but three variables. What we have not used yet is an expression which couples the voltages across the inductor with the current through it. The relationship is $V_1 - V_2 = sLI_L$, but because we do not know any of these three variables, we transfer everything to the left and write the last equation

$$V_1 - V_2 = sLI_L = 0 \tag{23.5}$$

All three can be put into a matrix form

$$\begin{bmatrix} G_1 + sC_1 & 0 & 1 \\ 0 & G_2 + sC_2 & -1 \\ 1 & -1 & -sL \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ I_L \end{bmatrix} = \begin{bmatrix} J \\ 0 \\ 0 \end{bmatrix}$$

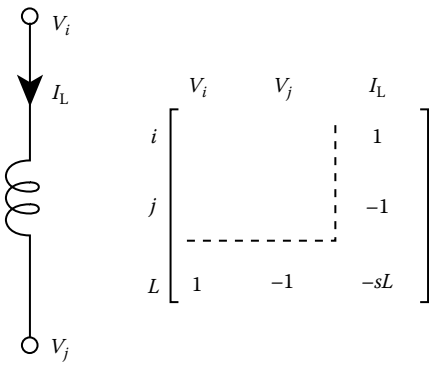

FIGURE 23.9 Stamp of an inductor.

In this equation, the nodal portion is the 2×2 matrix in the upper left corner and information about the inductor is collected in the right-most column and the lowest row. A larger network will have a larger nodal portion, but we still increase the matrix by one row and column for each inductor. This can be prepared as a general stamp as shown in Figure 23.9. The previous matrix is the empty box, separated by the dashed lines, the voltages and the current above the stamp indicate the variables relevant to the inductor, while on the left the letters i and j give the rows (node numbers) where L is connected. Should we have a network with two inductors, we add one row and one column for each.

The next element we take is the voltage-controlled current source; it was already mentioned is Section 23.2 as an

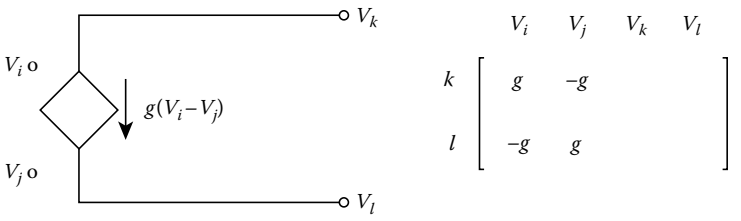

FIGURE 23.10 Stamp for a voltage-controlled current source.

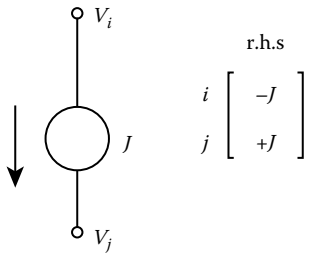

FIGURE 23.11 Stamp for an independent current source.

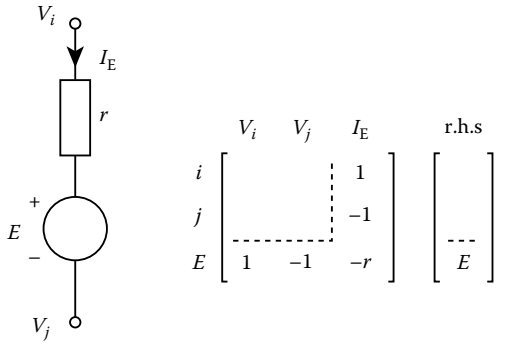

FIGURE 23.12 Stamp for an independent voltage source. The resistor value can be zero.

element which can be taken into the nodal formulation. The *VC* is shown in Figure 23.10. It adds the current $g(V_i - V_j)$ to node k and subtracts the same current at node l. It permits us to write the stamp, Figure 23.10. The element influences the balance of currents at node i and j, and the variables which multiply its transconductance are V_i and V_j.

Network theory defines two independent sources: the current and the voltage source. The current source can be taken into consideration in the right-hand side (r.h.s.) of the nodal portion; its stamp is in Figure 23.11. The independent voltage source cannot be taken directly and we must add its current as a new variable. Consider the source with a resistor in series, shown in Figure 23.12. The voltage relationships are

$$V_i - V_j - rI_E = E \tag{23.6}$$

The current I_E adds to the balance of currents at node i, because it flows away from it. It is subtracted from the balance of currents at node j. The current is taken as a new variable and the equation is attached to previous equations. The stamp is as shown. It is, in fact, a combined stamp for several elements. If we set $r = 0$, we have an ideal voltage source. If we set both r and E equal to zero, we have a stamp for a short circuit. For better understanding, consider the example in Figure 23.13. The network has two ungrounded nodes for which we can write the nodal equations:

$$(G_1 + sC_1)V_1 + I_E = 0$$
$$(G_2 + sC_2)V_2 - I_E = 0$$

To these equations, we must add the equation describing the properties of the ideal voltage source,

$$V_i - V_j = E \tag{23.7}$$

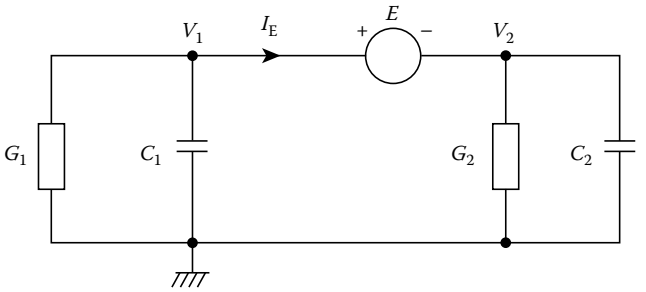

FIGURE 23.13 Example with a floating voltage source.

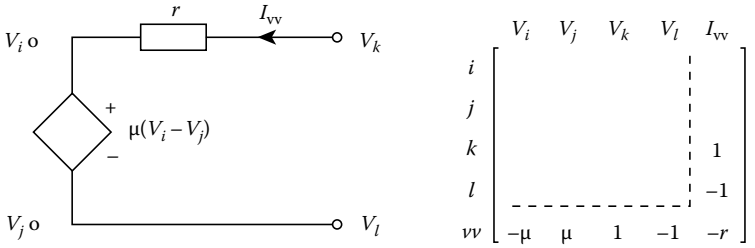

FIGURE 23.14 Stamp for a voltage-controlled voltage source. The resistor value can be zero.

Collecting into matrix form

$$\begin{bmatrix} G_1 + sC_1 & 0 & 1 \\ 0 & G_2 + sC_2 & -1 \\ 1 & -1 & 0 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ I_E \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ E \end{bmatrix}$$

We still need stamps for the remaining three dependent sources. The voltage controlled voltage source, *VV*, is shown in Figure 23.14. For generality, we added the internal resistor. The output is described by the equation

$$\mu(V_i - V_j) + rI_{VV} = V_k - V_l \tag{23.8}$$

None of the voltages is known, so we transfer everything to the left side. Input terminals do not influence the balance of currents, but the output terminals do. At node k we must add I_{VV}, and subtract the same at node l. The stamp is in Figure 23.14.

The current controlled current source, *CC*, is shown in Figure 23.15. The input terminals are short circuited and

$$V_i - V_j = 0 \tag{23.9}$$

No information is available about the output voltages, but we know that the current is α times the input current, and thus only one additional variable is needed. Balances of currents are influenced at all four nodes: positive I at node i, negative at node j, positive current αI at node k, and negative αI at node l. The stamp is in Figure 23.15, where the added column takes care of the currents and the additional row describes the properties of the short circuit.

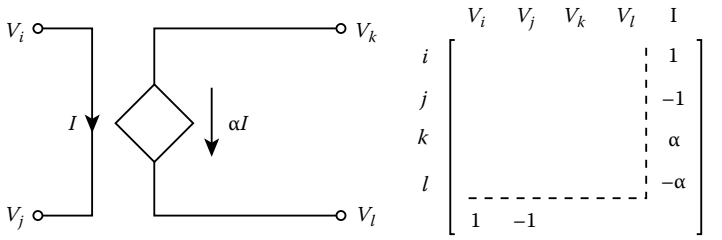

FIGURE 23.15 Stamp for a current-controlled current source.

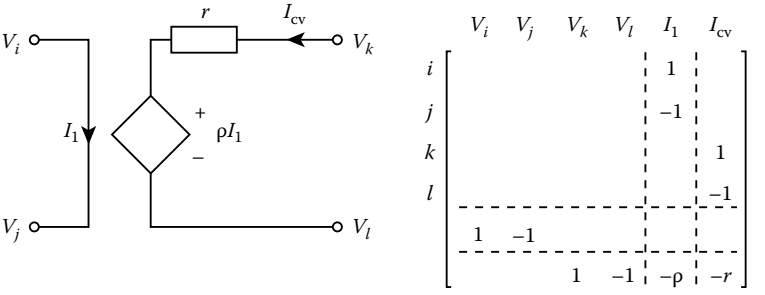

FIGURE 23.16 Stamp for a current-controlled voltage source. The resistor value can be zero.

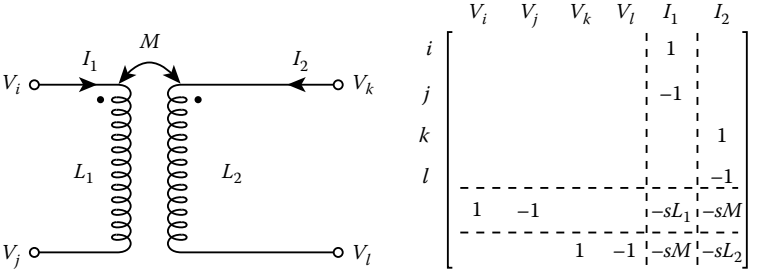

FIGURE 23.17 Stamp for a transformer.

The most complicated dependent source is the current-controlled voltage source, *CV*, shown in Figure 23.16. We can consider it as a combination of a short circuit and a voltage source. The equation for the short circuit is the same as for the *CC*. The output is defined by the equation

$$V_k - V_l = \rho I_1 + r I_{CV} \tag{23.10}$$

and because none of the variables is known, we transfer everything to the left. This element adds two rows and two columns to the previously defined matrix. Its stamp is in Figure 23.16. As before, the internal resistor r can be set equal to zero.

Modified nodal formulation easily takes into account a transformer (see Figure 23.17). It is described by the equations

$$\begin{aligned} V_i - V_j &= sL_1 I_1 + sMI_2 \\ V_k - V_l &= sL_1 I_1 + sL_2 I_2 \end{aligned} \tag{23.11}$$

None of the variables is known, and we transfer everything to the left. The currents influence the balance of currents at all nodes. The stamp of the transformer is in Figure 23.17.

The last element we consider is an ideal operational amplifier. It is sometimes taken as a voltage-controlled voltage source with very high gain, but it is preferable to have a stamp that can take into account ideal properties as well. The element is shown in Figure 23.18. The terminal l is usually grounded, but we will keep it floating to make the stamp more general. No current flows into the device at the input terminals. The output equation is

$$V_k - V_l = A(V_i - V_j) \tag{23.12}$$

Because a computer cannot handle infinity, it is advantageous to introduce the inverted gain

$$B = -1/A \tag{23.13}$$

and modify the previous equation to

$$V_i - V_j + BV_k - BV_l = 0 \tag{23.14}$$

This equation is attached to the set of equations and the balance of currents is influenced at nodes k and l. This leads to the stamp in Figure 23.18. If we set $B = 0$, the operational amplifier becomes ideal, with no approximation.

An example will show how the stamps are used. Consider the network in Figure 23.19. It has no practical application, but serves well for the demonstration of how to set up the modified nodal

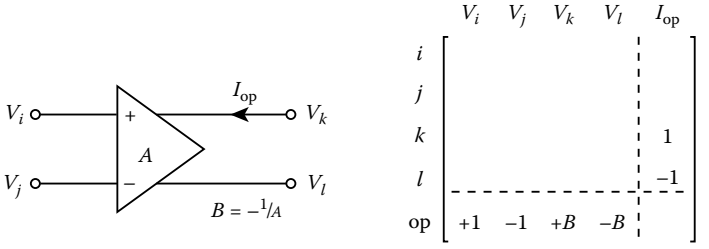

FIGURE 23.18 Stamp for an ideal operational amplifier.

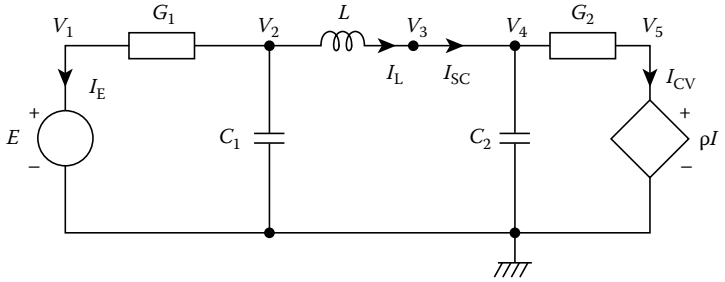

FIGURE 23.19 Example showing the use of modified nodal formulation.

matrix. A short circuit, indicating the controlling current of the current-controlled voltage source is taken into account by increasing the number of nodes. The network has five nongrounded nodes, and thus the dimension of its nodal portion will be 5. The voltage source will increase the system matrix by one row and one column, the inductor also, and the *CV* will need two more rows and columns; altogether the matrix will be 9×9. Write first the nodal portion by disregarding entirely the other elements. This creates the upper left partition. Using the stamps we add first the voltage source, then the inductor, next the short circuit, and finally the current-controlled voltage source. The system matrix is

Modified nodal formulation is the most important method for computer applications. The reader can find additional information in the books [1,2].

23.5 Nonlinear Elements

In previous sections, we used the Laplace transform to explain the various methods of formulation. Because we dealt with linear elements, the systems of equations were linear and it was possible to cast them into matrix forms.

If we must consider nonlinear elements, we face many restrictions. The Laplace transform cannot be used. Various concepts based on it, like the network functions, the poles and the zeros, cannot be applied. Only two types of analysis are available:

The dc solution (operating point)

Time-domain solution for a given input signal

Once we have nonlinear elements, we cannot write the equations in matrix form; all we can do is write KCL equations. We must also find another method for the solution of such nonlinear equations.

Consider two differentiable equations in two unknowns

$$\begin{aligned} f_1(v_1, v_2) &= 0 \\ f_2(v_1, v_2) &= 0 \end{aligned} \tag{23.15}$$

The functions can be expanded into Taylor series and the series truncated after the linear terms:

$$f_1(v_1 + \Delta v_1,\, v_2 + \Delta v_2) = f_1(v_1,\, v_2) + \frac{\partial f_1}{\partial v_1}\Delta v_1 + \frac{\partial f_1}{\partial v_2}\Delta v_2 + \cdots = 0$$

$$f_2(v_1 + \Delta v_1,\, v_2 + \Delta v_2) = f_2(v_1,\, v_2) + \frac{\partial f_2}{\partial v_1}\Delta v_1 + \frac{\partial f_2}{\partial v_2}\Delta v_2 + \cdots = 0$$

We are not considering higher-order terms, so the equation will not be exactly zero, but we can still try to find Δv_1 and Δv_2. Transferring the known function values to the right

$$\frac{\partial f_1}{\partial v_1}\Delta v_1 + \frac{\partial f_1}{\partial v_2}\Delta v_2 = -f_1(v_1, v_2)$$
$$\frac{\partial f_2}{\partial v_1}\Delta v_1 + \frac{\partial f_2}{\partial v_2}\Delta v_2 = -f_2(v_1, v_2)$$

This is a system of linear equations, and we can rewrite it in matrix form

$$\begin{bmatrix} \dfrac{\partial f_1}{\partial v_1} & \dfrac{\partial f_1}{\partial v_2} \\ \dfrac{\partial f_2}{\partial v_1} & \dfrac{\partial f_2}{\partial v_2} \end{bmatrix} \begin{bmatrix} \Delta v_1 \\ \Delta v_2 \end{bmatrix} = \begin{bmatrix} -f_1(v_1, v_2) \\ -f_2(v_1, v_2) \end{bmatrix} \tag{23.16}$$

The matrix on the left is called the Jacobian; on the right is the negative of the functions. Once this linear system is solved, we can get new values of the variables by writing

$$v_1^{(i+1)} = v_1^{(i)} + \Delta v_1^{(i)}$$
$$v_2^{(i+1)} = v_2^{(i)} + \Delta v_2^{(i)} \tag{23.17}$$

In this equation, we added the superscript to indicate iteration. The process is repeated until all Δv_i become sufficiently small. This iterative method is usually referred to as the Newton–Raphson iteration and is written in the form

$$\mathbf{J}(\mathbf{v}^{(i)})\ \Delta\mathbf{v}^{(i)} = -\mathbf{f}(\mathbf{v}^{(i)})$$
$$\mathbf{v}^{(i+1)} = \mathbf{v}^{(i)} + \Delta\mathbf{v}^{(i)} \tag{23.18}$$

Suppose that we now take the network in Figure 23.3, consider the conductances G_1 and G_3 as linear and replace G_2 by a nonlinear function

$$i = g(v_{\text{el}})$$

where v_{el} is the voltage across this element,

$$v_{\text{el}} = v_1 - v_2$$

and g represents a nonlinear function. The two KCL equations are

$$G_1 v_1 + g(v_{\text{el}}) - J = 0$$
$$-g(v_{\text{el}}) + G_3 v_2 = 0$$

For the Newton–Raphson equation, we need the derivatives with respect to v_1 and v_2. Consider now only the nonlinear element. Using the chain rule of differentiation we can write

$$\frac{\partial g(v_{\text{el}})}{\partial v_1} = \frac{\partial g(v_{\text{el}})}{\partial v_{\text{el}}}\ \frac{\partial v_{\text{el}}}{\partial v_1} = +\frac{\partial g(v_{\text{el}})}{\partial v_{\text{el}}}$$
$$\frac{\partial g(v_{\text{el}})}{\partial v_2} = \frac{\partial g(v_{\text{el}})}{\partial v_{\text{el}}}\ \frac{\partial v_{\text{el}}}{\partial v_2} = -\frac{\partial g(v_{\text{el}})}{\partial v_{\text{el}}}$$

With these preliminary steps, we can now write the Newton–Raphson equation:

$$\begin{bmatrix} G_1 + \dfrac{\partial g(v_{el})}{\partial v_{el}} & -\dfrac{\partial g(v_{el})}{\partial v_{el}} \\ -\dfrac{\partial g(v_{el})}{\partial v_{el}} & G_3 + \dfrac{\partial g(v_{el})}{\partial v_{el}} \end{bmatrix} \begin{bmatrix} \Delta v_1 \\ \Delta v_2 \end{bmatrix} = - \begin{bmatrix} G_1 v_1 + g(v_{el}) - J \\ -g(v_{el}) + G_3 v_3 \end{bmatrix}$$

Comparing the Jacobian of the Newton–Raphson equation with the nodal formulation, we reach the important conclusion, valid for networks of any size:

1. Linear elements will be in the Jacobian in the same position as they were in the linear system matrix.
2. Nonlinear elements will have entries in the same positions as if they were linear; only their numerical values will be equal to the derivative $\partial g/\partial v_{el}$, evaluated with already available variables.

This conclusion will also be true for the other formulations, similar to the tableau or the modified nodal. So far, we considered only nonlinear resistive elements and the operating point.

Nonlinear storage elements (capacitors and inductors) contribute to the equations with their fluxes and charges. The current through the nonlinear capacitor is defined by

$$i_c = \frac{dq(v_c)}{dt} \tag{23.19}$$

where $q(v_c)$ is the charge and v_c is the voltage across the capacitor. The voltage across the nonlinear inductor is given by

$$v_L = \frac{d\phi(i_L)}{dt} \tag{23.20}$$

with ϕ denoting the flux.

Integration of systems with storage elements is always done by first replacing the derivative by a suitable algebraic expression and then solving the resulting nonlinear algebraic system by the Newton–Raphson method derived previously.

Many methods are available to replace the time domain derivatives by algebraic expressions. Books on numerical analysis usually describe the Runge–Kutta method. We mention it here because it is not suitable for solution of networks. There are several reasons for this, the main one being that the preferred modified nodal formulation does not lead to systems of differential, but rather to systems of algebraic-differential equations. Only two methods are widely used, the trapezoidal formula and a family of backward differentiation formulas (BDFs). Among the BDFs, the simplest is the backward Euler, and we will base our explanations on this formula. It replaces the derivative by the difference of the previous and new value, divided by the step size, h,

$$\frac{dq(v_c)}{dt} \sim \frac{q_{new}(v_c) - q_{old}}{h}$$
$$\frac{d\phi(i_L)}{dt} \sim \frac{\phi_{new}(i_L) - \phi_{old}}{h}$$

Consider the network in Figure 23.20 with nonlinear storage elements and with a linear conductance, G. It can be described by three equations:

$$f_1 = \frac{dq(v_c)}{dt} + G(v_1 - v_2) - j(t) = 0$$

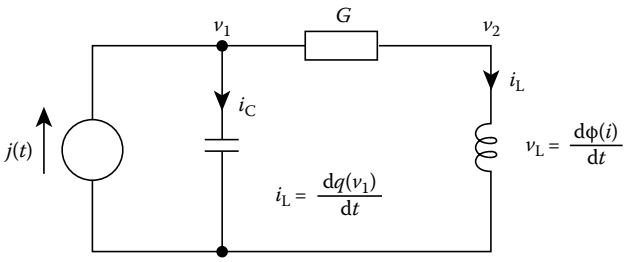

FIGURE 23.20 Network with a nonlinear capacitor and inductor.

$$f_2 = -G(v_1 - v_2) + i_L = 0$$
$$f_3 = v_2 - \frac{d\phi(I_L)}{dt} = 0$$

The time derivatives are replaced by the backward Euler formula

$$\frac{q_{new}(v_1) - q_{old}}{h} + G(v_1 - v_2) - j(t) = 0$$
$$-G(v_1 - v_2) + i_L = 0$$
$$v_2 - \frac{\phi_{new}(i_L) - \phi_{old}}{h} = 0$$

thus changing the system into an algebraic one. If we now differentiate with respect to the variables v_1, v_2, and i_L, we obtain the Jacobian

$$\begin{bmatrix} \frac{1}{h}\frac{\partial q_{new}(v_1)}{\partial v_1} + G & -G & 0 \\ -G & +G & 1 \\ 0 & 1 & -\frac{1}{h}\frac{\partial \phi_{new}(i_L)}{\partial i} \end{bmatrix}$$

It can be observed that values of the derivatives are in the same places as would be the values of $C(L)$ of linear capacitors (inductors). In addition, the variable s from the Laplace domain is replaced by $1/h$.

The example used a grounded capacitor and a grounded inductor. Figure 23.21 gives the stamps for floating nonlinear elements and for the Newton–Raphson iteration, based on the backward Euler formula.

23.6 Nodal Analysis of Active Networks

Low-frequency analog filters are often built with active RC networks and the active elements are almost always operational amplifiers. We have seen in Section 23.4 that each such element adds one row and one column to the modified nodal system matrix, thus making the system too large for hand solutions. We need a method that can reduce the size of the matrix to the minimum. Such reduction is possible [1,2], and becomes extremely simple if the voltage sources (dependent or independent) have one of their terminals grounded. Almost all practical networks meet this condition.

To introduce the method, consider the network in Figure 23.22. If we are not interested in the current through the voltage source, we can write only one nodal equation for the node on the right:

$$(G_1 + G_2)V_1 - EG_1 = 0$$

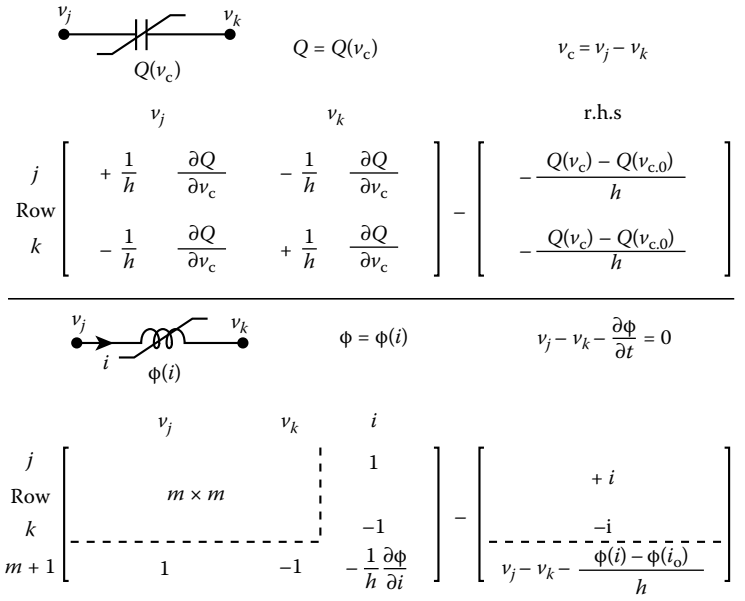

FIGURE 23.21 Stamp for a nonlinear capacitor and inductor.

The source is known, the term in which it appears is transferred to the right side and, instead of three equations of the modified nodal formulation, we must solve only one. Consider next the network in Figure 23.23 with a voltage source and an ideal operational amplifier. One of the output terminals of the operational amplifier is grounded. Such amplifier is described by the equation

$$(V_+ - V_-)A = V_{\text{out}} \tag{23.21}$$

where $A \to \infty$. Divide first by A and then substitute

$$B = -1/A \tag{23.22}$$

This changes the equation into

$$V_+ - V_- + BV_{\text{out}} = 0 \tag{23.23}$$

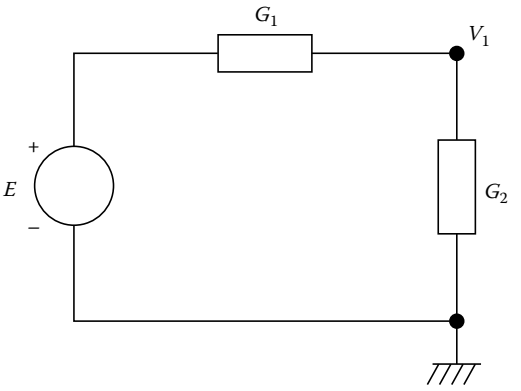

FIGURE 23.22 Example showing how to reduce the number of nodal equations.

If the operational amplifier is ideal, set $B = 0$ and in such case $V_+ = V_-$; the operational amplifier will have the same voltages at its input terminals. We can take this into consideration, by simply writing the voltage with the same subscript to both input terminals of the operational amplifier, as was done in Figure 23.23. We are not interested in the current of the voltage source, nor in the current flowing into the operational amplifier. We mark our lack of interest by crossing out the nodes that have grounded

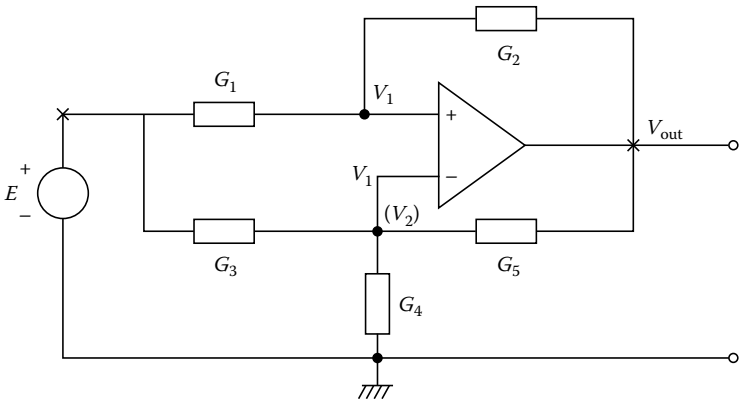

FIGURE 23.23 Nodal analysis of a network with one ideal operational amplifier.

voltage source; this was also done in Figure 23.23. Each node is given a voltage, but we write the nodal equations only at nodes that were not crossed out. For our example:

$$\begin{aligned}(G_1 + G_2)\ V_1 - G_2 V_{\text{out}} - EG_1 &= 0\\ (G_3 + G_4 + G_5)V_1 - G_5 V_{\text{out}} - EG_3 &= 0\end{aligned}$$

Terms with the known source voltage are transferred to the right and we have the system

$$\begin{bmatrix} G_1 + G_2 & -G \\ G_3 + G_4 + G_5 & -G_5 \end{bmatrix} \begin{bmatrix} V_1 \\ V_{\text{out}} \end{bmatrix} = \begin{bmatrix} G_1 E \\ G_3 E \end{bmatrix}$$

A modified modal formulation would have required six equations.

This method can be used for any network if one node of each voltage source, dependent or independent, is grounded. All we have to do is assign every node a voltage, cross out nodes with voltage sources, and write nodal equations for the rest. It is advantageous to use conductances for resistors, because this way we avoid the fractions.

The method remains valid if the operational amplifier is not ideal and has the inverted gain B. The only difference is that for a nonideal amplifier we cannot make any assumptions on the voltages at its input terminals and the subscripts of such voltages must be different. This second case is also illustrated in Figure 23.23 by the voltage V_2 (in brackets) at the lower node. We still write nodal equations for the two input terminals, but to complete the system we must also attach the equation of the operational amplifier. The result is

$$\begin{aligned}V_1(G_1 + G_2) - G_2 V_{\text{out}} &= G_1 E\\ V_1(G_3 + G_4 + G_5)V_2 - G_5 V_{\text{out}} &= G_3 E\\ V_1 - V_2 + BV_{\text{out}} &= 0\end{aligned}$$

and in matrix from

$$\begin{bmatrix} G_1 + G_2 & 0 & -G_2 \\ 0 & G_3 + G_4 + G_5 & -G_5 \\ 1 & -1 & B \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ V_{\text{out}} \end{bmatrix} \begin{bmatrix} G_1 E \\ G_3 E \\ 0 \end{bmatrix}$$

where B can be set zero for an ideal operational amplifier.

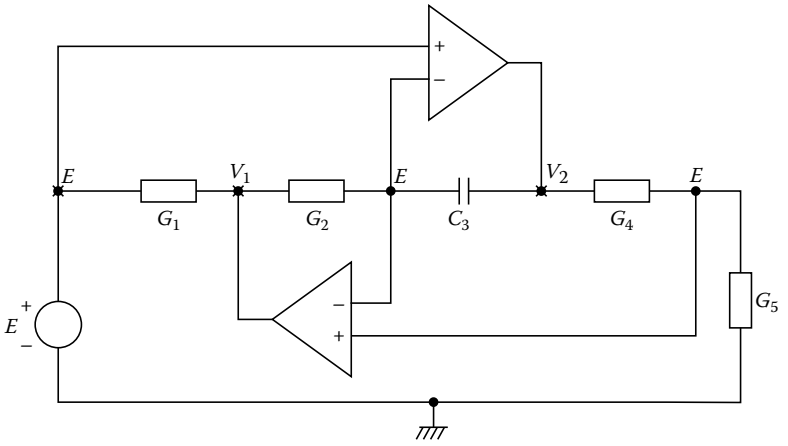

FIGURE 23.24 Nodal analysis of a network with two ideal operational amplifiers.

We will give one example of a practical network, Figure 23.24. The operational amplifiers are ideal and thus the input voltage, E, appears at three terminals of the network. The other terminal voltages are marked by V_1 and V_2. The terminals with voltage sources are marked by crosses and only nodes 3 and 5, counting from left, remain for writing the KCL. They are

$$(G_2 + sC_3)E - G_2V_1 - sC_3V_2 = 0$$
$$(G_4 + G_5)E - G_4V_2 = 0$$

Transferring terms containing the independent voltage source, E, to the other side of the equation, we arrive at the system

$$\begin{bmatrix} G_2 & sC_3 \\ 0 & G_4 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} (G_2 + sC_3)E \\ (G_4 + G_5)E \end{bmatrix}$$

Conclusion

It was demonstrated that hand calculations should use nodal or mesh formulations. Computer applications should be based on modified nodal formulation. For active networks, it is advantageous to use the method of Section 23.6.

24.1 Network Functions

Network functions are employed to characterize linear, time-invariant networks in the zero state for a single excitation. As described in Chapter 22 and other sections, network functions contain information concerning a network's stability and natural modes. They allow a designer to focus on obtaining a desired output signal for a given input signal.

In this section, it is shown that the concept of network functions is obtained as an extension of the (transformed) element defining equations for resistors, capacitors, and inductors. The relationships of network functions to transformed loop and node equations are also described. As a result of these relationships, a list of properties of network functions can be generated, which is useful in the analysis of linear networks. Much is known about a network function for a given network even before an analysis is performed and the function itself is obtained.

Ohm's law, $v_R(t) = Ri_R(t)$ where R is in ohms, describes the relationship between the voltage across the resistor and the current through the resistor. These variables and their reference polarity and direction are depicted in Figure 24.1. If elements of the equation for Ohm's law are transformed, we obtain $V(s) = RI(s)$ because R is a constant. Thus, we obtain an Ohm's law-like expression in the frequency domain.

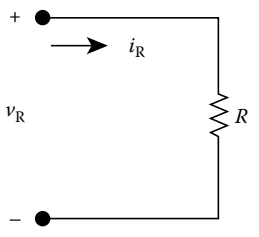

FIGURE 24.1 Reference polarity and direction for Ohm's law.

However, the capacitor's voltage and current are related by the integral

$$v_c(t) = \frac{1}{C}\int_{-\infty}^{t} i_c(t)\mathrm{d}t = \frac{1}{C}\int_{-\infty}^{0} i_C(t)\mathrm{d}t + \frac{1}{C}\int_{0}^{t} i_C(t)\mathrm{d}t$$

$$= V_o + \frac{1}{C}\int_{0}^{t} i_c(t)\mathrm{d}t \tag{24.1}$$

where the voltage reference polarity and the current reference direction are illustrated in Figure 24.2 and the capacitance C is given in farads (F). Unlike the resistor, the relation between the capacitor voltage and the capacitor current is not a simple Ohm's law-like expression in the time domain. In addition, the voltage across the capacitor at any time t, is dependent on the entire history of the current through the capacitor.

The integral expression for the voltage across the capacitor can be split into two terms where the first term is the initial voltage across the capacitor, $V_o = v_c(0)$. If the elements of the equation are transformed, we obtain

$$V_c(s) = \frac{V_o}{s} + \frac{1}{C}\frac{I_c(s)}{s} \tag{24.2}$$

Equation 24.2 shows that if $V_o = 0$, then the expression for the transform of the capacitor voltage becomes more nearly Ohm's law-like in its form. Furthermore, if we associate the s that arises because of the integral of the current with the capacitor C, and define the impedance of the capacitor as $Z(s) = V_c(s)/I_c(s) = 1/(sC)$, then the equation becomes Ohm's law-like in the frequency domain.

A similar process can be applied to the inductor. The current through the inductor is expressed as

$$i_L(t) = \frac{1}{L}\int_{-\infty}^{t} v_L(t)\mathrm{d}t = I_o + \frac{1}{L}\int_{0}^{t} v_L(t)\mathrm{d}t \tag{24.3}$$

where

L is expressed in henries (H)

$I_o = i_L(0)$ is the initial current through the inductor

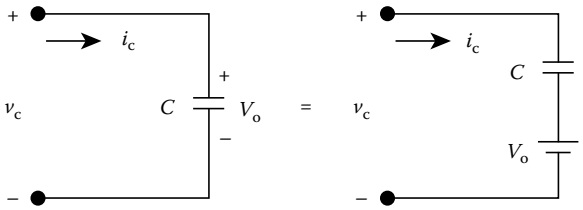

FIGURE 24.2 Capacitor representation showing reference polarities for voltages and reference direction for current.

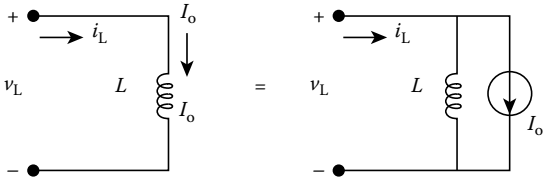

FIGURE 24.3 Inductor representation showing reference directions for currents and reference polarity for voltage.

Figure 24.3 depicts the reference polarity and direction for the inductor voltage and current. If the expression for the current through the inductor is transformed, the result is

$$I_L(s) = \frac{I_o}{s} + \frac{1}{L}\frac{V_L(s)}{s} \tag{24.4}$$

Again, as with the capacitor, if $I_o = 0$ and if the s that is included because of the integral of $v_L(t)$ is considered as associated with L, then the expression for the transform of the current through the inductor has an Ohm's law-like form if we define the impedance of the inductor as $Z(s) = V_L(s)/I_L(s) = sL$.

The impedance concept is an important one in network analysis. It allows us to combine dissimilar elements in the frequency domain—something we cannot do in the time domain. In fact, impedance is a frequency-domain concept. It is the ratio of the transform of the voltage across the port of the network to the transform of the current through the port with all independent sources within the network properly removed and with all initial voltages across capacitors and initial currents through inductors set to zero. Thus, when we indicate that independent sources are to be removed, we mean that initial conditions are to be set to zero as well.

The concept of impedance can be extended to linear, lumped, finite, time-invariant, one-port networks in general. We denote these networks as lumped, linear, finite, time-invariant (LLFT) networks. These networks are linear. That is, they are composed of elements including resistors, capacitors, inductors, transformers, and dependent sources with parameters that are not functions of the voltage across the element or the current through the element. Thus, the differential equations describing these networks are linear.

These networks are lumped and not distributed. That is, LLFT networks do not contain transmission lines as network elements, and the differential equations describing these networks are ordinary and not partial differential equations.

LLFT networks are finite, meaning that they do not contain infinite networks and require only a finite number of network elements in their representation. Infinite networks are sometimes useful in modeling such things as ground connections in the surface of the earth, but we exclude the discussion of them here.

LLFT networks are time-invariant or constant instead of time-varying. Thus, the ordinary, linear differential equations describing LLFT networks have constant coefficients.

The steps for finding the impedance of an LLFT one-port network are

1. Properly remove all independent sources in the network. By "properly" removing independent sources, we mean that voltage sources are replaced by short circuits and current sources are replaced by open circuits. Dependent sources are not removed.
2. Excite the network with a voltage source or a current source at the port, and find an equation or equations to solve for the other port variable.
3. Form $Z(s) = V(s)/I(s)$.

Simple networks do not need to be excited in order to determine their impedance, but in the general case an excitation is required. The next example illustrates these concepts.

Example 24.1

Find the impedances of the one-port networks in Figure 24.4.

Solution

The network in Figure 24.4a is composed of three elements connected in series. No independent sources are present, and there is zero initial voltage across the capacitor and zero initial current through the inductor. The impedance is determined as

$$Z(s) = R + sL + \frac{1}{sC} = L\left(\frac{s^2 + s\frac{R}{L} + \frac{1}{LC}}{s}\right)$$

The network in Figure 24.4b includes a dependent source that depends on the voltage across R_1. The impedance of this network is not obvious, and so we should excite the port. Also, the capacitor has an initial voltage V_c across it. This voltage is set to zero to find the impedance. Figure 24.5 is the network in Figure 24.4b prepared for finding the impedance. Using the impedance concept and two loop equations or two node equations, we obtain

$$Z(s) = \frac{V(s)}{I(s)} = \frac{R_1R_2\left(s + \frac{1}{CR_1}\right)}{[R_1(1-K) + R_2]\left(s + \frac{1}{C[R_1(1-K)+R_2]}\right)}$$

The expressions for impedance found in the previous example are rational functions of s, and the coefficients of s are functions of the elements of the network including the coefficient K of the dependent source in the network in Figure 24.4b. We will demonstrate that these observations are general for LLFT networks; but first we will extend the impedance concept in another direction.

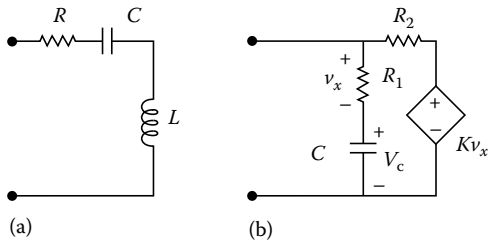

FIGURE 24.4 (a) Simple network. (b) A network containing a dependent source.

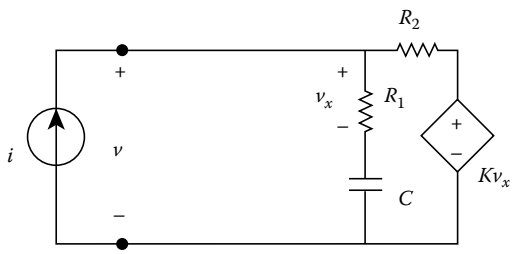

FIGURE 24.5 Network in Figure 24.4b prepared for analysis.

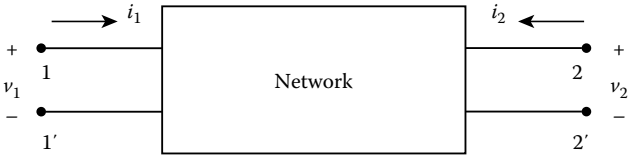

FIGURE 24.6 Reference polarities and reference directions for port variables of a two-port network.

We have defined the impedance of a one-port LLFT network. We can also define another network function—the admittance $Y(s)$. The admittance of a one-port LLFT network is the quotient of the transform of the current through the port to the transform of the voltage across the port with all independent sources within the network properly removed. One-port networks have only two linear network functions, impedance and admittance. Furthermore, $Z(s) = 1/Y(s)$ because both network functions concern the same port of the network, and the impedance or admittance relating the response to the excitation is the same whether a current excitation causes a voltage response or a voltage excitation causes a current response. An additional implication of this observation is that either network function can be determined with either type of excitation, voltage source or current source, applied to the network.

Figure 24.6 depicts a two-port network with the reference polarities and reference directions indicated for the port variables. Port one of the two-port network is formed from the two terminals labeled 1 and 1′. The two terminals labeled 2 and 2′ are associated to form port two. A two-port network has 12 network functions associated with it instead of only two, and so we will employ the following notation for these functions:

$$N_{\mathrm{RE}}(s) = R(s)/E(s)$$

where

$N_{\mathrm{RE}}(s)$ is a network function, the subscript "R" is the port at which the response variable exists, the subscript "E" is the port at which the excitation is applied

$R(s)$ is the transform of the response variable

$E(s)$ is the transform of the excitation that may be a current source or a voltage source depending on the particular network function

For example, for the two-port networks shown in Figure 24.7

$$Z_{21}(s) = \frac{V_2(s)}{I_1(s)} \quad \text{and} \quad G_{12}(s) = \frac{V_1(s)}{V_2(s)} \tag{24.5}$$

Note that a load impedance has been placed across port two, the response port for $Z_{21}(s)$, in Figure 24.7a. Also, a load has been connected across port one, the response port for $G_{12}(s) = V_1(s)/V_2(s)$ in Figure 24.7b. It is assumed that all independent sources have been properly removed in both networks

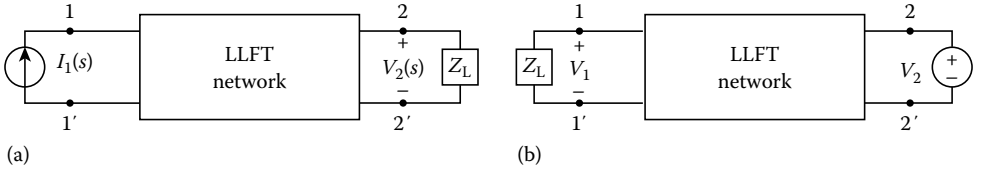

FIGURE 24.7 (a) Network configured for finding $Z_{21}(s)$. (b) Network for determining $G_{12}(s)$.

TABLE 24.1 Network Functions of Two-Port Networks

	Excitation Port	
Response Port	1	2
1	Z_{11}, Y_{11}	Z_{12}, Y_{12}, G_{12}, α_{12}
2	Z_{21}, Y_{21}, G_{21}, α_{21}	Z_{22}, Y_{22}

in Figure 24.7, and this assumption also applies to the loads. Of course, if a load impedance is changed, usually the network function will change. Thus, the load, if any, must be specified.

Table 24.1 lists the network functions of a two-port network. "G" denotes a voltage ratio, and "α" denotes a current ratio. The functions can also be grouped into driving-point and transfer functions. Driving-point functions are ones in which the excitation and response occur at the same port, and transfer network functions are ones in which the excitation and response occur at different ports. For example, $Z_{11}(s) = V_1(s)/I_1(s)$ is a driving-point network function, and $G_{21}(s) = V_2(s)/V_1(s)$ is a transfer network function. Of the twelve network functions for a two-port network, four are driving-point functions and eight are transfer functions. The two network functions for a one-port network are, of necessity, driving-point network functions.

Network functions are related to loop and node equations. Consider the LLFT network in Figure 24.8. Independent sources within the network have been properly removed. Assume the network has n independent nodes plus the ground node, and assume for simplicity that the network has no mutual inductance or dependent sources. Let us determine $Z_{11} = V_1/I_1$ in terms of a quotient of determinants of the nodal admittance matrix. The node equations, all written with currents leaving a node as positive currents, are

$$\begin{bmatrix} y_{11} & y_{12} & \cdots & y_{1n} \\ y_{21} & y_{22} & \cdots & y_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ y_{n1} & y_{n2} & \cdots & y_{nn} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ \vdots \\ V_n \end{bmatrix} = \begin{bmatrix} I_1 \\ 0 \\ \vdots \\ 0 \end{bmatrix} \tag{24.6}$$

where V_i, $i = 1, 2, \ldots, n$, are the unknown node voltages. The elements y_{ij}, $i, j = 1, 2, \ldots, n$, of the nodal admittance matrix above have the form

$$y_{ij} = \pm\left\{ g_{ij} + \frac{\Gamma_{ij}}{s} + sC_{ij} \right\} \tag{24.7}$$

where the plus sign is taken if $i = j$ and the minus sign is taken if i and j are unequal. The quantity g_{ij} is the sum of the conductances connected to node i if $i = j$, and if i does not equal j, it is the sum of the

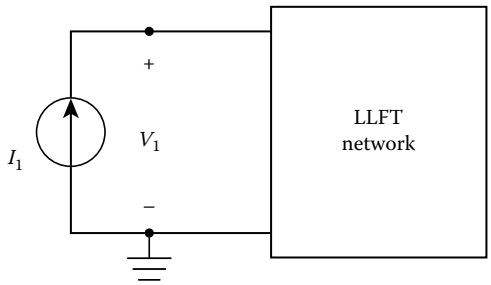

FIGURE 24.8 LLFT network with n independent nodes plus the ground node.

conductances connected between nodes i and j. A similar statement applies to C_{ij}. The quantity Γ_{ij} is the sum of the reciprocal inductances ($\Gamma = 1/L$) connected to node i if $i = j$, and it is the sum of the reciprocal inductances connected between nodes i and j if i does not equal j.

Solving for V_1 using Cramer's rule yields

$$V_1 = \frac{\begin{vmatrix} I_1 & y_{12} & \cdots & y_{1n} \\ 0 & y_{22} & \cdots & y_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & y_{n2} & \cdots & y_{nn} \end{vmatrix}}{\Delta'} \tag{24.8}$$

where Δ' is the determinant of the nodal admittance matrix. Thus,

$$V_1 = I_1 \frac{\Delta'_{11}}{\Delta'} \tag{24.9}$$

where Δ'_{11} is the cofactor of element y_{11} of the nodal admittance matrix. Thus, we can write

$$\frac{V_1}{I_1} = Z_{11} = \frac{\Delta'_{11}}{\Delta'} \tag{24.10}$$

If mutual inductance and dependent sources exist in the LLFT network, the nodal admittance matrix elements are modified. Furthermore, there may be more than one entry in the column matrix containing excitations. However, Z_{11} can still be expressed as a quotient of determinants of the nodal admittance matrix.

Next, consider the network in Figure 24.9, which is assumed to have n independent nodes plus a ground node. The response port exists between terminals j and k. In this network, we are making the pair of terminals j and k serve as the second port. Denote the transimpedance V_{jk}/I_1 as Z_{j1}. Let us express this transfer function Z_{j1} as a quotient of determinants. All independent sources within the network have been properly removed. Note that the node voltages are measured with respect to the ground terminal indicated, but the output voltage is the difference of the node voltages V_j and V_k. Thus, we have to solve for these two node voltages. Writing node equations, again taking currents leaving a node as positive currents, and solving for V_j using Cramer's rule we have

$$V_j = \frac{\begin{vmatrix} y_{11} & y_{12} & \cdots & y_{1(j-1)} & I_1 & y_{1k} & \cdots & y_{1n} \\ y_{21} & y_{22} & \cdots & y_{2(j-1)} & 0 & y_{2k} & \cdots & y_{2n} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ y_{n1} & y_{n2} & \cdots & y_{n(j-1)} & 0 & y_{nk} & \cdots & y_{nn} \end{vmatrix}}{\Delta'} \tag{24.11}$$

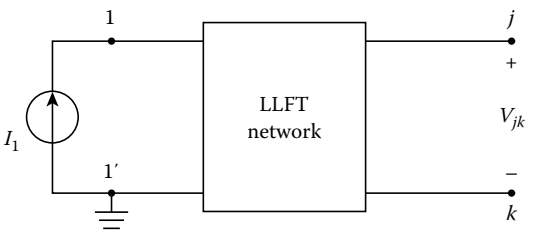

FIGURE 24.9 LLFT network with two ports indicated.

which can be written as

$$V_j = I_1 \frac{\Delta'_{1j}}{\Delta'} \tag{24.12}$$

where Δ'_{1j} is the cofactor of element y_{1j} of the nodal admittance matrix. Similarly, we can solve for V_k and obtain

$$V_k = I_1 \frac{\Delta'_{1k}}{\Delta'} \tag{24.13}$$

Then, the transimpedance Z_{j1} can be expressed as

$$Z_{j1} = \frac{V_j - V_k}{I_1} = \frac{\Delta'_{1j} - \Delta'_{1k}}{\Delta'} \tag{24.14}$$

If terminal k in Figure 24.9 is common with the ground node so that the network is a grounded two-port network, then V_k is zero, and Z_{j1} can be expressed as Δ'_{1j}/Δ'. This result can be extended so that if the output voltage is taken between any node h and ground, then the transimpedance can be expressed as $Z_{h1} = \Delta'_{1h}/\Delta'$.

These results can be used to obtain an expression for G_{21} in terms of the determinants of the nodal admittance matrix. Figure 24.10 shows an LLFT network with a voltage excitation applied at port 1 and with port 2 open. The current $I_1(s)$ is given by V_1/Z_{11}. Then, V_2 is given by $V_2(s) = I_1 Z_{21}$. Thus,

$$G_{21} = \frac{V_2}{V_1} = \frac{I_1 Z_{21}}{I_1 Z_{11}} = \frac{\Delta'_{12}}{\Delta'_{11}} \tag{24.15}$$

Note that the determinants in the quotient are of equal order so that G_{21} is dimensionless.

Of course, network functions can also be expressed in terms of determinants of the loop impedance matrix. Consider the two-port network in Figure 24.11, which is excited with a voltage source applied to

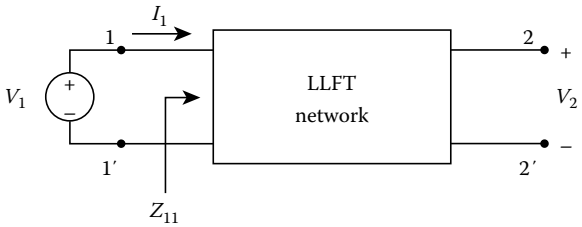

FIGURE 24.10 LLFT network with port 2 open.

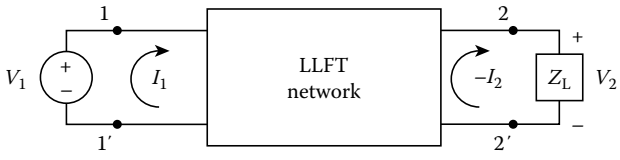

FIGURE 24.11 LLFT network with load Z_L connected across port 2.

port 1 and has a load Z_L connected across port 2. Let us find the voltage transfer function G_{21} using loop equations. Assume that n independent loops exist, of which two are illustrated explicitly in Figure 24.11, and assume that no independent sources are present within the network. Also, assume for simplicity that the network contains no dependent sources or mutual inductance and that the loops are chosen so that V_1 is in only one loop. The loop equations are

$$\begin{bmatrix} z_{11} & z_{12} & \cdots & z_{1n} \\ z_{21} & z_{22} & \cdots & z_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ z_{n1} & z_{n2} & \cdots & z_{nn} \end{bmatrix} \begin{bmatrix} I_1 \\ -I_2 \\ \vdots \\ I_n \end{bmatrix} = \begin{bmatrix} V_1 \\ 0 \\ \vdots \\ 0 \end{bmatrix} \tag{24.16}$$

where $I_j, j = 1, 3, \ldots, n$, and $-I_2$ are the loop currents, and the elements z_{ij} of the loop impedance matrix are given by

$$z_{ij} = \pm\left(R_{ij} + sL_{ij} + \frac{D_{ij}}{s}\right), \quad i, j = 1, 2, \ldots, n \tag{24.17}$$

where we have assumed that all loop currents are taken in the same direction such as clockwise. The plus sign applies if $i = j$, and the minus sign is used if $i \neq j$. R_{ij} is the sum of the resistances in loop i if $i = j$, and R_{ij} is the sum of the resistances common to loops i and j if $i \neq j$. L_{ij} is the sum of the inductances in loop i if $i = j$, and it is the sum of the inductances common to loops i and j if $i \neq j$. A similar statement applies to the reciprocal capacitances $D_{ij}(D = 1/C)$. However, the element z_{22} includes the extra term Z_L which could be a quotient of determinants itself. Solving for $-I_2$ using Cramer's rule, we have Δ, which is the determinant of the $n \times n$ loop impedance matrix, and Δ_{12} is the cofactor of element z_{12} of the loop impedance matrix.

$$-I_2 = \frac{\begin{vmatrix} z_{11} & V_1 & z_{13} & \cdots & z_{1n} \\ z_{21} & 0 & z_{23} & \cdots & z_{2n} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ z_{n1} & 0 & z_{n3} & \cdots & z_{nn} \end{vmatrix}}{\Delta} = V_1 \frac{\Delta_{12}}{\Delta} \tag{24.18}$$

The transform voltage V_2 is given by $-I_2(s)Z_L$, and the transfer function G_{21} can be expressed as

$$G_{21} = \frac{V_2}{V_1} = Z_L \frac{\Delta_{12}}{\Delta} \tag{24.19}$$

Thus, G_{21} can be represented as a quotient of determinants of the loop impedance matrix multiplied by Z_L.

In a similar manner, we can write

$$Y_{jk} = \frac{\Delta_{kj}}{\Delta}, \quad j, k = 1, 2 \tag{24.20}$$

Then, we can use this result to write

$$V_1 = I_1 \frac{1}{Y_{11}} \quad \text{and} \quad I_2 = V_1 Y_{21} \tag{24.21}$$

TABLE 24.2 Network Function in Terms of Quotients of Determinants

$Y_{jk} = \Delta_{kj}/\Delta$	$G_{jk} = \Delta'_{kj}/\Delta'_{kk}$
$Z_{jk} = \Delta'_{kj}/\Delta'$	$\alpha_{jk} = \Delta_{kj}/\Delta_{kk}$

Thus,

$$\frac{I_2}{I_1} = \alpha_{21} = \frac{\Delta_{12}}{\Delta_{11}} \tag{24.22}$$

Table 24.2 summarizes some of these results.

24.1.1 Properties of LLFT Network Functions

We now list properties of network functions of LLFT networks. These properties are useful as a check of an analysis of such networks.

1. Network functions of LLFT networks are real, rational functions of s, and therefore have the form

$$N(s) = \frac{P(s)}{Q(s)} = \frac{a_0 s^m + a_1 s^{m-1} + \cdots + a_{m-1}s + a_m}{b_0 s^n + b_1 s^{n-1} + \cdots + b_{n-1}s + b_n} \tag{24.23}$$

   where the coefficients in both the numerator and denominator polynomials are real.

   A network function of an LLFT network is a rational function because network functions can be expressed as quotients of determinants of nodal admittance matrices or of loop impedance matrices. The elements of these determinants are at most simple rational functions, and when the determinants are expanded and the fractions cleared, the result is always a rational function. The coefficients a_i, $i = 0, 1, \ldots, m$, and b_j, $j = 0, 1, \ldots, n$, are functions of the real elements of the network R, L, C, M, and coefficients of dependent sources. The constants R, L, C, and M are real. In most networks, the coefficients of dependent sources are real constants. Thus, the coefficients of LLFT network functions are real, and therefore the network function is a real function. It is possible for the "coefficients" of dependent sources in LLFT networks to themselves be real, rational functions of s. But when all the fractions are cleared, the result is a real, rational function.
2. LLFT network function is completely defined by its self-poles, self-zeros, and the scale factor H.

   If the numerator and denominator polynomials are factored and there are no common factors, we have

$$N(s) = \frac{P(s)}{Q(s)} = \frac{a_0}{b_0}\frac{(s - z_1)(s - z_2)\ldots(s - z_m)}{(s - p_1)(s - p_2)\ldots(s - p_n)} \tag{24.24}$$

   where $a_0/b_0 = \mathrm{H}$ is the scale factor. The values of $s = z_1, z_2, \ldots, z_m$ are zeros of the polynomial $P(s)$ and self-zeros of the network function. Also, $s = p_1, p_2, \ldots, p_{\mathrm{n}}$ are zeros of the polynomial $Q(s)$ and self-poles of the network function. In addition, $N(s)$ may have other poles or zeros at infinity. We call these poles and zeros mutual poles and mutual zeroes because they result from the difference in degrees of the numerator and denominator polynomials.
3. Counting both self and mutual poles and zeros, and counting a kth order pole or zero k times, $N(s)$ has the same number of poles as zeros, and this number is equal to the highest power of s in $N(s)$. If $m = n$, then there are n self-zeros and n self-poles and no mutual poles or zeros. If $n > m$, then there are m self-zeros and n self-poles. There are also $n - m$ mutual zeros. Thus, there are n poles and $m + (n - m) = n$ zeros. A similar statement can be constructed for $n < m$.

4. Complex roots of $P(s)$ and $Q(s)$ occur in conjugate pairs.

   This property follows from the fact that the coefficients of the numerator and denominator polynomials are real. Thus, complex factors of these polynomials have the form

$$(s + c + jd)(s + c - jd) = [(s + c)^2 + d^2] \tag{24.25}$$

   where c and d are real constants.
5. A driving point function of a network having no dependent sources can have neither poles nor zeros in the right-half s-plane (RHP), and poles and zeros on the imaginary axis must be simple. The same restrictions apply to the poles of transfer network functions of such networks but not to the zeros of transfer network functions.

   Elsewhere in this handbook it is shown that the denominator polynomials of LLFT networks having no dependent sources cannot have RHP roots, and roots on the imaginary axis, if any, must be simple. However, the reciprocal of a driving-point network function is also a network function. For example, $1/Y_{22} = Z_{22}$. Thus, restrictions on the locations of poles of driving-point network functions also apply to zeros of driving-point network functions.

   However, the reciprocal of a transfer network function is not a network function (see [5]). For example, $1/Y_{21} \neq Z_{21}$. Thus, restrictions on the poles of a transfer function do not apply to its zeros.

   We can make a classification of the factors corresponding to the allowed types of poles as follows:

   The Type A factor corresponds to a pole on the $-\sigma$-axis. If $a = 0$, then the factor corresponds to a pole on the imaginary axis, and so only one such factor is allowed. Type B factors correspond to poles in the left-half s-plane (LHP), and Type C factors correspond to poles on the imaginary axis.
6. The coefficients of the numerator and denominator polynomials of a driving-point network function of an LLFT network with no dependent sources are positive. The coefficients of the denominator polynomial of a transfer network function are all one sign. Without loss of generality, we take the sign to be positive. But some or all of the coefficients of the numerator polynomial of a transfer network function may be negative.

   A polynomial made up of the factors listed in Table 24.3 would have the form:

$$Q(s) = (s + a_1) \cdots \left[(s + b_1)^2 + c_1^2\right] \cdots \left(s^2 + d_1^2\right) \cdots$$

   Note that all the constants are positive in the expression for $Q(s)$, and so it is impossible for any of the coefficients of $Q(s)$ to be negative.
7. There are no missing powers of s in the numerator and denominator polynomials of a driving-point network function of an LLFT network with no dependent sources unless all even or all odd powers of s are missing or the constant term is missing. This statement holds for the denominator polynomials of transfer functions of such networks, but there may be missing powers of s in the numerator polynomials of transfer functions.

   Property 7 is easily illustrated by combining types of factors from Table 24.3. Thus, a polynomial consisting only of type A factors contains all powers of s between the highest power and the constant term unless one of the "a" constants is zero. Then, the constant term is missing. Two a

TABLE 24.3 A Classification of Factors of Network Functions of LLFT Networks Containing No Dependent Sources

Type	Factor(s)	Conditions
A	$(s + a)$	$a \geq 0$
B	$(s + b + jc)(s + b - jc)$	$b > 0$, $c > 0$
C	$(s + jd)(s - jd)$	$d > 0$

constants cannot be zero because then there would be two roots on the imaginary axis at the same location. The roots on the imaginary axis would not be simple.

A polynomial made up of only type B factors contains all powers of s, and a polynomial containing only type C factors contains only even powers of s. A polynomial constructed from type C factors except for one A type factor with $a = 0$ contains only odd powers of s. If a polynomial is constructed from type B and C factors, then it contains all power of s.

8. The orders of the numerator and denominator polynomials of a driving-point network function of an LLFT network, which contains no dependent sources can differ by no more than one.

   The limiting behavior at high frequency must be that of an inductor, a resistor, or a capacitor. That is, if $N_{dp}(s)$ is a driving-point network function, then

$$\lim_{s\to\infty} N_{dp}(s) = \begin{cases} K_1 s \\ K_2 \\ K_3/s \end{cases}$$

   where $K_i, = 1, 2, 3$, are real constants.

9. The terms of lowest order in the numerator and denominator polynomials of a driving-point network function of an LLFT network containing no dependent sources can differ in order by no more than one.

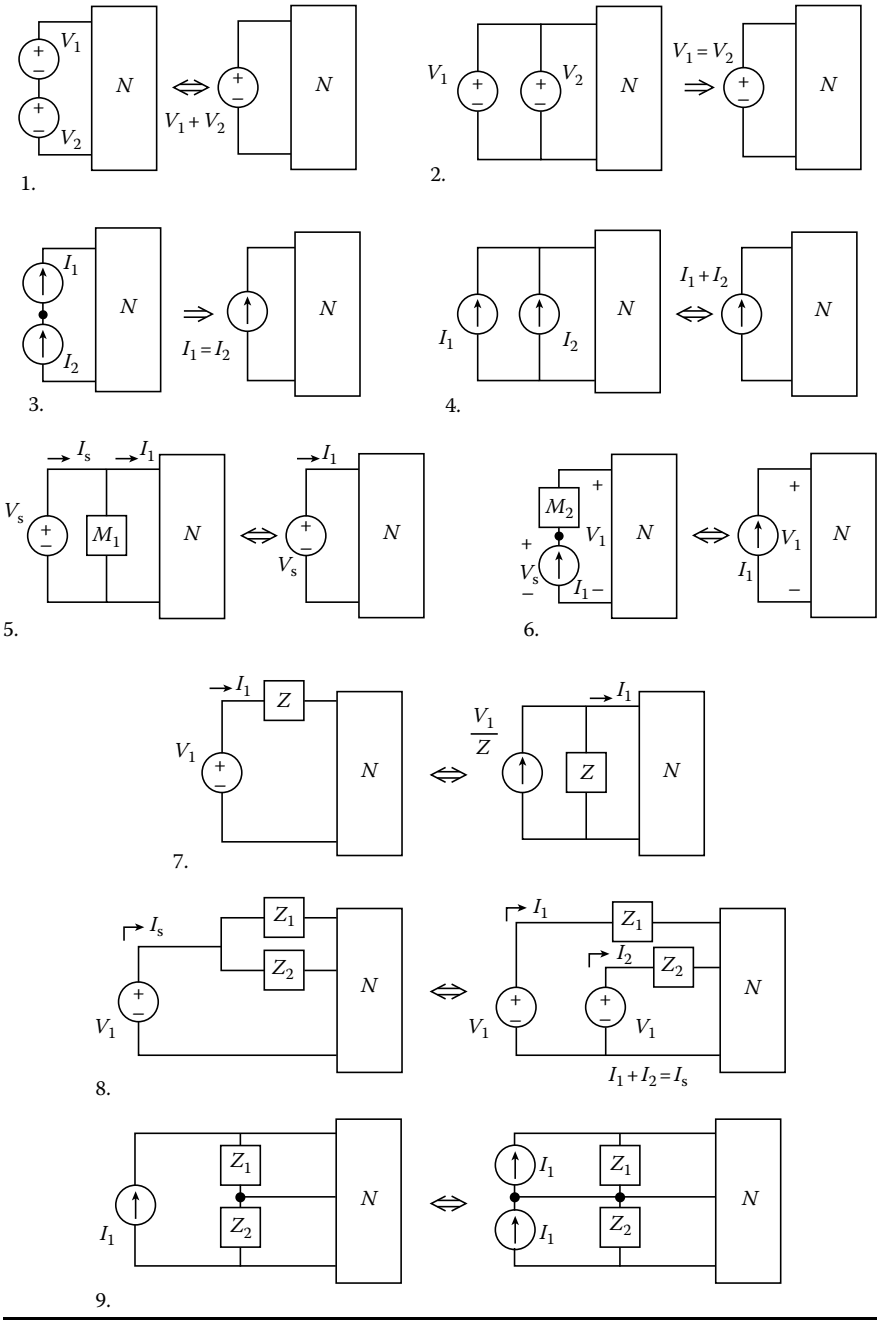
   The limiting behavior at low frequency must be that of an inductor, a resistor, or a capacitor. That is,

$$\lim_{s\to 0} N_{dp}(s) = \begin{cases} K_4 s \\ K_5 \\ K_6/s \end{cases}$$

   where the constants K_i, $i = 4, 5, 6$, are real constants.

10. The maximum order of the numerator polynomials of the dimensionless transfer functions G_{12}, G_{21}, α_{12}, and α_{21}, of an LLFT network containing no dependent sources is equal to the order of the denominator polynomials. The maximum order of the numerator polynomial of the transfer functions Y_{12}, Y_{21}, Z_{12}, and Z_{21} is equal to the order of the denominator polynomial plus 1. However, the minimum order of the numerator polynomial of any transfer function may be zero.

If dependent sources are included in an LLFT network, then it is possible for the network to have poles in the RHP or multiple poles at locations on the imaginary axis. However, an important application of stable networks containing dependent sources is to mimic (simulate) the behavior of LLFT networks that contain no dependent sources. For example, networks that contain resistors, capacitors, and dependent sources can mimic the behavior of networks containing only resistors, capacitors, and inductors. Thus, low-frequency filters can be constructed without the need for heavy, expensive inductors that would ordinarily be required in such applications.



24.2 Network Theorems

In this section, we provide techniques, strategies, equivalences, and theorems for simplifying the analysis of LLFT networks or for checking the results of an analysis. They can save much work in the analysis of some networks if one remembers to apply them. Thus, it is convenient to have them listed in one place. To begin, we list nine equivalences that are often called source transformations.

24.2.1 Source Transformations

Table 24.4 is a collection of memory aids for the nine source transformations. Source transformations are simple ways the elements and sources externally connected to a network N can be combined or

TABLE 24.4 Source Transformations

N is an arbitrary network in which analysis for a voltage or current is to be performed. M_1 is an arbitrary one-port network or network element except a voltage source. M_2 is an arbitrary one-port network or network element except a current source. It is assumed there is no magnetic coupling between *N* and M_1 or M_2. There are no dependent sources in *N* in source transformation five that depend on I_s. Furthermore, there are no dependent sources in *N* in source transformation six that depend on V_s. However, M_1 and M_2 can have dependent sources that depend on voltages or currents in *N*. *Z*, Z_1 and Z_2 are one-port impedances.

eliminated without changing the voltages and currents within network N thereby simplifying the problem of finding a voltage or current within N.

Source transformation one in Table 24.4 shows the equivalence between two voltage sources connected in series and a single voltage source having a value that is the sum of the voltages of the two sources. A double-headed arrow is shown between the two network representations because it is sometimes advantageous to use this source transformation in reverse. For example, if a voltage source that has both DC and AC components is applied to a linear network N, it may be useful to represent that voltage source as two voltage sources in series—one a DC source and the other an AC source.

Source transformation two shows two voltage sources connected in parallel. Unless V_1 and V_2 are equal, the network would not obey Kirchhoff's law as evidenced by a loop equation written in the loop formed by the two voltage sources. A network that does not obey Kirchhoff's laws is termed a contradiction. Thus, a single-headed arrow is shown between the two network representations.

Source transformations three and four are duals, respectively, of source transformations two and one. The current sources must be equal in transformation three or else Kirchhoff's law would not be valid at the node indicated, and the circuit would be a contradiction.

Source transformation five shows that the circuit M_1 can be removed without altering any of the voltages and currents inside N. Whether M_1 is connected as shown or is removed, the voltage applied to N remains V_s. However, the current supplied by the source V_s changes from I_s to I_1.

Source transformation six shows that circuit M_2 can be replaced by a short circuit without affecting voltages and currents in N. Whether M_2 is in series with the current source I_1 as shown or removed, the current applied to N is the same. However, if network M_2 is removed, then the voltage across the current source changes from V_s to V_1.

Source transformation seven is sometimes termed a Thévenin circuit to Norton circuit transformation. This transformation, as shown by the double-headed arrow, can be used in the reverse direction. Thévenin's theorem is discussed thoroughly later in this section.

Source transformation eight is sometimes described as ''pushing a voltage source through a node,'' but we will term it as ''splitting a voltage source.'' Loop equations remain the same with this transformation, and the current leaving network N through the lowest wire continues to be I_s.

Source transformation nine shows that if a current source is not in parallel with one element, then it can be ''split'' as shown. Now, each one of the current sources I_1 has an impedance in parallel. Thus, analysis of network N may be simplified because source transformation seven can be applied.

Source transformations cannot be applied to all networks, but when they can be employed, they usually yield useful simplifications of the network.

Example 24.2

Use source transformations to find V_0 for the network shown in Figure 24.12. Initial current through the inductor in the network is zero.

Solution

The network can be readily simplified by employing source transformation five from Table 24.4 to eliminate R_1 and also I_2. Then, source transformation six can be used to eliminate V_1 because it is an element in series with a current source. The results to this point are illustrated in Figure 24.13a. If we then apply transformation seven, we obtain the network in Figure 24.13b. Next, we can apply transformation

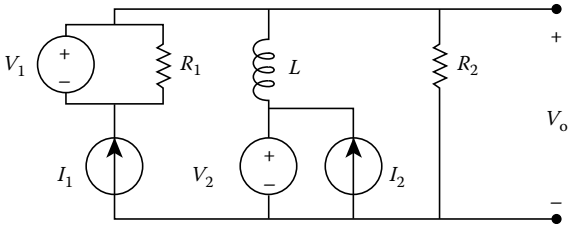


FIGURE 24.12 Network for Example 24.2.

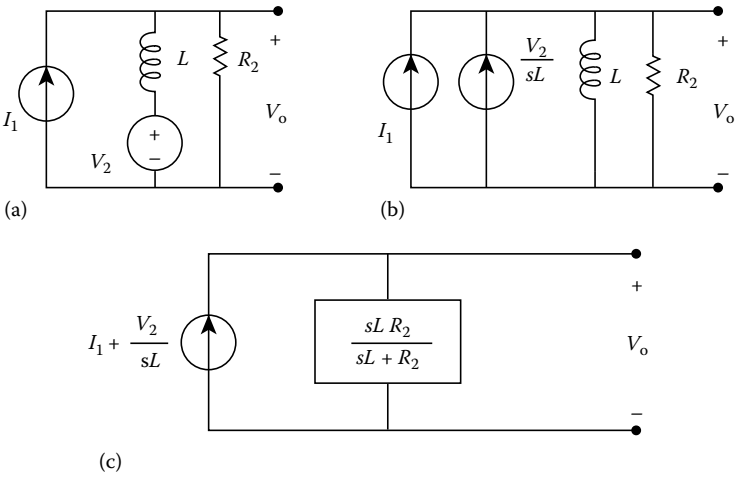

FIGURE 24.13 Application of source transformation six to eliminate V_1 as illustrated in (a), then applying transformation seven to obtain the network shown in (b), and finally applying transformation four to obtain the single loop network shown in (c).

four to obtain the single loop network in Figure 24.13c. The output voltage can be written in the frequency domain as

$$V_o = \left(I_1 + \frac{V_2}{sL}\right)\left(\frac{sLR_2}{sL + R_2}\right)$$

Source transformations can often be used advantageously with the following theorems.

24.2.2 Dividers

Current dividers and voltage dividers are circuits that are employed frequently, especially in the design of electronic circuits. Thus, dividers must be analyzed quickly. The relationships derived next satisfy this need.

Figure 24.14 is a current divider circuit. The source current I_s divides between the two impedances, and we wish to determine the current through Z_2. Writing a loop equation for the loop indicated, we have

$$I_2Z_2 - (I_s - I_2)Z_1 = 0 \tag{24.26}$$

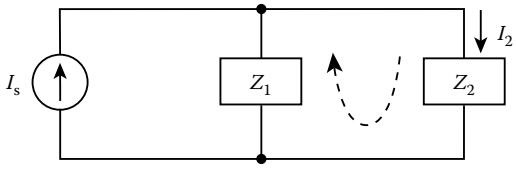

FIGURE 24.14 Current divider.

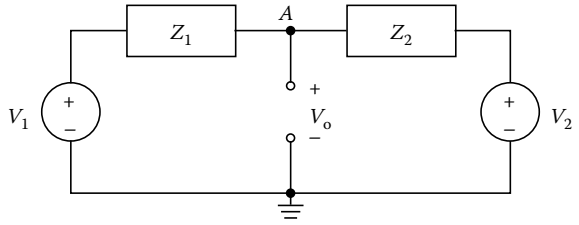

FIGURE 24.15 Enhanced voltage divider.

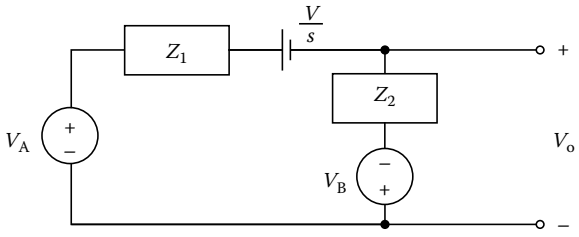

FIGURE 24.16 Circuit for Example 24.3.

from which we obtain

$$I_2 = I_s \frac{Z_1}{Z_1 + Z_2} \tag{24.27}$$

A circuit that we term an enhanced voltage divider is depicted in Figure 24.15. This circuit contains two voltage sources instead of the usual single source, but the enhanced voltage divider occurs more often in electronic circuits. Writing a node equation at node A and solving for V_o, we obtain

$$V_o = \frac{V_1 Z_2 + V_2 Z_1}{Z_1 + Z_2} \tag{24.28}$$

If V_2, for example, is zero, then the results from the enhanced voltage divider reduce to those of the single source voltage divider.

Example 24.3

Use Equation 24.28 to find V_o for the network in Figure 24.16.

Solution

The network in Figure 24.16 matches with the network used to derive Equation 24.28 even though it is drawn somewhat differently and has three voltage sources instead of two. However, we can use Equation 24.28 to write the answer for V_o by inspection.

$$V_o = \frac{(V_A - (V/s))Z_z - V_B Z_1}{Z_1 + Z_2}$$

The following example illustrates the use of source transformations together with the voltage divider.

Example 24.4

Find V_o for the network shown in Figure 24.17. The units of K, the coefficient of the dependent source, are ohms, and the capacitor is initially uncharged.

Solution

We note that the dependent voltage source is not in series with any one particular element and that the independent current source is not in parallel with any one particular element. However, we can split both the voltage source and the current source using source transformations eight and nine, respectively, from Table 24.4. Then, employing transformations five and seven, we obtain the network configuration depicted in Figure 24.18, for which we can use the voltage divider to write

$$V_o = \frac{I(K + R_1)R_2 + KI(R_1 + (1/sC))}{R_1 + R_2 + (1/sC)}$$

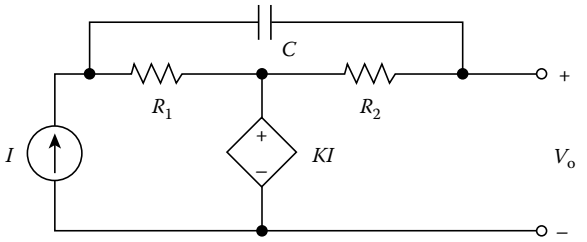

FIGURE 24.17 Network for Example 24.4.

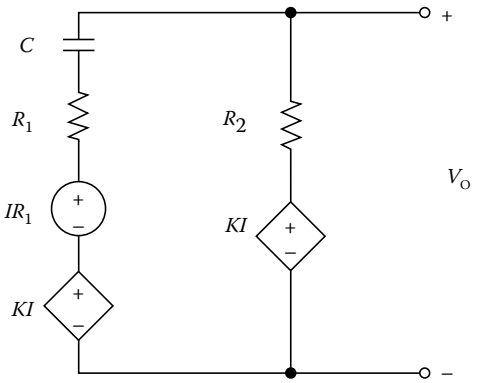

FIGURE 24.18 Results after employing source transformations on the network in Figure 24.17.

It should be mentioned that the method used to find V_0 in this example is not the most efficient one. For example, loops can be chosen for the network in Figure 24.17, so only one unknown loop is current. However, source transformations and dividers become more powerful analysis tools as they are coupled with additional network theorems.

24.2.3 Superposition

Superposition is a property of all linear networks, and whether it is used directly in the analysis of a network or not, it is a concept that is valuable in thinking about LLFT networks. Consider the LLFT network shown in Figure 24.19 in which, say, we wish to solve for I_1. Assume the network has n independent loops, and, for simplicity, assume no sources are within the box in the figure and that initial voltages across capacitors and initial currents through inductors are zero or are represented by independent sources external to the box. Note that one dependent source is shown in Figure 24.19 that depends on a voltage V_x in the network and that two independent sources, V_1 and V_2, are applied to the network. If loops are chosen so that each source has only one loop current flowing through it as indicated in Figure 24.19, then the loop equations can be written as

$$\begin{bmatrix} V_1 \\ V_2 \\ KV_x \\ 0 \\ \vdots \\ 0 \end{bmatrix} = \begin{bmatrix} z_{11} & z_{12} & \cdots & z_{1n} \\ z_{21} & z_{22} & \cdots & z_{2n} \\ \cdots & \cdots & \ddots & \cdots \\ z_{n1} & z_{n2} & \cdots & z_{nn} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \\ \vdots \\ I_n \end{bmatrix} \tag{24.29}$$

where the elements of the loop impedance matrix are defined in the section describing network functions. Solving for I_1 using Cramer's rule, we have

$$I_1 = V_1 \frac{\Delta_{11}}{\Delta} + V_2 \frac{\Delta_{21}}{\Delta} + KV_x \frac{\Delta_{31}}{\Delta} \tag{24.30}$$

where

Δ is the determinant of the loop impedance matrix
Δ_{j1}, $j = 1, 2, 3$, are the cofactors

The expression for I_1 given in Equation 24.30 is an intermediate and not a finished solution. The finished solution would express I_1 in terms of the independent sources and the parameters (*Rs*, *Ls*, *Cs*, *Ms*, and *Ks*) of the network and not in terms of an unknown V_x. Thus, one normally has to eliminate V_x from the

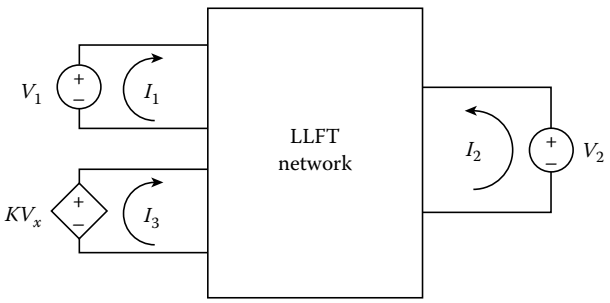

FIGURE 24.19 LLFT network with three voltage sources, of which one is dependent.

expression for I_1; but the intermediate expression for I_1 illustrates superposition. There are three components that add up to I_1 in Equation 24.30—one for each source including one for the dependent source. Furthermore, we see that each source is multiplied by a transadmittance (or a driving-point admittance in the case of V_1). Thus, we can write

$$I_1 = V_1 Y_{11} + V_2 Y_{12} + K V_x Y_{13} \tag{24.31}$$

where each admittance is found from the port at which a voltage source (whether independent or dependent) is applied. The response variable for each of these admittances is I_1 at port 1.

The simple derivation that led to Equation 24.30 is easily extended to both types of independent excitations (voltage sources and current sources) and to all four types of dependent sources. The generalization of Equation 24.30 leads to the conclusion:

> To apply superposition in the analysis of a network containing at least one independent source and a variety of other sources, dependent or independent, one finds the contribution to the response from each source in turn with all other source, dependent or independent, properly removed and then adds the individual contributions to obtain the total response. No distinction is made between independent and dependent sources in the application of superposition other than requiring the network to have at least one independent source.

However, if dependent sources are present in the network, the quantities (call them V_x and I_x) on which the dependent sources depend must often be eliminated from the answer by additional analysis if the answer is to be useful unless V_x or I_x are themselves the variables of independent sources or the quantities sought in the analysis.

Some examples will illustrate the procedure.

Example 24.5

Find V_0 for the circuit shown using superposition. In this circuit, only independent sources are present.

Solution

Two sources in the network, therefore, we abstract two fictitious networks from Figure 24.20. The first is shown in Figure 24.21a and is obtained by properly removing the current source I_1 from the original network. The impedance of the capacitor can then be combined in parallel with $R_1 + R_2$, and the contribution to V_o from V_1 can be found using a voltage divider. The result is

$$V_o \text{ due to } V_1 = V_1 \frac{s + \frac{1}{C(R_1+R_2)}}{s + \frac{R_1+R_2+R_3}{C(R_1+R_2)R_3}}$$

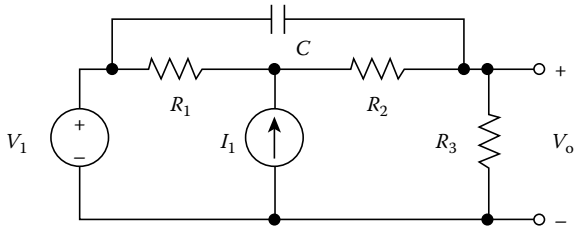

FIGURE 24.20 Network for Example 24.5.

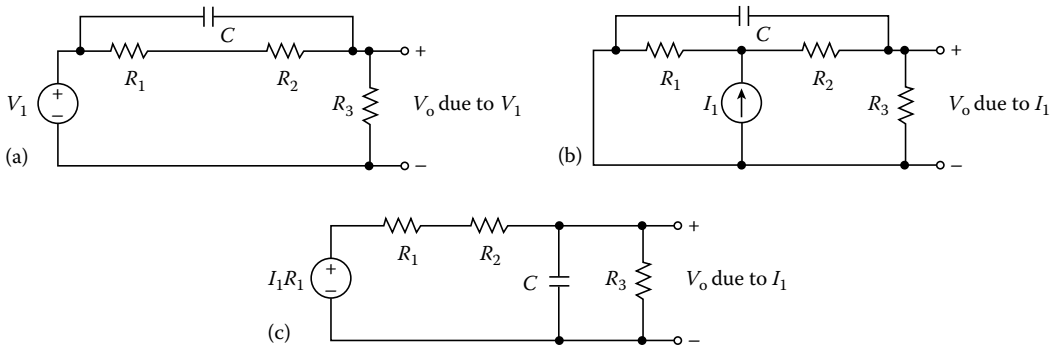

FIGURE 24.21 (a) Network obtained by properly removing the current source I_1 from the original network. (b) Network obtained from the original network by properly removing the voltage source V_1. (c) Final network obtained by redrawing the circuit and employing source transformation seven (in reverse).

The second fictitious network, shown in Figure 24.21b, is obtained from the original network by properly removing the voltage source V_1. Redrawing the circuit and employing source transformation seven (in reverse) yields the circuit in Figure 24.21c. Again, employing a voltage divider, we have

$$V_o \text{ due to } I_1 = I_1 \frac{\frac{R_1}{C(R_1+R_2)}}{s+\frac{R_1+R_2+R_3}{C(R_1+R_2)R_3}}$$

Then, adding the two contributions, we obtain

$$V_o = \frac{V_1\left[s+\frac{1}{C(R_1+R_2)}\right]+I_1\frac{R_1}{C(R_1+R_2)}}{s+\frac{R_1+R_2+R_3}{C(R_1+R_2)R_3}}$$

The next example includes a dependent source.

Example 24.6

Find i in the network shown in Figure 24.22 using superposition.

Solution

Since there are two sources, we abstract two fictitious networks from Figure 24.22. The first one is shown in Figure 24.23a and is obtained by properly removing the dependent current source. Thus,

$$i \text{ due to } v_1 = \frac{v_1}{R_1+R_2}$$

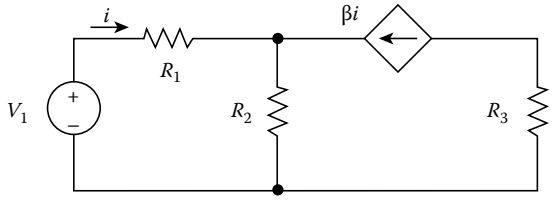

FIGURE 24.22 Network for Example 24.6.

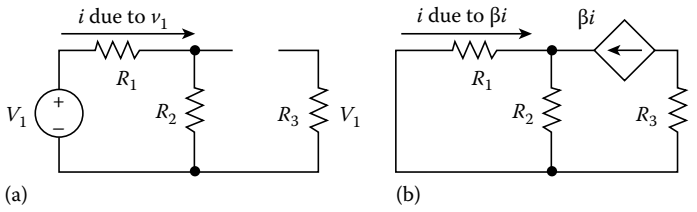

FIGURE 24.23 (a) Network obtained by properly removing the dependent current source. (b) Network obtained by properly removing the voltage source V_1.

Next, voltage source v_1 is properly removed yielding the fictitious network in Figure 24.23b. An important question immediately arises about this network. Namely, why is not i in this network zero? The reason i is not zero is that the network in Figure 24.23b is merely an abstracted network that concerns a step in the analysis of the original circuit. It is an artifice in the application of superposition, and the dependent source is considered to be independent for this step. Thus,

$$i \text{ due to } \beta i = -\frac{\beta i R_2}{R_1 + R_2}$$

Adding the two contributions, we obtain the intermediate result

$$i = \frac{v_1}{R_1 + R_2} - \frac{\beta i R_2}{R_1 + R_2}$$

Collecting the terms containing i, we obtain the finished solution for i:

$$i = \frac{v_1}{(\beta + 1)R_2 + R_1}$$

We note that the finished solution depends only on the independent source v_1 and parameters of the network, which are R_1, R_2, and β.

The following example involves a network in which a dependent source depends on a voltage that is neither the voltage of an independent source nor the voltage being sought in the analysis.

Example 24.7

Find V_o using superposition for the network shown in Figure 24.24. Note that K, the coefficient of the VCCS, has the units of siemens.

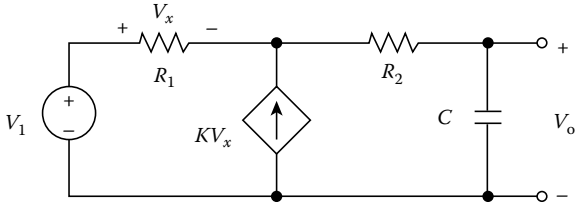

FIGURE 24.24 Network for Example 24.7.

Solution

When the dependent current source is properly removed, the network reduces to a simple voltage divider, and the contribution to V_o due to V_1 can be written as

$$V_o \text{ due to } V_1 = V_1 \frac{1}{sC(R_1 + R_2) + 1}$$

Then, reinserting the current source and properly removing the voltage source, we obtain the fictitious network shown in Figure 24.25. Using the current divider to obtain the current flowing through the capacitor and then multiplying this current by the impedance of the capacitor, we have

$$V_o \text{ due to } KV_x = \frac{KV_xR_1}{sC(R_1 + R_2) + 1}$$

Adding the individual contributions to form V_o provides the equation

$$V_o = \frac{V_1 + KV_xR_1}{sC(R_1 + R_2) + 1}$$

This is a valid expression for V_o. It is not a finished expression however, because it includes V_x, an unknown voltage. Superposition has taken us to this point in the analysis, but more work must be done to eliminate V_x. However, superposition can be applied again to solve for V_x, or other analysis tools can be used. The results for V_x are

$$V_x = \frac{V_1 sCR_1}{sC[R_1 + R_2 + R_1R_2K] + R_1K + 1}$$

Then, eliminating V_x from the equation for V_o, we obtain the finished solution as

$$V_o = V_1 \frac{R_1K + 1}{sC[R_1 + R_2 + R_1R_2K] + R_1K + 1}$$

Clearly, superposition is not the most efficient technique to use to analyze the network in Figure 24.24. Analysis based on a node equation written at the top end of the current source would yield a finished result for V_o with less algebra. However, this example does illustrate the application of superposition when a dependent source depends on a rather arbitrary voltage in the network.

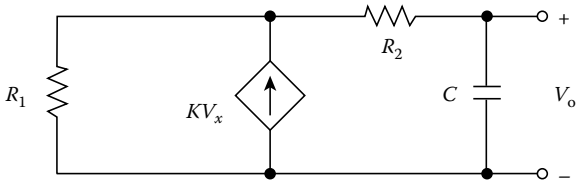

FIGURE 24.25 Fictitious network obtained when the voltage source is properly removed in Figure 24.24.

If the dependent current source in the previous example depended on V_1 instead of on the voltage across R_1, the network would be a different network. This is illustrated by the next example.

Example 24.8

Use superposition to determine V_o for the circuit in Figure 24.26.

Solution

If the current source is properly removed, the results are the same as for the previous example. Thus,

$$V_o \text{ due to } V_1 = \frac{V_1}{sC(R_1 + R_2) + 1}$$

Then, if the current source is reinserted, and the voltage source is properly removed, we have the circuit depicted in Figure 24.27. A question that can be asked for this circuit is why include the dependent source KV_1 if the voltage on which it depends, namely V_1, has been set to zero? However, the network shown in Figure 24.27 is merely a fictitious network that serves as an aid in the application of superposition, and superposition deals with all sources, whether they are dependent or independent, as if they were independent. Thus, we can write

$$V_o \text{ due to } KV_1 = \frac{KV_1R_1}{sC(R_1 + R_2) + 1}$$

Adding the contributions to form V_o, we obtain

$$V_o = V_1 \frac{KR_1 + 1}{sC(R_1 + R_2) + 1}$$

and this is the finished solution.

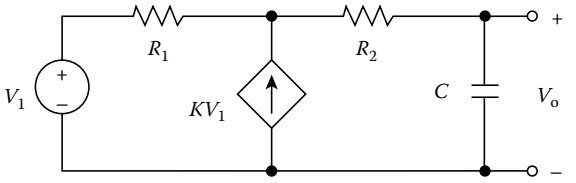

FIGURE 24.26 Network for Example 24.8.

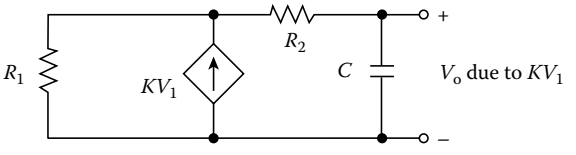

FIGURE 24.27 Step in the application of superposition to the network in Figure 24.26.

In this example, we did not have the task of eliminating an unknown quantity from an intermediate result for V_o because the dependent source depended on an independent source V_1, which is assumed to be known.

Superposition is often useful in the analysis of circuits having only independent sources, but it is especially useful in the analysis of some circuits having both independent and dependent sources because it deals with all sources as if they were independent.

24.2.4 Thévenin's Theorem

Thévenin's theorem is useful in reducing the complexity of a network so that analysis of the network for a particular voltage or current can be performed more easily. For example, consider Figure 24.28a, which is composed of two subnetworks A and B that have only two nodes in common. In order to facilitate analysis in subnetwork B, it is convenient to reduce subnetwork A to the network in Figure 24.28b which is termed the Thévenin equivalent of subnetwork A. The requirement on the Thévenin's equivalent network is that, when it replaces subnetwork A, the voltages and currents in subnetwork B remain unchanged. We assume that no inductive coupling occurs between the subnetworks, and that dependent sources in B are not dependent on voltages or currents in A. We also assume that subnetwork A is an LLFT network, but subnetwork B does not have to meet this assumption.

To find the Thévenin equivalent network, we need only determine V_{TH} and Z_{TH}. V_{TH} is found by unhooking B from A and finding the voltage that appears across the terminals of A. In other words, we abstract a fictitious network from the complete network as depicted in Figure 24.29a, and find the voltage that appears between the terminals that were common to B. This voltage is V_{TH}.

Z_{TH} is also obtained from a fictitious network that is created from the fictitious network used for finding V_{TH} by properly removing all independent sources. The effects that dependent sources have on the procedure are discussed later in this section. The fictitious network used for finding Z_{TH} is depicted in Figure 24.29b. Oftentimes, the expression for Z_{TH} cannot be found by mere inspection of this network, and, therefore, we must excite the network in Figure 24.29b by a voltage source or a current source and find an expression for the other variable at the port in order to find Z_{TH}.

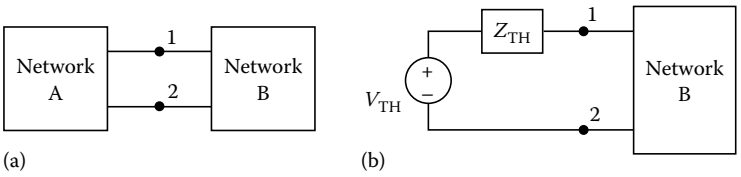

FIGURE 24.28 (a) Two subnetworks having a common pair of terminals. (b) The Thévenin equivalent for subnetwork *A*.

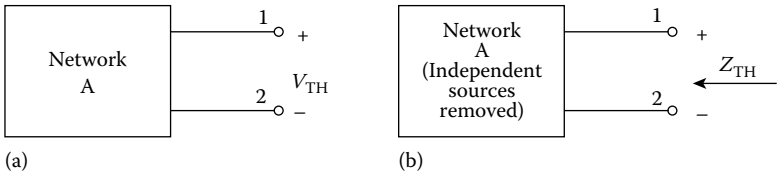

FIGURE 24.29 (a) Network used for finding V_{TH}. (b) Network used for obtaining Z_{TH}.

Example 24.9

Find the Thévenin equivalent of subnetwork *A* in Figure 24.30.

Solution

No dependent sources exist in subnetwork A, but the capacitor has an initial voltage *V* across it. However, the charged capacitor can be represented by an uncharged capacitor in series with a transformed voltage source *V*/*s*. The fictitious network used for finding V_{TH} is given in Figure 24.31a.

It should be noted that although subnetwork B has been removed and the two terminals that were connected to B are now "open circuited" in Figure 24.31a, current is still flowing in network A. V_{TH} is easily obtained using a voltage divider:

$$V_{TH} = \frac{V_1(s) + VCR}{sCR + 1}$$

Z_{TH} is obtained from the fictitious network in Figure 24.31b, which is obtained by properly removing the independent source and the voltage representing the initial voltage across the capacitor in Figure 24.31a. We see by inspection that $Z_{TH} = R/(sCR + 1)$. Thus, if subnetwork *A* is removed from Figure 24.30 and replaced by the Thévenin equivalent network, the voltages and currents in subnetwork B remain unchanged.

It is assumed that B in Figure 24.28 has no dependent sources that depend on voltages or currents in A, although dependent sources in B can depend on voltages and currents in B. However, A can have dependent sources, and these dependent sources create a modification in the procedure for finding the Thévenin equivalent network. There may be dependent sources in A that depend on voltages and currents that also exist in A. We call these dependent sources Case I-dependent sources. There may

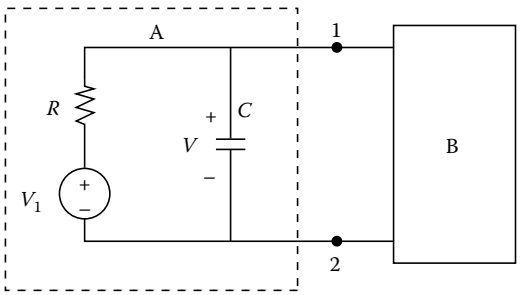

FIGURE 24.30 Network for Example 24.9.

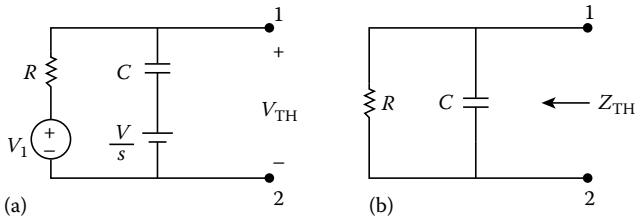

FIGURE 24.31 (a) Network of finding V_{TH}. (b) Network that yields Z_{TH}.

also be dependent sources in *A* that depend on voltages and currents in *B*, and we label these sources as Case II-dependent sources. Then, the procedure for finding the Thévenin equivalent network is:

V_{TH} is the voltage across the terminals of Figure 24.29a. The voltages and currents that Case I-dependent sources depend on must be eliminated from the expression for V_{TH} unless they happen to be the voltages of independent voltage sources or the currents of independent current sources in A. Otherwise, the expression for V_{TH} would not be a finished solution. However, Case II-dependent sources are handled as if they were independent sources. That is, Case II-dependent sources are included in the results for V_{TH} just as independent sources would be.

Z_{TH} is the impedance looking into the terminals in Figure 24.29b. In this fictitious network, independent sources are properly removed and Case II-dependent sources are properly removed. Case I-dependent sources remain in the network and influence the result for the Thévenin impedance. The finished solution for Z_{TH} is a function only of the parameters of the network in Figure 24.29b which are *Rs*, *Ls*, *Cs*, *Ms* (there may be inductive coupling between coils in this network), and the coefficients of the Case I-dependent sources.

Thus, Case II-dependent sources, sources that depend on voltages or currents in subnetwork B, are uniformly treated as if they were independent sources in finding the Thévenin equivalent network. Some examples will clarify the issue.

Example 24.10

Find the Thévenin equivalent network for subnetwork A in Figure 24.32. Assume the initial current through the inductor is zero.

Solution

There is one independent source and one Case I-dependent source. Figure 24.33a depicts the fictitious network to be analyzed to obtain V_{TH}. No current is flowing through R_2 in this figure, therefore, we can write $V_{TH} = V_1 - V_x$. To eliminate V_x from our intermediate expression for V_{TH}, we can use the results of the enhanced voltage divider to write

$$V_{TH} = \frac{V_1 R_1 + sKL(V_1 - V_{TH})}{R_1 + sL}$$

The finished solution for V_{TH} is

$$V_{TH} = V_1 \frac{sKL + R_1}{(K+1)sL + R_1}$$

Z_{TH} is obtained from Figure 24.33b where a current source excitation is shown already applied to the fictitious network. Two node equations, with unknown node voltages V and $-V_x$, enable us to obtain I in

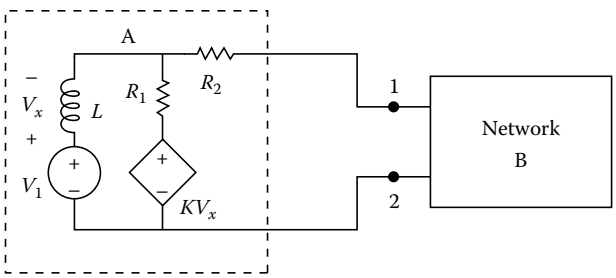

FIGURE 24.32 Network for Example 24.10.

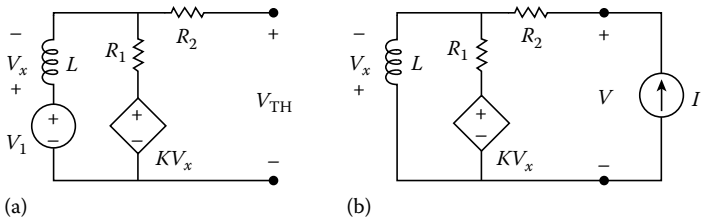

FIGURE 24.33 (a) Abstracted network for finding V_{TH}. (b) Abstracted network for finding Z_{TH}.

terms of V while eliminating V_x. We also note that Z_{TH} consists of resistor R_2 in series with some unknown impedance, so we could remove R_2 (replaced it by a short) if we remember to add it back later. The finished result for Z_{TH} is

$$Z_{TH} = R_2 + \frac{sLR_1}{(K+1)sL + R_1}$$

The following example involves a network having a Case II-dependent source.

Example 24.11

Find the Thévenin equivalent network for subnetwork *A* in the network illustrated in Figure 24.34. In this instance, subnetwork B is outlined explicitly.

Solution

Subnetwork A contains one independent source and one Case II-dependent source. Figure 24.35a is the abstracted network for finding V_{TH}. Thus,

$$V_{TH} = V_1 + KIR_1$$

Then, both V_1 and the dependent source KI are deleted from Figure 24.35a to obtain Figure 24.35b, the network used for finding Z_{TH}. Thus, $Z_{TH} = R_1$.

Of course, the subnetwork for which the Thévenin equivalent is being determined may have both Case I- and Case II-dependent sources, but these sources can be handled concurrently using the procedures given previously.

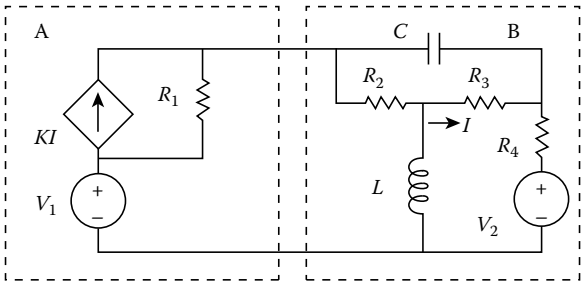

FIGURE 24.34 Network for Example 24.11.

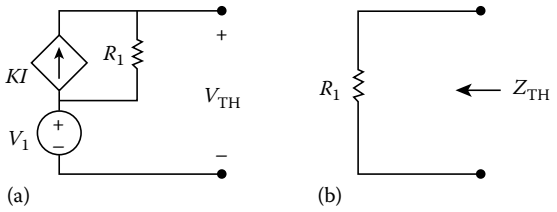

FIGURE 24.35 (a) Network used to find V_{TH}. (b) Network for finding Z_{TH}.

Special conditions can arise in the application of Thévenin's theorem. One condition is $Z_{TH} = 0$ and the other is $V_{TH} = 0$. The conditions for which Z_{TH} is zero are

1. If the circuit (subnetwork A) for which the Thévenin equivalent is being determined has an independent voltage source connected between terminals 1 and 2, then $Z_{TH} = 0$. Figure 24.36a illustrates this case.
2. If subnetwork A has a dependent voltage source connected between terminals 1 and 2, then Z_{TH} is zero provided neither of the port variables associated with the port formed by terminals 1 and 2 is coupled back into the network. Figure 24.36b is a subnetwork A for which Z_{TH} is zero. However, Figure 24.36c depicts a subnetwork A in which the port variable I is coupled back into A by the dependent source K_1I. If I is considered to be a variable of subnetwork A so that K_1I is a Case I-dependent source, then Z_{TH} is not zero.

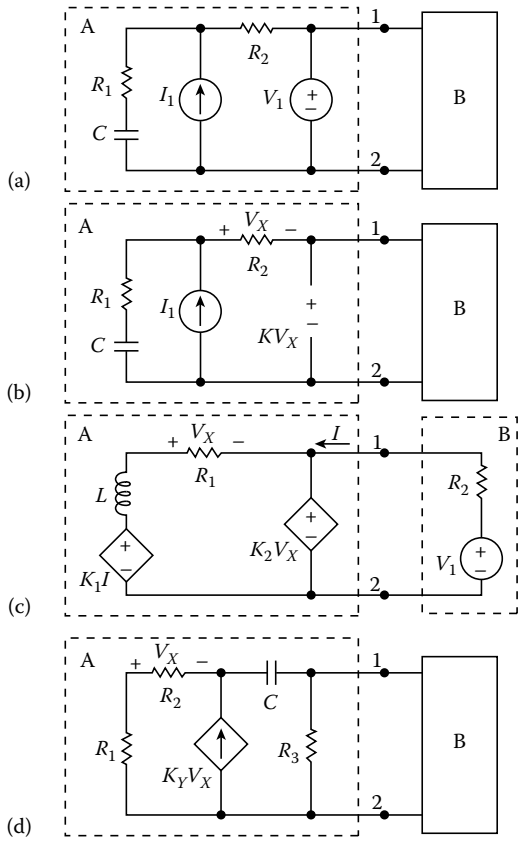

FIGURE 24.36 Special cases of Thévenin's theorem. (a, b) Z_{TH} equals zero. (c) A port variable is coupled back into A. (d) V_{TH} is zero.

The other special condition, $V_{TH} = 0$, occurs if subnetwork A contains only Case I-dependent sources, no independent sources, and no Case II-dependent sources. An example of such a network is given in Figure 24.36d. With subnetwork B disconnected, subnetwork A is a dead network, and its Thévenin voltage is zero.

The network in Figure 24.36c is of interest because the dependent source $K_1 I$ can be considered as a Case I or a Case II-dependent source hinging on whether I is considered a variable of subnetwork A or B.

Example 24.12

Solve for I in Figure 24.36c using two versions of the Thévenin equivalent for subnetwork A. For the first version, consider I to be associated with A, and therefore both dependent sources are Case I-dependent sources. In the second version, consider/to be associated with B.

Solution

If I is considered as associated with A, then V_{TH} is zero by inspection because A contains only Case I-dependent sources. Figure 24.37a depicts subnetwork A with a current excitation applied in order to determine Z_{TH}. Clearly, $V = K_2 V_x$. Also, writing a loop equation in the loop encompassed by the two dependent sources, we obtain

$$K_1 I - \frac{V_x}{R_1}(sL + R_1) = V$$

Eliminating V_x, we have

$$\frac{V}{I} = Z_{TH} = \frac{K_1 K_2 R_1}{sL + R_1(K_2 + 1)}$$

Once Z_{TH} is obtained, it is an easy matter to write from Figure 24.36c:

$$I = \frac{V_1}{R_2 + Z_{TH}} = \frac{V_1[sL + R_1(K_2 + 1)]}{sLR_2 + R_1 R_2(K_2 + 1) + K_1 K_2 R_1}$$

If I is associated with B, then V_{TH} is found from the network in Figure 24.37b with the source $K_1 I$ treated as if it were independent. The equation for V_{TH} may contain the variable I, but V_x must be eliminated from the finished expression for V_{TH}. We obtain

$$V_{TH} = I\frac{K_1 K_2 R_1}{sL + R_1(K_2 + 1)}$$

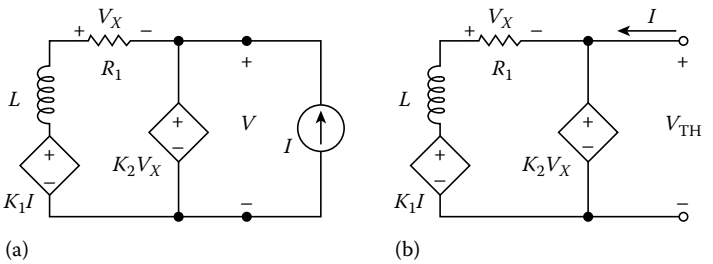

FIGURE 24.37 (a) Network for finding Z_{TH} when both sources are Case I-dependent sources. (b) Network for finding V_{TH} when a Case II-dependent source exists in the network.

Also, Z_{TH} is zero because if $K_1 I$ is removed, subnetwork A reduces to a network with only a Case I-dependent source and a port variable is not coupled back into the network. Finally, I can be written as

$$I = \frac{V_1 - V_{TH}}{R_2}$$

which yields the same result for I as was found previously.

The following example illustrates the interplay that can be achieved among these theorems and source transformations.

Example 24.13

Find V_0/V_1 for the bridged T network shown in Figure 24.38.

Solution

The application of source transformation eight to the network yields the ladder network in Figure 24.39a. Thévenin's theorem is particularly useful in analyzing ladder networks. If it is applied to the left and right sides of the network, taking care not to obscure the nodes between which V_0 exists, we obtain the single loop network in Figure 24.39b. Then, using a voltage divider, we obtain

$$\frac{V_o}{V_1} = \frac{Z_4[Z_1(Z_2 + Z_3) + Z_2Z_3 + Z_2Z_5]}{(Z_1 + Z_2)(Z_3Z_4 + Z_3Z_5 + Z_4Z_5) + Z_1Z_2(Z_4 + Z_5)}$$

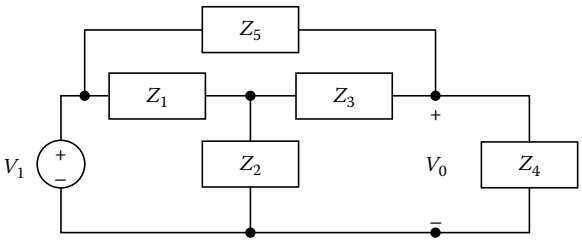

FIGURE 24.38 Network for Example 24.13.

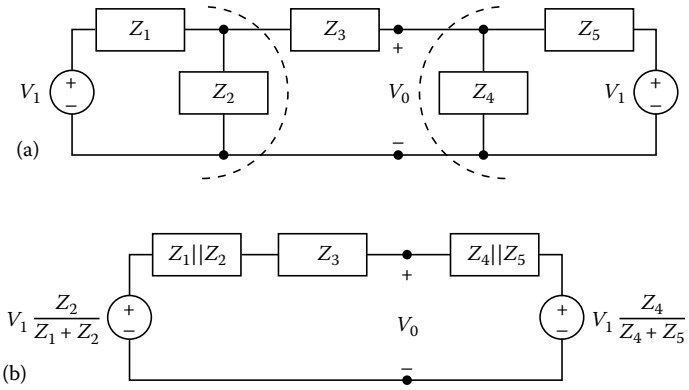

FIGURE 24.39 (a) Results after applying source transformation eight to the network shown in Figure 24.38. (b) Results of two applications of Thévenin's theorem.

24.2.5 Norton's Theorem

If a source transformation is applied to the Thévenin equivalent network consisting of V_{TH} and Z_{TH} in Figure 24.28b, then a Norton equivalent network, illustrated in Figure 24.40a, is obtained. The current source $I_{sc} = V_{TH}/Z_{TH}$, $Z_{TH} \neq 0$. If Z_{TH} equals zero in Figure 24.28b, then the Norton equivalent network does not exist. The subscripts sc on the current source stand for short circuit and indicate a procedure for finding the value of this current source. To find I_{sc} for subnetwork A in Figure 24.28a, we disconnet subnetwork B and place a short circuit between nodes 1 and 2 of subnetwork *A*. Then, I_{sc} is the current flowing through the short circuit in the direction indicated in Figure 24.40b. I_{sc} is zero if subnetwork A has only Case I-dependent sources and no other sources. Z_{TH} is found in the same manner as for Thévenin's theorem.

It is sometimes more convenient to find I_{sc} and V_{TH} instead of Z_{TH}.

Example 24.14

Find the Norton equivalent for the network "seen" by Z_L in Figure 24.41. That is, Z_L is subnetwork B and the rest of the network is A, and we wish to find the Norton equivalent network for A.

Solution

Figure 24.42a is the network with Z_L replaced by a short circuit. An equation for I_{sc} can be obtained quickly using superposition. This yields

$$I_{sc} = I_1 + \frac{KI_1}{R_2}$$

but I_1 must be eliminated from this equation. I_1 is obtained as: $I_1 = V_1/(sL + R_1)$. Thus,

$$I_{sc} = \frac{V_1\left(1 + \frac{K}{R_2}\right)}{sL + R_1}$$

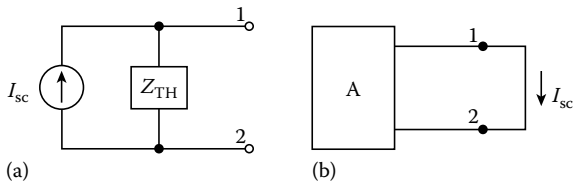

FIGURE 24.40 (a) Norton equivalent network. (b) Reference direction for I_{sc}.

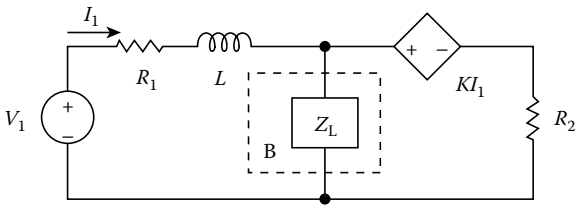

FIGURE 24.41 Network for Example 24.14.

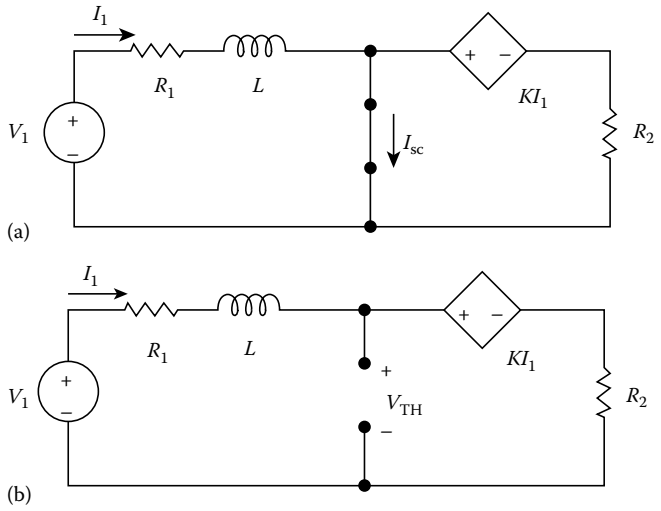

FIGURE 24.42 (a) Network for finding $I_{sc.}$ (b) Network for V_{TH}.

V_{TH} is found from the network shown in Figure 24.42b. The results are:

$$V_{TH} = \frac{V_1(K + R_2)}{sL + R_1 + R_2 + K}$$

Z_{TH} can be found as V_{TH}/I_{sc}.

24.2.6 Thévenin's and Norton's Theorems and Network Equations

Thévenin's and Norton's theorems can be related to loop and node equations. Here, we examine the relationship to loop equations by means of the LLFT network in Figure 24.43. Assume that the network N in Figure 24.43 has n independent loops with all the loop currents chosen in the same direction. Without loss of generality, assume that only one loop current, say I_1, flows through Z_L as shown so that Z_L appears in only one loop equation. For simplicity, assume that no dependent sources or inductive couplings in N exist, and that all current sources have been source-transformed so that only voltage source excitations remain. Then the loop equations are

$$\begin{bmatrix} V_1 \\ V_2 \\ \vdots \\ V_n \end{bmatrix} = \begin{bmatrix} z_{11} & z_{12} & \cdots & z_{1n} \\ z_{21} & z_{22} & \cdots & z_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ z_{n1} & z_{n2} & \cdots & z_{nn} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \\ \vdots \\ I_n \end{bmatrix} \tag{24.32}$$

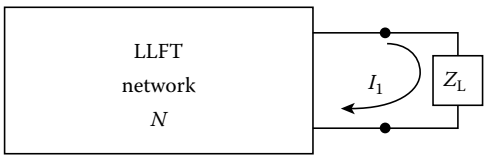

FIGURE 24.43 LLFT network N with n independent loops.

where V_i, $i = 1, 2, \ldots, n$, is the sum of all voltage sources in the ith loop. Thus, V_i may consist of several terms, some of which may be negative depending on whether a voltage source is a voltage rise or a voltage drop. Also, the impedances z_{ij} are given by

$$z_{ij} = \pm\left[R_{ij} + sL_{ij} + \frac{D_{ij}}{s}\right] \tag{24.33}$$

where $i, j = 1, 2, \ldots, n$, and where the plus sign is taken if $i = j$, and the minus sign is used if $i \neq j$. R_{ij} is the sum of the resistances in loop i if $i = j$, and R_{ij} is the sum of the resistances common to loops i and j if $i \neq j$. Similar statements apply to the inductances L_{ij} and to the reciprocal capacitances D_{ij}. The currents I_i, $i = 1, 2, \ldots, n$, are the unknown loop currents.

Note that Z_L is included only in z_{11} so that z_{11} can be written as $z_{11} = z_{11A} + Z_L$, where z_{11A} is the sum of all the impedances around loop one except Z_L. Solving for I_1 using Cramer's rule, we have

$$I_1 = \frac{\begin{vmatrix} V_1 & z_{12} & \cdots & z_{1n} \\ V_2 & z_{22} & \cdots & z_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ V_n & z_{n2} & \cdots & z_{nn} \end{vmatrix}}{\Delta} \tag{24.34}$$

where Δ is the determinant of the loop impedance matrix. Thus, we can write

$$I_1 = \frac{V_1\Delta_{11} + V_2\Delta_{21} + \cdots + V_n\Delta_{n1}}{z_{11}\Delta_{11} + z_{21}\Delta_{21} + \cdots + z_{n1}\Delta_{n1}} \tag{24.35}$$

or

$$I_1 = \frac{V_1 + V_2\frac{\Delta_{21}}{\Delta_{11}} + \cdots + V_n\frac{\Delta_{n1}}{\Delta_{11}}}{z_{11} + z_{21}\frac{\Delta_{21}}{\Delta_{11}} + \cdots + z_{n1}\frac{\Delta_{n1}}{\Delta_{11}}} \tag{24.36}$$

where Δ_{ij} are cofactors of the loop impedance matrix. Then, forming the product of I_1 and Z_L, we have

$$I_1 Z_L = \frac{Z_L\left(V_1 + V_2\frac{\Delta_{21}}{\Delta_{11}} + \cdots + V_n\frac{\Delta_{n1}}{\Delta_{11}}\right)}{Z_L + z_{11A} + z_{21}\frac{\Delta_{21}}{\Delta_{11}} + \cdots + z_{n1}\frac{\Delta_{n1}}{\Delta_{11}}} \tag{24.37}$$

If we take the limit of $I_1 Z_L$ as Z_L approaches infinity, we obtain the "open circuit" voltage V_{TH}. That is,

$$\lim_{Z_L \to \infty} I_1 Z_L = V_{TH} = \left(V_1 + V_2\frac{\Delta_{21}}{\Delta_{11}} + \cdots + V_n\frac{\Delta_{n1}}{\Delta_{11}}\right) \tag{24.38}$$

and if we take the limit of I_1 as Z_L approaches zero, we obtain the "short circuit" current I_{sc}:

$$\lim_{Z_L \to 0} I_1 = I_{sc} = \frac{V_{TH}}{z_{11A} + z_{21}\frac{\Delta_{21}}{\Delta_{11}} + \cdots + z_{n1}\frac{\Delta_{n1}}{\Delta_{11}}} \tag{24.39}$$

Finally, the quotient of V_{TH} and I_{sc} yields

$$\frac{V_{TH}}{I_{sc}} = Z_{TH} = z_{11A} + z_{21}\frac{\Delta_{21}}{\Delta_{11}} + \cdots + z_{n1}\frac{\Delta_{n1}}{\Delta_{11}} \tag{24.40}$$

If network N contains coupled inductors (but not coupled to Z_L), then some elements of the loop impedance matrix may be modified in value and sign. If network N contains dependent sources, then auxiliary equations can be written to express the quantities on which the dependent sources depend in terms of the independent excitations and/or the unknown loop currents. Thus, dependent sources may modify the elements of the loop impedance matrix in value and sign, and they may modify the elements of the excitation column matrix $[V_i]$. Nevertheless, we can obtain expressions similar to those obtained previously for V_{TH} and I_{sc}. Of course, we must exclude from this illustration dependent sources that depend on the voltage across Z_L because they violate the assumption that Z_L appears in only one loop equation and are beyond the scope of this discussion.

24.2.7 π–T Conversion

The π–T conversion is employed for the simplification of circuits, especially in power systems analysis. The "π" refers to a circuit having the topology shown in Figure 24.44. In this figure, the left-most and right-most loop currents have been chosen to coincide with the port currents for convenience of notation only.

A circuit having the topology shown in Figure 24.45 is referred to as a "T" or as a "Y." We wish to determine equations for Z_1, Z_2, and Z_3 in terms of Z_A, Z_B, and Z_C so that the π can be replaced by a T without affecting any of the port variables. In other words, if an overall circuit contains a π subcircuit,

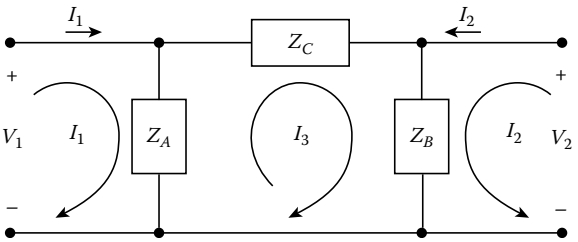

FIGURE 24.44 π network shown with loop currents.

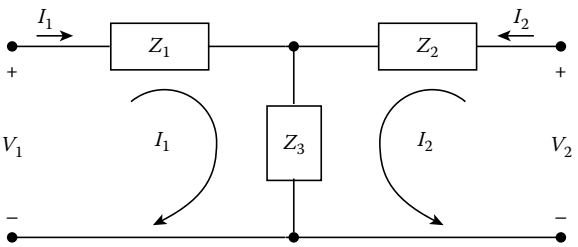

FIGURE 24.45 T network.

we wish to replace the π subscript with a T subscript without disturbing any of the other voltages and currents within the overall circuit. To determine what Z_1, Z_2, and Z_3 should be, we first write loop equations for the π network. The results are

$$V_1 = I_1 Z_A - I_3 Z_A \tag{24.41}$$

$$V_2 = I_2 Z_B + I_3 Z_B \tag{24.42}$$

$$0 = I_3(Z_A + Z_B + Z_C) - I_1 Z_A + I_2 Z_B \tag{24.43}$$

But the T circuit has only two loop equations given by

$$V_1 = I_1(Z_1 + Z_3) + I_2 Z_3 \tag{24.44}$$

$$V_2 = I_1 Z_3 + I_2(Z_2 + Z_3) \tag{24.45}$$

We must eliminate one of the loop equations for the π circuit, and so we solve for I_3 in Equation 24.43 and substitute the result into Equations 24.41 and 24.42 to obtain

$$V_1 = I_1\left[\frac{Z_A(Z_B + Z_C)}{Z_A + Z_B + Z_C}\right] + I_2\left[\frac{Z_A Z_B}{Z_A + Z_B + Z_C}\right] \tag{24.46}$$

$$V_2 = I_1\left[\frac{Z_A Z_B}{Z_A + Z_B + Z_C}\right] + I_2\left[\frac{Z_B(Z_A + Z_C)}{Z_A + Z_B + Z_C}\right] \tag{24.47}$$

From a comparison of the coefficients of the currents in Equations 24.46 and 24.47 with those in Equations 24.44 and 24.45, we obtain the following relationships.

24.2.7.1 Replacing π with T

$$Z_1 = \frac{Z_A Z_C}{S_Z}; \quad Z_2 = \frac{Z_B Z_C}{S_Z}; \quad Z_3 = \frac{Z_A Z_B}{S_Z} \tag{24.48}$$

where

$$S_Z = Z_A + Z_B + Z_C$$

We can also replace a T network by a π network. To do this we need equations for Z_A, Z_B, and Z_C in terms of Z_1, Z_2, and Z_3. The required equations can be obtained algebraically from Equation 24.48.

24.2.7.2 From T to π

$$Z_A = Z_1 + Z_3 + \frac{Z_1 Z_3}{Z_2}; \quad Z_B = Z_2 + Z_3 + \frac{Z_2 Z_3}{Z_1}; \quad Z_C = Z_1 + Z_2 + \frac{Z_1 Z_2}{Z_3} \tag{24.49}$$

24.2.8 Reciprocity

If an LLFT network contains only *Rs*, *Ls*, *Cs*, and transformers but contains no dependent sources, then its loop impedance matrix is symmetrical with respect to the main diagonal. That is, if z_{ij} is an element of

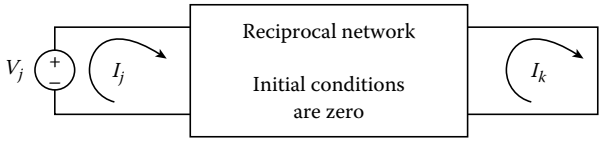

FIGURE 24.46 Reciprocal network with m independent loops.

the loop impedance matrix (see Equation 24.17), occupying the position at row i and column j, then $z_{ji} = z_{ij}$, where z_{ji} occupies the position at row j and column i. Such a network has the property of reciprocity and is termed a reciprocal network.

Assume that a reciprocal network, depicted in Figure 24.46, has m loops and is in the zero state. It has only one excitation—a voltage source in loop j. To solve for the loop current in loop k, we write the loop equations:

$$\begin{bmatrix} z_{11} & z_{12} & \cdots & z_{1m} \\ z_{21} & z_{22} & \cdots & z_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ z_{j1} & z_{j2} & \cdots & z_{jm} \\ z_{k1} & z_{k2} & \cdots & z_{km} \\ \vdots & \vdots & \ddots & \vdots \\ z_{m1} & z_{m2} & \cdots & z_{mm} \end{bmatrix} \begin{bmatrix} I_2 \\ I_2 \\ \vdots \\ I_j \\ I_k \\ \vdots \\ I_m \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ V_j \\ 0 \\ \vdots \\ 0 \end{bmatrix} \tag{24.50}$$

The column excitation matrix has only one nonzero entry. To determine I_k using Cramer's rule, we replace column k by the excitation column and then expand along this column. Only one nonzero term is in the column, therefore, we obtain a single term for I_k:

$$I_k = V_j \frac{\Delta_{jk}}{\Delta} \tag{24.51}$$

where

Δ_{jk} is the cofactor

Δ is the determinant of the loop impedance matrix

Next, we replace the voltage source by a short circuit in loop j, cut the wire in loop k, and insert a voltage source V_k. Figure 24.47 outlines the modifications to the circuit. Then, we solve for I_j obtaining

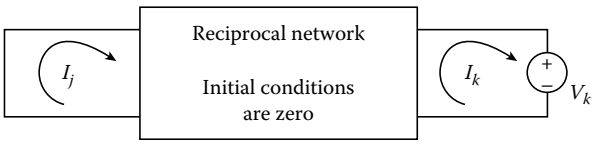

FIGURE 24.47 Interchange of the ports of excitation in the network in Figure 24.46.

$$I_j = V_k \frac{\Delta_{kj}}{\Delta} \tag{24.52}$$

Because the network is reciprocal, $\Delta_{jk} = \Delta_{kj}$ so that

$$\frac{I_k}{V_j} = \frac{I_j}{V_k} \tag{24.53}$$

Equation 24.53 is the statement of reciprocity for the network in Figures 24.46 and 24.47 with the excitations shown.

Figure 24.48a is a reciprocal network with a current excitation applied to node j and a voltage response, labeled V_k, taken between nodes k and m. We assume the network has n independent nodes plus the ground node indicated and is not a grounded network (does not have a common connection between the input and output ports shown). If we write node equations to solve for V_k in Figure 24.48a and use Cramer's rule, we have

$$V_k = I_j \frac{\Delta'_{jk} - \Delta'_{jm}}{\Delta'} \tag{24.54}$$

where the primes indicate node-basis determinants. Then, we interchange the ports of excitation and response as depicted in Figure 24.48b. If we solve for V_j in Figure 24.48b, we obtain

$$V_j = I_k \frac{\Delta'_{kj} - \Delta'_{mj}}{\Delta'} \tag{24.55}$$

Because the corresponding determinants in Equations 24.54 and 24.55 are equal because of reciprocity, we have

$$\frac{V_k}{I_j} = \frac{V_j}{I_k} \tag{24.56}$$

Note that the excitations and responses are of the opposite type in Figures 24.46 and 24.48. The results obtained in Equations 24.53 and 24.56 do not apply if the excitation and response are both voltages or both currents because when the ports of excitation and response are interchanged, the impedance levels of the network are changed [2].

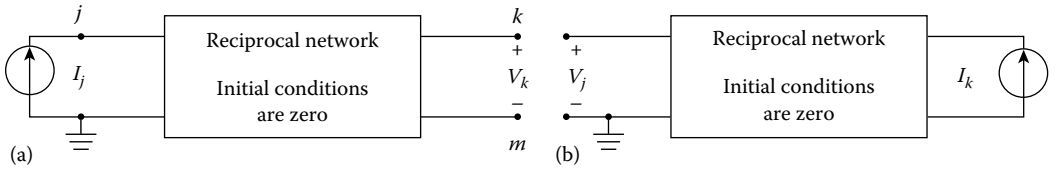

FIGURE 24.48 (a) Reciprocal ungrounded network with a current source excitation. (b) Interchange of the ports of excitation and response.

24.2.9 Middlebrook's Extra Element Theorem

Middlebrook's extra element theorem is useful in developing tests for analog circuits and for predicting the effects that parasitic elements may have on a circuit. This theorem has two versions: the parallel version and the series version. Both versions present the results of connecting an extra network element in the circuit as the product of the network function obtained without the extra element times a correction factor. This is a particularly convenient form for the results because it shows exactly the effects of the extra element on the network function.

Parallel version. Consider an arbitrary LLFT network having a transfer function $A_1(s)$. In the parallel version of the theorem, an impedance is added between any two independent nodes of the network. The modified transfer function is then obtained as $A_1(s)$ multiplied by a correction factor. Figure 24.49 is an arbitrary network in which the quantities U_i and U_o represent a general input and a general output, respectively, whether they are voltages or currents. The extra element is to be connected between terminals 1 and 1′ in Figure 24.49, and the port variables for this port are V_2 and I_2.

We can write

$$\begin{aligned} U_o &= A_1 U_i + A_2 I_2 \\ V_2 &= B_1 U_i + B_2 I_2 \end{aligned} \tag{24.57}$$

where

$$\begin{aligned} A_1 &= \left.\frac{U_o}{U_i}\right|_{I_2=0} \quad A_2 = \left.\frac{U_o}{I_2}\right|_{U_i=0} \\ B_1 &= \left.\frac{V_2}{U_i}\right|_{I_2=0} \quad B_2 = \left.\frac{V_2}{I_2}\right|_{U_i=0} \end{aligned} \tag{24.58}$$

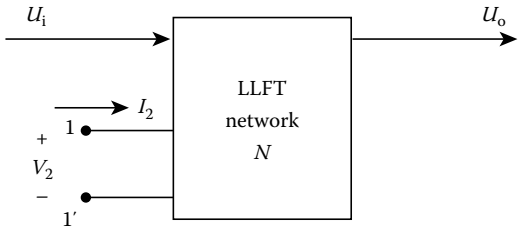

FIGURE 24.49 An arbitrary LLFT network.

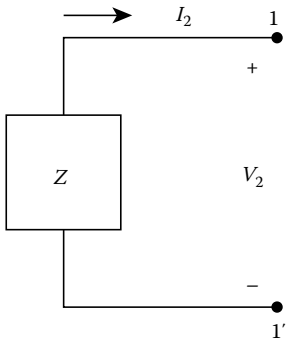

FIGURE 24.50 Extra element Z.

Note that A_1 is assumed to be known.

The extra element Z to be added across terminals 1 and 1′ is depicted in Figure 24.50. It can be described as $Z = V_2/(-I_2)$ which yields $I_2 = V_2/(-Z)$. Substituting this expression for I_2 into Equation 24.57 results in

$$\begin{aligned} U_o &= A_1 U_i + A_2\left(\frac{-V_2}{Z}\right) \\ V_2\left(1 + \frac{B_2}{Z}\right) &= B_1 U_i \end{aligned} \tag{24.59}$$

After eliminating V_2 and solving for U_o/U_i, we obtain

$$\frac{U_o}{U_i} = A_1\left[\frac{1 + \frac{1}{Z}\left(\frac{A_1B_2 - A_2B_1}{A_1}\right)}{1 + \frac{B_2}{Z}}\right] \tag{24.60}$$

Next, we provide physical interpretations for the terms in Equation 24.60. Clearly, B_2 is the

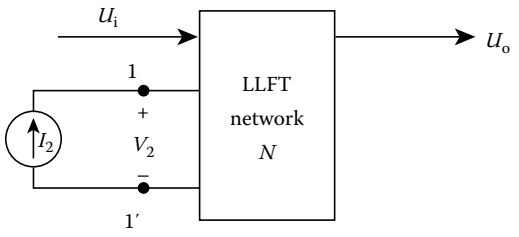

FIGURE 24.51 Network of Figure 24.49 with two excitations applied.

impedance seen looking into the network between terminals 1 and 1′ with $U_i = 0$. Thus, rename $B_2 = Z_d$ where d stands for "dead network."

To find a physical interpretation of $(A_1B_2 - A_2B_1)/A_1$, examine the network in Figure 24.51. Here, two excitations are applied to the network, namely U_i and I_2. Simultaneously adjust both inputs so as to null output U_o. Thus, with $U_o = 0$, we have from Equation 24.57,

$$U_i = \frac{-A_2}{A_1} I_2 \tag{24.61}$$

Substituting this result into the equation for V_2 in Equation 24.57, we have

$$V_2 = B_1 \left(\frac{-A_2}{A_1} \right) I_2 + B_2 I_2 \tag{24.62}$$

or

$$\left. \frac{V_2}{I_2} \right|_{U_o = 0} = \frac{A_1B_2 - A_2B_1}{A_1}$$

Because the quantity $(A_1B_2 - A_2B_1)/A_1$ is the ratio of V_2 to I_2 with the output nulled, we rename this quantity as Z_N. Then rewriting Equation 24.60 with Z_d and Z_N, we have

$$\frac{U_o}{U_i} = A_1 \left[\frac{1 + \frac{Z_N}{Z}}{1 + \frac{Z_d}{Z}} \right] \tag{24.63}$$

Equation 24.63 demonstrates that the results of connecting the extra element Z into the circuit can be expressed as the product of A_1, which is the network function with Z set to infinity, times a correction factor given in the brackets in Equation 24.63.

Example 24.15

Use the parallel version of Middlebrook's extra element theorem to find the voltage transfer function of the ideal op-amp circuit in Figure 24.52 when a capacitor C is connected between terminals 1 and 1′.

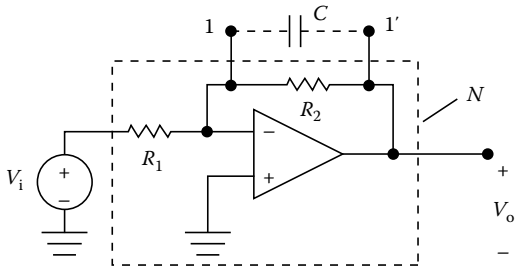

FIGURE 24.52 Ideal op-amp circuit for Example 24.15.

Solution

With the capacitor not connected, the voltage transfer function is

$$\left.\frac{V_o}{V_i}\right|_{Z=\infty} = -\frac{R_2}{R_1} = A_1$$

Next, we determine Z_d from the circuit illustrated in Figure 24.53a, where a model has been included for the ideal op-amp, the excitation V_i has been properly removed, and a current excitation I_2 has been applied to the port formed by terminals 1 and 1′. Because no voltage flows across R_1 in Figure 24.53a, no current flows through it, and all the current I_2 flows through R_2. Thus, $V_2 = I_2R_2$, and $Z_d = R_2$. We next find Z_N from Figure 24.53b. We observe in this figure that the right end of R_2 is zero volts above ground because V_i and I_2 have been adjusted so that V_o is zero. Furthermore, the left end of R_2 is zero volts above ground because of the virtual ground of the op-amp. Thus, zero is current flowing through R_2, and so V_2 is zero. Consequently, $Z_N = V_2/I_2 = 0$. Following the format of Equation 24.63, we have

$$\frac{V_o}{V_i} = -\frac{R_2}{R_1}\left(\frac{1}{1 + sCR_2}\right)$$

Note that for V_o to be zero in Figure 24.53b, V_i and I_2 must be adjusted so that $V_i/R_1 = -I_2$, although this information was not needed to work the example.

Series version. The series version of the theorem allows us to cut a loop of the network, add an impedance Z in series, and obtain the modified network function as $A_1(s)$ multiplied by a correction factor. A_1 is the

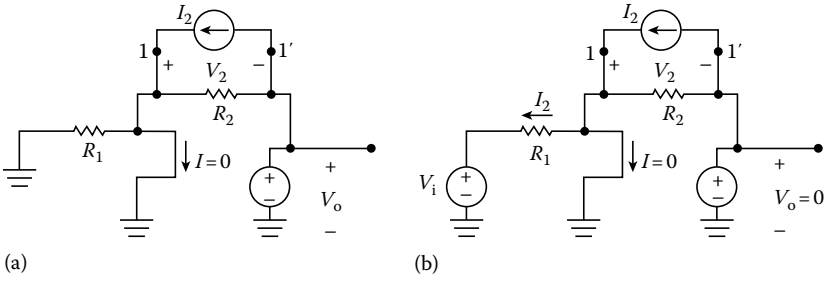

FIGURE 24.53 (a) Network for finding Z_d. (b) Network used to determine Z_N.

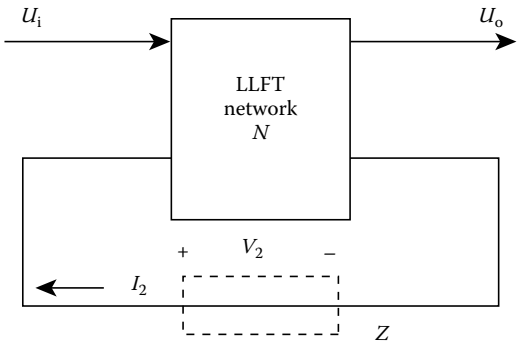

FIGURE 24.54 LLFT network used for the series version of Middlebrook's extra element theorem.

network function when $Z = 0$. Figure 24.54 is an LLFT network with part of a loop illustrated explicitly. The quantities U_i and U_o represent a general input and a general output, respectively, whether they be a voltage or a current. Define

$$\begin{aligned} A_1 &= \left.\frac{U_o}{U_i}\right|_{V_2=0} \quad A_2 = \left.\frac{U_o}{V_2}\right|_{U_i=0} \\ B_1 &= \left.\frac{I_2}{U_i}\right|_{V_2=0} \quad B_2 = \left.\frac{I_2}{V_2}\right|_{U_i=0} \end{aligned} \tag{24.64}$$

where V_2 and I_2 are depicted in Figure 24.54, and A_1 is assumed to be known. Then using superposition, we have

$$\begin{aligned} U_o &= A_1 U_i + A_2 V_2 \\ I_2 &= B_1 U_i + B_2 V_2 \end{aligned} \tag{24.65}$$

The impedance of the extra element Z can be described by $Z = V_2/(-I_2)$ so that $V_2 = -I_2 Z$. Substituting this relation for V_2 into Equation 24.65 and eliminating I_2, we have

$$\frac{U_o}{U_i} = A_1 \left[\frac{1 + Z\left(B_2 - B_1 \frac{A_2}{A_1}\right)}{1 + B_2 Z}\right] \tag{24.66}$$

Again, as we did for the parallel version of the theorem, we look for physical interpretations of the quantities in the square bracket in Equation 24.66. From Equation 24.65 we see that B_2 is the admittance looking into the port formed by cutting the loop in Figure 24.54 with $U_i = 0$. This is depicted in Figure 24.55a. Thus, B_2 is the admittance looking into a dead network, and so let $B_2 = 1/Z_d$.

To find a physical interpretation of the quantity $(A_1B_2 - A_2B_1)/A_1$, we examine Figure 24.55b in which both inputs, V_2 and U_i, are adjusted to null the output U_o. From Equation 24.65 with $U_o = 0$, we have

$$U_i = -\frac{A_2}{A_1} V_2 \tag{24.67}$$

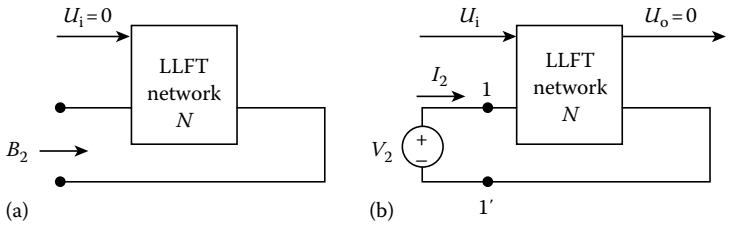

FIGURE 24.55 (a) Looking into the network with U_i equal zero. (b) U_i and V_2 are simultaneously adjusted to null the output U_o.

Then, eliminating U_i in Equation 24.65 we obtain

$$\frac{A_1B_2 - A_2B_1}{A_1} = \left.\frac{I_2}{V_2}\right|_{U_o=0} \tag{24.68}$$

Because this quantity is the admittance looking into the port formed by terminals 1 and 1′ in Figure 24.55b with U_o nulled, rename it as $1/Z_N$. Thus, from Equation 24.66 we can write

$$\frac{U_o}{U_i} = A_1\left[\frac{1+\frac{Z}{Z_N}}{1+\frac{Z}{Z_d}}\right] \tag{24.69}$$

Equation 24.69 is particularly convenient for determining the effects of adding an impedance Z into a loop of a network.

Example 24.16

Use the series version of Middlebrook's extra element theorem to determine the effects of inserting a capacitor C in the location indicated in Figure 24.56.

Solution

The voltage transfer function for the network without the capacitor is found to be

$$A_1 = \left.\frac{V_o}{V_i}\right|_{Z=0} = \frac{-\beta R_L}{R_s + (\beta+1)R_e\left(1+\frac{R_s}{R_b}\right)}$$

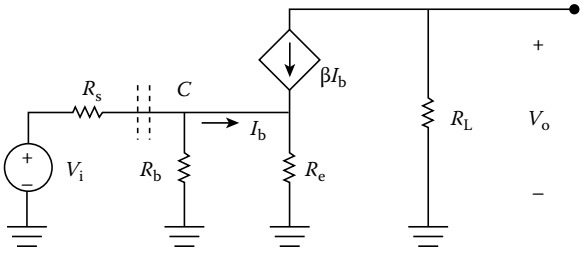

FIGURE 24.56 Network for Example 24.16.

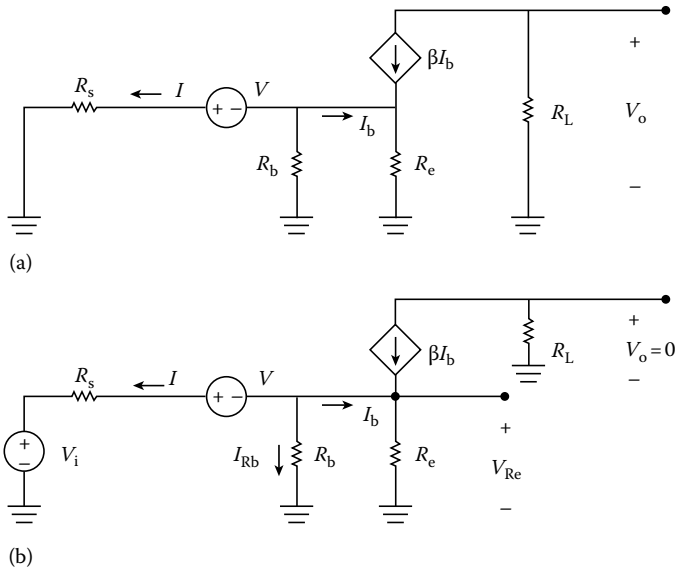

FIGURE 24.57 (a) Network used to obtain Z_d. (b) Network that yields Z_N.

Next, we find Z_d from Figure 24.57a. This yields

$$Z_d = \frac{V}{I} = R_s + [R_b \parallel (\beta + 1)R_e]$$

The impedance Z_N is found from Figure 24.57b where the two input sources, V_i and V, are adjusted so that V_o equals zero. If V_o equals zero, then βI_b equals zero because no current flows through R_L. Thus, I_b equals zero, which implies that V_{Re}, the voltage across R_e as indicated in Figure 24.57b, is also zero. We see that the null is propagating through the circuit. Continuing to analyze Figure 24.57b, we see that I_{Rb} is zero so that we conclude that I is zero. Because $Z_N = V/I$, we conclude that Z_N is infinite. Using the format given by Equation 24.69 with $Z = 1/(sC)$, we obtain the result as

$$\frac{V_o}{V_i} = A_1 \left\{ \frac{1}{1 + \frac{1/(sC)}{R_s + [R_b \parallel (\beta+1)R_e]}} \right\}$$

It is interesting to note that to null the output so that Z_N could be found in Example 24.16, V_i is set to V, although this fact is not needed in the analysis.

24.2.10 Substitution Theorem

Figure 24.58a is an LLFT network consisting of two subnetworks A and B, which are connected to each other by two wires. If the voltage $v(t)$ is known, the voltages and currents in subnetwork A remain unchanged if a voltage source of value $v(t)$ is substituted for subnetwork B as illustrated in Figure 24.58b.

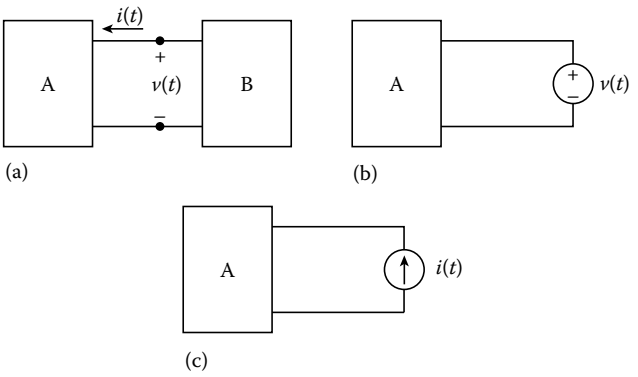

FIGURE 24.58 (a) An LLFT network consisting of two subnetworks A and B connected by two wires. (b) A voltage source can be substituted for subnetwork B if $v(t)$ is known in (a). (c) A current source can be substituted for B if i is a known current.

Example 24.17

Determine $i_1(t)$ in the circuit in Figure 24.59. The voltage $v_1(t)$ is known from a previous analysis.

Solution

Because $v_1(t)$ is known, the substitution theorem can be applied to obtain the circuit in Figure 24.60. Analysis of this simplified circuit yields

$$i_1 = i_{\text{in}} \frac{R_3}{R_2 + R_3} + v_1 \frac{1}{R_2 + R_3}$$

If the current $i(t)$ is known in Figure 24.58a, then the substitution in Figure 24.58c can be employed.

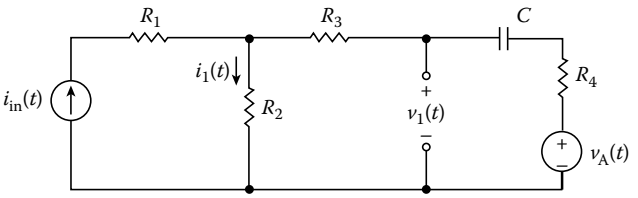

FIGURE 24.59 Circuit for Example 24.17.

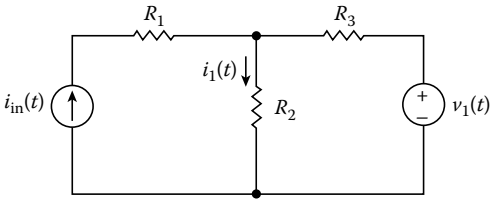

FIGURE 24.60 Circuit that results when the substitution theorem is applied to the circuit in Figure 24.59.

24.3 Sinusoidal Steady-State Analysis and Phasor Transforms

24.3.1 Sinusoidal Steady-State Analysis

In this section, we develop techniques for analyzing LLFT networks in the sinusoidal steady state. These techniques are important for analyzing and designing networks ranging from AC power generation systems to electronic filters.

To put the development of sinusoidal steady-state analysis in its context, we list the following definitions of responses of circuits:

1. Zero-input response is the response of a circuit to its initial conditions when the input excitations are set to zero.
2. Zero-state response is the response of a circuit to a given input excitation or set of input excitations when the initial conditions are all set to zero.

   The sum of the zero-input response and the zero-state response yields the total response of the system being analyzed. However, the total response can also be decomposed into the forced response and the natural response if the input excitations are DC, real exponentials, sinusoids, and/or sinusoids multiplied by real exponentials and if the exponent(s) in the input excitation differs from the exponents appearing in the zero-input response. These excitations are very common in engineering applications, and the decomposition of the response into forced and natural components corresponds to the particular and complementary (homogeneous) solutions, respectively, of the linear, constant coefficient, ordinary differential equations that characterize LLFT networks in the time domain. Therefore, we define
3. Forced response is the portion of the total response that has the same exponents as the input excitations.
4. Natural response is the portion of the total response that has the same exponents as the zero-input response.

   The sum of the forced and natural responses is the total response of the system.

   For a strictly stable LLFT network, meaning that the poles of the system transfer function $T(s)$ are confined to the open LHP, the natural response must decay to zero eventually. The forced response may or may not decay to zero depending on the excitation and the network to which it is applied, and so it is convenient to define the terms steady-state response and transient response:
5. Transient response is the portion of the response that dies away or decays to zero with time.
6. Steady-state response is the portion of the response that does not decay with time.

The sum of the transient and steady-state responses is the total response, but a specific circuit with a specific excitation may not have a transient response or it may not have a steady-state response. The following example illustrates aspects of these six definitions.

Example 24.18

Find the total response of the network shown in Figure 24.61, and identify the zero-state, zero-input, forced, natural, transient, and steady-state portions of the response.

Solution

Note that a nonzero initial condition is represented by V_c. Using superposition and the simple voltage divider concept, we can write

$$V_o(s) = \left[\frac{V_1}{s+1} + \frac{V_2}{s^2+1}\right]\frac{2}{s+2} + \frac{V_c}{s}\left(\frac{s}{s+2}\right)$$

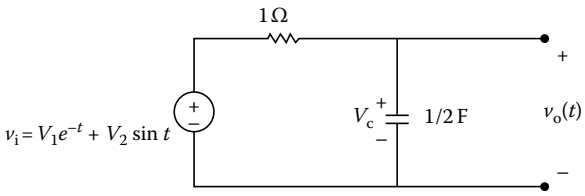

FIGURE 24.61 Circuit for Example 24.18.

The partial fraction expansion for $V_o(s)$ is

$$V_o(s) = \frac{A}{s+1} + \frac{B}{s+2} + \frac{Cs+D}{s^2+1}$$

where

$$\begin{aligned} A &= 2V_1 \\ B &= -2V_1 + 0.4V_2 + V_c \\ C &= -0.4V_2 \\ D &= 0.8V_2 \end{aligned}$$

Thus, for $t \geq 0$, $v_o(t)$ can be written as

$$v_o(t) = 2V_1e^{-t} - 2V_1e^{-2t} + 0.4V_2e^{-2t} + V_ce^{-2t} - 0.4V_2 \cos t + 0.8V_2 \sin t$$

With the aid of the angle sum and difference formula

$$\sin(\alpha \pm \beta) = \sin\alpha \ \cos\beta \ \pm \ \cos\alpha \ \sin\beta$$

and the sketch in Figure 24.62, we can combine the last two terms in the expression for $v_o(t)$ to obtain

$$v_o(t) = 2V_1e^{-t} - 2V_1e^{-2t} + 0.4V_2e^{-2t} + V_ce^{-2t} + 0.4\sqrt{5}V_2 \sin(t + \theta)$$

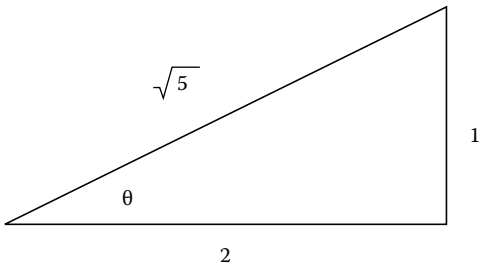

FIGURE 24.62 Sketch for determining the phase angle θ.

where

$$\theta = -\tan^{-1}\left(\frac{1}{2}\right)$$

The terms of $v_o(t)$ are characterized by our definitions as follows:

$$\begin{aligned}
\text{Zero-input response} &= V_c e^{-2t} \\
\text{Zero-state response} &= 2V_1 e^{-t} - 2V_1 e^{-2t} + 0.4V_2 e^{-2t} + 0.4\sqrt{5}V_2 \sin(t+\theta) \\
\text{Natural response} &= [-2V_1 + 0.4V_2 + V_c]e^{-2t} \\
\text{Forced response} &= 2V_1 e^{-t} + 0.4\sqrt{5}V_2 \sin(t+\theta) \\
\text{Transient response} &= 2V_1 e^{-t} + [-2V_1 + 0.4V_2 + V_c]e^{-2t} \\
\text{Steady-state response} &= 0.4\sqrt{5}V_2 \sin(t+\theta)
\end{aligned}$$

As can be observed by comparing the preceding terms above with the total response, part of the forced response is the steady-state response, and the rest of the forced response is included in the transient response in this example.

If the generator voltage in the previous example had been $v_i = V_1 + V_2 \sin(t)$, then there would have been two terms in the steady-state response—a DC term and a sinusoidal term. On the other hand, if the transfer function from input to output had a pole at the origin and the excitation were purely sinusoidal, there would also have been a DC term and a sinusoidal term in the steady-state response. The DC term would have arisen from the pole at the origin in the transfer function, and therefore would also be classed as a term in the natural response.

Oftentimes, it is desirable to obtain only the sinusoidal steady-state response, without having to solve for other portions of the total response. The ability to solve for just the sinusoidal steady-state response is the goal of sinusoidal steady-state analysis.

The sinusoidal steady-state response can be obtained based on analysis of the network using Laplace transforms. Figure 24.63 illustrates an LLFT network that is excited by the voltage sine wave $v_i(t) = V \sin(\omega t)$, where V is the peak amplitude of the sine wave and ω is the frequency of the sine wave in radians/second. Assume that the poles of the network transfer function $V_o(s)/V_i(s) = T(s)$ are confined to the open LHP except possibly for a single pole at the origin. Then, the forced response of the network is

$$v_{oss}(t) = V|T(j\omega)| \sin(\omega t + \theta) \tag{24.70}$$

where the extra subscripts "ss" on $v_o(t)$ indicate sinusoidal steady state, and where

$$\theta = \tan^{-1}\left(\frac{\Im T(j\omega)}{\Re T(j\omega)}\right) \tag{24.71}$$

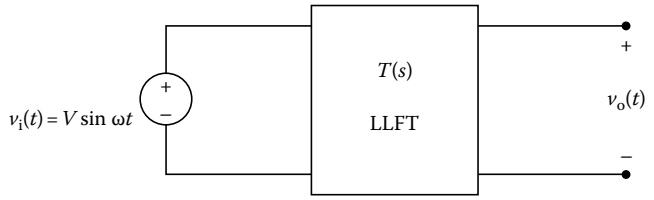

FIGURE 24.63 LLFT network with transfer function $T(s)$.

The symbols $\mathcal{I}$ and $\mathcal{R}$ are read as "imaginary part of" and "real part of," respectively. In other words, the LLFT network modifies the sinusoidal input signal in only two ways at steady state. The network multiplies the amplitude of the signal by $|T(j\omega)|$ and shifts the phase by θ. If the transfer function of the network is known beforehand, then the sinusoidal steady-state portion of the total response can be easily obtained by means of Equations 24.70 and 24.71.

To prove Equations 24.70 and 24.71, we assume that $T(s) = V_o(s)/V_i(s)$ in Figure 24.63 is real for s real and that the poles of $T(s)$ are confined to the open LHP except possibly for a single pole at the origin. Without loss of generality, assume the order of the numerator of $T(s)$ is at most one greater than the order of the denominator. Then the transform of the output voltage is

$$V_o(s) = V_i(s)T(s) = \frac{V\omega}{s^2 + \omega^2} T(s)$$

If $V_o(s)$ is expanded into partial fractions, we have

$$V_o(s) = \frac{A}{s - j\omega} + \frac{B}{s + j\omega} + \text{other terms due to the poles of } T(s)$$

The residue A is

$$\begin{aligned} A &= [(s - j\omega)V_o(s)]_{s=j\omega} = \left[\frac{V\omega}{s + j\omega} T(s)\right]_{s=j\omega} \\ &= \frac{V}{2j} T(j\omega) \end{aligned}$$

But

$$T(j\omega) = |T(j\omega)|e^{j\theta} \quad \text{where } \theta = \tan^{-1} \frac{\mathcal{I}T(j\omega)}{\mathcal{R}T(j\omega)}$$

Thus, we can write the residue A as

$$A = \frac{V}{2j} |T(j\omega)|e^{j\theta}$$

Also, $B = A^*$ where "*" denotes "conjugate," and so

$$\begin{aligned} B &= -\frac{V}{2j} T(-j\omega) = -\frac{V}{2j} T((j\omega)^*) \\ &= -\frac{V}{2j} T^*(j\omega) = -\frac{V}{2j} |T(j\omega)|e^{-j\theta} \end{aligned}$$

In the equation for the residue B, we can write $T((j\omega)^*) = T^*(j\omega)$ because of the assumption that $T(s)$ is real for s real (see property 1 in Section 24.1.1).

All other terms in the partial fraction of $V_o(s)$ will yield, when inverse transformed, functions of time that decay to zero except for a term arising from a pole at the origin of $T(s)$. A pole at the origin yields, when its partial fraction is inverse transformed, a DC term that is part of the steady-state solution in the time domain. However, only the first two terms in $V_o(s)$ will ultimately yield a sinusoidal function. We can rewrite these two terms as

$$V_{oss}(s) = \frac{V}{2j} |T(j\omega)| \left[\frac{e^{j\theta}}{s - j\omega} - \frac{e^{-j\theta}}{s + j\omega}\right]$$

The extra subscripts "*ss*" denote sinusoidal steady state. The time-domain equation for the sinusoidal steady-state output voltage is

$$\begin{aligned} v_{oss}(t) &= \frac{V}{2j}|T(j\omega)|\left[e^{j\theta}e^{j\omega t} - e^{-j\theta}e^{-j\omega t}\right] \\ &= V|T(j\omega)|\sin(\omega t + \theta) \end{aligned}$$

where θ is given by Equation 24.71. This completes the proof.

Example 24.19

Verify the expression for the sinusoidal steady-state response found in the previous example.

Solution

The transfer function for the network in Figure 24.61 is $T(s) = 2/(s+2)$, and the frequency of the sinusoidal portion of $v_i(t)$ is $\omega = 1$ rad/s. Thus,

$$T(j\omega) = \frac{2}{j+2} = \frac{2}{\sqrt{4+1}}e^{j\theta}$$

where

$$\theta = \tan^{-1}\left(\frac{-2}{4}\right) = -\tan^{-1}\left(\frac{1}{2}\right)$$

If the excitation in Figure 24.63 were $v_i(t) = V\sin(\omega t + \Phi)$, then the sinusoidal steady-state response of the network would be

$$v_{oss}(t) = V|T(j\omega)|\sin(\omega t + \Phi + \theta) \tag{24.72}$$

where θ is given by Equation 24.71. Similarly, if the excitation were $v_i(t) = V[\cos(\omega t + \Phi)]$, then the sinusoidal steady-state response would be expressed as

$$v_{oss}(t) = V|T(j\omega)|\cos(\omega t + \Phi + \theta) \tag{24.73}$$

with θ again given by Equation 24.71.

24.3.2 Phasor Transforms

In the sinusoidal steady-state analysis of stable LLFT networks, we find that both the inputs and outputs are sine waves of the same frequency. The network only modifies the amplitudes and the phases of the sinusoidal input signals; it does not change their nature. Thus, we need only keep track of the amplitudes and phases, and we do this by using phasor transforms. Phasor transforms are closely linked to Euler's identity:

$$e^{\pm j\omega t} = \cos(\omega t) \pm j\sin(\omega t) \tag{24.74}$$

If, for example, $v_i(t) = V \sin(\omega t + \Phi)$, then we can write $v_i(t)$ as

$$v_i(t) = \mathcal{I}[Ve^{j(\omega t+\Phi)}] = \mathcal{I}[Ve^{j\Phi}e^{j\omega t}] \tag{24.75}$$

Similarly, if $v_i(t) = V \cos(\omega t + \Phi)$, then we can write

$$v_i(t) = \mathcal{R}[Ve^{j(\omega t+\Phi)}] = \mathcal{R}[Ve^{j\Phi}e^{j\omega t}] \tag{24.76}$$

If we confine our analysis to single-frequency sine waves, then we can drop the imaginary sign and the term $e^{j\omega t}$ in Equation 24.75 to obtain the phasor transform. That is,

$$\wp[v_i(t)] = \wp[V \sin(\omega t + \Phi)] = \wp\{\mathcal{I}[Ve^{j\Phi}e^{j\omega t}]\} = Ve^{j\Phi} \tag{24.77}$$

The first and last terms in Equation 24.77 are read as "the phasor transform of $v_i(t)$ equals $Ve^{j\Phi}$." Note that $v_i(t)$ is not equal to $Ve^{j\Phi}$ as can be seen from the fact that $v_i(t)$ is a function of time while $Ve^{j\Phi}$ is not. Phasor transforms will be denoted with bold letters that are underlined as in $\wp[v_i(t)] = \underline{\boldsymbol{V}}_i$.

If our analysis is confined to single-frequency cosine waves, we perform the phasor transform in the following manner:

$$\wp[V \cos(\omega t + \Phi)] = \wp\{\mathcal{R}[Ve^{j\Phi}e^{j\omega t}]\} = Ve^{j\Phi} = \underline{V} \tag{24.78}$$

In other words, to perform the phasor transform of a cosine function, we drop both the real sign and the term $e^{j\omega t}$. Both sines and cosines are sinusoidal functions, but when we transform them, they lose their identities. Thus, before starting an analysis, we must decide whether to perform the analysis all in sines or all in cosines. The two functions must not be mixed when using phasor transforms. Furthermore, we cannot simultaneously employ the phasor transforms of sinusoids at two different frequencies. However, if a linear network has two excitations which have different frequencies, we can use superposition in an analysis for a voltage or current, and add the solutions in the time domain.

Three equivalent representations are used for a phasor $\underline{\boldsymbol{V}}$:

$$\underline{\boldsymbol{V}} = \begin{cases} Ve^{j\Phi} & \text{exponential form} \\ V(\cos\Phi + j\sin\Phi) & \text{rectangular form} \\ V\angle\Phi & \text{polar form} \end{cases} \tag{24.79}$$

If phasors are to be multiplied or divided by a complex number, the exponential or polar forms are the most convenient. If phasors are to be added or subtracted, the rectangular form is the most convenient. The relationships among the equivalent representations are illustrated in Figure 24.64. In this figure, the

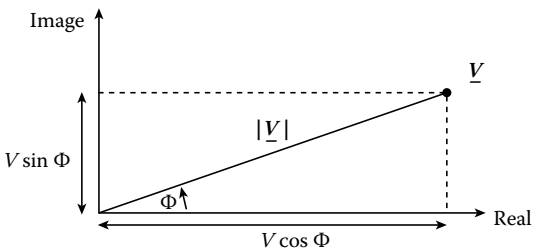

FIGURE 24.64 Relationships among phasor representations.

phasor $\underline{\boldsymbol{V}}$ is denoted by a point in the complex plane. The magnitude of the phasor, $|\underline{\boldsymbol{V}}| = V$, is illustrated by the length of the line drawn from the origin to the point. The phase of the phasor, Φ, is shown measured counterclockwise from the horizontal axis. The real part of $\underline{\boldsymbol{V}}$ is $V \cos \Phi$ and the imaginary part of $\underline{\boldsymbol{V}}$ is $V \sin \Phi$.

Phasors can be developed in a way that parallels, to some extent, the usual development of Laplace transforms. In the following theorems, we assume that the constants V_1, V_2, Φ_1, and Φ_2 are real.

THEOREM 24.1

For sinusoids of the same type (*either sines or cosines*) *and of the same frequency* ω, $\wp[V_1 \sin(\omega t + \Phi_1) + V_2 \sin(\omega t + \Phi_2)] = V_1 \wp[\sin(\omega t + \Phi_1)] + V_2 \wp[\sin(\omega t + \Phi_2)]$. *A similar relation can be written for cosines.*

This theorem demonstrates that the phasor transform is a linear transform.

THEOREM 24.2

If $\wp[V_1 \sin(\omega t + \Phi)] = V_1 e^{j\Phi}$, *then*

$$\wp\left[\frac{d}{dt} V_1 \sin(\omega t + \Phi)\right] = j\omega V_1 e^{j\Phi} \tag{24.80}$$

To prove Theorem 24.2, we can write

$$\begin{aligned}\wp\left[\frac{d}{dt} V_1 \mathfrak{I}(e^{j\Phi} e^{j\omega t})\right] &= \wp\left[V_1 \mathfrak{I}\left(e^{j\Phi} \frac{d}{dt} e^{j\omega t}\right)\right] \\ &= \wp\left[V_1 \mathfrak{I} e^{j\Phi} j\omega e^{j\omega t}\right] = V_1 j\omega e^{j\Phi}\end{aligned}$$

Note the interchange of the derivative and the imaginary sign in the proof of the theorem. Also, Theorem 24.2 can be generalized to

$$\wp\left[\frac{d^n}{dt^n} V_1 \sin(\omega t + \Phi)\right] = (j\omega)^n V_1 e^{j\Phi} \tag{24.81}$$

These results are useful for finding the sinusoidal steady-state solutions of linear, constant-coefficient, ordinary differential equations assuming the roots of the characteristic polynomials lie in the open LHP with possibly one at the origin.

THEOREM 24.3

If $\wp[V_1 \sin(\omega t + \Phi)] = V_1 e^{j\Phi}$, *then*

$$\wp\left[\int V_1 \sin(\omega t + \Phi) dt\right] = \frac{1}{j\omega} V_1 e^{j\Phi} \tag{24.82}$$

The proof of Theorem 24.3 is easily obtained by writing

$$\begin{aligned}\wp\left[\int V_1 \sin(\omega t + \Phi)\mathrm{d}t\right] &= \wp\left[\int \Im\left[V_1 e^{j(\omega t+\Phi)}\right]\mathrm{d}t\right] \\ &= \wp\left[\Im \int V_1 e^{j(\omega t+\Phi)}\mathrm{d}t\right] = \frac{V_1}{j\omega}e^{j\Phi}\end{aligned}$$

It should be noted that no constant of integration is employed because a constant is not a sinusoidal function and is therefore not permitted when using phasors. A constant of integration arises in LLFT network analysis because of initial conditions, and we are interested only in the sinusoidal steady-state response and not in a zero-input response. No limits are used with the integral either, because the (constant) lower limit would also yield a constant, which would imply that we are not at sinusoidal steady state.

Theorem 24.3 is easily extended to the case of n integrals:

$$\wp\left[\int \ldots \int V_1 \sin(\omega t + \Phi)(\mathrm{d}t)^n\right] = \frac{V_1}{(j\omega)^n}e^{j\Phi} \tag{24.83}$$

This result is useful for finding the sinusoidal steady-state solution of integro-differential equations.

24.3.3 Inverse Phasor Transforms

To obtain time domain results, we must be able to inverse transform phasors. The inverse transform operation is denoted by $\wp^{-1}$. This is an easy operation that consists of restoring the term $e^{j\omega t}$, restoring the imaginary sign (the real sign if cosines are used), and dropping the inverse transform sign. That is,

$$\begin{aligned}\wp^{-1}[V_1 e^{j\Phi}] &= \Im\left[V_1 e^{j\Phi}e^{j\omega t}\right] \\ &= V_1 \sin(\omega t + \Phi)\end{aligned} \tag{24.84}$$

The following example illustrates both the use of Theorem 24.2 and the inverse transform procedure.

Example 24.20

Determine the sinusoidal steady-state solution for the differential equation:

$$\frac{d^2 f(t)}{\mathrm{d}t^2} + 4\frac{df(t)}{\mathrm{d}t} + 3f(t) = V\sin(\omega t + \Phi)$$

Solution

We note that the characteristic polynomial, $D^2 + 4D + 3$, has all its roots in the open LHP. The next step is to phasor transform each term of the equation to obtain

$$-\omega^2 \underline{\boldsymbol{F}} + 4j\omega\underline{\boldsymbol{F}} + 3\underline{\boldsymbol{F}} = Ve^{j\Phi}$$

where $\underline{\boldsymbol{F}}(j\omega) = \wp[f(t)]$. Therefore, when we solve for $\underline{\boldsymbol{F}}$, we obtain

$$\begin{aligned}\underline{\boldsymbol{F}} &= \frac{Ve^{j\Phi}}{(3-\omega^2)+j4\omega} \\ &= \frac{Ve^{j\Phi}e^{j\theta}}{\sqrt{(3-\omega^2)^2+16\omega^2}}\end{aligned}$$

where

$$\theta = \tan^{-1}\frac{-4\omega}{3-\omega^2} = \tan^{-1}\frac{4\omega}{\omega^2-3}$$

Thus,

$$\underline{\boldsymbol{F}} = \frac{V}{\sqrt{\omega^4+10\omega^2+9}}e^{j(\phi+\theta)}$$

To obtain a time-domain function, we inverse transform $\underline{\boldsymbol{F}}$ to obtain

$$\mathcal{F}^{-1}[\underline{\boldsymbol{F}}(j\omega)] = f(t) = \frac{V}{\sqrt{\omega^4+10\omega^2+9}}\sin(\omega t+\Phi+\theta)$$

In this example, we see that the sinusoidal steady-state solution consists of the sinusoidal forcing term, $V\sin(\omega t+\Phi)$, modified in amplitude and shifted in phase.

24.3.4 Phasors and Networks

Phasors are time-independent representations of sinusoids. Thus, we can define impedances in the phasor transform domain and obtain Ohm's law-like expressions relating currents through network elements with the voltages across those elements. In addition, the impedance concept allows us to combine dissimilar elements, such as resistors with inductors, in the transform domain.

The time-domain expressions relating the voltages and currents for *Rs*, *Ls*, and *Cs*, repeated here for convenience, are

$$v_R(t) = i_R(t)R, \quad v_L(t) = \frac{L\mathrm{d}i_L}{\mathrm{d}t}, \quad v_C(t) = \frac{1}{C}\int i_C\mathrm{d}t$$

Note that initial conditions are set to zero. Then, performing the phasor transform of the time-domain variables, we have

$$Z_R = R, \quad Z_L = j\omega L, \quad Z_C = \frac{1}{j\omega C}$$

We can also write the admittances of these elements as $Y_R = 1/Z_R$, $Y_L = 1/Z_L$, and $Y_C = 1/Z_C$. Then, we can extend the impedance and admittance concepts for two-terminal elements to multiport networks in the same manner as was done in the development of Laplace transform techniques for network analysis. For example, the transfer function of the circuit shown in Figure 24.65 can be written as

$$\frac{\underline{\boldsymbol{V}}_o(j\omega)}{\underline{\boldsymbol{V}}_i(j\omega)} = G_{21}(j\omega)$$

where the $j\omega$ indicates that the analysis is being performed at sinusoidal steady state [1]. It is also assumed that no other excitations exist in *N* in Figure 24.65. With impedances and transfer functions defined, then all the theorems developed for Laplace transform analysis, including source transformations, have a phasor transform counterpart.

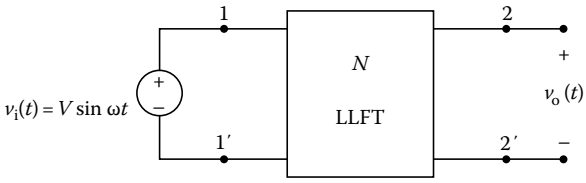

FIGURE 24.65 LLFT network excited by a sinusoidal voltage source.

Example 24.21

Use phasor analysis to find the transfer function $G_{21}(j\omega)$ and $v_{oss}(t)$ for the circuit in Figure 24.66.

Solution

The phasor transform of the output voltage can be obtained easily by means of the simple voltage divider. Thus,

$$\underline{\boldsymbol{V}}_o = \underline{\boldsymbol{V}}_i \frac{j\omega L + R_2}{j\omega L + R_2 + \frac{R_1}{1+j\omega CR_1}}$$

To obtain $G_{21}(j\omega)$, we form $\underline{\boldsymbol{V}}_o/\underline{\boldsymbol{V}}_i$, which yields

$$\frac{\underline{\boldsymbol{V}}_o}{\underline{\boldsymbol{V}}_i} = G_{21}(j\omega) = \frac{(R_2 + j\omega L)(1 + j\omega CR_1)}{(R_2 + j\omega L)(1 + j\omega CR_1) + R_1}$$

Expressing the numerator and denominator of G_{21} in exponential form produces

$$G_{21} = \frac{\sqrt{(R_2 - \omega^2 LCR_1)^2 + (\omega L + \omega CR_1R_2)^2}\, e^{j\alpha}}{\sqrt{(R_1 + R_2 - \omega^2 LCR_1)^2 + (\omega L + \omega CR_1R_2)^2}\, e^{j\beta}}$$

where

$$\alpha = \tan^{-1} \frac{(\omega L + \omega CR_1R_2)}{R_2 - \omega^2 LCR_1}$$
$$\beta = \tan^{-1} \frac{(\omega L + \omega CR_1R_2)}{R_1 + R_2 - \omega^2 LCR_1}$$

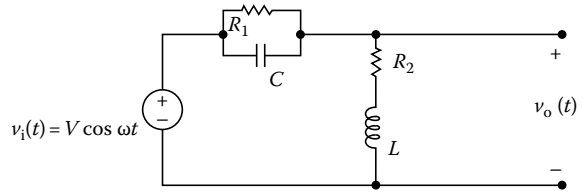

FIGURE 24.66 Circuit for Example 24.21.

Thus,

$$G_{21}(j\omega) = Me^{j\theta}$$

where

$$M = \sqrt{\frac{(R_2 - \omega^2 LCR_1)^2 + (\omega L + \omega CR_1R_2)^2}{(R_1 + R_2 - \omega^2 LCR_1)^2 + (\omega L + \omega CR_1R_2)^2}}$$

and

$$\theta = \alpha - \beta$$

The phasor transform of $v_i(t)$ is

$$\underline{\boldsymbol{V}}_i = \wp[V\Re e^{j\omega t}] = Ve^{j\theta} = V$$

and, therefore, the time-domain expression for the sinusoidal steady-state output voltage is

$$v_{oss}(t) = VM\cos(\omega t + \theta)$$

Driving point impedances and admittances as well as transfer functions are not phasors because they do not represent sinusoidal waveforms. However, an impedance or transfer function is a complex number at a particular real frequency, and the product of a complex number times a phasor is a new phasor.

The product of two arbitrary phasors is not ordinarily defined because $\sin^2(\omega t)$ or $\cos^2(\omega t)$ are not sinusoidal and have no phasor transforms. However, as we will see later, power relations for AC circuits can be expressed in efficient ways as functions of products of phasors. Because such products have physical interpretations, we permit them in the context of power calculations.

Division of one phasor by another is permitted only if the two phasors are related by a driving point or transfer network function such as $\underline{\boldsymbol{V}}_o/\underline{\boldsymbol{V}}_i = G_{21}(j\omega)$.

24.3.5 Phase Lead and Phase Lag

The terms ''phase lead'' and ''phase lag'' are used to describe the phase shift between two or more sinusoids of the same frequency. This phase shift can be expressed as an angle in degrees or radians, or it can be expressed in time as seconds. For example, suppose we have three sinusoids given by

$$v_1(t) = V_1\sin(\omega t), \quad v_2(t) = V_2\sin(\omega t + \Phi), \quad v_3 = V_3\sin(\omega t - \Phi)$$

where V_1, V_2, V_3, and Φ are all positive. Then, we say that v_2 leads v_1 and that v_3 lags v_1. To see this more clearly, we rewrite v_2 and v_3 as

$$v_2 = V_2\sin[\omega(t + t_0)] \quad v_3 = V_3\sin[\omega(t - t_0)]$$

where the constant $t_0 = \Phi/\omega$. Figure 24.67 plots the three sinusoids sketched on the same axis, and from this graph we see that the zero crossings of $v_2(t)$ occur t_0 seconds before the zero crossing of $v_1(t)$. Thus, $v_2(t)$ leads $v_1(t)$ by t_0 seconds. Similarly, we see that the zero crossings of $v_3(t)$ occur t_0 seconds after the zero crossings of $v_1(t)$. Thus, $v_3(t)$ lags $v_1(t)$. We can also say that $v_3(t)$ lags $v_2(t)$. When comparing the phases of sine waves with $V\sin(\omega t)$, the key thing to look for in the arguments of the sines are the signs of the angles following ωt. A positive sign means lead and a negative sign means lag. If two sines or two cosines have the same phase angle, then they are called ''in phase.''

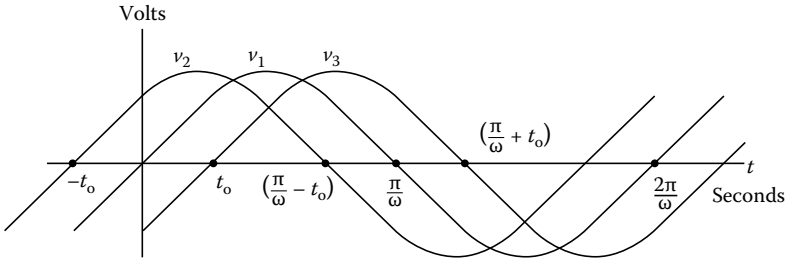

FIGURE 24.67 Three sinusoids sketched on a time axis.

If we have $i_1(t) = I_1\ [\cos(\omega t - \pi/4)]$ and $i_2(t) = I_2\ [\cos(\omega t - \pi/3)]$, then i_2 lags i_1 by $\pi/12$ rad or 15° because even though the phases of both cosines are negative, the phase of $i_1(t)$ is less negative than the phase of $i_2(t)$. We can also say that i_1 leads i_2 by 15°.

Example 24.22

Suppose we have five signals with equal peak amplitudes and equal frequencies but with differing phases. The signals are: $i_1 = I[\sin\ (\omega t)]$, $i_2 = I\ [\cos(\omega t)]$, $i_3 = I[\cos(\omega t + \theta)]$, $i_4 = -I[\sin(\omega t + \psi)]$, and $i_5 = -I[\cos(\omega t - \Phi)]$. Assume I, θ, ψ, and Φ are positive.

1. How much do the signals i_2 through i_5 lead i_1?
2. How much do the signals i_1 and i_3 through i_5 lead i_2?

Solution

For part (1), we express i_2 through i_5 as sines with lead angles. That is,

$$
\begin{aligned}
i_2 &= I\cos(\omega t) = I\sin\left(\omega t + \frac{\pi}{2}\right)\\
i_3 &= I\cos(\omega t + \theta) = I\sin\left(\omega t + \theta + \frac{\pi}{2}\right)\\
i_4 &= -I\sin(\omega t + \psi) = I\sin(\omega t + \psi \pm \pi)\\
i_5 &= -I\cos(\omega t - \Phi) = I\cos(\omega t - \Phi \pm \pi)\\
&= I\sin\left(\omega t - \Phi \pm \pi + \frac{\pi}{2}\right)
\end{aligned}
$$

Thus, i_2 leads i_1 by $\pi/2$ rad, and i_3 leads i_1 by $\theta + \pi/2$. For i_4, we can take the plus sign in the argument of the sign to obtain $\psi + \pi$, or we can take the minus sign to obtain $\psi - \pi$. The current i_5 leads i_1 by $(3\pi/2 - \Phi)$ or by $(-\pi/2 - \Phi)$. An angle of $\pm 2\pi$ can be added to the argument without affecting lead or lag relationships.

For part (2), we express i_1 and i_3 through i_5 as cosines with lead angles yielding

$$
\begin{aligned}
i_1 &= I\sin(\omega t) = I\cos\left(\omega t - \frac{\pi}{2}\right)\\
i_3 &= I\cos(\omega t + \theta)\\
i_4 &= -I\sin(\omega t + \psi) = I\sin(\omega t + \psi \pm \pi)\\
&= I\cos\left(\omega t + \psi \pm \pi - \frac{\pi}{2}\right)\\
i_5 &= -I\cos(\omega t - \Phi) = I\cos(\omega t - \Phi \pm \pi)
\end{aligned}
$$

We conclude that i_1 leads i_2 by $(-\pi/2)$ rad. (We could also say that i_1 lags i_2 by $(\pi/2)$ rad.) Also, i_3 leads i_2 by θ. The current i_4 leads i_2 by $(\psi + \pi/2)$ where we have chosen the plus sign in the argument of the cosine. Finally, i_5 leads i_2 by $(\pi - \Phi)$, where we have chosen the plus sign in the argument.

In the previous example, we have made use of the identities:

$$\cos(\alpha) = \sin\left(\alpha + \frac{\pi}{2}\right); \quad -\sin(\alpha) = \sin(\alpha \pm \pi)$$
$$-\cos(\alpha) = \cos(\alpha \pm \pi); \quad \sin(\alpha) = \cos\left(\alpha - \frac{\pi}{2}\right)$$

The concepts of phase lead and phase lag are clearly illustrated by means of phasor diagrams, which are described in Section 23.4.6.

24.3.6 Phasor Diagrams

Phasors are complex numbers that represent sinusoids, so phasors can be depicted graphically on a complex plane. Such graphical illustrations are called phasor diagrams. Phasor diagrams are valuable because they present a clear picture of the relationships among the currents and voltages in a network. Furthermore, addition and subtraction of phasors can be performed graphically on a phasor diagram. The construction of phasor diagrams is demonstrated in the next example.

Example 24.23

For the network in Figure 24.68a, find $\underline{\boldsymbol{I}}_1$, $\underline{\boldsymbol{V}}_{R1}$, and $\underline{\boldsymbol{V}}_C$. For Figure 24.68b, find $\underline{\boldsymbol{I}}_2$, $\underline{\boldsymbol{V}}_{R2}$, and $\underline{\boldsymbol{V}}_L$. Construct phasor diagrams that illustrate the relations of the currents to the voltage excitation and the other voltages of the networks.

Solution

For Figure 24.68a, we have

$$\wp[v(t)] = V\angle 0^\circ \quad \text{and} \quad \wp[i_1(t)] = \underline{\boldsymbol{I}}_1 = \frac{V}{R_1 + \frac{1}{j\omega C}}$$

Rewriting $\underline{\boldsymbol{I}}_1$, we have

$$\underline{\boldsymbol{I}}_1 = \frac{Vj\omega C}{1 + j\omega CR_1} = \frac{Vj\omega C}{1 + j\omega CR_1}\left[\frac{1 - j\omega CR_1}{1 - j\omega CR_1}\right] = V\left[\frac{\omega^2 C^2 R_1 + j\omega C}{\omega^2 C^2 R_1^2 + 1}\right] = \frac{V\omega C}{\sqrt{\omega^2 C^2 R_1^2 + 1}} e^{j\theta_1}$$

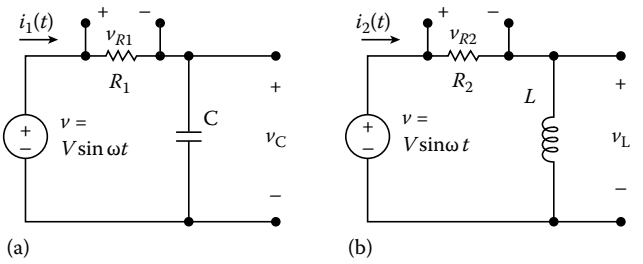

FIGURE 24.68 (a) An RC network. (b) An RL network.

where

$$\theta_1 = \tan^{-1} \frac{\omega C}{\omega^2 C^2 R_1} = \tan^{-1} \frac{1}{\omega C R_1}$$

Note that we have multiplied the numerator and denominator of $\underline{\boldsymbol{I}}_1$ by the conjugate of the denominator. The resulting denominator of $\underline{\boldsymbol{I}}_1$ is purely real, and so we need only consider the terms in the numerator of $\underline{\boldsymbol{I}}_1$ to obtain an expression for the phase. Thus, the resulting expression for the phase contains only one term which has the form:

$$\theta_1 = \tan^{-1} \frac{\mathcal{I}(\text{numerator})}{\mathcal{R}(\text{numerator})}$$

We could have obtained the same results without application of this artifice. In this case, we would have obtained

$$\theta_1 = \frac{\pi}{2} - \tan^{-1} \omega C R_1$$

For $\omega C R_1 \geq 0$, it is easy to show that the two expressions for θ_1 are equivalent.

Because the same current flows through both network elements, we have

$$\underline{\boldsymbol{V}_{R1}} = \frac{V \omega C R_1}{\sqrt{\omega^2 C^2 R_1^2 + 1}} e^{j\theta_1}$$

and

$$\underline{\boldsymbol{V}_C} = \underline{\boldsymbol{I}_1}\left(\frac{1}{j\omega C}\right) = \frac{-jV}{\sqrt{\omega^2 C^2 R_1^2 + 1}} e^{j\theta_1} = \frac{V}{\sqrt{\omega^2 C^2 R_1^2 + 1}} e^{j\psi}$$

where

$$\psi = -\frac{\pi}{2} + \theta_1 = -\tan^{-1} \omega C R_1$$

For $\underline{\boldsymbol{I}}_2$ in Figure 24.68b, we obtain

$$\underline{\boldsymbol{I}_2} = \frac{V \angle 0^\circ}{R_2 + j\omega L} = \frac{V}{\sqrt{R_2^2 + w^2 L^2}} e^{j\theta_2}$$

where θ_2 is given by

$$\theta_2 = -\tan^{-1} \frac{\omega L}{R_2}$$

The phasor current $\underline{\boldsymbol{I}}_2$ flows through both R_2 and L. So we have

$$\underline{\boldsymbol{V}_{R2}} = \underline{\boldsymbol{I}_2} R_2$$

and

$$\underline{\boldsymbol{V}}_{\mathrm{L}} = j\omega L\underline{\boldsymbol{I}}_2 = \frac{V\omega L}{\sqrt{\omega^2 L^2 + R_2^2}} e^{j\Phi}$$

where

$$\Phi = \frac{\pi}{2} + \theta_2$$

To construct the phasor diagram in Figure 24.69a for the RC network in Figure 24.68a, we first draw a vector corresponding to the phasor transform $\underline{\boldsymbol{V}} = V\angle 0°$ of the excitation. Because the phase of this phasor is zero, it is represented as a vector along the positive real axis. The length of this vector is $|\underline{\boldsymbol{V}}|$. Then we construct the vector representing $\underline{\boldsymbol{I}}_1 = |\underline{\boldsymbol{I}}_1|\ e^{j\theta 1}$. Again, the length of the vector is $|\underline{\boldsymbol{I}}_1|$, and it is drawn at the angle θ_1. The vector representing $\underline{\boldsymbol{V}}_{R1}$ lies along $\underline{\boldsymbol{I}}_1$ because the voltage across a resistor is always in phase or 180° out of phase with the current flowing through the resistor. The vector representing the current leads $\underline{\boldsymbol{V}}_{\mathrm{C}}$ by exactly 90°. It should be noted from the phasor diagram that $\underline{\boldsymbol{V}}_{R1}$ and $\underline{\boldsymbol{V}}_{\mathrm{C}}$ add to produce $\underline{\boldsymbol{V}}$ as required by Kirchhoff's law.

Figure 24.69b presents the phasor diagram for the RL network in Figure 24.68b. For this network, $\underline{\boldsymbol{I}}_2$ lags $\underline{\boldsymbol{V}}_{\mathrm{L}}$ by exactly 90°. Also, the vector sum of the voltages $\underline{\boldsymbol{V}}_{\mathrm{L}}$ and $\underline{\boldsymbol{V}}_{R2}$ must be the excitation voltage $\underline{\boldsymbol{V}}$ as indicated by the dotted lines in Figure 24.69b.

If the excitation $V\sin(\omega t)$ had been $V\sin(\omega t + \Phi)$ in Figure 24.68 in the previous example, then the vectors in the phasor diagrams in Figure 24.69 would have just been rotated around the origin by Φ. Thus, for example, $\underline{\boldsymbol{I}}_1$ in Figure 24.69a would have an angle equal to $\theta_1 + \Phi$. The lengths of the vectors and the relative phase shifts between the vectors would remain the same.

If R_1 in Figure 24.68a is decreased, then from the expression for $\theta_1 = \tan^{-1}(1/(\omega C R_1))$, we see that the phase of $\underline{\boldsymbol{I}}_1$ is increased. As R_1 is reduced further, θ_1 approaches 90°, and the circuit becomes more nearly like a pure capacitor. However, as long as $\underline{\boldsymbol{I}}_1$ leads $\underline{\boldsymbol{V}}$, we label the circuit as capacitive.

As R_2 in Figure 24.68b is decreased, then θ_2 in Figure 24.69b decreases (becomes more negative) and approaches −90°. Nevertheless, as long as $\underline{\boldsymbol{I}}_2$ lags $\underline{\boldsymbol{V}}$, we refer to the circuit as inductive.

If both inductors and capacitors are in a circuit, then it is possible for the circuit to appear capacitive at some frequencies and inductive at others. An example of such a circuit is provided in Section 24.3.7.

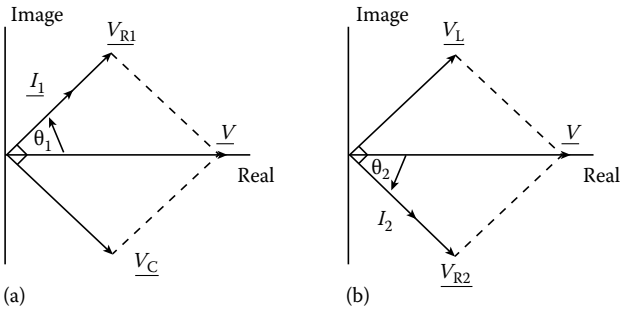

FIGURE 24.69 (a) Phasor diagram for the voltages and currents in Figure 24.68a. (b) Phasor diagram for Figure 24.68b.

24.3.7 Resonance

Resonant networks come in two basic types: the parallel resonant network and the series resonant (sometimes called antiresonant) network. More complicated networks may contain a variety of both types of resonant circuits. To see what happens at resonance, we examine a parallel resonant network at sinusoidal steady state [1]. Figure 24.70 is a network consisting of a capacitor and inductor connected in parallel, often called a tank circuit or tank, and an additional resistor R_1 connected in parallel with the tank. The phasor transforms of the excitation and the currents through the elements in Figure 24.70 are

$$\bar{\boldsymbol{V}} = V\angle 0^\circ; \quad \underline{\boldsymbol{I}_{R1}} = \frac{V}{R_1}; \quad \underline{\boldsymbol{I}_C} = j\omega CV; \quad \underline{\boldsymbol{I}_L} = \frac{V}{j\omega L} \tag{24.85}$$

where V is the peak value of the excitation. The transform of the current supplied by the source is

$$\underline{\boldsymbol{I}_1} = \boldsymbol{I}_1\angle\theta_1 = \underline{\boldsymbol{I}_{R1}} + \underline{\boldsymbol{I}_C} + \underline{\boldsymbol{I}_L} = V\left[\frac{1}{R_1} + j\omega C\left(1 - \frac{1}{\omega^2 LC}\right)\right] \tag{24.86}$$

The peak value of the current $i_1(t)$ at steady state is

$$I_1 = V\sqrt{\left(\frac{1}{R_1}\right)^2 + \omega^2 C^2\left(1 - \frac{1}{\omega^2 LC}\right)^2} \tag{24.87}$$

It is not difficult to determine that the minimum value of I_1 occurs at

$$\omega = \frac{1}{\sqrt{LC}} \tag{24.88}$$

which is the condition for resonance, and $I_{1\,\min}$ is given by

$$I_{1\,\min} = \frac{V}{R_1} \tag{24.89}$$

This result is somewhat surprising since it means that at resonance, the source in Figure 24.70 delivers no current to the tank at steady state. However, this result does not mean that the currents through the capacitor and inductor are zero. In fact, for $\omega^2 = 1/(LC)$ we have

$$\underline{\boldsymbol{I}_C} = jV\sqrt{\frac{C}{L}} \quad \text{and} \quad \underline{\boldsymbol{I}_L} = -jV\sqrt{\frac{C}{L}}$$

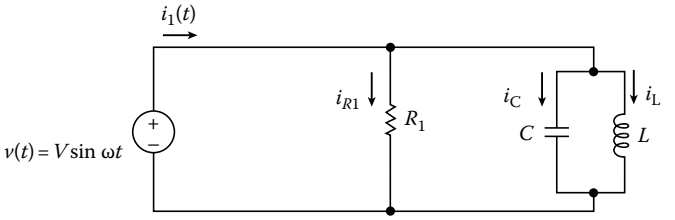

FIGURE 24.70 Parallel resonant circuit.

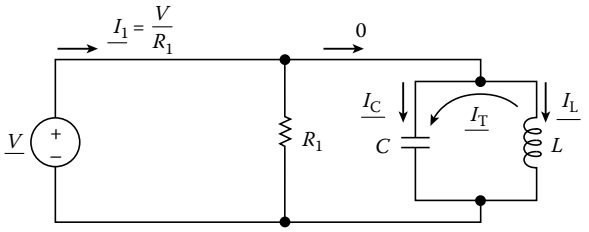

FIGURE 24.71 Circuit of Figure 24.70 at resonance. No current is supplied to the tank by the source, but a circulating current occurs in the tank.

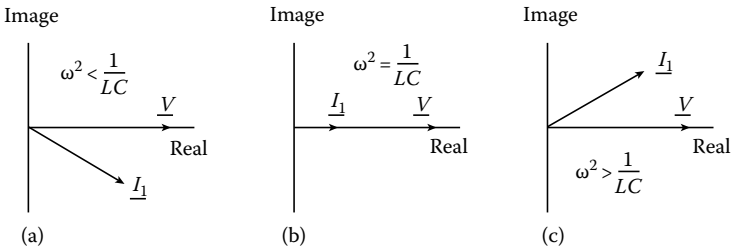

FIGURE 24.72 Phasor diagrams for the circuit in Figure 24.70. (a) $\omega^2 < 1/LC$. (b) Diagram at resonance. (c) $\omega^2 > 1/(LC)$.

That is, the current through the inductor is 180° out of phase with the current through the capacitor, and, because their magnitudes are equal, their sum is zero. Thus, at steady state and at the frequency given by Equation 24.88, the tank circuit looks like an open circuit to the voltage source. Yet, a circulating current occurs in the tank, labeled $\underline{\boldsymbol{I}}_T$ in Figure 24.71, which can be quite large depending on the values of C and L. That is, at resonance,

$$\underline{\boldsymbol{I}}_T = jV\sqrt{\frac{C}{L}} = \underline{\boldsymbol{I}}_C = -\underline{\boldsymbol{I}}_L \tag{24.90}$$

Therefore, energy is being transferred back and forth between the inductor and the capacitor. If the inductor and capacitor are ideal, the energy transferred would never decrease. In practice, parasitic resistances, especially in a physical inductor, would eventually dissipate this energy. Of course, parasitic resistances can be modeled as additional elements in the network.

Another interesting aspect of the network in Figure 24.70 is that, at low frequencies ($\omega^2 < 1/(LC)$), $\underline{\boldsymbol{I}}_1$ lags $\underline{\boldsymbol{V}}$, and so the network appears inductive to the voltage source. At high frequencies ($\omega^2 > 1/(LC)$), $\underline{\boldsymbol{I}}_1$ leads $\underline{\boldsymbol{V}}$, and the network looks capacitive to the voltage source. At resonance, the network appears as only a resistor R_1 to the source. Figure 24.72 depicts phasor diagrams of $\underline{\boldsymbol{V}}$ and $\underline{\boldsymbol{I}}_1$ at low frequency, at resonance, and at high frequency.

Figure 24.73 is the second basic type of resonant circuit—a series resonant circuit which is excited by a sinusoidal current source with phasor transform $\underline{\boldsymbol{I}} = I\angle 0°$. This circuit is dual to the circuit in Figure 24.70. The voltages across the network elements can be expressed as

$$\underline{\boldsymbol{V}}_R = IR; \quad \underline{\boldsymbol{V}}_C = -j\left(\frac{1}{\omega C}\right)I; \quad \underline{\boldsymbol{V}}_L = j\omega LI \tag{24.91}$$

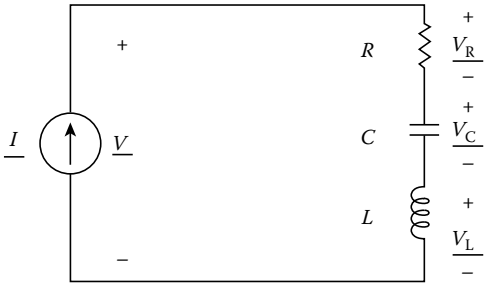

FIGURE 24.73 Series resonant circuit.

Then, the voltage $\underline{\boldsymbol{V}}$ is

$$\underline{\boldsymbol{V}} = I\left[R + j\left(\omega L - \frac{1}{\omega C}\right)\right] \tag{24.92}$$

The peak value of $\underline{\boldsymbol{V}}$ is

$$V = I\sqrt{R^2 + \left(\omega L - \frac{1}{\omega C}\right)^2} \tag{24.93}$$

where I is the peak value of $\underline{\boldsymbol{I}}$. The minimum value of V is

$$V_{\min} = IR \tag{24.94}$$

and this occurs at the frequency $\omega = 1/\sqrt{(LC)}$, which is the same resonance condition as for the circuit in Figure 24.70.

Equation 24.94 demonstrates that at resonance, the voltage across the LC subcircuit in Figure 24.73 is zero. However, the individual voltages across L and across C are not zero and can be quite large in magnitude depending on the values of the capacitor and inductor. These voltages are given by

$$\underline{\boldsymbol{V}}_C = -jI\sqrt{\frac{L}{C}} \quad \text{and} \quad \underline{\boldsymbol{V}}_L = jI\sqrt{\frac{L}{C}} \tag{24.95}$$

and therefore the voltage across the capacitor is exactly 180° out of phase with the voltage across the inductor.

At frequencies below resonance, $\underline{\boldsymbol{V}}$ lags $\underline{\boldsymbol{I}}$ in Figure 24.73, and therefore the circuit looks capacitive to the source. Above resonance, $\underline{\boldsymbol{V}}$ leads $\underline{\boldsymbol{I}}$, and the circuit looks inductive to the source. If the frequency of the source is $\omega = 1/\sqrt{(LC)}$ the circuit looks like a resistor of value R to the source.

24.3.8 Power in AC Circuits

If a sinusoidal voltage $v(t) = V\sin(\omega t + \theta_V)$ is applied to an LLFT network that possibly contains other sinusoidal sources having the same frequency ω, then a sinusoidal current $i(t) = I\sin(\omega t + \theta_I)$ flows at steady state as depicted in Figure 24.74. The instantaneous power delivered to the circuit by the voltage source is

$$p(t) = v(t)i(t) = VI\sin(\omega t + \theta_V)\sin(\omega t + \theta_I) \tag{24.96}$$

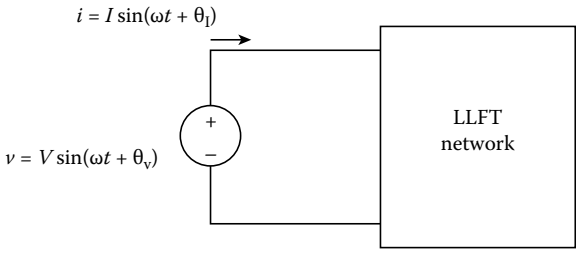

FIGURE 24.74 LLFT network that may contain other sinusoidal sources at the same frequency as the external generator.

where the units of $p(t)$ are watts (W). With the aid of the trigonometric identity

$$\sin\alpha\sin\beta = \frac{1}{2}[\cos(\alpha-\beta) - \cos(\alpha+\beta)]$$

we rewrite Equation 24.96 as

$$p(t) = \frac{1}{2}VI[\cos(\theta_v - \theta_I) - \cos(2\omega t + \theta_V + \theta_I)] \tag{24.97}$$

The instantaneous power delivered to the network in Figure 24.74 has a component that is constant and another component that has a frequency twice that of the excitation. At different instances of time, $p(t)$ can be positive or negative, meaning that the voltage source is delivering power to the network or receiving power from the network, respectively.

In AC circuits, however, it is usually the average power P that is of more interest than the instantaneous power $p(t)$ because average power generates the heat or performs the work.

The average over a period of a periodic function $f(t)$ with period T is

$$[f(t)]_{avg} = F = \frac{1}{T}\int_0^T f(t)\mathrm{d}t \tag{24.98}$$

The period of $p(t)$ in Equation 24.97 is $T = \pi/\omega$, and so

$$[p(t)]_{avg} = P = \frac{\omega}{\pi}\int_0^{\frac{\pi}{\omega}} p(t)\mathrm{d}t = \frac{1}{2}VI\cos(\theta_V - \theta_I) \tag{24.99}$$

The cosine term in Equation 24.99 plays an important role in power calculations and so is designated as the power factor (PF). Thus,

$$\text{Power factor} = \text{PF} = \cos(\theta_V - \theta_I) \tag{24.100}$$

If $|\theta_V - \theta_I| = \pi/2$, then PF = 0, and the average power delivered to the network in Figure 24.74 is zero; but if PF = 1, then P delivered to the network by the source is $VI/2$. If $0 < |\theta_V - \theta_I| < \pi/2$, then P is positive, and the source is delivering average power to the network. However, the network delivers average power to the source when P is negative, and this occurs if $\pi/2 < |\theta_V - \theta_I| < 3\pi/2$.

If the current leads the voltage in Figure 24.74, the convention is to consider PF as leading, and if current lags the voltage, the PF is regarded as lagging. However, it is not possible from PF alone to determine whether a current leads or lags voltage.

Example 24.24

Determine the average power delivered to the network shown in Figure 24.68a.

Solution

The phasor transform of the applied voltage is $\underline{\boldsymbol{V}} = V/0°$, and we determined in Example 24.24 that the current supplied was

$$\underline{\boldsymbol{I}}_1 = \frac{V\omega C e^{j\theta_1}}{\sqrt{\omega^2 C^2 R_1^2 + 1}}, \quad \theta_1 = \tan^{-1}\frac{1}{\omega C R_1}$$

The power factor is

$$\text{PF} = \cos(0 - \theta_1) = \cos(\theta_1)$$

which, with the aid of the triangle in Figure 24.75, can be rewritten as

$$\text{PF} = \frac{\omega C R_1}{\sqrt{(\omega C R_1)^2 + 1}}$$

Thus, the average power delivered to the circuit is

$$P = \frac{1}{2}\frac{V^2\omega C}{\sqrt{(\omega C R_1)^2 + 1}}\left[\frac{\omega C R_1}{\sqrt{(\omega C R_1)^2 + 1}}\right] = \frac{V^2\omega^2 C^2 R_1}{2(\omega^2 C^2 R_1^2 + 1)} = \frac{I_1^2 R_1}{2}$$

We note that if R_1 were zero in the previous example, then $P = 0$ because the circuit would be purely capacitive, and *PF* would be zero.

If no sources are in the network in Figure 24.74, then the network terminal variables are related by

$$\underline{\boldsymbol{V}} = \underline{\boldsymbol{I}} Z(j\omega) \tag{24.101}$$

where $Z(j\omega)$ is the input impedance of the network. Because Z is, general and complex, we can write it as

$$Z(j\omega) = R(\omega) + jX(\omega) = |Z|e^{j\theta_Z} \tag{24.102}$$

where

$$R(\omega) = \Re Z(j\omega); \quad X(\omega) = \Im Z(j\omega) \quad \text{and} \quad \theta_Z = \tan^{-1}\left(\frac{X(\omega)}{R(\omega)}\right) \tag{24.103}$$

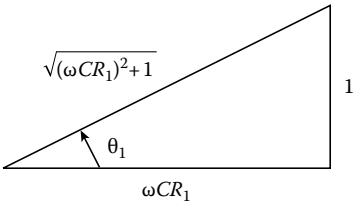

FIGURE 24.75 Triangle for determining *PF*.

In Equation 24.103, the (real) function $X(\omega)$ is termed the reactance. Employing the polar form of the phasors, we can rewrite Equation 24.101 as

$$V\angle\theta_V = I\angle\theta_I|Z|\angle\theta_Z = I|Z|\angle(\theta_I + \theta_Z) \tag{24.104}$$

Equating magnitudes and angles, we obtain

$$V = I|Z| \quad \text{and} \quad \theta_V = \theta_I + \theta_Z \tag{24.105}$$

Thus, we can express P delivered to the network as

$$P = \frac{1}{2}VI\cos(\theta_V - \theta_I) = \frac{1}{2}I^2|Z|\cos\theta_Z \tag{24.106}$$

But $|Z|\cos(\theta_Z) = R(\omega)$ so that

$$P = \frac{1}{2}I^2R(\omega) \tag{24.107}$$

Equation 24.107 indicates that the real part of the impedance absorbs the power. The imaginary part of the impedance, $X(\omega)$, does not absorb average power. Example 24.24 in this section provides an illustration of Equation 24.107.

An expression for average power in terms of the input admittance $Y(j\omega) = 1/Z(j\omega)$ can also be obtained. Again, if no sources are within the network, then the terminal variables in Figure 24.74 are related by

$$\underline{\boldsymbol{I}} = \underline{\boldsymbol{V}}Y(j\omega) \tag{24.108}$$

The admittance $Y(j\omega)$ can be written as

$$Y(j\omega) = |Y(j\omega)|e^{j\theta_Y} = G(\omega) + jB(\omega) \tag{24.109}$$

where $G(\omega)$ is conductance and $B(\omega)$ is susceptance, and where

$$G(\omega) = \Re Y(j\omega); \quad B(\omega) = \Im Y(j\omega) \quad \text{and} \quad \theta_Y = \tan^{-1}\left[\frac{B(\omega)}{G(\omega)}\right] \tag{24.110}$$

Then, average power delivered to the network can be expressed as

$$P = \frac{1}{2}V^2|Y|\cos\theta_Y = \frac{1}{2}V^2G(\omega) \tag{24.111}$$

If the network contains sinusoidal sources, then Equation 24.99 should be employed to obtain P instead of Equation 24.107 or 24.111.

Consider a resistor R with a voltage $v(t) = V\sin(\omega t)$ across it and therefore a current $i(t) = I\sin(\omega t) = v(t)/R$ through it. The instantaneous power dissipated by the resistor is

$$p(t) = v(t)i(t) = \frac{v^2(t)}{R} = i^2(t)R \tag{24.112}$$

The average power dissipated in R is

$$P = \frac{1}{T}\int_0^T i^2(t)R\mathrm{d}t = I_{\mathrm{eff}}^2 R \tag{24.113}$$

where we have introduced the new constant I_{eff}. From Equation 24.113, we can express I_{eff} as

$$I_{\mathrm{eff}} = \sqrt{\frac{1}{T}\int_0^T i^2(t)\mathrm{d}t} \tag{24.114}$$

This expression for I_{eff} can be read as "the square root of the mean (average) of the square of $i(t)$" or, more simply, as "the root mean square value of $i(t)$," or, even more succinctly, as "the RMS value of $i(t)$." Another designation for this constant is I_{rms}. Equation 24.114 can be extended to any periodic voltage or current.

The RMS value of a pure sine wave such as $i(t) = I\sin(\omega t + \theta_1)$ or $v(t) = V\sin(\omega t + \theta_v)$ is

$$I_{\mathrm{rms}} = \frac{I}{\sqrt{2}} \quad \text{or} \quad V_{\mathrm{rms}} = \frac{V}{\sqrt{2}} \tag{24.115}$$

where I and V are the peak values of the sine waves. Normally, the voltages and currents listed on the nameplates of power equipment and household appliances are given in terms of RMS values instead of peak values. For example, a 120 V, 100 W lightbulb is expected to dissipate 100 W when a voltage $120(\sqrt{2})[\sin(\omega t)]$ is impressed across it. The peak value of this voltage is 170 V.

If we employ *RMS* values, Equation 24.99 can be rewritten as

$$P = V_{\mathrm{rms}} I_{\mathrm{rms}} PF \tag{24.116}$$

Equation 24.116 emphasizes the fact that the concept of *RMS* values of voltages and currents was developed in order to simplify the calculation of average power.

Because $PF = \cos(\theta_v - \theta_1)$, we can rewrite Equation 24.116 as

$$\begin{aligned} P &= V_{\mathrm{rms}} I_{\mathrm{rms}} \cos(\theta_{\mathrm{V}} - \theta_{\mathrm{I}}) = \Re[V_{\mathrm{rms}} e^{j\theta_{\mathrm{V}}} I_{\mathrm{rms}} e^{-j\theta_{\mathrm{I}}}] \\ &= \Re[\underline{\boldsymbol{V}}\,\underline{\boldsymbol{I}}^{\star}] \end{aligned} \tag{24.117}$$

where $\underline{\boldsymbol{I}}^{\star}$ is the conjugate of $\boldsymbol{I}$. If $P = \Re[\underline{\boldsymbol{V}}\,\underline{\boldsymbol{I}}^{\star}]$, the question arises as to what the imaginary part of $\underline{\boldsymbol{V}}\,\underline{\boldsymbol{I}}^{\star}$ represents. This question leads naturally to the concept of complex power, denoted by the bold letter $\boldsymbol{S}$, which has the units of volt-amperes (VA). If P represents real power, then we can write

$$\boldsymbol{S} = P + jQ \tag{24.118}$$

where

$$\boldsymbol{S} = \underline{\boldsymbol{V}}\,\underline{\boldsymbol{I}}^{\star} \tag{24.119}$$

and where

$$Q = \Im[\underline{\boldsymbol{V}}\,\underline{\boldsymbol{I}}^{\star}] = V_{\mathrm{rms}} I_{\mathrm{rms}} \sin(\theta_{\mathrm{V}} - \theta_{\mathrm{I}}) \tag{24.120}$$

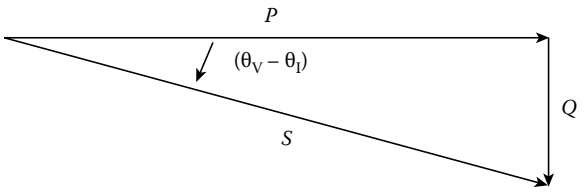

FIGURE 24.76 Power triangle for a capacitive circuit.

Thus, Q represents imaginary or reactive power. The units of Q are VARs, which stands for volt-amperes reactive. Reactive power is not available for conversion into useful work. It is needed to establish and maintain the electric and magnetic fields associated with capacitors and inductors [4]. It is an overhead required for delivering P to loads, such as electric motors, that have a reactive part in their input impedances.

The components of complex power can be represented on a power triangle. Figure 24.76 is a power triangle for a capacitive circuit. Real and imaginary power are added as shown to yield the complex power $\boldsymbol{S}$. Note that $(\theta_v - \theta_1)$ and Q are both negative for capacitive circuits. The following example illustrates the construction of a power triangle for an RL circuit.

Example 24.25

Determine the components of power delivered to the RL circuit in Figure 24.77. Provide a phasor diagram for the current and the voltages, construct a power triangle for the circuit, and show how the power diagram is related to the impedances of the circuit.

Solution

We have

$$\underline{\boldsymbol{V}} = Ve^{j\theta} \quad \text{and} \quad \underline{\boldsymbol{I}} = \frac{Ve^{j\theta_I}}{\sqrt{R^2 + (\omega L)^2}}$$

where

$$\theta_I = -\tan^{-1}\frac{\omega L}{R}$$

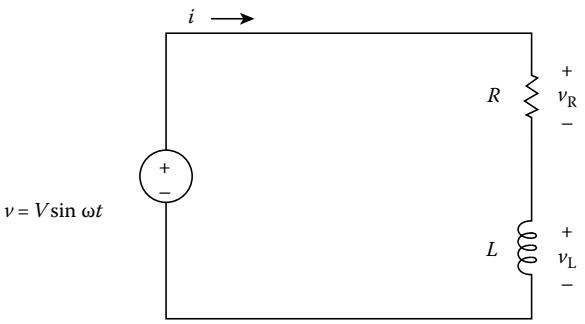

FIGURE 24.77 Network for Example 24.25.

Because $\theta_v = 0$, *PF* is

$$PF = \cos(\theta_V - \theta_I) = \frac{R}{\sqrt{R^2 + (\omega L)^2}}$$

and is lagging. The voltages across *R* and *L* are given by

$$\underline{\boldsymbol{V}}_R = \underline{\boldsymbol{I}}R = \frac{VRe^{j\theta_I}}{\sqrt{R^2 + (\omega L)^2}}$$
$$\underline{\boldsymbol{V}}_L = j\omega L\underline{\boldsymbol{I}} = \frac{V\omega L}{\sqrt{R^2 + (\omega L)^2}} e^{j\left(\frac{\pi}{2} + \theta_I\right)}$$

and *Z* is

$$Z = R + j\omega L = \sqrt{R^2 + (\omega L)^2} e^{-j\theta_I}$$

The real and imaginary components of the complex power are simply calculated as

$$P = I_{rms}^2 R(\omega) = \frac{V_{rms}^2 R}{R^2 + (\omega L)^2}$$
$$Q = \frac{V_{rms}^2 \omega L}{R^2 + (\omega L)^2}$$

Figure 24.78 presents the phasor diagram for this circuit in which we have taken the reference phasor as $\underline{\boldsymbol{I}}$ and therefore have shown $\underline{\boldsymbol{V}}$ leading $\underline{\boldsymbol{I}}$ by $(\theta_v - \theta_1)$. Also, we have moved $\underline{\boldsymbol{V}}_L$ parallel to itself to form a triangle. These operations cause the phasor diagram to be similar to the power triangle. Figure 24.79a shows a representation for the impedance in Figure 24.77. If each side of the triangle in Figure 24.79a is multiplied by I_{rms}, then we obtain voltage triangle in Figure 24.79b. Next, we multiply the sides of the voltage triangle by I_{rms} again to obtain the power triangle in Figure 24.79c. The horizontal side is the average power *P*, the vertical side is *Q*, and the hypotenuse has a length that represents the magnitude of the complex power $\boldsymbol{S}$. All three triangles in Figure 24.79 are similar. The angles between sides are preserved.

If *P* remains constant in Figure 24.76, but the magnitude of the angle becomes larger so that the magnitude of *Q* increases, then [$\boldsymbol{S}$] increases. If the magnitude of the voltage is fixed, then the magnitude of the current supplied must increase. But then, either power would be lost in the form of heat in the wires supplying the load or larger diameter, more expensive wires, would be needed. For this reason,

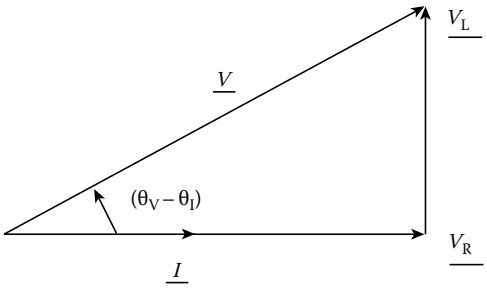

FIGURE 24.78 Phasor diagram for Example 24.25.

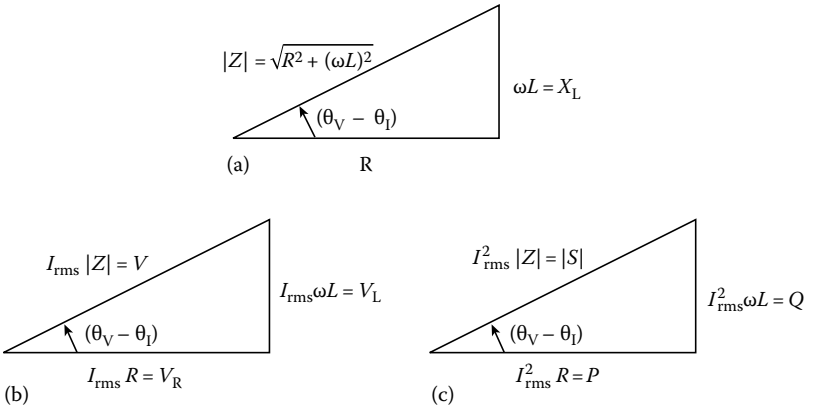

FIGURE 24.79 (a) Impedance triangle for circuit in Example 24.25. (b) Corresponding voltage triangle. (c) Power triangle.

power companies that supply power to large manufacturing firms that have many large motors impose unfavorable rates. However, the manufacturing firm can improve its rates if it improves its power factor. The following example illustrates how improving (correcting) *PF* is done.

Example 24.26

Determine the value of the capacitor to be connected in parallel with the RL circuit in Figure 24.80 to improve the PF of the overall circuit to one. The excitation is a voltage source having an amplitude of 120 V RMS and frequency $2\pi(60\text{ Hz}) = 377$ rad/s. What are the RMS values of the current supplied by the source at steady state before and after the capacitor is connected?

Solution

The current through the RL branch in Figure 24.80 is

$$\underline{\boldsymbol{I}}_{RL} = \frac{Ve^{j\theta}}{\sqrt{R^2 + (\omega L)^2}}; \quad \theta = -\tan^{-1}\frac{\omega L}{R}$$

and the current through the capacitor is

$$\underline{\boldsymbol{I}}_C = j\omega CV = V\omega Ce^{j(\pi/2)}$$

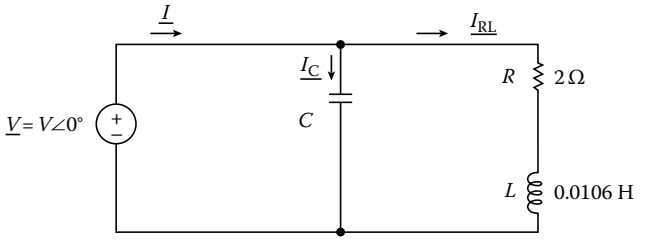

FIGURE 24.80 Circuit for Example 24.26.

Thus, the current supplied by the source to the *RLC* network is

$$\begin{aligned}\underline{\boldsymbol{I}} &= \underline{\boldsymbol{I}}_{\mathrm{RL}} + \underline{\boldsymbol{I}}_{\mathrm{C}} \\ &= \frac{V\cos\theta}{\sqrt{R^2 + (\omega L)^2}} + jV\left[\frac{-\omega L}{R^2 + (\omega L)^2} + \omega C\right]\end{aligned}$$

To improve the *PF* to one, the current $\underline{\boldsymbol{I}}$ should be in phase with $\underline{\boldsymbol{V}}$. Thus, we set the imaginary term in the equation for $\underline{\boldsymbol{I}}$ equal to zero, yielding:

$$C = \frac{L}{R^2 + (\omega L)^2} = 530\ \mu\mathrm{F}$$

a rather large capacitor. Before this capacitor is connected, the *RMS* value of the current supplied by the voltage source is $I_{\mathrm{rms}} = 26.833$ A. After the capacitor is connected, the source has to supply only 12 A RMS, a considerable reduction. In both cases, *P* delivered to the load is the same.

The following example also illustrates PF improvement.

Example 24.27

A load with PF = 0.7 lagging, depicted in Figure 24.81, consumes 12 kW of power. The line voltage supplied is 220 V RMS at 60 Hz. Find the size of the capacitor needed to correct the PF to 0.9 lagging, and determine the values of the currents supplied by the source both before and after the *PF* is corrected.

Solution

We will take the phase of the line voltage to be 0°. From $P = V_{\mathrm{rms}} I_{\mathrm{rms}} \mathrm{PF} = 12$ kW, we obtain $I_{\mathrm{rms}} = 77.922$ A. Because PF is 0.7 lagging, the phase of the current through the load relative to the phase of the line voltage is $-\cos^{-1}(0.7) = -45.57°$. Therefore, $\underline{\boldsymbol{I}}_{\mathrm{load}} = 77.922/(-45.57°°)$ A RMS. When *C* is connected in parallel with the load,

$$\begin{aligned}\underline{\boldsymbol{I}} &= \underline{\boldsymbol{I}}_{\mathrm{C}} + \underline{\boldsymbol{I}}_{\mathrm{load}} = 220(377)jC + 77.922e^{-j0.7954} \\ &= 54.54 - j[55.64 - 82{,}940C]\end{aligned}$$

If the PF were to be corrected to unity, we would set the imaginary part of the previous expression for current to zero; but this would require a larger capacitor (671 μF), which may be uneconomical. Instead, to retain a lagging but improved PF = 0.9, and corresponding to the current lagging the voltage by 25.84°, we write

$$0.9 = \frac{54.54}{\sqrt{54.54^2 + (55.64 - 82{,}940C)^2}}$$

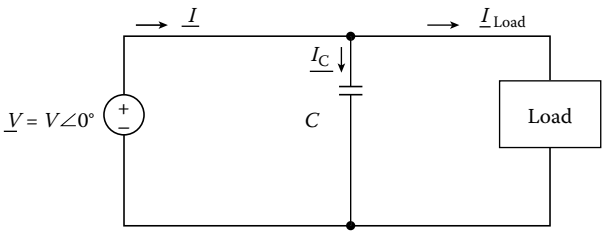

FIGURE 24.81 Circuit for Example 24.27 showing the load and the capacitor to be connected in parallel with the load to improve the power factor.

Therefore, $C = 352\ \mu$F. The line current is now

$$\underline{\boldsymbol{I}} = \underline{\boldsymbol{I}_C} + \underline{\boldsymbol{I}_{load}} = 60.615\angle(-25.87°)\ \text{A RMS}$$

Previous examples have employed ideal voltage sources to supply power to networks. However, in many electronic applications, the source has a fixed impedance associated with it, and the problem is to obtain the maximum average power transferred to the load [2]. Here, we assume that the resistance and reactance of the load can be independently adjusted. Let the source impedance be

$$Z_S(j\omega) = R_S(\omega) + jX_S(\omega)$$

The load impedance is denoted as

$$Z(j\omega) = R(\omega) + jX(\omega)$$

Figure 24.82 depicts these impedances. We assume that all the elements, including the voltage source, within the box formed by the dotted lines are fixed. The voltage source is $v(t) = V\sin(\omega t)$, and thus $i(t) = I\sin(\omega t + \theta)$, where V and I are peak values and

$$\theta = -\tan^{-1}\left[\frac{X_S(\omega) + X(\omega)}{R_S(\omega) + R(\omega)}\right]$$

The average power delivered to Z is

$$P = I_{rms}^2 R(\omega)$$

where $I_{rms} = I/\sqrt{2}$ and

$$I = \frac{V}{\sqrt{[R_S(\omega) + R(\omega)]^2 + [X_S(\omega) + X(\omega)]^2}} \tag{24.121}$$

Thus, the average power delivered to Z can be written as

$$P = \frac{V_{rms}^2 R(\omega)}{[R_S(\omega) + R(\omega)]^2 + [X_S(\omega) + X(\omega)]^2} \tag{24.122}$$

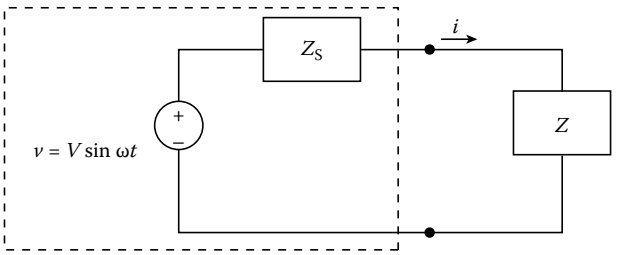

FIGURE 24.82 Z_S is fixed, and Z is to be chosen so that maximum average power is transferred to Z.

To maximize P, we first note that the term $[X_S(\omega) + X(\omega)]^2$ is always positive, and so this term always contributes to a larger denominator unless it is zero. Thus, we set

$$X(\omega) = -X_S(\omega) \tag{24.123}$$

and Equation 24.122 becomes

$$P = \frac{V_{rms}^2 R(\omega)}{[R_S(\omega) + R(\omega)]^2} \tag{24.124}$$

Second, we set the partial derivative with respect to $R(\omega)$ of the expression in Equation 24.124 to zero to obtain

$$\frac{\partial P}{\partial R} = V_{rms}^2 \frac{(R_S + R)^2 - 2R(R_S + R)}{(R_S + R)^4} = 0 \tag{24.125}$$

Equation 24.125 is satisfied for

$$R(\omega) = R_S(\omega) \tag{24.126}$$

and this value of $R(\omega)$ together with $X(\omega) = -X_S(\omega)$, yields maximum average power transferred to Z. Thus, we should adjust Z to

$$Z(j\omega) = Z_S^*(j\omega) \tag{24.127}$$

and we obtain

$$P_{max} = \frac{V_{rms}^2}{4R(\omega)} \tag{24.128}$$

Example 24.28

Find Z for the network in Figure 24.83 so that maximum average power is transferred to Z. Determine the value of P_{max}.

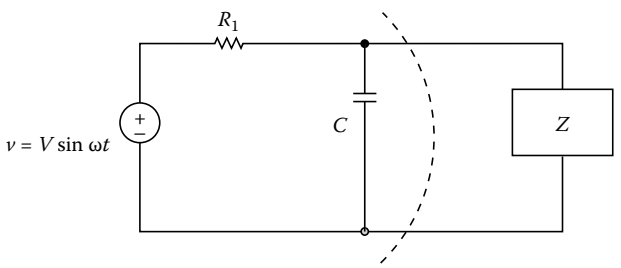

FIGURE 24.83 Circuit for Example 24.28.

Solution

We first obtain the Thévenin equivalent of the circuit to the left of the dotted arc in Figure 24.83 in order to reduce the circuit to the form of Figure 24.82.

$$\underline{\boldsymbol{V}}_{\mathrm{TH}} = \frac{\underline{\boldsymbol{V}}}{1 + j\omega R_1 C}$$
$$Z_{\mathrm{TH}} = \frac{R_1}{1 + j\omega R_1 C}$$

Thus,

$$Z = Z_{\mathrm{TH}}^{*} = \frac{R_1}{1 - j\omega R_1 C} = \frac{R_1}{1 + \frac{\omega R_1 C}{j}}$$
$$= \frac{jR_1}{j + \omega R_1 C} = \frac{j\frac{1}{\omega C}R_1}{R_1 + j\frac{1}{\omega C}}$$

The term $j(\omega C)$ appears inductive (at a single frequency), and so we equate it to $j\omega L$ to obtain

$$L = \frac{1}{\omega^2 C}$$

The impedance Z is therefore formed by the parallel connection of a resistor R_1 with the inductor L. Figure 24.84 depicts the resulting circuit. To determine $P_{\max}$, we note that the capacitor and inductor constitute a parallel circuit which is resonant at the frequency of excitation. It therefore appears as an open circuit to the source. Thus, $P_{\max}$ is easily obtained as

$$P_{\max} = I_{\mathrm{rms}}^2 R_1 = \frac{V^2}{8R_1}$$

where V is the peak value of $v(t)$.

Suppose Z is fixed and Z_S is adjustable in Figure 24.82. What should Z_S be so that maximum average power is delivered to Z? This is a problem that is applicable in the design of electronic amplifiers. The average power delivered to Z is given by Equation 24.122, and to maximize P, we set $X_S(\omega) = -X(\omega)$ as before. We therefore obtain Equation 24.124 again; but if R_S is adjustable instead of R, we see from Equation 24.124 that $P_{\max}$ is obtained when R_S equals zero.

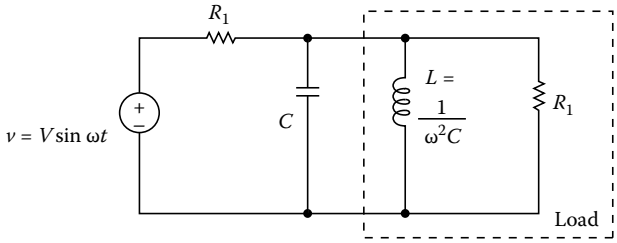

FIGURE 24.84 Circuit with load chosen to obtain maximum average power.

25.1 Introduction and Definition

Symbolic circuit analysis, simply stated, is a term that describes the process of studying the behavior of electrical circuits using symbols instead of, or in conjunction with, numerical values. As an example to illustrate the concept, consider the input resistance of the simple circuit in Figure 25.1.

Analyzing the circuit using the unique symbols for each resistor without assigning any numerical values to them yields the input resistance of the circuit in the form:

$$\frac{V_{\text{in}}}{I_{\text{in}}} = \frac{R_1R_2 + R_1R_3 + R_1R_4 + R_2R_3 + R_2R_4}{R_2 + R_3 + R_4} \tag{25.1}$$

Equation 25.1 is the symbolic expression for the input resistance of the circuit in Figure 25.1. The formal definition of symbolic circuit analysis can be written as

Definition 25.1: Symbolic circuit analysis is the process of producing an expression that describes a certain behavioral aspect of the circuit with one, some, or all the circuit elements represented as symbols.

The idea of symbolic circuit analysis is not new; engineers and scientists have been using the process to study circuits since the inception of the concept of circuits. Engineers have used symbolic circuit analysis during their education process. Most still use it in their every day job functions. As an example, all electrical engineers have symbolically analyzed the circuit in Figure 25.2.

The equivalent resistance between nodes i and j is known to be

$$\frac{1}{R_{ij}} = \frac{1}{R_1} + \frac{1}{R_2}$$

or

$$R_{ij} = \frac{R_1 R_2}{R_1 + R_2}$$

This is the most primitive form of symbolic circuit analysis.

The basic justification for performing symbolic analysis rather than numerical analysis on a circuit can be illustrated by considering the circuit in Figure 25.1 again. Assume that the values of all the resistances R_1 through R_4 are given as 1Ω and that the input resistance was analyzed numerically. The result obtained would be

$$\frac{V_{\text{in}}}{I_{\text{in}}} = \frac{5}{3} \approx 1.667\,\Omega \tag{25.2}$$

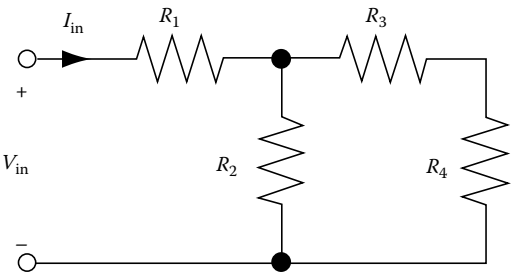

FIGURE 25.1 Symbolic circuit analysis example.

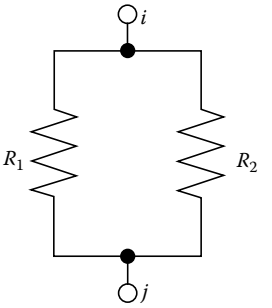

FIGURE 25.2 Common symbolic analysis problem.

Now consider the problem of increasing the input resistance of the circuit by adjusting only one of the resistor values. Equation 25.2 provides no insight into which resistor has the greatest impact on the input resistance. However, Equation 25.1 clearly shows that changing R_2, R_3, or R_4 would have very little impact on the input resistance since the terms appear in both the numerator and the denominator of the symbolic expression. It can also be seen that R_1 should be the resistor to change since it only appears in the numerator of the expression. Symbolic analysis has provided an insight into the problem.

From a circuit design perspective, numerical results from the simulation of a circuit can be obtained by evaluating the results of the symbolic analysis at a specific numerical point for each symbol. So ideally, only one simulation run is needed in order to analyze the circuit, and successive evaluations of the results replace the need for any extra iterations through the simulator. Other applications include sensitivity analysis [Lin92], [Bal04], circuit stability analysis, symbolic poles and zeros calculations [Con91], [Dro96], device modeling [Gie91], and circuit optimization [Kon92].

While the above ''hand calculations'' and somewhat trivial examples are used to illustrate symbolic circuit analysis, the thrust of the methods developed for symbolic analysis are aimed at computer implementations that are capable of symbolically analyzing circuits that cannot be analyzed ''by hand.'' Several such implementations have been developed over the years [Fer91], [Fid73], [Gie89], [Has89], [Lin70], [Mcn68], [Mie78], [Pot68], [San80], [Did91], [Sin77], [Som91], [Sta86], [Man91], [Wie89], [Kon88], [Hue89], [Has90], [Arn91], [Hsu93], [Lee92], [Li92], [Pie01], [Lib95], [Hen00].

Symbolic circuit analysis, referred to as simply symbolic analysis for the rest of this section, in its current form is limited to linear,* lumped, and time-invariant† networks. The scope of the analysis is

* Some references are made to the ability to analyze ''weakly nonlinear'' circuits [Gie91], [Top98]; however, the actual symbolic analysis is performed on a linearized model of the weakly nonlinear circuit. Other techniques are applicable to circuits with only a single strongly nonlinear variable [Wen98].

† One method, reported in [Lib93] and briefly discussed in Section 25.7, does deal with a limited class of time-variant networks.

primarily concentrated in the frequency domain, both *s*-domain [Fer91], [Fid73], [Gie89], [Has89], [Lin70], [Mcn68], [Mie78], [Pot68], [San80], [Did91], [Sin77], [Som91], [Sta86], [Man91], [Wie89], [Hue89], [Has93], [Hsu93], [Lee92] and *z*-domain [Mar93], [Li92], [Arn91], [Kon88]; however, the predominant development has been in the *s*-domain. Also, recent work has expanded symbolic analysis into the time domain [Als93], [Gre93], [Lib93], [Has91]. Sections 25.2 through 25.6 will discuss the basic methods used in symbolic analysis for mainly *s*-domain frequency analysis. However, Section 25.7 highlights the currently known time domain techniques.

25.2 Frequency Domain Analysis

Traditional symbolic circuit analysis is performed in the frequency domain where the results are in terms of the frequency variable *s*. The main goal of performing symbolic analysis on a circuit in the frequency domain is to obtain a symbolic transfer function of the form

$$H(s,\mathbf{x}) = \frac{N(s,\mathbf{x})}{D(s,\mathbf{x})}, \quad \mathbf{x} = \begin{bmatrix} x_1 & x_2 & \cdots & x_p \end{bmatrix}, p \le p_{\text{all}} \tag{25.3}$$

The expression is a rational function of the complex frequency variable *s*, and the variables x_1 through x_p representing the variable circuit elements, where p is the number of variable circuit elements and p_{all} is the total number of circuit elements. Both the numerator and the denominator of $H(s,\mathbf{x})$ are polynomials in *s* with real coefficients. Therefore, we can write

$$H(s,\mathbf{x}) = \frac{\sum_{i=0}^{m} a_i(\mathbf{x}) s^i}{\sum_{i=0}^{n} b_i(\mathbf{x}) s^i} = \frac{\prod_{i=1}^{m} [s - z_i(\mathbf{x})]}{\prod_{i=1}^{n} [s - p_i(\mathbf{x})]} \tag{25.4}$$

Most symbolic methods to date concentrate on the first form of $H(s,\mathbf{x})$ and several algorithms exist to obtain coefficients $a_i(\mathbf{x})$ and $b_i(\mathbf{x})$ in fully symbolic, partially symbolic (semisymbolic), or numerical form. The zero/pole representation of $H(s,\mathbf{x})$, although more useful in gaining insight into circuit behavior, proved to be very difficult to obtain in symbolic form for anything but very simple circuits. For large circuits, various approximation techniques must be employed [Hen00], [Con96].

A more recent approach to representing the above network function emerged in the 1980s and is based on a decomposed hierarchical form of Equation 25.3 [Sta86], [Has89], [Has93], [Sta96], [Pie96]. This hierarchical representation is referred to as a sequence of expressions (SoE) representation to distinguish it from the single expression representation of Equation 25.3 and is addressed in Section 25.4.

Several methodologies exist to perform symbolic analysis in the frequency domain. The early work was to produce a transfer function $H(s)$ with the frequency variable *s* being the only symbolic variable. Computer programs with these capabilities include CORNAP [Pot68] and NASAP [Mcn68]. The interest in symbolic analysis today is in the more general case when some or all of the circuit elements are represented by symbolic variables. The methods developed for this type of analysis fall under one of the following categories:

Traditional methods (single expression):

1. Tree enumeration methods
   a. Single graph methods
   b. Two graph methods
2. Signal flowgraph (SFG) methods
3. Parameter extraction methods
   a. Modified nodal analysis-based (MNA) methods
   b. Tableau formulation-based methods
4. Interpolation method

Hierarchical methods (sequence of expressions):

1. SFG methods
2. MNA-based methods

The classification above includes the exact methods only. For large circuits the traditional methods suffer from exponential growth of the number of terms in the formula with circuit size. If a certain degree of error is allowed, it may be possible to simplify the expression considerably, by including only the most significant terms. Several *approximate symbolic methods* have been investigated [Hsu93], [Yu96], [Hen00].

Sections 25.3 through 25.5 will discuss the basic theory for the above methods. Circuit examples are shown for all major methods except for the interpolation method due to its limited current usage* and its inability to analyze fully symbolic circuits.

25.3 Traditional Methods (Single Expressions)

This class of methods attempts to produce a single transfer function in the form of Equation 25.3. The major advantage of having a symbolic expression in that form is the insight that can be gained by observing the terms in both the numerator and the denominator. The effects of the different terms can, perhaps, be determined by inspection. This process is valid for the cases where there are relatively few symbolic terms in the expression.

Before indulging in the explanation of the different methods covered by this class, some definition of terms is in order.

Definition 25.2: *$RLCg_m$ circuit* is one that may contain only resistors, inductors, capacitors, and voltage-controlled current sources with the gain (transconductance) designated as g_m.

Definition 25.3: *Term cancellations* is the process in which two equal symbolic terms cancel out each other in the symbolic expression. This can happen in one of two ways: by having two equal terms with opposite signs added together, or by having two equal terms (regardless of their signs) divided by each other. For example, the equation

$$\frac{ab(ab+cd)-ab(cd-ef)}{ab(cd-gh)} \tag{25.5}$$

where a, b, c, d, e, f, g, and h are symbolic terms and can be reduced by observing that the terms ab in the numerator and denominator cancel each other and the terms $+cd$ and $-cd$ cancel each other in the numerator. The result is

$$\frac{ab+ef}{cd-gh} \tag{25.6}$$

Definition 25.4: *Cancellation-free*: Equation 25.6 is said to be a cancellation-free equation (i.e., no possible cancellations exist in the expression) while Equation 25.5 is not.

---

* The main applications of the polynomial interpolation method in symbolic analysis are currently in numerical reference generation for symbolic approximation [Fer98] and calculation of numerical coefficients in semisymbolic analysis [Pie93].

Definition 25.5: *Cancellation-free algorithm*: The process of term cancellation can occur during the execution of an algorithm where a cancellation-free equation is generated directly rather than generating an expression with possible term cancellations in it. Cancellation-free algorithms are more desirable because, otherwise, an overhead is needed to generate and keep the terms that are to be canceled later. The different methods that fall under the traditional class are explained next.

25.3.1 Tree Enumeration Methods

Several programs have been produced based on this method [Cal65], [Mcc72], [Gat70], [Man72]. Practical implementations of the method can only handle small circuits in the range of 15 nodes and 30 branches [Chu75]. The main reason is the exponential growth in the number of symbolic terms generated. The method can only handle one type of controlled sources, namely voltage-controlled current sources. So only $RLCg_m$ circuits can be analyzed. Also, the method does not produce any symbolic term cancellations for RLC circuits, and produces only a few for $RLCg_m$ circuits.

The basic idea of the tree enumeration method is to construct an augmented circuit (a slightly modified version of the original circuit), its associated directed graph, and then enumerating all the directed trees of the graph. The admittance products of these trees are then used to find the node admittance matrix (NAM) determinant and cofactors (the matrix itself is never constructed) to produce the required symbolic transfer functions. For a circuit with n nodes (with node n designated as the reference node) where the input is an excitation between nodes 1 and n and the output is taken between nodes 2 and n, the transfer functions of the circuit can be written as

$$Z_{\text{in}} = \frac{V_1}{I_1} = \frac{\Delta_{11}}{\Delta} \tag{25.7}$$

$$\frac{V_{\text{o}}}{I_{\text{in}}} = \frac{V_2}{I_1} = \frac{\Delta_{12}}{\Delta} \tag{25.8}$$

$$\frac{V_{\text{o}}}{V_{\text{in}}} = \frac{V_2}{V_1} = \frac{\Delta_{12}}{\Delta_{11}} \tag{25.9}$$

where

Δ is the determinant of the NAM $\mathbf{Y}_n$ (dimension $n-1 \times n-1$)
Δ_{ij} is the ijth cofactor of $\mathbf{Y}_n$

It can be shown that a simple method for obtaining Δ, Δ_{11}, and Δ_{12} is to construct another circuit comprised of the original circuit with an extra admittance $\hat{y}_{\text{S}}$ in parallel with a voltage-controlled current source, $\hat{g}_{\text{m}}V_2$, connected across the input terminals (nodes 1 and n). The determinant of $\hat{\mathbf{Y}}_n$ (the NAM for the new, slightly modified, circuit) can be written as

$$\hat{\Delta} = \Delta + \hat{y}_{\text{S}}\Delta_{11} + \hat{g}_{\text{m}}\Delta_{12} \tag{25.10}$$

This simple trick allows the construction of the determinant expression of the original circuit and its two needed cofactors by simply formulating the expression for the new augmented circuit. Example 25.1 illustrates this process.

The basic steps of the tree enumeration algorithm are (condensed from [Chu75])

1. Construct the augmented circuit from the original circuit by adding an admittance $\hat{y}_{\text{S}}$ and a transconductance $\hat{g}_{\text{m}}V_2$, in parallel between the input node and the reference node.
2. Construct a directed graph $\mathbf{G}_{\text{ind}}$ associated with the augmented circuit. The stamps used to generate $\mathbf{G}_{\text{ind}}$ are shown in Figure 25.3.
3. Find all directed trees for $\mathbf{G}_{\text{ind}}$. A directed tree rooted at node i is a subgraph of $\mathbf{G}_{\text{ind}}$ with node i having no incoming branches and each other node having exactly one incoming branch.

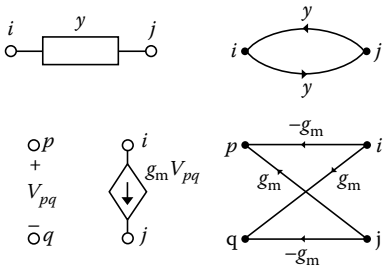

FIGURE 25.3 Element stamps for generating $\mathbf{G}_{ind}$.

4. Find the admittance product for each directed tree. An admittance product of a directed tree is simply a term that is the product of all the weights of the branches in that tree.
5. Apply Theorem 25.1.

THEOREM 25.1: [CHU75]

For any RLCg_m circuit, the determinant of the NAM (with any node as the reference node) is equal to the sum of all directed tree admittance products of $\mathbf{G}_{ind}$ (with any node as the root).

In other words

$$\hat{\Delta} = \sum \text{tree admittance products} \tag{25.11}$$

Arranging Equation 25.11 in the form of Equation 25.10 results in the necessary determinant and cofactors of the original circuit and the required transfer functions are generated from Equations 25.7 through 25.9.

Example 25.1

A circuit and its augmented counterpart are shown in Figure 25.4. The circuit is the small-signal model of a simple inverting CMOS amplifier, shown with the coupling capacitance C_C taken into account. Figure 25.5 shows the directed graph associated with the augmented circuit constructed using the rules shown in Figure 25.3. The figure also shows all the directed trees rooted at node 3 of the graph. Parallel branches heading in the same direction are combined into one branch with a weight equal to the sum of the weights of the individual parallel branches.

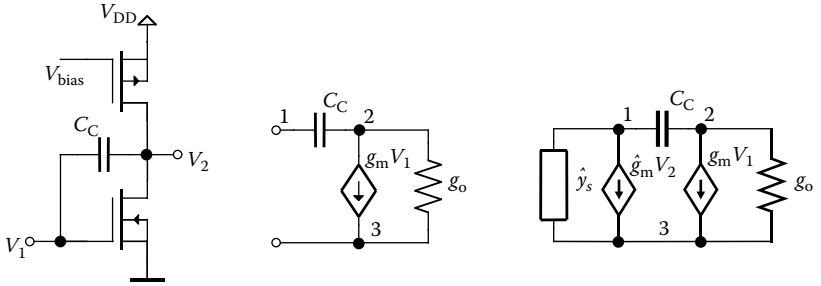

FIGURE 25.4 Circuit of Example 25.1 and its augmented equivalent diagram.

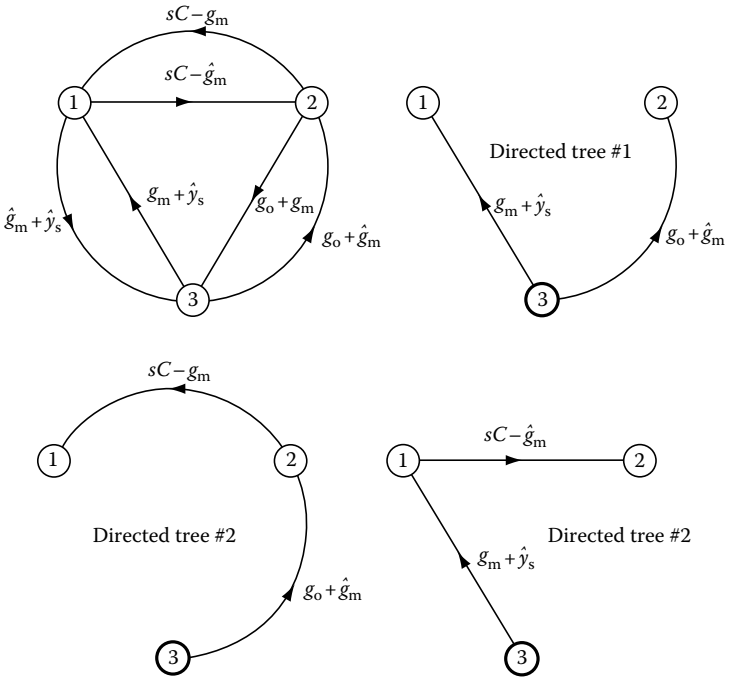

FIGURE 25.5 Graph and its directed trees of Example 25.1.

Applying Equation 25.11 and rearranging the terms results in

$$\begin{aligned}\hat{\Delta} &= (g_m+\hat{y}_S)(g_o+\hat{g}_m)+(sC_C-g_m)(g_o+\hat{g}_m)+(g_m+\hat{y}_S)(sC_C-\hat{g}_m)\\ &= \underbrace{sC_C(g_m+g_o)}_{\Delta}+\hat{y}_S\underbrace{(sC_C-g_o)}_{\Delta_{11}}+\hat{g}_m\underbrace{(sC_C-g_m)}_{\Delta_{12}}\end{aligned} \tag{25.12}$$

Note the fact that Equation 25.12, which is the direct result of the algorithm, is not cancellation-free. Some terms cancel out to result in the determinant of the original circuit and its two cofactors of interest. The final transfer functions can be readily obtained by substituting the above results into Equations 25.7 through 25.9.

25.3.2 Signal Flowgraph Method

Two types of flowgraphs are used in symbolic analysis. The first is referred to as a Mason's SFG and the second as Coates graph. Mason's SFG is by far a more popular and well-known SFG which has been used extensively in symbolic analysis among other control applications. Both the Mason's SFG and the Coates graph are used as basis for hierarchical symbolic analysis. However, the Coates graph was introduced to symbolic analysis by [Sta86] solely for the purpose of performing hierarchical symbolic analysis. This section will cover the Mason's SFG only.

The symbolic methods developed here are based on the idea formalized by Mason [Mas56] in the 1950s. Formulation of the SFG and then the evaluation of the gain formula associated with it (Mason's formula) is the basis for symbolic analysis using this method. This method is used in the publicly available programs NASAP [Mcn68], [Okr70], and SNAP [Lin70]. The method has the same circuit size limitations as the tree enumeration method due to the exponential growth in the number of symbolic terms. However, the SFG method allows all four types of controlled sources to be analyzed which made it a more popular method for symbolic analysis. The method is not cancellation-free which contributes to

the circuit size limitation mentioned earlier. An improved SFG method that avoids term cancellations was described in [Mie78].

The analysis process of a circuit consists of two parts, the first is constructing the SFG for the given circuit and the second is to perform the analysis on the SFG. Some definitions are needed before proceeding to the details of these two parts.

Definition 25.6: *Signal flowgraph*: An SFG is a weighted directed graph representing a system of simultaneous linear equations. Each node (x_i) in the SFG represents a circuit variable (node voltage, branch voltage, branch current, capacitor charge, or inductor flux) and each branch weight (w_{ij}) represents a coefficient relating x_i to x_j.

Every node in the SFG can be looked at as a summer. For a node x_k with m incoming branches

$$x_k = \sum_i w_{ik} x_i \tag{25.13}$$

where i spans the indices of all incoming branches from x_i to x_k.

Definition 25.7: *Path weight*: The weight of a path from x_i to x_j (P_{ij}) is the product of all the branch weights in the path.

Definition 25.8: *Loop weight*: The weight of a loop is the product of all the branch weights in that loop. This also holds for a loop with only one branch in it (self-loop).

Definition 25.9: *nth order loop*: An nth order loop is a set of n loops that have no common nodes between any two of them. The weight of an nth order loop is the product of the weights of all n loops.

Any transfer function x_j/x_i, where x_i is a source node, can be found by the application of Mason's formula:

$$\frac{x_j}{x_i} = \frac{1}{\Delta} \sum_k P_k \Delta_k \tag{25.14}$$

where

$$\begin{aligned} \Delta = 1 &- \sum_{\text{all}} \text{directed loop weights} \\ &+ \sum_{\text{all}} \text{2nd order loop weights} \\ &- \sum_{\text{all}} \text{3rd order loop weights} \\ &+ \cdots \end{aligned} \tag{25.15}$$

$$\begin{aligned} P_k &= \text{weight of the } k\text{th path from the source node } x_i \text{ to } x_j \\ \Delta_k &= \Delta \text{ with all loop contributions that are touching } P_k \text{ eliminated} \end{aligned} \tag{25.16}$$

The use of the above equations can be illustrated via Example 25.2.

Example 25.2

Consider the circuit in Figure 25.6.

The formulation of the SFG for this circuit takes on the following steps:

1. Find a tree and a cotree of the circuit such that all current sources are in the cotree and all voltage sources are in the tree.
2. Use Kirchhoff's current law (KCL), branch admittances, and tree branch voltages to find an expression for every cotree link current. In the case of a controlled source, simply use the branch relationship. For the previous example, this yields:

$$I_C = sC_C(V_1 - V_2) = sC_C V_1 - sC_C V_2$$
$$I = g_m V_1$$

3. Use Kirchhoff's voltage law (KVL), branch impedances, and cotree link currents to find an expression for every tree branch voltage. In the case of a controlled source, simply use the branch relationship. For the previous example, this yields:

$$V_{g_o} = V_2 = \frac{1}{g_o}(-I + I_C)$$

4. Create the SFG by drawing a node for each current source, voltage source, tree branch voltage, and cotree link current.
5. Use Equation 25.13 to draw the branches between the nodes that realize the linear equations developed in the previous steps.

Figure 25.7 shows the result of executing the above five steps on the example circuit. This formulation is referred to as the compact SFG. Any other variables that are linear combinations of the variables in the SFG (e.g., node voltages) can be added to the SFG by simply adding the extra node and implementing the linear relationship using SFG branches. A more detailed discussion of SFGs can be found in [Chu75] and [Lin91].

Now applying Equations 25.15 and 25.16 yields:

$$P_1 = -\frac{g_m}{g_o}, \quad P_2 = \frac{sC_C}{g_o}, \quad L_1 = -\frac{sC_C}{g_o}, \quad \Delta = 1 - \left(-\frac{sC_C}{g_o}\right), \quad \Delta_1 = 1, \quad \Delta_2 = 1$$

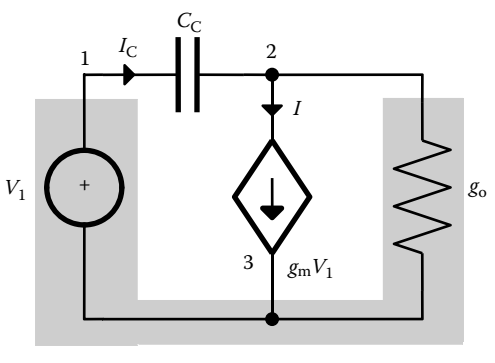

FIGURE 25.6 Circuit for Example 25.2 with its tree highlighted.

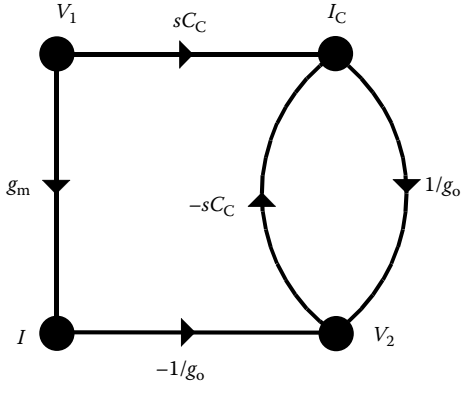

FIGURE 25.7 SFG for Example 25.2.

Equation 25.14 then produces the final transfer function

$$\frac{V_2}{V_1} = \frac{1}{1 + \frac{sC_C}{g_o}} \left(-\frac{g_m}{g_o} + \frac{sC_C}{g_o} \right) = \frac{sC_C - g_m}{sC_C + g_o}$$

25.3.3 Parameter Extraction Method

This method is best suited when few parameters in a circuit are symbolic while the rest of the parameters are in numeric form (s being one of the symbolic variables). The method was introduced in 1973 [Ald73]. Other variations on the method were proposed later in [Sin77], [San80], and [Pie93]. The advantage of the method is that it is directly related to the basic determinant properties of widely used equation formulation methods like the modified nodal method [Ho75] and the tableau method [Hac71]. As the name of the method implies, it provides a mechanism for extracting the symbolic parameters out of the matrix formulation breaking the matrix solution problem into a numeric part and a symbolic part. The numeric part can then be solved using any number of standard techniques and recombined with the extracted symbolic part. The method has the advantage of being able to handle larger circuits than the previously discussed fully symbolic methods if only a few parameters are represented symbolically. If the number of symbolic parameters in a circuit is high, the method will exhibit the same exponential growth in the number of symbolic terms generated and will have the same circuit size limitations as the other algorithms previously discussed.

The method does not limit the type of matrix formulation used to analyze the circuit. However, the extraction rules depend on the pattern of the symbolic parameters in the matrix. [Ald70] use the indefinite admittance matrix (IAM) as the basis of the analysis and the rules depend on the appearance of a symbolic parameter in four locations in the matrix: (i, i), (i, j), (j, i), and (j, j). Singhal and Vlach [Sin77] use the tableau equations and can handle a symbolic parameter that only appears once in the matrix. Sannuti and Puri [San80] force the symbolic parameters to appear only on the diagonal using a two-graph method [Chu75] to write the tableau equations. The parameter extraction method was further simplified in [Pie93] where the formula is given to calculate a coefficient (generally a polynomial in s) at every symbol combination. Some invalid symbol combinations (i.e., the ones that do not appear in the final formula) can be eliminated before calculations by topological considerations. To illustrate both approaches to parameter extraction, this section will present the IAM formulation and the most recent two-graph method. Details of other formulations can be found in [Lin91], [Sin77], [San80], and [Mie78].

25.3.3.1 Indefinite Admittance Matrix Approach

One of the basic properties of the IAM is the symmetric nature of the entries sometimes referred to as *quadrantal* entries [Chu75], [Lin91]. A symbolic variable α will always appear in four places in the IAM, $+\alpha$ in entries (i, k) and (j, m), and $-\alpha$ in entries (i, m) and (j, k) as shown in the following equation:

$$\begin{array}{c} \\ i \\ \\ j \\ \\ \end{array} \begin{array}{c} \begin{array}{ccc} k & & m \end{array} \\ \begin{bmatrix} \vdots & & \vdots \\ \alpha & \cdots & -\alpha \\ \vdots & & \vdots \\ -\alpha & \cdots & \alpha \\ \vdots & & \vdots \end{bmatrix} \end{array}$$

where $i \neq j$ and $k \neq m$. For the case of an admittance y between nodes i and j, we have $k = i$ and $j = m$. The basic process of extracting the parameter (the symbol) α can be performed by applying the following equation [Chu75], [Ald73]:

$$\text{Cofactor of } \mathbf{Y}_{\text{ind}} = \text{cofactor of } \mathbf{Y}_{\text{ind},\alpha=0} + (-1)^{j+m}\alpha \text{ (cofactor of } \mathbf{Y}_{\alpha}) \tag{25.17}$$

where $\mathbf{Y}_\alpha$ is a matrix that does not contain α and is obtained by

1. Adding row j to row i
2. Adding column m to column k
3. Deleting row j and column m

For the case where several symbols exist, the above extraction process can be repeated and would result in

$$\text{cof}(\mathbf{Y}_{\text{ind}}) = \sum_j P_j \,\text{cof}(\mathbf{Y}_j)$$

where

P_j is some product of symbolic parameters including the sign
$\mathbf{Y}_j$ is a matrix with the frequency variable s, possibly, being the only symbolic variable

The cofactor of $\mathbf{Y}_j$ may be evaluated using any of the usual evaluation methods [Chu75], [Vla94]. Programs implementing this technique include NAPPE2 [Lin91] and SAPWIN [Lib95].

Example 25.3: [Chu75]

Consider the resistive circuit in Figure 25.8. The goal is to find the input impedance Z_{14} using the parameter extraction method where g_m is the only symbolic variable in the circuit. In order to use Equations 25.7 and 25.10 an admittance $\hat{y}_S$ is added across the input terminals of the circuit to create the augmented circuit.

The IAM is then written as (conductances in siemens [S])

$$\hat{\mathbf{Y}}_{\text{ind}} = \begin{bmatrix} 6+\hat{y}_S & -5 & -1 & -\hat{y}_S \\ g_m - 5 & 15.1 & -g_m - 10 & -0.1 \\ -g_m - 1 & -10 & g_m + 13 & -2 \\ -\hat{y}_S & -0.1 & -2 & \hat{y}_S + 2.1 \end{bmatrix}$$

Applying Equation 25.17 to extract $\hat{y}_S$ results in

$$\text{cof}(\hat{\mathbf{Y}}_{\text{ind}}) = \text{cof}\begin{bmatrix} 6 & -5 & -1 & 0 \\ g_m - 5 & 15.1 & -g_m - 10 & -0.1 \\ -g_m - 1 & -10 & g_m + 13 & -2 \\ 0 & -0.1 & -2 & 2.1 \end{bmatrix} + \hat{y}_S \text{cof}\begin{bmatrix} 8.1 & -5.1 & -3 \\ g_m - 5.1 & 15.1 & -g_m - 10 \\ -g_m - 3 & -10 & g_m + 13 \end{bmatrix}$$

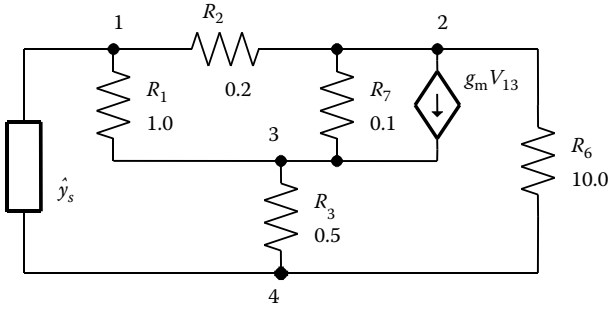

FIGURE 25.8 Circuit for the parameter extraction method (resistances in Ω).

Applying Equation 25.17 again to extract g_m yields

$$\text{cof}(\hat{\mathbf{Y}}_{\text{ind}}) = \text{cof}\begin{bmatrix} 6 & -5 & -1 & 0 \\ -5 & 15.1 & -10 & -0.1 \\ -1 & -10 & +13 & -2 \\ 0 & -0.1 & -2 & 2.1 \end{bmatrix} + g_m\ \text{cof}\begin{bmatrix} 5 & -5 & 0 \\ -3 & 5.1 & -2.1 \\ -2 & -0.1 & 2.1 \end{bmatrix}$$
$$+ \hat{y}_S\text{cof}\begin{bmatrix} 8.1 & -5.1 & -3 \\ -5.1 & 15.1 & -10 \\ -3 & -10 & 13 \end{bmatrix} + \hat{y}_S g_m\ \text{cof}\begin{bmatrix} 5.1 & -5.1 \\ -5.1 & 5.1 \end{bmatrix}$$

After evaluating the cofactors numerically, the equation reduces to

$$\text{cof}(\hat{\mathbf{Y}}_{\text{ind}}) = 137.7 + 10.5g_m + 96.3\hat{y}_S + 5.1\hat{y}_S g_m$$

From Equation 25.10 this results in

$$Z_{14} = \frac{\Delta_{11}}{\Delta} = \frac{96.3 + 5.1g_m}{137.7 + 10.5g_m}$$

25.3.3.2 Two Graph-Based Tableau Approach [Pie93]

This approach also employs the circuit augmentation by $\hat{y}_S$ and $\hat{g}_m V_o$, as in the tree enumeration method. It calls for a construction of two graphs: the voltage graph (G_V or V-graph) and the current graph (G_I or I-graph). For the purpose of parameter extraction (as well as generation of approximate symbolic expressions, Section 25.5), it is required that both graphs have the same number of nodes (n). This means that the method can be directly applied only to RLCg_m circuits. (All basic circuit components, including ideal op-amps, can be handled by this approach after some circuit transformations [Lin91], [Vla94]. For the sake of simplicity, however, only RLCg_m circuits will be considered in this presentation.) The two graphs are constructed based on the element stamps shown in Figure 25.9. Once the two graphs are constructed, a *common spanning tree* (i.e., a set of $n-1$ branches that form a spanning tree in both voltage and current graphs) is chosen. Choosing the common spanning tree (referred to just as ''tree'' in the remainder of this section) uniquely determines the cotree in each graph.

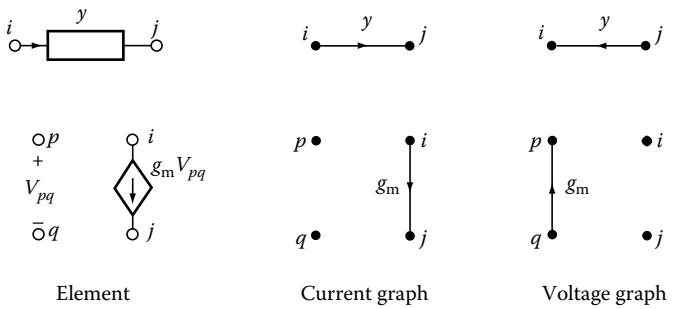

FIGURE 25.9 Element stamps for generating G_V and G_I.

The tableau equation for such a network can be written as

$$\mathbf{Hx} = \begin{bmatrix} \mathbf{1} & \mathbf{0} & -\mathbf{Z}_T & \mathbf{0} \\ \mathbf{B}_T & \mathbf{1} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{1} & \mathbf{Q}_C \\ \mathbf{0} & -\mathbf{Y}_C & \mathbf{0} & \mathbf{1} \end{bmatrix} \begin{bmatrix} \mathbf{V}_T \\ \mathbf{V}_C \\ \mathbf{I}_T \\ \mathbf{I}_C \end{bmatrix} = \mathbf{0} \tag{25.18}$$

The first and last rows of the system matrix **H** in Equation 25.18 consists of tree ($\bullet_T$) and cotree ($\bullet_C$) branch voltage–current relationships and the second and third rows consist of fundamental loop and fundamental cut-set equations for G_V and G_I, respectively.

Let the circuit have n nodes and b branches and contain k symbolic components ($Y_{S_1}, \ldots, Y_{S_k}$) in the cotree branches (links) and l symbolic components ($Z_{S_1}, \ldots, Z_{S_l}$) in the tree branches; we define $w = b - n - k + 1$, $t = n - l - 1$. Diagonal matrices $\mathbf{Y}_C$ and $\mathbf{Z}_T$ can be partitioned as follows:

$$\mathbf{Y}_C = \begin{bmatrix} \mathbf{Y}_{Cs} & \mathbf{0} \\ \mathbf{0} & \mathbf{Y}_{Cn} \end{bmatrix}, \quad \mathbf{Z}_T = \begin{bmatrix} \mathbf{Z}_{Ts} & \mathbf{0} \\ \mathbf{0} & \mathbf{Z}_{Tn} \end{bmatrix}$$

where subscript "s" denotes immitances of symbolic components and subscript "n" denotes immitances of components given numerically.

Matrices $\mathbf{B}_T$ (fundamental loop matrix in G_V) and $\mathbf{Q}_C$ (fundamental cut-set matrix in G_I) can also be partitioned as follows:

$$\mathbf{B}_T = \begin{bmatrix} \mathbf{B}_{11} & \mathbf{B}_{12} \\ \mathbf{B}_{21} & \mathbf{B}_{22} \end{bmatrix}, \quad \mathbf{Q}_C = \begin{bmatrix} \mathbf{Q}_{11} & \mathbf{Q}_{12} \\ \mathbf{Q}_{21} & \mathbf{Q}_{22} \end{bmatrix}$$

Rows of $\mathbf{B}_{11}$ and $\mathbf{B}_{12}$ correspond to symbolic cotree branches (in G_V) and their columns correspond to symbolic and numeric tree branches, respectively. Rows of $\mathbf{B}_{21}$ and $\mathbf{B}_{22}$ correspond to numeric cotree branches. Rows of $\mathbf{Q}_{11}$ and $\mathbf{Q}_{12}$ correspond to symbolic tree branches and their columns correspond to symbolic and numeric cotree branches, respectively. Rows of $\mathbf{Q}_{21}$ and $\mathbf{Q}_{22}$ correspond to numeric tree branches. The submatrices are therefore of the following order: $\mathbf{B}_{11}$: $k \times l$, $\mathbf{B}_{22}$: $w \times t$, $\mathbf{Q}_{11}$: $l \times k$, $\mathbf{Q}_{22}$: $t \times w$.

Let $S_x = \{1, 2, \ldots, x\}$. For a given matrix **F** of order $a \times b$, let $\mathbf{F}(I_u, J_v)$ be the submatrix of **F** consisting of the rows and columns corresponding to the integers in the sets I_u, J_v, respectively. The sets $I_u = \{i_1, i_2, \ldots, i_u\}$ and $J_v = \{j_1, j_2, \ldots, j_v\}$ are subsets of S_a and S_b, respectively. Let us also introduce the following notation:

$$\mathbf{1}_d^c = \text{diag}[\, e_1 \quad e_2 \quad \cdots \quad e_d \,]; \quad c < d$$

$$e_x = \begin{cases} 0 & \text{for } x \in \{1, 2, \ldots, c\} \\ 1 & \text{for } x \in \{c+1, c+2, \ldots, d\} \end{cases}$$

The determinant of the system matrix **H** in Equation 25.18, when some parameters take fixed numerical values, is

$$\begin{aligned} \det \mathbf{H} = a &+ \sum_{J_v} b(\alpha_v) Z_{S_{j1}} Z_{S_{j2}} \cdots Z_{S_{jv}} + \sum_{I_u} c(\beta_u) Y_{S_{i1}} Y_{S_{i2}} \cdots Y_{S_{iu}} \\ &+ \sum_{I_u} \sum_{J_v} d(\alpha_v \beta_u) Z_{S_{j1}} Z_{S_{j2}} \cdots Z_{S_{jv}} Y_{S_{i1}} Y_{S_{i2}} \cdots Y_{S_{iu}} \end{aligned} \tag{25.19}$$

where the summations are taken over all possible symbol combinations α_v (symbolic tree elements) and β_u (symbolic cotree elements), and the numerical coefficients are given by

$$
\begin{aligned}
\det H &= a + \sum_{J_v} b(\alpha_v) Z_{s_{j1}} Z_{s_{j2}} \cdots Z_{s_{jv}} + \sum_{I_u} c(\beta_u) Y_{s_{i1}} Y_{s_{i2}} \cdots Y_{s_{iu}} \\
&\quad + \sum_{I_u} \sum_{J_v} d(\alpha_v \beta_u) Z_{s_{j1}} Z_{s_{j2}} \cdots Z_{s_{jv}} Y_{s_{i1}} Y_{s_{i2}} \cdots Y_{s_{iu}} \\
a &= \det\left[\mathbf{1}_w + \mathbf{B}'_{22}\left(-\mathbf{Q}'_{22}\right)\right] = \det\left[\mathbf{1}_t + \left(-\mathbf{Q}'_{22}\right)\mathbf{B}'_{22}\right] \\
b(\alpha_v) &= \det\left(\mathbf{1}^v_{t+v} + \begin{bmatrix} -\mathbf{Q}_{12}(J_v, I_w) \\ -\mathbf{Q}'_{22} \end{bmatrix} \begin{bmatrix} \mathbf{B}'_{21}(I_w, J_v) & \mathbf{B}'_{22} \end{bmatrix}\right) \\
c(\beta_u) &= \det\left(\mathbf{1}^u_{w+u} + \begin{bmatrix} \mathbf{B}_{12}(I_u, J_t) \\ \mathbf{B}'_{22} \end{bmatrix} \begin{bmatrix} -\mathbf{Q}'_{21}(J_t, I_u) & -\mathbf{Q}'_{22} \end{bmatrix}\right) \\
d(\alpha_v \beta_u) &= \det\left(\mathbf{1}^v_{v+t+u} + \begin{bmatrix} -\mathbf{Q}_{11}(J_v, I_u) & -\mathbf{Q}_{12}(J_v, I_w) \\ -\mathbf{Q}'_{21}(J_t, I_u) & -\mathbf{Q}'_{22} \\ \mathbf{1}_u & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{B}_{11}(I_u, J_v) & \mathbf{B}_{12}(I_u, J_t) & -\mathbf{1}_u \\ \mathbf{B}'_{21}(I_w, J_v) & \mathbf{B}'_{22} & \mathbf{0} \end{bmatrix}\right)
\end{aligned}
\tag{25.20}
$$

In the above equations, $\mathbf{0}$ represents a zero matrix of appropriate order, and the submatrices $\mathbf{B}'_{ij}$ and $\mathbf{Q}'_{ij}$ are defined as

$$
\begin{aligned}
\mathbf{B}'_{21}(I_w, J_v) &= \mathbf{Y}_{Cn}\mathbf{B}_{21}(I_w, J_v), \quad \mathbf{B}'_{22} = \mathbf{Y}_{Cn}\mathbf{B}_{22} \\
\mathbf{Q}'_{21}(J_t, I_u) &= \mathbf{Z}_{Tn}\mathbf{Q}_{21}(J_t, I_u), \quad \mathbf{Q}'_{22} = \mathbf{Z}_{Tn}\mathbf{Q}_{22}
\end{aligned}
\tag{25.21}
$$

where the submatrix $\mathbf{B}_{21}(I_w, J_v)$ is obtained from the submatrix $\mathbf{B}_{21}$ by including all of its rows and only columns corresponding to a particular combination (α_v) of symbolic tree elements; submatrix $\mathbf{Q}_{21}(J_t, I_u)$ is obtained from the submatrix $\mathbf{Q}_{21}$ by including all of its rows and only columns corresponding to a particular combination (β_u) of symbolic cotree elements.

Application of Equations 25.19 and 25.20 for a circuit with m symbolic parameters requires, theoretically, the calculation of 2^m determinants. Not all of these determinants may need to be calculated due to the following property of the determinants in Equation 25.20. If a set of symbolic tree elements (α_v) forms a cut-set in G_I (*symbolic tree cut-set*), then the corresponding coefficients $b(\alpha_v)$ and $d(\alpha_v\beta_u)$ in Equation 25.19 equal to zero. Likewise, if the set of symbolic cotree elements (β_u) forms a loop in G_V (*symbolic cotree loop*), the corresponding coefficients $c(\beta_u)$ and $d(\alpha_v\beta_u)$ in Equation 25.19 equal to zero.

Once the determinant det($\mathbf{H}$) is obtained from Equation 25.19, the sorting scheme, identical to that expressed in Equation 25.10, is applied and the required network functions can be calculated using Equations 25.7 through 25.9.

The main feature of this approach is the fact that each coefficient at a valid symbol combination is obtained directly by calculating a single, easily formulated determinant (a polynomial in s, in general case). The method was implemented in a computer program UTSSNAP [Pie98]. Example 25.4 illustrates this technique of parameter extraction.

Example 25.4

Consider again the circuit in Figure 25.8. Assume this time that two components, R_1 and g_m, are given symbolically. The goal is again to find the input impedance Z_{41} in a semisymbolic form using the parameter extraction method based on the two-graph tableau formulation.

The voltage and current graphs of the circuit are shown in Figure 25.10. The common spanning tree chosen is $T = \{R_1, R_2, R_3\}$ with one symbolic element. For this circuit we have $n = 4$, $b = 7$, $k = 2$, $l = 1$, $w = 2$, and $t = 2$.

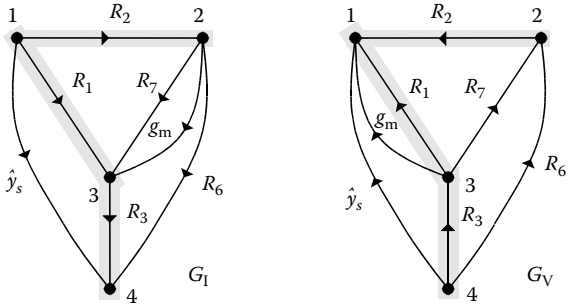

FIGURE 25.10 The current and voltage graphs for the circuit in Figure 25.8 with the common spanning tree highlighted.

The matrices, $\mathbf{Y}_C$, $\mathbf{Z}_T$, $\mathbf{Q}_C$, and $\mathbf{B}_T$, can now be determined as

$$\mathbf{Y}_C = \left[\begin{array}{cc|c} \hat{y}_S & & \\ & g_m & \\ \hline & & \begin{matrix} 0.1 & \\ & 10 \end{matrix} \end{array}\right] \quad \mathbf{Z}_T = \left[\begin{array}{c|cc} R_1 & & \\ \hline & 0.2 & \\ & & 0.5 \end{array}\right]$$

$$\mathbf{Q}_C = \left[\begin{array}{cc|cc} 1 & 1 & 1 & 1 \\ 0 & -1 & -1 & -1 \\ \hline 1 & 0 & 1 & 0 \end{array}\right] \quad \mathbf{B}_T = \left[\begin{array}{c|cc} -1 & 0 & -1 \\ -1 & 0 & 0 \\ \hline -1 & 1 & -1 \\ -1 & 1 & 0 \end{array}\right]$$

Using Equation 25.21 we can calculate matrices $\mathbf{B}'_{22}$ and $\mathbf{Q}'_{22}$:

$$\mathbf{B}'_{22} = \begin{bmatrix} 0.1 & 0 \\ 0 & 10 \end{bmatrix}\begin{bmatrix} 1 & -1 \\ 1 & 0 \end{bmatrix} = \begin{bmatrix} 0.1 & -0.1 \\ 10 & 0 \end{bmatrix}, \quad \mathbf{Q}'_{22} = \begin{bmatrix} 0.2 & 0 \\ 0 & 0.5 \end{bmatrix}\begin{bmatrix} -1 & -1 \\ 1 & 0 \end{bmatrix} = \begin{bmatrix} -0.2 & -0.2 \\ 0.5 & 0 \end{bmatrix}$$

Now, applying Equation 25.20, the coefficient a in Equation 25.19 is calculated as

$$a = \det\left(\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} + \begin{bmatrix} 0.1 & -0.1 \\ 10 & 0 \end{bmatrix}\begin{bmatrix} 0.2 & 0.2 \\ -0.5 & 0 \end{bmatrix}\right) = \det\begin{bmatrix} 1.07 & 0.02 \\ 2 & 3 \end{bmatrix} = 3.17$$

Since there is only one symbolic tree element, namely R_1, we have: $\boldsymbol{\alpha}_v = \{R_1\}$ and the associated sets: $J_v = \{1\}$, $I_w = \{1, 2\}$. Using Equation 25.21, we calculate

$$\mathbf{B}'_{21}(I_w, J_v) = \mathbf{Y}_{Cn}\mathbf{B}_{21}(I_w, J_v) = \begin{bmatrix} 0.1 & 0 \\ 0 & 10 \end{bmatrix}\begin{bmatrix} -1 \\ -1 \end{bmatrix} = \begin{bmatrix} -0.1 \\ -10 \end{bmatrix}$$

The coefficient $b(R_1)$ can be now obtained from

$$b(R_1) = \det\left(\begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} + \left[\begin{array}{cc} -1 & -1 \\ \hline 0.2 & 0.2 \\ -0.5 & 0 \end{array}\right]\begin{bmatrix} -0.1 & 0.1 & -0.1 \\ -10 & 10 & 0 \end{bmatrix}\right)$$

$$= \det\begin{bmatrix} 10.1 & -10.1 & 0.1 \\ -2.02 & 3.02 & -0.02 \\ 0.05 & -0.05 & 1.05 \end{bmatrix} = 10.6$$

Other numerical coefficients in Equation 25.19 are calculated in similar way:

$c(\hat{y}_S) = 1.51$, $c(g_m) = 0$, $c(\hat{y}_S g_m) = 0$, $d(R_1\hat{y}_S) = 8.12$, $d(R_1 g_m) = 1.05$, $d(R_1\hat{y}_S g_m) = 0.51$

Adding all terms, sorting according to Equation 25.10, and applying Equation 25.7 finally results in

$$Z_{41} = \frac{1.51 + 8.12R_1 + 0.51R_1 g_m}{3.17 + 10.6R_1 + 1.05R_1 g_m}$$

Matrices in Equation 25.20 may contain terms dependent on the complex frequency s. Determinants of such matrices are polynomials in s as long as all matrix elements are of the form: $a = \alpha + s\beta$. An interpolation method may be used to calculate the coefficients of those polynomials. One such method is briefly described in Section 25.3.4.

25.3.4 Interpolation Method

This method is best suited when s is the only symbolic variable. In such case, a transfer function has the rational form

$$H(s) = \frac{N(s)}{D(s)} = \frac{\sum_{i=0}^{m} a_i s^i}{\sum_{i=0}^{n} b_i s^i}$$

where $N(s)$ and $D(s)$ are polynomials in s with real coefficients and $m \leq n$.

Coefficients of an nth order polynomial

$$P(s) = \sum_{k=0}^{n} p_k s^k$$

can be obtained by calculating the value of $P(s)$ at $n+1$ distinct points s_i and then solving the following set of equations:

$$\begin{bmatrix} 1 & s_0 & s_0^2 & \cdots & s_0^n \\ 1 & s_1 & s_1^2 & \cdots & s_1^n \\ & \vdots & & & \\ 1 & s_n & s_n^2 & \cdots & s_n^n \end{bmatrix} \begin{bmatrix} p_0 \\ p_1 \\ \vdots \\ p_n \end{bmatrix} = \begin{bmatrix} P(s_0) \\ P(s_1) \\ \vdots \\ P(s_n) \end{bmatrix} \tag{25.22}$$

Since the matrix in Equation 25.22 is nonsingular, the unique solution exists. It is well known [Sin74], [Vla94] that for numerical accuracy and stability the best choice of the interpolation points is a set of $q \geq n+1$ points s_i uniformly spaced on the unit circle in the complex plane. Once all the values of $P(s_i)$ are known, the polynomial coefficients can be calculated through the discrete Fourier transform (DFT).

To apply this technique to the problem of finding a transfer function, let us assume that a circuit behavior is described by a linear equation

$$\mathbf{Ax} = \mathbf{b} \tag{25.23}$$

in which the coefficient matrix has entries of the form $a = \alpha + s\beta$ (both the modified nodal and the tableau methods have this property). Then, each transfer function of such circuit has the same denominator $D(s) = |\mathbf{A}|$. If the circuit Equation 25.23 is solved by LU factorization at $s = s_i$, both the transfer function $H(s_i)$ and its denominator $D(s_i)$ are obtained simultaneously. The value of the numerator is then

calculated simply as $N(s_i) = H(s_i)D(s_i)$. Repeating this process for all points s_i ($i = 0, 1, \ldots, q$) and then applying the DFT to both sets of values, $D(s_i)$ and $N(s_i)$, give the required coefficients of the numerator and denominator polynomials.

If the number of interpolation points is an integer power of 2 ($q = 2^k$), the method has the advantage that the fast Fourier transform (FFT) can be used to find the coefficients. This greatly enhances the execution time [Lin91]. The method has been extended to handle several symbolic variables in addition to s [Sin74]. The program implementation [Vla94] allows a maximum of five symbolic parameters in a circuit.

With the emergence of approximate symbolic analysis, the polynomial interpolation method has attracted new interest. (It is desirable to know the accurate numerical value of polynomial coefficients before one attempts an approximation.) Recently a new adaptive scaling mechanism was proposed [Fer98] that significantly increases the circuit size that can be handled accurately and efficiently.

There are other classifications of symbolic methods that have been reported [Gie91]. These methods can be considered as variations on the above basic four methods. The reported methods include elimination algorithms, recursive determinant-expansion algorithms, nonrecursive nested-minors method. All three are based on the use of Cramer's rule to find the determinant and the cofactors of a matrix. Another reported class of algorithms uses MNA [Ho75] as the basis of the analysis, sometime referred to as a direct network approach [Has89], [Lib93]. This class of methods is covered in Section 25.4.

The first generation of computer programs available for symbolic circuit simulation based on these methods includes NASAP [Mcn68] and SNAP [Lin70]. Research in the late 1980s and early 1990s has produced newer symbolic analysis programs. These programs include ISSAC [Gie89], SCAPP [Has89], ASAP [Fer91], EASY [Som91], SYNAP [Sed92], SAPEC [Man91], SAPWIN [Lib95], SCYMBAL [Kon88], GASCAP [Hue89], SSPICE [Wie89], and STAINS [Pie01].

25.4 Hierarchical Methods (Sequence of Expressions)

All of the methods presented in Section 25.3 have circuit size limitations. The main problem is the exponential growth of the number of symbolic terms involved in the expression for the transfer function in Equation 25.3 as the circuit gets larger. The solution to analyze large-scale circuits lies in a total departure from the traditional procedure of trying to state the transfer function as a single expression and using a SoE procedure instead. The idea is to produce a succession of small expressions with a backward hierarchical dependency on each other. The growth of the number of expressions in this case will be, at worse case, quadratic [Has89].

The advantage of having the transfer function stated in a single expression lies in the ability to gain insight to the relationship between the transfer function and the network elements by inspection [Lin73]. For large expressions, though, this is not possible and the single expression loses that advantage. ISSAC [Wam92], ASAP [Fer92], SYNAP [Sed92], and Analog Insydes [Hen00] attempt to handle larger circuits by maintaining the single expression method and using circuit-dependent approximation techniques. The trade-off is accuracy for insight. Therefore, the SoE approach is more suitable for accurately handling large-scale circuits. Example 25.5 illustrates the features of the SoE.

Example 25.5

Consider the resistance ladder network in Figure 25.11.

The goal is to obtain the input impedance function of the network, $Z_{in} = V_{in}/I_{in}$. The single expression transfer function Z_4 is

$$Z_4 = \frac{R_1R_3 + R_1R_4 + R_2R_3 + R_2R_4 + R_3R_4}{R_1 + R_2 + R_3}$$

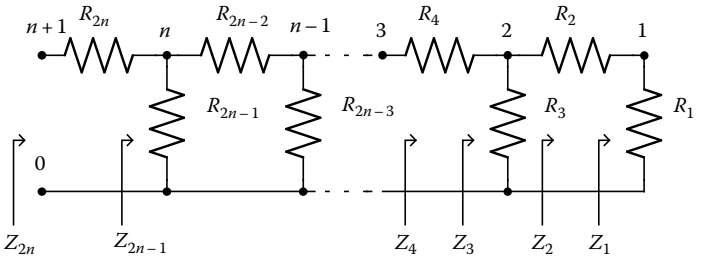

FIGURE 25.11 Resistance ladder network.

The number of terms in the numerator and denominator is given by the Fibonacci numbers satisfying the following difference equation:

$$y_{k+2} = y_{k+1} + y_k,\ k = 0, 1, 2, \ldots; \quad y_0 = 0; \quad y_1 = 1$$

An explicit solution to the above equation is

$$y_n = \frac{1}{\sqrt{5}}\left(\frac{1+\sqrt{5}}{2}\right)^n - \left(\frac{1-\sqrt{5}}{2}\right)^n \approx 0.168 \cdot 1.618^n \text{ for large } n$$

The solution shows that the number of terms in Z_n increases exponentially with n. Any single expression transfer function has this inherent limitation.

Now using the SoE procedure the input impedance can be obtained from the following expressions:

$$Z_1 = R_1; \quad Z_2 = Z_1 + R_2; \quad Z_3 = \frac{Z_2 R_3}{Z_2 + R_3}; \quad Z_4 = Z_3 + R_4$$

It is obvious for each additional resistance added, the SoE will grow by one expression, either of the form $Z_{i-1} + R_i$ or $Z_{i-1}R_i/(Z_{i-1} + R_i)$. The number of terms in the SoE can be calculated from the formula:

$$y_n = \begin{cases} 2.5n - 2 & \text{for } n \text{ even} \\ 2.5n - 1.5 & \text{for } n \text{ odd} \end{cases}$$

which exhibits a linear growth with respect to n. Therefore, to find the input impedance of a 100 resistor ladder network the single expression methods would produce 7.9×10^{20} terms which requires unrealistically huge computer storage capabilities. On the other hand, the SoE method would produce only 248 terms, which is even within the scope of some desk calculators.

Another advantage of the SoE is the number of arithmetic operations needed to evaluate the transfer function. To evaluate Z_9, for example, the single expression methods would require 302 multiplications and 87 additions. The SoE method would only require eight multiplications and eight additions, a large reduction in computer evaluation time. All this makes the concept of symbolic circuit simulation of large-scale networks very possible.

Two topological analysis methods for symbolic simulation of large-scale circuits have been proposed in [Sta86] and [Has93]. The first method utilizes the SoE idea to obtain the transfer functions. The method operates on the Coates graph [Coa59] representing the circuit. A partitioning is proposed onto the flowgraph and not the physical network. The second method also utilizes the SoE and a Mason's signal flowgraph [Mas56] representation of the circuit. The method makes use of partitioning on the physical level rather than on the graph level. Therefore, for a hierarchical circuit, the method can operate on the subcircuits in a hierarchical fashion in order to produce a final solution. The fundamentals of both signal flowgraph methods were described in the Section 25.3.2.

Another hierarchical approach is one that is based on MNA [Ho75]. This method [Has89] exhibits a linear growth (for practical circuits) in the number of terms in the symbolic solutions. The analysis methodology introduces the concept of the reduced modified nodal analysis (RMNA) matrix. This allows the characterization of symbolic circuits in terms of only a small subset of the network variables (external variables) rather than the complete set of variables. The method was made even more effective by introducing a locally optimal pivot selection scheme during the reduction process [Pie01]. For a circuit containing several identical* subcircuits, the analysis algorithm is most efficient when network partitioning is used. For other circuits, the best results (the most compact SoE) are obtained when the entire circuit is analyzed without partitioning.

The SoE generation process starts with the formulation of a symbolic modified NAM (MNAM) for a circuit [Lin91], [Vla94]. Then all internal variables are suppressed one by one using Gaussian elimination with locally optimal pivot selection. Each elimination step produces a series of expressions and modifies some entries in the remaining portion of the MNAM. When all internal variables are suppressed, the resulting matrix is known as the reduced MNAM (RMNAM). Usually it will be a 2×2 matrix of a two-port.† Most transfer functions of interest to circuit designer can be represented by formulas involving the elements of RMNAM and the terminating admittances. A detailed discussion of the method can be found in [Pie01]. Based on this approach a personal computer program STAINS has been developed [Hue02].

For a circuit with several identical subcircuits the reduction process is first applied to all internal variables‡ of the subcircuit, resulting in an intermediate RMNAM describing the subcircuit. Those RMNAMs are then recombined with the MNAM of the remaining circuit and the reduction process is repeated on the resulting matrix. To further illustrate the SoE approach, we present Example 25.6.

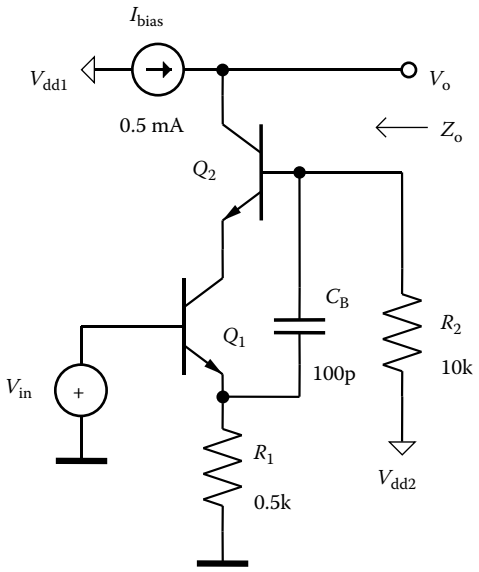

FIGURE 25.12 Bipolar cascode stage.

Example 25.6

Consider a bipolar cascode stage with bootstrap capacitor C_B, shown in Figure 25.12 [Gie91]. With the BJTs replaced by their low-frequency hybrid-π models (with r_π, g_m, and r_o only), the full symbolic analysis yields the output admittance formula shown in Figure 25.13. The formula requires 48 additions and 117 multiplication/division operations. Program STAINS can generate several different sequences of expressions. One of them is shown in Figure 25.14. It requires only 24 additions and 17 multiplications/divisions.§

Although SoE techniques can produce very compact exact expressions for network functions, they are of limited use if one wishes to obtain symbolic expressions for coefficients at individual powers of s in Equation 25.4. Sections 25.5 and 25.6 describe two possible approaches to this problem.

* The subcircuits have to be truly identical, that is, they must have the same topology and component symbols. A typical example would be a large active filter containing a number of identical, nonideal op-amps.

† In sensitivity calculations using SoE [Bal04] the final RMNAM may need to be larger than 2×2.

‡ The internal variables are the variables not directly associated with the subcircuit's connections to the rest of the circuit.

§ Counting of visible arithmetic operations gives only a rough estimate of the SoE complexity, especially when complex numbers are involved. Issues related to SoE computational efficiency are discussed in [Rod00].

FIGURE 25.14 The SoE generated by STAINS for the cascode in Figure 25.12.

The SoE approach offers a solution for the exact symbolic analysis of large circuits. For some applications, it may be more important to obtain a simpler inexact expression, but the one that would clearly identify the dominant circuit components and their role in determining circuit behavior. Approximate symbolic analysis provides the answer. Of course, manual approximation (simplification) techniques have been known and practiced by engineers for decades. To obtain compact and meaningful expressions by computer, symbolic analysis software must be capable of performing those approximations that are applied in manual circuit analysis in an automatic fashion. In addition to that, computer algorithms should be able to employ simplification strategies not available (or impractical) in manual approximation.

In the last decade, a number of symbolic approximation algorithms have been developed and implemented in symbolic circuit analysis programs. Depending on the stage in the circuit analysis process in which they are applied, these algorithms can be categorized as *Simplification before Generation* (SBG), *Simplification during Generation* (SDG), and *Simplification after Generation* (SAG). Figure 25.15, adapted from [Hen00], presents an overview of the three types of approximation algorithms.

SBG involves removing circuit components and/or individual entries in the circuit matrix (the *sifting* approach [Hsu93]) or eliminating some graph branches (the *sensitivity-based two-graph simplification* [Yu96]) that do not contribute significantly to the final formula.

SDG is based on generation of symbolic terms in a decreasing order of magnitude. The generation process is stopped when the error reaches the specified level. The most successful approach to date is based on the two graph formulation [Wam98]. It employs an algorithm to generate the common spanning trees in strictly decreasing order of magnitude [Kat81]. In the case of frequency dependent circuit, this procedure is applied separately to different powers of s. Mathematical formalism of *matroids* is well suited to describe problems of SDG [Yu96]. Matroid-based algorithms are inherently slow. More efficient methods for generating s-expanded network functions, based on determinant decision diagrams (DDDs), have been recently developed [Shi00], [Shi01], [Ver02]. They will be briefly described in Section 25.6.

When applied alone, SAG is a very ineffective technique, as it requires generation and storage of a large number of unnecessary terms. When combined with SBG and SDG methods, however, it can

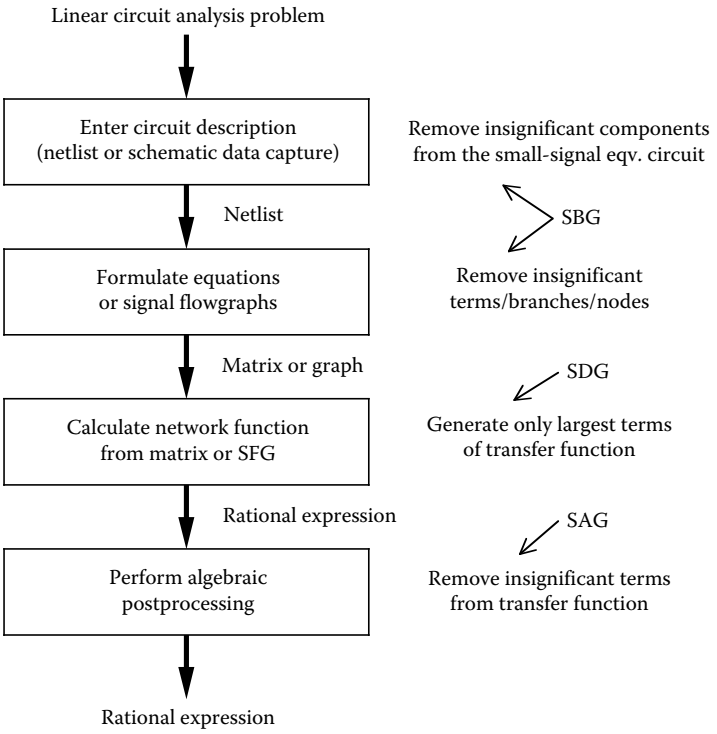

FIGURE 25.15 Classification of symbolic approximation techniques (From Henning, E., Symbolic Approximation and Modeling Techniques for Analysis and Design of Analog Circuits, Doctoral dissertation, University of Kaiserslautern, Shaker Verlag, Aachen, Germany, 2000. With permission.)

produce most compact expressions by pruning redundant terms not detected earlier in the simplification process.

All simplification techniques require careful monitoring of the approximation amplitude and phase errors (ε_A and ε_p). The error criteria can be expressed as follows:

$$\left|\frac{|H(s,\mathbf{x})| - |H^{\star}(s,\mathbf{x})|}{|H(s,\mathbf{x})|}\right| \leq \varepsilon_A$$
$$|\angle H(s,\mathbf{x}) - \angle H^{\star}(s,\mathbf{x})| \leq \varepsilon_p$$

for $s = j\omega$, $\omega \in (\omega_1, \omega_2)$, $\mathbf{x} \in (\mathbf{x}_1, \mathbf{x}_2)$, where $H(s,\mathbf{x})$ is the exact transfer function, defined by Equation 25.3, and $H^{\star}(s,\mathbf{x})$ is the approximating function. The majority of the approximation methods developed to date use the simplified criteria, where the errors are measured only for a given set of circuit parameters $\mathbf{x}^0$ (the nominal design point) [Kon99].

Example 25.7, although quite simple, illustrates very well the advantages of approximate symbolic analysis.

Example 25.7: [Gie91]

Consider again the bipolar cascode stage, shown in Figure 25.12 and its fully symbolic expression for the output impedance, shown in Figure 25.13. Even for such a simple circuit, the full symbolic result is very hard to interpret and therefore not able to provide insight into the circuit behavior. Sequential form of the output impedance formula, presented in Figure 25.14, is more compact than the full expression but also cannot be utilized for interpretation.

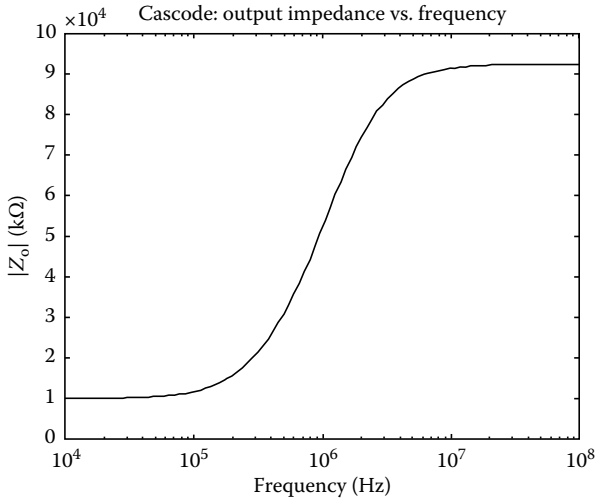

FIGURE 25.16 Plot of $|Z_o|$ of the cascode, obtained numerically from the exact formula.

A graph of $|Z_o|$ for a nominal set of component values ($r_\pi = 5$ kΩ, $g_m = 20$ mS, $r_o = 100$ kΩ for both BJTs), obtained numerically from the SoE in Figure 25.14, is plotted in Figure 25.16.

By examining the graph, one can appreciate the general behavior of the function but it is difficult to predict the influence of various circuit components on the output impedance.

Applying symbolic approximation techniques, we can obtain less accurate but still more revealing formulas. If a 10% maximum amplitude error is accepted, the simplified function takes the following form:

$$Z_{o(10\%)} = \frac{g_{m1}(g_{m2} + G_1)(G_2 + sC_B)}{g_{o1}g_{\pi 1}[G_2(g_{m2} + G_1) + sC_B(G_1 + g_{\pi 2})]}$$

If we allow a 25% magnitude error,* the output impedance formula can be simplified further:

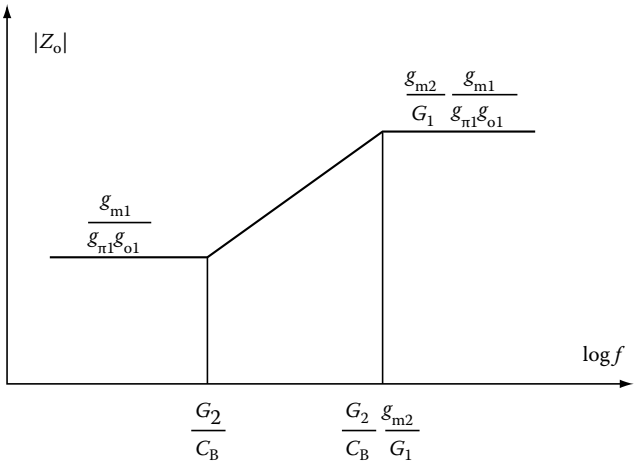
$$Z_{o(25\%)} = \frac{g_{m1}g_{m2}(G_2 + sC_B)}{g_{o1}g_{\pi 1}(G_2 g_{m2} + sC_B G_1)} \tag{25.24}$$

The impedance levels as well as pole and zero estimates can be easily obtained from Equation 25.24:

$$\begin{aligned} Z_o(\text{low } f) &\cong \frac{g_{m1}}{g_{\pi 1}g_{o1}} = \frac{\beta_1}{g_{o1}} \\ Z_o(\text{high } f) &\cong \frac{g_{m1}g_{m2}}{g_{\pi 1}g_{o1}G_1} = \frac{g_{m2}}{G_1} Z_o(\text{low } f) \\ z &\cong -\frac{G_2}{C_B} \\ p &\cong -\frac{g_{m2}G_2}{G_1 C_B} \end{aligned} \tag{25.25}$$

An asymptotic graph of $|Z_o|$, based on Equation 25.25, is plotted in Figure 25.17.

* It is important to note that the approximate expressions were developed taking into account variations of BJT parameters; the fact that both simplified formulas give identical results at the nominal design point is purely coincidental.



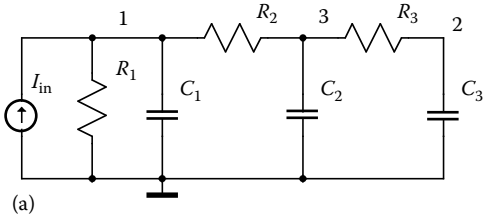


FIGURE 25.17 Asymptotic plot of $|Z_o|$ of the cascode based on Equation 25.25.

25.6 Methods Based on Determinant Decision Diagrams [Shi00], [Shi01], [Ver02]

To fully exploit the power of symbolic circuit analysis in helping designers gain insight into the circuit behavior, network functions in the *s*-expanded symbolic form are often required, as illustrated in Section 25.5. However, the approximate expressions may not be adequate for complete circuit characterization such as symbolic pole-zero derivation and sensitivity computation [Gie94]. Although there exists a mathematically elegant method for generating all terms at a given power of *s* in Equation 25.4 [Yu96], its practical applications are severely limited due to exponential dependence of time and storage complexity on circuit size.

Recently, a method was developed that employs DDDs to compactly represent the determinant of a circuit matrix and its cofactors [Shi00]. In order to represent individual coefficients of the powers of *s*, a notion of *multiroot DDDs* was introduced in [Shi01]. In order to introduce the DDD method we will resort again to a simple circuit example.

(a)

$$\begin{bmatrix} G_1+G_2+sC_1 & 0 & -G_2 \\ 0 & G_3+sC_3 & -G_3 \\ -G_2 & -G_3 & G_2+G_3+sC_2 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ V_3 \end{bmatrix} = \begin{bmatrix} I_{in} \\ 0 \\ 0 \end{bmatrix}$$

(b)

FIGURE 25.18 An example circuit (a) and its node equation (b) (Note: $G_i = 1/R_i$).

Example 25.8

Consider a circuit in Figure 25.18a. Using nodal analysis (e.g., [Rod08]), we can formulate the system of node equations for this circuit, $\mathbf{Y}\cdot\mathbf{V} = \mathbf{J}$, as shown in Figure 25.18b.

Let us denote each entry of the nodal admittance matrix $\mathbf{Y}$ in Figure 25.18b by a distinct symbol as follows: $A = G_1 + G_2 + sC_1$, $B = -G_2$, $C = G_3 + sC_3$, $D = -G_3$, $E = -G_2$, $F = -G_3$, $G = G_2 + G_3 + sC_2$. The input impedance (as seen by the current source, I_{in}) is given by the expression (cf. Equation 25.6):

$$Z_{in} = \frac{V_1}{I_{in}} = \frac{\Delta_{11}}{\Delta} = \frac{GC - FD}{AGC - AFD - BEC} \tag{25.26}$$

A DDD can be used to represent the determinant of a matrix and its cofactors. Formally, a DDD is a signed, directed, acyclic graph with two terminal vertices, namely, the *zero-terminal* vertex and the *one-terminal* vertex. Each nonterminal vertex D is labeled by a symbol *D.label* and a positive or negative sign *D.sign*. It originates two outgoing edges, called *one-edge* (represented by a solid line in Figure 25.19) and *zero-edge* (represented by a broken line in Figure 25.19) pointing to its two children *D.child*1 and *D.child*0, respectively. Each vertex D represents a symbolic expression *D.expr*, defined recursively as follows:

1. If D is the one-terminal vertex, then $D.expr = 1$.
2. If D is the zero-terminal vertex, then $D.expr = 0$.
3. If D is a nonterminal vertex, then $D.expr = D.sign^{*}D.label^{*}(D.child1)expr + (D.child0)expr$, where $(D.child1)expr$ and $(D.child0)expr$ represent symbolic expressions corresponding to the vertices *D.child*1 and *D.child*0, respectively.

For example, it can be verified that Figure 25.19 is a DDD representation of $\Delta = \det(\mathbf{Y})$.

Given a vertex, a *one-path* is a path from that vertex to the one-terminal. A one-path represents a product of symbols that are labels of those vertices that *originate* all the one-edges along the one-path. For example, in Figure 25.19 there exist three one-paths from the root vertex labeled by A. They represent three product terms: AGC, $A(-F)D$, and $(-B)EC$. The root vertex A represents the sum of these product terms, being the determinant of $\mathbf{Y}$.

In order to achieve certain desired properties of a DDD, each vertex D is assigned an index *D.index*. Indices are chosen to be consecutive integers, starting from one and satisfying the following inequalities:

$$D.index > (D.child1).index$$

$$D.index > (D.child0).index$$

The process of assigning the indices is called *vertex ordering*. For example, the DDD in Figure 25.19 is formulated with a vertex order A, B, E, G, F, D, C (a number next to each vertex is its corresponding index).

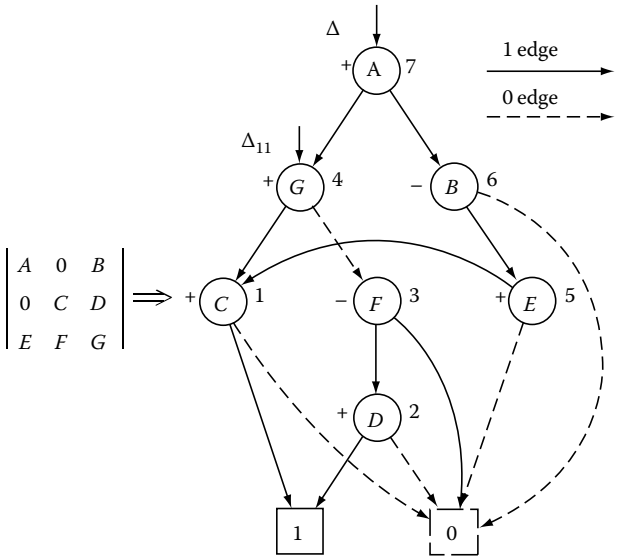

FIGURE 25.19 Example of matrix determinant and its DDD representation.

A network function is always a ratio of some cofactors (or the determinant and a cofactor) of a circuit matrix. To represent a network function using a DDD approach, the DDDs for the determinant and cofactors are constructed using the same vertex ordering. This results in sharing all common subgraphs (thus sharing all common subexpressions). This leads to one *shared DDD with multiple roots*, where each root represents either the determinant or a cofactor of the circuit matrix. For example, Figure 25.19 is a shared representation of Δ and Δ_{11} required in Equation 25.26. A *root* can be a vertex with no incoming edges or any vertex representing the cofactor of interest. The roots are marked by an additional single-ended incoming edge on the diagram.

The power of DDD-based approach lies in the fact that multiple roots share their common subgraphs. Thus, DDDs are capable of representing the determinants and cofactors of circuit matrices with the number of vertices of many orders of magnitude smaller than that of the product terms. Moreover, most symbolic analysis algorithms can be performed on a DDD with time complexity linear with the size of a DDD (i.e., the number of its vertices).

The DDD technique was originally developed for matrices with unique entries. When it is applied to the NAM of a circuit, the term cancellation occurs, dramatically slowing down the algorithm (by generating a large number of terms unnecessarily). Considerable improvement was achieved by introduction of the *just-in-time decancellation* [Ver02]. Other modifications to the DDD method were also reported in [Ver02], making the DDD-based approach very effective in both exact and approximate symbolic analyses.

The data structures and algorithms for creating DDDs and using them to obtain transfer functions are too complex to be presented in this short section. Interested readers should consult the literature, referenced here.

25.7 Time Domain Analysis

Sections 25.2 through 25.6 have discussed the different frequency domain techniques for symbolic analysis. Symbolic analysis methods in the transient domain have not appeared until the beginning of the 1990s [Has91], [Als93], [Gre93], [Lib93]. The main limitation to symbolic time domain analysis is the difficulty in handling the symbolic integration and differentiation needed to handle the energy storage elements (mainly capacitors and inductors). This problem, of course, does not exist in the frequency domain because of the use of Laplace transforms to represent these elements. While there exist symbolic algebra software packages that can be used to perform integration and differentiations like MATHMATICA, MAXIMA, and MAPLE, they have not been applied to transient symbolic analysis due to the execution time complexity of these programs. All but one of the approaches in the time domain is actually semisymbolic. The semisymbolic algorithms use a mixture of symbolic and numeric techniques to perform the analysis. The work here is still in its infancy. This section will lightly discuss the three contributions published in the literature so far.

All symbolic time domain techniques deal with linear circuits and can be classified under one of the two categories.

25.7.1 Fully Symbolic

Only one method has been reported in the literature that is fully symbolic [Gre94]. This method utilizes a direct and hierarchical symbolic transient analysis approach similar to the one reported in [Has89]. The formulation is based on the well-known discrete models for numerical integration of linear differential equations. Three of these integration methods are implemented symbolically, the Backward Euler, the Trapezoidal, and Gear's 2nd order backward differentiation [Gre94]. The inherent accuracy problems due to the approximations in these methods show up when the symbolic expressions are evaluated numerically. A detailed discussion of this method can be found in [Gre94].

25.7.2 Semisymbolic

Three such algorithms have been reported in the literature so far. Two of them [Lib93], [Has91] simply take the symbolic expressions in the frequency domain, evaluate them numerically for a range of frequencies and then perform a numeric inverse Laplace transformation or a FFT on the results. The approach reported in [Lib93] uses an MNA then a state-variable symbolic formulation to get the frequency domain response and can handle time-varying circuits, namely switch power converters. The approach in [Has91] uses a hierarchical network approach [Has89] to generate the symbolic frequency domain response. The third algorithm reported in [Als93] is a hierarchical approach that uses an MNA and a state-variable symbolic formulation and then uses the eigenvalues of the system to find a closed-form numerical transient solution.

26.1 Signal Types

26.1.1 Introduction

Because information into and out of a circuit is carried via time domain signals we look first at some of the basic signals used in continuous time circuits. All signals are taken to depend on continuous time t over the full range $-\infty < t < \infty$. It is important to realize that not all signals of interest are functions in the strict mathematical sense; we must go beyond them to generalized functions (e.g., the impulse), which play a very important part in the signal processing theory of circuits.

26.1.2 Step, Impulse, and Ramp

The unit step function, denoted $1(\cdot)$, characterizes sudden jumps, such as when a signal is turned on or a switch is thrown; it can be used to form pulses, to select portions of other functions, and to define the ramp and impulse as its integral and derivative. The unit step function is discontinuous and jumps between two values, 0 and 1, with the time of jump between the two taken as $t = 0$. Precisely,

$$1(t) = \begin{cases} 1 & \text{if } t > 0 \\ 0 & \text{if } t < 0 \end{cases} \tag{26.1}$$

which is illustrated in Figure 26.1 along with some of the functions to follow.

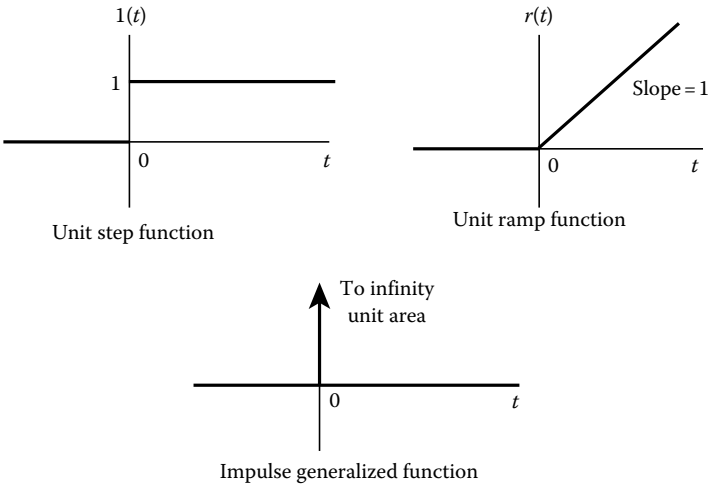

FIGURE 26.1 Step, ramp, and impulse functions.

Here, the value at the jump point, $t = 0$, purposely has been left free because normally it is immaterial and specifying it can lead to paradoxical results. Physical step functions used in the laboratory are actually continuous functions that have a continuous rise between 0 and 1, which occurs over a very short time. Nevertheless, instances occur in which one may wish to set 1(0) equal to 0 or to 1 or to 1/2 (the latter, for example, when calculating the values of a Fourier series at a discontinuity). By shifting the time argument the jump can be made to occur at any time, and by multiplying by a factor the height can be changed. For example, $1(t - t_0)$ has a jump at time t_0 and $a[1(t) - 1(t - t_0)]$ is a pulse of width t_0 and height a going up to a at $t = 0$ and down to 0 at time t_0. If $a = a(t)$ is a function of time, then that portion of $a(t)$ between 0 and t_0 is selected. The unit ramp, $r(\cdot)$ is the continuous function which ramps up linearly (with unit slope) from zero starting at $t = 0$; the ramp results from the unit step by integration

$$r(t) = \int_{-\infty}^{t} 1(\tau)\mathrm{d}\tau = t\ 1(t) = \begin{cases} t & \text{if } t > 0 \\ 0 & \text{if } t < 0 \end{cases} \tag{26.2}$$

As a consequence the unit step is the derivative of the unit ramp, while differentiating the unit step yields the unit impulse generalized function, $\delta(\cdot)$ that is

$$\delta(t) = \frac{d^1(t)}{\mathrm{d}t} = \frac{d^2 r(t)}{\mathrm{d}t^2} \tag{26.3}$$

In other words, the unit impulse is such that its integral is the unit step; that is, its area at the origin, $t = 0$, is 1. The impulse acts to sample continuous functions which multiply it, i.e.,

$$a(t)\delta(t - t_0) = a(t_0)\delta(t - t_0) \tag{26.4}$$

This sampling property yields an important integral representation of a signal $x(\cdot)$

$$\begin{aligned} x(t) &= \int_{-\infty}^{\infty} x(\tau)\delta(t - \tau)\mathrm{d}\tau \\ &= \int_{-\infty}^{\infty} x(\tau)\delta(t - \tau)\mathrm{d}\tau = x(t) \int_{-\infty}^{\infty} \delta(t - \tau)\mathrm{d}\tau \end{aligned} \tag{26.5}$$

where the validity of the first line is seen from the second line, and the fact that the integral of the impulse through its jump point is unity. Equation 26.5 is actually valid even when $x(\cdot)$ is discontinuous and, consequently, is a fundamental equation for linear circuit theory. Differentiating $\delta(t)$ yields an even more discontinuous object, the doublet $\delta'(\cdot)$. Strictly speaking, the impulse, all its derivatives, and signals of that class are not functions in the classical sense, but rather they are operators [1] or functionals [2], called generalized functions or, often, distributions. Their evaluations take place via test functions, just as voltages are evaluated on test meters.

The importance of the impulse lies in the fact that if a linear time-invariant system is excited by the unit impulse, then the response, naturally called the impulse response, is the inverse Laplace transform of the network function. In fact, if $h(t)$ is the impulse response of a linear time-invariant (continuous and continuous time) circuit, the forced response $y(t)$ to any input $u(t)$ can be obtained without leaving the time domain by use of the convolution integral, with the operation of convolution denoted by$\star$

$$y(t) = h \star u = \int_{-\infty}^{\infty} h(t-\tau)u(\tau)\mathrm{d}\tau \tag{26.6}$$

Equation 26.6 is mathematically rigorous, but justified on physical grounds through Equation 26.5 as follows. If we let $h(t)$ be the output when $\delta(t)$ is the input, then, by time invariance, $h(t-\tau)$ is the output when the input is shifted to $\delta(t-\tau)$. Scaling the latter by $u(\tau)$ and summing via the integral, as designated in Equation 26.5, we obtain a representation of the input $u(t)$. This must result in the output representation being in the form of Equation 26.6 by linearity of the system through similar scaling and summing of $h(t-\tau)$, as was performed on the input.

26.1.3 Sinusoids

Sinusoidal signals are important because they are self-reproducing functions (i.e., eigenfunctions) of linear time-invariant circuits. This is true basically because the derivatives of sinusoids are sinusoidal. As such, sinusoids are also the natural outputs of oscillators and are delivered in power sources, including laboratory signal generators and electricity for the home derived from the power company.

26.1.4 Eternal

Eternal signals are defined as being of the same nature for all time, $-\infty < t < \infty$, in which case an eternal cosine repeats itself eternally in both directions of time, with an origin of time, $t = 0$, being arbitrarily fixed. Because eternal sinusoids have been turned on forever, they are useful in describing the steady operation of circuits. In particular, the signal $A\cos(\omega t + \theta)$ over $-\infty < t < \infty$ defines an eternal cosine of amplitude A, radian frequency $\omega = 2\pi f$ (with f being real frequency, in hertz, which are cycles per second), at phase angle θ (in radians and with respect to the origin of time), with A, ω, and θ real numbers. When $\theta = \pi/2$ this cosine also represents a sine, so that all eternal sinusoidal signals are contained in the expression $A\cos(\omega t + \theta)$.

At times, it is important to work with sinusoids that have an exponential envelope, with the possibility that the envelope increases or decreases with time, that is, with positively or negatively damped sinusoids. These are described by $Ae^{st}\cos(\omega t + \theta)$, where the real number is the damping factor, giving signals that damp out in time when the damping factor is positive and signals that increase with time when the damping factor is negative. Of most importance when working with this class of signals is the identity

$$e^{\sigma t + j\omega t} = e^{st} = e^{\sigma t}[\cos(\omega t) + j\sin(\omega t)] \tag{26.7}$$

where $s = \sigma + j\omega$ with $j = \sqrt{-1}$. Here, s is called the complex frequency, with its imaginary part being the real (radian) frequency, ω. When no damping is present, $s = j\omega$, in which case the exponential form of

Equation 26.7 represents pure sinusoids. In fact, we see in this expression that the cosine is the real part of an exponential and the sine is its imaginary part. Because exponentials are usually easier than sinusoids to treat analytically, the consequence for real linear networks is that we can do most of the calculations with exponentials and convert back to sinusoids at the end. In other words, if a real linear system has a cosine or a damped cosine as a true input, it can be analyzed by using instead the exponential of which it is the real part as its (fictitious) input, finding the resulting (fictitious) exponential output, and then taking the real part at the end of the calculations to obtain the true output for the true input. Because exponentials are probably the easiest signals to work with in theory, the use of exponentials rather than sinusoids usually greatly simplifies the theory and calculations for circuits operating under steady-state conditions.

26.1.5 Causal

Because practical circuits have not existed since $t = -\infty$ they usually begin to be considered at a suitable starting time, taken to be $t = 0$, in which case the associated signals can be considered to be zero for $t < 0$. Mathematically, these functions are said to have support bounded on the left. The support of a signal is (the closure of) that set of times for which the signal is nonzero, therefore, the support of these signals is bounded on the left by zero. When signals are discontinuous functions they have the important property that they can be represented by multiplying with unit step functions signals which are differentiable and have nonbounded support. For example, $g(t) = e^{st} \cdot 1(t)$ has a jump at $t = 0$ with support at the half line 0 to ∞ but has e^{st} infinitely differential of "eternal" support.

A causal circuit is one for which the response is only nonzero after the input becomes nonzero. Thus, if the inputs are zero for $t < 0$, the outputs of causal circuits are also zero for $t < 0$. In such cases the impulse response, $h(t)$, or the response to an input impulse of "infinite jump" at $t = 0$, satisfies $h(t) = 0$ for $t < 0$ and the convolution form of the output, Equation 26.4, takes the form

$$y(t) = \left[\int_0^t h(t - \tau) u(\tau) \mathrm{d}\tau \right] 1(t) \tag{26.8}$$

26.1.6 Periodic and Aperiodic Waveforms

The pure sinusoids, although not the sinusoids with nonzero damping, are special cases of periodic signals. In other words, ones which repeat themselves in time every T seconds, where T is the period. Precisely, a time-domain signal $g(\cdot)$ is periodic of period T if $g(t) = g(t + T)$, where normally T is taken to be the smallest nonzero T for which this is true. In the case of the sinusoids, $A \cos(\omega t + \theta)$ with $\omega = 2\pi f$, the period is given by $T = 1/f$ because $\{2\pi[f(t + T)] + \theta\} = \{2\pi ft + 2\pi(fT) + \theta\} = \{2\pi ft + (2\pi + \theta)\}$, and sinusoids are unchanged by a change of 2π in the phase angle. Periodic signals need to be specified over only one period of time, e.g., $0 \le t < T$, and then can be extended periodically for all time by using $t = t \bmod(T)$ where $\bmod(\cdot)$ is the modulus function; in other words, periodic signals can be looked upon as being defined on a circle, if we imagine the circle as being a clock face.

Periodic signals represent rhythms of a system and, as such, contain recurring information. As many physical systems, especially biomedical systems, either possess directly or to a very good approximation such rhythms, the periodic signals are of considerable importance. Even though countless periodic signals are available besides the sinusoids, it is important to note that almost all can be represented by a Fourier series. Exponentials are eigenfunctions for linear circuits, thus, the Fourier series is most conveniently expressed for circuit considerations in terms of the exponential form. If $g(t) = g(t + T)$, then

$$g(t) \cong \sum_{n=-\infty}^{\infty} c_n e^{j(2\pi nt/T)} \tag{26.9}$$

where the coefficients are complex and are given by

$$c_n = \frac{1}{T}\int_0^T g(t)e^{-j(2\pi nt/T)}\mathrm{d}t = a_n + jb_n \tag{26.10}$$

Strictly speaking, the integral is over the half-open interval $[0,T)$ as seen by considering $g(\cdot)$ defined on the circle. In Equation 26.9, the symbol $>$ is used to designate the expression on the right as a representation that may not exactly agree numerically with the left side at every point when $g(\cdot)$ is a function; for example, at discontinuities the average is obtained on the right side. If $g(\cdot)$ is real, that is, $g(t) = g(t)$,* where the superscript * denotes complex conjugate, then the complex coefficients c_n satisfy $c_n = c_{-n}^*$. In this case the real coefficients a_n and b_n in Equation 26.10 are even and odd in the indices; n and the a_n combine to give a series in terms of cosines, and the b_n gives a series in terms of sines.

As an example the square wave, sqw(t), can be defined by

$$\mathrm{sqw(t)} = 1(t) - 1(t - [T/2])0 \le t < T \tag{26.11}$$

and then extended periodically to $-\infty < t < \infty$ by taking $t = t \bmod(T)$. The exponential Fourier series coefficients are readily found from Equation 26.10 to be

$$c_n = \begin{cases} 1/2 & \text{if } n = 0 \\ \frac{1}{j\pi n}\begin{cases} 0 & \text{if } n = 2k \neq 0 \ \ (\text{even} \neq 0) \\ 1 & \text{if } n = 2k+1 \ \ (\text{odd}) \end{cases} \end{cases} \tag{26.12}$$

for which the Fourier series is

$$\mathrm{sqw}(t) \cong \frac{1}{2} + \sum_{k=-\infty}^{\infty} \frac{1}{j\pi[2k+1]} e^{j2\pi[2k+1]t/T} \tag{26.13}$$

The derivative of sqw(t) is a periodic set of impulses

$$\frac{d[\mathrm{sqw}(t)]}{\mathrm{d}t} = \delta(t) - \delta(t - [T/2])\ 0 \le t < T \tag{26.14}$$

for which the exponential Fourier series is easily found by differentiating Equation 26.13, or by direct calculation from Equation 26.10, to be

$$\sum_{i=-\infty}^{\infty} (\delta(t - iT) - \delta(t - iT - [T/2]) \cong \sum_{k=-\infty}^{\infty} \frac{2}{T} e^{j(2\pi[2k+1]t/T)} \tag{26.15}$$

Combining the exponentials allows for a sine representation of the periodic generalized function signal. Further differentiation can take place, and by integrating Equation 26.15 we get the Fourier series for the square wave if the appropriate constant of integration is added to give the DC value of the signal. Likewise, a further integration will yield the Fourier series for the sawtooth periodic signal, and so on.

The importance of these Fourier series representations is that a circuit having periodic signals can always be considered to be processing these signals as exponential signals, which are usually self-reproducing signals for the system, making the design or analysis easy. The Fourier series also allows

visualization of which radian frequencies, $2\pi n/T$, may be important to filter out or emphasize. In many common cases, especially for periodically pulsed circuits, the series may be expressed in terms of impulses. Thus, the impulse response of the circuit can be used in conjunction with the Fourier series.

26.2 First-Order Circuits

26.2.1 Introduction

First-order circuits are fundamental to the design of circuits because higher order circuits can be considered to be constructed of them. Here, we limit ourselves to single-input-output linear time-invariant circuits for which we take the definition of a first-order circuit to be one described by the differential equation

$$d_1 \cdot \frac{dy}{\mathrm{d}t} + d_0 \cdot y = n_1 \cdot \frac{\mathrm{d}u}{\mathrm{d}t} + n_0 \cdot u \tag{26.16}$$

where

d_0 and d_1 are the "denominator" constants and n_0 and n_1 are the "numerator" constants
$y = y(\cdot)$ is the output and $u = u(\cdot)$ is the input
both u and y are the generalized functions of time t

So that the circuit truly will be first order, we require that $d_1 n_0 - d_0 n_1 \neq 0$, which guarantees that at least one of the derivatives is actually present, but if both derivatives occur, the expressions in y and in u are not proportional, which would lead to cancellation, forcing y and u to be constant multiples of each other. Because a factorization of real higher-order systems may lead to complex first-order systems, we will allow the numerator and denominator constants to be complex numbers; thus, y and u may be complex-valued functions.

If the derivative is treated as an operator, $p = d[\cdot]/\mathrm{d}t$, then Equation 26.16 can be conveniently written as

$$y = \frac{n_1 p + n_0}{d_1 p + d_0} u = \begin{cases} \left[\dfrac{n_1}{d_0} p + \dfrac{n_0}{d_0}\right] u & \text{if } d_1 = 0 \\ \left[\dfrac{n_1}{d_1} + \dfrac{d_1 n_0 - d_0 n_1}{p + (d_0/d_1)}\right] u & \text{if } d_1 \neq 0 \end{cases} \tag{26.17}$$

where the two cases in terms of d_1 are of interest because they provide different forms of responses, each of which frequently occurs in first-order circuits. As indicated by Equation 26.17, the transfer function

$$H(p) = \frac{n_1 p + n_0}{d_1 p + d_0} \tag{26.18}$$

is an operator (as a function of the derivative operator p), which characterizes the circuit. Table 26.1 lists some of the more important types of different first-order circuits along with their transfer functions and causal impulse responses.

The following treatment somewhat follows that given in [1], although with a slightly different orientation in order to handle all linear time-invariant continuous time continuous circuits.

TABLE 26.1 Typical Transfer Functions of First-Order Circuits

Transfer Function	Description	Impulse Response
$\frac{n_1}{d_0}p$	Differentiator	$\frac{n_1}{d_0}\delta'(t)$
$\frac{n_0}{d_1 p}$	Integrator	$\frac{n_0}{d_1}1(t)$
$\frac{n_1 p + n_0}{d_1}$	Leaky differentiator	$\frac{n_0}{d_1}\delta(t) + \frac{n_1}{d_1}\delta'(t)$
$\frac{n_0}{d_1 p + d_0}$	Low-pass filter; lossy integrator	$\frac{n_0}{d_1}e^{-\frac{d_0}{d_1}t} \cdot 1(t)$
$\frac{n_1 p}{d_1 p + d_0}$	High-pass filter	$\frac{n_1}{d_1}\delta(t) + \frac{n_1 d_0}{d_1^2}e^{-\frac{d_0}{d_1}t} \cdot 1(t)$
$\frac{n_1}{d_1}\frac{p - (d_0/d_1)}{p + (d_0/d_1)}$	All-pass filter	$\frac{n_1}{d_1}\left[\delta(t) - 2\frac{d_0}{d_1}e^{-\frac{d_0}{d_1}t} \cdot 1(t)\right]$

26.2.2 Zero-Input and Zero-State Response

The response of a linear circuit is, via the linearity, the sum of two responses, one due to the input when the circuit is initially in the zero state, called the zero-state response, and the other due to the initial state when no input is present, the zero-input response. By the linearity the total response is the sum of the two separate responses, and thus we may proceed to find each separately. In order to investigate these two types of responses, we introduce the state vector $x(\cdot)$ and the state-space representation (as previously $p = \mathrm{d}[\cdot]/\mathrm{d}t$)

$$\begin{aligned} px &= Ax + Bu \\ y &= Cx + Du + Epu \end{aligned} \tag{26.19}$$

where A, B, C, D, E are constant matrices. For our first-order circuit two cases are exhibited, depending upon d_1 being zero or not. In the case of $d_1 = 0$,

$$y = (n_1/d_0)u + (n_1/d_0)pu \quad d_1 = 0 \tag{26.20a}$$

Here, $C = 0$ and A and B can be chosen anything, including empty. When $d_1 \neq 0$, our first-order circuit has the following set of (minimal size) state-variable equations

$$\begin{aligned} px &= \left[-\frac{d_0}{d_1}\right] \cdot x + [d_1 n_0 - d_0 n_1] \cdot u \\ & \qquad\qquad\qquad\qquad d_1 \neq 0 \\ y &= [1] \cdot x + \left[\frac{n_1}{d_1}\right] \cdot u \end{aligned} \tag{26.20b}$$

By choosing $u = 0$ in Equation 26.2, we obtain the equations that yield the zero input response. Specifically, the zero-input response is

$$y(t) = \begin{cases} 0 & \text{if } d_1 = 0 \\ e^{-\frac{d_0}{d_1}t} \cdot y(0) & \text{if } d_1 \neq 0 \end{cases} \tag{26.21}$$

which is also true by direct substitution into Equation 26.16. Here, we have set, in the $d_1 \neq 0$ case, the initial value of the state, $x(0)$, equal to the initial value of the output, $y(0)$, which is valid by our choice of state-space equations. Note that Equation 26.21 is valid for all time and y at $t = 0$ assumes the assigned initial value $y(0)$, which must be zero when the input is zero and no derivative occurs on the output.

The zero-state response is explained as the solution of Equation 26.21 when $x(0) = 0$. In the case that $d_1 = 0$, the zero-state response is

$$y = \frac{n_0}{d_0}u + \frac{n_1}{d_0}pu = \left\{\frac{n_0}{d_0}\delta(t) + \frac{n_1}{d_0}\delta'(t)\right\} \star u \quad d_1 = 0 \tag{26.22a}$$

where

$\star$ denotes convolution
$\delta(\cdot)$ is the unit impulse
$1(\cdot)$ is the unit step function

While in the case that $d_1 \neq 0$

$$y = \left\{\frac{n_1}{d_1}\delta(t) + \left[\frac{d_1 n_0 - d_0 n_1}{d_1}\right]e^{-\frac{d_0}{d_1}t}1(t)\right\} \star u \quad d_1 \neq 0 \tag{26.22b}$$

which is found by eliminating x from Equation 26.20b and can be checked by direct substitution into Equation 26.16. The terms in the braces are the causal impulse responses, $h(t)$, which are checked by letting $u = \delta$ with otherwise zero initial conditions, that is, with the circuit initially in the zero state. Actually, infinitely many noncausal impulse responses could be used in Equation 26.22b. One such response is found by replacing $1(t)$ by $-1(-t)$]. However, physically the causal responses are of most interest.

If $d_1 \neq 0$, the form of the responses is determined by the constant d_0/d_1, the reciprocal of which (when $d_0 \neq 0$) is called the time constant, t_c, of the circuit because the circuit impulse response decays to $1/e$ at time $t_c = d_1/d_0$. If the time constant is positive, the zero-input and the impulse responses asymptotically decay to zero as time approaches positive infinity, and the circuit is said to be asymptotically stable. On the other hand, if the time constant is negative, then these two responses grow without bounds as time approaches plus infinity, and the circuit is called unstable. It should be noted that as time goes in the reverse direction to minus infinity, the unstable zero-input response decays to zero. If $d_0/d_1 = 0$ the zero-input and impulse responses are still stable, but neither decay nor grow as time increases beyond zero.

By linearity of the circuit and its state-space equations, the total response is the sum of the zero-state response and the zero-input response; thus, even when $d_0 = 0$ or $d_1 = 0$

$$y(t) = e^{-\frac{d_0}{d_1}}y_0 + h(t) \star u(t) \tag{26.23}$$

Assuming that u and h are zero for $t < 0$ their convolution is also zero for $t < 0$, although not necessarily at $t = 0$, where it may even take on impulsive behavior. In such a case, we see that y_0 is the value of the output instantaneously before $t = 0$. If we are interested only in the circuit for $t > 0$, surprisingly, an input will yield the zero input response. That is, an equivalent input u_0 exists, which will yield the zero input response for $t > 0$, this being $u_0(t) = d_1 y_0 \exp(-t d_0/d_1)1(t)$. Thus, $y = h \star (u + u_0)$ gives the same result as Equation 26.23.

When $d_1 = 0$, the circuit acts as a differentiator and within the state-space framework it is treated as a special case. However, in practice it is not a special case because the current, i, versus voltage, v, for a

capacitor of capacitance C, in parallel with a resistor of conductance G is described by $i = Cpv + Gv$. Consequently, it is worth noting that all cases can be handled identically in the semistate description

$$\begin{bmatrix} d_1 & d_1 - 1 \\ 0 & 0 \end{bmatrix} px = \begin{bmatrix} -d_0 & -d_0 \\ 0 & 1 \end{bmatrix} x + \begin{bmatrix} n_0 \\ n_1 \end{bmatrix} u$$
$$y = \begin{bmatrix} 1 & 1 \end{bmatrix} x \tag{26.24}$$

where $x(\cdot)$ is the semistate instead of the state, although the first components of the two vectors agree in many cases. In other words, the semistate description is more general than the state description, and handles all circuits in a more convenient fashion [2].

26.2.3 Transient and Steady-State Responses

This section considers stable circuits, although the techniques are developed so that they apply to other situations. In the asymptotically stable case, the zero input response decays eventually to zero; that is, transient responses due to initial conditions eventually will not be felt and concentration can be placed upon the zero-state response. Considering first eternal exponential inputs, $u(t) = U \exp(\text{st})$ for $-\infty < t < \infty$ at the complex frequency $s = \sigma + j\omega$, where s is chosen as different from the natural frequency $s_n = -d_0/d_1 = -1/t_c$ and U is a constant, we note that the response is $y(t) = Y(s) \exp(\text{st})$, as is observed by direct substitution into Equation 26.16; this substitution yields directly

$$Y(s) = \frac{n_1 s + n_0}{d_1 s + d_0} \cdot U \tag{26.25}$$

where $y(t) = Y(s) \exp(\text{st})$ for $u(t) = U \exp(\text{st})$ over $-\infty < t < \infty$. That is, an exponential excitation yields an exponential response at the same (complex) frequency $s = \sigma + j\omega$ as that for the input. When $\sigma = 0$, the excitation and response are both sinusoidal and the resulting response is called the sinusoidal steady state (SSS). Equation 26.25 shows that the SSS response is found by substituting the complex frequency $s = j\omega$ into the transfer function, now evaluated on complex numbers instead of differential operators as in Equation 26.18,

$$H(s) = \frac{n_1 s + n_0}{d_1 s + d_0} \tag{26.26}$$

This transfer function represents the impulse response, $h(t)$, of which it is actually the Laplace transform, and as we found earlier, the causal impulse response is

$$h(t) = \begin{cases} \dfrac{n_0}{d_0}\delta(t) + \dfrac{n_1}{d_0}\delta'(t), & \text{if } d_1 = 0 \\ \dfrac{n_1}{d_1}\delta(t) + \left[\dfrac{d_1 n_0 - d_0 n_1}{d_1}\right] e^{-\frac{d_0}{d_1}t} 1(t), & \text{if } d_1 \neq 0 \end{cases} \tag{26.27}$$

However, practical signals are started at some finite time, normalized here to $t = 0$, instead of at $t = -\infty$, as used for the preceding exponentials. Thus, consider an input of the same type but applied only for $t > 0$; i.e., let $u(t) = U \exp(\text{st}) 1(t)$. The output is found by using the convolution $y = h * u$; after a slight amount of calculation is evaluated to

$$\begin{aligned} y(t) &= h(t) * U e^{st} 1(t) \\ &= \begin{cases} H(s) U e^{st} 1(t) + \dfrac{n_1}{d_0} U \delta(t) & \text{for } d_1 = 0 \\ H(s) U e^{st} 1(t) - \dfrac{[d_1 n_0 - d_0 n_1]}{d_1 s + d_0} U e^{-\frac{d_0}{d_1}} 1(t) & \text{for } d_1 \neq 0 \end{cases} \end{aligned} \tag{26.28}$$

For $t > 0$, the SSS remains present, while there is another term of importance when $d_1 \neq 0$. This is a transient term, which disappears after a sufficient waiting time in the case of an asymptotically stable circuit. That is, the SSS is truly a steady state, although one may have to wait for it to dominate. If a nonzero zero-input response exists, it must be added to the right side of Equation 26.28, but for $t > 0$ this is of the same form as the transient already present, therefore, the conclusion is identical (the SSS eventually predominates over the transient terms for an asymptotically stable circuit).

Because a cosine is the real part of a complex exponential and the real part is obtained as the sum of two terms, we can use linearity of the circuit to quickly obtain the output to a cosine input when we know the output due to an exponential. We merely write the input as the sum of two complex conjugate exponentials and then take the complex conjugates of the outputs that are summed. In the case of real coefficients in the transfer function, this is equivalent to taking the real part of the output when we take the real part of the input; that is, $y = \Re(h \star u_3) = h \star u$, when $u = \Re(u_e)$, if y is real for all real u.

26.2.4 Network Time Constant

The time constant, t_c, was defined earlier as the time for which a transient decays to $1/e$ of the initial value. As such, the time constant shows up in signals throughout the circuit and is a very useful parameter when identifying a circuit from its responses. In an RC circuit, the time constant physically results from the interaction of the equivalent capacitor (of which only one exists in a first-order circuit) of capacitance C_{eq}, and the Thévenin's equivalent resistor, of resistance R_{eq}, that it sees. Thus, $t_c = R_{eq}C_{eq}$.

Closely related to the time constant is the rise time. Considering the low-pass case, the rise time, t_r is defined as the time for the unit step response to go between 10% and 90% of its final value from its initial value. This is easily calculated because the unit step response is given by

$$y_{1(\cdot)}(t) = h(t) \star 1(t) = \frac{n_0}{d_0}\left[1 - e^{-\frac{d_0}{d_1}t}\right] \cdot 1(t) \tag{26.29}$$

Assuming a stable circuit and setting this equal to 0.1 and 0.9 times the final value, n_0/d_0, it is readily found that

$$t_r = \frac{d_1}{d_0} \cdot \ln(9) = [\ln(9)] \cdot t_c \approx 2.2t_c \tag{26.30}$$

At this point, it is worth noting that for theoretical studies the time constant can be normalized to 1 by normalizing the time scale. Thus, assuming d_1 and $d_0 \neq 0$ the differential equation can be written as

$$d_0 \cdot \left[\frac{d_1}{d_0} \cdot \frac{dy}{d(d_1/d_0)(t(d_1/d_0))} + y\right] = d_0\left[\frac{dy}{dt_n} + y\right] \tag{26.31}$$

where $t_n = (d_0/d_1)t$ is the normalized time.

26.3 Second-Order Circuits

26.3.1 Introduction

Because real transfer functions can be factored into real second-order transfer functions, second-order circuits are probably the most important circuits available; most designs are based upon them. As with first-order circuits, this chapter is limited to single-input-single-output linear time-invariant circuits, and unless otherwise stated, here real-valued quantities are assumed. By definition a second-order circuit is described by the differential equation

$$d_2 \cdot \frac{d^2y}{dt^2} + d_1 \cdot \frac{dy}{dt} + d_0 \cdot y = n_2 \cdot \frac{d^2u}{dt^2} + n_1 \cdot \frac{du}{dt} + n_0 \cdot u \tag{26.32}$$

where d_i and n_i are "denominator" and "numerator" constants, $i = 0, 1, 2$, which, unless mentioned to the contrary, are taken to be real. Continuing the notation used for first-order circuits, $y = y(\cdot)$ is the output and $u = u(\cdot)$ is the input; both u and y are generalized functions of time t. Assume that $d_2 \neq 0$, which is the normal case because any of the other special cases can be considered as cascades of real degree one circuits.

Again, treating the derivative as an operator, $p = d[\cdot]/dt$, Equation 26.32 is written as

$$y = \frac{n_2p^2 + n_1p + n_0}{d_2p^2 + d_1p + d_0}u \tag{26.33}$$

with the transfer function

$$\begin{aligned} H(p) &= \frac{1}{d_2}\left[\frac{n_2p^2 + n_1p + n_0}{p^2 + (d_1/d_2)p + (d_0/d_2)}\right] \\ &= \frac{1}{d_2}\left[n_2 + \frac{(n_1 - (d_1/d_2)n_2)p + (n_0 - (d_0/d_2)n_2)}{p^2 + (d_1/d_2)p + (d_0/d_2)}\right] \end{aligned} \tag{26.34}$$

where the second form results by long division of the denominator into the numerator. Because they occur most frequently when second-order circuits are discussed, we rewrite the denominator in two equivalent customarily used forms:

$$p^2 + \frac{d_1}{d_2}p + \frac{d_0}{d_2} = p^2 + \frac{\omega_n}{Q}p + \omega_n^2 = p^2 + 2\zeta\omega_n p + \omega_n^2 \tag{26.35}$$

where

ω_n is the undamped natural frequency ≥ 0
Q is the quality factor
ζ is the damping factor $= 1/(2Q)$

The transfer function is accordingly

$$H(p) = \frac{1}{d_2}\left[\frac{n_2p^2 + n_1p + n_0}{p^2 + (\omega_n/Q)p + \omega_n^2}\right] = \frac{1}{d_2}\left[\frac{n_2p^2 + n_1p + n_0}{p^2 + 2\zeta\omega_n p + \omega_n^2}\right] \tag{26.36}$$

Table 26.2 lists several of the more important transfer functions, which, as in the first-order case, are operators as functions of the derivative operator p.

TABLE 26.2 Typical Second-Order Circuit Transfer Functions

Transfer Function	Description	Impulse Response
$\frac{n_0}{d_2}\frac{1}{p^2+2\zeta\omega_n p+\omega_n^2}$	Low-pass	$h_{\rm lp}(t)=\frac{n_0}{d_2}\frac{e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}\omega_n}\sin\left(\sqrt{1-\zeta^2}\omega_n t\right)1(t)$
$\frac{n_2}{d_2}\frac{p^2}{p^2+2\zeta\omega_n p+\omega_n^2}$	High-pass $0=\arctan2\left(\frac{\zeta}{\sqrt{1-\zeta^2}}\right)$	$h_{\rm hp}(t)=\frac{n_2}{d_2}\left[\delta(t)-\frac{\omega_n e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}}\sin\left(\sqrt{1-\zeta^2}\omega_n t+2\theta\right)1(t)\right]$
$\frac{n_1}{d_2}\frac{p}{p^2+2\zeta\omega_n p+\omega_n^2}$	Bandpass $\theta=\arctan2\left(\frac{\zeta}{\sqrt{1-\zeta^2}}\right)$	$h_{\rm bp}(t)=\frac{n_1}{d_2}\frac{e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}}\cos\left(\sqrt{1-\zeta^2}\omega_n t+\theta\right)1(t)$
$\frac{n_2}{d_2}\frac{p^2+\omega_0^2}{p^2+2\zeta\omega_n p+\omega_n^2}$	Band-stop	$h_{\rm bs}(t)=h_{\rm hp}(t)+\frac{n_2\omega_0^2}{n_0}h_{\rm lp}(t)$
$\frac{n_2}{d_2}\frac{p^2-2\zeta\omega_n p+\omega_n^2}{p^2+2\zeta\omega_n p+\omega_n^2}$	All-pass	$h_{\rm ap}(t)=\frac{n_2}{d_2}\left[\delta(t)-\frac{4\zeta\omega_n e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}}\cos\left(\sqrt{1-\zeta^2}\omega_n t+\theta\right)1(t)\right]$
$\frac{n_0}{d_2}\frac{1}{p^2+\omega_n^2}$	Oscillator, when $u=0$	$h_{\rm osc}(t)=\frac{n_0}{d_2}\sin(\omega_n t)\cdot 1(t)$ $\lvert y(t)\rvert_{u=0}=y(0)\cdot\cos(\omega_n t)+\frac{y'(0)}{\omega_n}\cdot\sin(\omega_n t)$

26.3.2 Zero-Input and Zero-State Response

Again, as in the first-order case, a convenient tool for investigating the time-domain behavior of a second-order circuit is the state variable description. Letting the state vector be $x(\cdot)$, the state-space representation is

$$\begin{aligned} px &= Ax + Bu \\ y &= Cx + Du \end{aligned} \tag{26.37}$$

where, as above, $p = d[\cdot]/dt$, and A, B, C, D are constant matrices. In the present case, these matrices are real and one convenient choice, among many, is

$$\begin{aligned} px &= \begin{bmatrix} 0 & 1 \\ -\frac{d_0}{d_2} & -\frac{d_1}{d_2} \end{bmatrix} x + \begin{bmatrix} n_1 - \frac{d_1}{d_2}n_2 \\ \left(n_0 - \frac{d_0}{d_2}n_2\right) - \left(n_1 - \frac{d_1}{d_2}n_2\right) \end{bmatrix} u \\ y &= \begin{bmatrix} \frac{1}{d_2} & 0 \end{bmatrix} x + \begin{bmatrix} \frac{n_1}{d_2} \end{bmatrix} u \end{aligned} \tag{26.38}$$

Here, the state is the two-vector $x = [x_1\ x_2]^{\rm T}$, with the superscript T denoting transpose. Normally, the state would consist of capacitor voltages and/or inductor currents, although at times one may wish to use linear combinations of these. From these state variable equations, a generic operational-amplifier (op-amp) RC circuit to realize any of this class of second-order circuits is readily designed and given in Figure 26.2. In the figure, all voltages are referenced to ground and normalized capacitor and resistor values are listed. Alternate designs in terms of only CMOS differential pairs and capacitors can also be given [3], while a number of alternate circuits exist in the catalog of Sallen and Key [4].

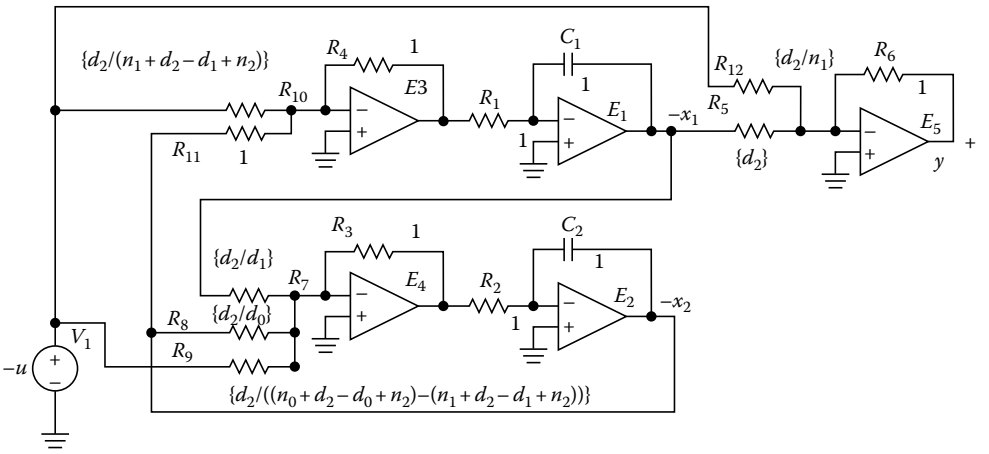

FIGURE 26.2 Generic, second-order op-amp RC circuit.

Because Equation 26.38 represents a set of linear constant coefficient differential equations, superposition applies and its solution can again be broken into two parts, the part due to initial conditions, $x(0)$, called the zero-input response, and the part due solely to the input u, the zero-state response.

The zero-input response is readily found by solving the state equations with $u = 0$ and initial conditions $x(0)$. The result is $y(t) = C\exp(At)\,x(0)$, which can be evaluated by several means, including the following. Using a prime to designate the time derivative, first note that when $u = 0$, $x_1(t) = d_2 y(t)$ and (from the first row of A) $x_1(t)' = x_2(t) = d_2 y(t)'$. Thus, $x_1(0) = d_2 y(0)$ and $x_2(0) = d_2\, y'(0)$, which allow the initial conditions to be expressed in terms of the measurable output quantities. To evaluate $\exp(At)$, note that its terms are linear combinations of terms with complex frequencies that are zeroes of the characteristic polynomial

$$\begin{aligned}\det(s1_2 - A) = \det\begin{pmatrix} s & -1 \\ \omega_n^2 & s + 2\zeta\omega_n \end{pmatrix} &= s^2 + 2\zeta\omega_n s + \omega_n^2 \\ &= (s - s_-)(s - s_+)\end{aligned} \tag{26.39}$$

For which the roots, called natural frequencies, are

$$s_\pm = \left(-\zeta \pm \sqrt{\zeta^2 - 1}\right)\omega_n = \left(-1 \pm \sqrt{1 - 4Q^2}\right)\frac{\omega_n}{2Q} \tag{26.40}$$

The case of equal roots will only occur when $\zeta^2 = 1$, which is the same as $Q^2 = 1/4$, for which the roots are real. Indeed, if the damping factor, ζ, is >1 in magnitude, or equivalently, if the quality factor, Q, is $<1/2$ in magnitude, the roots are real and the circuit can be considered a cascade of two first-order circuits. Thus, assume here and in the following that unless otherwise stated, $Q^2 > 0.25$, which is the same as $\zeta^2 < 1$, in which case the roots are complex conjugates, $s_- = s_+^*$

$$s_\pm = \left(-\zeta \pm j\sqrt{1 - \zeta^2}\right)\omega_n = \left(-1 \pm j\sqrt{4Q^2 - 1}\right)\frac{\omega_n}{2Q}, \quad j = \sqrt{-1} \tag{26.41}$$

By writing $y(t) = a \cdot \exp(s_+ t) + b \cdot \exp(s_- t)$, for unknown constants a and b, differentiating and setting $t = 0$ we can solve for a and b, and after some algebra and trigonometry obtain the zero-input response

$$y(t) = \frac{e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}} \left\{ y(0) \cdot \cos\left(\sqrt{1-\zeta^2}\omega_n t - \theta\right) + \frac{y'(0)}{\omega_n} \cdot \sin\left(\sqrt{1-\zeta^2}\omega_n t\right) \right\} \tag{26.42}$$

where $\theta = \arctan2\left(\zeta/\sqrt{1-\zeta^2}\right)$ with $\arctan2(\cdot)$ being the arc tangent function that incorporates the sign of its argument.

The form given in Equation 26.42 allows for some useful observations. Remembering that this assumes $\zeta^2 < 1$, first note that if no damping occurs, that is, $\zeta = 0$, then the natural frequencies are purely imaginary, $s_+ = j\omega_n$ and $s_- = -s_+$, and the response is purely oscillatory, taking the form shown in the last line of Table 26.2. If the damping is positive, as it would be for a passive circuit having some loss, usually via positive resistors, then the natural frequencies lie in the left half s-plane, and y decays to zero at positive infinite time so that any transients in the circuit die out after a sufficient wait. The circuit is then called asymptotically stable. However, if the damping is negative, as it could be for some positive feedback circuits or those with negative resistance, then the response to nonzero initial conditions increases in amplitude without bound, although in an oscillatory manner, as time increases, and the circuit is said to be unstable. In the unstable case, as time decreases through negative time the amplitude also damps out to zero, but usually the responses backward in time are not of as much interest as those forward in time.

For the zero-state response, the impulse response, $h(t)$, is convoluted with the input, that is, $y = h * u$, for which we can use the fact that $h(t)$ is the inverse Laplace transform of $H(s) = C[sI_2 - A]^{-1}B$. The denominator of $H(s)$ is $\det(sI_2 - A) = s^2 + 2\zeta\omega_n s + \omega^2{}_n$, for which the causal inverse Laplace transform is

$$e^{s_+ t}1(t) * e^{s_- t}1(t) = \begin{cases} \dfrac{e^{s_+ t} - e^{s_- t}}{s_+ - s_-}1(t) & \text{if } s_- \neq s_+ \\ te^{s_+ t}1(t) & \text{if } s_- = s_+ \end{cases} \tag{26.43}$$

Here, the bottom case is ruled out when only complex natural frequencies are considered, following the assumption of handling real natural frequencies in first-order circuits, made previously. Consequently,

$$e^{s_+ t}1(t) * e^{s_- t}1(t) = \frac{e^{s_+ t} - e^{s_- t}}{s_+ - s_-}1(t) = \frac{e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2\omega_n}} \sin\left(\sqrt{1-\zeta^2\omega_n t}\right) \cdot 1(t) \tag{26.44}$$

Again, assuming $\zeta^2 < 1$ using the preceding calculations give the zero-state response as

$$\begin{aligned} y(t) &= \frac{1}{d_2}\left\{ \frac{e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}\omega_n} \sin\left(\sqrt{1-\zeta^2}\omega_n t\right)1(t) * \right. \\ &\quad \left. \left[\left(n_1 - \frac{d_1}{d_2}n_2\right)\delta'(t) + \left(n_0 - \frac{d_0}{d_2}n_2\right)\delta(t)\right] + n_2\delta(t) \right\} * u(t) \\ &= \frac{1}{d_2}\left\{ \frac{e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}\omega_n} \sin\left(\sqrt{1-\zeta^2}\omega_n t\right)1(t) * \right. \\ &\quad \left. [n_2\delta''(t) + n_1\delta'(t) + n_0\delta(t)] \right\} * u(t) \end{aligned} \tag{26.45}$$

The bottom equivalent form is easily seen to result from writing the transfer function $H(p)$ as the product of two terms $1/[d_2(p^2 + 2\zeta\omega_n p + \omega_n^2)]$ and $[n_2 p^2 + n_1 p + n_0]$ convoluting the causal impulse response (the

inverse of the left half-plane converging Laplace transform), of each term. From Equation 26.45, we directly read the impulse response to be

$$h(t) = \frac{1}{d_2}\left\{ \frac{e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}\omega_n} \sin\left(\sqrt{1-\zeta^2}\omega_n t\right) 1(t) \right.$$
$$\left. *[n_2\delta''(t) + n_1\delta'(t) + n_0\delta(t)] \right\} \tag{26.46}$$

Equations 26.45 and 26.46 are readily evaluated further by noting that the convolution of a function with the second derivative of the impulse, the first derivative of the impulse, and the impulse itself is the second derivative of the function, the first derivative of the function, and the function itself, respectively. For example, in the low-pass case we find the impulse response to be, using Equation 26.46,

$$h_{\text{lp}}(t) = \frac{n_0}{d_2} \frac{e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}\omega_n} \sin\left(\sqrt{1-\zeta^2}\omega_n t\right) 1(t) \tag{26.47}$$

By differentiating we find the bandpass and then high-pass impulse responses to be, respectively,

$$h_{\text{bp}}(t) = \frac{n_1}{d_2} \frac{e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}} \cos\left(\sqrt{1-\zeta^2}\omega_n t + \theta\right) 1(t) \tag{26.48}$$

$$h_{\text{hp}}(t) = \frac{n_2}{d_2}\left[\delta(t) - \frac{\omega_n e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}} \sin\left(\sqrt{1-\zeta^2}\omega_n t + 2\theta\right) 1(t)\right] \tag{26.49}$$

In both cases, the added phase angle is given, as in the zero input response, via $\theta = \arctan2\left(\zeta/\sqrt{1-\zeta^2}\right)$. By adding these last three impulse responses suitably scaled the impulse responses of the more general second-order circuits are obtained.

Some comments on normalizations are worth mentioning in passing. Because $d_2 \neq 0$, one could assume d_2 to be 1 by absorbing its actual value in the transfer function numerator coefficients. If $\omega_n \neq 0$, time could also be scaled so that $\omega_n = 1$ could be taken, in which case a normalized time, t_n, is introduced.

Thus, $t = \omega_n t_n$ and, along with normalized time, comes a normalized differential operator $p_n = d[\cdot]/\mathrm{d}t_n = d[\cdot]/\mathrm{d}(t/\omega_n) = \omega_n p$. This, in turn, leads to a normalized transfer function by substituting $p = p_n/\omega_n$ into $H(p)$. Thus, much of the treatment could be carried out on the normalized transfer function x

$$H_n(p_n) = H(p) = \frac{n_{2n}p_n^2 + n_{1n}p_n + n_{0n}}{p_n^2 + 2\zeta p_n + 1} \quad p_n = \omega_n p \tag{26.50}$$

In this normalized form, it appears that the most important parameter in fixing the form of the response is the damping factor $\zeta = 1/(2Q)$.

26.3.3 Transient and Steady-State Responses

Let us now excite the circuit with an eternal exponential input, $u(t) = U\exp(\mathrm{st})$ for $-\infty < t < \infty$ at the complex frequency $s = \sigma + j\omega$, where s is chosen as different from either of the natural frequencies, $s_{\pm}$, and U is a constant. As with the first-order and, indeed, any higher-order, case the response is $y(t) = Y(s)\exp(\mathrm{st})$, as is observed by direct substitution into Equation 26.32. This substitution yields directly

$$Y(s) = \frac{1}{d_2}\left[\frac{n_2 s^2 + n_1 s + n_0}{s^2 + 2\zeta\omega_n s + \omega_n^2}\right] \cdot U \tag{26.51}$$

where $y(t) = Y(s)\exp(st)$ for $u(t) = U\exp(st)$ over $-\infty < t < \infty$. That is, an exponential excitation yields an exponential response at the same (complex) frequency $s = \sigma + j\omega$ as that for the input, as long as s is not one of the two natural frequencies. (s may have positive as well as negative real parts and is best considered as a frequency and not as the Laplace transform variable because the latter is limited to regions of convergence.) Because the denominator polynomial of $Y(\dot{s})$ has roots which are the natural frequencies, the magnitude of Y becomes infinite as the frequency of the excitation approaches s_+ or s_-. Thus, the natural frequencies s_+ and s_- are also called poles of the transfer function.

When $\sigma = 0$ the excitation and response are both sinusoidal and the resulting response is called the SSS. From Equation 26.51, the SSS response is found by substituting the complex frequency $s = j\omega$ into the transfer function, now evaluated on complex numbers rather than differential operators as above,

$$H(s) = \frac{1}{d_2}\left[\frac{n_2 s^2 + n_1 s + n_0}{s^2 + 2\zeta\omega_n s + \omega_n^2}\right] \tag{26.52}$$

Next, an exponential input is applied, which starts at $t = 0$ instead of at $t = -\infty$; i.e., $u(t) = U\exp(st)1(t)$. Then, the output is found by using the convolution $y = h * u$, which, from the discussion at Equation 26.45, is expressed as

$$\begin{aligned} y(t) = h * u &= \frac{1}{d_2} e^{s_+ t}1(t) * e^{s_- t}1(t) * [n_2\delta''(t) + n_1\delta'(t) + n_0\delta(t)] * e^{st}1(t) \\ &= H(s)Ue^{st}1(t) + \left\{\frac{1}{d_2(s_+ - s_-)}\left[\left(\frac{N(s)}{s_+ - s} + n_2(s + s_+) + n_1\right)e^{s_+ t}\right.\right. \\ &\quad \left.\left. -\left(\frac{N(s)}{s_+ - s} + n_2(s + s_-) + n_1\right)e^{s_- t}\right]1(t)\right\} \end{aligned} \tag{26.53}$$

in which $N(s)$ is the numerator of the transfer function and we have assumed that s is not equal to a natural frequency. The second term on the right within the braces varies at the natural frequencies and as such is called the transient response, while the first term is the term resulting directly from an eternal exponential, but now with the negative time portion of the response removed. If the system is stable, the transient response decays to zero as time increases and, thus, if we wait long enough the transient response of a stable system can be ignored if the complex frequency of the input exponential has a real part that is greater than that of the natural frequencies. Such is the case for exponentials that yield sinusoids; in that case $\sigma = 0$, or $s = j\omega$. In other words, for an asymptotically stable circuit the output approaches that of the SSS when the input frequency is purely imaginary. If we were to excite at a natural frequency then the first part of Equation 26.53 still could be evaluated using the time-multiplied exponential of Equation 26.43; however, the transient and the steady state are now mixed, both being at the same "frequency."

Because actual sinusoidal signals are real, we use superposition and the fact that the real part of a complex signal is given by adding complex conjugate terms:

$$\cos(\omega t) = \Re[e^{j\omega t}] = \frac{e^{j\omega t} + e^{-j\omega t}}{2} \tag{26.54}$$

This leads to the SSS response for an asymptotically stable circuit excited by $u(t) = U\cos(\omega t)1(t)$ to be

$$\begin{aligned} y(t) &= \frac{H(j\omega)Ue^{j\omega t} + H(-j\omega)U^* e^{-j\omega t}}{2} \\ &= |H(j\omega)||U|\cos(\omega t + \angle H(j\omega) + \angle U) \end{aligned} \tag{26.55}$$

Here, we assumed that the circuit has real-valued components such that $H(-j\omega)$ is the complex conjugate of $H(j\omega)$. In which case, the second term in the middle expression is the complex conjugate of the first.

26.3.4 Network Characterization

Although the impulse response is useful for theoretical studies, it is difficult to observe it experimentally due to the impossibility of creating an impulse. However, the unit step response is readily measured, and from it the impulse response actually can be obtained by numerical differentiation if needed. However, it is more convenient to work directly with the unit step response and, consequently, practical characterizations can be based upon it. The treatment most conveniently proceeds from the normalized low-pass transfer function

$$H(p) = \frac{1}{p^2 + 2\zeta p + 1}, \quad 0 < \zeta < 1 \tag{26.56}$$

The unit step response follows by applying the input $u(t) = 1(t)$ and noting that the unit step is the special case of an exponential multiplied unit step, where the frequency of the exponential is zero. Conveniently, Equation 26.43 can be used to obtain

$$y_{\text{us}}(t) = 1(t) - \frac{e^{-\zeta t}}{\sqrt{1-\zeta^2}} \cos\left(\sqrt{1-\zeta^2}t - \theta\right) \cdot 1(t), \quad \theta = \arctan\left(\frac{\zeta}{\sqrt{1-\zeta^2}}\right) \tag{26.57}$$

Typical unit step responses are plotted in Figure 26.3 where, for a small damping factor, overshoot can be considerable, with oscillations around the final value and in addition, a long settling time before reaching the final value. In contrast, with a large damping factor, although no overshoot or oscillation occurs, the rise to the final value is long. A compromise for obtaining a quick rise to the final value with no oscillations is given by choosing a damping factor of 0.7, this being called the critical value; i.e., critical damping is $\zeta_{\text{crit}} = 0.7$.

27.1 Concept of States

For resistive (or memoryless) circuits, given the circuit structure, the present output depends only on the present input. In order to analyze a dynamic circuit, however, in addition to the present input it is also necessary to know the state of the circuit at some time t_0. The state of the circuit at t_0 represents the condition of the circuit at $t = t_0$, and is related to the energy storage of the circuit, or the voltage (or electric charge) across the capacitor and the currents (or magnetic fluxes) through the inductors. These voltages and currents are considered as the state of the circuit at $t = t_0$. For $t > t_0$, the behavior of the circuit is completely characterized by these variables. In view of the preceding, a definition for the state of a circuit can now be given.

Definition: The state of a circuit at time t_0 is the minimum amount of information at t_0 that, along with the input to the circuit for $t \geq t_0$, uniquely determines the behavior of the circuit for $t \geq t_0$.

The concept of states is closely related to the order of complexity of the circuit. The order of complexity of a circuit is the minimum number of initial conditions which, along with the input, is sufficient to determine the future behavior of the circuit. Furthermore, if a circuit is described by an nth-order linear differential equation, it is well-known that the general solution for $t \geq t_0$ contains n arbitrary constants which are determined by n initial conditions. This set of n initial conditions contains information concerning the circuit prior to $t = t_0$ and constitutes the state of the circuit at $t = t_0$. Thus, the order of complexity or the order of a circuit is the same as the order of the differential equation that describes the circuit, and it is also the same as the number of state variables that can be defined in a circuit. For an nth-order circuit, the state of the circuit at $t = t_0$ consists of a set of n numbers that denotes a vector in an n-dimensional state space spanned by the n corresponding state variables. This key number n can simply be obtained by inspection of the circuit. Knowing the total number of energy storage elements, n_{LC}, the total number of independent capacitive loops, n_C, and the total number of independent inductive cutsets, n_L, the order of complexity n of a circuit is given by

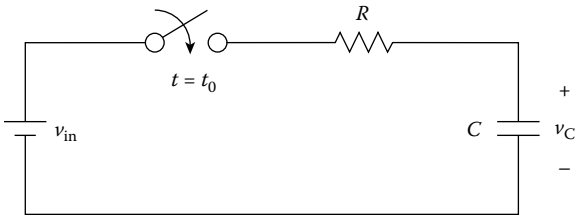

FIGURE 27.1 Simple RC circuit.

$$n = n_{LC} - n_L - n_C \tag{27.1}$$

A capacitive loop is defined as one that consists of only capacitors and possibly voltage sources while an inductive cutset represents a cutset that contains only inductors and possibly current sources. The following two examples illustrate the concept of states.

Example 27.1

Consider a simple *RC*-circuit in Figure 27.1. The circuit equation is

$$RC\frac{dv_c(t)}{dt} + v_c(t) = v_{in} \quad \text{for } t \geq t_0 \tag{27.2}$$

and the corresponding capacitor voltage is easily obtained as

$$v_c(t) = [v_c(t_0) - v_{in}]e^{-\frac{1}{RC}(t-t_0)} + v_{in} \quad \text{for } t \geq t_0 \tag{27.3}$$

For this first-order circuit, it is clear from Equation 27.3 the capacitor voltage for $t \geq t_0$ is uniquely determined by the initial condition $v_c(t_0)$ and the input voltage v_{in} for $t \geq t_0$. This is independent of the charging circuit for the capacitor prior to t_0. Hence, $v_c(t_0)$ is the state of the circuit at $t = t_0$ and $v_c(t)$ is regarded as the state variable of the circuit.

Example 27.2

As another illustration, consider the circuit of Figure 27.2, which is a slight modification of the circuit considered in the previous example. The circuit equation and its corresponding solution are readily obtained as

$$\frac{dv_{C_1}(t)}{dt} = -\frac{1}{R(C_1 + C_2)}v_{C_1}(t) + \frac{1}{R(C_1 + C_2)}v_{in} \tag{27.4}$$

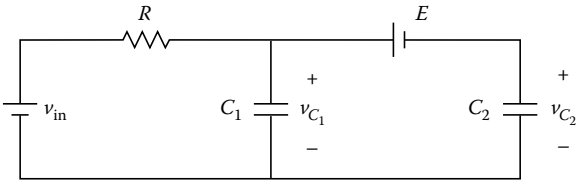

FIGURE 27.2 Circuit for Example 27.2.

and

$$v_{C_1}(t) = (v_{C_1}(t_0) - v_{\text{in}})e^{\frac{-1}{R(C_1+C_2)}(t-t_0)} + v_{\text{in}} \quad \text{for } t \geq t_0 \tag{27.5}$$

respectively. Even though two energy storage elements exist, one can only arbitrarily specify one independent initial condition. Once the initial condition on C_1, $v_{C_1}(t_0)$, is specified, the initial voltage on C_2 is automatically constrained by the loop equation $v_{C_2}(t) = v_{C_1}(t) - E$ at t_0. The circuit is thus still first order and only one state variable can be assigned for the circuit. It is clear from Equation 27.5 that with the input v_{in}, $v_{C_1}(t_0)$ is the minimum amount of information that is needed to uniquely determine the behavior of this circuit. Hence, $v_{C_1}(t)$ is the state variable of the circuit. One can just as well analyze the circuit by solving a first-order differential equation in terms of $v_{C_2}(t)$ with $v_{C_2}(t_0)$ defined as the state of the circuit at $t = t_0$. The selection of state variables is thus not unique. In this example, either $v_{C_1}(t)$ or $v_{C_2}(t)$ can be defined as the state variable of the circuit. In fact, it is easily shown that any linear combination of $v_{C_1}(t)$ and $v_{C_2}(t)$ can also be regarded as state variables.

27.2 State-Variable Formulation via Network Topology

Various mathematical descriptions of circuits are available. Depending on the type of analysis used, different formulations of circuit equations may result. In the state variable formulation, a system of n first-order differential equations is written in the form

$$\dot{\mathbf{x}} = \mathbf{f}\ (\mathbf{x}, t) \tag{27.6}$$

where

$\mathbf{x}$ is an $n \times 1$ vector consisting of n state variables for an nth-order circuit
t represents the time variable

This set of equations is usually referred to as the state equation in normal form.

When compared with other circuit descriptions, the state-variable representation is not necessarily the simplest. It does, however, simultaneously provide the solution of all state variables and hence yields the behavior of the entire circuit. The state equation is also particularly suitable for analysis by numerical techniques. Another distinct advantage of the state-variable approach is that it can be easily extended to nonlinear and/or time varying circuits.

Example 27.3

Consider the linear circuit of Figure 27.3. By inspection, the order of complexity of this circuit is three. Hence, three state variables are selected as $x_1 = v_{C_1}$, $x_2 = v_{C_2}$, and $x_3 = i_{\text{L}}$. Because the left-hand side of the normal form equation is the derivative of the state vector, it is necessary to express the voltage across

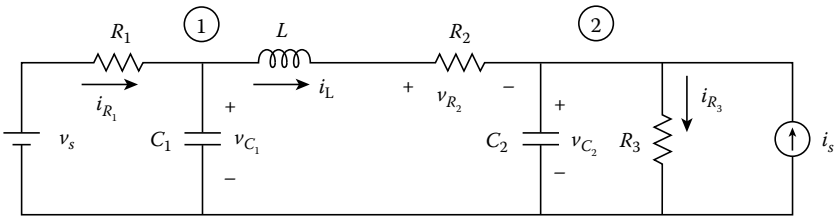

FIGURE 27.3 Circuit for Example 27.3.

the inductors and the currents through the capacitors in terms of the state variables and the input sources.

The current through C_1 can be obtained by writing a Kirchhoff's current law (KCL) equation at node 1 to yield

$$\begin{aligned} C_1 \frac{dv_{C_1}}{dt} &= i_{R_1} - i_L \\ &= \frac{1}{R_1}(v_s - v_{C_1}) - i_L \end{aligned}$$

or

$$\frac{dv_{C_1}(t)}{dt} = -\frac{1}{R_1 C_1} v_{C_1} - \frac{1}{C_1} i_L + \frac{1}{R_1 C_1} v_s \tag{27.7}$$

In a similar manner, applying KCL to node 2 gives

$$\begin{aligned} C_2 \frac{dv_{C_2}}{dt} &= i_L - i_{R_3} + i_s \\ &= i_L - \frac{1}{R_3} v_{C_2} + i_s \end{aligned}$$

or

$$\frac{dv_{C_2}(t)}{dt} = -\frac{1}{R_3 C_2} v_{C_2} + \frac{1}{C_2} i_L + \frac{1}{C_2} i_s \tag{27.8}$$

The expression for the inductor voltage is derived by applying KVL to the mesh containing L, R_2, C_2, and C_1 yielding

$$L \frac{di_L}{dt} = v_{C_1} - v_{C_2} - R_2 i_L$$

or

$$\frac{di_L}{dt} = \frac{1}{L} v_{C_1} - \frac{1}{L} v_{C_2} - \frac{R_2}{L} i_L \tag{27.9}$$

Equations 27.7 through 27.9 are the state equations that can be expressed in matrix form as

$$\begin{bmatrix} \frac{dv_{C_1}}{dt} \\ \frac{dv_{C_2}}{dt} \\ \frac{di_L}{dt} \end{bmatrix} = \begin{bmatrix} -\frac{1}{R_1 C_1} & 0 & -\frac{1}{C_1} \\ 0 & -\frac{1}{R_3 C_2} & \frac{1}{C_2} \\ \frac{1}{L} & -\frac{1}{L} & -\frac{R_2}{L} \end{bmatrix} \begin{bmatrix} v_{C_1} \\ v_{C_2} \\ i_L \end{bmatrix} + \begin{bmatrix} \frac{1}{R_1 C_1} & 0 \\ 0 & \frac{1}{C_2} \\ 0 & 0 \end{bmatrix} \begin{bmatrix} v_s \\ i_s \end{bmatrix} \tag{27.10}$$

Any number of branch voltages and/or currents may be chosen as output variables. If i_{R_1} and v_{R_2} are considered as outputs for this example, then the output equations, written as a linear combination of state variables and input sources become

$$i_{R_1} = \frac{1}{R_1}(v_s - v_{C_1}) \tag{27.11}$$

$$v_{R_2} = R_2 i_L \tag{27.12}$$

or in matrix form

$$\begin{bmatrix} i_{R_1} \\ v_{R_2} \end{bmatrix} = \begin{bmatrix} -\frac{1}{R_1} & 0 & 0 \\ 0 & 0 & R_2 \end{bmatrix} \begin{bmatrix} v_{C_1} \\ v_{C_2} \\ i_L \end{bmatrix} + \begin{bmatrix} \frac{1}{R_1} & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} v_s \\ i_s \end{bmatrix} \tag{27.13}$$

In general, for an nth-order linear circuit with r input sources and m outputs, the state and output equations are represented by

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{u} \tag{27.14}$$

and

$$\mathbf{y} = \mathbf{C}\mathbf{x} + \mathbf{D}\mathbf{u} \tag{27.15}$$

where

$\mathbf{x}$ is an $n \times 1$ state vector
$\mathbf{u}$ is an $r \times 1$ vector representing the r input sources
$m \times 1$-vector $\mathbf{y}$ denotes the m output variables, $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$, and $\mathbf{D}$ are of order $n \times n$, $n \times r$, $m \times n$, and $m \times r$, respectively

In the preceding example, the state equations are obtained by inspection for a simple circuit by writing voltage equations for inductors and current equations for capacitors and properly eliminating the nonstate variables. For more complicated circuits, a systematic procedure for eliminating the nonstate variables is desirable. Such a procedure can be generated with the aid of a proper tree. A proper tree is a tree obtained from the associated network graph that contains all capacitors, independent voltage sources, and possibly some resistive elements, but does not contain inductors and independent current sources. The selection of such a tree is always possible if the circuit contains no capacitive loops and no inductive cutsets. The reason for providing such a tree for writing state equations is obvious. With each tree branch, there is a unique cutset known as the fundamental cutset that contains only one tree branch and some links. Thus, if capacitors are in the tree, a fundamental cutset equation may be written for the corresponding currents through the capacitors. Similarly, every link (together with some tree branches) forms a unique loop called a fundamental loop. If inductors are selected as links, inductor voltages may be obtained by writing the corresponding fundamental loop equations. With the selection of a proper tree, state variables can be defined as the capacitor tree-branch voltages and inductive link currents. In view of the above observation, a systematic procedure for writing state equations can now be stated as follows:

Step 1: From the associated directed graph, pick a proper tree.

Step 2: Write fundamental cutset equations for the capacitive tree branches and express the capacitor currents in terms of link currents.

Step 3: Write fundamental loop equations for the inductive links and express the inductor voltages in terms of tree-branch voltages.

Step 4: Define the state variables. Capacitive tree-branch voltages and inductive link currents are selected as state variables. Other quantities such as capacitor charges and inductor fluxes may also be used.

Step 5: Group the branch relations and the remaining fundamental equations according to their element types into three sets: resistor, inductor, and capacitor equations. Solve for the nonstate variables that appeared in the equations obtained in Steps 2 and 3 from the corresponding set of equations in terms of the state variables and independent sources.

Step 6: Substitute the result of Step 5 into the equations obtained in Steps 2 and 3, and rearrange them in normal form.

Example 27.4

Consider again the same circuit in Figure 27.3. The various steps outlined previously are used to write the state equations.

Step 1: The associated graph and the proper tree of the circuit are shown in Figure 27.4. The tree branches include v_s, C_1, C_2, and R_2.

Step 2: The fundamental cutset associated with C_1 consists of tree branch C_1 and two links R_1 and L. By writing the current equation for this cutset, the capacitor current i_{c1} is expressed in terms of link currents as

$$i_{C_1} = i_{R_1} - i_L \tag{27.16}$$

Similarly, the fundamental cutset $\{L, C_2, R_3, i_s\}$ associated with C_2 leads to

$$i_{C_2} = i_L - i_{R_3} + i_s \tag{27.17}$$

Step 3: The fundamental loop associated with link L consists of L and tree branches R_2, C_2, and C_1. By writing the voltage equation around this loop, the inductor voltage can be written in terms of tree-branch voltages as

$$v_L = v_{C_1} - v_{C_2} - v_{R_2} \tag{27.18}$$

Step 4: The tree-branch capacitor voltages v_{C_1}, V_{C_1}, and inductive link current i_L are defined as the state variables of the circuit.

Step 5: The branch relation and the remaining two fundamental loops for R_1 and R_2, and the fundamental cutset equation for R_2 are grouped into three sets.

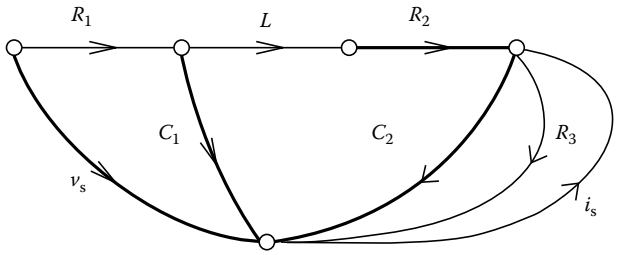

FIGURE 27.4 Directed graph associated with the circuit of Figure 27.3.

Resistor equations:

$$v_{R_1} + v_{C_1} - v_s = 0 \tag{27.19}$$

$$i_{R_1} = \frac{1}{R_1} v_{R_1} \tag{27.20}$$

$$i_{R_2} - i_L = 0 \tag{27.21}$$

$$v_{R_2} = R_2 i_{R_2} \tag{27.22}$$

$$v_{R_3} - v_{C_2} = 0 \tag{27.23}$$

$$v_{R_3} = R_3 i_{R_3} \tag{27.24}$$

Inductor equations:

$$\phi_L = L i_L \quad \text{or} \quad v_L = \frac{d\phi_L}{dt} = L \frac{di_L}{dt} \tag{27.25}$$

Capacitor equations:

$$q_1 = C_1 v_{C_1} \quad \text{or} \quad i_{C_1} = \frac{dq_1}{dt} = C_1 \frac{dv_{C_1}}{dt} \tag{27.26}$$

$$q_2 = C_2 v_{C_2} \quad \text{or} \quad i_{C_2} = \frac{dq_2}{dt} = C_2 \frac{dv_{C_2}}{dt} \tag{27.27}$$

The resistive link currents r_{R_1}, i_{R_3}, and resistive tree-branch voltage V_{R_2} are solved from Equations 27.19 through 27.24 in terms of the inductive link current i_L, the capacitive tree-branch voltages v_{C_1} and v_{C_2}, and sources as

$$i_{R_1} = \frac{1}{R_1}(v_s - v_{C_1}) \tag{27.28}$$

$$i_{R_3} = \frac{1}{R_3} v_{C_2} \tag{27.29}$$

and

$$v_{R_2} = R_2 i_L \tag{27.30}$$

For this example, i_L, v_{C_1}, and v_{C_2} have already been defined as state variables.

Step 6: Substituting Equations 27.28 through 27.30 into Equations 27.16 through 27.18 yields the desired state equation in matrix form:

$$\begin{bmatrix} \frac{dv_{C_1}}{dt} \\ \frac{dv_{C_2}}{dt} \\ \frac{di_L}{dt} \end{bmatrix} = \begin{bmatrix} -\frac{1}{R_1 C_1} & 0 & -\frac{1}{C_1} \\ 0 & -\frac{1}{R_3 C_2} & \frac{1}{C_2} \\ \frac{1}{L} & -\frac{1}{L} & -\frac{R_2}{L} \end{bmatrix} \begin{bmatrix} v_{C_1} \\ v_{C_2} \\ i_L \end{bmatrix} + \begin{bmatrix} \frac{1}{R_1 C_1} & 0 \\ 0 & \frac{1}{C_2} \\ 0 & 0 \end{bmatrix} \begin{bmatrix} v_s \\ i_s \end{bmatrix} \tag{27.31}$$

which, as expected, is the same as Equation 27.10 obtained previously by inspection.

As mentioned earlier, the selection of state variables is not unique. Instead of using capacitor voltages and inductor currents as state variables, basic quantities such as the capacitor charges and inductor fluxes may also be considered. If q_1, q_2, and ϕ_L are defined as state variables in Step 4, the inductive link current i_L and capacitive tree-branch voltages, v_{C_1} and v_{C_2}, can be solved from the inductor and capacitor equations in terms of state variables and possibly sources in Step 5 as

$$i_L = \frac{1}{L}\phi_L \tag{27.32}$$

$$v_{C_1} = \frac{1}{C_1}q_1 \tag{27.33}$$

$$v_{C_2} = \frac{1}{C_2}q_2 \tag{27.34}$$

Finally, state equations are obtained by substituting Equations 27.28 through 27.30 and Equations 27.32 through 27.34 into Equations 27.16 through 27.18 as

$$\begin{bmatrix} \frac{dq_1}{dt} \\ \frac{dq_2}{dt} \\ \frac{d\phi_L}{dt} \end{bmatrix} = \begin{bmatrix} -\frac{1}{R_1C_1} & 0 & -\frac{1}{L} \\ 0 & -\frac{1}{R_3C_2} & \frac{1}{L} \\ \frac{1}{C_1} & -\frac{1}{C_2} & -\frac{R_2}{L} \end{bmatrix} \begin{bmatrix} q_1 \\ q_2 \\ \phi_L \end{bmatrix} + \begin{bmatrix} \frac{1}{R_1} & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} v_s \\ i_s \end{bmatrix} \tag{27.35}$$

In the systematic procedure outlined previously, it is assumed that the network exists with neither inductive cutsets nor capacitive loops so that the selection of proper tree is always guaranteed. For networks that do have these constraints, it is not possible to include all the capacitors in a tree without forming a closed path. Also, in order for a tree to contain all the nodes, some inductors will have to be included in a tree. A tree that includes independent voltage sources, some resistors, and a maximum number of capacitors but no independent current sources is called a modified proper tree. In writing a state equation for such networks, the same systematic procedure can be applied with the selection of a modified proper tree. However, if capacitor tree-branch voltages and inductive link currents are defined as the state variables, the standard (**A**, **B**, **C**, **D**) description (Equations 27.14 and 27.15) may not exist. In fact, if inductive cutsets contain independent current sources and/or capacitive loops contain independent voltage sources, the derivative of these sources will appear in the state equation and the general equation is of the form

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}_1\mathbf{u} + \mathbf{B}_2\dot{\mathbf{u}} \tag{27.36}$$

where $\mathbf{B}_1$ and $\mathbf{B}_2$ are $n \times r$ matrices and **A**, **x**, and **u** are defined as before. To recast Equation 27.36 into the standard form, it is necessary to redefine.

$$\mathbf{z} = \mathbf{x} - \mathbf{B}_2\mathbf{u} \tag{27.37}$$

as new state variables. Substituting Equation 27.37 into 27.36, yields

$$\dot{\mathbf{z}} = \mathbf{A}\mathbf{z} + \mathbf{B}\mathbf{u} \tag{27.38}$$

where

$$\mathbf{B} = \mathbf{B}_1 + \mathbf{A}\mathbf{B}_2 \tag{27.39}$$

It is noted from Equation 27.37, the new state variables represent a linear combination of sources and capacitor voltages or inductor currents which, except for the mathematical convenience, may not have sound physical significance. To avoid such state variables and transformation (Equation 27.37), Step 4 of the systematic procedure described earlier needs to be modified. By defining state variables as the algebraic sum of capacitor charges in the fundamental cutset associated with each of the capacitor tree branches, and the algebraic sum of inductor fluxes in the fundamental loop associated with each of the inductive links, the resulting state equation will be in the standard form. The preceding generalizations are illustrated by the following two examples.

Example 27.5

As a simple illustration, consider the same circuits given in Figure 27.2, where the constant DC voltage source E is replaced by a time-varying source $e(t)$. It can easily be demonstrated that the equation describing the circuit now becomes

$$\frac{dv_{C_1}(t)}{dt} = -\frac{1}{R(C_1 + C_2)}v_{C_1} + \frac{1}{R(C_1 + C_2)}v_{in}(t) + \frac{C_2}{R(C_1 + C_2)}\frac{de(t)}{dt} \tag{27.40}$$

The preceding equation is the same as the state Equation 27.4 with the exception of an additional term involving the first-order derivative of source $e(t)$. Equation 27.40 is clearly not the standard state equation described in Equation 27.41 with capacitor voltage v_{C_1} defined as the state variable.

Example 27.6

As another illustration, consider the circuit shown in Figure 27.5 which consists of an inductive cutset $\{L_1, L_2, i_s\}$ and a capacitive loop (C_1, v_{s_2}, C_2). The state equations are determined from the systematic procedure by first using the transformation (Equation 27.37) and then by defining the algebraic sum of charges and fluxes as state variables.

Step 1: The directed graph of the circuit is shown in Figure 27.6 where branches denoted by v_{s_1}, v_{s_2}, C_1, R_2, and L_2 are selected to form a modified proper tree.

Step 2: The fundamental cutset associated with C_1 consists of branches R_1, C_1, L_1, i_s, C_2, and R_3. Applying KCL to this cutset yields

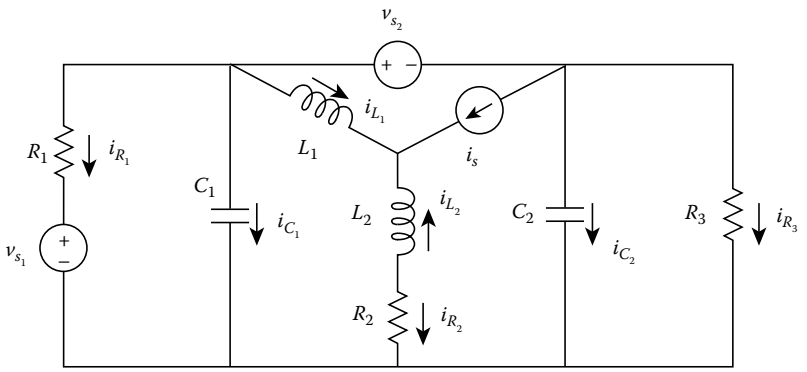

FIGURE 27.5 Circuit with a capacitive loop and an inductive cutset.

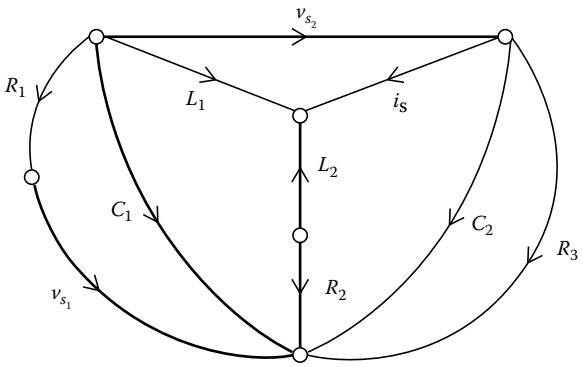

FIGURE 27.6 Directed graph associated with the circuit of Figure 27.5.

$$i_{C_1} = -i_{R_1} - i_{L_1} - i_s - i_{C_2} - i_{R_3} \tag{27.41}$$

Step 3: The fundamental loop equation associated with the inductive link L_1 is given by

$$v_{L_1} = v_{C_1} + v_{L_2} - v_{R_2} \tag{27.42}$$

where the link voltage v_{L_1} has been expressed in terms of tree-branch voltages.

Step 4: In the first illustration, the tree-branch capacitor voltage v_{C_1} and the inductive link current i_{L_1} are defined as the state variables.

Step 5: The branch relation and the remaining two fundamental equations are grouped into the following three sets:

Resistor equations:

$$v_{R_1} + v_{s_1} - v_{C_1} = 0 \tag{27.43}$$

$$v_{R_1} = R_1 i_{R_1} \tag{27.44}$$

$$i_{R_2} - i_{L_1} - i_s = 0 \tag{27.45}$$

$$v_{R_2} = R_2 i_{R_2} \tag{27.46}$$

$$v_{R_3} - v_{C_1} + v_{s_2} = 0 \tag{27.47}$$

$$v_{R_3} = R_3 i_{R_3} \tag{27.48}$$

Inductor equations:

$$i_{L_2} + i_{L_1} + i_s = 0 \tag{27.49}$$

$$\phi_{L_1} = L_1 i_{L_1} \quad \text{or} \quad v_{L_1} = L_1 \frac{\mathrm{d}i_{L_1}}{\mathrm{d}t} \tag{27.50}$$

$$\phi_{L_2} = L_2 i_{L_2} \quad \text{or} \quad v_{L_2} = L_2 \frac{\mathrm{d}i_{L_2}}{\mathrm{d}t} \tag{27.51}$$

Capacitor equations:

$$v_{C_2} - v_{C_1} + v_{s_2} = 0 \tag{27.52}$$

$$q_1 = C_1 v_{C_1} \quad \text{or} \quad i_{C_1} = C_1 \frac{\mathrm{d}v_{C_1}}{\mathrm{d}t} \tag{27.53}$$

$$q_2 = C_2 v_{C_2} \quad \text{or} \quad i_{C_2} = C_2 \frac{\mathrm{d}v_{C_2}}{\mathrm{d}t} \tag{27.54}$$

For this example, the nonstate variables are identified as i_{R_1}, v_{R_2}, i_{R_3}, v_{L_2}, and i_{C_2}, from Equations 27.41 and 27.42. These variables are now solved from the corresponding group of equations in terms of state variables and independent sources:

$$i_{R_1} = \frac{1}{R_1}(v_{C_1} - v_{s_1}) \tag{27.55}$$

$$v_{R_2} = R_2(i_{L_1} + i_s) \tag{27.56}$$

$$i_{R_3} = \frac{1}{R_3}(v_{C_1} - v_{s_2}) \tag{27.57}$$

$$v_{L_2} = -L_2 \frac{\mathrm{d}i_{L_1}}{\mathrm{d}t} - L_2 \frac{\mathrm{d}i_s}{\mathrm{d}t} \tag{27.58}$$

$$i_{C_2} = C_2 \frac{\mathrm{d}v_{C_1}}{\mathrm{d}t} - C_2 \frac{\mathrm{d}v_{s_2}}{\mathrm{d}t} \tag{27.59}$$

Step 6: Assuming the existence of the first-order derivatives of sources with respect to time and substituting Equations 27.50, 27.53, and 27.55 through 27.59 into Equations 27.41 and 27.42 yields

$$\begin{bmatrix} \frac{\mathrm{d}v_{C_1}}{\mathrm{d}t} \\ \frac{\mathrm{d}i_{L_1}}{\mathrm{d}t} \end{bmatrix} = \begin{bmatrix} -\frac{R_1+R_3}{R_1R_3(C_1+C_2)} & -\frac{1}{C_1+C_2} \\ \frac{1}{L_1+L_2} & -\frac{R_2}{L_1+L_2} \end{bmatrix} \begin{bmatrix} v_{C_1} \\ i_{L_1} \end{bmatrix} + \begin{bmatrix} \frac{1}{R_1(C_1+C_2)} & \frac{1}{R_3(C_1+C_2)} & -\frac{1}{(C_1+C_2)} \\ 0 & 0 & -\frac{R_2}{L_1+L_2} \end{bmatrix} \begin{bmatrix} v_{s_1} \\ v_{s_2} \\ i_s \end{bmatrix} + \begin{bmatrix} 0 & \frac{C_2}{(C_1+C_2)} & 0 \\ 0 & 0 & -\frac{L_2}{L_1+L_2} \end{bmatrix} \begin{bmatrix} \frac{\mathrm{d}v_{s_1}}{\mathrm{d}t} \\ \frac{\mathrm{d}v_{s_2}}{\mathrm{d}t} \\ \frac{\mathrm{d}i_s}{\mathrm{d}t} \end{bmatrix} \tag{27.60}$$

Clearly, Equation 27.60 is not in the standard form. Applying transformation (Equation 27.37) with $x_1 = v_{C_1}$, $x_1 = i_{L_2}$, $u_1 = v_{C_1}$, $u_2 = v_{s_2}$, and $u_3 = i_s$ gives the state equation in normal form

$$\begin{bmatrix} \frac{\mathrm{d}z_1}{\mathrm{d}t} \\ \frac{\mathrm{d}z_2}{\mathrm{d}t} \end{bmatrix} = \begin{bmatrix} -\frac{R_1+R_2}{R_1R_3(C_1+C_2)} & -\frac{1}{C_1+C_2} \\ \frac{1}{L_1+L_2} & -\frac{R_2}{L_1+L_2} \end{bmatrix} \begin{bmatrix} z_1 \\ z_2 \end{bmatrix} + \begin{bmatrix} \frac{1}{R_1(C_1+C_2)} & \frac{R_1C_1-R_3C_2}{R_1R_3(C_1+C_2)^2} & -\frac{L_1}{(L_1+L_2)(C_1+C_2)} \\ 0 & \frac{C_2}{(L_1+L_2)(C_1+C_2)} & -\frac{R_2L_1}{(L_1+L_2)^2} \end{bmatrix} \times \begin{bmatrix} v_{s_1} \\ v_{s_2} \\ i_s \end{bmatrix} \tag{27.61}$$

where new state variables are defined as

$$\mathbf{z} = \begin{bmatrix} z_1 \\ z_2 \end{bmatrix} = \begin{bmatrix} v_{C_1} & -\frac{C_2}{C_1+C_2} v_{s_2} \\ i_{L_1} & +\frac{L_2}{L_1+L_2} i_s \end{bmatrix} \tag{27.62}$$

Alternatively, if the state variables are defined in Step 4 as

$$q_a = q_1 + q_2 \tag{27.63}$$

$$\phi_b = \phi_1 - \phi_2 \tag{27.64}$$

then Equations 27.41 and 27.42 become

$$\frac{dq_a}{dt} = \frac{dq_1}{dt} + \frac{dq_2}{dt} = -i_{R_1} - i_{L_1} - i_s - i_{R_3} \tag{27.65}$$

$$\frac{d\phi_b}{dt} = \frac{d\phi_1}{dt} - \frac{d\phi_2}{dt} = -v_{L_1} - v_{L_2} = v_{C_1} - v_{R_2} \tag{27.66}$$

respectively. In Step 5, the resistive link currents i_{R_1}, i_{R_3}, and the resistive tree-branch voltage V_{R_2} are solved from resistive Equations 27.43 through 27.48 in terms of inductive link currents, capacitive tree-branch voltages, and independent sources. The results are those given in Equations 27.55 through 27.57. By solving the inductor Equations 27.49, 27.50, and 27.64, inductive link current i_{L_1} is expressed as a function of state variables and independent sources:

$$i_{L_1} = \frac{1}{L_1 + L_2}(\phi_b - L_2 i_s) \tag{27.67}$$

Similarly, solving v_{C_1} from capacitor Equations 27.52 through 27.54, and 27.63, yields the capacitor tree-branch voltage

$$v_{C_1} = \frac{1}{C_1 + C_2}(q_a + C_2 v_{s_2}) \tag{27.68}$$

Finally, in Step 6, Equations 27.55 through 27.57, 27.67, and 27.68 are substituted into Equations 27.65 and 27.66 to form the state equation in normal form:

$$\begin{bmatrix} \frac{dq_a}{dt} \\ \frac{d\phi_b}{dt} \end{bmatrix} = \begin{bmatrix} -\frac{R_1+R_3}{R_1R_3(C_1+C_2)} & -\frac{1}{L_1+L_2} \\ \frac{1}{C_1+C_2} & -\frac{R_2}{L_1+L_2} \end{bmatrix} \begin{bmatrix} q_a \\ \phi_b \end{bmatrix} + \begin{bmatrix} \frac{1}{R_1} & \frac{R_1C_1-R_3C_2}{R_1R_3(C_1+C_2)} & -\frac{L_1}{(L_1+L_2)} \\ 0 & \frac{C_2}{(C_1+C_2)} & -\frac{R_2L_1}{(L_1+L_2)} \end{bmatrix} \begin{bmatrix} v_{s_1} \\ v_{s_2} \\ i_s \end{bmatrix} \tag{27.69}$$

27.3 Natural Response and State Transition Matrix

In Section 27.2, the state-variable description has been presented for linear time-invariant circuits. The response of the circuit depends on the solution of the state equation. The behavior of the circuit due to any arbitrary input sources can easily be obtained once the zero-input response or the natural response of the circuit is known. In order to find its natural response, the homogeneous state equation of the circuit.

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} \tag{27.70}$$

is considered, where independent source term $u(t)$ has been set equal to zero. The preceding state equation is analogous to the scalar equation

$$\dot{x} = ax \tag{27.71}$$

where the solution is given by

$$x(t) = e^{at}x(0) \tag{27.72}$$

for any arbitrary initial condition $x(0)$ given at $t = 0$, or

$$x(t) = e^{a(t-t_0)}x(t_0) \tag{27.73}$$

if the initial time is specified at $t = t_0$.

It is thus reasonable to assume a solution for Equation 27.70 of the form

$$\mathbf{x}(t) = e^{(t-t_0)\lambda}\mathbf{p} \tag{27.74}$$

where λ is a scalar constant and $\mathbf{p}$ is a constant n-vector. Substituting Equation 27.74 into Equation 27.70 leads to

$$\mathbf{A}\mathbf{p} = \lambda\mathbf{p} \tag{27.75}$$

Therefore, Equation 27.74 is a solution of Equation 27.70 precisely when $\mathbf{p}$ is an eigenvector of $\mathbf{A}$ associated with the eigenvalue λ. For simplicity, it is assumed that $\mathbf{A}$ has n distinct eigenvalues $\lambda_1, \lambda_2, \ldots, \lambda_n$. Because the corresponding eigenvectors denoted by $\mathbf{p}_1, \mathbf{p}_2, \ldots, \mathbf{p}_n$ are linearly independent, the general solution of Equation 27.70 can be uniquely written as a linear combination of n distinct normal modes of the form Equation 27.74:

$$\mathbf{x}(t) = c_1 e^{(t-t_0)\lambda_1}\mathbf{p}_1 + c_2 e^{(t-t_0)\lambda_2}\mathbf{p}_2 + \cdots + c_n e^{(t-t_0)\lambda_n}\mathbf{p}_n \tag{27.76}$$

where $c_1, c_2, \ldots, c_n$ are n arbitrary constants determined by the given initial conditions. Specifically,

$$\mathbf{x}(t_0) = c_1\mathbf{p}_1 + c_2\mathbf{p}_2 + \cdots + c_n\mathbf{p}_n \tag{27.77}$$

The general solution (Equation 27.76) can also be written in the form

$$\mathbf{x}(t) = e^{(t-t_0)\mathbf{A}}\mathbf{x}(t_0) \tag{27.78}$$

where the exponential function of a matrix is defined by a power series:

$$\begin{aligned} e^{(t-t_0)\mathbf{A}} &= \mathbf{I} + (t-t_0)\mathbf{A} + \frac{(t-t_0)^2}{2!}\mathbf{A}^2 + \cdots \\ &= \sum_{k=0}^{\infty} \frac{(t-t_0)^k}{k!}\mathbf{A}^k \end{aligned} \tag{27.79}$$

In fact, taking the derivative of Equation 27.78 with respect to t yields

$$\begin{aligned}\frac{d\mathbf{x}}{dt} &= \frac{d}{dt}\left[\mathbf{I} + (t-t_0)\mathbf{A} + \frac{(t-t_0)^2}{2!}\mathbf{A}^2 + \cdots\right]\mathbf{x}(t_0) \\ &= \left[\mathbf{A} + (t-t_0)\mathbf{A}^2 + \frac{(t-t_0)^2}{2!}\mathbf{A}^3 + \cdots\right]\mathbf{x}(t_0) \\ &= \mathbf{A}\left[\mathbf{I} + (t-t_0)\mathbf{A} + \frac{(t-t_0)^2}{2!}\mathbf{A}^2 + \cdots\right]\mathbf{x}(t_0) \\ &= \mathbf{A}e^{(t-t_0)\mathbf{A}}\mathbf{x}(t_0) = \mathbf{A}\mathbf{x}(t)\end{aligned} \tag{27.80}$$

Also, at $t = t_0$, Equation 27.78 gives

$$\mathbf{x}(t_0) = \mathbf{I}\mathbf{x}(t_0) = \mathbf{x}(t_0) \tag{27.81}$$

Thus, expression (Equation 27.78) satisfies both Equation 27.70 and the initial conditions and hence is the unique solution. The matrix $e^{(t-t_0)\mathbf{A}}$, usually denoted by $\mathbf{\Phi}(t-t_0)$, is called the state transition matrix or the fundamental matrix of the circuit described by Equation 27.70. The transition of the initial state $\mathbf{x}(t_0)$ to the state $\mathbf{x}(t)$ at any time t is thus governed by

$$\mathbf{x}(t) = \mathbf{\Phi}(t-t_0)\mathbf{x}(t_0) \tag{27.82}$$

where

$$\mathbf{\Phi}(t-t_0) = e^{(t-t_0)\mathbf{A}} \tag{27.83}$$

is an $n \times n$ matrix with the following properties:

$$\mathbf{\Phi}(t_0 - t_0) = \mathbf{\Phi}(0) = \mathbf{I} \tag{27.84}$$

$$\mathbf{\Phi}(t+\tau) = \mathbf{\Phi}(t)\mathbf{\Phi}(\tau) \tag{27.85}$$

$$\mathbf{\Phi}(t_2 - t_1)\mathbf{\Phi}(t_1 - t_0) = \mathbf{\Phi}(t_2 - t_0) \tag{27.86}$$

$$\mathbf{\Phi}(t_2 - t_1) = \mathbf{\Phi}^{-1}(t_1 - t_2) \tag{27.87}$$

$$\mathbf{\Phi}^{-1}(t) = \mathbf{\Phi}(-t) \tag{27.88}$$

Once the state transition matrix is known, the solution of the state equation can be obtained from Equation 27.82. In general, it is rather difficult to obtain a closed-form solution from the infinite series representation of the state transition matrix. The formula given by Equation 27.79 is useful only if numerical solution by digital computer is desired. Several methods are available for finding a closed form expression for $\mathbf{\Phi}(t-t_0)$. The relationship between solution (Equation 27.76) and the state transition matrix is first established.

For simplicity, let $t_0 = 0$. According to Equation 27.82, the first column of $\mathbf{\Phi}(t)$ is the solution of the state equation generated by the initial condition

$$\mathbf{x}(0) = \mathbf{x}^{(1)}(0) = \begin{bmatrix} 1 \\ 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix} \tag{27.89}$$

Indeed, if Equation 27.89 is substituted into Equation 27.82, then

$$\mathbf{x}(t) \triangleq \mathbf{x}^{(1)}(t) = \mathbf{\Phi}(t)\mathbf{x}^{(1)}(0) = \begin{bmatrix} \phi_{11} & \phi_{12} & \cdots & \phi_{1n} \\ \phi_{21} & \phi_{22} & \cdots & \phi_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ \phi_{n1} & \phi_{n2} & \cdots & \phi_{nn} \end{bmatrix} \begin{bmatrix} 1 \\ 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix} = \begin{bmatrix} \phi_{11} \\ \phi_{21} \\ \vdots \\ \phi_{n1} \end{bmatrix} \tag{27.90}$$

which can be computed from Equation 27.76 and the arbitrary constants $c_i = \Delta c_i^{(1)}$ for $i = 1, 2, \ldots, n$ are solved from Equation 27.77. The first column of the state transition matrix is thus given by

$$\begin{bmatrix} \phi_{11} \\ \phi_{21} \\ \vdots \\ \phi_{n1} \end{bmatrix} = c_1^{(1)} e^{\lambda_1 t}\mathbf{P}_1 + c_2^{(1)} e^{\lambda_2 t}\mathbf{P}_2 + \cdots + c_n^{(1)} e^{\lambda_n t}\mathbf{P}_n \tag{27.91}$$

Instead of Equation 27.89, if

$$\mathbf{x}(0) = \mathbf{x}^{(2)}(0) = \begin{bmatrix} 0 \\ 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix} \tag{27.92}$$

is used, the arbitrary constants $c_1, c_2, \ldots, c_n$ denoted by $c_1^{(2)}, c_2^{(2)}, \ldots c_n^{(2)}$ are solved. Then, the second column of $\mathbf{\Phi}(t)$ is given

$$\begin{bmatrix} \phi_{12} \\ \phi_{22} \\ \vdots \\ \phi_{n2} \end{bmatrix} = c_1^{(2)} e^{\lambda_1 t}\mathbf{P}_1 + c_2^{(2)} e^{\lambda_2 t}\mathbf{P}_2 + \cdots + c_n^{(2)} e^{\lambda_n t}\mathbf{P}_n \tag{27.93}$$

In a similar manner, the remaining columns of $\mathbf{\Phi}(t)$ are determined.

The closed form expression for state transition matrix can also be obtained by means of a similarity transformation of the form

$$\mathbf{AP} = \mathbf{PJ}$$

or

$$\mathbf{J} = \mathbf{P}^{-1}\mathbf{AP} \tag{27.94}$$

where $\mathbf{P}$ is a nonsingular matrix. If the eigenvalues of $\mathbf{A}$, $\lambda_1, \lambda_2, \ldots, \lambda_n$, are assumed to be distinct, $\mathbf{J}$ is a diagonal matrix with eigenvalues on its main diagonal:

$$\mathbf{J} = \begin{bmatrix} \lambda_1 & 0 & \cdots & 0 \\ 0 & \lambda_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \lambda_n \end{bmatrix} \tag{27.95}$$

and

$$\mathbf{P} = \begin{bmatrix} \mathbf{p}_1 & \mathbf{p}_2 & \cdots & \mathbf{p}_n \end{bmatrix} \tag{27.96}$$

where $\mathbf{p}_i$'s, for $i = 1, 2, \ldots n$, are the corresponding eigenvectors associated with the eigenvalue λ_i, for $i = 1, 2, \ldots, n$. Substituting Equation 27.94 into 27.83, the state transition matrix can now be written in the closed form

$$\begin{aligned} \mathbf{\Phi}(t - t_0) = e^{(t-t_0)\mathbf{A}} &= e^{(t-t_0)\mathbf{P}\mathbf{J}\mathbf{P}^{-1}} \\ &= \mathbf{P}e^{(t-t_0)J}\mathbf{P}^{-1} \end{aligned} \tag{27.97}$$

where

$$e^{(t-t_0)\mathbf{J}} = \begin{bmatrix} e^{(t-t_0)\lambda_1} & 0 & \cdots & 0 \\ 0 & e^{(t-t_0)\lambda_2} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & e^{(t-t_0)\lambda_n} \end{bmatrix} \tag{27.98}$$

is a diagonal matrix.

In the more general case, where the **A** matrix has repeated eigenvalues, a diagonal matrix of the form Equation 27.95 may not exist. However, it can be shown that any square matrix **A** can be transformed by a similarity transformation to the Jordan canonical form

$$\mathbf{J} = \begin{bmatrix} \mathbf{J}_1 & 0 & \cdots & 0 \\ 0 & \mathbf{J}_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \mathbf{J}_l \end{bmatrix} \tag{27.99}$$

where $\mathbf{J}_i$'s, for $i = 1, 2, \ldots, l$ are known as Jordan blocks. Assuming that **A** has m distinct eigenvalues, λ_i, with multiplicity r_i, for $i = 1, 2, \ldots, m$, and $r_1 + r_2 + \cdots + r_m = n$. Associated with each λ_i there may exist several Jordan blocks. A Jordon block is a block diagonal matrix of order $k \times k (k \leq r_i)$ with λ_i on its main diagonal, all 1's on the superdiagonal, and zeros elsewhere. In the special case when $k = 1$, the Jordan block reduces to a 1×1 scalar block with only one element λ_i.

In fact, the number of Jordan blocks associated with the eigenvalue λ_i is equal to the dimension of the null space of $(\lambda_i \mathbf{I} - \mathbf{A})$. For each $k \times k$ Jordan block $\mathbf{J}(k)$ associated with the eigenvalue λ_i of the form

$$\mathbf{J}(k) = \begin{bmatrix} \lambda_i & 1 & 0 & 0 & \cdots & 0 \\ 0 & \lambda_i & 1 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & 1 \\ 0 & 0 & 0 & 0 & \cdots & \lambda_i \end{bmatrix} \tag{27.100}$$

the exponential function of $\mathbf{J}(k)$ takes the form

$$e^{(t-t_0)\mathbf{J}(k)} = \begin{bmatrix} 1 & t & \frac{t^2}{2!} & \cdots & \frac{t^{k-1}}{(k-1)!} \\ 0 & 1 & t & \cdots & \frac{t^{k-2}}{(k-2)!} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \end{bmatrix} e^{(t-t_0)\lambda_i} \tag{27.101}$$

and the corresponding k columns of $\mathbf{P}$, known as the generalized eigenvectors, satisfy the equations

$$\begin{aligned}(\lambda_i\mathbf{I}-\mathbf{A})\mathbf{p}_i^{(1)} &= 0\\ (\lambda_i\mathbf{I}-\mathbf{A})\mathbf{p}_i^{(2)} &= -\mathbf{p}_i^{(1)}\\ &\vdots\\ (\lambda_i\mathbf{I}-\mathbf{A})\mathbf{p}_i^{(k)} &= -\mathbf{p}_i^{(k-1)}\end{aligned} \tag{27.102}$$

The closed form expression $\mathbf{\Phi}(t-t_0)$ for this general case now becomes

$$\mathbf{\Phi}(t-t_0) = \mathbf{P}e^{(t-t_0)\mathbf{J}}\mathbf{P}^{-1} \tag{27.103}$$

where

$$e^{(t-t_0)\mathbf{J}} = \begin{bmatrix} e^{(t-t_0)\mathbf{J}_1} & 0 & \cdots & 0\\ 0 & e^{(t-t_0)\mathbf{J}_2} & \cdots & 0\\ \vdots & \vdots & \ddots & \vdots\\ 0 & 0 & \cdots & e^{(t-t_0)\mathbf{J}_l}\end{bmatrix} \tag{27.104}$$

and each of the $e^{(t-t_0)\mathbf{J}_i}$, for $i=1, 2, \ldots, l$, is of the form given in Equation 27.101.

The third approach for obtaining closed form expression for the state transition matrix involves the Laplace transform technique. Taking the Laplace transform of Equation 27.70 yields

$$s\mathbf{X}(s)-\mathbf{x}(0) = \mathbf{A}\mathbf{X}(s)$$

or

$$\mathbf{X}(s) = (s\mathbf{I}-\mathbf{A})^{-1}\mathbf{x}(0) \tag{27.105}$$

where $(s\mathbf{I}-\mathbf{A})^{-1}$ is known as the resolvent matrix. The time response

$$\mathbf{x}(t) = +^{-1}\left[(s\mathbf{I}-\mathbf{A})^{-1}\right]\mathbf{x}(0) \tag{27.106}$$

is obtained by taking the inverse Laplace transform of Equation 27.105. It is observed by comparing Equation 27.106 to Equations 27.82 and 27.83 with $t_0=0$ that

$$\mathbf{\Phi}(t) = e^{t\mathbf{A}} = \mathcal{L}^{-1}\left[(s\mathbf{I}-\mathbf{A})^{-1}\right] \tag{27.107}$$

By way of illustration, the following example is considered. The state transition matrix is obtained by using each of the three approaches presented previously.

Example 27.7

Consider the parallel *RLC* circuit in Figure 27.7. The state equation of the circuit is obtained as

$$\begin{bmatrix}\frac{di_L}{dt}\\ \frac{dv_C}{dt}\end{bmatrix} = \begin{bmatrix}0 & \frac{1}{L}\\ -\frac{1}{C} & -\frac{1}{RC}\end{bmatrix}\begin{bmatrix}i_L\\ v_C\end{bmatrix} + \begin{bmatrix}0\\ \frac{1}{C}\end{bmatrix}i_s \tag{27.108}$$

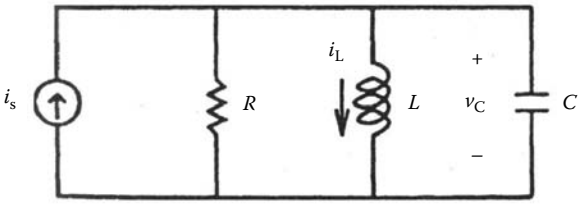

FIGURE 27.7 Parallel RLC circuit.

With $R = 2/3\ \Omega$, $L = 1\ H$, and $C = 1/2\ F$, the **A** matrix becomes

$$\mathbf{A} = \begin{bmatrix} 0 & 1 \\ -2 & -3 \end{bmatrix} \tag{27.109}$$

(a) *Normal mode approach:* The eigenvalues and the corresponding eigenvectors of the **A** are found to be

$$\lambda_1 = -1 \quad \lambda_2 = -2 \tag{27.110}$$

and

$$\mathbf{p}_1 = \begin{bmatrix} 1 \\ -1 \end{bmatrix}, \quad \mathbf{p}_2 = \begin{bmatrix} 1 \\ -2 \end{bmatrix} \tag{27.111}$$

Therefore, the natural response of the circuit is given as a linear combination of the two distinct normal modes as

$$\begin{bmatrix} i_L(t) \\ v_C(t) \end{bmatrix} = c_1 e^{-t} \begin{bmatrix} 1 \\ -1 \end{bmatrix} + c_2 e^{-2t} \begin{bmatrix} 1 \\ -2 \end{bmatrix} \tag{27.112}$$

When evaluated at $t = 0$, Equation 27.112 becomes

$$\begin{bmatrix} i_L(0) \\ v_C(0) \end{bmatrix} = \begin{bmatrix} c_1 + c_2 \\ -c_1 - 2c_2 \end{bmatrix} \tag{27.113}$$

In order to find the first column of $\mathbf{\Phi}(t)$, it is assumed that

$$\begin{bmatrix} i_L(0) \\ v_C(0) \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \tag{27.114}$$

With this initial condition, the solution of Equation 27.113 becomes

$$c_1 \stackrel{\Delta}{=} c_1^{(1)} = 2 \quad \text{and} \quad c_2 \stackrel{\Delta}{=} c_2^{(1)} = -1 \tag{27.115}$$

Substituting Equation 27.115 into 27.112 results in the first column of $\mathbf{\Phi}(t)$:

$$\begin{bmatrix} \phi_{11} \\ \phi_{21} \end{bmatrix} = \begin{bmatrix} 2e^{-t} - e^{-2t} \\ -2e^{-t} + 2e^{-2t} \end{bmatrix} \tag{27.116}$$

Similarly, for

$$\begin{bmatrix} i_L(0) \\ v_C(0) \end{bmatrix} = \begin{bmatrix} 0 \\ 1 \end{bmatrix} \tag{27.117}$$

constants c_1 and c_2 are solved from Equation 27.113 to give

$$c_1 \stackrel{\Delta}{=} c_2^{(2)} = 1 \quad \text{and} \quad c_2 \stackrel{\Delta}{=} c_2^{(2)} = -1 \tag{27.118}$$

The second column of $\mathbf{\Phi}(t)$:

$$\begin{bmatrix} \phi_{12} \\ \phi_{22} \end{bmatrix} = \begin{bmatrix} e^{-t} - e^{-2t} \\ -e^{-t} + 2e^{-2t} \end{bmatrix} \tag{27.119}$$

is obtained by substituting Equation 27.118 into 27.112. Combining Equations 27.116 and 27.119 yields the state transition matrix in closed form

$$\mathbf{\Phi}(t) = \begin{bmatrix} 2e^{-t} - e^{-2t} & e^{-t} - e^{-2t} \\ -2e^{-t} + 2e^{-2t} & -e^{-t} + 2e^{-2t} \end{bmatrix} \tag{27.120}$$

(b) *Similarity transformation method:* The eigenvalues are distinct, so the nonsingular transformation **P** is constructed from Equation 27.96 by the eigenvectors of **A**:

$$\mathbf{P} = [\,\mathbf{p}_1 \quad \mathbf{p}_2\,] = \begin{bmatrix} 1 & 1 \\ -1 & -2 \end{bmatrix} \tag{27.121}$$

with

$$\mathbf{P}^{-1} = \begin{bmatrix} 2 & 1 \\ -1 & -1 \end{bmatrix} \tag{27.122}$$

Substituting λ_1, λ_2, and **P** into Equations 27.97 and 27.98 yields the desired state transition matrix

$$\begin{aligned} \mathbf{\Phi}(t) = \mathbf{P}e^{\mathbf{J}t}\mathbf{P}^{-1} &= \begin{bmatrix} 1 & 1 \\ -1 & -2 \end{bmatrix} \begin{bmatrix} e^{-t} & 0 \\ 0 & e^{-2t} \end{bmatrix} \begin{bmatrix} 2 & 1 \\ -1 & -1 \end{bmatrix} \\ &= \begin{bmatrix} 2e^{-t} - e^{-2t} & e^{-t} - e^{-2t} \\ -2e^{-t} + 2e^{-2t} & -e^{-t} + 2e^{-2t} \end{bmatrix} \end{aligned} \tag{27.123}$$

which is in agreement with Equation 27.120.

(c) *Laplace transform technique:* The state transition matrix can also be computed in the frequency domain from Equation 27.107. The resolvent matrix is

$$\begin{aligned} (s\mathbf{I} - \mathbf{A})^{-1} &= \begin{bmatrix} s & -1 \\ 2 & s+3 \end{bmatrix}^{-1} \\ &= \begin{bmatrix} \frac{s+3}{(s+1)(s+2)} & \frac{1}{(s+1)(s+2)} \\ \frac{-2}{(s+1)(s+2)} & \frac{s}{(s+1)(s+2)} \end{bmatrix} \\ &= \begin{bmatrix} \frac{2}{s+1} - \frac{1}{s+2} & \frac{1}{s+1} - \frac{1}{s+2} \\ \frac{2}{s+1} + \frac{2}{s+2} & -\frac{1}{s+1} + \frac{2}{s+2} \end{bmatrix} \end{aligned} \tag{27.124}$$

where partial-fraction expansion has been applied. Taking the inverse Laplace transform of Equation 27.124 yields the same closed form expression as given previously in Equation 27.120 for $\mathbf{\Phi}(t)$.

27.4 Complete Response

When independent sources are present in the circuit, the complete response depends on the initial states of the circuits as well as the input sources. It is well-known that the complete response is the sum of the zero-input (or natural) response and the zero-state (or forced) response and satisfies the nonhomogeneous state equation

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{u}(t) \tag{27.125}$$

subject to the given initial condition $\mathbf{x}(t_0) = \mathbf{x}_0$. Equation 27.125 is again analogous to the scalar equation

$$\dot{x}(t) = ax(t) + bu(t) \tag{27.126}$$

which has the unique solution of the form

$$x(t) = e^{(t-t_0)a}x(t_0) + \int_{t_0}^{t} e^{(t-\tau)a}bu(\tau)\ \mathrm{d}\tau \tag{27.127}$$

It is thus assumed that the solution to the state equation is given by

$$\begin{aligned}\mathbf{x}(t) &= e^{(t-t_0)\mathbf{A}}\mathbf{x}(t_0) + \int_{t_0}^{t} e^{(t-\tau)\mathbf{A}}\mathbf{B}\mathbf{u}(\tau)\ \mathrm{d}\tau \\ &= \mathbf{\Phi}(t-t_0)\mathbf{x}(t_0) + \int_{t_0}^{t} (t-\tau)\mathbf{B}\mathbf{u}(\tau)\ \mathrm{d}\tau\end{aligned} \tag{27.128}$$

Indeed, one can show by direct substitution that Equation 27.128 satisfies the state Equation 27.125. Differentiating both sides of Equation 27.128 with respect to t yields

$$\begin{aligned}\dot{\mathbf{x}}(t) &= \frac{d}{\mathrm{d}t}\mathbf{\Phi}(t-t_0)\mathbf{x}(t_0) + \frac{d}{\mathrm{d}t}\int_{t_0}^{t}\mathbf{\Phi}(t-\tau)\mathbf{B}\mathbf{u}(\tau)\ \mathrm{d}\tau \\ &= \mathbf{A}\mathbf{\Phi}(t-t_0)\mathbf{x}(t_0) + \int_{t_0}^{t}\frac{d}{\mathrm{d}t}\mathbf{\Phi}(t-\tau)\mathbf{B}\mathbf{u}(\tau)\ \mathrm{d}\tau + \mathbf{\Phi}(t-t)\mathbf{B}\mathbf{u}(t) \\ &= \mathbf{A}\mathbf{\Phi}(t-t_0)\mathbf{x}(t_0) + \int_{t_0}^{t}\mathbf{A}\mathbf{\Phi}(t-\tau)\mathbf{B}\mathbf{u}(\tau)\mathrm{d}\tau + \mathbf{B}\mathbf{u}(t) \\ &= \mathbf{A}\left[\mathbf{\Phi}(t-t_0)\mathbf{x}(t_0) + \int_{t_0}^{t}\mathbf{\Phi}(t-\tau)\mathbf{B}\mathbf{u}(\tau)\mathrm{d}\tau\right] + \mathbf{B}\mathbf{u}(t) \\ &= \mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{u}(t)\end{aligned} \tag{27.129}$$

Also, at $t = t_0$, Equation 27.128 becomes

$$\begin{aligned}\mathbf{x}(t_0) &= \mathbf{\Phi}(t_0 - t_0)\mathbf{x}(t_0) + \int_{t_0}^{t_0} \mathbf{\Phi}(t_0 - \tau)\mathbf{B}\mathbf{u}(\tau)\mathrm{d}\tau \\ &= \mathbf{I}\mathbf{x}(t_0) + \mathbf{0} = \mathbf{x}(t_0)\end{aligned} \tag{27.130}$$

The assumed solution (Equation 27.128) thus satisfies both the state Equation 27.125 and the given initial condition. Hence, $\mathbf{x}(t)$ as given by Equation 27.128 is the unique solution.

It is observed from Equation 27.128 that if $\mathbf{u}(t)$ is set to zero, the solution reduces to the zero-input response or the natural response given in Equation 27.82. On the other hand, if the original circuit is relaxed, i.e., $\mathbf{x}(t_0) = 0$, the solution represented by the convolution integral, the second term on the right-hand side of Equation 27.128, is the forced response on the zero-state response. Thus, Equation 27.128 verifies the fact that the complete response is the sum of the zero-input response and the zero-state response. The previous result is illustrated by means of the following example.

Example 27.8

Consider again the same circuit given in Example 27.7, where the input current source is assumed to be a unit step function applied to the circuit at $t = 0$.

The state equation of the circuit is found from Equation 27.108 to be

$$\begin{bmatrix} \frac{\mathrm{d}i_L}{\mathrm{d}t} \\ \frac{\mathrm{d}v_C}{\mathrm{d}t} \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -2 & -3 \end{bmatrix} \begin{bmatrix} i_L \\ v_C \end{bmatrix} + \begin{bmatrix} 0 \\ 2 \end{bmatrix} i_s(t) \tag{27.131}$$

where the state transition matrix $\mathbf{\Phi}(t)$ is given in Equation 27.120.

The zero-state response for $t > 0$ is obtained by evaluating the convolution integral indicated in Equation 27.128:

$$\begin{aligned}\int_0^t \mathbf{\Phi}(t - \tau)\mathbf{B}\mathbf{u}(\tau)\mathrm{d}\tau &= \int_0^t \begin{bmatrix} 2e^{-(t-\tau)} - e^{-2(t-\tau)} & e^{-(t-\tau)} - e^{-2(t-\tau)} \\ -2e^{-(t-\tau)} + 2e^{-2(t-\tau)} & -e^{-(t-\tau)} + 2e^{-2(t-\tau)} \end{bmatrix} \begin{bmatrix} 0 \\ 2 \end{bmatrix} \mathrm{d}\tau \\ &= 2\int_0^t \begin{bmatrix} e^{-(t-\tau)} - e^{-2(t-\tau)} \\ -e^{-(t-\tau)} + 2e^{-2(t-\tau)} \end{bmatrix} \mathrm{d}\tau = \begin{bmatrix} 1 - 2e^{-t} + e^{-2t} \\ 2e^{-t} - 2e^{-2t} \end{bmatrix}\end{aligned} \tag{27.132}$$

By adding the zero-input response represented by $\mathbf{\Phi}(t)\mathbf{x}(0)$ to Equation 27.132, the complete response for any given initial condition $\mathbf{x}(0)$ becomes

$$\begin{bmatrix} i_L(t) \\ v_C(t) \end{bmatrix} = \begin{bmatrix} 2e^{-t} - e^{-2t} & e^{-t} - e^{-2t} \\ -2e^{-t} + 2e^{-2t} & -e^{-t} + 2e^{-2t} \end{bmatrix} \begin{bmatrix} i_L(0) \\ v_C(0) \end{bmatrix} + \begin{bmatrix} 1 - 2e^{-t} + 2e^{-2t} \\ 2e^{-t} - 2e^{-2t} \end{bmatrix} \tag{27.133}$$

for $t > 0$.

Chirp z-transform algorithm, 5-17
Circuit elements
characterization
dynamic model, 13-9–13-10
formal methods, 13-3–13-4
memristive element, 13-8
reactive element, 13-7–13-8
resistive element, 13-4–13-7
connecting multiport (CMP)
linear circuit, KCL and KVL, 13-10–13-11
nonlinear circuit and partition, 13-1–13-2
lumped circuit approximation, 13-1
tableau formulation, 13-11
CMOS, *see* Complementary metal oxide semiconductor
Coates' gain formula
coefficient matrix, 8-7–8-8
n×n matrix, 8-6–8-7
nonsingular matrix, 8-5
topological formula, 8-4
Common-mode rejection ratio (CMRR), 15-27
common-mode gain, 16-16–16-17
differential and noninverting configuration, 16-17
total output voltage, 16-17–16-18
Continuous-time Fourier transform
convergence, 4-10–4-11
CT and the DT sampled model, 4-5–4-6
exponential Fourier series, 4-7–4-8
Fourier spectrum, 4-6
periodic continuous-time signals, 4-11
properties, 4-2–4-5
trigonometric expansion, 4-8–4-10
Continuous-time signals
convergence, 4-10–4-11
CT and the DT sampled model, 4-5–4-6
exponential Fourier series, 4-7–4-8
Fourier spectrum, 4-6
periodic continuous-time signals, 4-11
properties, 4-2–4-5

trigonometric expansion, 4-8–4-10
Continuous wavelet transform (CWT), 6-15
Controlled circuit elements
controlled sources
CCCS and CCVS, 14-4–14-7
circuit representation, 14-1, 14-2
VCCS and VCVS, 14-1–14-4
signal converters
circulator, 14-12–14-15
current negative impedance converter, 14-11–14-12
definition, 14-15
gyrator, 14-8–14-10
network ports, 14-7–14-8
voltage negative impedance converter, 14-11
Cooley–Tukey FFT, 10-11
Cored inductor
advanced inductor, 11-56
closed magnetic circuit
air gap, 11-51–11-53
apparent permeability, 11-54
equivalent dimensions and parameters, 11-50–11-51
incomplete coupling, 11-53
joint effect, 11-54–11-55
leakage coefficient, 11-54
open magnetic circuit, 11-55–11-56
parameters, 11-49–11-50
power loss
definition, 11-56–11-57
dielectric loss, 11-59–11-60
magnetic loss, 11-57–11-59
resistive loss, 11-57
sinusoidally excited inductor, 11-60
Cramer's rule, 1-19
Critical temperature resistors (CTR), 11-10
Current-controlled current source (CCCS)
circuit implementation, 14-7
circuit schematic symbol, 18-3, 18-4
equivalent circuit, 14-6
SPICE format, 14-6
Current-controlled voltage source (CCVS), 14-4
circuit implementation, 14-5–14-6
circuit schematic symbol, 18-3
SPICE format, 14-5
Current feedback op-amp (CFOA)
bipolar realization, 17-5
buffer and CFOA implementation
frequency response, 17-7, 17-9
open-loop transimpedance, 17-7, 17-9
output impedance characteristics, 17-7–17-8
schematics and layout plot, 17-6–17-7
step response and harmonic distortion, 17-11
voltage buffer performance, 17-7
closed-loop gain, 17-3–17-4
CMOS compound device, 17-5
macromodel, 17-2–17-3
total impedance, 17-3
Current-mode op-amp
closed-loop characteristics, 16-35–16-36
dynamics, 16-37–16-38
higher-order effects, 16-38–16-40
Cutset-loop circuit analysis
analogous problem, mesh analysis, 19-31
circuit representation, 19-39–19-41
failure, nodal analysis, 19-30–19-31
fundamental cutset and loop, 19-32
graphical representation, 19-31–19-32
KCL equation, 19-32–19-34
KVL equation, 19-34
norator, 19-35–19-36
nullator and equivalent subcircuit, 19-37
passive element and equivalent circuits, 19-36–19-37
three-terminal/two-port element, 19-37–19-39
two-terminal element, 19-35–19-40

D

Determinant decision diagrams (DDD)
matrix determinant and representation, 25-24–25-25
nodal analysis, 25-23–25-24
vertex and vertex ordering, 25-24
Differential-input op-amp circuit, 21-7
Digital filter banks
basis function, 6-29–6-30
half-band filter, 6-27
paraunitary filter bank
parametrization, 6-27
reconstruction system, 6-25–6-27
polyphase representation, 6-24–6-25
subband reconstruction
conjugate quadrature filter, 6-23–6-24
PR property, 6-23
tree-structured system, 6-28–6-29
two-channel filter bank, 6-22
Digital filters
continuous-time frequency response, 10-15
discrete-time frequency response, 10-15–10-16
magnitude response, 10-16
quadrantal and octagonal symmetry, 10-29–10-30
rotational and diagonal symmetry, 10-30
Dirac delta function
definition, 3-42–3-43
doublet signal, 3-44
impulse function, 3-43
Discrete Fourier transform (DFT), 25-16
FFT algorithm
applications, 4-19
ordered inputs and bit-reversed outputs, 4-18–4-19
types and development, 4-17
properties, 4-15–4-17

Discrete-time Fourier transform (DTFT)
vs. CT spectra, 4-14–4-15
DTFT pairs
definition and bilateral *z*-transform, 4-12
types, 4-13
properties, 4-13–4-14
Doubly terminated passive filter, 21-4

E

Eigenvalues
inverse matrix, 1-18
singular-value decomposition (SVD), 1-17
Electrical circuit
classifications
active *vs.* passive, 18-12
linear *vs.* nonlinear, 18-11–18-12
lumped *vs.* distributed, 18-13–18-15
time-varying *vs.* time-invariant, 18-12–18-13
current polarity
charge transport, 18-5–18-6
current flow, 18-4–18-5
energy and voltage, 18-7–18-8
power
calculations, 18-8–18-9
conversation, 18-8–18-9
schematic symbols
controlled sources, 18-2–18-4
multiterminal elements, 18-1–18-2
two-terminal elements, 18-1, 18-2
voltage-mode operational amplifier, 18-4, 18-5
Electromagnetic interference (EMI), 11-49
Energetic power capacitor, 11-28, 11-29
Equivalence transformation, 1-14–1-15
Equivalent series inductance (ESI), 11-34
Equivalent series resistance (ESR), 11-25
Eternal signals, 26-3–26-4

F

Fast Fourier transform (FFT), 25-17
algorithms
applications, 4-19
ordered inputs and bit-reversed outputs, 4-18–4-19
types and development, 4-17
centrosymmetry, 10-13
quadrantal symmetry, 10-14
symmetry-based 1-D FFT, 10-11–10-12
Ferrodielectric capacitor, 11-31–11-32
Filter banks
digital filter banks
basis function, 6-29–6-30
half-band filter, 6-27
paraunitary properties, 6-25–6-27
polyphase representation, 6-24–6-25
subband construction, 6-22–6-24
tree-structured system, 6-28–6-29
two-channel filter bank, 6-22
paraunitary filter banks
dilation equation application, 6-63–6-64
infinite product convergence, 6-64–6-65
orthonormal wavelet basis, 6-65–6-70
parametrization, 6-27
wavelet tight frames, 6-70–6-71
synthesis and reconstruction, 6-13–6-14
time–frequency representation, 6-13
wavelet function design, 6-14–6-15
Filter transfer function
all-pole transfer function, 21-20
differential-input op-amp circuit, 21-17
dummy branch insertion, 21-13
four op-amp circuit, 21-18–21-19
gain function, 21-12–21-13
lowpass filter specifications, 21-19
Mason's gain formula, 21-12
RC-op-amp circuits, 21-14–21-15
state variable biquad, 21-19–21-20
transfer voltage ratio, 21-11
two op-amp circuit realizations, 21-15–21-16
First-order circuits, time domain analysis
network time constant, 26-10
transfer functions, 26-6–26-7
transient and steady-state responses, 26-9–26-10
zero-input response, 26-7–26-8
zero-state response, 26-8–26-9
Fixed capacitor, 11-26–11-27
Fixed resistor
chip resistor, 11-6, 11-7
dynamic tolerance Δ and resistor class, 11-2–11-3, 11-4
high-ohmic, high-voltage resistor, 11-6
high-power resistor, 11-6–11-7
resistive network, 11-5–11-6
temperature coefficient of resistance (TCR), 11-3, 11-5
Fourier transform
adaptive fault tolerance (AFT), 4-27–4-28
complex Fourier transform, 4-6–4-7
continuous-time signals
convergence, 4-10–4-11
CT and the DT sampled model, 4-5–4-6
exponential Fourier series, 4-7–4-8
Fourier spectrum, 4-6
periodic continuous-time signals, 4-11
properties, 4-2–4-5
trigonometric expansion, 4-8–4-10
discrete Fourier transform (DFT)
FFT algorithm, 4-17–4-19
properties, 4-15–4-17
discrete-time Fourier transform (DTFT)
vs. CT spectra, 4-14–4-15
DTFT pairs, 4-12–4-13
properties, 4-13–4-14

FFT spectral analysis
leakage and the picket-fence effect, 4-21–4-22
windowing and zero-padding, 4-21
FIR digital filter design
bandpass FIR filter, 4-22–4-23
frequency response, 4-22
functional relationships, 4-19–4-20
real-time filtering, Fourier block processing
block algorithms, 4-24
overlap-add processing, 4-23–4-24
overlap-save processing, 4-23
transform domain adaptive filter (TDAF)
adaptive tap vector, 4-25
autocorrelation matrix, 4-24–4-25
characteristics, 4-26–4-27
filter output and LMS adaptive algorithm, 4-24
Karhunen–Loe've transform (KLT), 4-26
power, 4-25–4-26
transformed outputs, 4-25
Fractal capacitors
boost factor *vs.* horizontal spacing, 12-7
bottom-plate parasitic capacitance, 12-5–12-6
fractal dimension, 12-4–12-6
high-density capacitor, 12-2
interdigitated capacitor, 12-7–12-8
lateral flux capacitors, 12-2–12-3
parallel-plate and MOS, 12-1–12-2
quality factor and lateral spacing, 12-7
three-dimensional representation, 12-5, 12-6
woven structure, 12-8
Frequency-dependent negative resistance (FDNR), 14-10
Frequency-domain analysis
advanced network analysis
CCCS and VCVS gain, 22-34–22-35
circuit branch admittance, 22-27–22-30
circuit branch impedance, 22-30
circuit transadmittance, 22-31–22-33
circuit transimpedance, 22-31
driving point impedances, 22-35–22-39
engineering utility, 22-18–22-25
fundamental concepts, 22-11–12-15
Kron–Bode formula, 22-25–22-27
Kron's formula, 22-15–22-18
sensitivity analysis, 22-39
transposed connection vector, 22-14
LLFT network
capacitor voltage and current, 24-2
dividers, 24-15–24-18
inductor voltage and current, 24-3
Middlebrook's extra element theorem, 24-38–24-42
Norton's theorem, 24-31–24-32
Ohm's law, 24-1–24-2
one-port LLFT network, 24-5
properties, 24-10–24-12
π–T conversion, 24-34–24-35
reciprocity, 24-35–24-37
network functions
Cramer's rule, 22-3
definition, 22-1
inductor current, 22-5–22-6
Laplace transform, 22-9–22-10
modified nodal, 22-4
network stability, 22-8–22-9
output and input impedance, 22-2
output voltage and input voltage, 22-1
ratio of two polynomials, 22-6
roots of the numerator and denominator, 22-7
stability, 22-8–22-9
time-domain response, 22-10
transfer function, 22-3
sinusoidal steady state analysis
AC circuit power, 24-62–24-73
network transfer function, 24-46–24-47
output voltage, 24-48
phase lead and lag, 24-55–24-57
phasor and network, 24-53–24-55
RC and RL network, 24-57–24-59
resonance, 24-60–24-62
steady-state output voltage, 24-49
transient and steady-state response, 24-45
source transformations, 24-12–24-15
substitution theorem, 24-43–24-44
superposition theorem
dependent and independent source, 24-19–24-20
loop impedance matrix, 24-18
Thévenin's theorem
application, 24-28–24-29
dependent sources, 24-24–24-25
impedance, 24-26
source transformation, 24-29–24-30
subnetworks, 24-24
two-port networks, 24-5–24-6
Front-end amplifier, *see* RF low-noise amplifiers

G

Gate-drain capacitance (C_{gd}) effect, 17-14–17-15
Generalized impedance convertor (GIC), 14-10
Geometric mean distance (GMD), 12-13
Graph theory
arc coloring theorem
graph painting, 7-25–7-26
induction hypothesis, 7-26
resistances and voltages, 7-27
circuit and cutset
circuit matrix, 7-12
cut matrix, 7-10–7-11

electrical networks
KCL and the KVL, 7-19
loop and cutset methods, 7-20–7-21
network elements and directed graph, 7-18
incidence matrix
determinant, 7-10
directed graph, 7-9
incidence vector, 7-9–7-10
orthogonality relation, 7-12–7-14
relative orientations, 7-12
Tellegen theorem
2-port network, 7-21–7-22
adjoint elements, 7-23–7-24
open-circuit voltage ratio, 7-24
voltage and current change, 7-22
tree enumeration spanning
Binet–Cauchy theorem, 7-15–7-16
directed graph, 7-17
undirected graph, 7-16–7-17

H

Haar wavelet basis, 6-11–6-12
Hierarchical methods
advantage, 25-17, 25-18
bipolar cascode stage, 25-19–25-20
modified nodal analysis and NAM, 25-19
resistance ladder network, 25-17–25-18
topological analysis, 25-18
Higher-order log-domain filters, 17-45
High-frequency (HF) amplifiers
current feedback op-amp (CFOA)
bipolar realization, 17-5
buffer and CFOA implementation, 17-7–17-11
closed-loop gain, 17-3–17-4
CMOS compound device, 17-5
macromodel, 17-2–17-3
total impedance, 17-3
high-Q resonators
gm-C bandpass biquad, 17-32–17-34
IF-sampling, 17-29–17-30
triode region transconductor, 17-31
unity-gain frequency, 17-32
log-domain process
basic log-domain integrator, 17-41–17-44
filter synthesis, 17-36–17-37
higher-order log-domain filters, 17-45
instantaneous companding, 17-34–17-36
performance aspects, 17-37–17-40
operation layout
feedback reduction, 17-23
flip-chip connection, 17-24
high-frequency (HF) ground, 17-23
input/output isolation, 17-23
I/O pads, 17-23
optical low-noise preamplifiers
front-end noise sources, 17-17–17-18
receiver performance criteria, 17-19–17-21
transimpedance (TZ) amplifiers, 17-21–17-22
RF low-noise amplifiers
cascode common source LNA, 17-15–17-16
CMOS common-source LNA, 17-12–17-15
gain, 17-10–17-12
input impedance matching and linearity, 17-12
noise, 17-8
RF power amplifier
classification, 17-24–17-25
PA requirements, 17-24
practical considerations, 17-27
wireless transceiver, 17-2
High-pass filter (HPF)
coefficients and specification, 10-34
contour and 3-D magnitude plots, 10-35
High-Q resonators
gm-C bandpass biquad
biquad bandpass and SFDR, 17-33
Q passive on-chip inductors, 17-32
simulated bandpass frequency response, 17-34
IF-sampling
ADC and sampling receiver, 17-29
continuous-time Sigma-Delta modulator, 17-30
linear region transconductor implementation
triode region transconductor, 17-31
unity-gain frequency, 17-32
High-voltage capacitor, 11-28–11-29
Hilbert space frame
arbitrary vector representation, 6-44
definition, 6-44
dual frame and sequence, 6-47
frame operator, 6-46
Riesz basis, 6-44–6-45
tight frame, 6-46
Hölder regularity index, 6-74
Hurwitz polynomials
analogs
2-V polynomials, zeroes continuity property, 9-7–9-10
broad-sense Hurwitz polynomial (BHP), 9-5
Hurwitz polynomial in the strict sense (HPSS), 9-6
immittance Hurwitz polynomial (IHP), 9-7
narrow-sense Hurwitz polynomial (NHP), 9-5
reactance Hurwitz polynomial (RHP), 9-7
scattering Hurwitz polynomial (SHP), 9-5–9-6
self-paraconjugate polynomial and SPHP, 9-5
very strict Hurwitz polynomial (VSHP), 9-6

preliminaries and notations
analog biplane, 9-2–9-3
infinite distant points, 9-2
isolated and continuum of zeroes, 9-3
two-dimensional Hurwitz polynomials, 9-11–9-12
two-variable polynomial, infinity
1-D complex plane, 9-3
2-D biplane, 9-4
nonessential singularities second kind (NSSK), 9-4
2-V very strict Hurwitz polynomial (VSHP), 9-10–9-11
Hybrid parameters
bipolar transistors, 20-11–20-12
circuit model, 20-10–20-11
common emitter configuration, 20-11

I

Ideal bandpass wavelet
Fourier transform, 6-5–6-6
frequency axis splitting, 6-6–6-7
impulse response, 6-8
vs. low-pass, 6-5–6-6
Ideal operational amplifier
circuit applications
frequency dependence, 16-5–16-6
instrumentation amplifiers, 16-8
inverting configuration, 16-5
multiple input circuits, 16-7–16-8
noninverting configuration, 16-4–16-5
nonlinear transfer functions, 16-6
simple attenuator, 16-4
unity gain buffer, 16-3
comparators, 16-9–16-10
inverting amplifier configuration, 16-10–16-11
open-loop equivalent circuit characterization, 16-1
types and configurations, 16-2–16-3
voltage op-amps, 16-3
Immittance Hurwitz polynomial (IHP), 9-7
Impact avalanche transit time (IMPATT) diode, 11-73
Indefinite admittance matrix (IAM) approach
basics, 25-10–25-11
resistive circuit, 25-11–25-12
Inductive link current
capacitive tree-branch voltages, 27-7–27-8
state equations, 27-5–27-6
Inductor
air inductor
advantages, 11-48
coil dimensions, 11-45–11-47
design guidance, 11-47
disadvantages, 11-49
frequency ranges, 11-48
quality factor, 11-47–11-48
circuit representation, 11-45
cored inductor
advanced inductor, 11-56
closed magnetic circuit, 11-50–11-55
open magnetic circuit, 11-55–11-56
parameters, 11-49–11-50
power loss, 11-56–11-60
definition, 11-63–11-64
functions and parameters, 11-44
fundamental observations, 11-42, 11-43
graphical symbols, 11-40
inductance, 11-40–11-42
magnetic core materials, 11-61–11-63
nonlinearity, 11-60–11-61
physical irregularities, 11-63
qualifiers and attributes, 11-42–11-43
Integrated circuit (IC) amplifiers, 15-3
active loads, 15-10–15-11
BJT differential pair, 15-20–15-21
cascode stage
advantages, 15-15–15-16
high-frequency equivalent circuit, 15-16–15-17
circuit efficiency, 15-31–15-32
class-B output stage
bias circuit, 15-33
Darlington output stages, 15-33
short-circuit proof, 15-32
class-D output stage, PWM amplifier
advantage and disadvantage, 15-35
architecture, 15-33, 15-34
configurations, 15-35–15-36
duty cycle, 15-33–15-34
common-base stage, 15-13–15-14
common emitter stage
configuration, 15-11
equivalent circuit, 15-11–15-12
upper corner frequency, 15-12–15-13
differential stage
advantages and configuration, 15-18
mode of operation, 15-19–15-20
emitter follower, 15-14–15-15
limitations, power output, 15-29–15-30
small-signal models
hybrid-π model, 15-8–15-9
unilateral equivalent circuit, 15-9–15-10
thermal resistance, 15-30–15-31
Interference suppression capacitor, 11-30
Inverse Laplace transform
partial fraction expansion (PFE)
repeated linear factors, 3-31
repeated quadratic factors, 3-31–3-32
simple linear factors, 3-27–3-29
simple quadratic factors, 3-29–3-30
residue theory
differentiated time function, 3-24
LT occurrence, 3-25
Taylor series expansion, 3-23
time function, 3-22
Inverse z-transform
contour integration
Cauchy's residue theorem, 5-7
order interchanging, 5-6–5-7
residues, 5-6–5-7

inspection method and power series expansion, 5-8
partial fraction expansion, 5-7–5-8
Inversion negative impedance converter (INIC), 14-11

K

Kirchhoff's current law (KCL), 13-10–13-11
circuit paths, 19-6–19-7
cutset-loop circuit analysis, 19-32–19-34
Gaussian surface, 19-5–19-6
illustration, 19-4–19-5
mesh analysis, 19-24, 19-25
voltage rise and drop, 19-7
Kirchhoff's voltage law (KVL)
circuit analysis, 19-8–19-9
circuit paths, 19-8
cutset-loop circuit analysis, 19-34
illustration, 19-7–19-8
mesh analysis, 19-24–19-26
Kron's formula
engineering utility
bipolar junction transistor amplifier, 22-23
Bode's theory, 22-21
common emitter amplifier, 22-21–22-22
perturbed voltage gain, 22-18–22-19
transfer function sensitivity, 22-20–22-21
generalization
I–O transfer characteristic node, 22-25
return ratio, 22-26–22-27
transfer function and return ratio, 22-26
impedance inclusion, 22-15–22-16
output voltage, 22-17–22-18
Thévenin voltage and impedance, 22-16–22-17

L

Laplace transformation
bilateral Laplace transform (BLT), 3-8–3-9
Dirac delta function
definition, 3-42–3-43
doublet signal, 3-44
impulse function, 3-43
discrete-time Laplace transform (DTLT), 3-45
forced response, 3-4
homogeneous solution and natural response, 3-2–3-3
inverse Laplace transform
partial fraction expansion (PFE), 3-27–3-32
residue theory, 3-23–3-27
time function, 3-22
Laplace-domain phasor circuits, 3-41–3-42
linear system
differential equation, 3-32–3-34
generalized phasor, 3-34–3-35
magnitude and phase response, 3-35–3-37
nonhomogeneous solution and forced response, 3-4–3-5
phasor concept generalization
complex number, 3-7
generalized phasor, 3-7–3-8
pole–zero analysis
BIBO stability, 3-38–3-39
general function, $F(s)$, 3-15
natural modes, 3-37–3-38
polynomial factorization, 3-16
ROC, 3-16–3-18
stability and natural modes, 3-39–3-41
properties
convolution property, 3-20–3-21
modulation property, 3-19
square wave, 3-19
time-differentiation property, 3-20
ULT, 3-18
series RLC circuit, 3-2
solution scrutinization, 3-6–3-7
total solution, 3-5–3-6
unilateral Laplace transforms
direct computation, 3-11–3-15
operational properties, 3-18–3-22
Linear capacitor
adjustable capacitor, 11-27–11-28
energetic power capacitor, 11-28, 11-29
fixed capacitor-class 1, 11-26–11-27
high-voltage capacitor, 11-28–11-29
interference suppression capacitor, 11-30
Linear operators and matrices
bijective function, 1-4
characteristics
eigenvalues, 1-15–1-17
eigenvectors, 1-16
singular values, 1-17–1-18
determinants
definition, 1-8
first-and second order matrix, 1-10
Laplace's expansion, 1-9
linear systems
Cramer's rule, 1-19
input and output system, 1-18
poles and zeros, 1-18–1-19
matrix operations
matrix addition, 1-7
matrix multiplication, 1-7–1-8
matrix transposition, 1-8
vector addition, 1-6
matrix representations, 1-6
transformations
equivalence transformation, 1-14–1-15
similarity transformation, 1-12–1-14
vector spaces over fields
field F, properties, 1-2
F-vector space, 1-2–1-3
n-dimensional vector space, 1-3–1-4
Linear resistor, 11-1–11-2
fixed resistor
chip resistor, 11-6, 11-7
dynamic tolerance Δ and resistor class, 11-2–11-3, 11-4
high-ohmic, high-voltage resistor, 11-6
high-power resistor, 11-6–11-7
resistive network, 11-5–11-6
temperature coefficient of resistance (TCR), 11-3, 11-5

variable resistor, potentiometers
electric circuit, 11-7, 11-8
tapers, 11-9
types, 11-7–11-9
Linear time-invariant systems, *z*-Transform
one-sided *z*-transform, 5-14
system transfer function, 5-13–5-14
Log-domain process
basic log-domain integrator
component mismatch, 17-41
frequency limitations, 17-43–17-44
noise, 17-44
Ohmic resistance, 17-42–17-43
filter synthesis, 17-36–17-37
higher-order log-domain filters, 17-45
instantaneous companding, 17-34–17-36
performance aspects
finite current gain, 17-38–17-39
frequency performance, 17-39–17-40
tuning range, 17-37–17-38
Low-pass filter (LPF)
coefficients and specification, 10-33
contour and 3-D magnitude plots, 10-34
Lumped, linear, finite, time-invariant (LLFT) networks
capacitor voltage and current, 24-2
impedance concept
one-port network, 24-3–24-5
two-port networks, 24-5–24-6
independent nodes, 24-6–24-7
inductor voltage and current, 24-3
inverse transform phasors, 24-52–24-53
LLFT networks, 24-3–24-4
loop impedance matrix, 24-9–24-10
Middlebrook's extra element theorem
parallel version, 24-38–24-40
series version, 24-40–24-43
nodal admittance matrix, 24-6–24-7
Ohm's law, 24-1–24-2
one-port LLFT network, 24-5
phasor transforms
Euler's identity, 24-49
integration constant, 24-52
sine and cosine function, 24-50
properties
driving-point network function polynomial, 24-11–24-12
poles and zeroes, 24-10
transfer function, 24-12
π–T conversion
loop equation, 24-35
networks, 24-34–24-35
T replacement, 24-35
reciprocity
circuit modification, 24-36–24-37
excitation and response, 24-37
reciprocal network, 24-35–24-36
sinusoidal steady state analysis
AC circuit power, 24-62–24-73
network transfer function, 24-46–24-47
output voltage, 24-48
phase lead and lag, 24-55–24-57
phasor and network, 24-53–24-55
RC and RL network, 24-57–24-59
resonance, 24-60–24-62
steady-state output voltage, 24-49
transient and steady-state response, 24-45
source transformations, 24-12–24-15
substitution theorem, 24-43–24-44
superposition
dependent and independent source, 24-19–24-20
loop impedance matrix, 24-18
Thévenin's theorem
application, 24-28–24-29
dependent sources, 24-24–24-25
impedance, 24-26
source transformation, 24-29–24-30
subnetworks, 24-24
two-port networks, 24-5–24-6
voltage excitation, 24-8–24-9

M

Magnitude response symmetry
2-D polynomials determination
diagonal symmetry, 10-25–10-26
fourfold rotational symmetry, 10-26
octagonal symmetry, 10-27
quadrantal symmetry, 10-21–10-25
analog 2-D filter
quadrantal and octagonal symmetry, 10-28–10-29
rotational and diagonal symmetry, 10-29
transfer function, 10-27
applications
continuous-time frequency response, 10-15
discrete-time frequency response, 10-15–10-16
magnitude-squared functions, 10-16
bandpass filter
MATLAB optimization, 10-32
specifications, 10-31–10-32
bandstop filter
coefficients and specification, 10-35
contour and 3-D magnitude plots, 10-36
digital filters
continuous-time frequency response, 10-15
discrete-time frequency response, 10-15–10-16
magnitude response, 10-16
quadrantal and octagonal symmetry, 10-29–10-30
rotational and diagonal symmetry, 10-30

high-pass filter
coefficients and specification, 10-34
contour and 3-D magnitude plots, 10-35
low-pass filter
coefficients and specification, 10-33
contour and 3-D magnitude plots, 10-34
magnitude-squared functions, 10-16
Mason's gain formula
feedback loops, 8-10
j self-loops, 8-9
Mason graph, 8-8–8-9
Matrix operations
addition, 1-7
multiplication, 1-7–1-8
transposition, 1-8
vector addition, 1-6
Maximum power transfer theorem
load resistance, 19-55–19-58
power *vs*. resistance, 19-55, 19-56
Mesh analysis
circuit graph, 19-22–19-23
current sources, 19-26
deactivated current, 19-27
dependent source, 19-28–19-30
features and constraints, 19-27–19-28
independent source, 19-30
KCL, 19-24, 19-25
KVL, 19-24–19-26
mesh current, 19-24, 19-25
one-mesh circuit, 19-23
two-mesh circuit, 19-23–19-24
Metal–insulator–metal (MIM), 11-14
Metal-oxide-semiconductor field-effect transistor (MOSFET), 18-1, 18-2
Middlebrook's extra element theorem
parallel version, 24-38–24-40
series version, 24-40–24-43
Miller effect capacitance, 15-9–15-10
Modified nodal analysis (MNA), 25-19
Modified *z*-transform, 5-16
Multidimensional *z*-transforms, 5-15

N

Narrow-sense Hurwitz polynomial (NHP), 9-5
Negative impedance converter (NIC), 14-8
Negative temperature coefficient (NTC) thermistor, 11-10
Network analysis
CCCS and VCVS gain, 22-34–22-35
circuit branch admittance, 22-27–22-30
circuit branch impedance, 22-30
circuit transadmittance
linear circuit, 22-31–22-32
voltage feedback amplifier, 22-33
circuit transimpedance, 22-31
driving point impedances
Blackman's formula, 22-37
critical circuit parameters, 22-35
transimpedance, 22-36
zero parameter, 22-36–22-37
functions
Cramer's rule, 22-3
definition, 22-1
inductor current, 22-5–22-6
Laplace transform, 22-9–22-10
modified nodal, 22-4
network stability, 22-8–22-9
output and input impedance, 22-2
output voltage and input voltage, 22-1
ratio of two polynomials, 22-6
roots of the numerator and denominator, 22-7
stability, 22-8–22-9
time-domain response, 22-10
transfer function, 22-3
fundamental concepts
branch linear network, 22-11–22-12
impedance and transimpedance, 22-14–12-15
nodal admittance matrix, 22-12–22-13
Norton equivalent circuit, 22-11–22-12
vector concept, 22-13
voltage gain, 12-15
Kron–Bode formula, 22-25–22-27
Kron's formula
bipolar junction transistor amplifier, 22-23
Bode's theory, 22-21
common emitter amplifier, 22-21–22-22
impedance inclusion, 22-15–22-16
I–O transfer characteristic node, 22-25
output voltage, 22-17–22-18
perturbed voltage gain, 22-18–22-19
return ratio, 22-26–22-27
Thévenin voltage and impedance, 22-16–22-17
transfer function and return ratio, 22-26
transfer function sensitivity, 22-20–22-21
sensitivity analysis, 22-39
transposed connection vector, 22-14
Network laws and theorems
basic circuit theory, 19-3
circuit analysis, 19-3–19-4
conductors and elements, 19-1, 19-2
current measurement, 19-2–19-3
cutset-loop circuit analysis
analogous problem, mesh analysis, 19-31
circuit graph, 19-31–19-32
example circuit, 19-39–19-41
failure, nodal analysis, 19-30–19-31
fundamental cutset and loop, 19-32
KCL equation, 19-32–19-34
KVL equation, 19-34
norator, 19-35–19-36
nullator and equivalent subcircuit, 19-37
passive element and equivalent circuits, 19-36–19-37
three-terminal/two-port element, 19-37–19-39
two-terminal element, 19-35–19-40

Kirchhoff's current law (KCL)
  circuit paths, 19-6–19-7
  Gaussian surface, 19-5–19-6
  illustration, 19-4–19-5
  voltage changes, 19-7
Kirchhoff's voltage law (KVL)
  circuit analysis, 19-8–19-9
  circuit paths, 19-8
  illustration, 19-7–19-8
linear circuit
  KCL, 19-42–19-43
  superposition and homogeneity condition, 19-43–19-44
maximum power transfer theorem
  load resistance, 19-55–19-58
  power *vs*. resistance, 19-55, 19-56
mesh analysis
  circuit graph, 19-22–19-23
  current sources, 19-26
  deactivated current, 19-27
  dependent source, 19-28–19-30
  features and constraints, 19-27–19-28
  independent source, 19-30
  KCL, 19-24, 19-25
  KVL, 19-24–19-26
  mesh current, 19-24, 19-25
  one-mesh circuit, 19-23
  two-mesh circuit, 19-23–19-24
nodal analysis
  deactivated circuit configuration, 19-14–19-15
  dependent source, 19-16–19-17
  differentiation and integration operators, 19-19–19-20
  dynamic circuit analysis, 19-20–19-22
  dynamic element relationships, 19-18–19-19
  floating element, 19-10–19-12
  independent voltage source, 19-13–19-14
  node voltage concept, 19-9–19-10
  nonessential node, 19-17–19-18
  reference node, 19-10, 19-11
  resistive circuit, 19-12–19-13
  supernode and essential node, 19-15, 19-18
Norton theorem
  current calculation and power dissipation, 19-54–19-55
  equivalent circuit, 19-51–19-52
  mesh equation method, 19-52–19-53
reciprocity theorem
  statement, 19-58
  verification, 19-58–19-59
superposition theorem
  current calculation, 19-46–19-47
  deactivated sources, 19-44–19-46
Thévenin theorem
  current calculation, 19-48–19-50
  voltage determination, 19-50–19-51
  voltage divider circuit, 19-47–19-48
voltage rise and drop, 19-7
voltmeter, 19-1–19-2
Nodal analysis
  deactivated circuit configuration, 19-14–19-15
  dependent source, 19-16–19-17
  differentiation and integration operators, 19-19–19-20
  dynamic circuit analysis, 19-20–19-22
  dynamic element relationships, 19-18–19-19
  floating element, 19-10–19-12
  independent voltage source, 19-13–19-14
  node voltage concept, 19-9–19-10
  nonessential node, 19-17–19-18
  reference node, 19-10, 19-11
  resistive circuit, 19-12–19-13
  supernode and essential node, 19-15, 19-18
Node admittance matrix (NAM)
  determinant, 25-5
Non ideal op-amp
  common-mode rejection ratio (CMRR)
    common-mode gain, 16-16–16-17
    differential and noninverting configuration, 16-17
    total output voltage, 16-17–16-18
  electrical noise
    amplifier noise, 16-21–16-22
    circuit's noise performance, 16-23
    white-noise voltage and density, 16-23–16-24
  finite differential gain
    frequency dependent gain, 16-11–16-12
    noninverting configuration, 16-13
    output saturation, 16-13–16-14
  finite input impedance, 16-18–16-19
  input bias currents
    input offset current, 16-20
    nonzero offset current, 16-20–16-21
  nonzero output impedance, 16-19–16-20
  offset voltage
    output offset voltage, 16-15–16-16
    transfer function, 16-14–16-15
  power-supply rejection ratio, 16-18
Norton theorem, 24-31–24-32
  current calculation and power dissipation, 19-54–19-55
  equivalent circuit, 19-51–19-52
  mesh equation method, 19-52–19-53

O

Ohm's law, 24-1–24-2
On-chip transformers
  analytical transformer models
    capacitances, 12-18
    stacked transformer, 12-17
    tapped transformer, 12-16

monolithic transformer realizations
models and coupling expression, 12-15–12-16
port applications, 12-16–12-7
Operational amplifier (op-amp)
BJT
analog computer, 15-21–15-22
classical architecture, 15-22–15-23
features, 15-22
high-gain differential stage, 15-23–15-24
second amplifier stage, 15-24–15-26
specifications, 15-26–15-27
circuit schematic symbol, 18-4, 18-5
current feedback op-amp (CFOA)
bipolar realization, 17-5
closed-loop gain, 17-3–17-4
CMOS compound device, 17-5
frequency response, 17-7, 17-9
macromodel, 17-2–17-3
open and close-loop transimpedance, 17-7, 17-9
output impedance characteristics, 17-7–17-8
schematics and layout plot, 17-6–17-7
step response and harmonic distortion, 17-11
total impedance, 17-3
voltage buffer performance, 17-7
current-mode op-amp
closed-loop characteristics, 16-35–16-36
current-mode op-amp dynamics, 16-37–16-38
higher-order effects, 16-38–16-40
ideal op-amp
circuit applications, 16-3–16-8
comparators, 16-9–16-10
inverting amplifier configuration, 16-10–16-11
open-loop equivalent circuit, 16-1–16-3
voltage op-amps, 16-3–16-11
nonideal op-amp
common-mode rejection ratio (CMRR), 16-16–16-18
electrical noise, 16-21–16-24
finite differential gain, 16-11–16-14
finite input impedance, 16-18–16-19
input bias currents, 16-20–16-21
nonzero output impedance, 16-19–16-20
offset voltage, 16-14–16-16
power-supply rejection ratio, 16-18
voltage-mode op-amps
closed-loop frequency response, 16-26–16-30
closed-loop transient response, 16-30–16-32
current-mode op amps, 16-32–16-34
open-loop voltage gain, 16-26
SPICE stimulation, 16-32
Optical low-noise preamplifiers
front-end noise sources
amplifier and resistor noise, 17-18
PIN photodiode noise, 17-17–17-18
receiver performance criteria
dynamic range, 17-21
equivalent input noise current, 17-18–17-19
intersymbol interference, 17-20–17-21
optical sensitivity, 17-19–17-20
photodiode terminal, SNR, 17-20
transimpedance (TZ) amplifiers, 17-21–17-22

P

Parameter extraction method
indefinite admittance matrix (IAM) approach
basics, 25-10–25-11
resistive circuit, 25-11–25-12
interpolation method, 25-16–25-17
techniques and limitations, 25-10
two graph-based tableau approach
determinants and cotree, 25-13–25-14
element stamps, 25-12
matrices, 25-13, 25-15
tableau equation, 25-13
voltage and current graph, 25-12, 25-14–25-15
Paraunitary filter banks
dilation equation application, 6-63–6-64
infinite product convergence, 6-64–6-65
multiresolution analysis
fast wavelet transform, 6-58
orthonormal multiresolution, 6-57
power symmetric filter, 6-56
wavelet generation, 6-57–6-58
orthonormal wavelet basis
Haar basis, 6-69
L^2 and pointwise convergence, 6-67–6-68
Lawton's eigenfunction condition, 6-68
nonorthonormal, 6-69–6-70
scaling and wavelet functions, 6-68
parametrization, 6-27
wavelet tight frames, 6-70–6-71
Partial fraction expansion (PFE)
repeated linear factors, 3-31
repeated quadratic factors, 3-31–3-32
simple linear factors, 3-27–3-30
simple quadratic factors, 3-29–3-30
Passive circuit elements
active filter synthesis, SFG
bandpass passive filter, 21-9
Butterworth low-pass filter, 21-7–21-9
Chebyshev low-pass response, 21-10
component op-amp circuits, 21-5–21-7
doubly terminated passive filter, 21-4

general ladder network, 21-4–21-5
leapfrog realization, 21-4–21-5
normalization, 21-10–21-11
capacitor
dielectric constant, 11-24
geometry, 11-34, 11-36–11-37
linear capacitor, 11-26–11-30
nonideal linear capacitor, 11-37–11-39
nonlinear capacitor, 11-31–11-33
power and quality factor, 11-25
properties, 11-33–11-35
v' index, 11-25–11-26
inductor
air inductor, 11-45–11-49
circuit representation, 11-45
cored inductor, 11-49–11-60
definition, 11-63–11-64
functions and parameters, 11-44
fundamental observations, 11-42, 11-43
graphical symbols, 11-40
inductance, 11-40–11-42
International Standards, 11-63
magnetic core materials, 11-61, 11-62
magnetic material measurements, 11-61, 11-63
nonlinearity, 11-60–11-61
physical irregularities, 11-63
qualifiers and attributes, 11-42–11-43
resistor
fixed resistor, 11-2–11-7
magnetic geometry, 11-17–11-20
magnetic properties, 11-11–11-17
nonideal linear resistor, 11-20–11-23
photoresistor and magnetoresistor, 11-11
thermistor, 11-10–11-11
variable resistor, 11-7–11-9
varistor, 11-9–11-10
semiconductor diode
depletion capacitances, 11-79–11-80
diode capacitances, 11-78–11-79
impurity profiles, 11-73, 11-74
nonlinear static I-V characteristics, 11-73–11-78
piecewise linear model, 11-83–11-84
as switch, 11-80–11-82
symbols, 11-84
temperature properties, 11-82–11-83
transformer
characteristics, 11-66–11-67
circuit model, 11-70–11-72
definition, 11-66, 11-72
ideal transformer model, 11-67–11-68
leakage and magnetizing inductances, 11-69–11-70
linear transformer model, 11-68–11-69
Phasor transforms
Euler's identity, 24-49
integration constant, 24-52
sine and cosine function, 24-50
Polar polymer dielectric capacitor, 11-32–11-33
Pole–zero analysis
linear system, LT
BIBO stability, 3-38–3-39
natural modes, 3-37–3-38
stability and natural modes, 3-39–3-41
ULT and BLT
general function, $F(s)$, 3-15
polynomial factorization, 3-16
ROC, 3-16–3-18
Port representations
feedback systems
Beta Network, 20-16–20-17
phase and gain margins, 20-15
Tow–Thomas biquad, 20-18–20-19
transfer function, 20-15
voltage-controlled voltage source (VCVS), 20-16
two-port network
bipolar transistor, 20-11–20-12
calculation, 20-7
Cramer's rule and circuit models, 20-10–20-11
hybrid parameters, 20-8–20-9
interconnections, 20-13–20-14
port voltages and current, 20-5
transmission parameters, 20-6, 20-14–20-15
y parameters, 20-6–20-8
z parameters, 20-6
Positive real function (PRF), 9-3
Positive temperature coefficient (PTC), 11-10
Power supply rejection ratio (PSRR), 15-27
Pulse-width modulation (PWM) amplifier
advantage and disadvantage, 15-35
architecture, 15-33, 15-34
configurations, 15-35–15-36
duty cycle, 15-33–15-34
IC amplifier, 15-3
Pulse-width modulation (PWM) IC amplifier, 15-3

R

Reactance function (RF), 9-3
Reactance Hurwitz polynomial (RHP), 9-7
Real-time filtering, Fourier block
block algorithms, 4-24
overlap-add processing, 4-23–4-24
overlap-save processing, 4-23
Reciprocity theorem
statement, 19-58
verification, 19-58–19-59
Resistive circuit element
bipolar NPN transistor, 13-5–13-6
op-amp, 13-6–13-7
photodiode, 13-4–13-5
tunnel diode, 13-5

Resistor
geometry
fail-safe resistor, 11-19–11-20
potentiometer, shape complication, 11-19
resistive element shape, 11-17–11-19
linear resistor
fixed resistor, 11-2–11-7
Ohm's law and types, 11-1–11-2
variable resistor, 11-7–11-9
nonideal linear resistor
noise, 11-20, 11-21
potentiometer, regulation curve, 11-21–11-23
rotational noise and CRV, 11-21
voltage coefficient of resistance (VCR), 11-20–11-22
nonlinear resistor
photoresistor and magnetoresistor, 11-11
thermistor, 11-10–11-11
varistor, 11-9–11-10
properties
ceramic substrate influence, 11-16–11-17
parameter comparison, 11-15–11-16
polymer resistor, 11-15
pyrolytic carbon resistor, 11-14
TCR, 11-11–11-17
thick film resistor, 11-14–11-15
thin film resistor, 11-13–11-14
RF low-noise amplifiers
cascode common source LNA
input matching, 17-15
noise figure, 17-16
voltage gain, 17-15–17-16
CMOS common-source LNA
CS input stage, noise, 17-13
gate-drain capacitance (C_{gd}) effect, 17-14–17-15
input impedance matching, 17-12–17-13
simplified analysis, 17-12
voltage amplifier, inductive load, 17-14
gain, 17-10–17-12
input impedance matching and linearity, 17-12
noise, 17-8
RF passive IC components
fractal capacitors
boost factor *vs.* horizontal spacing, 12-7
bottom-plate parasitic capacitance, 12-5–12-6
fractal dimension, 12-4–12-5, 12-6
high-density capacitor, 12-2
interdigitated capacitor, 12-7–12-8
lateral flux capacitors, 12-2–12-3
parallel-plate and MOS, 12-1–12-2
quality factor and lateral spacing, 12-7
three-dimensional representation, 12-5, 12-6
woven structure, 12-8
on-chip transformers, 12-4
analytical transformer models, 12-16–12-19
monolithic transformer realizations, 12-15–12-17
spiral inductors
noise coupling, 12-8–12-9
planar spiral inductors, 12-11–12-14
substrate effects, 12-9–12-11
RF power amplifier
classification, 17-24–17-25
PA requirements, 17-24
practical considerations, 17-27

S

Scattering Hurwitz polynomial (SHP), 9-5–9-6
Scattering matrix, circulator, 14-12–14-14
Second-order circuits, time domain analysis
network characterization, 26-17
transfer function, 26-11–26-12
transient and steady-state responses, 26-15–26-17
zero-input response, 26-13–26-14
zero-state response, 26-14–26-15
Semiconductor diode
depletion capacitances, 11-79–11-80
diode capacitances, 11-78–11-79
impurity profiles, 11-73, 11-74
nonlinear static I–V characteristics, 11-73
forward I–V diode characteristics, 11-75, 11-77–11-78
p–n junction equation, 11-74–11-76
reverse I–V characteristics, 11-75, 11-78
piecewise linear model, 11-83–11-84
as switch, 11-80–11-82
symbols, 11-84
temperature properties, 11-82–11-83
Sequence of expressions (SoE), *see* Hierarchical methods

Mason's SFG, 25-7–25-8
Similarity transformation, 1-12–1-14
Singular-value decomposition (SVD), 1-17
Sinusoidal steady state analysis
AC circuit power
average power and RMS values, 24-65–24-66
average power delivered, 24-71
input impedance, 24-64
load impedance, 24-70–24-71
maximum average power, 24-72–24-73
power factor (PF), 24-63
power triangle, 24-67
sinusoidal sources, 24-62–24-63
network transfer function, 24-46–24-47
output voltage, 24-48
phase lead and lag, 24-55–24-57
phasor and network, 24-53–24-55
RC and RL network, 24-57–24-59
resonance
parallel resonant circuit, 24-60–24-61
series resonant circuit, 24-61–24-62
steady-state output voltage, 24-49
transient and steady-state response, 24-45
Sinusoids, 26-3
Spiral inductors
noise coupling, 12-8–12-9
planar spiral inductors
current sheet approximation, 12-3–12-14
data-fitted monomial expression, 12-14, 12-15
layouts, 12-11–12-12, 12-13
modified Wheeler formula, 12-12–12-3
substrate effects
patterned ground shield (PGS), 12-10–12-11
physical model, 12-9–12-10
State transition matrix
complete response, 27-20–27–21
Jordan canonical form, 27-16
Laplace transform technique, 27-17
normal mode approach, 27-18
parallel RLC circuit, 27-17
similarity transformation method, 27-19
zero-input response, 27-21
State-variable techniques
complete response, 27-20–27-21
concept of states
capacitive loop, 27-2–27-3
definition, 27-1
simple RC circuit, 27-2
network topology
capacitive tree-branch voltages, 27-8
first-order differential equation, 27-3
inductive link current, 27-8
KCL and KVL, 27-4
order of complexity, 27-1–27-2
resistive link currents, 27-7
state equations, 27-5–27-6
state transition matrix
Jordan canonical form, 27-16
Laplace transform technique, 27-17
normal mode approach, 27-18
parallel RLC circuit, 27-17
similarity transformation method, 27-19
zero-input response, 27-21
Superposition theorem
current calculation, 19-46–19-47
deactivated sources, 19-44–19-46

Symbolic analysis
approximate symbolic analysis
bipolar cascode stage, 25-21–25-23
classification, 25-20–25-21
error criteria, 25-21
determinant decision diagrams (DDD)
matrix determinant and representation, 25-24–25-25
nodal analysis, 25-23–25-24
vertex and vertex ordering, 25-24
frequency domain analysis, 25-3
hierarchical methods
advantage, 25-17, 25-18
bipolar cascode stage, 25-19–25-20
modified nodal analysis and NAM, 25-19
resistance ladder network, 25-17–25-18
topological analysis, 25-18
illustration, 25-1–25-2
time domain analysis
fully symbolic, 25-25
problems and limitation, 25-25
semisymbolic, 25-26
traditional methods
cancellation-free equation, 25-4–25-5
interpolation method, 25-16–25-17
parameter extraction method, 25-10–25-16
$RLCg_m$ circuit and term cancellations, 25-4
signal flowgraph method (SFG), 25-7–25-9, 25-10
tree enumeration methods, 25-5–25-7
Symmetric magnitude response
analog 2-D filter
quadrantal and octagonal symmetry, 10-28–10-29
rotational and diagonal symmetry, 10-29
transfer function, 10-27
bandpass filter
MATLAB optimization, 10-32
specifications, 10-31–10-32
bandstop filter
coefficients and specification, 10-35
contour and 3-D magnitude plots, 10-36
digital filters
quadrantal and octagonal symmetry, 10-29–10-30
rotational and diagonal symmetry, 10-30
high-pass filter
coefficients and specification, 10-34
contour and 3-D magnitude plots, 10-35
low-pass filter
coefficients and specification, 10-33
contour and 3-D magnitude plots, 10-34
magnitude-squared functions, 10-16
Symmetry applications
2-D Fourier transform
continuous-time continuous-frequency case, 10-7–10-8
continuous-time discrete-frequency case, 10-8
discrete-time continuous-frequency case, 10-9
discrete-time discrete-frequency case, 10-9–10-10
2-D magnitude response
continuous-time frequency response, 10-15
discrete-time frequency response, 10-15–10-16
magnitude-squared functions, 10-16
2-D polynomials determination
diagonal symmetry, 10-25–10-26
fourfold rotational symmetry, 10-26
octagonal symmetry, 10-27
quadrantal symmetry, 10-21–10-25
analog 2-D filter stability, magnitude response
quadrantal and octagonal symmetry, 10-28–10-29
rotational and diagonal symmetry, 10-29
transfer function, 10-27
digital filter stability, magnitude response
quadrantal and octagonal symmetry, 10-29–10-30
rotational and diagonal symmetry, 10-30
FFT
one dimensional, 10-11–10-12
symmetrical decomposition, 10-14
two dimensional, 10-12–10-14
filter design, magnitude response
bandpass filter, 10-31–10-33
bandstop filter, 10-35–10-36
high-pass filter, 10-34–10-35
low-pass filter, 10-33–10-34
objective function, 10-29–10-30
transfer function, 10-29
magnitude-squared function
polynomial P, 10-19–10-20
quadrantal symmetry, 10-20
spectral forms, 10-20–10-21
polynomial operations
anti-self-paraconjugate polynomial, 10-18–10-19
paraconjugate operation, 10-17
self-paraconjugate polynomial, 10-17–10-18
T-ψ symmetries
basic symmetries, 10-4–10-5
quadrantal and diagonal symmetry, 10-5–10-6
rotational and octagonal symmetry, 10-6–10-7

T

Taylor series, 3-23
Tellegen theorem
2-port network, 7-21–7-22
adjoint elements, 7-23–7-24
open-circuit voltage ratio, 7-24
voltage and current change, 7-22
Temperature coefficient of capacitance (TCC), 11-24

Tensor
  basis tensors
    finite-dimensional vector spaces, 2-5–2-8
    Kronecker product, 2-8
  tensor product
    arbitrary bilinear operator, 2-4
    isomorphism, 2-5
Terminal representation
  four-terminal network
    first application, 20-3
    passive circuit, 20-1–20-2
    second application, 20-4
  indefinite admittance matrix, 20-3
  network analysis, 20-5
  nodal admittance matrix, 20-2–20-3
Thévenin theorem
  application, 24-28–24-29
  current calculation, 19-48–19-50
  dependent sources, 24-24–24-25

port voltages and current, 20-5
transmission parameters, 20-6, 20-14–20-15
y parameters, 20-6–20-8
z parameters, 20-6
Two-variable polynomial
1-D complex plane, 9-3
2-D biplane, 9-4
nonessential singularities second kind (NSSK), 9-4

U

Unilateral Laplace transforms
direct computation, 3-11–3-15
operational properties, 3-18–3-22

V

Variable resistor
electric circuit, 11-7, 11-8
tapers, 11-9
types, 11-7–11-9
Vector spaces over fields
field *F*, properties, 1-2
F-vector space, 1-2–1-3
n-dimensional vector space, 1-3–1-4
Very strict Hurwitz polynomial (VSHP), 9-6
Voltage-controlled current source (VCCS)
circuit implementation, 14-2–14-3
circuit schematic symbol, 18-3
equivalent circuit, MOSFET, 14-1–14-2
SPICE format, 14-2, 14-4
Voltage-controlled voltage source (VCVS), 14-3
circuit schematic symbol, 18-1–18-3
dynamic model, op-amp, 13-9, 13-10
SPICE format and circuit implementation, 14-4
Voltage-dependent resistor (VDR), 11-9
Voltage inversion negative impedance converter (VNIC), 14-11
Voltage-mode op-amps
closed-loop frequency response
closed-loop small-signal bandwidth, 16-28
crossover frequency, 16-29
feedback factor, 16-27
closed-loop transient response, 16-30–16-32
current-mode op amps, 16-32–16-34
open-loop voltage gain, 16-26
SPICE stimulation, 16-32
2-V very strict Hurwitz polynomial (VSHP), 9-10–9-11

W

Walsh–Hadamard transform (WHT), 4-20–4-21
Wavelet transform (WT) technique
basis functions, 6-10
digital filter banks
basis function, 6-29–6-30
half-band filter, 6-27
paraunitary filter banks, parametrization, 6-27
paraunitary properties, 6-25–6-27
polyphase representation, 6-24–6-25
subband construction, 6-22–6-24
tree-structured system, 6-28–6-29
two-channel filter bank, 6-22
filter banks
synthesis and reconstruction, 6-13–6-14
time–frequency representation, 6-13
wavelet function design, 6-14–6-15
Fourier basis, 6-15
Haar wavelet basis, 6-11–6-12
Hilbert space frame
arbitrary vector representation, 6-44
definition, 6-44
dual frame and sequence, 6-47
frame operator, 6-46
Riesz basis, 6-44–6-45
tight frame, 6-46
ideal bandpass wavelet
Fourier transform, 6-5–6-6
frequency axis splitting, 6-6–6-7
impulse response, 6-8
vs. low-pass, 6-5–6-6
L^1 and L^2 signal space
convolution integral, 6-36–6-37
Lebesgue integrals, 6-31–6-32
L^P signal, 6-32–6-34
L^2 functions, 6-8–6-10
multiresolution and wavelets
continuous time filter banks, 6-59–6-60
frequency domain, 6-51
ideal filter, 6-51–6-52
paraunitary filter banks, 6-56–6-58
time domain, 6-50
notations and acronyms, 6-3
octave-band splitting scheme, 6-8, 6-9
orthogonal projections, 6-10
orthonormal wavelet, 6-71–6-72
short-time Fourier transform
definition, 6-16–6-17
filter impulse response, 6-17
Gabor window, time–frequency resolution, 6-18–6-19
invertibility, 6-47–6-48
limitations, 6-30
orthonormality, 6-48–6-49

shifted filters, analysis bank, 6-18
time–frequency localization, 6-49–6-50
wavelet regularity
ninth-order FIR filter, 6-73–6-74
smoothness and Hölder regularity index, 6-74
time-domain decay and regularity, 6-77–6-78
two-scale dilation equation, 6-72–6-73
wavelet transforms
coefficient computation, 6-10–6-11
CWT and DWT, 6-15
definition, 6-11
frequency response, 6-16
properties, 6-12–6-13
vs. short-time Fourier transform, 6-19–6-22
Wideband amplifiers
composite stages, 15-27–15-28
feedback cascades, 15-28–15-29

Upon its initial publication, *The Circuits and Filters Handbook* broke new ground. It quickly became **the** resource for comprehensive coverage of issues and practical information that can be put to immediate use. Not content to rest on his laurels, in addition to updating the second edition, editor Wai-Kai Chen divided it into tightly focused texts that made the information easily accessible and digestible. These texts have been revised, updated, and expanded so that they continue to provide solid coverage of standard practices and enlightened perspectives on new and emerging techniques.

Fundamentals of Circuits and Filters draws together international contributors who provide a unified view of key concepts in the theory of linear circuits and filters, emphasizing interrelated concepts and providing a mathematical reference to the handbook itself. They include a brief introduction to the theory and application of the z-transform, explain the advantages of the wavelet transform and the reason for its recent popularity, present a self-contained development of graph theory, and develop signal flow graphs following the closely related methods of Coates and Mason. The book describes the limited palette of options available in passive energy storage elements and how to make the most use out of what is available. It presents amplifier designs, terminal and port representations of circuits, and an overview of the different approaches to network analysis, highlighting the advantages and disadvantages of each.

Revised chapters:

- Linear Operators and Matrices
- Bilinear Operators and Matrices
- Fourier Methods for Signal Analysis and Processing
- Application of Symmetry: Two-Dimensional Polynomials, Fourier Transforms, and Filter Design
- Passive Circuit Elements
- Bipolar Junction Transistor Amplifiers
- Operational Amplifiers
- Terminal and Port Representations
- Symbolic Analysis

This volume will undoubtedly take its place as the engineer's first choice in looking for solutions to problems encountered in the analysis and behavior predictions of circuits and filters.

Preface

The purpose of this book is to provide in a single volume a comprehensive reference work covering the broad spectrum of monolithic device models, high-performance analog circuits, radio-frequency communications and PLL circuits, digital systems, and data converters. This book is written and developed for the practicing electrical engineers and computer scientists in industry, government, and academia. The goal is to provide the most up-to-date information in the field.

Over the years, the fundamentals of the field have evolved to include a wide range of topics and a broad range of practice. To encompass such a wide range of knowledge, this book focuses on the key concepts, models, and equations that enable the design engineer to analyze, design, and predict the behavior of large-scale circuits and systems. While design formulas and tables are listed, emphasis is placed on the key concepts and theories underlying the processes.

This book stresses fundamental theories behind professional applications and uses several examples to reinforce this point. Extensive development of theory and details of proofs have been omitted. The reader is assumed to have a certain degree of sophistication and experience. However, brief reviews of theories, principles, and mathematics of some subject areas are given. These reviews have been done concisely with perception.

The compilation of this book would not have been possible without the dedication and efforts of Professor John Choma, Jr., and most of all the contributing authors. I wish to thank them all.

Wai-Kai Chen

Editor-in-Chief

Wai-Kai Chen is a professor and head emeritus of the Department of Electrical Engineering and Computer Science at the University of Illinois at Chicago. He received his BS and MS in electrical engineering at Ohio University, where he was later recognized as a distinguished professor. He earned his PhD in electrical engineering at the University of Illinois at Urbana–Champaign.

Professor Chen has extensive experience in education and industry and is very active professionally in the fields of circuits and systems. He has served as a visiting professor at Purdue University, the University of Hawaii at Manoa, and Chuo University in Tokyo, Japan. He was the editor-in-chief of the *IEEE Transactions on Circuits and Systems*, *Series I and II*, the president of the IEEE Circuits and Systems Society, and is the founding editor and the editor-in-chief of the *Journal of Circuits, Systems and Computers*. He received the Lester R. Ford Award from the Mathematical Association of America; the Alexander von Humboldt Award from Germany; the JSPS Fellowship Award from the Japan Society for the Promotion of Science; the National Taipei University of Science and Technology Distinguished Alumnus Award; the Ohio University Alumni Medal of Merit for Distinguished Achievement in Engineering Education; the Senior University Scholar Award and the 2000 Faculty Research Award from the University of Illinois at Chicago; and the Distinguished Alumnus Award from the University of Illinois at Urbana–Champaign. He is the recipient of the Golden Jubilee Medal, the Education Award, and the Meritorious Service Award from the IEEE Circuits and Systems Society, and the Third Millennium Medal from the IEEE. He has also received more than a dozen honorary professorship awards from major institutions in Taiwan and China.

A fellow of the Institute of Electrical and Electronics Engineers (IEEE) and the American Association for the Advancement of Science (AAAS), Professor Chen is widely known in the profession for the following works: *Applied Graph Theory* (North-Holland), *Theory and Design of Broadband Matching Networks* (Pergamon Press), *Active Network and Feedback Amplifier Theory* (McGraw-Hill), *Linear Networks and Systems* (Brooks/Cole), *Passive and Active Filters: Theory and Implements* (John Wiley), *Theory of Nets: Flows in Networks* (Wiley-Interscience), *The Electrical Engineering Handbook* (Academic Press), and *The VLSI Handbook* (CRC Press).

1.1 Bipolar Junction Transistor

Bogdan M. Wilamowski and Guofu Niu

The bipolar junction transistor (BJT) is historically the first solid-state analog amplifier and digital switch, and formed the basis of integrated circuits (ICs) in the 1970s. Starting in the early 1980s, the MOSFET had gradually taken over, particularly for main stream digital ICs. However, in the 1990s, the invention of silicon–germanium base heterojunction bipolar transistor (SiGe HBT) brought the bipolar transistor back into high-volume commercial production, mainly for the now widespread wireless and wire line communications applications. Today, SiGe HBTs are used to design radio-frequency (RF) ICs and systems for cell phones, wireless local area network (WLAN), automobile collision avoidance

radar, wireless distribution of cable television, millimeter wave radios, and many more applications, due to its outstanding high-frequency performance and ability to integrate with CMOS for realizing digital, analog, and RF functions on the same chip.

Below we first introduce the basic concepts of BJT using a historically important equivalent circuit model, the Ebers–Moll model. Then the Gummel–Poon model is introduced, as it is widely used for computer-aided design, and is the basis of modern BJT models like the VBIC, Mextram, and HICUM models. Current gain, high-current phenomena, fabrication technologies, and SiGe HBTs are then discussed.

1.1.1 Ebers–Moll Model

A NPN BJT consists of two closely spaced PN junctions connected back to back sharing the same p-type region, as shown in Figure 1.1a. The drawing is not drawn to scale. The emitter and base layers are thin, typically less than 1 μm, and the collector is much thicker to support a high output voltage swing. For forward mode operation, the emitter–base (EB) junction is forward biased, and the collector–base (CB) junction is reverse biased. Minority carriers are injected from emitter to base, travel across the base, and are then collected by the reverse biased CB junction. Therefore, the collector current is transported from the EB junction, and thus proportional to the EB junction current. In the forward-active mode, the current–voltage characteristic of the EB junction is described by the well-known diode equation

$$I_{EF} = I_{E0}\left[\exp\left(\frac{V_{BE}}{V_T}\right) - 1\right] \tag{1.1}$$

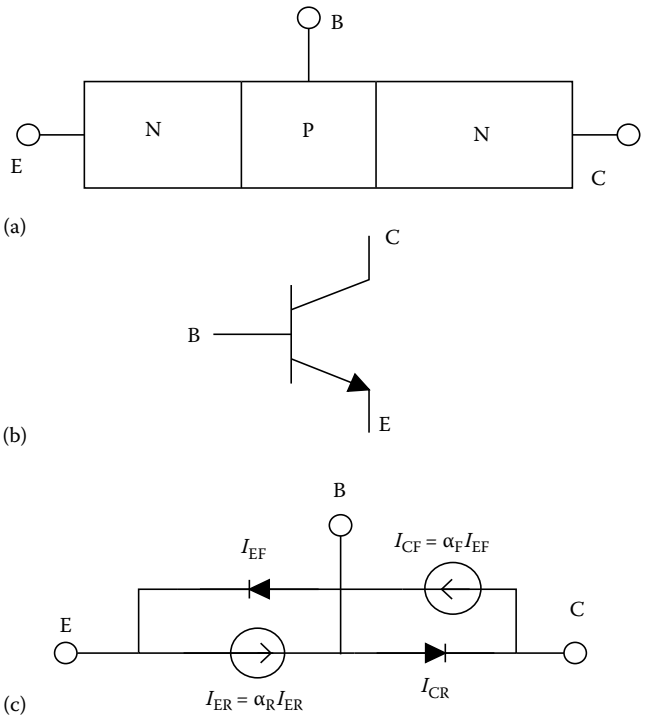

FIGURE 1.1 (a) Cross-sectional view of a NPN BJT. (b) Circuit symbol. (c) The Ebers–Moll equivalent circuit model.

where

I_{E0} is the EB junction saturation current

$V_T = kT/q$ is the thermal potential (about 25 mV at room temperature)

The collector current is typically smaller than the emitter current $I_{CF} = \alpha_F I_{EF}$, where α_F is the forward current gain.

Under reverse mode operation, the CB junction is forward biased and the EB junction is reverse biased. Like in the forward mode, the forward biased CB junction current gives the collector current

$$I_{CF} = I_{C0}\left[\exp\left(\frac{V_{BC}}{V_T}\right) - 1\right] \tag{1.2}$$

where I_{C0} is the CB junction saturation current. Similarly $I_{ER} = \alpha_R I_R$, where α_R is the reverse current gain. Under general biasing conditions, it can be proven that to first order, a superposition of the above described forward and reverse mode equivalent circuits can be used to describe transistor operation, as shown in Figure 1.1b. The forward transistor operation is described by Equation 1.1, and the reverse transistor operation is described by Equation 1.2. From the Kirchoff's current law one can write $I_C = I_{CF} - I_{CR}$, $I_E = I_{EF} - I_{ER}$, and $I_B = I_E - I_C$. Using Equations 1.1 and 1.2 the emitter and collector currents can be described as

$$\begin{aligned} I_E &= a_{11}\left(\exp\frac{V_{BE}}{V_T} - 1\right) - a_{12}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \\ I_C &= a_{21}\left(\exp\frac{V_{BE}}{V_T} - 1\right) - a_{22}\left(\exp\frac{V_{BC}}{V_T} - 1\right) \end{aligned} \tag{1.3}$$

which are known as the Ebers–Moll equations [1]. The Ebers–Moll coefficients a_{ij} are given as

$$a_{11} = I_{E0}, \quad a_{12} = \alpha_R I_{C0}, \quad a_{21} = \alpha_F I_{E0}, \quad a_{22} = I_{C0} \tag{1.4}$$

The Ebers–Moll coefficients are a very strong function of the temperature

$$a_{ij} = K_x T^m \exp\frac{V_{go}}{V_T} \tag{1.5}$$

where

K_x is proportional to the junction area and independent of the temperature

$V_{go} = 1.21$ V is the bandgap voltage in silicon (extrapolated to 0 K)

m is a material constant with a value between 2.5 and 4

When both EB and CB junctions are forward biased, the transistor is called to be working in the saturation region. Current injection through the collector junction may activate parasitic transistors in ICs using p-type substrate, where base acts as emitter, collector as base, and substrate as collector. In typical ICs, bipolar transistors must not operate in saturation. Therefore, for the integrated bipolar transistor the Ebers–Moll equations can be simplified to the form

$$\begin{aligned} I_E &= a_{11}\left(\exp\frac{V_{BE}}{V_T} - 1\right) \\ I_C &= a_{21}\left(\exp\frac{V_{BE}}{V_T} - 1\right) \end{aligned} \tag{1.6}$$

where $a_{21}/a_{11} = \alpha_F$. This equation corresponds to the circuit diagram shown in Figure 1.1c.

1.1.2 Gummel–Poon Model

In real bipolar transistors the current voltage characteristics are more complex than those described by the Ebers–Moll equations. Typical current–voltage characteristics of the bipolar transistor, plotted in semilogarithmic scale, are shown in Figure 1.2. At small-base emitter voltages, due to the generation–recombination phenomena, the base current is proportional to

$$I_{BL} \propto \exp\frac{V_{BE}}{2V_T} \tag{1.7}$$

Also, due to the base conductivity modulation at high-level injections, the collector current for larger voltages can be expressed by the similar relation

$$I_{CH} \propto \exp\frac{V_{BE}}{2V_T} \tag{1.8}$$

Note, that the collector current for wide range is given by

$$I_C = I_s \exp\frac{V_{BE}}{V_T} \tag{1.9}$$

The saturation current is a function of device structure parameters

$$I_s = \frac{qAn_i^2 V_T \mu_B}{\int_0^{w_B} N_B(x)\mathrm{d}x} \tag{1.10}$$

where

$q = 1.6 \times 10^{-19}$ C is the electron charge
A is the EB junction area
n_i is the intrinsic concentration ($n_i = 1.5 \times 10^{10}$ at 300 K)
μ_B is the mobility of the majority carriers in the transistor base
w_B is the effective base thickness
$N_B(x)$ is the distribution of impurities in the base

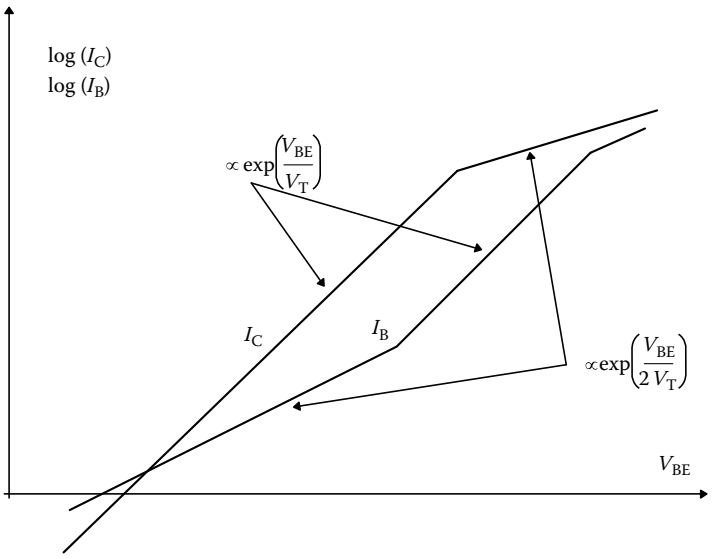

FIGURE 1.2 Collector and base currents as a function of base–emitter voltage.

Note, that the saturation current is inversely proportional to the total impurity dose in the base. In the transistor with the uniform base, the saturation current is given by

$$I_s = \frac{qAn_i^2 V_T \mu_B}{w_B N_B} \tag{1.11}$$

When a transistor operates in the reverse-active mode (emitter and collector are switched) then the current of such biased transistor is given by

$$I_E = I_s \exp \frac{V_{BC}}{V_T} \tag{1.12}$$

Note, that the I_s parameter is the same for forward and reverse mode of operation. The Gummel–Poon transistor model [2] was derived from the Ebers–Moll model using the assumption that $a_{12} = a_{21} = I_s$. For the Gummel–Poon model, Equations 1.3 are simplified to the form

$$\begin{aligned} I_E &= I_s \left(\frac{1}{\alpha_F} \exp \frac{V_{BE}}{V_T} - \exp \frac{V_{BC}}{V_T} \right) \\ I_C &= I_s \left(\exp \frac{V_{BE}}{V_T} - \frac{1}{\alpha_R} \exp \frac{V_{BC}}{V_T} \right) \end{aligned} \tag{1.13}$$

These equations require only three coefficients, while the Ebers–Moll requires four. The saturation current I_s is constant for a wide range of currents. The current gain coefficients α_F and α_R have values smaller, but close to unity. Often instead of using the current gain as $\alpha = I_C/I_E$, the current gain β as a ratio of the collector current to the base current $\beta = I_C/I_B$ is used. The mutual relationships between α and β coefficients are given by

$$\alpha_F = \frac{\beta_F}{\beta_F + 1}, \quad \beta_F = \frac{\alpha_F}{1 - \alpha_F}, \quad \alpha_R = \frac{\beta_R}{\beta_R + 1}, \quad \beta_R = \frac{\alpha_R}{1 - \alpha_R} \tag{1.14}$$

The Gummel–Poon model was implemented in Simulation Program with Integrated Circuit Emphasis (SPICE) [3] and other computer programs for circuit analysis. To make the equations more general, the material parameters η_F and η_R were introduced

$$I_C = I_s \left[\exp \frac{V_{BE}}{\eta_F V_T} - \left(1 + \frac{1}{\beta_R} \right) \exp \frac{V_{BC}}{\eta_R V_T} \right] \tag{1.15}$$

The values of η_F and η_R vary from 1 to 2.

1.1.3 Current Gains of Bipolar Transistors

The transistor current gain β is limited by two phenomena: base transport efficiency and emitter injection efficiency. The effective current gain β can be expressed as

$$\frac{1}{\beta} = \frac{1}{\beta_I} + \frac{1}{\beta_T} + \frac{1}{\beta_R} \tag{1.16}$$

where

β_I is the transistor current gain caused by emitter injection efficiency
β_T is the transistor current gain caused by base transport efficiency
β_R is the recombination component of the current gain

As one can see from Equation 1.16, smaller values of β_I, β_T, and β_R dominate. The base transport efficiency can be defined as a ratio of injected carriers into the base, to the carriers that recombine within the base. This ratio is also equal to the ratio of the minority carrier life time, to the transit time of carriers through the base. The carrier transit time can be approximated by an empirical relationship

$$\tau_{transit} = \frac{w_B^2}{V_T \mu_B (2 + 0.9\eta)}, \quad \eta = \ln\left(\frac{N_{BE}}{N_{BC}}\right) \tag{1.17}$$

where
- μ_B is the mobility of the minority carriers in base
- w_B is the base thickness
- N_{BE} is the impurity doping level at the emitter side of the base
- N_{BC} is the impurity doping level at the collector side of the base

Therefore, the current gain due to the transport efficiency is

$$\beta_T = \frac{\tau_{life}}{\tau_{transit}} = (2 + 0.9\eta)\left(\frac{L_B}{w_B}\right)^2 \tag{1.18}$$

where $L_B = \sqrt{V_T \mu_B \tau_{life}}$ is the diffusion length of minority carriers in the base.

The current gain β_I, due to the emitter injection efficiency, is given

$$\beta_I = \frac{\mu_B \int_0^{w_E} N_{Eeff}(x)dx}{\mu_E \int_0^{w_B} N_B(x)dx} \tag{1.19}$$

where
- μ_B and μ_E are minority carrier mobilities in the base and in the emitter
- $N_B(x)$ is impurity distribution in the base
- N_{Eeff} is the effective impurity distribution in the emitter

The recombination component of current gain β_R is caused by the different current–voltage relationship of base and collector currents as can be seen in Figure 1.2. The slower base current increase is due to the recombination phenomenon within the depletion layer of the base–emitter junction. Since the current gain is a ratio of the collector current to the base current, the relation for β_R can be found as

$$\beta_R = K_{R0} I_C^{1-(1/\eta_R)} \tag{1.20}$$

As it can be seen from Figure 1.2, the current gain β is a function of the current. This gain–current relationship is illustrated in Figure 1.3. The range of a constant current gain is wide for bipolar transistors with a technology characterized by a lower number of generation–recombination centers.

With an increase of CB voltage, the depletion layer penetrates deeper into the base. Therefore, the effective thickness of the base decreases. This leads to an increase of transistor current gain with applied collector voltages. Figure 1.4 illustrates this phenomenon, which is known as the Early's effect. The extensions of transistor characteristics (dotted lines in Figure 1.4) are crossing the voltage axis at

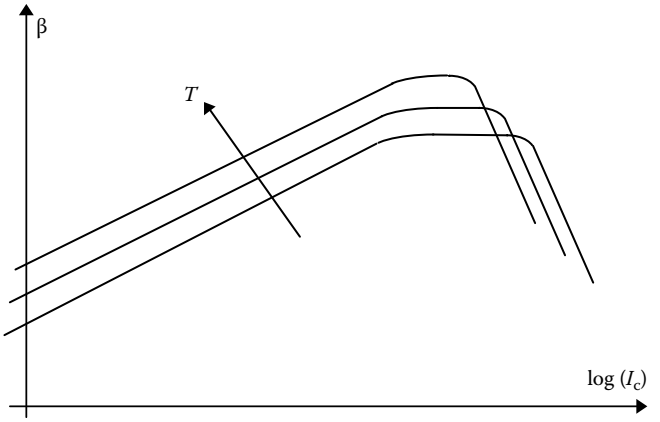

FIGURE 1.3 Current gain β as a function of collector current.

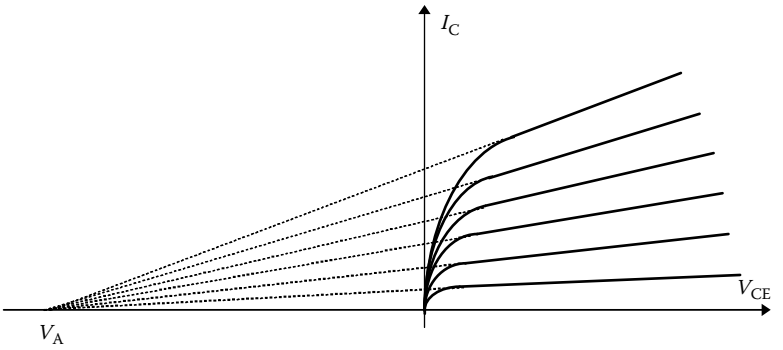

FIGURE 1.4 Current–voltage characteristics of a bipolar transistor.

the point $-V_A$, where V_A is known as the Early voltage. The current gain β, as a function of collector voltage, is usually expressed using the relation

$$\beta = \beta_o\left(1 + \frac{V_{CE}}{V_A}\right) \tag{1.21}$$

Similar equation can be defined for the reverse mode of operation.

1.1.4 High-Current Phenomena

The concentration of minority carriers increases with the rise of transistor currents. When the concentration of moving carriers exceeds a certain limit, the transistor property degenerates. Two phenomena are responsible for this limitation. The first is related to the high concentration of moving carriers (electrons in the NPN transistor) in the base–collector depletion region. This is known as the Kirk effect. The second phenomenon is caused by a high level of carriers injected into the base. When the concentration of injected minority carriers in the base exceeds the impurity concentration there, then the base conductivity modulation limits the transistor performance.

To understand the Kirk effect consider the NPN transistor in forward-active mode with the base–collector junction reversely biased. The depletion layer consists of the negative lattice charge of the base

region and the positive lattice charge of the collector region. Boundaries of the depletion layer are such that total the positive and negative charges are equal. When a collector current, carrying negatively charged electrons, flows through the junction, effective negative charge on the base side of junction increases. Also, the positive lattice charge of the collector side of the junction is compensated by negative charge of moving electrons. This way, the CB space charge region moves toward the collector, resulting in a thicker effective base. With a large current level, the thickness of the base may be doubled or tripled. This phenomenon, known as the Kirk effect, becomes very significant when the charge of moving electrons exceeds the charge of the lightly doped collector N_C. The threshold current for the Kirk effect is given by

$$I_{max} = qAv_{sat}N_C \tag{1.22}$$

where v_{sat} is the saturation velocity for electrons ($v_{sat} = 10^7$ cm/s for silicon).

The conductivity modulation in the base, or high-level injection, starts when the concentration of injected electrons into the base exceeds the lowest impurity concentration in the base N_{Bmin}. This occurs for the collector current I_{max} given by

$$I_{max} < qAN_{Bmax}, \quad \nu = \frac{qAV_T\mu_B N_{Bmax}(2 + 0.9\eta)}{w_B} \tag{1.23}$$

The above equation is derived using Equation 1.17 for the estimation of base transient time.

The high-current phenomena are significantly enlarged by the current crowding effect. The typical cross section of bipolar transistor is shown in Figure 1.5. The horizontal flow of the base current results in the voltage drop across the base region under the emitter. This small voltage difference on the base–emitter junction causes a significant difference in the current densities at the junction. This is due to the very nonlinear junction current–voltage characteristics. As a result, the base–emitter junction has very nonuniform current distribution across the junction. Most of the current flows through the part of the junction closest to base contact. For transistors with larger emitter areas, the current crowding effect is more significant. This nonuniform transistor current distribution makes the high-current phenomena, such as the base conductivity modulation and the Kirk effect, start for smaller currents than given by Equations 1.22 and 1.23. The current crowding effect is also responsible for the change of the effective base resistance with a current. As base current increases, the larger part of emitter current flows closer to the base contact, and the effective base resistance decreases.

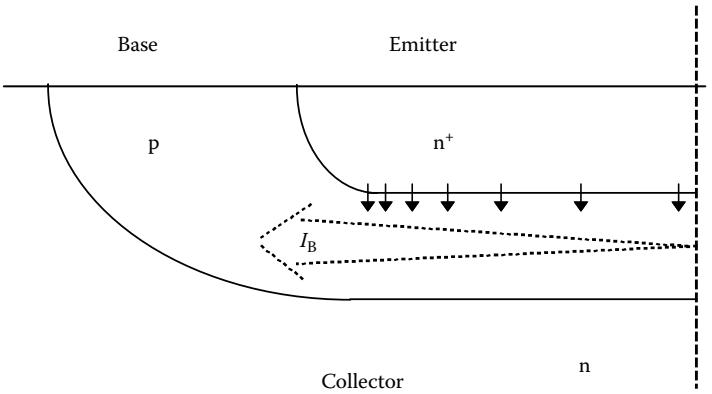

FIGURE 1.5 Current crowding effect.

1.1.5 Small-Signal Model

Small-signal transistor models are essential for AC circuit design. The small-signal equivalent circuit of the bipolar transistor is shown in Figure 1.6a. The lumped circuit shown in Figure 1.6a is only an approximation. In real transistors resistances and capacitances have a distributed character. For most design tasks, this lumped model is adequate, or even the simple equivalent transistor model shown in Figure 1.6b can be considered. The small-signal resistances, r_π and r_o, are inversely proportional to the transistor currents, and the transconductance g_m is directly proportional to the transistor currents

$$r_\pi = \frac{\eta_F V_T}{I_B} = \frac{\eta_F V_T \beta_F}{I_C}, \quad r_o = \frac{V_A}{I_C}, \quad g_m = \frac{I_C}{\eta_F V_T} \tag{1.24}$$

where

η_F is the forward emission coefficient, ranging form 1.0 to 2.0
V_T is the thermal potential ($V_T = 25$ mV at room temperature)

Similar equations to Equation 1.24 can be written for the reverse transistor operation as well.

The series base, emitter, and collector resistances R_B, R_E, and R_C are usually neglected for simple analysis (Figure 1.6b). However, for high-frequency analysis it is essential to use at least the base series resistance R_B. The series emitter resistance R_E usually has a constant, bias-independent value. The collector resistance R_C may significantly vary with the biasing current. The value of the series collector resistance may lower by one or two orders of magnitude if the collector junction becomes forward biased. A large series collector resistance may force the transistor into the saturation mode. Usually, when collector–emitter voltage is large enough, the effect of collector resistance is not significant. The SPICE model assumes constant value for the collector resistance R_C.

The series base resistance R_B may significantly limit the transistor performance at high frequencies. Due to the current crowding effect and the base conductivity modulation, the series base resistance is a function of the collector current I_C [4]

$$R_B = R_{Bmin} + \frac{R_{B0} - R_{Bmin}}{0.5 + \sqrt{0.25 + \frac{i_C}{I_{KF}}}} \tag{1.25}$$

where

I_{KF} is β_F high-current roll-off corner
R_{B0} is the base resistance at very small currents
R_{Bmin} is the minimum base resistance at high currents

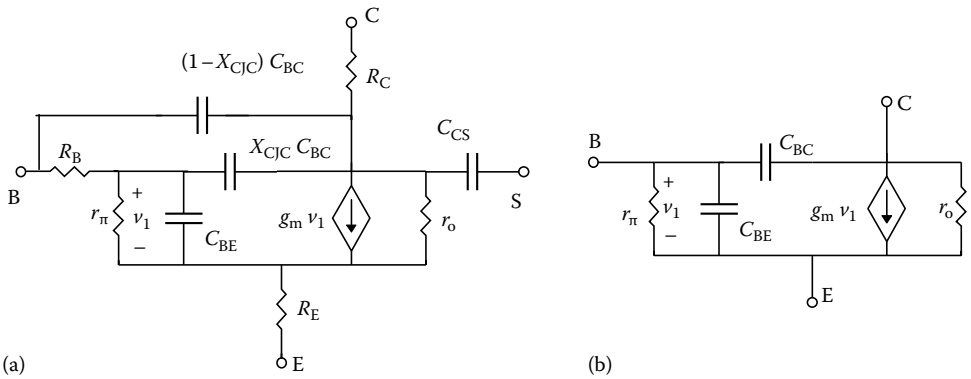

FIGURE 1.6 Bipolar transistor equivalent diagrams. (a) SPICE model and (b) simplified model.

Another possible approximation of the base series resistance R_B, as a function of the base current I_B, is [4]

$$R_B = 3(R_{B0} - R_{Bmin})\frac{\tan z - z}{z\tan^2 z} + R_{Bmin}, \quad z = \frac{\sqrt{1 + \frac{1.44 I_B}{\pi^2 I_{RB}}} - 1}{\frac{24}{\pi^2}\sqrt{\frac{I_B}{I_{RB}}}} \tag{1.26}$$

where I_{RB} is the base current for which the base resistance falls halfway to its minimum value.

The base–emitter capacitance C_{BE} is composed of two terms: the diffusion capacitance, which is proportional to the collector current, and the depletion capacitance, which is a function of the base–emitter voltage V_{BE}. The C_{BE} capacitance is given by

$$C_{BE} = \tau_F \frac{I_C}{\eta_F V_T} + C_{JE0}\left(1 - \frac{v_{BE}}{V_{JE0}}\right)^{-m_{JE}} \tag{1.27}$$

where

V_{JE0} is the base–emitter junction potential
τ_F is the base transit time for forward direction
C_{JE0} is the base–emitter zero-bias junction capacitance
m_{JE} is the base–emitter grading coefficient

The base–collector capacitance C_{BC} is given by a similar expression as Equation 1.27. In the case when the transistor operates in forward-active mode, it can be simplified to

$$C_{BC} = C_{JC0}\left(1 - \frac{v_{BC}}{V_{JC0}}\right)^{-m_{JC}} \tag{1.28}$$

where

V_{JC0} is the base–collector junction potential
C_{JC0} is the base–collector zero-bias junction capacitance
m_{JC} is the base–collector grading coefficient

In the case when the bipolar transistor is in the integrated form, the collector–substrate capacitance C_{CS} has to be considered

$$C_{CS} = C_{JS0}\left(1 - \frac{V_{CS}}{V_{JS0}}\right)^{-m_{JS}} \tag{1.29}$$

where

V_{JS0} is the collector–substrate junction potential
C_{JS0} the collector–substrate zero-bias junction capacitance
m_{JS} is the collector–substrate grading coefficient

When the transistor enters saturation, or it operates in the reverse-active mode, Equations 1.27 and 1.28 should be modified to

$$C_{BE} = \tau_F \frac{I_S \exp\left(\frac{V_{BE}}{\eta_F V_T}\right)}{\eta_F V_T} + C_{JE0}\left(1 - \frac{V_{BE}}{V_{JE0}}\right)^{-m_{JE}} \tag{1.30}$$

$$C_{BC} = \tau_R \frac{I_S \exp\left(\frac{V_{BC}}{\eta_R V_T}\right)}{\eta_R V_T} + C_{JC0}\left(1 - \frac{V_{BC}}{V_{JC0}}\right)^{-m_{JC}} \tag{1.31}$$

1.1.6 Technologies

The bipolar technology was used to fabricate the first ICs more than 40 years ago. A similar standard bipolar process is still used. In recent years, for high-performance circuits and for BiCMOS technology, the standard bipolar process was modified by using the thick selective silicon oxidation instead of the p-type isolation diffusion. Also, the diffusion process was substituted by the ion implantation process, low-temperature epitaxy, and Chemical Vapor Deposition (CVD).

1.1.6.1 Integrated NPN Bipolar Transistor

The structure of the typical integrated bipolar transistor is shown in Figure 1.7. The typical impurity profile of the bipolar transistor is shown in Figure 1.8. The emitter doping level is much higher than the base doping, so large current gains are possible (see Equation 1.19). The base is narrow and it has an impurity gradient, so the carrier transit time through the base is short (see Equation 1.17). Collector concentration near the base–collector junction is low, therefore, the transistor has a large breakdown voltage, large Early voltage V_{AF}, and CB depletion capacitance is low. High impurity concentration in the buried layer leads to a small collector series resistance. The emitter strips have to be as narrow as technology allows, reducing the base series resistance and the current crowding effect. If large emitter area is required, many narrow emitter strips interlaced with base contacts have to be used in a single

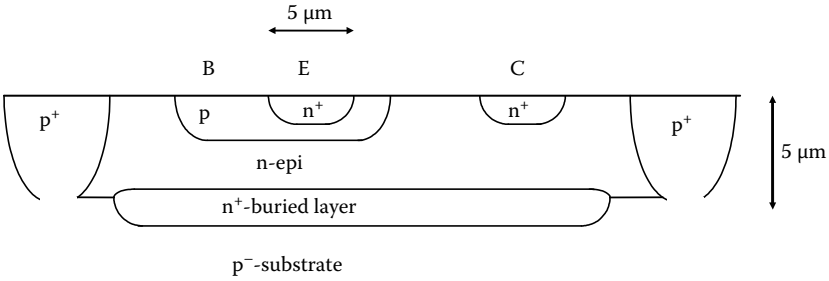

FIGURE 1.7 NPN bipolar structure.

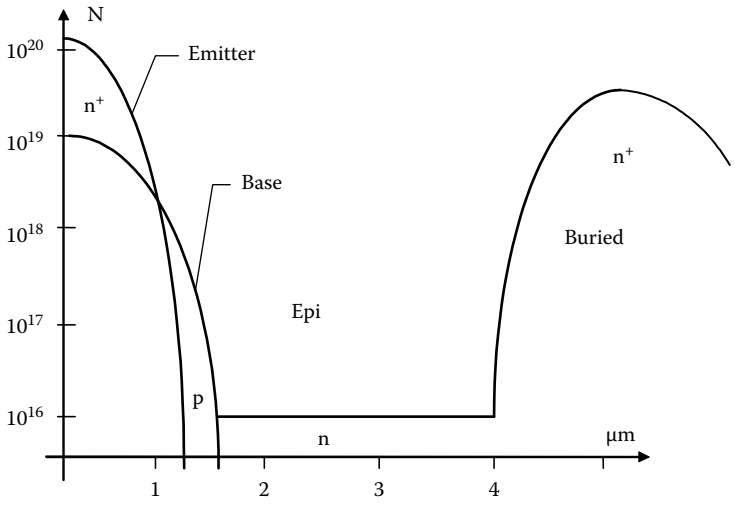

FIGURE 1.8 Cross section of a typical bipolar transistor.

transistor. Special attention has to be taken during the circuit design, so the base–collector junction is not forward biased. If the base–collector junction is forward biased, then the parasitic PNP transistors activate. This leads to undesired circuit operation. Thus, the integrated bipolar transistors must not operate in reverse or in saturation modes.

1.1.6.2 Lateral and Vertical PNP Transistors

The standard bipolar technology is oriented for fabrication of the NPN transistors with the structure shown in Figure 1.7. Using the same process, other circuit elements, such as resistors and PNP transistors, can be fabricated as well.

The lateral transistor, shown in Figure 1.9a uses the base p-type layer for both emitter and collector fabrication. The vertical transistor, shown in Figure 1.9b uses the p-type base layer for emitter, and the p-type substrate as collector. This transistor is sometimes known as the substrate transistor. In both transistors the base is made of the n-type epitaxial layer. Such transistors with a uniform and thick base are slow. Also, the current gain β of such transistors is small. Note, that the vertical transistor has the collector shorted to the substrate as Figure 1.10b illustrates. When a PNP transistor with a large current gain is required, then the concept of the composite transistor can be implemented. Such a composite transistor, known also as superbeta transistor, consists a PNP lateral transistor, and the standard NPN transistor connected as shown in Figure 1.10c. The composed transistor acts as the PNP transistor and it has a current gain β approximately equal to $\beta_{pnp}\beta_{npn}$.

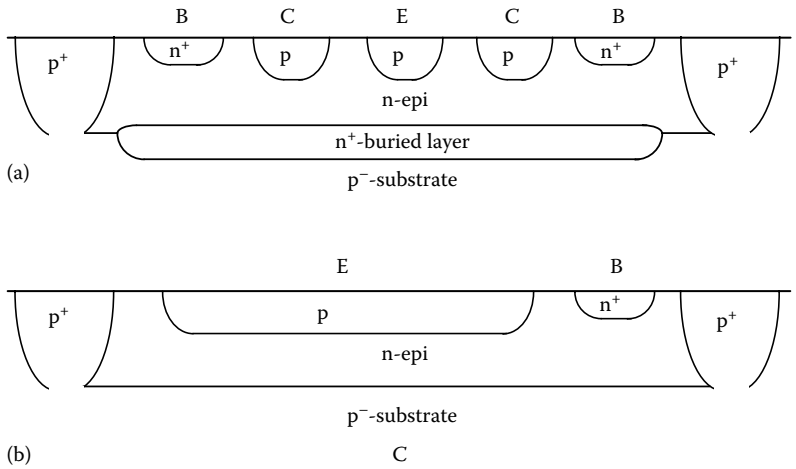

FIGURE 1.9 Integrated PNP transistors: (a) lateral PNP transistor, and (b) substrate PNP transistor.

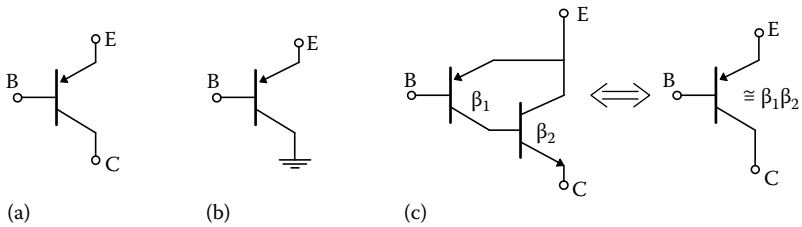

FIGURE 1.10 Integrated PNP transistors: (a) lateral transistor, (b) substrate transistor, and (c) composed transistor.

1.1.7 Model Parameters

It is essential to use proper transistor models in the computer aided design tools. The accuracy of simulation results depends on the model accuracy, and on the values of the model parameters used. In Section 1.1, the thermal and second-order effect in the transistor model are discussed. The SPICE bipolar transistor model parameters are discussed.

1.1.7.1 Thermal Sensitivity

All parameters of the transistor model are temperature dependent. Some parameters are very strong functions of temperature. To simplify the model description, the temperature dependence of some parameters are often neglected. In this chapter, the temperature dependence of the transistor model is described based on the model of the SPICE program [3–5]. Deviations from the actual temperature dependence will also be discussed. The temperature dependence of junction capacitance is given by

$$C_J(T) = C_J\left\{1 + m_J\left[4.010^{-4}(T - T_{NOM}) + 1 - \frac{V_J(T)}{V_J}\right]\right\} \tag{1.32}$$

where T_{NOM} is the nominal temperature, which is specified in the SPICE program in the .OPTIONS statement. The junction potential $V_J(T)$ is a function of temperature

$$V_J(T) = V_J\frac{T}{T_{NOM}} - 3V_T\ln\left(\frac{T}{T_{NOM}}\right) - E_G(T) + E_G\frac{T}{T_{NOM}} \tag{1.33}$$

The value of 3 in the multiplication coefficient of above equation is from the temperature dependence of the effective state densities in the valence and conduction bands. The temperature dependence of the energy gap is computed in the SPICE program from

$$E_G(T) = E_G - \frac{7.0210^{-4}T^2}{T + 1108} \tag{1.34}$$

The transistor saturation current as a function of temperature is calculated as

$$I_s(T) = I_s\left(\frac{T}{T_{NOM}}\right)^{X_{TI}}\exp\left[\frac{E_G(T - T_{NOM})}{V_T T_{NOM}}\right] \tag{1.35}$$

where E_G is the energy gap at the nominal temperature. The junction leakage currents I_{SE} and I_{SC} are calculated using

$$I_{SE}(T) = I_{SE}\left(\frac{T}{T_{NOM}}\right)^{X_{TI}-X_{TB}}\exp\left[\frac{E_G(T - T_{NOM})}{\eta_E V_T T_{NOM}}\right] \tag{1.36}$$

and

$$I_{SC}(T) = I_{SC}\left(\frac{T}{T_{NOM}}\right)^{X_{TI}-X_{TB}}\exp\left[\frac{E_G(T - T_{NOM})}{\eta_C V_T T_{NOM}}\right] \tag{1.37}$$

The temperature dependence of the transistor current gains β_F and β_R are modeled in the SPICE as

$$\beta_F(T) = \beta_F\left(\frac{T}{T_{NOM}}\right)^{X_{TB}}, \quad \beta_R(T) = \beta_R\left(\frac{T}{T_{NOM}}\right)^{X_{TB}} \tag{1.38}$$

The SPICE model does not give accurate results for the temperature relationship of the current gain β at high currents. For high current levels the current gain decreases sharply with the temperature, as can be seen from Figure 1.3. Also, the knee current parameters IKF, IKR, IKB are temperature-dependent, and this is not implemented in the SPICE program.

1.1.7.2 Second-Order Effects

The current gain β is sometimes modeled indirectly by using different equations for the collector and base currents [4,5]

$$I_C = \frac{I_S(T)}{Q_b}\left(\exp\frac{V_{BE}}{\eta_F V_T} - \exp\frac{V_{BC}}{\eta_R V_T}\right) - \frac{I_S(T)}{\beta_R(T)}\left(\exp\frac{V_{BC}}{\eta_R V_T} - 1\right) - I_{SC}(T)\left(\exp\frac{V_{BC}}{\eta_C V_T} - 1\right) \tag{1.39}$$

where

$$Q_b = \frac{1 + \sqrt{1 + 4Q_X}}{2\left(1 - \frac{V_{BC}}{V_{AF}} - \frac{V_{BE}}{V_{AR}}\right)} \tag{1.40}$$

$$Q_X = \frac{I_s(T)}{I_{KF}}\left(\exp\frac{V_{BE}}{\eta_F V_T} - 1\right) + \frac{I_s(T)}{I_{KR}}\left(\exp\frac{V_{BC}}{\eta_R V_T} - 1\right) \tag{1.41}$$

and

$$I_B = \frac{I_S}{\beta_F}\left(\exp\frac{V_{BE}}{\eta_F V_T} - 1\right) + I_{SE}\left(\exp\frac{V_{BE}}{\eta_E V_T} - 1\right) + \frac{I_S}{\beta_R}\left(\exp\frac{V_{BC}}{\eta_R V_T} - 1\right) + I_{SC}\left(\exp\frac{V_{BC}}{\eta_C V_T} - 1\right) \tag{1.42}$$

where

I_{SE} is the base–emitter junction leakage current
I_{SC} is the base–collector junction leakage current
η_E is the base–emitter junction leakage emission coefficient
η_C is the base–collector junction leakage emission coefficient

The forward transit time τ_F is a function of biasing conditions. In the SPICE program the τ_F parameter is computed using

$$\tau_F = \tau_{F0}\left[1 + X_{TF}\left(\frac{I_{CC}}{I_{CC} + I_{TF}}\right)^2 \exp\frac{V_{BC}}{1.44 V_{TF}}\right], \quad I_{CC} = I_s\left(\exp\frac{V_{BE}}{\eta_F V_T} - 1\right) \tag{1.43}$$

At high frequencies the phase of the collector current shifts. This phase shift is computed in the SPICE program following way

$$I_C(\omega) = I_C \exp(j\omega P_{TF}\tau_F) \tag{1.44}$$

where P_{TF} is a coefficient for excess phase calculation.

Noise is usually modeled as the thermal noise for parasitic series resistances, and as shot and flicker noise for collector and base currents

$$\overline{i_B^2} = \frac{4kT\Delta f}{R} \tag{1.45}$$

$$\overline{i_B^2} = \left(2qI_B + \frac{K_F I_B^{A_F}}{F}\right)\Delta f \tag{1.46}$$

$$\overline{i_C^2} = 2qI_C\Delta f \tag{1.47}$$

where K_F and A_F are the flicker-noise coefficient and flicker-noise exponent. More detailed information about noise modeling is given in Section 3.2.

1.1.7.3 SPICE Model of the Bipolar Transistor

The SPICE model of bipolar transistor uses similar or identical equations as described in this chapter [3–5]. Table 1.1 shows the parameters of the bipolar transistor model and its relation to the parameters used in this chapter.

TABLE 1.1 Parameters of SPICE Bipolar Transistor Model

Name Used	Equations	SPICE Name	Parameter Description	Unit	Typical Value	SPICE Default
I_s	1.10, 1.11	IS	Saturation current	A	10^{-15}	10^{-16}
I_{SE}	1.39	ISE	B–E leakage saturation current	A	10^{-12}	0
I_{SC}	1.39	ICS	B–C leakage saturation current	A	10^{-12}	0
β_F	1.14, 1.16, 1.21	BF	Forward current gain	—	100	100
β_R	1.14, 1.16, 1.21	BF	Reverse current gain	—	0.1	1
η_F	1.15, 1.24, 1.30, 1.31, 1.39 through 1.41	NF	Forward current emission coefficient	—	1.2	1.0
η_R	1.15, 1.24, 1.30, 1.31, 1.39 through 1.42	NR	Reverse current emission coefficient	—	1.3	1.0
η_E	1.39	NE	B–E leakage emission coefficient	—	1.4	1.5
η_C	1.39	NC	B–C leakage emission coefficient	—	1.4	1.5
V_{AF}	1.21, 1.40	VAF	Forward Early voltage	V	200	∞
V_{AR}	1.21, 1.40	VAR	Reverse Early voltage	V	50	∞
I_{KF}	1.22, 1.23, 1.40	IKF	β_F high-current roll-off corner	A	0.05	∞
I_{KR}	1.22, 1.23, 1.40	IKR	β_R high-current roll-off corner	A	0.01	∞
I_{RB}	1.26	IRB	Current where base resistance falls by half	A	0.1	∞
R_B	1.25, 1.26	RB	Zero base resistance	Ω	100	0
R_{Bmin}	1.25, 1.26	RBM	Minimum base resistance	Ω	10	RB
R_E	Figure 1.6	RE	Emitter series resistance	Ω	1	0
R_C	Figure 1.6	RC	Collector series resistance	Ω	50	0
C_{JE0}	1.27	CJE	B–E zero-bias depletion capacitance	F	10^{-12}	0
C_{JC0}	1.28	CJC	B–C zero-bias depletion capacitance	F	10^{-12}	0
C_{JS0}	1.29	CJS	Zero-bias collector–substrate capacitance	F	10^{-12}	0
V_{JE0}	1.27	VJE	B–E built-in potential	V	0.8	0.75

X_{TI}	1.35 through 1.37	XTI	Temperature exponent for effect on I_s	—	3.5	3
K_F	1.46	KF	Flicker-noise coefficient	—		0
A_F	1.46	AF	Flicker-noise exponent	—		1
F_C		FC	Coefficient for the forward biased depletion capacitance formula	—	0.5	0.5
T_{NOM}	1.32 through 1.38	TNOM	Nominal temperature specified in .OPTION statement	K	300	300

The SPICE [3] was developed mainly for analysis of ICs. During the analysis it is assumed that the temperatures of all circuit elements are the same. This is not true for power ICs where the junction temperatures may differ by 30 K or more. This is obviously not true for circuits composed of the discrete elements where the junction temperatures may differ by 100 K and more. These temperature effects, which can significantly affect the analysis results, are not implemented in the SPICE program.

Although the SPICE bipolar transistor model uses more than 40 parameters, many features of the bipolar transistor are not included in the model. For example, the reverse junction characteristics are described by Equation 1.32. This model does not give accurate results. In the real silicon junction the leakage current is proportional to the thickness of the depletion layer, which is proportional to $V^{1/m}$. Also the SPICE model of the bipolar transistor assumes that there is no junction breakdown voltage. A more accurate model of the reverse junction characteristics is described in Section 11.5 of *Fundamentals of Circuits and Filters*. The reverse transit time τ_R is very important to model the switching property of the lumped bipolar transistor, and it is a strong function of the biasing condition and temperature. Both phenomena are not implemented in the SPICE model.

1.1.8 SiGe HBTs

The performance of the Si bipolar transistor can be greatly enhanced with proper engineering of the base bandgap profile using a narrower bandgap material, SiGe, an alloy of Si and Ge. Structure wise, a SiGe

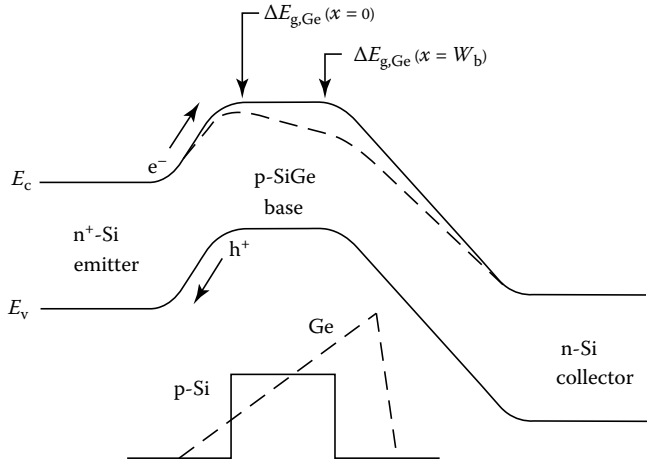

FIGURE 1.11 Energy band diagram of a graded base SiGe HBT and a comparably constructed Si BJT.

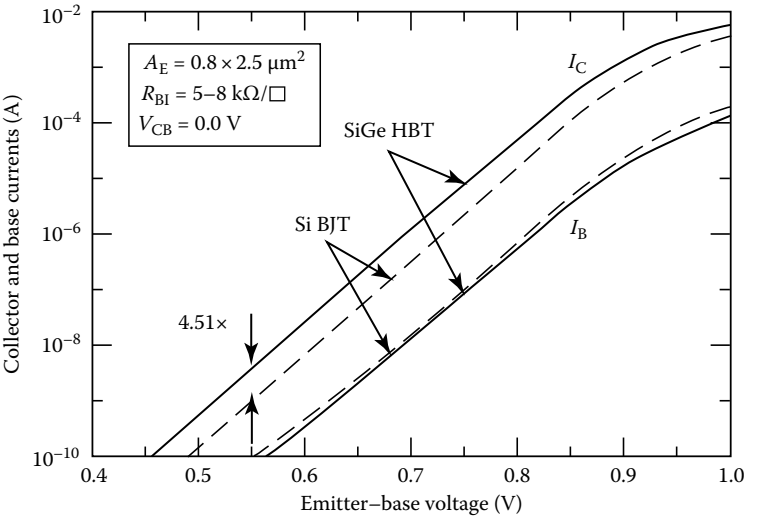

FIGURE 1.12 Experimental collector and base currents versus EB voltage for SiGe HBT and Si BJT.

HBT is essentially a Si BJT with a SiGe base. Its operation and circuit level performance advantages can be illustrated with the energy band diagram in Figure 1.11 [13]. Here the Ge content is linearly graded from emitter toward collector to create a large accelerating electric field that speeds up minority carrier transport across the base, thus making transistor speed much faster and cutoff frequency much higher. Everything else being the same, the potential barrier for electron injection into the base is reduced, thus exponentially enhancing the collector current. The base current is the same for SiGe HBT and Si BJT, as the emitter is typically made the same. Beta is thus higher in SiGe HBT. Figure 1.12 confirms these expectations experimentally with data from a typical first-generation SiGe HBT technology. The measured doping and Ge profiles are shown in Figure 1.13. The metallurgical base width is only 90 nm, and the neutral base width is around 50 nm. Figure 1.14 shows experimental cutoff frequency f_T improvement from using a graded SiGe base, which also directly translates into maximum oscillation frequency f_{max} improvement.

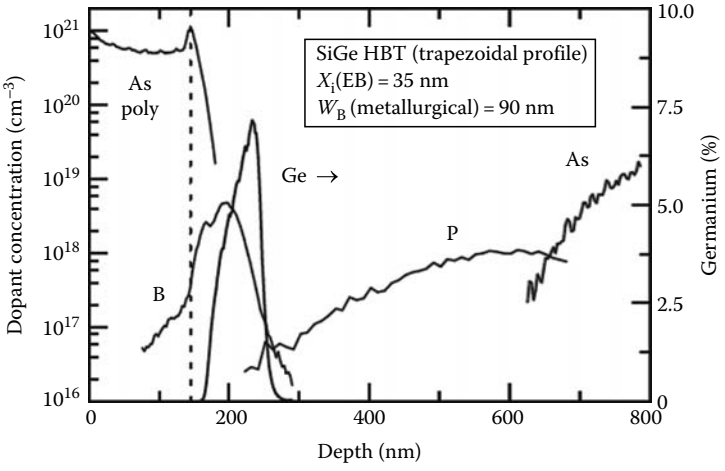

FIGURE 1.13 Measured doping and Ge profiles of a modern SiGe HBT.

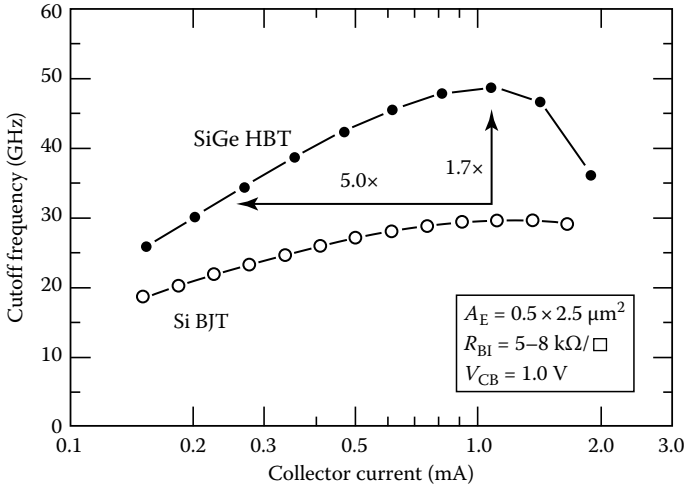

FIGURE 1.14 Experimental cutoff frequency versus collector current for SiGe HBT and Si BJT.

1.1.8.1 Operation Principle and Performance Advantages over Si BJT

In modern transistors, particularly with the use of polysilicon emitter, beta may be sufficient. If so, the higher beta potential of SiGe HBT can then be traded for reduced base resistance, through the use of higher base doping. The unique ability of simultaneously achieving high beta, low base resistance, and high cutoff frequency makes SiGe HBT attractive for many RF circuits. Broadband noise is naturally reduced, as low base resistance reduces transistor input noise voltage, and high beta as well as high f_T reduces transistor input noise current [13]. Experimentally, $1/f$ noise at the same base current was found to be approximately the same for SiGe HBT and Si BJT [14]. Consequently, $1/f$ noise is often naturally reduced in SiGe HBT circuits for the same biasing collector current, as base current is often smaller due to higher beta, as shown in Figure 1.15 using corner frequency as a figure-of-merit.

These, together with circuit-level optimization, can lead to excellent low-phase noise oscillators and frequency synthesizers suitable for both wireless and wire line communication circuits. Another less

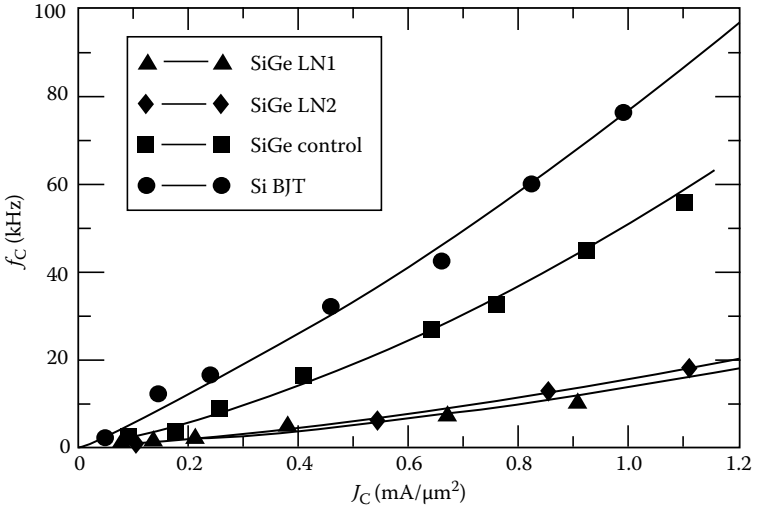

FIGURE 1.15 Experimentally measured corner frequency as a function of collector current density for three SiGe HBTs with different base SiGe designs, and a comparatively constructed Si BJT.

obvious advantage from grading Ge is the collector side of the neutral base has less impact on the collector current than the emitter side of the neutral base. Consequently, as collector voltage varies and the collector side of the neutral base is shifted toward the emitter due to increased CB junction depletion layer thickness, the collector current is increased to a much lesser extent than in a comparably constructed Si BJT, leading to a much higher output impedance or Early voltage. The $\beta \times V_A$ product is thus much higher in SiGe HBT than in Si BJT.

1.1.8.2 Industry Practice and Fabrication Technology

The standard industry practice today is to integrate SiGe HBT with CMOS, to form a SiGe BiCMOS technology. The ability to integrate with CMOS is also a significant advantage of SiGe HBT over III–V HBT. Modern SiGe BiCMOS combines the analog and RF performance advantages of the SiGe HBT, and the lower power logic, high integration level, and memory density of Si CMOS, into a single cost-effective system-on-chip (SoC) solution. Typically, SiGe HBTs with multiple breakdown voltages are offered through selective collector implantation, to provide more flexibility in circuit design.

The fabrication process of SiGe HBT and its integration with CMOS has been constantly evolving in the past two decades, and varies from company to company. Below are some common fabrication elements and modules shared by many if not all commercial first-generation (also most wide spread in manufacturing at present) SiGe technologies:

1. A starting N^+ subcollector around 5 Ω/sq on a p-type substrate at $5 \times 10^{15}/cm^3$, typically patterned to allow CMOS integration.
2. A high-temperature, lightly doped n-type collector, around 0.4–0.6 μm thick at $5 \times 10^{15}/cm^3$.
3. Polysilicon-filled deep trenches for isolation from adjacent devices, typically 1 μm wide and 7–10 μm deep.
4. Oxide filled shallow trenches or LOCOS for local device isolation, typically 0.3–0.6 μm deep.
5. An implanted collector reach through to the subcollector, typically at 10–20 Ωμm^2.
6. A composite SiGe epi layer consisting of a 10–20 nm Si buffer, a 70–100 nm boron-doped SiGe active layer, with or without C doping to help suppress boron out diffusion, and a 10–30 nm Si cap. The integrated boron dose is typically $1–3 \times 10^{13}/cm^2$.

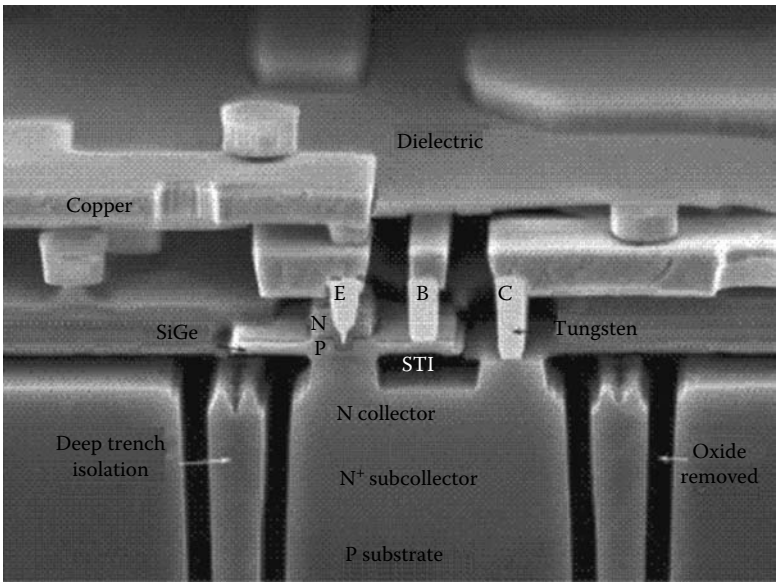

FIGURE 1.16 Structure of a modern SiGe HBT.

7. A variety of EB self-alignment scheme, depending on device structure and SiGe growth approach. All of them utilize some sort of spacer that is 100–300 nm wide.
8. Multiple self-aligned collector implantation to allow multiple breakdown voltages on the same chip.
9. Polysilicon extrinsic base, usually formed during SiGe growth over shallow trench oxide, and additional self-aligned extrinsic implantation to lower base resistance.
10. A silicided extrinsic base.
11. A 100–200 nm thick heavily doped ($>5 \times 10^{20}/\text{cm}^3$) polysilicon emitter, either implanted or in situ doped.
12. A variety of multiple level back-end-of-line metallization schemes using Al or Cu, typically borrowed from parent CMOS process.

These technological elements can also be seen in the electronic image of a second-generation SiGe HBT shown in Figure 1.16.

1.2 Metal–Oxide–Silicon Field Effect Transistor

John Choma, Jr.

1.2.1 Introduction

Integrated electronic circuits realized in metal–oxide–silicon field effect transistor (MOSFET) technology are ubiquitous in both the commercial and military sectors of the technical community. To be sure, transistors manufactured in certain bipolar and III–V compound transistor technologies compete successfully with their MOSFET counterparts from such performance perspectives as switching speed, wideband frequency response, and insensitivity to electromagnetic interference and irradiated environments. Nevertheless, the MOSFET reigns supreme in the extant state of the electronics art for several reasons. The first of these reasons derives from the fact that the cross-section geometry of a MOSFET, when compared to that of most other solid-state transistors, is simpler. This simplicity affords a relative ease of foundry processing, which in turn promotes high device yield and therefore, cost-effective manufacturing. A second reason is that the surface area consumed on chip, or *footprint*, of a MOSFET is generally smaller than that of a comparably performing bipolar or III–V compound transistors. This feature allows increased packing density, which is particularly advantageous for digital signal processors that commonly require upwards of millions of transistors for system functionality. Third, MOSFETs can deliver acceptable circuit performance at low standby power levels, which is a laudable attribute in light of the aforementioned high device density digital architectures and the portability culture in which society is immersed presently. Finally, the native insulating oxide indigenous to the monolithic processing of silicon semiconductors renders MOSFET technologies amenable to the implementation of complex electronic systems on a single chip. No such native oxide prevails in III–V compound technologies, thereby rendering awkward the electrical isolation among the various components, subsystems, and subcircuits that comprise the overall electronic system.

The penchant toward adopting MOSFET technology for analog signal processing applications can also be rationalized. In particular, the nature of modern integrated systems is rarely exclusively digital or exclusively analog. Such systems are, in fact, ''mixed signal'' architectures that embody both digital and analog signal processing on the same chip. Because of the simplicity, packing density, and power dissipation attributes of MOSFETs, virtually 100% of digital architectures are realized in MOSFET technology. Prudence alone accordingly dictates a MOSFET technology realization of the analog cells implicit to a mixed signal framework if only to facilitate the electrical interface between the analog and digital units.

Aside from the operating flexibility and programmability advantages boasted by digital circuit schema, digital circuits in mixed signal architectures are often required to assure and sustain performance optimality of the analog signal flow paths in an electronic system. Unlike most digital networks, high-performance analog circuits are sensitive to specific values, or at least specific ranges of values, of several of the key physical and electrical parameters that effectively define the electrical properties of MOSFETs. Unfortunately, attaining the requisite accuracy in the numerical delineation of these parameters becomes

progressively more daunting as the performance metrics imposed on an analog network become more challenging and as device geometries scale to meet omnipresent quests for wider signal processing passbands. In these high-performance systems, digital subsystems are often deployed to sense the observable performance metrics of an analog signal flow path, compare said metrics to their respective optimal design goals, and then appropriately adjust the relevant electrical parameters or signal excitations implicit to the signal path. In effect, the combined digital controller and analog network behave as a seamless adaptive system that automatically corrects for manufacturing vagaries, increased device operating temperatures, and certain environmental effects.

The most commonly utilized MOSFETs in modern electronic systems come in two flavors: the N-channel MOSFET (NMOS), diagrammed in Figure 1.17 and the P-channel MOSFET (PMOS) shown in Figure 1.18. In the NMOS device of Figure 1.17, the bulk substrate is P-type and is doped to an average acceptor impurity concentration of N_A, for which a representative range of values is $5(10^{14})$ atoms/cm^3 $< N_A <$ 10^{16} atoms/cm^3. Its vertical depth, which is not expressly highlighted in the figure, is many times larger than the depth, Y_d, (of the order of a few tenths of microns) of either the source or drain diffusions or implants. These regions, whose widths are indicated as L_{diff} and which are connected electrically to the source (S) and drain (D) terminals of the MOSFET, are very strongly doped in that their donor impurity concentrations are $N_D = 10^{20}$ atoms/cm^3 or larger. The width, L_{diff}, is typically two- or three-times the channel length, indicated as L in the diagram. The metallization contact that forms the electrical terminal of the semiconductor bulk (B) is generally connected to the most negative potential available in the circuit into which the subject transistor is embedded. Such a connection reverse biases the PN junctions formed between the bulk and source regions and between the bulk and drain regions. This reverse biasing ensures that for at least low signal frequencies, the source and drain regions are electrically isolated from each other and from the bulk substrate. In certain types of multiwell IC processes, bulk–source and bulk–drain reverse biasing is assured simply by returning the bulk terminal directly to the source region contact.

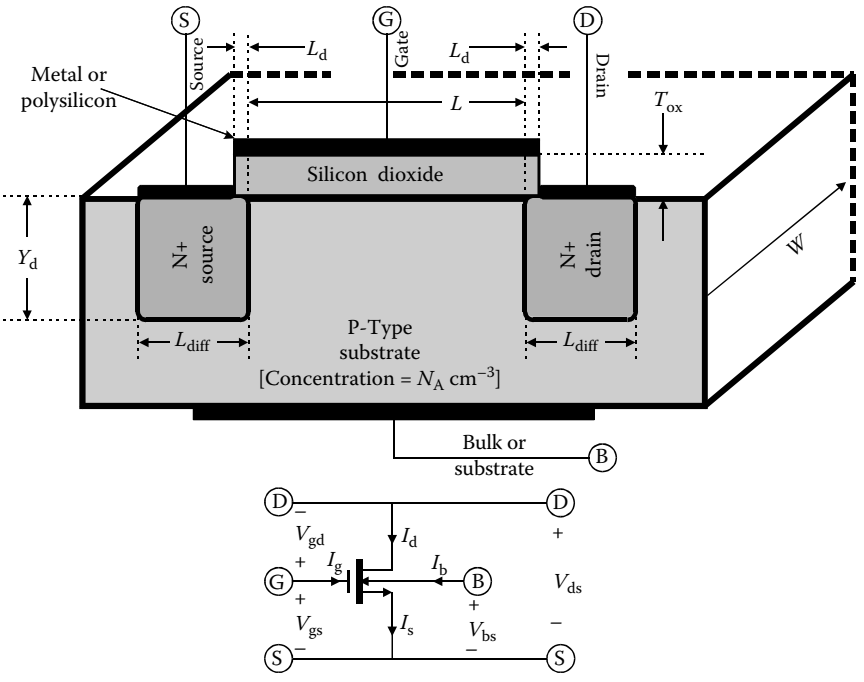

FIGURE 1.17 A simplified three-dimensional depiction of an N-channel MOSFET (NMOS) and its corresponding electrical schematic symbol. The diagram is not drawn to scale.

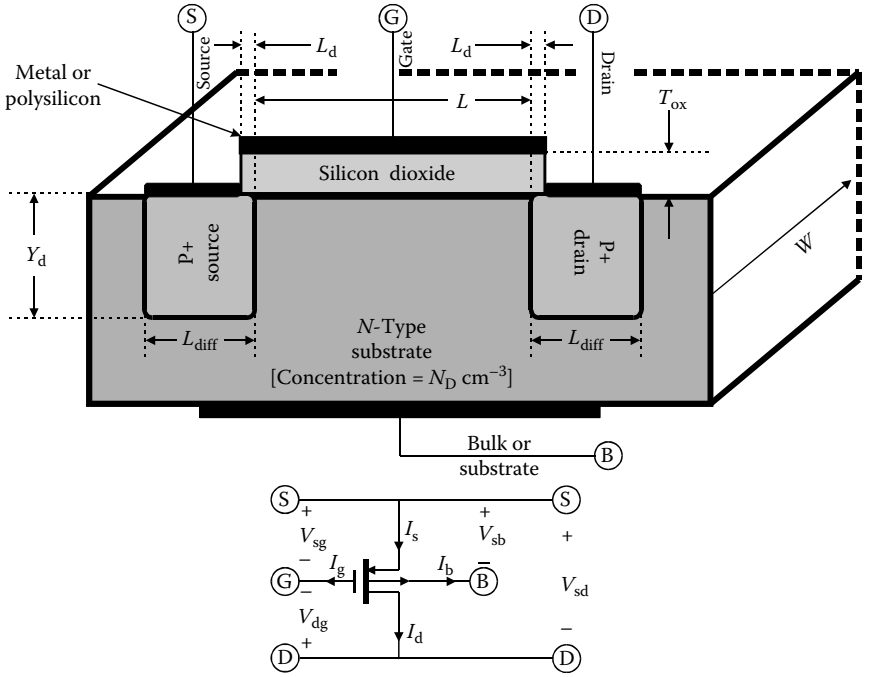

FIGURE 1.18 A simplified three-dimensional depiction of an P-channel MOSFET (PMOS) and its corresponding electrical schematic symbol. The diagram is not drawn to scale.

Lying atop the P-type bulk substrate is an insulating silicon dioxide layer of thickness T_{ox} that extends into the page as shown by a gate width, W. The oxide thickness in the extant state of the art is of the order of several tens of angstroms, where 1 Å is 10^{-8} cm. This oxide layer entirely covers the channel length, L, that separates the source region from the drain region, and it may overlap the source and drain regions by the amount, L_d, indicated in the diagram. The overlap of the source and drain regions is undesirable in that it limits broadband frequency responses in certain types of MOSFET amplifiers. In processes boasting self-aligned gate capabilities, L_d is ideally reduced to zero. But for state of the art processes delivering channel lengths as small as 65–130 nM, gate self-alignment focused on reducing L_d to no more than 5% of L is a challenging undertaking. The gate width, W, can be no smaller than the minimum channel length that can be produced by the identified foundry process. Subject to this proviso, the gate aspect ratio, W/L, is a designable parameter selected in accordance with the operating requirements of the circuit application for which the considered MOSFET is utilized.

The gate terminal (G) is formed by a contact made of a metallic or a polycrystalline silicon layer deposited directly atop the gate oxide. The gate metal of choice is aluminum. If the MOSFET under consideration is used in high-temperature environments and/or in applications that exploit low power supply voltages, polycrystalline silicon, which is commonly referred to as polysilicon, supplants the aluminum gate.

In addition to the simplified cross-section diagram of the N-channel MOSFET, Figure 1.17 inserts the electrical schematic symbol of the NMOS transistor. Of particular interest are the positive reference conventions adopted for four device currents and four device voltages. Specifically, positive drain current, I_d, flows into the transistor, as do the gate current, I_g, and the bulk, or substrate, current, I_b, while positive source current, I_s, flows out of the transistor. It follows from Kirchhoff's current law that

$$I_s = I_d + I_g + I_b. \tag{1.48}$$

However, since the gate contact is isolated from the semiconductor bulk by an insulating oxide layer, I_g is zero at the low frequencies for which capacitive phenomena associated with the insulating gate dielectric are insignificant. Moreover, the bulk current, I_b, is likewise almost zero at low signal frequencies, provided, as is usually the case, that care is taken to ensure reverse biasing of the bulk–drain and bulk–source PN junctions. Accordingly, the source and drain currents, I_s and I_d, respectively, are essentially identical when the frequencies of signals applied to the MOSFET are low. The pages that follow demonstrate that the static and low-frequency value of the drain, and hence the source, current is controlled by the gate-to-source voltage, V_{gs}, the drain-to-source voltage, V_{ds}, and, to a somewhat lesser extent, the bulk-to-source voltage V_{bs}. Stipulating an additional dependence of drain current on gate-to-drain voltage V_{gd} is superfluous, for by Kirchhoff's voltage law,

$$V_{ds} = V_{gs} - V_{gd}. \tag{1.49}$$

The P-channel MOSFET abstracted in Figure 1.18 is architecturally identical to its N-channel counterpart. The notable differences are that the bulk substrate in PMOS is N-type and the source and drain regions are heavily doped with P-type impurities. It follows that electrical isolation between the source region and the bulk, as well as between the drain region and the bulk, requires that the bulk substrate terminal of a PMOS device be connected either to the most positive of available circuit potentials or, if the process allows, to the source terminal. All of the geometrical parameters and their representative values remain the same as stipulated in conjunction with the NMOS unit. The PMOS electrical schematic symbol, which is also shown in the figure at hand, differs from the NMOS symbol in that the directions of the source terminal and bulk terminal arrows are reversed, as are the positive reference directions of all four transistor currents. While Equation 1.48 remains applicable, the analytical expression for the drain current, I_d, which now flows out of the transistor, is more conveniently couched in terms of the source-to-gate voltage, V_{sg}, the source-to-drain voltage, V_{sd}, and the source-to-bulk voltage, V_{sb}. The drain-to-gate voltage, V_{dg}, derives from

$$V_{sd} = V_{sg} - V_{dg}, \tag{1.50}$$

which mirrors Equation 1.49 subsequent to multiplying both sides of this equation by -1.

1.2.2 Channel Charge

A fundamental understanding of the physical charge storage and charge transport mechanisms that underpin the observable volt–ampere characteristics of considered transistors facilitates the reliable and reproducible design of high-performance analog networks in MOSFET technology. Aside from establishing a foundation upon which the static characteristic curves of a MOSFET can be constructed in a physically sound framework, these charge profiles also serve to define the voltage-dependent nature of the capacitance characteristics of a MOSFET. In effect, the subject charge profiles posture the MOSFET as a plausible varactor, which is useful in the monolithic design of voltage controlled oscillators, active filters, and other electronic networks.

The profile of charge stored in the channel between the source and drain regions of a MOSFET is best examined in terms of the simple circuit given in Figure 1.19a. In this circuit, the drain terminal is short circuited to the source to pin the drain–source voltage, V_{ds}, to zero. A zero bias is applied as indicated between the bulk and source, thereby establishing a charge depletion region about the PN junction formed between the substrate and source regions. Since the source and the drain are electrically connected to one another, the zero bias applied between bulk and source establishes an identical depletion zone about the bulk–drain PN junction. These depletion layers are delineated in the companion cross-section diagram of Figure 1.19b, as are the surface potential, φ_o, and the potential, V_{ox}, dropped across the gate silicon dioxide layer. With $V_{ds} = 0$, Equation 1.49 ensures a gate–source voltage, V_{gs}, that

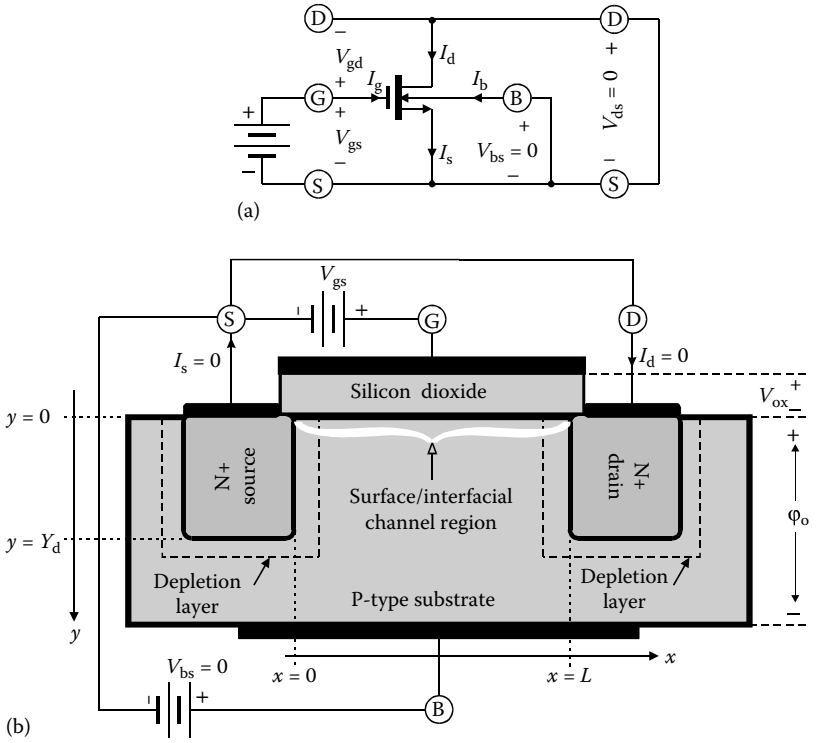

FIGURE 1.19 (a) NMOS transistor operated with $V_{ds} = 0$ and $V_{bs} = 0$. Although the battery connected between the gate and the source ensures $V_{gs} > 0$, $V_{gs} \leq 0$ is allowed in the discussion that references this circuit. (b) Cross-section diagram corresponding to the circuit in (a). Note that all applied voltages are referred to the source terminal. The diagram in (b) is not drawn to scale.

mirrors the gate–drain voltage, V_{gd}, regardless of the voltage applied between gate and source or gate and bulk terminals. In the absence of drain, source, bulk, and gate currents, $V_{ds} = 0$ also guarantees that surface potential φ_o, measured from the oxide semiconductor interface-to-the neutral zone of the bulk substrate, is the same throughout the channel region extending from $x = 0$-to-$x = L$ in the subject diagram. The aforementioned voltage, V_{ox}, includes the effects of parasitic trapped charge in the gate oxide, but it does not include the ramifications of work function differences that unavoidably prevail between the gate contact and the oxide and at the oxide–semiconductor interface. Note then that the voltage, V_{gb}, measured at the gate terminal with respect to the bulk terminal is, ignoring work function phenomena, simply

$$V_{gb} = V_{ox} + \varphi_o. \tag{1.51}$$

1.2.2.1 Surface Charge Density

A pivotally important analytical tool serving to define the charge, capacitance, and static volt–ampere characteristics of a MOSFET, is the charge density, $Q_o(\varphi_o)$, in units of coulombs per unit area, established at the semiconductor surface as a function of the surface potential, φ_o. Several authors have identified this charge profile as [1–3]

$$Q_o(\varphi_o) = -\text{sgn}(\varphi_o)\left(\frac{\sqrt{2}\varepsilon_s V_T}{D_b}\right)\sqrt{G(-\varphi_o) + G(\varphi_o)e^{-2V_F/V_T}}, \tag{1.52}$$

where $\varepsilon_s = 1.037$ pF/cm denotes the dielectric constant of silicon, and

$$\text{sgn}(\varphi_o) = \begin{cases} +1 & \text{for } \varphi_o > 0 \\ -1 & \text{for } \varphi_o < 0 \end{cases}. \tag{1.53}$$

In Equation 1.52,

$$V_T = kT/q \tag{1.54}$$

is the familiar semiconductor thermal voltage for which $k = (1.38)(10^{-23})$ J/K is Boltzmann's constant, $q = (1.60)(10^{-19})$ C is the magnitude of electron charge, and T is the absolute temperature of the semiconductor surface. The voltage, V_F, in the radical on the right-hand side of Equation 1.52 is the Fermi potential, which is given by

$$V_F \triangleq V_T \ln\left(\frac{N_A}{N_i}\right), \tag{1.55}$$

where N_A is the previously defined average acceptor impurity concentration of the bulk substrate in NMOS and $N_i = (1.45)(10^{10})$ atoms/cm^3 is the intrinsic carrier concentration of silicon at $T = 27°$C. The parameter, D_b, is known as the electron Debye length and is given by

$$D_b \triangleq \sqrt{\frac{\varepsilon_s V_T}{qN_A}}. \tag{1.56}$$

Finally, the function, $G(\varphi_o)$, in Equation 1.52 is

$$G(\varphi_o) = e^{\varphi_o/V_T} - 1 - \frac{\varphi_o}{V_T}, \tag{1.57}$$

where it is understood that the surface potential, φ_o, measured with respect to the charge neutral zone in the bulk in Figure 1.19 is established in response to an applied gate–bulk voltage, V_{gb}, or an applied gate–source voltage, V_{gs}. Observe that $G(\varphi_o) = G(-\varphi_o) = 0$ for $\varphi_o = 0$, which delivers the expected result in Equation 1.52 of $Q_o(0) = 0$. It should be understood that Equation 1.52 is premised on Poisson's equation and the Boltzmann carrier relationship,

$$p(0) = N_A e^{-\varphi_o/V_T}, \tag{1.58}$$

where $p(0)$ signifies the hole concentration at the surface if complete ionization of substrate dopant atoms is tacitly presumed. Since

$$p(0)n(0) = N_i^2, \tag{1.59}$$

the corresponding concentration of free surface electrons, $n(0)$, is

$$n(0) = \frac{N_i^2}{N_A} e^{\varphi_o/V_T} = N_A e^{(\varphi_o - 2V_F)/V_T}, \tag{1.60}$$

where Equation 1.55 has been exploited.

Because $G(\varphi_o)$ in Equation 1.57, as well as its companion relationship, $G(-\varphi_o)$, is a nonnegative number for all positive and negative values of the surface potential, the radical on the right-hand side of Equation 1.52 is a positive real number. Accordingly, Equation 1.53 forces $Q_o(\varphi_o) > 0$ for $\varphi_o < 0$ and $Q_o(\varphi_o) < 0$ for $\varphi_o > 0$. The positive nature of the surface charge density for negative surface potentials is indicative of bulk substrate holes attracted to the semiconductor surface because of the force exerted by the surface electric field established in response to negative surface potential. From Gauss' law, this field, say $E_o(\varphi_o)$ is simply

$$E_o(\varphi_o) = -\frac{Q_o(\varphi_o)}{\varepsilon_s} = \text{sgn}(\varphi_o)\left(\frac{\sqrt{2}V_T}{D_b}\right)\sqrt{G(-\varphi_o) + G(\varphi_o)e^{-2V_F/V_T}}, \tag{1.61}$$

which is indeed negative for $\varphi_o < 0$. Observe that Equation 1.58 supports the contention of an enhanced surface hole concentration when the potential established at the semiconductor surface is negative.

An equilibrium condition, which is more commonly referred to in the literature as the *flatband operating condition*, is reached when the applied gate–bulk or gate–source voltage produces a null surface potential, that is, $\varphi_o = 0$. For $\varphi_o = 0$, the net surface charge, $Q_o(\varphi_o)$, in Equation 1.52 is zero, as is the surface electric field, $E_o(\varphi_o)$, in Equation 1.61. Note further that by Equation 1.58, $p(0) = N_A$, which is the equilibrium hole concentration indicative of the NMOS bulk substrate for the transistor abstracted in Figure 1.17, assuming complete ionization of all substrate acceptor impurity atoms.

The negative surface charge prevailing for positive surface potentials, which gives rise to positive surface fields (field lines directed from the surface-to-the bulk substrate), reflects the surface charge depletion forged in response to holes repelled from the surface by $\varphi_o > 0$. Once again, Equation 1.58 is supportive of the proffered rationale in that it confirms a diminished surface hole concentration for progressively larger φ_o. Since departed holes leave in their wake a depletion zone of negative acceptor ions, the negative surface charge density resulting from positive surface potential is hardly surprising.

In addition to repelling holes from the semiconductor surface, Equation 1.60 indicates that the surface electron concentration increases as the surface potential, φ_o, rises above zero. Moreover, Equation 1.52 lends credence to this enhanced electron concentration claim since $Q_o(\varphi_o)$ is seen as becoming monotonically more negative as surface potential φ_o rises above zero. Indeed, the impact of the positive electric field associated with $\varphi_o > 0$ is to establish a force serving to attract the minority carriers (electrons) in the bulk substrate to the surface. For a surface potential in the range, $0 < \varphi_o < V_F$, the depletion charge contribution to the net surface charge continues to dominate over the charge associated with electrons cajoled to the surface, and the surface is said to operate in *depletion mode*. But as φ_o approaches and ultimately surpasses the Fermi potential, V_F, the impact on the nature of the surface charge becomes increasingly more interesting. For example, consider $\varphi_o = V_F$, for which Equations 1.58 and 1.60 yield $p(0) \equiv n(0) = N_i$, that is, the hole and electron concentrations at the surface are identically equal to the intrinsic carrier concentration. In effect, the surface region of the semiconductor changes from obviously P-type-to-intrinsic type, which is to say that the surface at $\varphi_o = V_F$ is neither P-type nor N-type.

For $V_F < \varphi_o < 2V_F$, Equations 1.58 and 1.60 project a surface electron concentration that actually exceeds the surface hole concentration, despite the originally P-type character of the semiconductor surface. In this range of surface potentials, the depletion layer at the surface continues to expand into the substrate but because of the enhanced electron concentration, the surface is said to operate in a condition of *weak inversion*. Weak inversion is significant from an engineering perspective in that it begins to establish the necessary condition for promoting observable drain and source current flow. In particular, suppose that the drain–source voltage, V_{ds}, were to be increased from its present null value to a suitably positive value. The presence of a significant mobile surface charge density in the form of free electrons allows said electrons to be transported from the source-to-the drain by the force associated with the lateral electric field established in response to $V_{ds} > 0$. In turn, this charge transport gives rise to a drain current flowing into the transistor and a source current flowing out of the device.

When φ_o rises to the value, $2V_F$, Equation 1.60 confirms a surface electron concentration that is numerically equal to the substrate doping concentration, N_A. In other words, the surface electron concentration precipitated by the strong positive electric fields implicit to $\varphi_o = 2V_F$ is identical to the equilibrium hole concentration evidenced in a silicon mass whose impurity concentration of completely ionized acceptor atoms is N_A. The surface has effectively changed its sex from its former P-type state to a field-induced (hence the terminology, ''field-effect,'' in the FET nomenclature) N-type state. Since the resultant surface electron concentration, $n(0)$, is rendered substantive, appreciable drain and source currents can flow for even modest values of applied drain–source voltages. In effect, the transistor can be said to be ''turned on'' when φ_o rises to twice the Fermi potential in the sense that a capability for substantial drain current flow is forged. When $\varphi_o \geq 2V_F$, the semiconductor surface is *strongly inverted*, or simply *inverted*.

Figure 1.20 displays a representative surface charge density profile as a function of the surface potential. Since a logarithmic charge scale is required to display all salient features of the charge density, the negative nature of the surface charge for positive surface potentials compels plotting the magnitude of the surface charge density on the vertical (charge) scale in the subject figure. The horizontal (voltage) scale is normalized to the thermal voltage, V_T. The plot invokes the presumptions of a 27°C semiconductor surface temperature and a substrate impurity concentration of $N_A = 10^{15}$ atoms/cm^3. For these stipulations, the thermal voltage is $V_T = 25.89$ mV, and the Fermi potential is $V_F = 288.4$ mV, whence $V_F/V_T = 11.14$. The plot displayed in Figure 1.20 clearly identifies the regions of hole accumulation ($\varphi_o < 0$), surface depletion ($0 < \varphi_o < 2V_F$), weak inversion, as typified by the increased concentration of free electrons at the surface ($V_F < \varphi_o < 2V_F$), and strong inversion, for which $\varphi_o \geq 2V_F$.

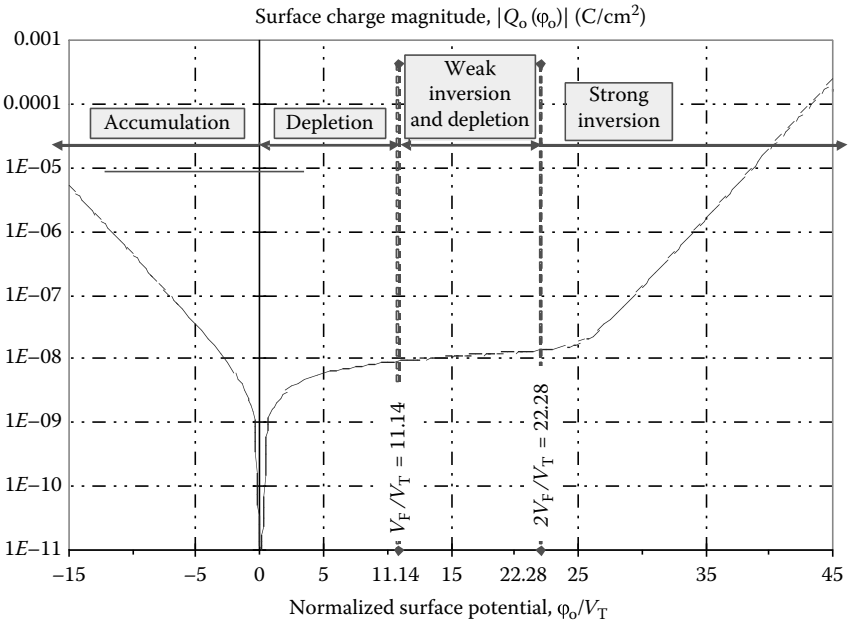

FIGURE 1.20 The magnitude of the surface charge density in the channel interfacial region for the MOSFET configured as shown in Figure 1.19b. A surface temperature of 27°C is assumed, as is a substrate impurity concentration of $N_A = 10^{15}$ atoms/cm^2.

1.2.2.2 Gate–Bulk Capacitance

The density of the net gate-to-bulk capacitance, $C_{gb}(\varphi_o)$, of the MOSFET whose cross-section diagram appears in Figure 1.19b is a series combination of the oxide capacitance density, C_{ox}, and the density of capacitance $C_d(\varphi_o)$, which is established between the oxide–substrate interface and the charge neutral region of the bulk. The pertinent equivalent circuit for $V_{ds} = 0$ is the structure depicted in Figure 1.21b, for which

$$C_{gb}(\varphi_o) = \frac{C_{ox}C_d(\varphi_o)}{C_{ox} + C_d(\varphi_o)}. \tag{1.62}$$

In Equation 1.62,

$$C_{ox} = \frac{\varepsilon_{ox}}{T_{ox}}, \tag{1.63}$$

where $\varepsilon_{ox} = 345$ fF/cm is the dielectric constant of silicon dioxide. Moreover,

$$C_d(\varphi_o) = \frac{d|Q_o(\varphi_o)|}{d\varphi_o}, \tag{1.64}$$

where the surface charge density, $Q_o(\varphi_o)$, is defined by Equation 1.52. After a trifle of differential calculus pain, it can be shown that

$$C_d(\varphi_o) = \text{sgn}(\varphi_o)\frac{\varepsilon_s}{\sqrt{2}D_b}\left[\frac{\left(e^{\varphi_o/V_T} - 1\right)e^{-2V_F/V_T} - \left(e^{-\varphi_o/V_T} - 1\right)}{\sqrt{G(-\varphi_o) + G(\varphi_o)e^{-2V_F/V_T}}}\right]. \tag{1.65}$$

The result at hand defines the surface capacitance density for all values of the surface potential, φ_o. A problem arises for $\varphi_o = 0$ in that the right-hand side becomes an indeterminate 0/0 form. This problem is circumvented by supplanting the exponential terms on the right-hand side of Equation 1.65, inclusive of those embedded in the functions, $G(\varphi_o)$ and $G(-\varphi_o)$, by their second order MacLaurin series expansions. Upon replacement of these exponential terms by said expansions, the surface capacitance density at the flatband condition, $\varphi_o = 0$, is found to be

$$C_d(0) = \frac{\varepsilon_s}{D_b}\sqrt{1 + e^{-2V_F/V_T}} \approx \frac{\varepsilon_s}{D_b} \triangleq C_{FB}, \tag{1.66}$$

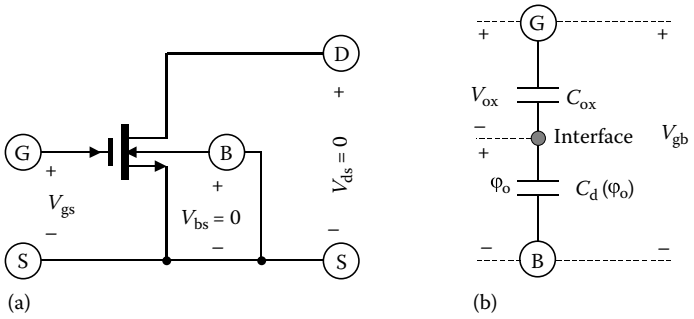

FIGURE 1.21 (a) NMOS transistor of Figure 1.19a operated with $V_{ds} = 0$ and $V_{bs} = 0$. (b) Circuit model between the gate and bulk terminals of the transistor in (a).

where C_{FB} is termed the surface flatband capacitance. The indicated approximation exploits the presumption that the impurity concentration, N_A, in the bulk substrate is significantly larger than the intrinsic carrier concentration, N_i, of silicon. It follows from Equation 1.62 that

$$\frac{C_{gb}(\varphi_o)}{C_{ox}} = \frac{1}{1 + \frac{C_{ox}}{C_d(\varphi_o)}}, \tag{1.67}$$

for which

$$\frac{C_{gb}(0)}{C_{ox}} \approx \frac{1}{1 + \left(\frac{\varepsilon_{ox}}{\varepsilon_s}\right)\left(\frac{D_b}{T_{ox}}\right)}. \tag{1.68}$$

Figure 1.22 displays a plot of the normalized gate–bulk capacitance, $C_{gb}(\varphi_o)/C_{ox}$, as a function of the normalized surface potential, φ_o/V_T, at room temperature (27°C) conditions. The relevant MOSFET is presumed to have an acceptor impurity concentration, N_A, in the bulk of 10^{15} atoms/cm^2, and a gate silicon dioxide thickness, T_{ox}, of 30 Å. The curve shows that in strong accumulation where $\varphi_o \ll 0$, the gate–bulk capacitance per unit area approaches the density of the oxide capacitance, C_{ox}. This observation reflects engineering expectations in that $\varphi_o \ll 0$ attracts a very large concentration of holes to the surface, for which the associated charge density serves to increase dramatically the surface density of capacitance, $C_d(\varphi_o)$. Indeed, for $\varphi_o \ll 0$, it is a simple matter to show that Equation 1.65 collapses to

$$C_d(\varphi_o)\big|_{\varphi_o \ll 0} \approx \frac{\varepsilon_s}{\sqrt{2}D_b}\sqrt{e^{-\varphi_o/V_T} - 1} \approx \frac{\varepsilon_s}{\sqrt{2}D_b}e^{|\varphi_o|/2V_T}, \tag{1.69}$$

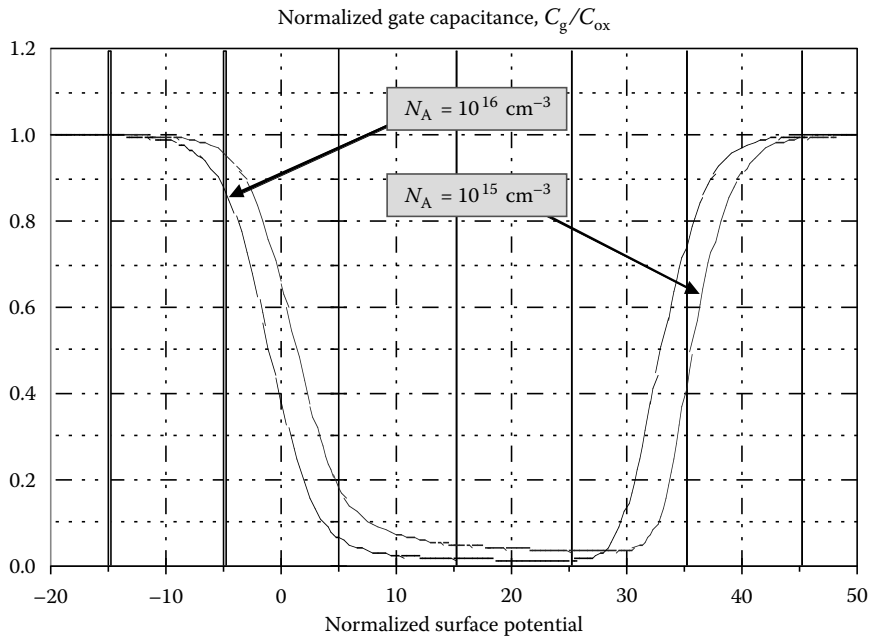

FIGURE 1.22 The normalized gate-to-bulk capacitance of the N-channel MOSFET shown in Figure 1.21a as a function of the indicated normalized surface potential. The temperature of the oxide–semiconductor interface is taken to be $T = 27$°C, the oxide thickness is $T_{ox} = 30$ Å, and the acceptor impurity concentration in the bulk is $N_A = 10^{15}$ atoms/cm^2. The curve is applicable to only low signal frequencies.

which clearly suggests a sharp rise in capacitance density with the absolute value of the negative surface potential. Since the surface capacitance density can be viewed as a ratio of the silicon dielectric constant, ε_s, to an effective and voltage-dependent dielectric thickness, say $y(\varphi_o)$, observe a dielectric thickness associated with Equation 1.69 of

$$y(\varphi_o)\big|_{\varphi_o \ll 0} \approx \sqrt{2} D_b e^{-|\varphi_o|/2V_T}, \tag{1.70}$$

which diminishes rapidly with progressively more negative surface potentials.

As the surface potential increases toward and beyond zero, the normalized capacitance plotted in Figure 1.22 decreases because a depletion layer begins to form at the interface. This depletion layer acts as a dielectric whose thickness increases as a nominal square root function of the surface potential. Under the depletion condition, the surface capacitance given by Equation 1.65 can be approximated by

$$C_d(\varphi_o)\big|_{\text{Depletion}} \approx \frac{\varepsilon_s}{\sqrt{2} D_b \sqrt{\frac{\varphi_o}{V_T} - 1}}, \tag{1.71}$$

which implies a depletion layer thickness, say y_d, (not to be confused with Y_d, the depth of the source and drain regions) of

$$y_d \triangleq y(\varphi_o)\big|_{\text{Depletion}} \approx D_b \sqrt{2\left(\frac{\varphi_o}{V_T} - 1\right)}. \tag{1.72}$$

Equation 1.71 approximates the actual surface capacitance density to within an error magnitude of nominally less than 10% for $3V_T \le \varphi_o \le 20V_T$. This allowable range of surface potential can actually be extended to embrace $\varphi_o \le 2V_F$ since for $\varphi_o > V_F$, an appreciable portion of the charge observed at the interface can be attributed to free electrons, and not simply to the ionic charge in the depletion layer forged by holes repelled from the interface.

As φ_o continues to increase, $C_d(\varphi_o)$, and hence $C_{gb}(\varphi_o)$, continues decreasing toward a minimum value that is achieved at a value close to a surface potential of $2V_F$, which is the threshold of strong surface inversion. At this potential, the thickness of the depletion layer implicit to the interfacial capacitance density is maximized since further increases in the surface charge density derive dominantly from electrons attracted to the surface. Rather than indulge in the academic propriety of using Equation 1.65 to compute the exact surface potential commensurate with minimal surface capacitance density, engineering prudence encourages the simplified approach of presuming $\varphi_o = 2V_F$ to be a sufficiently accurate requirement for minimal depletion capacitance. Upon adoption of this stance, Equation 1.72 is suitable for computing the maximum thickness, say W_d, of the depletion layer. Accordingly,

$$W_d \triangleq y(2V_F) \approx D_b \sqrt{2\left(\frac{2V_F}{V_T} - 1\right)}, \tag{1.73}$$

and since $2V_F$ is invariably much larger than the thermal voltage, V_T, Equation 1.56 allows this result to be written as

$$W_d \approx 2\sqrt{\frac{\varepsilon_s V_F}{qN_A}}. \tag{1.74}$$

The resultant minimum density of surface depletion capacitance is

$$C_{\rm d}(2V_{\rm F}) = \frac{\varepsilon_{\rm s}}{W_{\rm d}} \approx \frac{1}{2}\sqrt{\frac{qN_{\rm A}\varepsilon_{\rm s}}{V_{\rm F}}}. \tag{1.75}$$

Using Equations 1.67 and 1.63, the corresponding density, $C_{\rm min}$, of minimum gate–bulk capacitance is

$$C_{\rm min} \approx C_{\rm gb}(2V_{\rm F}) \approx \frac{\varepsilon_{\rm ox}/T_{\rm ox}}{1 + 2\left(\frac{\varepsilon_{\rm ox}}{T_{\rm ox}}\right)\sqrt{\frac{V_{\rm F}}{qN_{\rm A}\varepsilon_{\rm s}}}}. \tag{1.76}$$

Observe that the maximum factor by which the effective gate–bulk capacitance can be reduced is

$$\frac{C_{\rm ox}}{C_{\rm min}} \approx 1 + 2\left(\frac{\varepsilon_{\rm ox}}{T_{\rm ox}}\right)\sqrt{\frac{V_{\rm F}}{qN_{\rm A}\varepsilon_{\rm s}}}, \tag{1.77}$$

which involves parameters that are largely out of the control of the circuit designer. By inspection of Figure 1.22, this capacitance perturbation requires a surface potential swing extending from roughly $-15V_{\rm T}$ (about -400 mV at 27°C) to $2V_{\rm F}$ (generally smaller than 600 mV). Although the requisite surface potential excursion is somewhat large for maximal capacitance modulation, it should be noted that the maximum capacitance change factor predicted by Equation 1.77 can be as large as almost 100.

As $\varphi_{\rm o}$ increases beyond twice the Fermi potential, the interface charge density increases robustly as the semiconductor surface begins to invert strongly. Figure 1.22 resultantly displays an increasing bulk–gate capacitance density, not unlike the increased capacitance prevailing in strong accumulation because of holes attracted to the interface. Under actual measurement conditions, however, the indicated increased capacitance for $\varphi_{\rm o} > 2V_{\rm F}$ is observed only when the frequencies of signals established between the gate and bulk are below a few tens of hertz [4–6]. The problem is that for most practical signal frequencies, the recombination–generation rates of electrons in NMOS devices are unable to track with the signal-induced exchanges in charge between the neutral bulk and the inversion layer. Figure 1.23 displays the true gate–bulk capacitance characteristics for practical signal frequencies, wherein the dashed segment drawn for $\varphi_{\rm o} > 2V_{\rm F}$ is the applicable high-voltage capacitance trace for frequencies above a few tens of hertz.

1.2.2.3 Approximate Depletion Zone Analysis

As delineated in the discussion pertaining to the surface charge density defined by Equation 1.52, the MOSFET in Figure 1.21a exhibits depletion at the oxide–semiconductor interface for surface potentials satisfying the constraint, $0 < \varphi_{\rm o} < 2V_{\rm F}$. The formation of the surface depletion zone is critically important to the establishment of the volt–ampere characteristics of a MOSFET because it serves as a precursor to the surface inversion that comprises the necessary condition for drain and source current conduction. Recall, for example, that weak inversion is said to initiate at $\varphi_{\rm o} = V_{\rm F}$, in the sense that the original P-type character of the interfacial semiconductor is transformed to intrinsic material. When $\varphi_{\rm o}$ is elevated to $2V_{\rm F}$, the surface is strongly inverted in that the concentration of free electrons at the surface increases to a value that is identical to the average impurity concentration in the substrate. Although the concentration of surface electrons begins to increase for $\varphi_{\rm o}$ barely above zero, as is highlighted by Equation 1.60, an electron concentration commensurate with the possibility of substantial drain and source current flow does not materialize until the surface potential, $\varphi_{\rm o}$, reaches the immediate neighborhood of twice the Fermi potential. An attribute of Equation 1.52 is that this relationship does not explicitly distinguish between immobile depletion charge and mobile electron charge, both of which contribute to the observed surface charge density. A shortfall of Equation 1.52 is that its analytically cumbersome nature all but precludes the development of mathematically tractable expressions for the volt–ampere characteristics of

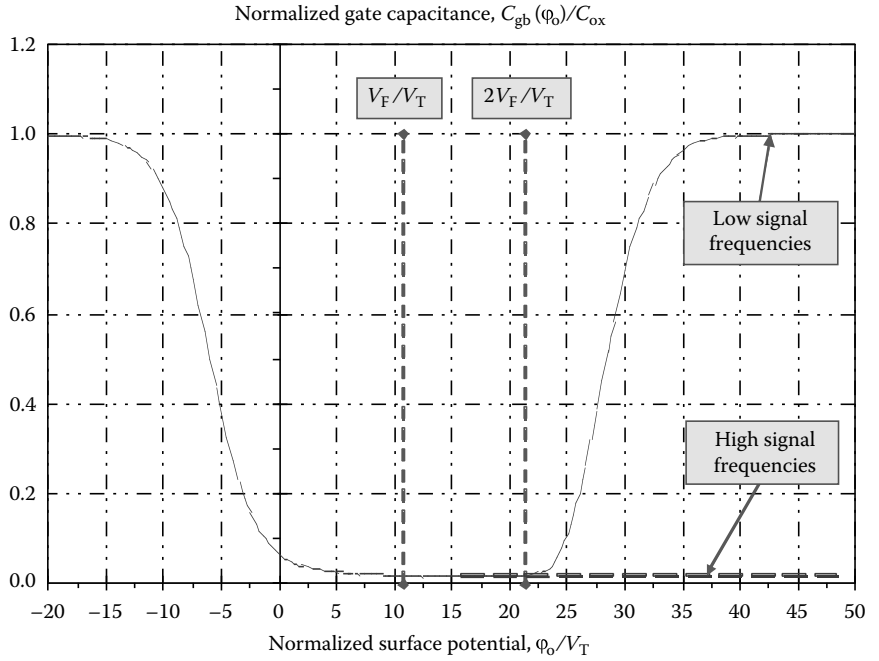

FIGURE 1.23 The capacitance characteristics of Figure 1.22 for the conditions of both low and high signal frequencies.

a MOSFET. Fortunately, the awkwardness of Equation 1.52 is mitigated if the reasonable approximation is made that for $0 < \varphi_o < 2V_F$, the charge in the surface channel region derives exclusively from depletion phenomena, that is, a substantive density of free electron charge does not materialize at the surface until $\varphi_o = 2V_F$.

To the extent that the entire substrate region is uniformly doped at the indicated impurity concentration of N_A and assuming complete ionization of all substrate impurity atoms, the resultant concentration, say $\rho(y)$, of immobile ionic charge in the depletion zone throughout the channel region from source-to-drain is nominally constant at the value, $-qN_A$. Of course, the electron concentration at the surface increases in proportion to the decreased hole population therein but as long as φ_o remains smaller than $2V_F$, Equation 1.60 confirms that the free electron concentration is significantly smaller than N_A.

Figure 1.24a depicts the depletion charge density, $\rho(y)$, beneath the oxide–semiconductor interface, where W_d represents the depth of the depletion layer established at the interface. Using Gauss' law, the electric field, $E(y)$, promoted by this charge concentration profile derives from

$$\frac{dE(y)}{dy} = \frac{\rho(y)}{\varepsilon_s}. \tag{1.78}$$

Since $\rho(y) = -qN_A$ for $0 \le y \le W_d$, Equation 1.78 implies

$$\int_{E(y)}^{E(W_d)} dE(y) = -\frac{qN_A}{\varepsilon_s} \int_{y}^{W_d} dy. \tag{1.79}$$

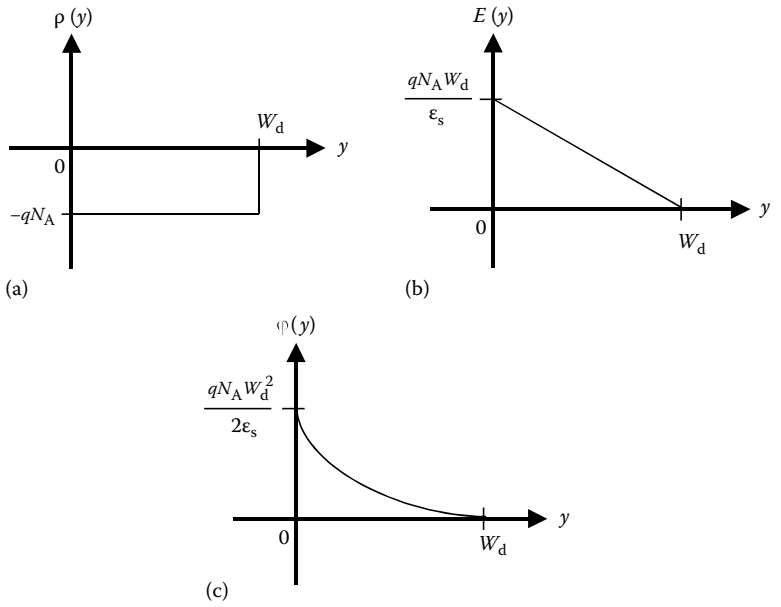

FIGURE 1.24 (a) The approximate profile of the depletion charge concentration at the surface of the MOSFET depicted in Figure 1.21a. (b) The electric field intensity as a function of bulk substrate depth measured with respect to the interfacial surface, corresponding to the charge profile in (a). (c) The potential implied by the electric field plot in (b).

In view of the fact that $E(W_d)$ is zero in the undepleted, charge neutral substrate region corresponding to $W \geq W_d$, Equation 1.79 produces the linear electric field relationship,

$$E(y) = \frac{qN_A W_d}{\varepsilon_s}\left(1 - \frac{y}{W_d}\right) = \frac{V_T W_d}{D_b^2}\left(1 - \frac{y}{W_d}\right), \tag{1.80}$$

where Equation 1.56 for the Debye length is invoked. Equation 1.80 is sketched as a function of the substrate depth variable, y, in Figure 1.24b. Observe that maximum field intensity prevails at surface where

$$E(0) \triangleq E_o = \frac{V_T}{D_b}\left(\frac{W_d}{D_b}\right). \tag{1.81}$$

The potential, $\varphi(y)$, corresponding to the field intensity, $E(y)$, stipulated by Equation 1.80 satisfies

$$-\frac{d\varphi(y)}{dy} = E(y) = \frac{qN_A}{\varepsilon_s}(W_d - y). \tag{1.82}$$

If zero reference potential is ascribed to the substrate depth, W_d, beyond which the substrate is charge neutral, Equation 1.82 sets forth

$$\int_{\varphi(y)}^{0} d\varphi(y) = \frac{qN_A}{\varepsilon_s}\int_{y}^{W_d}(W_d - y)dy, \tag{1.83}$$

whence the bulk substrate potential, $\varphi(y)$, referenced to the potential evidenced at the substrate depletion depth, W_d, is

$$\varphi(y) = \frac{qN_A W_d^2}{2\varepsilon_s}\left(1 - \frac{y}{W_d}\right)^2 = \frac{1}{2}V_T\left(\frac{W_d}{D_b}\right)^2\left(1 - \frac{y}{W_d}\right)^2, \tag{1.84}$$

whose functional dependence on variable y is sketched in Figure 1.24c. Equation 1.84 suggests that the surface potential, $\varphi(0)$, which is effectively the net voltage dropped across the depleted region of the bulk substrate, is

$$\varphi(0) \triangleq \varphi_o = \frac{qN_A W_d^2}{2\varepsilon_s} = \frac{1}{2}V_T\left(\frac{W_d}{D_b}\right)^2 \equiv \frac{E_o W_d}{2}, \tag{1.85}$$

Since the interface potential, φ_o, and hence the depletion depth, W_d, is controlled externally by the applied gate-to-bulk voltage, V_{gb}, it is of interest to determine φ_o as an explicit function of V_{gb}. To this end, the electric field intensity, E_{ox}, in the silicon dioxide layer of the structure of Figure 1.19b is uniform throughout the oxide thickness by virtue of the insulating nature of the oxide. Ignoring work function phenomena prevailing between the gate contact and gate oxide, as well as between the oxide and semiconductor surface, this field is simply

$$E_{ox} = \frac{V_{gb} - \varphi_o}{T_{ox}}. \tag{1.86}$$

Equation 1.86 also invokes the approximation that the voltage dropped from the bottom of the depletion region-to-the bulk terminal is essentially zero. This assumption is reasonable in that the substrate is ultimately reverse biased to preclude substantive bulk current flow. Moreover, the holes displaced from the interface region-to-the neutral bulk render the neutral substrate zone a low resistivity volume. Because the field immediately below the interface is E_o, as defined by Equation 1.81, continuity constraints mandate

$$\varepsilon_{ox}E_{ox} = \varepsilon_s E_o, \tag{1.87}$$

or

$$\varepsilon_{ox}\left(\frac{V_{gb} - \varphi_o}{T_{ox}}\right) = \varepsilon_s\left(\frac{V_T W_d}{D_b^2}\right) \approx C_{FB}\left(\frac{W_d}{D_b}\right)V_T. \tag{1.88}$$

Armed with Equations 1.86, 1.63, and 1.85, parameter W_d in Equation 1.88 can be eliminated to arrive at the utilitarian expression,

$$V_{gb} = \varphi_o + \sqrt{2V_\theta\varphi_o}, \tag{1.89}$$

where the voltage metric, V_θ, termed the *body effect voltage*, is given by

$$V_\theta = V_T\left(\frac{C_{FB}}{C_{ox}}\right)^2 = V_T\left(\frac{\varepsilon_s}{\varepsilon_{ox}}\right)^2\left(\frac{T_{ox}}{D_b}\right)^2 = \frac{qN_A\varepsilon_s}{C_{ox}^2}. \tag{1.90}$$

Parameter V_θ is generally of the order of the mid-tens of microvolts.* Observe that V_θ is proportional to the square of the oxide thickness, T_{ox} and is therefore reduced sharply with diminishing gate oxide thickness.

The final step to the problem of determining the dependence of interface potential φ_o on applied gate-to-bulk voltage V_{gb} involves a straightforward solution of Equation 1.89 for φ_o. The result is

$$\varphi_o = V_{gb} + V_\theta - \sqrt{V_\theta\left(2V_{gb} + V_\theta\right)}. \tag{1.91}$$

As expected, $\varphi_o = 0$ for $V_{gb} = 0$. Ordinarily, V_θ is much smaller than practical values of the gate-to-bulk voltage, V_{gb}, so that Equation 1.91 can be approximated as

$$\varphi_o \approx V_{gb} - \sqrt{2V_\theta V_{gb}}, \tag{1.92}$$

which is similar in form to Equation 1.89.

1.2.2.4 Threshold

The approximate depletion regime analysis executed in Section 1.2.2.3 conveniently precipitates an analytical definition of the threshold condition, that is, the condition whereby strong inversion materializes at the oxide–semiconductor interface. It has been demonstrated that the onset of the threshold condition corresponds to a surface potential, φ_o, of twice the Fermi potential. Accordingly, threshold requires that the gate–bulk voltage V_{gb}, in Equation 1.89 rise to a value, say V_{gbh}, such that

$$V_{gbh} = 2V_F + 2\sqrt{V_\theta V_F}. \tag{1.93}$$

It is to be understood that a gate-to-bulk voltage, V_{gb}, satisfying the constraint, $V_{gb} \geq V_{gbh}$, is commensurate with instilling strong inversion at the surface of the MOSFET depicted in Figure 1.21a. On the presumption that the depth, W_d, of the depletion layer, corresponding to $\varphi_o = 2V_F$ is unaltered by gate–bulk voltage increases beyond the threshold value, V_{gbh}, the resultant charge profile offered in Figure 1.24a changes into the form diagrammed in Figure 1.25. In this diagram, N_s is the concentration of free

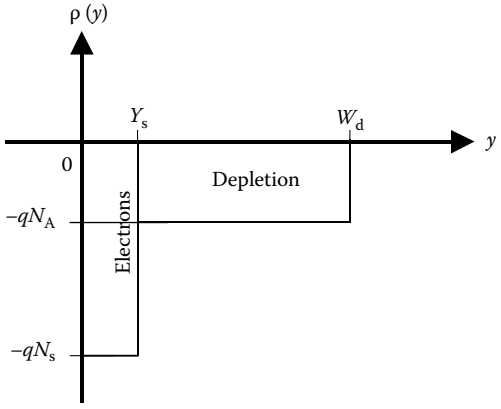

FIGURE 1.25 The approximate profile of the charge concentration for a strongly inverted surface in the MOSFET depicted in Figure 1.21a.

* Most HSPICE and other SPICE simulators use a *body effect parameter* to compute the extent to which the bulk–source voltage perturbs the gate–source threshold voltage. This body effect parameter, γ, derives from $\gamma^2 = 2V_\theta$.

electrons in the surface inversion layer, and Y_s is the thickness of the inversion layer. Depending on the value of the gate–bulk voltage excess, $(V_{gb} - V_{gbh})$, Y_s is typically 20%–50% larger than the electron Debye length.

Two circumstances limit the utility of Equation 1.93. The first of these is that MOSFETs are often operated with nonzero bulk–source bias, as opposed to the zero bias presumed to this juncture. If a bulk–source voltage, V_{bs}, is applied to the MOSFET in Figure 1.21a, the potentials at both the oxide–semiconductor interface and the bottom of the depletion layer are elevated by an amount, V_{bs}, which, in concert with earlier admonitions, is invariably a negative voltage to ensure reverse biasing of the bulk–source and bulk–drain PN junctions. Thus, the results documented in Section 1.2.2.3 remain valid because the voltage developed across the depletion layer is still the surface potential, φ_o, exploited therein. However, since the surface potential rises by V_{bs}, one of the necessary modifications to results disclosed earlier is that Equation 1.60 for the free electron concentration at the surface must be modified as

$$n(0) = \frac{N_i^2}{N_A} e^{(\varphi_o + V_{bs})/V_T} = N_A e^{(\varphi_o + V_{bs} - 2V_F)/V_T}. \tag{1.94}$$

Recall that the measure for the onset of strong inversion in a MOSFET is a surface electron concentration, $n(0)$, that equals to the hole concentration, N_A, in the equilibrium substrate. In order to effect this strong inversion condition, Equation 1.94 suggests the necessity of a surface potential that is at least as large as $(2V_F - V_{bs})$, as opposed to merely $2V_F$. Accordingly, the effect of bulk–source biasing on the gate–bulk threshold voltage can be embraced by replacing the voltage, $2V_F$, in Equation 1.93 by the voltage $(2V_F - V_{bs})$ so that

$$V_{gbh} = (2V_F - V_{bs}) + \sqrt{2V_\theta(2V_F - V_{bs})}. \tag{1.95}$$

The second shortfall of Equation 1.93 stems from the fact in actual circuit design environments, it is far more convenient to stipulate the minimum gate–source voltage, V_{gs}, and not the minimum gate–bulk voltage, V_{bs}, that establishes the onset of strong inversion. Since V_{gs} is the voltage sum, $(V_{gb} + V_{bs})$, adding V_{bs} to both sides of Equation 1.95 delivers a gate-to-source threshold voltage, say V_h, of the form,

$$V_h = V_{ho} + 2\sqrt{V_\theta V_F}\left(\sqrt{1 - \frac{V_{bs}}{2V_F}} - 1\right), \tag{1.96}$$

where V_{ho}, which represents the zero bias ($V_{bs} = 0$) value of the gate–source threshold potential, is

$$V_{ho} = 2\left(V_F + \sqrt{V_\theta V_F}\right). \tag{1.97}$$

In practice, the zero bias value, V_{ho}, of gate–source threshold voltage is best evaluated through measurement since it is strongly influenced by gate region work function phenomena and parasitic charges trapped in the gate oxide layer, whose engineering effects are difficult to quantify accurately and reliably. Observe in Equation 1.96 that the effect of an increasing bulk-to-source reverse bias ($V_{bs} < 0$) is to increase the threshold voltage above its zero bias value, V_{ho}, as a square root function of V_{bs}. This bulk-induced modulation of the threshold potential is rendered small by small values of the square root of parameter V_θ, which Equation 1.90 projects as directly dependent on the gate oxide thickness, T_{ox}. One reason for the current penchant toward progressively decreased oxide thickness is the minimization of threshold voltage modulation, which is generally an undesirable effect in MOSFETs deployed in analog network applications.

1.2.3 Volt–Ampere Characteristics

The static volt–ampere characteristics of the N-channel MOSFET in Figure 1.17 stipulate the dependence of the static drain current, I_d, on the static values of the gate–source voltage, V_{gs}, the drain–source voltage, V_{ds}, and the bulk–source voltage, V_{bs}, which is invariably a nonpositive voltage. It is convenient to partition these characteristics into three segments; namely, the *cutoff regime*, the *ohmic regime*, and the *saturation regime*.

1.2.3.1 Cutoff Regime

The cutoff regime is the most boring of the three MOSFET operating domains in that no drain current flows in cutoff, despite all reasonable positive value of the drain–source voltage, V_{ds}. Since drain current conduction requires surface inversion at the oxide–substrate interface, zero current is assured when no such charge inversion prevails. In turn, no inversion layer is formed when the gate–source voltage, V_{gs}, lies below its threshold value, V_h. Thus, in cutoff,

$$I_d = 0, \quad \text{if } V_{gs} < V_h. \tag{1.98}$$

As V_{gs} rises above zero but remains below V_h, a subthreshold current is induced from the drain-to-the source regions for $V_{ds} > 0$ [7]. This current is manifested by the fact that, as is conveyed by Equation 1.94, the interfacial free electron concentration increases slightly for surface potentials above 0 V. However, the current evidenced in the subthreshold regime is small because of the limited availability of free surface electrons. As a result, the gain and frequency response, in addition to the actual drain current, that the transistor is capable of mustering are limited. Although subthreshold operation enjoys utility in certain types of low-power system applications, such as hearing aids, where neither gain nor bandwidth are daunting requirements, it is rarely exploited in broadband and other high-performance applications.

1.2.3.2 Ohmic Regime

In the ohmic regime, which is sometimes called the *triode regime*, $V_{gs} \geq V_h$ and $V_{ds} \leq (V_{gs} - V_h)$. Thus, the interfacial surface of a MOSFET is strongly inverted in the ohmic domain, and simultaneously, a relatively small voltage is applied from the drain-to-the source. The voltage difference, $(V_{gs} - V_h)$, is commonly referenced as the *drain saturation voltage*, V_{dsat}, that is,

$$V_{dsat} \triangleq V_{gs} - V_h. \tag{1.99}$$

Because of Equation 1.49, observe that the provision, $V_{ds} \leq (V_{gs} - V_h)$, is equivalent to the requirement, $V_{gd} \geq V_h$. This is to say that a MOSFET operates in the ohmic regime if and only if both the gate–source and the gate–drain voltages are larger than the threshold potential. Viewed in yet another fashion, $V_{gs} \geq V_h$ and $V_{gd} \geq V_h$ ensure that both the source and the drain ends of the interfacial surface between the source and the drain regions are strongly inverted. A conduit, or channel, of free electrons that electrically couples the source to the drain is thereby established.

The aforementioned channel of free electrons is highlighted in the device cross section abstracted in Figure 1.26. Because $V_{gs} \geq V_h$ and $V_{gd} \geq V_h$, the electron inversion layer extends throughout the entire surface region from the source-to-the drain. But since $V_{gd} = (V_{gs} - V_{ds})$ and $V_{ds} > 0$, the gate-to-drain bias, V_{gd}, is necessarily smaller than its gate-to-source counterpart, V_{gs}. It follows that the surface potential in the neighborhood of the drain region is smaller than that prevailing near the source region, whence the electron concentration near the drain is smaller than it is at the source. Accordingly, the channel of electrons depicted in the figure at hand does not have a uniform depth (y-direction) and is, in fact, deeper at the source site, where $x = 0$, than it is at the drain site, which is typified analytically by $x = L$. For analogous reasons, the depletion region established about the source, at the interface, and at the drain is widest near the drain.

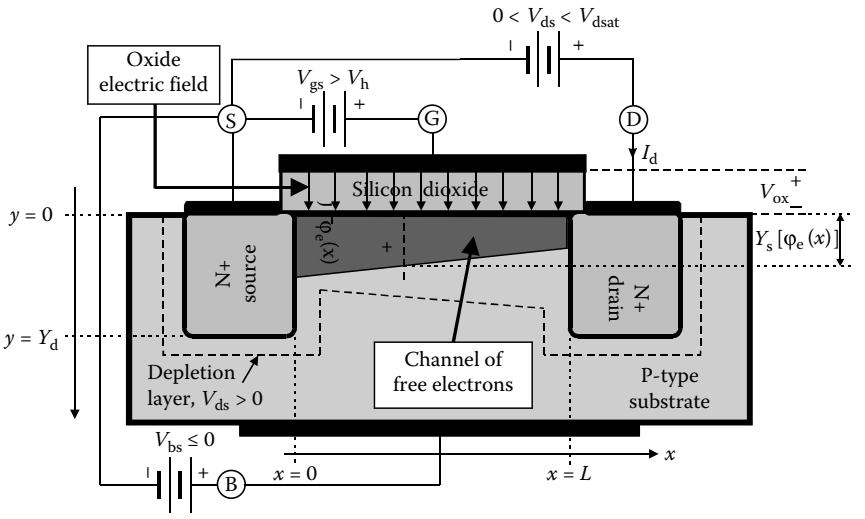

FIGURE 1.26 Cross section of the N-channel MOSFET operated in its ohmic regime. Note that all applied voltages are referred to the source terminal. The diagram is not drawn to scale.

An additionally important point is that the channel potential, symbolized in Figure 1.26 as $\varphi_c(x)$, is measured with respect to the source site. This notation is not to be confused with the previously invoked variable, $\varphi_o(y)$, which measures the potential at the interfacial surface with respect to the neutral region of the bulk substrate. The change in symbolism is reasonable and is encouraged by two issues addressed in the Section 1.2.3.3. The first of these issues is that the bulk–source biasing voltage, V_{bs}, has been absorbed into the threshold voltage metric stipulated by Equation 1.96. Second, this threshold voltage has been defined in terms of the gate voltage, V_{gs}, measured with respect to the source, as opposed to the gate voltage, V_{gb}, referenced to the bulk terminal. Because V_{ds} is nonzero, the channel potential, $\varphi_c(x)$, is not a constant but instead, it varies continuously from $\varphi_c(0) = 0$ at the source site where $x = 0$ to $\varphi_c(L) = V_{ds}$ at the drain site where $x = L$.

An applied drain–source voltage, V_{ds}, launches a lateral electric field, say $E_x(\varphi_c(x))$, that is directed from the drain site-to-the source site and is functionally dependent on the channel potential, $\varphi_c(x)$. This electric field is given by the familiar relationship,

$$E_x(\varphi_c(x)) = -\frac{d\varphi_c(x)}{dx}. \tag{1.100}$$

If μ_n denotes the mobility of electrons, whose concentration within the surface inversion layer postulated in Figures 1.26 and 1.25 is $N_s(\varphi_c(x))$, the static drain current, I_d, promoted by this lateral field is

$$\begin{aligned} I_d &= -q\mu_n W[Y_s(\varphi_c(x))][N_s(\varphi_c(x))]E_x(\varphi_c(x)) \\ &= q\mu_n W[Y_s(\varphi_c(x))][N_s(\varphi_c(x))]\frac{d\varphi_c(x)}{dx}, \end{aligned} \tag{1.101}$$

where $Y_s(\varphi_c(x))$ is the inversion layer thickness introduced in Figure 1.25 and depicted as dependent on the channel potential, $\varphi_c(x)$, in Figure 1.26. It is worthwhile noting that the product, $\mu_n E_x(\varphi_c(x))$, is the velocity of electrons propagated through the inversion layer. This velocity is zero, thereby implying zero drain current, if the gradient, $d\varphi_c(x)/dx$, of channel potential is null. In turn, the channel potential gradient is zero if the applied drain–source voltage, V_{ds}, is zero.

If it is assumed that increases in the channel potential over and above the threshold level incur no change in the geometry of the interfacial depletion region and instead, only cause electrons to be attracted to the surface, Gauss's law predicts

$$q[Y_s(\varphi_c(x))][N_s(\varphi_c(x))] = \varepsilon_{ox}E_{ox}(\varphi_c(x)), \tag{1.102}$$

with $E_{ox}(\varphi_c(x))$ symbolizing the oxide electric field, which is given by

$$E_{ox}(\varphi_c(x)) = \frac{V_{ox}}{T_{ox}} = \frac{V_{gs} - V_h - \varphi_c(x)}{T_{ox}}. \tag{1.103}$$

Recalling Equations 1.63, 1.103, and 1.102 combine with Equation 1.101 to deliver

$$I_d dx = \mu_n C_{ox} W\left[V_{gs} - V_h - \varphi_c(x)\right] d\varphi_c(x). \tag{1.104}$$

An integration of the left-hand side of this result from $x = 0$ to $x = L$ is tantamount to integrating the right-hand side of said result from $\varphi_c(0) = 0$ to $\varphi_c(L) = V_{ds}$. Assuming constant electron mobility through the channel, the requisite integration is straightforward and leads to the desired volt–ampere relationship,

$$I_d = K_n\left(\frac{W}{L}\right)V_{ds}\left(V_{gs} - V_h - \frac{V_{ds}}{2}\right), \tag{1.105}$$

where

$$K_n \triangleq \mu_n C_{ox} \tag{1.106}$$

is the so-called *transconductance coefficient* of the MOSFET. Although K_n is termed a transconductance coefficient, it is not actually a transconductance in that its physical dimension is that of siemens/volt, or mhos/volt.

Several interesting and enlightening features are advanced by Equation 1.105. The first of these is that zero drain current prevails if $V_{ds} = 0$, which is reassuring in that a current flow for null drain–source voltage violates engineering reason, if not the minor issue of conservation of energy. A second, and more significant, point is that the drain current is directly proportional to the gate aspect ratio, W/L. Thus, for fixed gate–source and drain–source voltages, the drain current can be increased or decreased in proportion to this geometric ratio. This controllability over the drain current renders the gate aspect ratio a designable circuit parameter, subject to the proviso that the circuit designer not attempt to make the gate width, W, smaller than the minimum channel length, L, that the process foundry is capable of producing. Thus, if the foundry boasts a 130 nm channel length process, the smallest practical value of W is, in fact, also 130 nm.

A third important feature of Equation 1.105 is the existence of a value of V_{ds} for which drain current I_d is maximized. By setting to zero the partial derivative of I_d in Equation 1.105 with respect to V_{ds}, this extremum is determined to lie at $V_{ds} = (V_{gs} - V_h) = V_{dsat}$, for which the corresponding maximum current, say I_{dsat}, is

$$I_{dsat} = \frac{K_n}{2}\left(\frac{W}{L}\right)\left(V_{gs} - V_h\right)^2 = \frac{K_n}{2}\left(\frac{W}{L}\right)V_{dsat}^2. \tag{1.107}$$

Recalling Equation 1.99, $V_{ds} = V_{dsat}$ corresponds to a gate–drain voltage, V_{gd}, of $V_{gd} = V_h$, which implies that the surface potential at the drain end of the channel barely sustains the onset of strong inversion. In effect, the depth of the electron channel is reduced to zero at the drain site for $V_{ds} = V_{dsat}$,

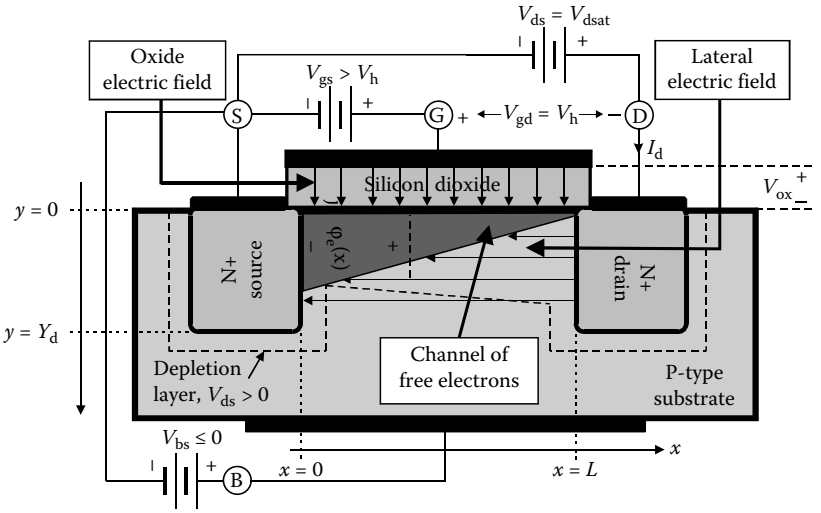

FIGURE 1.27 Cross section of the N-channel MOSFET operated in channel pinch off. The diagram is not drawn to scale.

which justifies the common vernacular of a channel that is *pinched off* at the drain. The situation at hand is diagrammed in Figure 1.27.

At first blush, it may appear incongruous that a pinched off channel, which might be viewed as a means to cut off the supply of electrons to the drain site, can sustain a drain current, yet alone the maximum drain current postulated by Equation 1.107. The current is indeed sustained because of two prevailing phenomena. First, the electric field, $-\mathrm{d}\varphi_c(x)/\mathrm{d}x$, within the inversion layer encourages the transit of electrons toward the tapered edge of the channel at the drain site. Second, electrons reaching the channel edge are influenced immediately by the lateral electric field established by the applied positive drain-to-source voltage. This field, which is abstracted in Figure 1.27 by the indicated horizontal vectors directed from the drain region-to-the source region, sweeps those electrons at the inversion layer boundary into the drain region. The resultant current arising from the transport of electrons across the depletion zone between the tapered channel edge and the drain is, like the current within the inversion layer, proportional to the mobility of electrons. In the depletion zone, this carrier mobility is minority carrier mobility, which is inversely proportional to the background impurity concentration of the bulk substrate. A fundamental reason for maintaining relatively low impurity concentration in the bulk is the assurance of relatively high minority carrier (electron) mobility therein so that carriers are swept across the depletion zone at high velocity, thereby facilitating fast transistor switching and broadband circuit responses.

The fourth interesting feature surrounding Equation 1.105 lends credence to the term, "ohmic," as a descriptive for the operating regime at hand. In particular, Equation 1.105 can be expressed in the form,

$$I_d = K_n\left(\frac{W}{L}\right)V_{ds}\left(V_{gs} - V_h - \frac{V_{ds}}{2}\right) = \frac{V_{ds}}{R_{ds}(V_{gs})}, \tag{1.108}$$

with

$$R_{ds}(V_{gs}) = \frac{1}{K_n(W/L)\left(V_{gs} - V_h - \frac{V_{ds}}{2}\right)}. \tag{1.109}$$

In other words, and as is proffered in Figure 1.28, a MOSFET operated in its ohmic regime, where $V_{gs} \ge V_h$ and $V_{ds} \le V_{dsat}$, behaves as a drain-to-source resistance, $R_{ds}(V_{gs})$, whose resistance value is

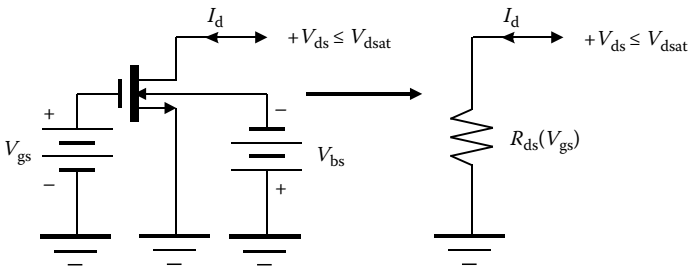

FIGURE 1.28 Static circuit model of an N-channel MOSFET operated in its ohmic regime. The transistor can be operated in such a way that its drain–source terminals emulate a voltage-controlled, nominally linear resistance.

controlled by the applied gate–source voltage, V_{gs}. Moreover, the synthesized resistance is approximately independent of the voltage, V_{ds}, developed across its terminals, and therefore emulates a linear resistance, if $V_{ds} \ll 2(V_{gs} - V_h) \equiv 2V_{dsat}$. In effect, the ohmic regime MOSFET is an electronic approximation of a linear potentiometer whose resistance setting is inversely proportional to the applied gate–source voltage.

1.2.3.3 Saturation Regime

In saturation, which is the volt–ampere domain in which MOSFETs embedded in high-performance analog circuits function, $V_{gs} \ge V_h$ and $V_{ds} \ge (V_{gs} - V_h)$. To first order, the drain current in saturation is taken to be the drain saturation current given by Equation 1.107, which is independent of drain–source voltage, V_{ds}, that is,

$$I_d = \frac{K_n}{2}\left(\frac{W}{L}\right)\left(V_{gs} - V_h\right)^2 \quad \text{for } V_{gs} > V_h, \quad \text{and} \quad V_{ds} \ge \left(V_{gs} - V_h\right). \tag{1.110}$$

The logic underlying this approximation is that the drain current in saturation is determined by the surface electron concentration established for the drain–source voltage, $V_{ds} = (V_{gs} - V_h) = V_{dsat}$, which barely allows for an electron channel spanning the entire source-to-drain spacing. Any increase in the drain-to-source voltage above its saturated value, V_{dsat}, simply adds impetus to the attractive force exerted on inversion layer electrons by the lateral electric field promoted by the drain–source voltage.

The problem with the foregoing logic is that the drain current given by Equation 1.107 is premised on Equation 1.105, which in turn invokes the presumption of an electron inversion layer length that is identical to the channel spacing length, L, separating the source region from the drain region. If $V_{ds} = V_{dsat}$ incurs pinch off at the drain site, and hence an inversion layer length equal to the channel length, L, as illustrated in Figures 1.27 and 1.29a, $V_{ds} > V_{dsat}$ necessarily incurs pinch off within the source–drain spacing, as is suggested in Figure 1.29b. Because of the indicated reduction in the effective channel length from L to $(L - \Delta L)$, the integrated form of Equation 1.104 is now

$$\int_0^{L-\Delta L} I_d dx = \int_0^{V_{dsat}} \mu_n C_{ox} W\left[V_{gs} - V_h - \varphi_c(x)\right] d\varphi_c(x). \tag{1.111}$$

The result of this integration exercise is easily demonstrated to be

$$I_d = \frac{K_n}{2}\left(\frac{W}{L - \Delta L}\right)\left(V_{gs} - V_h\right)^2 = I_{dsat}\left(\frac{L}{L - \Delta L}\right), \tag{1.112}$$

where the current, I_{dsat}, is given by Equation 1.107 and represents the drain current at the transition boundary between ohmic and saturation operational regimes. For most practical applications of

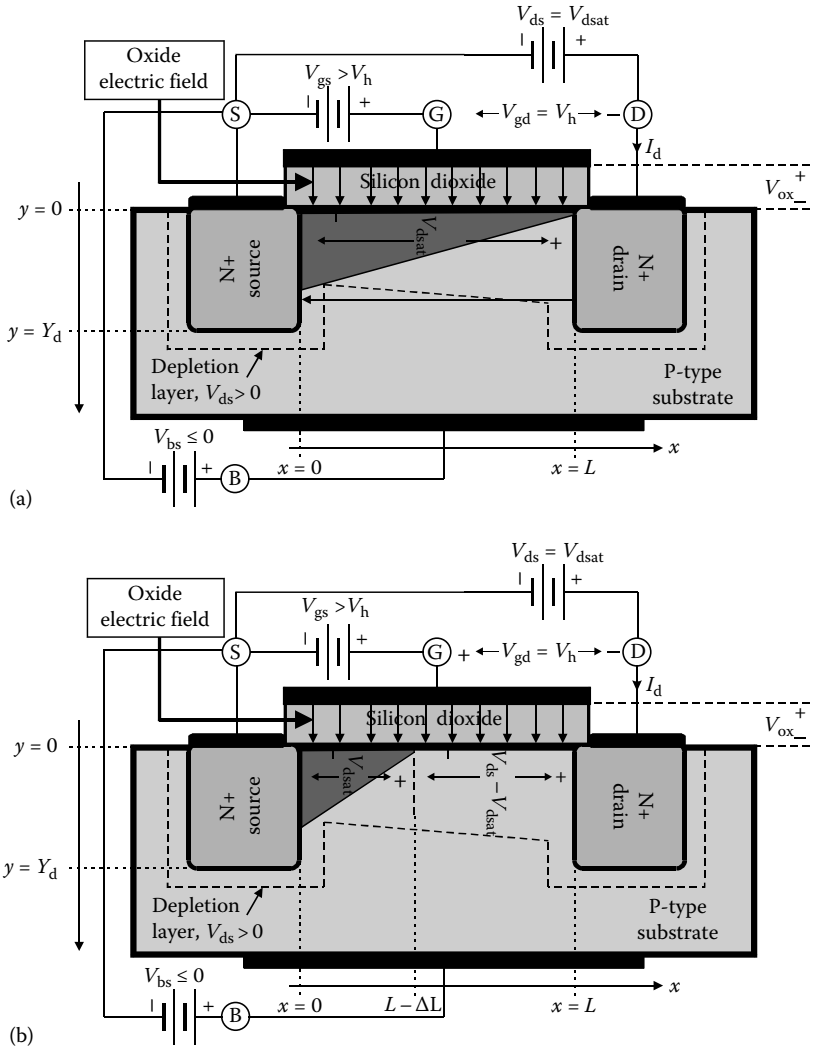

FIGURE 1.29 (a) Cross section of N-channel MOSFET operated in strong inversion and with $V_{ds} = V_{dsat}$. (b) Cross section of the MOSFET in (a) operated with $V_{ds} > V_{dsat}$. The diagrams are not drawn to scale.

MOSFETs [8], the effective reduction, $(L - \Delta L)$, in channel length relates to the drawn channel length, L, as

$$\frac{L}{L - \Delta L} \approx 1 + \frac{V_{ds} - V_{dsat}}{V_\lambda}, \tag{1.113}$$

where V_λ, termed the *channel length modulation voltage*,* is given by the semiempirical expression,

$$V_\lambda = \left(\frac{L}{D_b}\right)\left(\frac{V_j}{V_F}\right)^2 \sqrt{32 V_T \left(V_{ds} - V_{dsat} + V_j\right)}. \tag{1.114}$$

* Most HSPICE and other SPICE simulators use a *channel length parameter* to compute the degree to which the drain–source voltage affects the drain saturation current. This channel length parameter, λ, is $\lambda = 1/V_\lambda$.

In Equation 1.114, V_T is the familiar thermal voltage, D_b is the electron Debye length delineated in Equation 1.56, and V_j is the *built-in potential* of the bulk–drain PN junction. Specifically,

$$V_j = V_T \ln\left(\frac{N_A N_D}{N_i^2}\right), \tag{1.115}$$

with N_A, N_D, and N_i respectively denoting the average impurity concentration in the bulk substrate, the average impurity concentration of the drain diffusion (or implant), and the intrinsic carrier concentration of silicon. Equation 1.114 delivers acceptable analytical accuracy for channel lengths, L, that are no smaller than 0.09 μ and drain–source voltages, V_{ds}, that lie within breakdown ratings of the considered transistor.

The drain current in the saturation regime is now expressible as

$$I_d \approx \frac{K_n}{2}\left(\frac{W}{L}\right)(V_{gs} - V_h)^2\left(1 + \frac{V_{ds} - V_{dsat}}{V_\lambda}\right) = I_{dsat}\left(1 + \frac{V_{ds} - V_{dsat}}{V_\lambda}\right), \tag{1.116}$$

where it is understood that the gate–source and drain–source voltages, V_{gs} and V_{ds}, respectively, are constrained to satisfy the saturation requirements, $V_{gs} > V_h$ and $V_{ds} \geq (V_{gs} - V_h) = V_{dsat}$. Clearly, the saturation regime drain current is no longer independent of the drain–source voltage. The current is seen to rise with V_{ds} with a slope of I_{dsat}/V_λ. Note, however, that this slope is not constant owing to its square root dependence on V_{ds}. For large V_λ, which is manifested by long transistor channel length, L, this rate of current rise with V_{ds} is modest and indeed, the slope of the current–voltage characteristic curve approaches zero in the limit as V_λ approaches infinity. These observations and Equation 1.116 itself suggest that the drain–source port of a MOSFET does not behave as a constant current source whose value, I_{dsat}, is controlled exclusively by gate–source voltage V_{gs}. Instead, the drain–source port is a practical controlled current source comprised of a constant current generator, albeit controlled by gate–source voltage V_{gs}, in shunt with a resistive branch. To wit, Equation 1.116 can be written as

$$I_d \approx I_{dsat} + \frac{V_{ds} - V_{dsat}}{V_\lambda / I_{dsat}}, \tag{1.117}$$

which suggests the static circuit model provided in Figure 1.30. The subject model is more useful conceptually than computationally since a change made to V_{gs} for the purpose of adjusting the nominal drain current, I_{dsat}, influences the resistance value, V_λ/I_{dsat}, and the voltage offset, V_{dsat}, introduced in the drain–source port.

A complication of the channel length embellishment to the saturation drain current expression is that Equation 1.116 is discontinuous with the ohmic domain drain current expression in Equation 1.105 at the transition boundary between respective operating domains. Simple software fixes in commonly

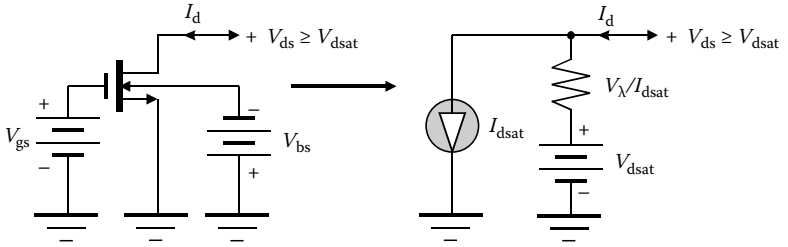

FIGURE 1.30 A large-signal circuit model for an N-channel MOSFET biased to operate in its saturation domain.

available circuit simulators rectify this incongruity. From an analytical perspective, the problem can be tacitly ignored, if V_λ in Equation 1.114 abides by the previously disclosed channel length and voltage restrictions.

For the convenience of the reader, the relevant expressions for the volt–ampere characteristic curves of an N-channel MOSFET are synopsized herewith. In particular,

$$I_d \approx \begin{cases} 0, & V_{gs} < V_h \\ K_n\left(\frac{W}{L}\right) V_{ds}\left(V_{gs} - V_h - \frac{V_{ds}}{2}\right), & V_{gs} \geq V_h;\ V_{ds} < V_{dsat} \\ \frac{K_n}{2}\left(\frac{W}{L}\right)\left(V_{gs} - V_h\right)^2\left(1 + \frac{V_{ds} - V_{dsat}}{V_\lambda}\right), & V_{gs} \geq V_h;\ V_{ds} \geq V_{dsat} \end{cases}, \tag{1.118}$$

where V_{dsat} is the voltage difference, $(V_{gs} - V_h)$. It is to be understood that the positive reference direction of the drain current in NMOS is a current flowing into the drain, while the positive reference voltage polarities reflect those highlighted in Figure 1.17. Moreover, V_h is recalled as a threshold level dependent on the bulk–source voltage, V_{bs}, in accordance with Equation 1.96. A representative plot of the static volt–ampere characteristics of an NMOS transistor appear in Figure 1.31.

In the interests of clarity and completeness, the PMOS counterpart to Equation 1.118 is

$$I_d \approx \begin{cases} 0, & V_{sg} < V_h \\ K_p\left(\frac{W}{L}\right) V_{sd}\left(V_{sg} - V_h - \frac{V_{sd}}{2}\right), & V_{sg} \geq V_h;\ V_{sd} < V_{dsat} \\ \frac{K_p}{2}\left(\frac{W}{L}\right)\left(V_{sg} - V_h\right)^2\left(1 + \frac{V_{sg} - V_{dsat}}{V_\lambda}\right), & V_{sg} \geq V_h;\ V_{sd} \geq V_{dsat} \end{cases}, \tag{1.119}$$

where, in terms of the source–gate voltage, V_{sg}, V_{dsat} is now given by, $(V_{sg} - V_h)$, the threshold voltage, which is dependent on source–bulk voltage V_{sb} in Equation 1.96, remains a positive number, and

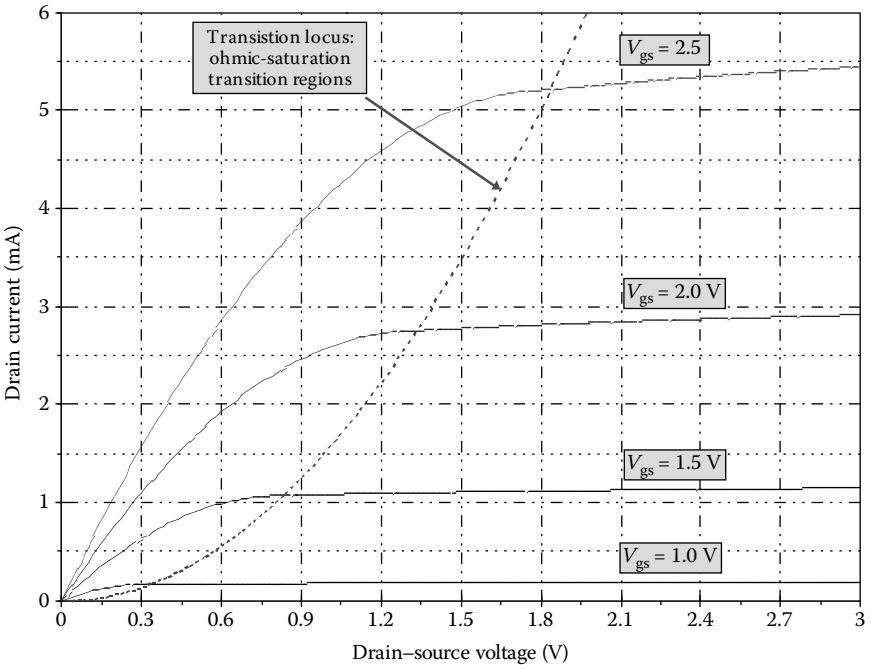

FIGURE 1.31 Common-source volt–ampere characteristic curves for an NMOS transistor.

transconductance parameter K_p is now the product of oxide capacitance density and hole mobility. The positive reference direction of the drain current in PMOS is a current flowing out of the drain, while the positive reference voltage polarities pertain to those delineated in Figure 1.18.

1.2.3.4 Refinements to the Static Model

The static volt–ampere characteristic in Equations 1.118 and 1.119 exhibit observable errors when computed currents are compared to experimental measurements executed on deep submicron MOSFET technology transistors. The principle source of these errors is two types of mobility degradation to which carriers in the source-to-drain channel are subjected. The first form of mobility degradation derives from the large lateral electric fields evidenced when even relatively small drain-to-source voltages are applied across channels whose lengths are smaller than approximately 0.25 μ. The second form of mobility impairment is caused by the strong vertical electric fields established by gate–source voltages applied across thin oxide layers.

1.2.3.4.1 Lateral Electric Fields

The NMOS and PMOS volt–ampere characteristic equations in Equations 1.118 and 1.119 are predicated on the presumption that the drift velocity, say v_c, of carriers propagated through the inverted channel at the oxide–semiconductor interface is proportional to the lateral electric field, $E_x[\varphi_c(x)]$. This field is, of course, established in the channel by applied drain–source voltage, V_{ds}, (in the case of NMOS) or applied source–drain voltage V_{sd} (in the case of PMOS). In particular,

$$v_c = \mu_o |E_x|, \tag{1.120}$$

where μ_o represents either the low field value of the electron mobility, μ_n, in N-channel devices or the low field value of the hole mobility, μ_p, in PMOS. The simpler notation, E_x is adopted in Equation 1.120 to represent the potential-dependent field function, $E_x[\varphi_c(x)]$. The need for the absolute value operation on the right-hand side of Equation 1.120 materializes from the fact that the carrier velocity, which is always a positive metric, is directed against the direction of the channel field in NMOS. In the case of NMOS transistors, carriers drift in the direction of the source-to-the drain, whereas the field is directed from drain-to-source and is therefore negative. For PMOS, no algebraic sign problems are manifested, since carriers drift in the same direction as the lateral field, whence E_x is positive.

The simplicity of Equation 1.120 belies the fact that the carrier drift velocity does not continually increase in proportion to the electric field. In fact, the carrier velocity saturates at a value, say v_{max}, which is of the order of 0.15 μm/ps in silicon, when electric fields are excessive. In recognition of this physical phenomenon, Equation 1.120 is supplanted by the empirical relationship,

$$v_c = \frac{\mu_o |E_x|}{1 + |E_x|/E_c}, \tag{1.121}$$

where

$$E_c = \frac{v_{max}}{\mu_o} \tag{1.122}$$

is termed the *critical electric field*. Typically, E_c is in the range of 3–5 V/μm. A comparison of Equation 1.121 with Equation 1.120 suggests an effective mobility, μ_e, of

$$\mu_e = \frac{\mu_o}{1 + |E_x|/E_c}. \tag{1.123}$$

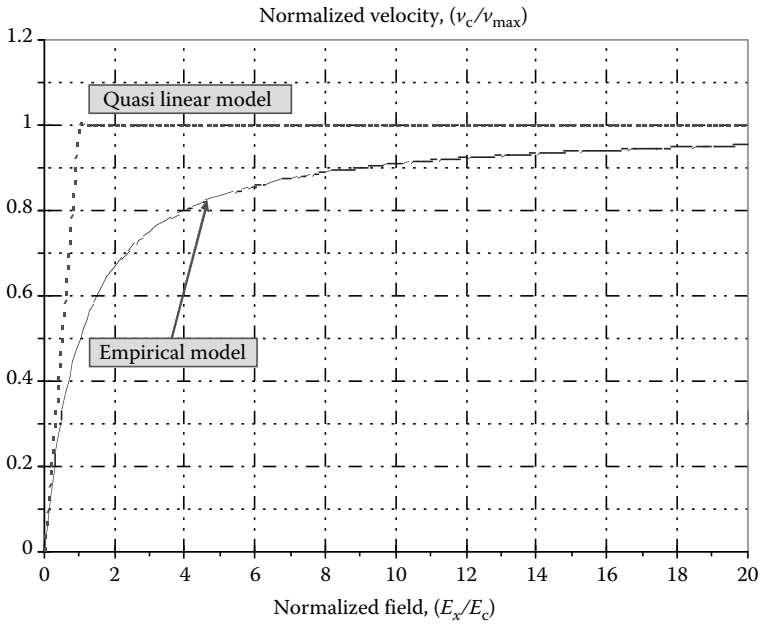

FIGURE 1.32 The dependence of carrier velocity on electric field in a semiconductor. The dashed curve represents the elementary low field approximation to the velocity-field relationship.

The mobility degradation inferred by the last disclosure bodes potentially decreased frequency response attributes of considered transistors, since the less mobile free electrons are in the inverted channel, the longer is the average time required for their transport from the source-to-the drain. Figure 1.32 sketches the velocity-field relationship implied by Equation 1.121. Note in this plot that the linear, or low field, approximation to the velocity characteristic is reasonably accurate up to about only 30% of the saturated limited velocity.

The effect on the ohmic regime drain current of the mobility degradation incurred by strong lateral electric fields can be studied by returning to Equation 1.104 and replacing the electron mobility, μ_n, therein by an adjusted mobility, μ_{ne}, such that

$$\mu_{ne} = \frac{\mu_n}{1 - E_x/E_c} = \frac{\mu_n}{1 + \frac{1}{E_c}\frac{d\varphi_c(x)}{dx}}, \tag{1.124}$$

where Equation 1.100 is applied and μ_n is understood to be the low field value of electron mobility in the inverted source-to-drain channel. Equation 1.104 becomes

$$I_d = \frac{\mu_n C_{ox} W\left[V_{gs} - V_h - \varphi_c(x)\right]}{1 + \frac{1}{E_c}\frac{d\varphi_c(x)}{dx}}\frac{d\varphi_c(x)}{dx}, \tag{1.125}$$

which leads to

$$I_d\left[\int_0^L dx + \frac{1}{E_c}\int_0^{V_{ds}} d\varphi_c(x)\right] = \mu_n C_{ox} W \int_0^{V_{ds}} \left[V_{gs} - V_h - \varphi_c(x)\right] d\varphi_c(x). \tag{1.126}$$

The requisite integrations produce

$$I_{\mathrm{d}} = K_n\left(\frac{W}{L}\right)\left[\frac{V_{\mathrm{ds}}\left(V_{\mathrm{gs}} - V_{\mathrm{h}} - \frac{V_{\mathrm{ds}}}{2}\right)}{1 + \frac{V_{\mathrm{ds}}}{V_{\mathrm{le}}}}\right], \tag{1.127}$$

where

$$V_{\mathrm{le}} = E_{\mathrm{c}}L = \left(\frac{v_{\max}}{\mu_n}\right)L \tag{1.128}$$

might be termed the *lateral electric field modulation voltage*. Observe that Equation 1.127 differs from the ohmic region volt–ampere relationship in Equation 1.118 by only the dimensionless factor in the denominator on the right-hand side of Equation 1.127. Appealing to Equation 1.128, this factor is seen to approach one when the channel length, L, is long. Of course, the subject factor also tends toward unity if the drain–source voltage, V_{ds}, is small. The latter point reflects engineering expectations in that small V_{ds} incurs lateral electric fields that are small enough to minimize field-induced mobility degradation.

A complication spawned by Equation 1.127 is that it no longer delivers the simple relationship for the drain saturation voltage witnessed in Equation 1.99. By definition, the drain saturation voltage, V_{dsat}, is the value of the drain–source voltage, V_{ds}, for which the slope of the ohmic regime I_{d} versus V_{ds} characteristic is zero. An application of this definition to Equation 1.127 leads to the revised drain saturation voltage,

$$V_{\mathrm{dsat}} = M_{\mathrm{sat}}\left(V_{\mathrm{gs}} - V_{\mathrm{h}}\right), \tag{1.129}$$

where, with

$$\alpha \triangleq \frac{V_{\mathrm{gs}} - V_{\mathrm{h}}}{V_{\mathrm{le}}}, \tag{1.130}$$

$$M_{\mathrm{sat}} = \frac{\sqrt{1 + 2\alpha} - 1}{\alpha}. \tag{1.131}$$

It can be demonstrated that $M_{\mathrm{sat}} \leq 1$ for $\alpha \geq 0$ and thus, an impact of carrier mobility degradation incurred by strong lateral fields in the inverted channel is a decrease in the low field value of the drain saturation voltage. While mobility degradation is generally an undesirable phenomenon, the drain saturation voltage decrease is actually good news in low-voltage applications that require MOSFETs to function in their saturated regimes.

The drain saturation current corresponding to the revised estimate of the drain saturation voltage can be determined by substituting Equation 1.129 into 1.127. This activity produces the aesthetically pleasing result,

$$I_{\mathrm{dsat}} = \frac{K_n}{2}\left(\frac{W}{L}\right)V_{\mathrm{dsat}}^2 = \frac{K_n}{2}\left(\frac{W}{L}\right)M_{\mathrm{sat}}^2\left(V_{\mathrm{gs}} - V_{\mathrm{h}}\right)^2. \tag{1.132}$$

In the limit of large channel lengths, V_{le} in Equation 1.128 is large, thereby rendering parameter α in Equation 1.130 small. But for very small α, M_{sat} in Equation 1.131 approaches unity. It is therefore reassuring that in the limit of large channel lengths, which are incapable of supporting large electric fields in the inverted channel, I_{dsat} in Equation 1.132 collapses to Equation 1.107, a relationship that implicitly

reflects tacit neglect of field-induced carrier mobility degradation. In contrast, very small channel lengths give rise to small V_{le} and large α, whence M_{sat} in Equation 1.131 reduces to

$$M_{sat}\big|_{\text{small L}} = \frac{\sqrt{1+2\alpha}-1}{\alpha}\bigg|_{\text{large }\alpha} \approx \sqrt{\frac{2}{\alpha}}. \tag{1.133}$$

Upon combining the last result with Equation 1.132, the short channel value of I_{dsat} is found to be

$$I_{dsat}\big|_{\text{small L}} \approx WC_{ox}v_{max}\left(V_{gs}-V_h\right), \tag{1.134}$$

where Equations 1.128 and 1.106 are exploited. Observe that the resultant drain saturation current is independent of the channel length, L. This independence stems from the fact that in the limit of very small channel lengths, carriers (electrons in the present case of an NMOS transistor) are transported through the inverted channel at their saturated limited, or maximum, velocity. This maximum velocity of carrier propagation renders L inconsequential with respect to the average time of carrier transport from the source region-to-the drain region. But perhaps the most interesting aspect of Equation 1.134 is that the short channel drain saturation current is a linear function of the gate–source voltage, V_{gs}. The linearity posed by Equation 1.134 is an obvious advantage for most analog signal processing applications, but achieving the velocity saturation implicit to this observed linearity may present voltage biasing challenges.

Of course, Equation 1.129 through 1.133 apply to the saturation regime of device operation in that in saturation, the drain current is merely the transistor current, I_{dsat}, evidenced at the boundary of ohmic and saturation regimes, corrected by channel length modulation effects. To wit, short channel phenomena imply that for $V_{gs} \geq V_h$ and $V_{ds} \geq V_{dsat}$,

$$I_d = \frac{K_n}{2}\left(\frac{W}{L}\right)M_{sat}^2\left(V_{gs}-V_h\right)^2\left(1+\frac{V_{ds}-V_{dsat}}{V_\lambda}\right), \tag{1.135}$$

where it is essential to remember that the drain saturation voltage, V_{dsat}, is now given by Equation 1.129. It is clear that M_{sat} in Equation 1.129 is properly viewed as a drain saturation voltage correction factor in a short channel (indeed, deep submicron) environment. Because of Equation 1.135, the square of M_{sat} can be accorded the stature of a current correction factor pertinent to short channel drain currents in the saturation regime. The dependence on parameter α of these correction factors is displayed in the plots submitted in Figure 1.33. The indicated correction factors are significant. For example, consider $\alpha = 2$, which might typically represent a gate–source voltage, V_{gs}, that is about a volt over the threshold potential. The curves in the figure at hand suggest an approximate 38% reduction in the drain saturation voltage predicted by the simple long channel model, which corresponds to $\alpha = 0$, as well as about a 62% attenuation of the corresponding drain saturation current.

Although Equations 1.135 and 1.129 are analytically elegant, their utility in a design-oriented environment is questionable in light of the dependence of factor M_{sat} on parameter α set forth by Equation 1.131. In light of this dilemma, an approximate curve fit of both M_{sat} and its square is judicious from an engineering design perspective. A numerical study of Equation 1.131 reveals that the empirical approximation,

$$M_{sat} = \frac{\sqrt{1+2\alpha}-1}{\alpha} \approx 1-\frac{\sqrt{\alpha}}{4}, \tag{1.136}$$

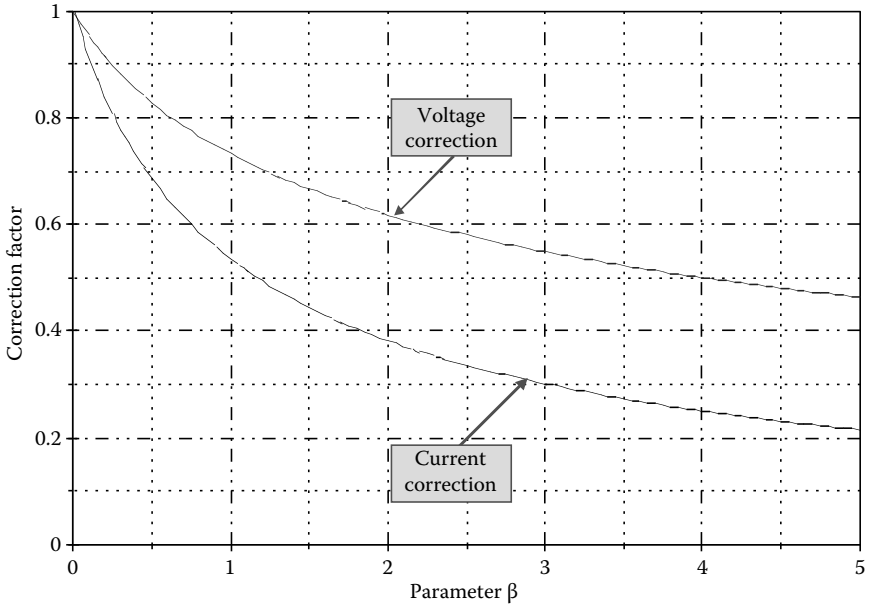

FIGURE 1.33 Voltage and current correction factors precipitated by large lateral electric fields in short channel MOSFETs. The parameter, α, is the effective gate–source voltage, $(V_{gs} - V_h)$, normalized to the lateral electric field modulation voltage, V_{le}.

results in an error of at most 4.8% for $0 \leq \alpha \leq 5$. On the other hand, a similar numerical exercise produces

$$M_{sat}^2 = \left(\frac{\sqrt{1+2\alpha}-1}{\alpha}\right)^2 \approx \frac{1}{1+0.78\alpha} \tag{1.137}$$

to a computational error of at most 5.1% for $0 \leq \alpha \leq 5$. For most design-oriented purposes, Equation 1.129 can therefore be supplanted by

$$\begin{aligned} V_{dsat} = M_{sat}(V_{gs} - V_h) &\approx \left(1 - \frac{\sqrt{\alpha}}{4}\right)(V_{gs} - V_h) \\ &= \left(1 - \frac{1}{4}\sqrt{\frac{V_{gs} - V_h}{V_{le}}}\right)(V_{gs} - V_h), \end{aligned} \tag{1.138}$$

while Equation 1.135 becomes for circuit design applications of MOSFETs operated in saturated regimes,

$$\begin{aligned} I_d &= \frac{K_n}{2}\left(\frac{W}{L}\right)M_{sat}^2(V_{gs} - V_h)^2\left(1 + \frac{V_{ds} - V_{dsat}}{V_\lambda}\right) \\ &\approx \frac{K_n}{2}\left(\frac{W}{L}\right)(V_{gs} - V_h)^2\left(\frac{1 + \frac{V_{ds} - V_{dsat}}{V_\lambda}}{1 + 0.78\alpha}\right) \\ &= \frac{K_n}{2}\left(\frac{W}{L}\right)(V_{gs} - V_h)^2\left(\frac{1 + \frac{V_{ds} - V_{dsat}}{V_\lambda}}{1 + 0.78\left(\frac{V_{gs} - V_h}{V_{le}}\right)}\right). \end{aligned} \tag{1.139}$$

The academic purist who may understandably balk at the foregoing numerical empiricisms is respectfully reminded that the mobility expression in Equation 1.123 and the "long channel" velocity relationship of Equation 1.120 are hardly grounded in sound physical phenomenology. Moreover, it is interesting to note that of the more than 275 parameters indigenous to the commonly exploited Level 49 HSPICE model of a MOSFET, most are curve fit disclosures that bear no clarion relationship to the physical charge storage and charge transport mechanisms that underpin the volt–ampere characteristics of a MOSFET.

1.2.3.4.2 Vertical Electric Fields

Apart from the carrier mobility degradation incurred by strong lateral fields in the inverted channel of a MOSFET, mobility is impacted by the vertical electric field resulting from the applied effective interface potential, $(V_{gs} - V_h)$, in the case of NMOS or $(V_{sg} - V_h)$ for PMOS devices. In NMOS, increases in V_{gs} strengthens this vertical field so that free electrons transported from the source-to-the drain are encouraged to drift ever closer to the oxide–semiconductor interface. Unfortunately, the interface is far from a perfectly smooth boundary, if for no other reason than routine device processing invariably produces ionic contamination therein. The imperfect boundary causes potentially significant carrier scattering, which in turn results in diminished carrier mobility.

To first order, the mobility attenuation resulting from increased gate overdrive can be addressed analytically by replacing the low field mobility, μ_n (for NMOS), to which K_n in Equation 1.139 is directly proportional, by an effective carrier mobility, μ_{eff}, such that

$$\mu_{eff} = \frac{\mu_n}{1 + \frac{V_{gs} - V_h}{V_{ve}}}. \tag{1.140}$$

In this expression, V_{ve} is the *vertical electric field modulation voltage*, which is nominally directly proportional to the thickness, T_{ox}, of the oxide layer. Of course, an expression analogous to Equation 1.140 prevails for hole mobility in the inverted channel of PMOS transistors. To a very rough approximation,

$$V_{ve} = T_{ox}/15, \tag{1.141}$$

where T_{ox} in units of angstroms returns V_{ve} in units of volts. Because of Equations 1.140 and 1.139 for the saturation domain current becomes

$$\begin{aligned} I_d &= \frac{K_n}{2}\left(\frac{W}{L}\right) M_{sat}^2 \frac{\left(V_{gs} - V_h\right)^2}{\left(1 + \frac{V_{gs} - V_h}{V_{ve}}\right)} \left(1 + \frac{V_{ds} - V_{dsat}}{V_\lambda}\right) \\ &\approx \frac{K_n}{2}\left(\frac{W}{L}\right) \frac{\left(V_{gs} - V_h\right)^2}{\left(1 + \frac{V_{gs} - V_h}{V_{ve}}\right)} \left(\frac{1 + \frac{V_{ds} - V_{dsat}}{V_\lambda}}{1 + 0.78\left(\frac{V_{gs} - V_h}{V_{le}}\right)}\right). \end{aligned} \tag{1.142}$$

An analogous modification, which amounts to an effective reduction of the transconductance parameter, K_n, can be made to the ohmic domain current.

Obviously, Equation 1.142 is inordinately more cumbersome than is the simple, square law, volt–ampere characteristic advanced by Equation 1.110 for device operation in the saturation domain. As a result, the design-oriented determination of a suitable gate–source voltage for a desired drain current and corresponding drain–source voltage can be a daunting challenge. But in addition to the computational problems precipitated merely by algebraic complexity, engineering difficulties are additionally encountered with respect to the accurate numerical delineation of the model metrics, K_n, V_h, V_{ve}, V_λ, and V_{le}. These

latter difficulties derive from the unfortunate fact that the physical device and charge transport properties (saturation velocity, carrier mobility, regional concentrations, etc.) on which these and other model parameters depend are invariably unavailable to the circuit designer. At best, the circuit designer can reasonably expect to have presumably reliable, detailed device model parameters suitable for computer-aided simulation of transistor performance. For example, process foundries routinely supply their customers with device models in the form of Level 49 HSPICE or other computer-based files. Unfortunately, many, if not most, of the hundreds of numerical entries indigenous to these files are themselves nonphysical entities that defy satisfying mathematical relationships to the physical model metrics discussed in earlier paragraphs. These and related other design-oriented problems can prove exasperating. The aforementioned issues are best mitigated by coalescing manual design strategies and calculations with suitable computer-based simulations of device properties and volt–ampere characteristics.

1.2.3.5 Temperature Effects

The operating temperature of the inverted interfacial channel affects the drain current of a transistor in three ways. First, because thermal energy imparted to free carriers increases their scattering, the carrier mobility decreases in response to increased operating temperatures. To first order, the electron mobility, $\mu_n(T)$, at absolute temperature T relates to the mobility, $\mu_n(T_o)$, at a reference temperature, T_o, in accordance with the three-halves power law,

$$\mu_n(T) = \mu_n(T_o)\left(\frac{T_o}{T}\right)^{3/2}. \tag{1.143}$$

Because parameter K_n in Equation 1.142 is directly proportional to carrier mobility, Equation 1.143 implies that the drain current of a MOSFET is characterized by a negative temperature coefficient, that is, the drain current, I_d, decreases with increasing operating temperature.

A second effect of increased thermal energy is a perturbation of threshold voltage. A computation of this perturbation is best initiated by returning to Equation 1.96 to evaluate the derivative of the threshold voltage, V_h, with respect to the Fermi potential, V_F. Recalling Equations 1.96 and 1.97, and noting that the body effect voltage, V_θ, in Equation 1.90 is independent of temperature,

$$\frac{dV_h}{dV_F} = 2 + \sqrt{\frac{V_\theta}{V_F}} + \frac{V_h - V_{ho}}{2V_F} + \left(\frac{V_\theta}{2V_F}\right)\left(\frac{V_{bs}}{V_h - V_{ho} + 2\sqrt{V_\theta V_F}}\right), \tag{1.144}$$

where V_{ho} is recalled as signifying the zero bias ($V_{bs} = 0$) value of the threshold potential. Note that the last two terms on the right-hand side of this expression vanish when a MOSFET is operated with $V_{bs} = 0$. The sensitivity of the threshold voltage with respect to temperature follows as

$$\frac{dV_h}{dT} = \frac{dV_h}{dV_F} \times \frac{dV_F}{dT}. \tag{1.145}$$

The temperature derivative of the Fermi potential derives from Equation 1.55, with the proviso that due account be made of the temperature dependence of the intrinsic carrier concentration, N_i. To this end, a commonly used empiricism is

$$N_i = N_{io} 2^{(T - T_o)/T_n}, \tag{1.146}$$

where T_n is generally taken to be 10°C and, assuming the reference temperature, T_o, is 27°C, N_{io}, the intrinsic carrier concentration at $T = T_o$, is the previously used number, $(1.45)(10^{10})$ atoms/°C. With

$T_n = 10°C$, Equation 1.146 allows N_i to double for each 10°C rise above the reference temperature. Armed with Equations 1.146 and 1.55 produces

$$\frac{dV_F}{dT} = \frac{V_F}{T} - \frac{V_T}{T_n} \ln 2. \tag{1.147}$$

Equations 1.144 and 1.147 combine to yield the final result,

$$\frac{dV_h}{dT} = \left[2 + \sqrt{\frac{V_\theta}{V_F}} + \frac{V_h - V_{ho}}{2V_F} + \left(\frac{V_\theta}{2V_F}\right)\left(\frac{V_{bs}}{V_h - V_{ho} + 2\sqrt{V_\theta V_F}}\right)\right]\left(\frac{V_F}{T} - \frac{V_T}{T_n} \ln 2\right), \tag{1.148}$$

where parameters V_{ho}, V_h, and V_T, are computed at the reference temperature, T_o. The indicated temperature derivative of the threshold voltage is invariably a positive number in the range of 1.5–2.4 mV/°C. Thus, the threshold voltage increases with increasing operating temperatures, thereby leading to a decrease in the drain current. In other words, the temperature dependence of both the carrier mobility and the threshold voltage conduce a drain current exuding a negative temperature coefficient.

The algebraic form of Equation 1.148 is thoroughly depressing and is hardly a relationship stored in the human memories of circuit designers. Fortunately, for MOSFETs featuring thin gate oxides (under 50 Å) and substrate doping concentrations no smaller than 10^{15} atoms/cm^3, the terms in V_θ, $(V_h - V_{ho})$, and V_T/T_n are generally negligible, especially if the bulk–source bias, V_{bs}, is no more negative than 1.5 V. In this event,

$$\frac{dV_h}{dT} \approx \frac{2V_F}{T}, \tag{1.149}$$

which can be shown to be always larger—generally by no more than 5% or 6%—than the result predicted by Equation 1.148. For a substrate doping concentration of $N_A = (5)(10^{15})$ atoms/cm^3, Equation 1.149 predicts a threshold voltage sensitivity at $T = 27°C = 300.16$ K of 2.2 mV/°C.

1.2.4 Transistor Capacitances

At this juncture, the volt–ampere characteristic equations given by Equations 1.118, 1.119, 1.139, and 1.142 pertain to MOSFETs operated exclusively under static or low-frequency signal conditions. Specifically, the drain currents predicted by these relationships are unrealistically cavalier in that they respond instantaneously to applied gate–source, drain–source, and bulk–source excitations. When high-frequency signals are applied, the current responses are slowed by device capacitances arising from the charge storage that prevails in the inverted channel and within the depletion regions formed about the source and drain diffusions or implants. The engineering implications of this inherent inability of drain currents to respond instantly to signal excitations are MOSFET circuits exuding constrained bandwidths, nonzero input/output (I/O) delays and phase shifts, and nonzero rise and fall times in transient responses. In extreme cases, the interaction of these device capacitances with the energy storage elements of the peripheral circuit can produce excessive response peaking in either the frequency or time domains and even outright instability.

1.2.4.1 Depletion Capacitances

The first of the two principle sources of transistor capacitances is the depletion capacitance indigenous to both of the PN junctions formed respectively between the bulk and drain and between the bulk and source. In turn, each of these two transition region capacitances consists of a planar component and a peripheral, or sidewall, component. The planar component embodies the depletion layer established

between the bulk substrate region and the underside of the source and drain regions. On the other hand, the sidewall capacitance embraces the depletion layers in the areas of the source and drain regions that are proximate to the front surface, the back surface, and the side surface area adjacent to the active channel region. For the bulk–drain depletion capacitance, C_{bd},

$$C_{bd} = \frac{A_d C_j}{\left(1 - \frac{V_{bd}}{V_j}\right)^{M_j}} + \frac{P_d C_{jsw}}{\left(1 - \frac{V_{bd}}{V_j}\right)^{M_{jsw}}}, \tag{1.150}$$

where the forms of each of the terms on the right-hand side are observed to mirror the traditional depletion capacitance associated with a back biased PN junction. In Equation 1.150, C_j is the zero bias (meaning, $V_{bd} = 0$), value of the capacitance density, in units of farads/meter^2, associated with the planar component of the bulk–drain capacitance, while C_{jsw} is the zero bias lineal capacitance, in units of farads/meter, of the aforementioned sidewall areas. The planar drain area, A_d, is

$$A_d = WL_{dif}, \tag{1.151}$$

where L_{dif} is recalled in Figures 1.17 and 1.18 to represent the width of the drain region, which is generally identical to the width of the source implant. Generally, the dimension, L_{dif}, must be extracted empirically from measured data but as a rule of thumb, L_{dif} is nominally of the order of twice the channel length, L. Parameter P_d, is the effective length of the perimeter of the sidewall area and is stipulated by

$$P_d = W + 2L_{dif}. \tag{1.152}$$

Voltage V_j in Equation 1.150 is the built-in potential given by Equation 1.115, while M_j and M_{jsw} are the grading coefficients of the planar and sidewall PN junctions, respectively.* Typically $M_j = 0.5$ and $M_{jsw} = 0.33$. An analogous expression, whose terms convey equally analogous engineering interpretations, prevails for the net bulk–source depletion capacitance, C_{bs}. In particular,

$$C_{bs} = \frac{A_s C_j}{\left(1 - \frac{V_{bs}}{V_j}\right)^{M_j}} + \frac{P_s C_{jsw}}{\left(1 - \frac{V_{bs}}{V_j}\right)^{M_{jsw}}}, \tag{1.153}$$

where in general,

$$\left.\begin{aligned} A_s &\equiv A_d = WL_{dif} \approx 2WL \\ P_s &\equiv P_d = W + 2L_{dif} \approx W + 4L \end{aligned}\right\}. \tag{1.154}$$

1.2.4.2 Gate Capacitances

The second source of MOSFET capacitances is the gate capacitance, which itself is comprised of three distinct components. The first of these components appears between the gate and the bulk substrate. As is apparent from Figure 1.23, this particular capacitance has a very small nonzero frequency value in both weak and strong channel inversion modes, which suggests that the channel inversion layer effectively shields the gate from the bulk substrate. Because the gate–bulk capacitance is invariably very small, it bodes little consequence to achievable MOSFET circuit performance and therefore, it is usually ignored tacitly.

* In HSPICE and other forms of SPICE simulators, the built-in potential, V_j, is symbolized by P_B.

The other two components of net gate capacitance are the gate–source capacitance, C_{gs}, and the gate–drain capacitance, C_{gd}. Each of these energy storage elements is a superposition of an intrinsic module, which derives from the gate, gate oxide, and inverted channel, and an extrinsic constituent, which is attributed to gate oxide overlap at the source and drain sites. Since the inversion layer extends from source-to-drain in only the ohmic regime of operation, different values of these two capacitances prevail for ohmic and saturated operation. The maximum possible intrinsic capacitance established between the gate and the inversion layer is clearly WLC_{ox}. In the ohmic operating regime, this maximum capacitance is partitioned equally between the source and the drain to give identical intrinsic gate–source and gate–drain capacitance values; namely, $WLC_{ox}/2$. Accordingly, in the ohmic regime, the effective gate–source capacitance is

$$C_{gs} = \frac{WLC_{ox}}{2} + WC_{gso}, \tag{1.155}$$

where C_{gso} is the capacitance per unit length associated with the oxide–source overlap. Similarly, the effective gate–drain capacitance in the ohmic operating regime is

$$C_{gd} = \frac{WLC_{ox}}{2} + WC_{gdo}, \tag{1.156}$$

where C_{gdo} is the drain overlap capacitance counterpart to the source overlap region. Typically, C_{gso} and C_{gdo} are as small as 0.25 fF/μm in minimal geometry transistors. Thus, for a transistor characterized by $L = 180$ nm, $W/L = 20$, and an oxide thickness of $T_{ox} = 30$ Å, $C_{gs} = C_{gd} = 4.63$ fF. Observe herewith that the net overlap capacitance is $WC_{gso} = WC_{gdo} = 0.9$ fF, which is almost 20% of the total gate–source (or gate–drain) capacitance.

The capacitance situation in saturation is a bit more intricate than that which prevails in the ohmic regime. In saturated domains where $V_{ds} > V_{dsat}$, pinch off occurs within the source-to-drain channel, thereby leaving an effective depletion zone that is free of mobile carriers near the drain site. Accordingly, the drain–source voltage exerts no influence on the channel charge, and the resultant gate–drain capacitance derives exclusively from the oxide overlap with the drain, that is, the gate–drain capacitance, C_{gd}, in saturation is simply

$$C_{gd} = WC_{gdo}. \tag{1.157}$$

In contrast to the charge depletion prevailing in the channel region adjacent to the drain, a large free carrier population is concentrated near the source. Since this concentration is influenced strongly by interface potential, which is determined by the applied gate–source voltage, it is only logical to expect a comparatively substantial intrinsic gate–source capacitance.

An analytical disclosure of the foregoing gate-to-source capacitance commences with a return to Equations 1.102 and 1.103. If these two equations are combined and if Equation 1.63 is recalled,

$$q[Y_s(\varphi_c(x))][N_s(\varphi_c(x))] = C_{ox}\left[V_{gs} - V_h - \varphi_c(x)\right], \tag{1.158}$$

where the left-hand side of this relationship is understood to be the density of mobile charge in the inversion layer. Upon multiplication of both sides of Equation 1.158 by the gate width, W, the resultant left-hand side of the modified expression represents the net mobile charge per unit length of the inversion layer. It follows that the net differential mobile charge (amassed by electrons in NMOS), say $dq_n[\varphi_c(x)]$, contained in a differential channel volume of depth $Y_s[\varphi_c(x)]$, width W, and length extending from x to $(x + dx)$, is

$$dq_n(\varphi_c(x)) = WC_{ox}\left[V_{gs} - V_h - \varphi_c(x)\right]dx. \tag{1.159}$$

Ignoring mobility degradation incurred by lateral electric fields, Equation 1.104 can be used to recast Equation 1.58 in the form

$$\mathrm{d}q_n(\varphi_c(x)) = \frac{\mu_n(WC_{ox})^2}{I_d}\left[V_{gs} - V_h - \varphi_c(x)\right]^2 \mathrm{d}\varphi_c(x). \tag{1.160}$$

Equation 1.59 can be integrated conveniently from $\varphi_c(0)$ to $\varphi_c(V_{dsat})$, where the indicated interfacial potential limits correspond to the boundaries of the channel inversion layer evidenced in saturation. Such an integration of the left-hand side of Equation 1.59 brackets the net mobile charge, say $Q_n(V_{gs})$, observed in saturation for a stipulated gate–source voltage, V_{gs}. In particular,

$$\begin{aligned} Q_n(V_{gs}) &= \int_0^{V_{dsat}} \mathrm{d}q_n(\varphi_c(x)) = \frac{\mu_n(WC_{ox})^2}{I_d} \int_o^{V_{dsat}} \left[V_{gs} - V_h - \varphi_c(x)\right]^2 \mathrm{d}\varphi_c(x) \\ &= \frac{\mu_n(WC_{ox})^2}{3I_d}\left(V_{gs} - V_h\right)^3, \end{aligned} \tag{1.161}$$

where Equation 1.99 is exploited. Using Equation 1.109 to replace the drain current variable, I_d, in this relationship results in

$$Q_n(V_{gs}) = \frac{2}{3} WLC_{ox}\left(V_{gs} - V_h\right). \tag{1.162}$$

The saturation region value of the intrinsic gate–source capacitance now follows as

$$\frac{\mathrm{d}Q_n(V_{gs})}{\mathrm{d}V_{gs}} = \frac{2}{3} WLC_{ox}, \tag{1.163}$$

whereupon the saturation region value of the net gate–source capacitance, C_{gs}, inclusive of oxide overlap effects at the source site, is

$$C_{gs} = \frac{2}{3} WLC_{ox} + WC_{gso}. \tag{1.164}$$

1.2.4.3 Large-Signal Model

At this juncture, the large signal, or nonlinear, model of an N-channel MOSFET is the structure advanced in Figure 1.34. Depending on whether the transistor undergoing assessment is operated as an ohmic regime or as a saturated device, the equation for the indicated controlled current source, I_d, derives from expressions formulated in Section 1.2.3.2 or Section 1.2.3.3 or, for that matter, the model refinements addressed in Section 1.2.3.4. The depletion capacitances, C_{bs} and C_{bd}, are not affected by the domain of transistor operation, but the appropriate regional values of the capacitances, C_{gs} and C_{gd}, must be culled from the discourse in Section 1.2.4.2.

The model at hand also incorporates four resistive elements. The resistances, r_d and r_s, are respectively associated with the strongly doped drain and source regions, respectively. These resistances are specified in HSPICE simulation software by a sheet resistance parameter, R_{sh}, and drain and source geometric parameters, N_{rd} and N_{rs}. In particular,

$$\left.\begin{aligned} r_d &= N_{rd}R_{sh} \\ r_s &= N_{rs}R_{sh} \end{aligned}\right\}. \tag{1.165}$$

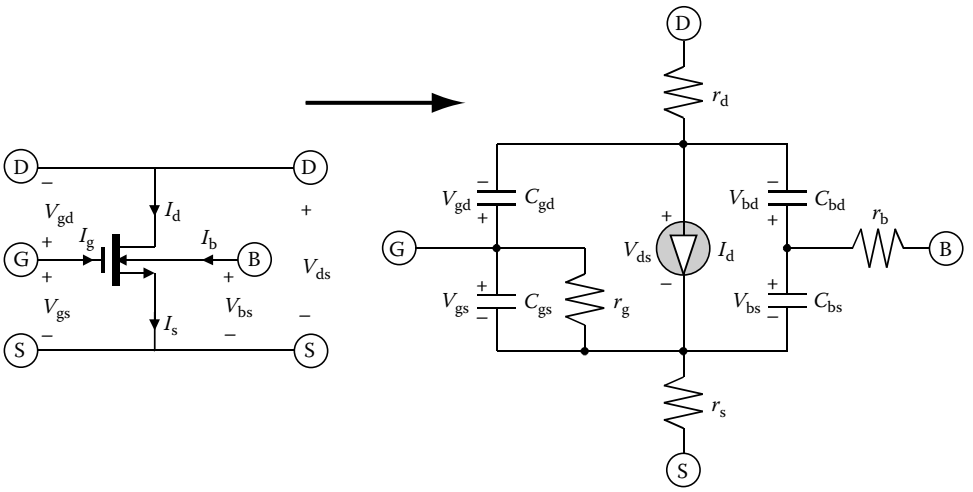

FIGURE 1.34 Large-signal model of an N-channel MOSFET. A topologically identical equivalent circuit prevails for P-channel MOSFETs.

Owing to the high doping concentrations of the drain and the source, which begets a small *sheet resistance* parameter, R_{sh}, resistances r_d and r_s are generally sufficiently small to justify their tacit neglect in most analog circuit applications. In contrast, resistance, r_b, which represents an effective spreading resistance in the bulk substrate, can be as large as the high tens to low hundreds of ohms. Despite its relatively large value, its impact on analog circuit performance is muted by the fact that the bulk rarely conducts significant currents, even at high signal frequencies. However, this resistance does influence the thermal noise characteristics of the drain–source channel.

Like resistance r_b, the gate resistance, r_g, is likewise important from a thermal noise perspective in that it captures the salient effects that thermally agitated mobile charge carriers exert on channel potential. It also looms significant with respect to design problems associated with maximum signal power transfer in radio frequency (RF) circuits [9]. This resistance is computed as [10]

$$r_g = \frac{5}{(\omega C_{gs})^2 R_{ch}}, \tag{1.166}$$

where R_{ch} represents the $V_{ds} = 0$ value of the drain–source channel resistance. Recalling Equation 1.109,

$$R_{ch} = \frac{1}{K_n\left(\frac{W}{L}\right)(V_{gs} - V_h)} = \frac{M_{sat} V_{dsat}}{2I_{dsat}}, \tag{1.167}$$

where Equations 1.129 and 1.132 have been used. Because of the inverse dependence of r_g on the square of radial signal frequency, ω, r_g is infinity for quiescent operating conditions and extremely large for low to even reasonably high frequencies.

1.2.5 Small-Signal Operation

As noted in Section 1.2.1, MOSFETs are the active device of choice in a plethora of high-performance analog integrated circuits. When the fundamental objective of these analog networks is linear I/O signal processing, each MOSFET therein is commonly biased in a saturated regime that ensures, for all applied signals of interest, an instantaneous drain–source voltage, v_{ds}, that is never any smaller than the

instantaneous drain–source saturation voltage, v_{dsat}. To be sure, linear signal processing can also be achieved when transistors operate in their ohmic regimes. But when high performance, in such senses as high gain, wide bandwidth, large dynamic range, and acceptable driving point I/O impedance levels, is a fundamental design objective, saturation is the regime of choice. Accordingly, ohmic linear equivalent circuits of transistors are ignored herewith and left as an investigation exercise for the reader.

A casual inspection of Equation 1.142 suggests that the instantaneous drain current, i_d, flowing in an N-channel MOSFET is a function of three device voltages: the instantaneous gate–source voltage, v_{gs}, the instantaneous drain–source voltage, v_{ds}, and the instantaneous bulk–source voltage, v_{bs} which covertly influences the threshold potential, V_h. An analogous statement applies to P-channel transistors, subject to the current and voltage conventions adopted earlier. Thus, Equation 1.142 can be generalized as

$$i_d \approx \frac{K_n}{2}\left(\frac{W}{L}\right)M_{sat}^2\left(v_{gs}-V_h\right)^2\left(\frac{1+\frac{v_{ds}-v_{dsat}}{V_\lambda}}{1+\frac{v_{gs}-V_h}{V_{ve}}}\right)=f\left(v_{gs},\, v_{ds},\, v_{bs}\right). \tag{1.168}$$

Under zero signal conditions, which is tantamount to operating the considered MOSFET at its quiescent operating point, it is understood that Equation 1.168 yields

$$I_d = f\left(V_{gs}, V_{ds}, V_{bs}\right), \tag{1.169}$$

where the indicated variables in capital letters designate static, or quiescent, device currents and voltages. In other words, the MOSFET described mathematically by Equation 1.169 is in a standby mode that awaits the application of dynamic, invariably time-varying, signals. Prior to signal excitation, the transistor maintains quiescent values of drain current, gate–source voltage, drain–source voltage, and bulk–source voltage that respectively equal I_d, V_{gs}, V_{ds}, and V_{bs}. Signals applied as a current, say I_{ds}, to the drain lead and/or a voltages, say V_1 to the gate–source port, V_2 to the bulk–source port, or V_3 to the drain–source port perturb the quiescent, or *Q-point*, counterparts of these electrical variables to deliver the observable net instantaneous current and voltage responses,

$$\left.\begin{aligned} i_d &= I_d + I_{ds} \\ v_{gs} &= V_{gs} + V_1 \\ v_{bs} &= V_{bs} + V_2 \\ v_{ds} &= V_{ds} + V_3 \end{aligned}\right\}. \tag{1.170}$$

In concert with these relationships, the MOSFET under consideration is said to operate linearly if and only if the signal-induced changes, I_{ds}, V_1, V_2, and V_3, interrelate linearly and if and only if the Q-point currents and voltages are independent of signal strengths. It is crucial to understand that operational linearity in an electronic device does not imply linear relationships among the instantaneous device variables, nor does it imply linearity among the corresponding quiescent values of these variables. Instead, operational linearity implies merely that a selected variable in the selected set of four perturbed variables in Equation 1.170 linearly superimpose with the remaining three electrical signal components.

1.2.5.1 Fundamental Small-Signal Model

Because of the obviously nonlinear nature of Equation 1.168, questions abound as to the plausibility of achieving the aforementioned linearity condition among the electrical perturbations induced by applied signals. Despite its inherently nonlinear nature, Equation 1.168 is a well-behaved functional relationship, which suggests that the desired linearity might be approximated adequately by limiting all signal excursions about respective operating point values to sufficiently small levels. This sufficiently small-signal mandate defines the concept of *small-signal analysis* and produces a *small-signal model* of the

MOSFET. A small-signal analysis reflective of a mathematical exploitation of the corresponding small-signal model are deemed both appropriate and useful if the retention of only the linear terms of the Taylor series expansion of Equation 1.168 about the operating point of the considered device leads to minimal errors in the resultant expression for the signal component of the drain current. Thus,

$$i_d \approx I_d + \left.\frac{\partial i_d}{\partial v_{gs}}\right|_Q (v_{gs} - V_{gs}) + \left.\frac{\partial i_d}{\partial v_{bs}}\right|_Q (v_{bs} - V_{bs}) + \left.\frac{\partial i_d}{\partial v_{ds}}\right|_Q (v_{ds} - V_{ds}), \tag{1.171}$$

where each of the three derivatives on the right-hand side of this relationship are evaluated at the *Q*-point of the MOSFET, that is, at $i_d = I_d$, $v_{gs} = V_{gs}$, $v_{bs} = V_{bs}$, and $v_{ds} = V_{ds}$. Using Equation 1.170 and noting that each of the three subject derivatives is a constant having units of conductance, Equation 1.171 can be couched in the form

$$I_{ds} \approx g_m V_1 + g_{mb} V_2 + \frac{V_3}{r_o}, \tag{1.172}$$

where

$$\left.\begin{aligned} g_m &\triangleq \left.\frac{\partial i_d}{\partial v_{gs}}\right|_Q \\ g_{mb} &\triangleq \left.\frac{\partial i_d}{\partial v_{bs}}\right|_Q \\ \frac{1}{r_o} &\triangleq \left.\frac{\partial i_d}{\partial v_{ds}}\right|_Q \end{aligned}\right\}. \tag{1.173}$$

Equation 1.71 gives rise to the small-signal, low-frequency equivalent circuit depicted in Figure 1.35a. The subject circuit becomes the small-signal, high-frequency MOSFET model if the four capacitances, C_{gs}, C_{gd}, C_{bd}, and C_{bs}, discussed in Section 1.2.4 are appended as indicated in Figure 1.35b. It is important to underscore the fact that either of the models in Figure 1.35 gives no information about the instantaneous electrical variables of a MOSFET, nor does either model allow for the computation of the quiescent values of these variables. Indeed, the models at hand require a priori knowledge of the *Q*-point since the small-signal parameters, g_m, g_{mb}, and r_o, depend on the operating point, as is implied by Equation 1.173. Moreover, the four capacitive elements in the model of Figure 1.35b likewise depend on the *Q*-point at which the considered transistor is biased. In short, the models in Figure 1.35 give first order approximations of the interrelationships among only the small-signal components of the net currents and voltages indigenous to a MOSFET. Although the topologies of both the models drawn in Figure 1.35 pertain to both the ohmic and saturation regimes of N-channel MOSFET operation, the equations to be developed shortly for the low-frequency parameters of these models apply exclusively to the saturation region. Moreover, while Figure 1.35 makes explicit reference to an N-channel transistor, or NMOS, the small-signal, low- and high-frequency equivalent circuits of PMOS units are identical to their NMOS counterparts. This topological identity stems from the fundamental fact that the small-signal models intertwine only signal-induced changes of device currents and voltages about their respective quiescent values. In an attempt to dispel possible confusion, the latter models are offered in Figure 1.36.

In the low-frequency models of either Figure 1.35a or Figure 1.36a the signal component of the bulk current, I_{bs}, flows into an open circuit because the bulk–drain and bulk–source junctions of devices embedded in analog networks are commonly reversed biased. The low-frequency signal component of the gate current, I_{gs}, is very nearly zero because the gate resistance, r_g, is, by Equation 1.166, inversely proportional to the square of the signal frequency. Of course, both of these currents are substantively

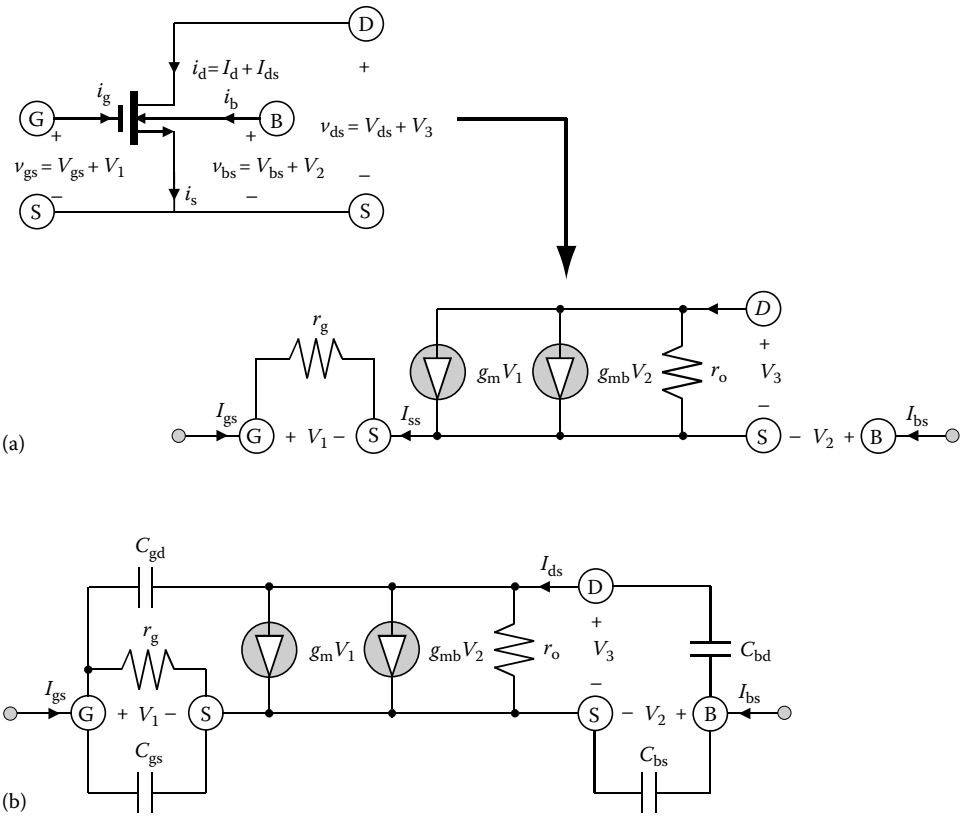

FIGURE 1.35 (a) Small-signal, low-frequency equivalent circuit of an N-channel MOSFET. (b) Small-signal, high-frequency equivalent circuit of an N-channel MOSFET. The topological structures of either model apply to both the ohmic and saturation regimes of operation.

larger at high frequencies where the various capacitances in the models of Figures 1.35b and 1.36b become poor approximations of the open circuits they mirror at low signal frequencies.

The parameter, g_m, is termed the *forward transconductance*. It is a critical analog circuit metric in that it serves as a measure of achievable forward gain. In particular, parameter g_m, when multiplied by the applied gate–source signal voltage, V_1, determines the amount of drain signal current, I_{ds}, manifested by the applied gate–source signal. On the other hand, the *bulk transconductance*, g_{mb}, measures the ability of a MOSFET to transfer applied bulk–source signal, V_2, to the drain signal current response. The controlled current, $g_{mb}V_2$, is negligible when it is much smaller than is its forward transconductance counterpart current, $g_m V_1$. However, it should be noted that depending on the selected quiescent operating point, parameter g_{mb} can be as much as 15%–25% of the forward transconductance, g_m. The current, $g_{mb}V_2$, is entirely inconsequential in numerous analog circuits that configure their utilized MOSFETs in such a way as to operate both the bulk and source terminals at signal ground, which renders $V_2 = 0$. Finally, r_o, the *drain–source channel resistance*, appears as a shunting resistive element across the drain and source terminals. If r_o is infinitely large (which, to be sure, it is not in practical MOSFETs) the drain-to-source small-signal port of a MOSFET behaves as an ideal Norton equivalent current source, that is, the current level determined largely by $g_m V_1$ is unaffected by modulations in the drain–source signal voltage, V_3. It follows that to the extent that the gate–source terminals serve as an input signal port boasting infinitely large impedance and the drain–source terminals function as the output port, the MOSFET emulates an ideal transconductance amplifier if the channel resistance, r_o, is large.

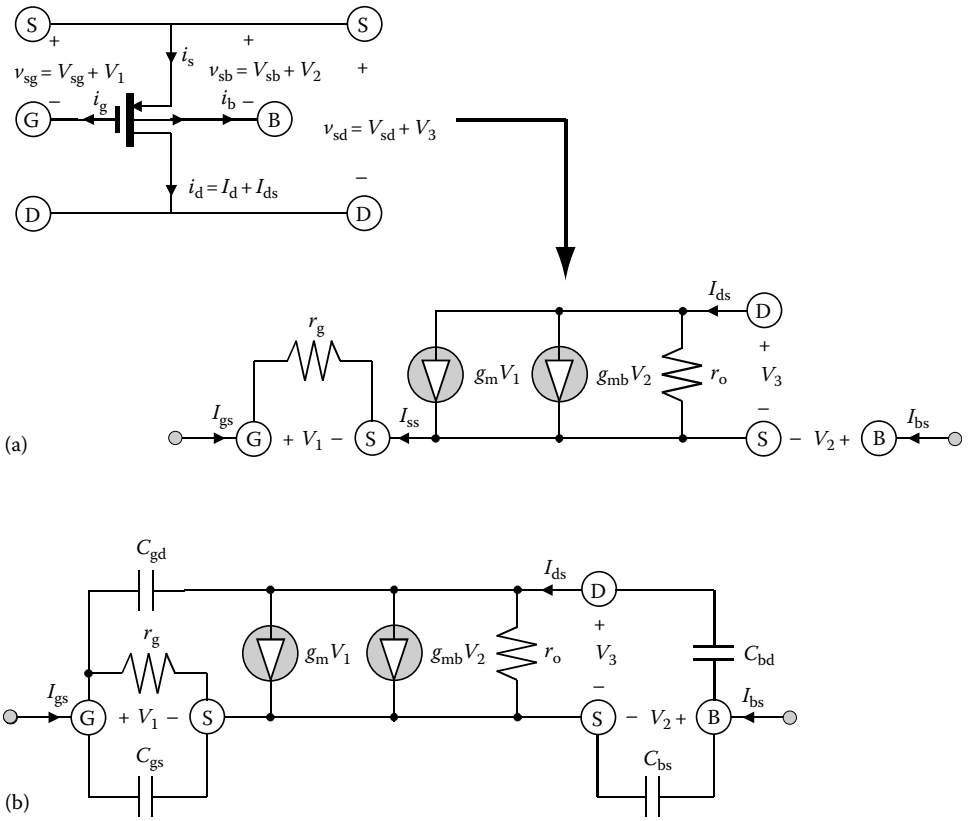

FIGURE 1.36 (a) Small-signal, low-frequency equivalent circuit of a P-channel MOSFET. (b) Small-signal, high-frequency equivalent circuit of a PMOS device.

The determination of the three low-frequency parameters defined in Equation 1.173 requires that the indicated derivatives of the drain current expression in Equation 1.168 be evaluated. This evaluation is an algebraically trying task that borders on a futile engineering enterprise in that many of the physical parameters implicit to Equation 1.168 are rarely disclosed to the circuit designer. It is therefore prudent to condescend to first order approximations of the subject small-signal parameters by replacing Equation 1.168 with the simpler expression,

$$i_d \approx \frac{K_n}{2}\left(\frac{W}{L}\right)(v_{gs} - V_h)^2\left(1 + \frac{v_{ds} - v_{dsat}}{V_\lambda}\right), \tag{1.174}$$

which effectively ignores the influence of both lateral and vertical electric fields in the MOSFET channel. By ignoring the effects of lateral fields, parameter M_{sat} in Equation 1.131 is one, whence the drain saturation voltage in Equation 1.129 is simply the voltage difference, $v_{dsat} = (v_{gs} - V_h)$. Accordingly, Equations 1.173 and 1.174 yield a forward transconductance of

$$g_m \triangleq \left.\frac{\partial i_d}{\partial v_{gs}}\right|_Q \approx \frac{2I_d}{V_{gs} - V_h} - \frac{I_d}{V_\lambda + V_{ds} - V_E}, \tag{1.175}$$

where it is understood that the variables, I_d, V_{gs}, V_h, V_λ, and V_{dsat} reflect the Q-point of the transistor undergoing study. Biasing voltage and standby power constraints ordinarily compel that the transistor be

biased at a drain–source voltage that is only slightly above the drain saturation voltage. Accordingly, V_λ is typically much larger than $(V_{ds} - V_{dsat})$. Moreover, V_λ is generally significantly larger than $V_{dsat}/2$. It follows that the second term on the right-hand side of Equation 1.175 is often negligible, whereupon Equations 1.168 and 1.175 combine for the case of large V_λ to deliver

$$g_m \triangleq \left.\frac{\partial i_d}{\partial v_{gs}}\right|_Q \approx \frac{2I_d}{V_{gs} - V_h} \approx \sqrt{2K_n(W/L)I_d}. \tag{1.176}$$

The result suggests that the forward transconductance of a MOSFET increases with the square root of the product of quiescent drain current and transistor gate aspect ratio. Accordingly, high gain requirements in certain MOSFET amplifiers compel relatively large standby drain currents and/or suitably large gate widths. The former tack conflicts with omnipresent desires for low power operation, while the latter begets increased device capacitances and hence, potentially degraded frequency responses. Observe that while the term in V_λ in Equation 1.175 is usually negligibly small, significant channel length modulation (which translates to small V_λ) is deleterious to high gain objectives.

An evaluation of the bulk transconductance, g_{mb}, requires that Equation 1.96 be considered analytically in conjunction with the threshold voltage term in Equation 1.174. After a bit of messy algebra, it can be shown that

$$g_{mb} \triangleq \left.\frac{\partial i_d}{\partial v_{bs}}\right|_Q \approx \lambda_b g_m, \tag{1.177}$$

where λ_b, which might be termed a *bulk modulation factor*, is

$$\lambda_b = \sqrt{\frac{V_\theta/2}{2V_F - V_{bs}}}. \tag{1.178}$$

Recall a previous assertion to the extent that the bulk transconductance, g_{mb}, may be insignificant in comparison to the small-signal impact of the forward transconductance, g_m. From Equations 1.177 and 1.178, λ_b, and hence g_{mb}, are small if V_θ, the body effect potential defined by Equation 1.90, is small. Since V_θ is proportional to the square of the gate oxide thickness, thin oxide layers conduce small bulk transconductances. It is interesting to note in Equation 1.178 that the small values of the bulk modulation factor that are precipitated by thin oxides are made even smaller by increases in the reverse bias applied between the bulk and source.

The drain–source channel resistance, r_o, in Equation 1.173 is readily confirmed to derive from

$$\frac{1}{r_o} \triangleq \left.\frac{\partial i_d}{\partial v_{ds}}\right|_Q \approx \frac{I_d}{V_\lambda + V_{ds} - V_{dsat}}. \tag{1.179}$$

The result shows that a large channel length modulation voltage, V_λ, gives rise to a large channel resistance, r_o, which in turn implies that the drain–source port of a MOSFET emulates the volt–ampere characteristics of an ideal current source. For conventional values of V_λ, large r_o is seen to require a small drain bias current, I_d.

1.2.5.2 Unity Gain Frequency

The models of Figures 1.35 and 1.36 provide an analytical path for computing a commonly invoked figure of merit for MOSFETs; namely, the *unity gain frequency*, which in radial units is symbolized as ω_T. Although this metric offers a meaningful basis for comparing the high-frequency signal processing

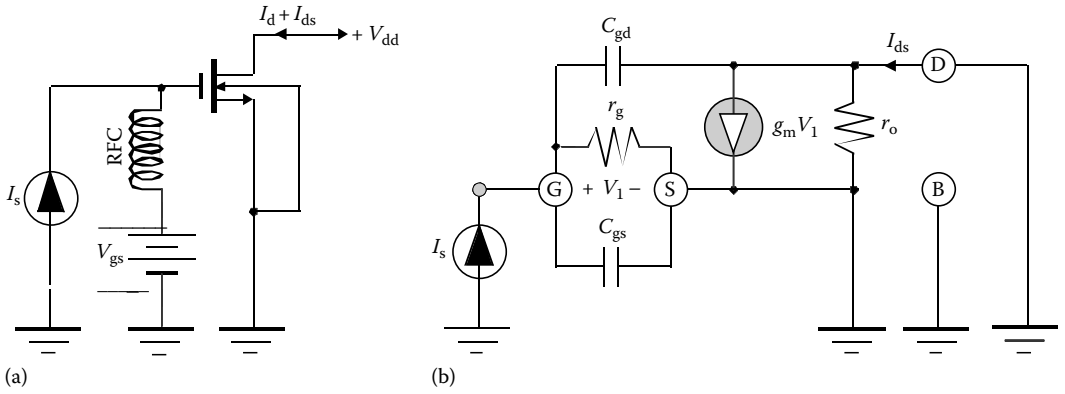

FIGURE 1.37 (a) N-channel common-source MOSFET configured for the evaluation of the unity gain frequency, ω_T, of the transistor. (b) Small-signal, high-frequency equivalent circuit of the network in (a).

capabilities of competing transistors and their associated fabrication processes, its value to bracketing the achievable bandwidths and response speeds of MOSFET circuits is dubious. The latter contention stems from the very definition of the metric. In particular, ω_T is the radial value of signal frequency at which the magnitude of the small-signal, short-circuit current gain of a common-source amplifier degrades to unity. The circuit of relevance is the topology of Figure 1.37a, in which a current signal, I_s is applied to the gate of a MOSFET whose source terminal is incident with signal ground. The radio frequency choke (RFC) provides a conduit for establishing a gate–source bias, V_{gs}, above threshold, while providing a dynamic impedance in series with the gate biasing voltage that is large enough to cajole most of the input signal current to enter the gate terminal.

An input current applied to a gate lead that inherently comprises an open circuit at low frequencies is hardly rational from a circuits perspective. This irrationality is exacerbated by the fact that the drain terminal, where the small-signal current signal response, I_{ds}, to input signal current I_s is extracted, is connected directly to the power supply rail, V_{dd}, thereby rendering the drain terminal short circuited to signal ground (hence the nomenclature, "short circuit" current gain). In other words, the current gain, I_{ds}/I_s, is computed for a common-source amplifier whose gate is driven by signal current and whose drain is short circuited to signal ground, which is hardly a viable analog circuit cell.

Assuming that the transistor at hand operates in saturation, the small-signal equivalent model of the circuit in Figure 1.37a is the structure given in Figure 1.37b. Because the drain, in addition to the bulk and the source, is grounded for signal conditions, the current gain, I_{ds}/I_s, tacitly ignores the high-frequency effects of bulk–drain and bulk–source transistor capacitances. Moreover, the connection of the bulk terminal to the source obviates the need for the bulk transconductance generator, $\lambda_b g_m V_2$, in the model at hand, while short circuiting the drain terminal to the source terminal renders the channel resistance, r_o, inconsequential. Accordingly, an analysis of the structure in Figure 1.37b yields

$$\left.\begin{aligned} I_{ds} &= g_m V_1 - j\omega C_{gd} V_1 \\ I_s &= \frac{V_1}{r_g} + j\omega C_{gs} V_1 + j\omega C_{gd} V_1 \end{aligned}\right\}, \tag{1.180}$$

whence

$$\frac{I_{ds}}{I_s} = \frac{g_m r_g \left(1 - j\omega C_{gd}/g_m\right)}{1 + j\omega r_g \left(C_{gs} + C_{gd}\right)}. \tag{1.181}$$

Since r_g in Equation 1.166 is infinitely large at zero signal frequency, the short circuit gain is seen to be infinity at zero frequency, which reflects engineering intuition in that the gate can conduct no current at zero frequency. In addition, r_g is likely to remain very large in the neighborhood of the 3 dB frequency projected by this gain relationship so that

$$\frac{I_{ds}}{I_s} \approx \frac{g_m}{j\omega\left(C_{gs} + C_{gd}\right)}. \tag{1.182}$$

Equation 1.182 also invokes the reasonable presumption that the frequency, g_m/C_{gd}, of the right half plane zero evidenced on the right-hand side of Equation 1.181 is significantly larger than the aforementioned 3 dB bandwidth. This presumption is tantamount to neglecting the gate-to-drain feedforward through the gate–drain capacitance, C_{gd}, in comparison to the I/O feedforward promoted by the transistor transconductance, g_m. While this approximation is suspect at very high signal frequencies, the approximations leading to Equation 1.182 allow an extrapolated value of the unity gain frequency of

$$\omega_T = 2\pi f_T = \frac{g_m}{C_{gs} + C_{gd}}. \tag{1.183}$$

Clearly, f_T is a highly optimistic estimate of achievable circuit performance, for it pertains expressly to the special case of a drain that is short circuited to the source terminal, thereby quashing the impact on bandwidth of bulk–drain capacitance and any load capacitance that might be driven by the subject transistor. Using Equations 1.106, 1.156, 1.164, 1.176, and 1.174 with V_λ presumed large, the last result is expressible as

$$\omega_T = 2\pi f_T \approx \frac{3\mu_n\left(V_{gs} - V_h\right)}{2L^2\left[1 + \frac{3\left(C_{gso} + C_{gdo}\right)}{2LC_{ox}}\right]}, \tag{1.184}$$

which reflects a direct dependence of the unity gain frequency on free carrier mobility. The result also infers that to the extent that $2LC_{ox} \gg 3(C_{gso} + C_{gdo})$, which may indeed be an engineering stretch for minimal geometry, deep submicron devices, f_T is inversely proportional to the square of channel length. A significant increase in f_T is therefore portended by even a relatively modest shortening of the channel length. The fact that the unity gain frequency value is common corporate banter in the marketing of state of the art transistors and processes arguably underpins the widespread process-engineering penchant for progressively decreased channel lengths.

With the gate resistance, r_g, presumed very large over the signal frequency range of interest, the resultant short circuit current gain in Equation 1.182 is dependent on only frequency-invariant small-signal transistor parameters. Accordingly, Equation 1.183 allows Equation 1.182 to be generalized as the complex frequency domain expression,

$$\frac{I_{ds}}{I_s} \approx \frac{\omega_T}{s}. \tag{1.185}$$

Moreover, the model in Figure 1.35b reduces to the equivalent circuit shown in Figure 1.38a, where signal current I_1 is identified as the current conducted by the gate–source capacitance, C_{gs}. Since signal voltage V_1 is clearly I_1/sC_{gs}, the voltage controlled current, $g_m V_1$, is

$$g_m V_1 = \frac{g_m I_1}{sC_{gs}} = \frac{\omega_T\left(C_{gs} + C_{gd}\right)I_1}{sC_{gs}} = \left(\frac{k_g\omega_T}{s}\right)I_1, \tag{1.186}$$

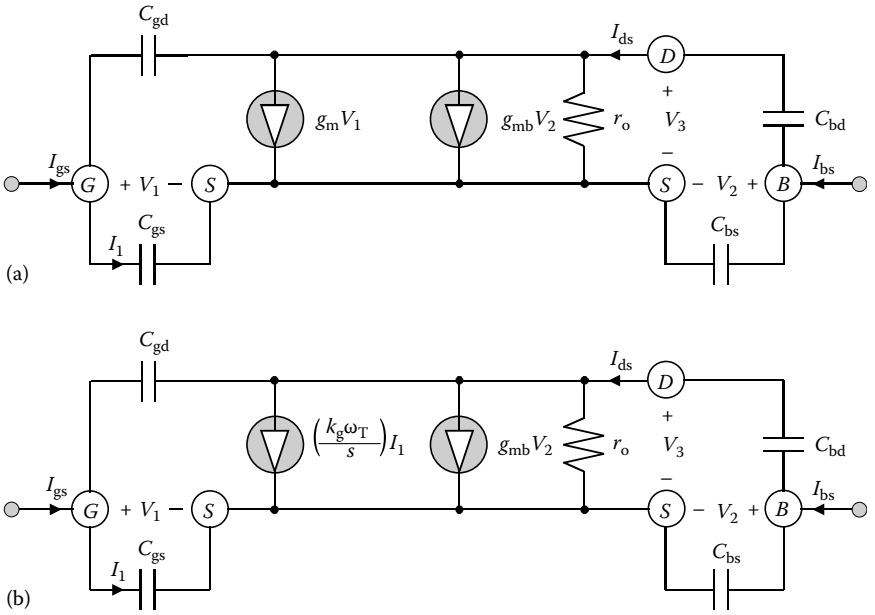

FIGURE 1.38 (a) Small-signal model of Figure 1.35b with gate resistance r_g ignored. (b) Alternative CCCS form of the equivalent circuit in (a).

where

$$k_g = 1 + \frac{C_{gd}}{C_{gs}}. \tag{1.187}$$

Equation 1.186 allows the voltage-controlled current source (VCCS) form of the model shown in Figure 1.38a to be transformed into the equivalent current-controlled structure offered in Figure 1.38b. The latter form proves useful in assessing the performance of amplifiers, such as certain forms of low noise bandpass structures, which utilize source degeneration inductances.

1.2.5.3 Small-Signal Model Development

While the small-signal transistor models shown in Figures 1.35 and 1.36 are topologically correct and conceptually useful from the perspective of linear active network design and first order performance assessment, their engineering utility is limited by two issues. First, the analytical expressions for the parameters embedded in these structures are predicated on a plethora of approximations stemming from the neglect of the effects of lateral and vertical electric fields and simplifications surrounding the charge storage mechanisms of devices and their associated capacitive profiles. These analytically simplifying approximations often place laboratory characterizations of device behavior at odds with physical reality. For example, the substrate doping concentration is not a constant, as is presumed in all foregoing analytical disclosures, but it is less than immediately clear if some sort of weighted average of this dopant level is appropriate for a satisfying voltage–current–charge characterization of a considered transistor. Second, the subject small-signal parameters are dependent on variables, such as carrier mobility, oxide overlap dimensions, doping concentrations, densities of charges trapped in the oxide, regional perimeter dimensions, and the like that are either not released to the circuit designer or are otherwise only vaguely known to the processing foundry.

Because of the foregoing parametric anomalies, reasonably accurate and physically sound assessments of small-signal device and associated circuit performance require that the numerical explication of all relevant small-signal parameters derive from appropriate laboratory measurements conducted on either test device structures or on entire test cells of the circuits undergoing development. A commonly used vehicle toward this characterization end is the *scattering parameters*, or *S-parameters*, measured for a grounded source, grounded gate, or grounded drain interconnection of a subject transistor excited for a suitable range of biasing levels and over an appropriate range of signal frequencies [11]. These parameters are extracted with fixed and known—generally 50 ohm—reference terminations at the input and output ports of the device undergoing test. The measured *S*-parameters, S_{ij}, are then converted into short circuit admittance (*y*-) parameters, y_{ij}. The latter two-port parameters are virtually impossible to discern directly in the laboratory because their numerical delineation mandates the imposition of input and output port signal short circuits, which are difficult to sustain over broad frequency passbands. Once the y_{ij} are determined, it is an involved, but nonetheless straightforward, matter to infer realistic values of most of the parameters implicit to the structures of Figures 1.35 and 1.36.

If the process foundry provides a reliable large-signal HSPICE model, such as the fundamentally heuristic Level 49 MOSFET model, of the device under consideration, the short circuit admittance parameters of the subject transistor can be deduced through appropriate small-signal computer-aided simulations. For example, consider the N-channel MOSFET in Figure 1.39, which is shown connected as a grounded source, three-port configuration. The battery voltage, V_{gg}, biases the gate–source terminals at a greater than threshold value of voltage that establishes the desired quiescent drain current, I_d. Of course, zero quiescent gate current flows in the gate lead of the transistor. On the other hand, the battery voltage, V_{dd}, which modestly influences the quiescent drain current, I_d, is chosen to ensure saturation regime operation of the transistor. Finally, the voltage, V_{bb}, biases the bulk substrate terminal, where it is understood that V_{bb} is ordinarily at most zero. In concert with the traditional stipulations of reverse-biased bulk–source and bulk–drain junctions, zero quiescent gate current is presumed to flow into the bulk. The application of any one or more of the three indicated signal voltages, V_{1s}, V_{2s}, and V_{3s}, produces signal current responses in the gate, bulk, and drain of I_{gs}, I_{bs}, and I_{ds}, respectively. Selecting the "AC" simulation option to manifest a strictly linear HSPICE analysis of the aforementioned current signal responses about respective quiescent values allows the applied signal voltages, V_{1s}, V_{2s}, and V_{3s}, to be set conveniently to amplitudes of 1 V.

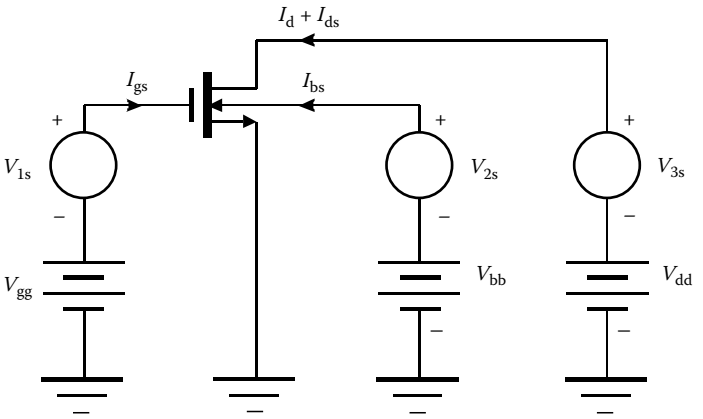

FIGURE 1.39 Common-source test cell of an N-channel transistor configured as a three-port network.

If the applied signal voltages subscribe to the small-signal, linear-operational constraint, superposition theory applies, and the three signal current responses can be described by the linear admittance parameter matrix,

$$\begin{bmatrix} I_{gs} \\ I_{bs} \\ I_{ds} \end{bmatrix} = \begin{bmatrix} y_{11} & y_{12} & y_{13} \\ y_{21} & y_{22} & y_{23} \\ y_{31} & y_{32} & y_{33} \end{bmatrix} \begin{bmatrix} V_{1s} \\ V_{2s} \\ V_{3s} \end{bmatrix}. \tag{1.188}$$

In Equation 1.188, the short-circuit admittance parameters, y_{ij}, which are invariably complex numbers, are extracted over signal frequency. In particular,

$$\left.\begin{array}{lll} y_{11} = I_{gs}/V_{1s}|_{V_{2s}=V_{3s}=0}, & y_{12} = I_{gs}/V_{2s}|_{V_{1s}=V_{3s}=0}, & y_{13} = I_{gs}/V_{3s}|_{V_{1s}=V_{2s}=0} \\ y_{21} = I_{bs}/V_{1s}|_{V_{2s}=V_{3s}=0}, & y_{22} = I_{bs}/V_{2s}|_{V_{1s}=V_{3s}=0}, & y_{23} = I_{bs}/V_{3s}|_{V_{1s}=V_{2s}=0} \\ y_{31} = I_{ds}/V_{1s}|_{V_{2s}=V_{3s}=0}, & y_{32} = I_{ds}/V_{2s}|_{V_{1s}=V_{3s}=0}, & y_{33} = I_{ds}/V_{3s}|_{V_{1s}=V_{2s}=0} \end{array}\right\}. \tag{1.189}$$

The real and imaginary parts of all nine of these *y*-parameters can be readily evaluated from a small-signal HSPICE analysis of the structure in Figure 1.39 or alternatively, they can be discerned in terms of scattering parameters gleaned from measurements of a test structure analogous to that of the subject figure.

If the algebraic form of parameter y_{12} in Equation 1.188 is defined as

$$y_{12} \triangleq g_{12} - j\omega C_{12}, \tag{1.190}$$

the first of the equations in Equation 1.188 can be written as

$$I_{gs} = (y_{11} + y_{13} - j\omega C_{12})V_{1s} + g_{12}V_{2s} - y_{13}(V_{1s} - V_{3s}) + j\omega C_{12}(V_{1s} - V_{2s}), \tag{1.191}$$

which can be couched in the form,

$$I_{gs} = \left(\frac{1}{R_i} + j\omega C_i\right)V_{1s} + g_{12}V_{2s} + \left(\frac{1}{R_f} + j\omega C_f\right)(V_{1s} - V_{3s}) + j\omega C_{12}(V_{1s} - V_{2s}). \tag{1.192}$$

The first parenthesized term on the right-hand side of this expression represents a gate-to-ground shunt interconnection of a resistance,

$$R_i = \frac{1}{\mathrm{Re}(y_{11}) + \mathrm{Re}(y_{13})}, \tag{1.193}$$

and a capacitance,

$$C_i = \frac{\mathrm{Im}(y_{11}) + \mathrm{Im}(y_{13})}{\omega} - C_{12}, \tag{1.194}$$

where from Equation 1.190,

$$C_{12} = -\frac{\mathrm{Im}(y_{12})}{\omega}. \tag{1.195}$$

The resistance, R_i, tends to vary as the inverse square of the radial signal frequency. Thus, it is expedient to write R_i as

$$R_i = \frac{K_{Ri}}{\omega^2}, \tag{1.196}$$

where K_{Ri} is a constant boasting the strange dimensions of ohms–(rad/s)^2.

The second term in Equation 1.192 represents a VCCS whose bulk-to-gate transconductance is

$$g_{12} = \mathrm{Re}(y_{12}). \tag{1.197}$$

The second parenthesized factor on the right-hand side of the subject equation connotes a gate-to-drain shunt combination of resistance

$$R_\mathrm{f} = -\frac{1}{\mathrm{Re}(y_{13})} \tag{1.198}$$

and capacitance

$$C_\mathrm{f} = -\frac{\mathrm{Im}(y_{13})}{\omega}. \tag{1.199}$$

As is the case with resistance R_i, R_f also varies as the inverse square of the radial signal frequency. Accordingly,

$$R_\mathrm{f} = \frac{K_\mathrm{Rf}}{\omega^2}. \tag{1.200}$$

Finally, the last term in Equation 1.192 is merely a capacitance, C_{12}, incident between gate and bulk terminals. It is appropriate to interject that over a broad range of signal frequencies that do not exceed the transistor unity gain frequency, f_T, the capacitances, C_i, C_{12}, and C_f, are nearly constants, which suggests that $\mathrm{Im}(y_{11})$, $\mathrm{Im}(y_{12})$, and $\mathrm{Im}(y_{13})$ are nominally linear functions of the radial signal frequency. An analogous statement prevails for all of the other capacitances defined in the forthcoming paragraphs. While resistances R_i and R_f decrease sharply with signal frequency, they are so large (hundreds or even thousands of megohms) that they can usually be neglected in the course of most design-oriented analog circuit analyses.

Letting

$$y_{ij} = g_{ij} - j\omega C_{ij} \tag{1.201}$$

denote the general short circuit admittance parameter, y_{ij}, Equation 1.188 allows the signal current, I_bs, conducted by the bulk to be expressed as

$$I_\mathrm{bs} = (g_{21} - j\omega C_x)V_\mathrm{1s} + \left(\frac{1}{R_\mathrm{bb}} + j\omega C_\mathrm{bb}\right)V_\mathrm{2s} + (g_{23} - j\omega C_{23})V_\mathrm{3s} + j\omega C_{12}(V_\mathrm{2s} - V_\mathrm{1s}), \tag{1.202}$$

where, recalling Equation 1.201,

$$C_x = C_{21} - C_{12} = \frac{\mathrm{Im}(y_{12}) - \mathrm{Im}(y_{21})}{\omega}. \tag{1.203}$$

and

$$g_{21} = \mathrm{Re}(y_{21}). \tag{1.204}$$

The term, $(g_{21} - j\omega C_x)$ in Equation 1.202 is a transadmittance linking the signal gate voltage to the bulk signal current. The second parenthesized term on the right-hand side of Equation 1.202 reflects a bulk-to-ground parallel combination of a frequency-dependent resistance

$$R_{bb} = \frac{1}{\mathrm{Re}(y_{22})} = \frac{K_{Rbb}}{\omega^2}, \tag{1.205}$$

and capacitance

$$C_{bb} = \frac{\mathrm{Im}(y_{22})}{\omega} - C_{12}. \tag{1.206}$$

A second transadmittance factor, $(g_{23} - j\omega C_{23})$, surfaces to model the coupling of the drain signal voltage, V_{3s}, to the bulk signal current, I_{bs}, where

$$\left.\begin{aligned} g_{23} &= \mathrm{Re}(y_{23}) \\ C_{23} &= -\frac{\mathrm{Im}(y_{23})}{\omega} \end{aligned}\right\}. \tag{1.207}$$

Finally, the last term in Equation 1.200 complements its last term counterpart in Equation 1.192 in that it accounts for the bilateral capacitive coupling prevailing between the drain and bulk terminals.

The only current not yet addressed is the signal drain current, I_{ds}. From Equation 1.188,

$$I_{ds} = (g_m - j\omega C_m)V_{1s} + (g_{mb} - j\omega C_{mb})V_{2s} + \left(\frac{1}{R_o} + j\omega C_o\right)V_{3s} + \left(\frac{1}{R_f} + j\omega C_f\right)(V_{3s} - V_{1s}). \tag{1.208}$$

The factor, $(g_m - j\omega C_m)$, is the forward transadmittance that couples the gate signal voltage to the drain signal current. Its constituent variables are

$$\left.\begin{aligned} g_m &= \mathrm{Re}(y_{31}) - \mathrm{Re}(y_{13}) \\ C_m &= \frac{\mathrm{Im}(y_{13}) - \mathrm{Im}(y_{31})}{\omega} \end{aligned}\right\}. \tag{1.209}$$

On the other hand, $(g_{mb} - j\omega C_{mb})$ is the bulk transadmittance serving to bracket the signal drain current response to the signal bulk voltage, V_{2s}. The variables, g_{mb} and C_{mb}, are

$$\left.\begin{aligned} g_{mb} &= \mathrm{Re}(y_{32}) \\ C_{mb} &= -\frac{\mathrm{Im}(y_{32})}{\omega} \end{aligned}\right\}. \tag{1.210}$$

Following Equation 1.177, the bulk modulation factor, λ_b, can be discerned to be

$$\lambda_b = \frac{g_{mb}}{g_m} = \frac{\mathrm{Re}(y_{32})}{\mathrm{Re}(y_{31}) - \mathrm{Re}(y_{13})}. \tag{1.211}$$

The parenthesized factor of the third term on the right-hand side of Equation 1.206 is the drain-to-ground shunt interconnection of resistance R_o and capacitance C_o, such that

$$\left.\begin{aligned} R_o &= \frac{1}{\mathrm{Re}(y_{33}) + \mathrm{Re}(y_{13})} \\ C_o &= \frac{\mathrm{Im}(y_{33}) + \mathrm{Im}(y_{13})}{\omega} \end{aligned}\right\}. \tag{1.212}$$

The last term in Equation 1.208 reflects the previously introduced, bilateral R_f–C_f coupling between the gate and the drain terminals.

Equation 1.192 for the signal gate current, I_{gs}, Equation 1.202 for the signal bulk current, I_{bs}, and Equation 1.208 for the signal drain current, I_{ds}, can now be exploited to develop the foreboding three-port common-source MOSFET model diagrammed in Figure 1.40a. While the model is intractable for manual circuit analysis and considerably more complicated than its simplified brethren in Figures 1.35 and 1.36, it does serve to bolster circuit design insights. First, and perhaps most obviously, the model at hand illustrates the complex interactions of the bulk with the gate, drain, and source regions of a MOSFET. For example, the bulk signal voltage, V_{2s}, precipitates a real controlled source, $\lambda_b g_m V_{2s}$, in addition to a quadrature controlled source, $j\omega C_{mb} V_{2s}$, at the drain–source port. The first of these sources is the expected effect of bulk-induced modulation of MOSFET threshold voltage, but the latter controlled element is slightly south of transparent. The bulk also gives rise to a VCCS, $g_{12} V_{2s}$, in the gate–source port, which accounts for observable bulk-induced increases in high-frequency gate current. These intricacies, together with the complex transadmittance coupling, $(g_{23} + j\omega C_{23})V_{3s}$, from the drain-to-the bulk seemingly encourage, whenever possible and prudent, operating the MOSFET with its bulk terminal returned to the transistor source terminal. Under such a topological constraint, the model in Figure 1.40a collapses to the almost shockingly simpler network offered in Figure 1.40b.

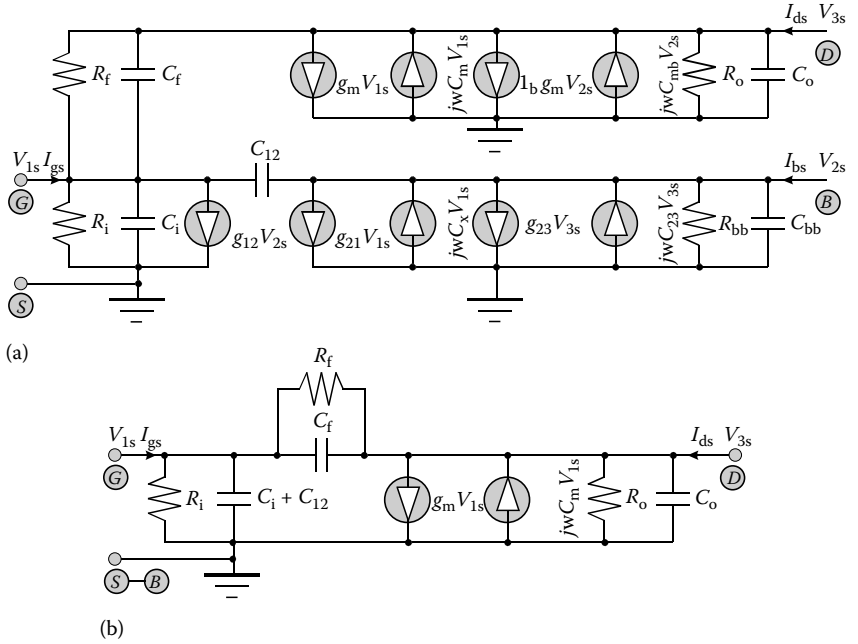

FIGURE 1.40 (a) Small-signal, three-port equivalent circuit for the common-source interconnection of a MOSFET. The three terminal voltages, V_{1s}, V_{2s}, and V_{3s}, denote signal voltages developed with respect to ground at the gate, bulk, and drain terminals, respectively. (b) The equivalent circuit of (a) with the bulk terminal connected directly to the MOSFET source terminal.

A comparison of the model in Figure 1.40b with that of Figure 1.35b suggests that the gate–source resistance, R_i, is effectively the gate resistance, r_g, introduced in Equation 1.166. The resistance, R_f, in Figure 1.40b has no counterpart in Figure 1.35b. Throughout the range of frequencies extending through the unity gain frequency of the considered transistor, both R_i and R_f are so large that they can be ignored for most small-signal analysis ventures, save possibly for a small-signal analysis entailing an assessment of the noise properties of a transistor. The resistance, R_o, is akin to the channel resistance, r_o, in Figure 1.35b. Unlike R_i and R_f, r_o is nominally frequency invariant through the device unity gain frequency metric. With R_i and R_f tacitly ignored and in view of the fact that r_o is independent of frequency, the steady state frequency variable, $j\omega$, in Figure 1.40 can be replaced by the Laplace operator, s, thereby allowing for small-signal step response and other transient investigations of MOSFET amplifiers.

The net capacitance, $(C_i + C_{12})$, in Figure 1.40 is the effective gate–source capacitance, C_{gs}, in Figure 1.35b. Because of the inclusion of capacitance C_{12}, this net gate–source capacitance accounts for gate-to-bulk capacitance, which earlier models presented in this discourse ignore tacitly, primarily because of the high-frequency capacitance characteristics advanced by Figure 1.23. The capacitance, C_f, is the effective gate–drain capacitance, C_{gd}, while capacitance C_o represents the effective bulk–drain capacitance, C_{bd}.

The model in Figure 1.35b highlights a real forward transconductance of g_m, while the models in Figure 1.40 project a complex forward transadmittance, Y_m, of

$$Y_m = g_m - j\omega C_m = g_m e^{j\varphi_m(\omega)} \sqrt{1 + \left(\frac{\omega C_m}{g_m}\right)^2}, \tag{1.213}$$

where

$$\varphi_m(\omega) = -\tan^{-1}\left(\frac{\omega C_m}{g_m}\right) \tag{1.214}$$

denotes an *excess phase angle* associated with the transport of minority carriers in the gate-induced channel extending from the source region-to-the drain region. Equivalently, the angle, $\varphi_m(\omega)$, is associated with an *excess envelope delay*, $T_m(\omega)$, such that

$$T_m(\omega) = -\frac{d\varphi_m(\omega)}{d\omega} = \frac{C_m/g_m}{1 + \left(\frac{\omega C_m}{g_m}\right)^2}, \tag{1.215}$$

whose low-frequency and, in this case, maximum value is obviously (C_m/g_m). Excess delay, for which no account prevails in the simpler models of Figures 1.35 and 1.36, looms potentially critical in feedback circuits in that it acts to degrade the achievable phase margin of the open loop response.

VCCSs having an imaginary transadmittance can be synthesized easily for small-signal, computer-based analyses through the use of a voltage-controlled voltage source (VCVS), a capacitor, and a current-controlled current source (CCCS), as depicted in Figure 1.41a. In this figure, the controlling current, I_i, of the CCCS, αI_i, is

$$I_i = j\omega C\mu V_i, \tag{1.216}$$

whence the indicated controlled current, I_o, is

$$I_o = \alpha I_i = j\omega C\alpha\mu V_i. \tag{1.217}$$

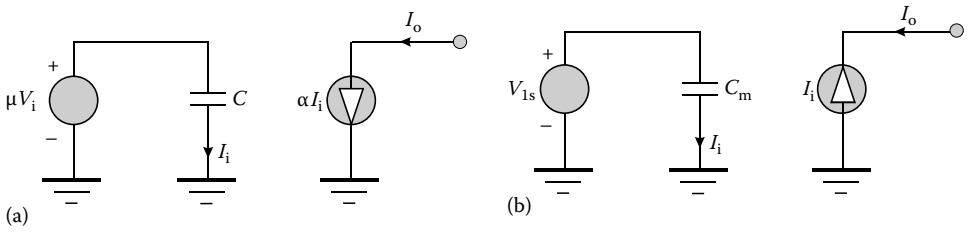

FIGURE 1.41 (a) Synthesis of a VCCS whose transadmittance is imaginary and proportional to radial signal frequency. (b) The synthesis of the controlled current, $-j\omega C_m V_{1s}$, in the models shown in Figure 1.40.

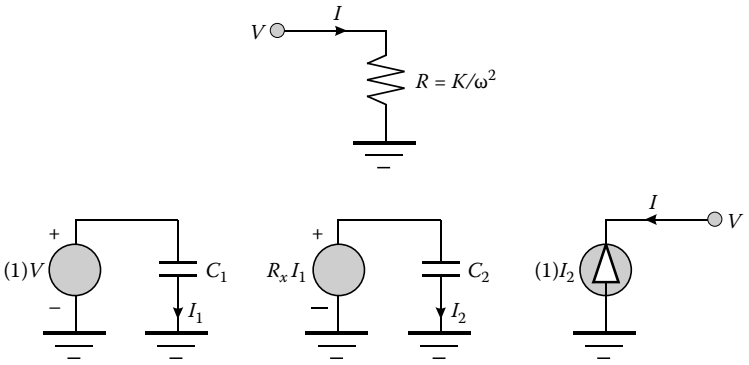

FIGURE 1.42 Synthesis of a branch resistance whose value is inversely proportional to the square of the radial signal frequency. The indicated resistance, R, is synthesized if $R_x = 1/KC_1C_2$.

Thus, for the imaginary component, $j\omega C_m$, of the forward transadmittance, Y_m, in Equation 1.211, $\mu = 1$, $C = C_m$, and $\alpha = -1$ gives the desired controlled current, $-j\omega C_m V_{1s}$, as is abstracted in Figure 1.41b.

Similarly, the frequency variant resistances, R_i, R_f, and R_{bb}, can be synthesized for small-signal, computer-aided analysis purposes using a VCVS, a current-controlled voltage source (CCVS), and a CCCS. This contention is illustrated in Figure 1.42 for the general case of a resistance, R, given by

$$R = -\frac{K}{s^2}, \tag{1.218}$$

which for steady state sinusoidal conditions is the generalized relationship,

$$R = \frac{K}{\omega^2}, \tag{1.219}$$

advanced by Equations 1.196, 1.200, and 1.205. To wit, the controlled current, I_1, generated by the VCVS, $(1)V$, is $I_1 = sC_1V$, while the current, I_2, established in response to the CCVS, (R_xI_1), is $I_2 = sC_2R_xI_1 = s^2C_1C_2R_xV$. It follows that the resistance, R, presented to the port driven by the CCCS, $(1)I_2$, is

$$R = \frac{V}{-I_2} = \frac{V}{-s^2C_1C_2R_xV} = -\frac{1}{s^2C_1C_2R_x}. \tag{1.220}$$

For arbitrary values of capacitances C_1 and C_2, selecting

$$R_x = \frac{1}{KC_1C_2} \tag{1.221}$$

achieves the desired resistance value set forth by Equation 1.218.

Parameterization example:
An N-channel transistor featuring a channel length of 180 nm has the Level 49 HSPICE parameters that appear in Table 1.2. The transistor is implemented with a gate aspect ratio of $W/L = 25$, and is biased at $V_{gs} = 1.1$ V, $V_{ds} = 1$ V and $V_{bs} = 0$ V. The device undergoing study is earmarked for analog small-signal applications that embrace a signal frequency range extending from 100 MHz to 10 GHz. For this frequency passband, determine nominal values of all of the parameters indigenous to the small-signal, common-source model of Figure 1.40b. Also, compute the extrapolated unity gain frequency of the transistor at the given quiescent operating point. Express these results as maximum value, minimum value, average value, and standard deviation (referred to the average value) over a frequency passband extending from 100 MHz to 10 GHz.

Results:

1. Before proceeding with the simulation, the planar source and drain areas, A_s and A_d, as well as the source and drain peripheral dimensions, P_s and P_d, must be computed through an appeal to Equation 1.154. These are $A_s = A_d = (1.62)(10^{-12})$ m^2 and $P_s = P_d = (5.22)(10^{-6})$ *m*. In arriving at these figures, use is made of the fact that for a channel length of $L = 180$ nm and a gate aspect ratio of $W/L = 25$, the gate width is $W = 4.5$ μm. The parameters, L, W, A_s, A_d, P_s, and P_d are inserted directly on the model line of the HSPICE net list. For example, the model line used in the simulations executed herewith is

$$M2\ 6\ 4\ 0\ 7\ 180\ \text{nM}, \quad L = 180\text{n}, \quad W = 4.5\ \text{u}, \quad A_S = 1.62\ \text{p}, \quad A_D = 1.62\ \text{P},$$
$$P_S = 5.22\ \text{u}, \quad P_D = 5.22\ \text{u}.$$

   In this model line, *M*2 identifies the transistor undergoing examination, ''6'' is the number of the drain node, ''4'' is the gate node number, ''0'' is the number of the grounded source node, and ''7'' is the number of the bulk substrate node. The insert, ''180 nM,'' identifies the name of the model used for the subject transistor.

   An HSPICE simulation of the simple test cell shown in Figure 1.39 can now be straightforwardly executed. In this test structure, $V_{gg} = 1.1$ V, $V_{dd} = 1$ V, and $V_{bb} = 0$ V combine to set the desired operating point of the transistor. The operating point information disclosed by the static HSPICE simulation is as follows.

   ID 8.9407E-04 (drain current is $I_d = 894.1$ μA)
   IS -8.9407E-04 (source current flows out of device and is virtually identical to the drain current)
   IB -1.0002E-12 (bulk current is about one picoampere and flows out of the device)
   IBD -9.9417E-13 (bulk current is sum of the bulk–drain and bulk–source junction currents)
   IBS -6.0237E-15 (bulk current is sum of the bulk–drain and bulk–source junction currents)
   VGS 1.1000 (desired gate–source quiescent voltage)
   VDS 1.0000 (desired drain–source quiescent voltage)
   VBS 0.0000 (desired bulk–source quiescent voltage)
   VTH 0.5102 (simulated threshold voltage is $V_h = 510.2$ mV)
   VDSAT 0.3149 (simulated drain saturation voltage is $V_{dsat} = 314.9$ mV)

   It should be noted that the quiescent drain source voltage, $V_{ds} = 1.0$ V, is certainly larger than the simulated drain saturation voltage, $V_{dsat} = 314.9$ mV. Accordingly, the device at hand operates in its saturation regime for suitable small-signal excitations.

2. A small-signal, computer-aided simulation of the test circuit in Figure 1.39 can now be executed at the quiescent operating point established in the preceding step of this exercise. The objective of this simulation is to ascertain the real and imaginary components of each of the nine short circuit admittance parameters, y_{ij}, introduced in Equation 1.188. The model parameters then derive from the pertinent equations given in Section 1.2.5.3.

   Gate-to-drain resistance coefficient, K_{Rf}:
   Maximum value is $(7.93)(10^{27})$
   Minimum value is $(7.92)(10^{27})$
   Average value is $(7.93)(10^{27})$
   Standard deviation is 0.03%

   Gate-to-drain capacitance, C_f:
   Maximum value is 3.22 fF
   Minimum value is 3.21 fF

Average value is 3.22 fF

Minimum value is 0.42 fF
Average value is 0.42 fF
Standard deviation is 0%

Forward transconductance, g_m:
Maximum value is 2.03 mmho
Minimum value is 2.03 mmho
Average value is 2.03 mmho
Standard deviation is 0.01%

Transadmittance capacitance, C_m:
Maximum value is 2.00 fF
Minimum value is 1.99 fF
Average value is 2.00 fF
Standard deviation is 0.05%

Gate–bulk transconductance, g_{21}:
Maximum value is 0.82 μmho
Minimum value is 0 μmho
Average value is 0.18 μmho
Standard deviation is 191.97%

Gate–bulk transadmittance capacitance, C_x:
Maximum value is 0.68 fF
Minimum value is 0.67 fF
Average value is 0.67 fF
Standard deviation is 0.03%

Bulk transconductance modulation factor, λ_b:
Maximum value is 0.21
Minimum value is 0.21

Average value is 0.21
Standard deviation is 0.03%

Drain–bulk transconductance, g_{23}:
Maximum value is 0 μmho
Minimum value is −0.41 μmho
Average value is −0.05 μmho
Standard deviation is 191.97%

Bulk transadmittance capacitance, C_{mb}:
Maximum value is 3.19 fF
Minimum value is 3.18 fF
Average value is 3.19 fF
Standard deviation is 0.02%

Drain–bulk transadmittance capacitance, C_{23}:
Maximum value is 2.63 fF
Minimum value is 2.63 fF
Average value is 2.63 fF
Standard deviation is 0.02%

Drain–source channel resistance, R_o:
Maximum value is 10.38 kΩ
Minimum value is 10.33 kΩ
Average value is 10.37 kΩ
Standard deviation is 0.09%

Bulk-to-source resistance coefficient, K_{Rbb}:
Maximum value is $(7.03)(10^{27})$
Minimum value is $(6.78)(10^{27})$
Average value is $(6.99)(10^{27})$
Standard deviation is 0.76%

Drain–source capacitance, C_o:
Maximum value is 2.62 fF
Minimum value is 2.62 fF
Average value is 2.62 fF
Standard deviation is 0.03%

Bulk–source capacitance, C_{bb}:
Maximum value is 6.83 fF
Minimum value is 6.82 fF
Average value is 6.83 fF
Standard deviation is 0.02%

3. Equation 1.183 is the pertinent equation for the computation of the extrapolated unity gain frequency. To this end, the average forward transconductance has been computed to be $g_m = 2.03$ mmho. The effective gate–source capacitance, C_{gs}, is the computed average value, $C_i = 7.55$ fF, which accounts for gate–source overlap and any other second order phenomena embraced by the utilized HSPICE model. On the other hand, the effective average gate–drain capacitance, C_{gd}, is $C_f = 3.22$ fF, which, like C_i, incorporates all pertinent high order device characterization phenomena. Accordingly

$$f_T = \frac{g_m}{2\pi(C_i + C_f)} = 30.0 \text{ GHz}.$$

Comments: With the exception of parameters g_{12}, g_{21}, and g_{23}, the quoted standard deviation numbers indicate an excellent model fit to circuit theoretic issues. These three transconductances can also be made to agree well with theoretical disclosures if they are each allowed to vary as the square of the radial signal frequency. However, their values are so small as to render overt concern of them unproductive.

The computed unity gain frequency, f_T, is within range of the expected frequency performance of representative MOSFETs manufactured in a 180 nM technology process. It is interesting to note, however, that the effective gate–drain capacitance (3.22 fF), which is traditionally ignored in first order, high-frequency circuit analysis ventures, is, in this case, almost 43% of the effective gate–source capacitance (7.55 fF).

1.2.6 Design-Oriented Analysis Strategy

When a MOSFET is exploited for a linear analog signal processing application, an essential early design requirement entails the implementation of suitable biasing. Generally, this biasing must ensure that for all pertinent signal levels, each transistor used to supply gain, impedance conversion, constant current, constant voltage, or other I/O properties operates in its saturated domain where its drain–source voltages, V_{ds}, is at least as large as its drain saturation voltage, V_{dsat}. When $V_{ds} \geq V_{dsat}$, Equation 1.142 is the applicable relationship for ascertaining a gate–source voltage, V_{gs}, commensurate with a target drain current, I_d, conducted at a given or desired value of drain–source voltage.

Unfortunately, academic satisfaction does not often resonate with the engineering reality that underlies predictable, reliable, and reproducible integrated circuit design. For the biasing issue at hand, Equation 1.142 is fraught with numerous shortfalls. Despite its algebraic cumbersomeness, Equation 1.142 is only an approximation of the static volt–ampere characteristics of a MOSFET operated in saturation, owing to a variety of analytical liberties exploited with respect to charge storage, charge transport, carrier mobility, and the other phenomenological issues discussed in preceding sections. Even if Equation 1.142 were an accurate disclosure of the aforementioned static characteristics, challenges surround its utilization because circuit and system designers are rarely privy to the physical and process parameters on which the metrics, K_n, V_h, V_{dsat}, V_{ve}, V_{le}, and V_λ, are dependent. These model variables can be discerned reliably through only laboratory measurement of static device responses or via analyses conducted on appropriate computer-based simulations founded on accurate and reliable transistor models.

On the tacit presumption that the foregoing six model variables can be extracted satisfactorily from measurement and/or simulation, Equation 1.142 might be supplanted by the more familiar, nominally square law relationship,

$$I_d = \frac{K_{ne}}{2}\left(\frac{W}{L}\right)\left(V_{gs} - V_h\right)^2\left(1 + \frac{V_{ds} - V_{dsat}}{V_\lambda}\right), \tag{1.222}$$

where K_{ne} symbolizes the effective transconductance coefficient,

$$K_{ne} = \frac{K_n M_{sat}^2}{1 + \frac{V_{gs} - V_h}{V_{ve}}} \approx \frac{K_n}{\left(1 + \frac{V_{gs} - V_h}{V_{ve}}\right)\left[1 + 0.78\left(\frac{V_{gs} - V_h}{V_{le}}\right)\right]}. \tag{1.223}$$

This effective transconductance coefficient accounts for mobility degradation deriving from strong vertical (gate-to-channel) electric fields through the variable, V_{ve}, as well as mobility degradation caused by lateral (drain-to-source) electric fields, which is monitored by variable V_{le}. While Equation 1.222 suggests a relatively straightforward square law dependence of drain current on the so called *excess,* or *effective, gate–source voltage*, $(V_{gs} - V_h)$, particularly for the commonly encountered situation of $(V_{ds} - V_{dsat}) \ll V_\lambda$, it should be noted that K_{ne} is inversely proportional to a quadratic function of the

excess gate–source voltage. Typically, V_{ve} is of the order of 5- to 20-fold the value of V_{le} and thus, the possibility of simplifying Equation 1.223 to ease computational strain, while preserving computational accuracy, is dubious.

Example:

An N-channel transistor featuring a channel length of 180 nM has the Level 49 HSPICE parameters given in Table 1.2. The transistor is to be biased in saturation at $V_{ds} = 1$ V and $I_d \approx 1$ mA to achieve a small-signal transconductance, g_m, of at least 3 mmhos. Assuming that the bulk terminal is incident with the transistor source terminal, choose a reasonable gate aspect ratio, W/L, determine the required gate–source voltage bias, V_{gs}, and estimate the model parameters implicit to Equation 1.222.

Results:

1. The applicable circuit for computer-aided investigation is offered in Figure 1.43, where the transistor model parameters are those that appear in Table 1.2, and the gate aspect ratio, W/L, is to be determined. The null voltage source in the drain circuit of the device facilitates the extraction of the quiescent drain current, I_d. It is understood that for biasing purposes, the area and perimeter parameters, A_s, A_d, P_s, and P_d, are of no consequence and can therefore be defaulted to any convenient value. Initially, set $V_{gs} = 1$ V and $W/L = 1$ and, of course, $V_{ds} = 1$ V. The HSPICE static simulation reveals $I_d = 46.4$ μA, $V_{dsat} = 262.8$ mV, $V_h = 519.7$ mV, and $g_m = 136.5$ μmho. Since $V_{gs} = 1$ V is certainly larger than $V_h = 519.7$ mV and $V_{ds} = 1$ V $> V_{dsat} = 262.8$ mV, the transistor is clearly turned on and operates in its saturation domain.
2. With $W/L = 1$, the simulated drain current is a factor of 21.55 times smaller than the target current of 1 mA. This observation seemingly suggests the need for increasing the gate aspect ratio from 1 to 21.55, since the drain current is ostensibly proportional to W/L. In truth, the actual drain current is not directly proportional to W/L because of numerous second order effects, including weak dependencies of threshold voltage, drain saturation voltage, and parameter M_{sat} on gate width W. Experience shows that a more viable gate aspect ratio adjustment is about twice that computed or in this case, about 40. With $W/L = 40$ and $V_{gs} = V_{ds} = 1$ V, HSPICE delivers $I_d = 1.08$ mA, $V_{dsat} = 278.2$ mV, $V_h = 510.2$ mV, and $g_m = 3.17$ mmho. The simulated transconductance value satisfies its design target. Although V_{gs} can be decreased modestly to reduce the drain current to 1 mA, this exercise is unnecessary in view of the effects of routinely encountered device processing

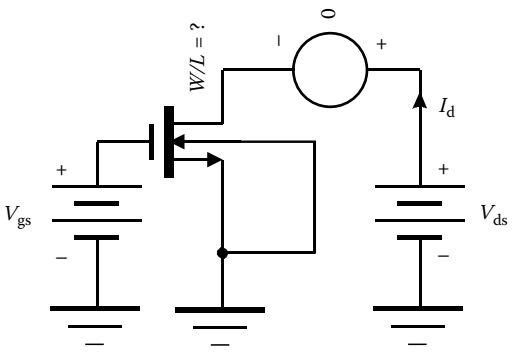

FIGURE 1.43 Circuit structure for MOSFET biasing simulation. The Level 49 HSPICE parameters of the transistor are delineated in Table 1.2.

vagaries and model parameter uncertainties. Thus the design requirement is satisfied for $W/L = 40$ and $V_{gs} = V_{ds} = 1$ V.

3. The model parameterization exercise begins by using Equation 1.141 to compute the voltage, V_{ve}. From Table 1.2, the oxide thickness is $T_{ox} = 4(10^{-9})$ m, which is 40 Å. Accordingly, $V_{ve} = 40/15 = 2.667$ V.
4. The next step in the parameterization process entails operating the transistor undergoing study at a V_{ds} value that equals its saturated value of 278.2 mV. This tack reduces the last parenthesized factor on the right-hand side of Equation 1.222 to unity, thereby simplifying the computation of the effective transconductance parameter, K_{ne}. With $W/L = 40$, $V_{gs} = 1$ V, and $V_{ds} = V_{dsat} = 278.2$ mV, HSPICE produces $I_d = 878.33$ μA and $V_h = 510.0$ mV. Appealing to Equation 1.222, parameter K_{ne} follows forthwith as $K_{ne} = 182.9$ μmho/V.
5. Recalling that $V_{dsat} = 278.2$ mV and $(V_{gs} - V_h) = (1 - 0.510)$ V $= 0.490$ V, Equation 1.129 delivers $M_{sat} = 0.5678$. The previously documented approximate equation, Equation 1.136, relating M_{sat} to variable α can be used to determine the numerical value of α for $V_{gs} = 1$ V and $V_h = 510.0$ mV. Alternatively, Equation 1.131 can be solved for α directly to yield

$$\alpha = \frac{2(1 - M_{sat})}{M_{sat}^2} = 2.682. \tag{E1.1}$$

   Using Equation 1.130, parameter V_{le} follows forthwith as $V_{le} = 182.7$ mV.
6. With $K_{ne} = 182.9$ μmho/V, $V_{ve} = 2.667$ V, $M_{sat} = 0.5678$, $V_{gs} = 1$ V, and $V_h = 510.0$ mV, the device transconductance parameter, K_n, follows from Equation 1.223 as $K_n = 671.7$ μmho/V. It is interesting to observe that the effective transconductance factor, K_{ne}, is almost 3.7 times smaller that the "actual" transconductance coefficient, K_n. Experience testifies to the apparent fact that for deep submicron devices, $2.5 \leq K_n/K_{ne} \leq 4$ is typical.
7. In principle, V_{ve}, V_{le}, V_h, V_{dsat}, K_n, and thus K_{ne}, do not vary with changes in the drain–source voltage, V_{ds}. Accordingly, the ratio of the drain current (1.08 mA) for $V_{ds} = 1$ volt to the drain current (878.33 μA) at $V_{ds} = V_{dsat} = 278.2$ mV is solely attributed to the last parenthesized factor on the right-hand side of Equation 1.222, that is,

$$\frac{I_d|_{V_{ds}=1\text{ V}}}{I_d|_{V_{ds}=V_{dsat}}} = \frac{1.08\text{ mA}}{878.33\ \mu\text{A}} = 1.230 = 1 + \frac{V_{ds} - V_{dsat}}{V_\lambda}. \tag{E1.2}$$

   It follows that the channel length modulation voltage is $V_\lambda = 3.144$ V.
8. In an attempt to demonstrate the propriety of the foregoing modeling exercise, the forward static transfer characteristic of the subject transistor is modeled in HSPICE for both $V_{ds} = 1$ V and $V_{ds} = 1.5$ V. The simulated results are then compared with calculations deriving from Equations 1.222 and 1.223 using the computed values of V_{ve}, V_{le}, and V_λ and the simulated disclosures for W/L, V_{dsat}, and V_h. Specifically, $V_{ve} = 2.667$ volts, $V_{le} = 182.7$ mV, $V_\lambda = 3.144$ volts, $W/L = 40$, $V_{dsat} = 278.2$ mV, and $V_h = 510.0$ mV.

Figures 1.44 and 1.45 display the results of the foregoing comparative study. In Figure 1.44, the simulated and calculated forward transistor characteristics in the saturation domain are displayed for a drain–source voltage, V_{ds}, of 1.0 V. The calculations corroborate reasonably well with pertinent simulations in that ±15% error is observed for $0.73\text{ V} < V_{gs} < 1.89$ V. It is notable that $V_{gs} = 0.73$ V is only slightly larger than 200 mV above threshold level, while at $V_{gs} = 1.89$ V, the transistor no longer operates in its saturation domain when $V_{ds} = 1$ V. Figure 1.45 confirms better corroboration between calculated and simulated results for $V_{ds} = 1.5$ V. In particular, the computational error is within ±9% for $0.92\text{ V} < V_{gs} < 2$ V and is within ±15% for $0.78\text{ V} < V_{gs} < 2$ V.

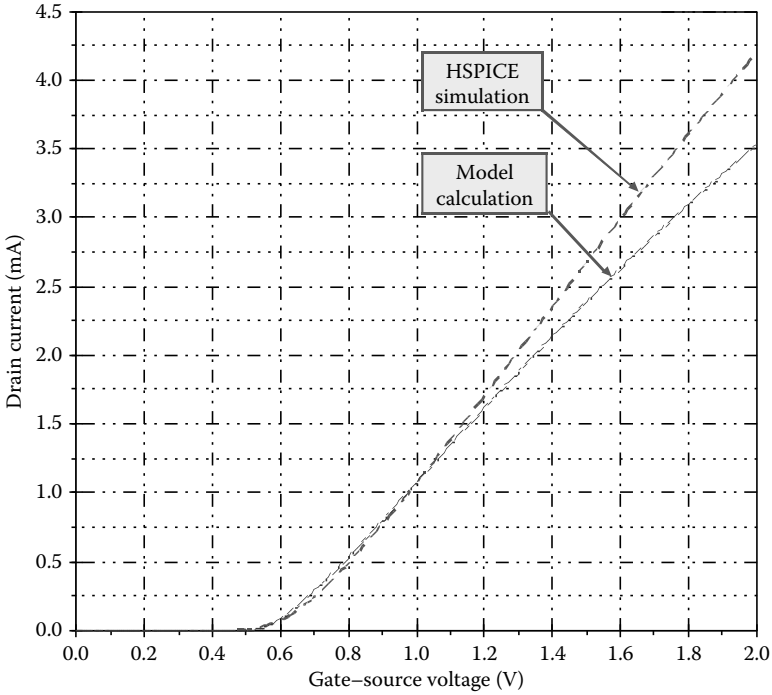

FIGURE 1.44 Simulated and calculated forward static transfer characteristic for the NMOS transistor whose model parameters are delineated in Table 1.2. The transistor is operated at a drain–source voltage, V_{ds}, of 1 V.

Comments: In Step #2 of the foregoing computational procedure, the gate aspect ratio, W/L, is the pivotal metric for achieving the desired transconductance and transistor drain current. If power dissipation is a dominant design concern, W/L can be increased above the value of 40 discerned in this example, with the understanding that the gate–source voltage, V_{gs}, can be reduced commensurately, thereby reducing the static drain current and hence, the power dissipation of the transistor. Of course, the primary penalty of large gate aspect ratio is a possible degradation of high-frequency circuit response since, as is confirmed by Equation 1.154, the capacitance area and peripheral dimensions increase in proportion to the gate width, W.

In Step #3, the metric, V_{ve}, is evaluated in terms of a purely empirical, and indeed crude first order, relationship to the oxide thickness, T_{ox}. A possible way around this dilemma is to compute V_{ve} and all of the other requisite modeling parameters by curve fitting Equation 1.222 to simulated or actually measured static data. While this approach may be academically satisfying, it may be imprudent from a design time perspective. Keep in mind that biasing is not the fundamental performance objective of an analog circuit; rather, biasing is the necessary condition that expedites the desired analog responses.

The drain saturation voltage, V_{dsat}, is obviously a nonlinear function of the excess gate voltage, $(V_{gs}-V_h)$, owing to the parameter, M_{sat}. But in addition, V_{dsat} changes slightly with the applied drain–source voltage, V_{ds}. Indeed, the Level 49 model parameters account for a slight sensitivity of threshold voltage on V_{ds}, which is as anticipated since the interface potential throughout the entire channel varies somewhat as a function of the lateral (drain-to-source) field engendered by V_{ds}.

Finally, it should be noted that the computed value (3.144 V) of the channel length modulation voltage, V_λ, is appreciably smaller than values often propounded in the textbook literature. However, V_λ is indeed a relatively small voltage for deep submicron MOS technology transistors. This anemic voltage is the principle cause of correspondingly small drain–source channel resistances, which renders the

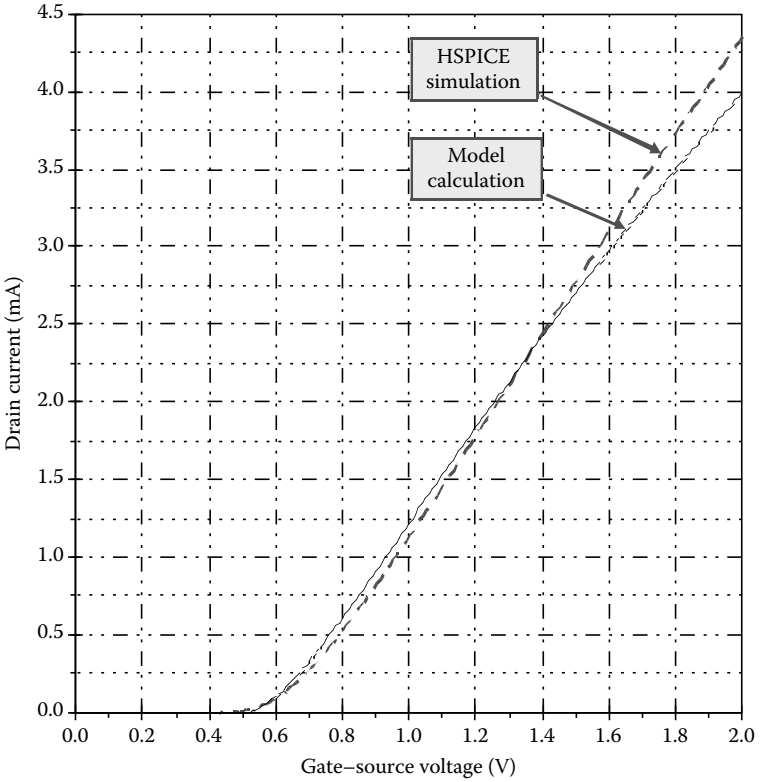

FIGURE 1.45 Simulated and calculated forward static transfer characteristic for the NMOS transistor whose model parameters are delineated in Table 1.2. The transistor is operated at a drain–source voltage, V_{ds}, of 1.5 V.

realization of transconductor amplifiers, as might be used in operational transconductor amplifier-capacitor (OTA-C) filters, a daunting challenge. The desire for accuracy surrounding the enumeration of V_λ is exacerbated by the fact that parameter V_λ is not the constant that is presumed tacitly in the foregoing demonstration. Instead, and as is suggested by Equation 1.114, V_λ is functionally dependent on drain–source voltage, drain saturation voltage, and threshold voltage. If V_λ or the drain–source channel resistance is critical in an analog circuit design endeavor, care must therefore be exercised to ensure that model parameters are extracted in terms of measured or simulated data that largely mirror the desired or expected operating state of the utilized transistor.

1.3.1 Introduction

Many types of field effect devices are used in analog IC and RFIC design. Section 1.2 described the MOSFET and associated device models. MOSFETs are currently the predominant field effect device used in analog circuit applications due to the pervasive CMOS technology. CMOS fabrication is relatively inexpensive when not scaled below 0.25 μm. However, mask costs for 130 nm and below increase very rapidly, limiting applications to only those requiring extremely high volume. Also, drain breakdown voltage is quite low, of the order of 1 V for 65 nm CMOS. This constrains dynamic range or power output in certain applications.

Other field effect devices are available, but are considered niche market devices in most cases. This would include the legacy silicon JFET technology, still used in conjunction with bipolar transistors for some lower frequency analog applications. Compound semiconductor-based field effect devices (MESFET, HEMT, p-HEMT, m-HEMT) are often the FET of choice for applications requiring very wide bandwidth, extremely low noise, high gain at mm-wave frequencies, and high output powers at frequencies above 2 GHz. Cost of fabrication is frequently less than that of CMOS in smaller volume applications because the mask set costs are typically an order of magnitude less. Also, the compound semiconductor devices are grown on semi-insulating substrates. Passive components such as spiral inductors, MIM capacitors and deposited resistors have less parasitic capacitance and higher Q than is typical for silicon-based RFICs.

In this section, the silicon JFET and the main compound semiconductor HEMT devices will be described. Special emphasis will be placed on the GaN HEMTs whose performance is exceptionally good for microwave and mm-wave power amplifiers.

1.3.2 Silicon JFET Device Operation and Technology

Although the silicon JFET is today a legacy device, it is still used in some bipolar analog ICs to provide an inexpensive BiFET IC technology. Also, the description of its current–voltage characteristic is similar to any FET which uses a pn or Schottky metal–semiconductor junction for the gate electrode. The JFET consists of a conductive channel with source and drain contacts whose conductance is controlled by a gate electrode. The channel can be fabricated in either conductivity type, n or p, and both normally-on (depletion mode) and normally-off (enhancement mode) type devices are possible. The circuit symbols typically used for JFETs are shown in Figure 1.46 along with the bias polarities of active region operation for these four device possibilities. For analog circuit applications, the depletion mode is almost exclusively utilized because it provides a larger range of input voltage and therefore greater dynamic range. In silicon,

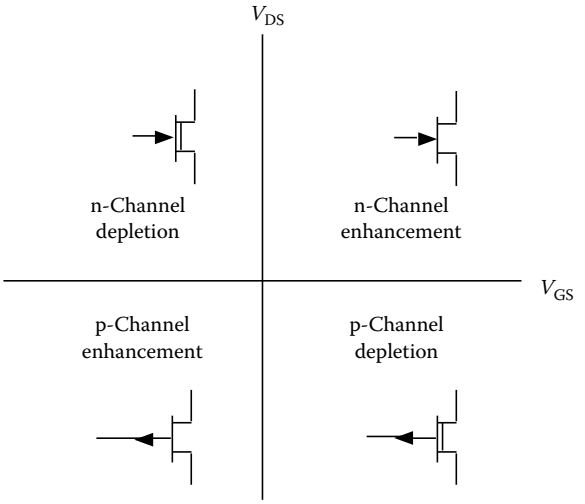

FIGURE 1.46 The circuit symbols typically used for JFETs are shown with the bias polarities for active region operation.

both p- and n-channel JFETs are used, but when compound semiconductor materials such as GaAs or InGaAs are used to build the FET, n-channel devices are used almost exclusively.

When fabricated with silicon, the JFET is used in analog IC processes for its high input impedance, limited by the depletion capacitance and leakage current of a reverse-biased pn junction. When the JFETs are used at the input stage, an op-amp with low input bias current, at least at room temperature, can be built. Fortunately, a p-channel JFET can be fabricated with a standard bipolar process with few additional process steps. This enables inexpensive BiFET processes to be employed for such applications. Unfortunately, the simple process modifications required for integrating JFETs and BJTs are not consistent with the requirements for high-performance devices. Short-gate lengths and high-channel doping levels are generally not possible. So the transconductance per channel width and the gain–bandwidth product of JFETs integrated with a traditional analog BJT process are not very good. The short-circuit current gain–bandwidth product (f_T) is about 50 MHz for an integrated p-channel JFET. The MOSFETs in a BiCMOS process are much better devices, however, a BiCMOS process does not often include both NPN and PNP BJTs needed for high-performance analog circuits.

Discrete silicon JFETs are available with much better performance because they can be fabricated with a process optimized for the JFET. Typical applications are for low-noise amplifiers up to the VHF/UHF range. Noise figures less than 0.1 dB can be obtained at low frequencies with high source impedances and 2 dB at high frequencies at the noise matching input condition with high performance discrete silicon JFETs. The low input gate current, I_G, which can be in the picoamp range, causes the shot noise (proportional to $\sqrt{I_G}$) component to be very low. The input equivalent noise current of the JFET is mainly due to input referred channel (Johnson) noise. This property gives very low noise performance when presented with a high source impedance. In this case, the JFET is often superior to a BJT for noise. For low source impedances, the BJT is generally better.

Compound semiconductor materials such as GaAs and InGaAs are used to fabricate JFET-like devices called metal-semiconductor FET (MESFETs) and high electron mobility transistor (HEMTs). The reason for using these materials is superior performance at high frequencies. These devices are unequaled for gain–bandwidth, ultralow noise, and power amplification at frequencies above 10 GHz and up to 300 GHz. Integrated analog microwave circuits are fabricated with these devices and are commercially available for use in low noise receiver and power amplifier applications. Some representative results will be summarized in Table 1.5.

1.3.2.1 JFET Static *I–V* Characteristics

The JFET differs in structure and in the details of its operation from the MOSFET discussed in Section 1.3.2. Figure 1.47 shows an idealized cross section of a JFET. The channel consists of a doped region, which can be either p- or n-type, with source and drain contacts at each end. The channel is generally isolated from its surrounding substrate material by a reverse biased p–n junction. The depletion regions are bounded in Figure 1.47 by dashed lines and are unshaded. The thin, doped channel region forms a resistor of width W into the page and height d. A gate electrode is located at the center of the channel, defined by a semiconductor region of opposite conductivity type of length L. An n-channel structure is shown here for purposes of illustration. The p-type gate constricts the channel, both through the depth of the diffusion or implant used to produce the gate and through the depletion layer formed at the p–n junction. The height of the channel can be varied by biasing the gate relative to the source (V_{GS}). A reverse bias increases the depletion layer thickness, reducing the channel height and the drain current. If V_{GS} is large enough that the channel is completely depleted, the drain current will become very small. This condition corresponds to the cutoff and subthreshold current regions of operation, and the V_{GS} required to cut-off the channel is called V_P, the pinch-off voltage. V_P corresponds to the threshold voltage that was defined for the MOSFET. Similarly, a forward bias between gate and channel can be used to increase drain current, up to the point where the gate junction begins to conduct. Most JFETs are designed to be depletion-mode (normally on); drain current can flow when $V_{GS} = 0$ and they are normally operated with a reverse-biased gate junction. It is also possible, however, to fabricate enhancement-mode JFETs by use of a thinner or more lightly doped channel.

The pinch-off voltage is a sensitive function of the doping and thickness of the channel region. It can be found if the channel-doping profile, $N(x)$, is known through Poisson's equation. For a nonuniform profile,

$$V_P = V_{BI} - \frac{q}{\varepsilon}\int_0^d xN(x)\mathrm{d}x \tag{1.224}$$

For uniform doping, $N(x) = N_D$ and the familiar result in Equation 1.225 shows that the pinch-off voltage depends on the square of the thickness. This result shows that very precise control of profile depth is needed if good matching and reproducibility of pinch-off voltage is to be obtained [7].

$$V_P - V_{BI} - \frac{qN_D d^2}{2\varepsilon} \tag{1.225}$$

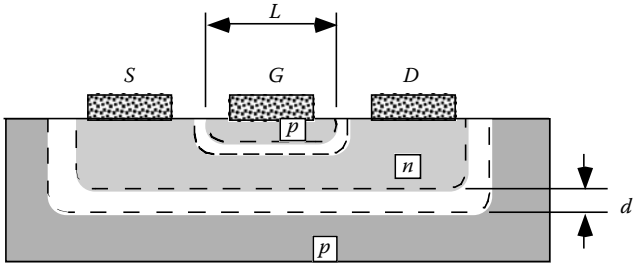

FIGURE 1.47 Idealized cross section of a JFET. The depletion regions are bounded with dashed lines and are unshaded.

1.3.2.2 JFET Operating Regions

The static current–voltage characteristics of the JFET can be categorized by the five regions of operation shown in Figure 1.48 for an n-channel device. The mechanisms that produce these regions can be qualitatively understood by referring to the channel cross sections in Figure 1.49. In these figures, the doped channel region is shaded, and the depletion region is white. First, consider the JFET in Figure 1.49a with small V_{DS} ($\ll V_{GS} - V_P$). This condition corresponds to the ohmic region (sometimes called linear or triode region) where current and voltage are linearly related. At small drain voltages, the depletion layer height is nearly uniform, the electric fields in the channel are too small to saturate the carrier velocity, and thus the channel behaves like a linear resistor. The resistance can be varied by changing V_{GS}. The channel height is reduced by increasing the reverse bias on the gate leading to an increased resistance.

As V_{DS} increases, the depletion layer thickness grows down the length of the channel as shown in Figure 1.49b. This occurs because the drain current causes a voltage increase along the channel as it flows through the channel resistance. Since the depletion layer thickness is governed by the gate-to-channel voltage (V_{GC}), there is an increasing reverse bias that leads to constriction of the channel at the drain end of the gate. Ideally, when $V_{DS} = V_{GS} - V_P$, then $V_{GC} = V_P$, and the channel height will approach zero (pinch-off). The constricted channel will cause the drain current to saturate as shown. Further increases in V_{DS} do not cause the drain current to increase since the channel has already constricted to a minimum height and the additional potential is accommodated by lateral extension of the depletion region at the drain end of the gate. This region of operation is generally described as the pinch-off region (rather than the saturation region in order to avoid confusion with BJT saturation). The height of the channel is not actually zero but is limited by the mobile channel charge, which travels at saturated drift velocity in this high field region.

If $V_{GS} < 0$, then the initial channel height at the source is reduced, I_D is less, and the pinch-off region occurs at a smaller drain voltage $V_{DS} = V_{GS} - V_P$. The saturation of drain current can also occur at smaller V_{DS} if the gate length is very small. In this case, the electric field in the channel is large, and the carrier velocity will saturate before the channel can reach pinch-off. Velocity saturation will also limit drain current.

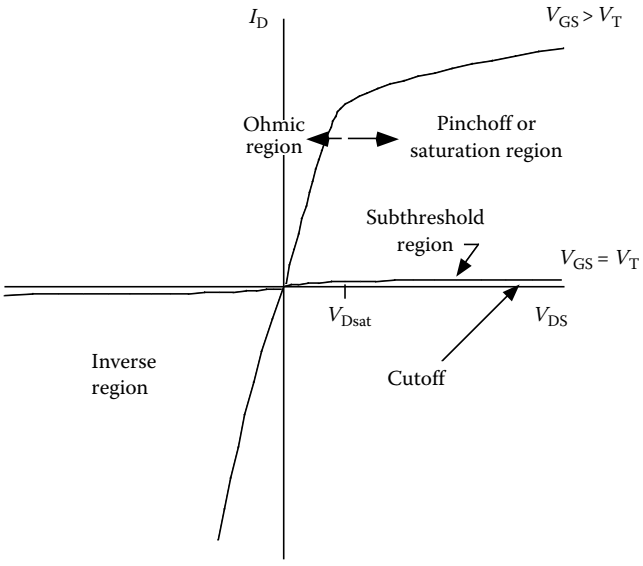

FIGURE 1.48 The static current–voltage characteristics of the JFET can be categorized by five regions of operation. An n-channel device is shown in this illustration.

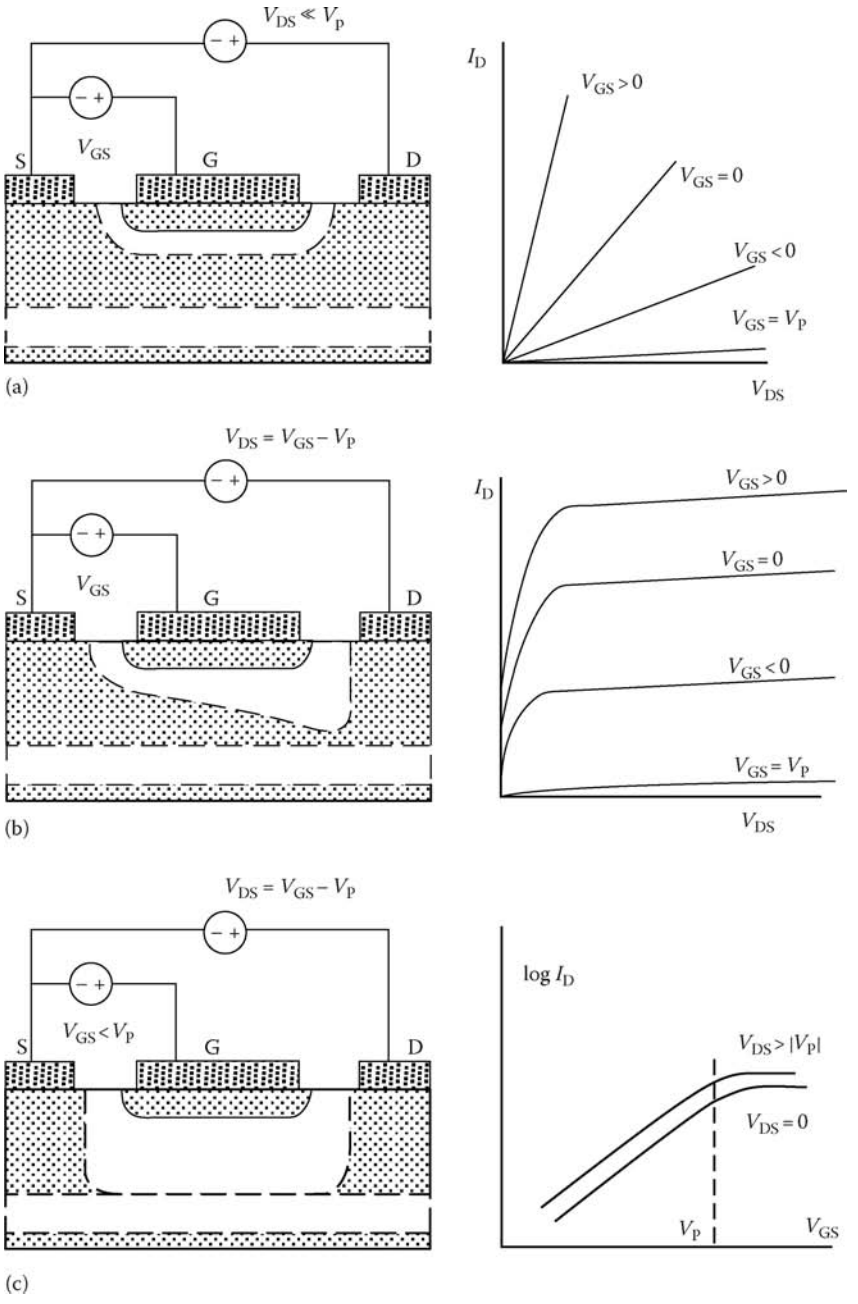

FIGURE 1.49 (a) Ohmic region with small V_{DS} ($\ll V_{GS} - V_P$). (b) When $V_{DS} = V_{GS} - V_P$, the channel height will become narrow at the drain end of the gate. The device enters pinch-off. The constricted channel will cause the drain current to saturate as shown. (c) Cutoff and subthreshold current regions occur when the depletion region extends through the channel.

The subthreshold region of operation, shown in Figure 1.49c is defined when small drain currents continue to flow even though $V_{GS} \leq V_P$. While technically this gate bias should produce cutoff, some small fraction of the electrons from the source region will have sufficient energy to overcome the

potential barrier caused by the gate depletion region and will drift into the drain region and produce a current. Since the energy distribution is exponential with potential, the current flow in this region varies exponentially with V_{GS}.

The inverse region occurs when the polarity of the drain bias is reversed. This region is of little interest for the JFET since gate-to-drain conduction of the gate diode limits the operation to the linear region only.

1.3.2.3 Channel-Length Modulation Effect

A close look at the *I–V* characteristic in the pinch-off region shows that the incremental conductivity or slope of this region is not equal to zero. There is some finite slope that is not expected from the simple velocity saturation or pinch-off models. Channel length modulation is one explanation for this increase; the position under the gate where pinch-off or velocity-saturation first occurs moves toward the source as V_{DS} increases. This is due to the expansion of the drain side depletion region at large V_{DS}. Figure 1.50 illustrates this point. Here, a channel cross section is shown for $V_{DS} = V_{GS} - V_P$ in Figure 1.50a and for $V_{DS} \gg V_{GS} - V_P$ in Figure 1.50b. While pinch-off always occurs when the gate-to-channel voltage is V_P, the higher drain voltage causes the location of this point ($x = L$) to move closer to the source end of the channel. Since the electric field in this region, E, is roughly proportional to $(V_{GS} - V_P)/L$ where L is now a function of V_{DS} and V_{GS} and the carrier velocity $v = \mu E$ (by assumption), then the current must increase as the channel length decreases due to increasing carrier velocity. If the channel length is short, velocity saturation may cause the drain current to saturate. In this case, the velocity saturation point moves closer to the source as drain voltage is increased. Since the length has decreased, less gate-to-channel voltage is needed to produce the critical field for velocity saturation. Less voltage implies a wider channel opening, hence more current.

1.3.2.4 Temperature Effects

There are two mechanisms that influence the drain current of the JFET when temperature is changed [8,9]. First, the pinch-off voltage becomes more negative (for n-channel) with increase in temperature, therefore requiring lower V_{GS} to cut off the channel or to enter the pinch-off region. Therefore, when the device is operating in the pinch-off region, and $V_{GS} - V_P$ is small, the drain current will increase with temperature. This effect is caused by the decrease in the built-in voltage of the gate-to-channel junction with increasing temperature. Second, the carrier mobility and saturated drift velocity decreases with temperature. This causes a reduction in drain current that is in opposition to the first effect. This effect dominates for large $V_{GS} - V_P$. Therefore, there is a V_{GS} value for which the drain current is exactly compensated by the two effects. This is illustrated qualitatively in Figure 1.51.

The gate current is also affected by temperature, as it is the reverse current of a pn junction. The current increases roughly by a factor of 2 for each 10°C increase in temperature. At high temperatures, the input current of a JFET input stage may become comparable to that of a well-designed BJT input stage of an op-amp, thus losing some of the benefit of the mixed BJT–JFET circuit design.

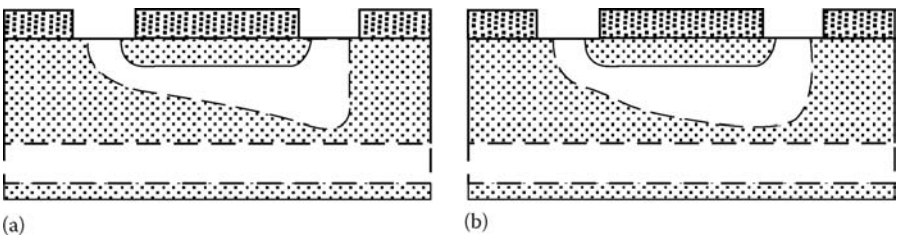

FIGURE 1.50 A channel cross section is shown for $V_{DS} = V_{GS} - V_P$ in (a) and for $V_{DS} \gg V_{GS} - V_P$ in (b). While pinch-off always occurs when the gate-to-channel voltage is V_P, the higher drain voltage causes the location of this point ($x = L$) to move closer to the source end of the channel.

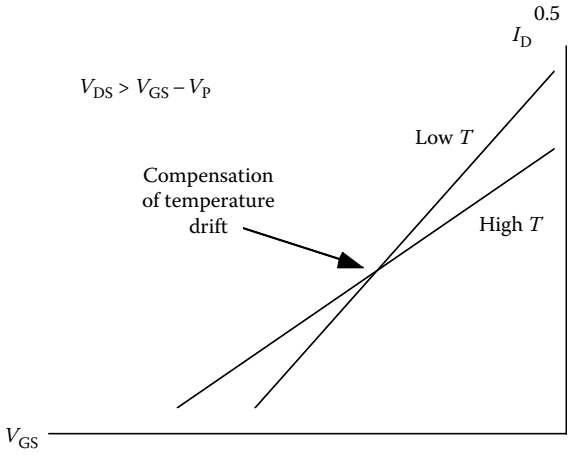

FIGURE 1.51 Effect of temperature on the drain current in the pinch-off region.

1.3.2.5 JFET Models

Most applications of the JFET in analog ICs employ the pinch-off region of operation. It is this region that provides power gain and buffer (source follower) capability for the device, so the models for the JFET presented below will concentrate on this region. It will also be assumed that the gate–source junction will not be biased into forward conduction. Although forward conduction is simple to model using the ideal diode equation within the FET equivalent circuit models, this bias condition is not useful for the principal analog circuit applications of the JFET and will also be avoided in the discussion that follows.

1.3.2.5.1 Large-Signal Model: Drain Current Equations

Equations modeling the large signal JFET $I_D - V_{GS}$ characteristic can be derived for the two extreme cases of FET operation in the pinch-off region. A gradually decreasing channel height and mobility limited drift velocity in the channel are appropriate assumptions for very long gate length FETs. A fixed channel height at pinch-off with velocity saturation limited drift velocity are more suitable for short gate lengths.

The square-law transfer characteristic [10] given by Equation 1.226 provides a good

$$I_D = I_{DSS}\left(1 - \frac{V_{GS}}{V_P}\right)^2 (1 + \lambda V_{DS}) \tag{1.226}$$

approximation to measured device characteristics in the case of long gate length (>5 μm) or very low electric fields in the channel $(V_{GS} - V_P)/L < E_{sat}$. In both cases, the channel height varies slowly and the velocity remains proportional to mobility. E_{sat} is the critical field for saturation of drift velocity, about 3.5 kV/cm for GaAs and 20 kV/cm for Si. I_{DSS} is defined as the drain current in the pinch-off region when $V_{GS} = 0$. The first two terms of the equation are useful for approximate calculation of DC biasing. The third term models the finite drain conductance caused by the channel length modulation effect. The parameter λ in this term is derived from the intercept of the drain current when extrapolated back to zero as shown in Figure 1.52.

Equation 1.226 is also used to represent the pinch-off region in the SPICE JFET model. It is parameterized in a slightly different form as shown below in Equation 1.227.

$$I_D = \beta(V_{GS,i} - V_{T0})^2 (1 + \lambda V_{DS}) \tag{1.227}$$

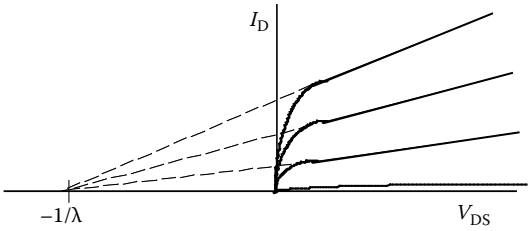

FIGURE 1.52 The channel length modulation parameter λ is defined by the extrapolation of the drain current in saturation to $I_D = 0$.

These equations are the same if $V_{T0} = V_P$, and

$$\beta = \frac{I_{DSS}}{V_P^2} \tag{1.228}$$

and

$$\begin{aligned} V_{GS,i} &= V_{GS} - I_D R_S \\ V_{DS,i} &= V_{DS} - I_E(R_S + R_D) \end{aligned} \tag{1.229}$$

The pinch-off region is defined for $V_{DS,i} \geq V_{GS,i} - V_{T0}$ as is usual for the gradual channel approximation. R_S and R_D are the parasitic source and drain resistances associated with the contacts and the part of the channel that is outside of the gate junction. These resistances will reduce the internal device voltages below the applied terminal voltages as shown in Equations 1.229.

For shorter gate length devices, improved models have been proposed and implemented in SPICE3 and some of the many commercial SPICE products, often in the MESFET model. The Statz model [11] is frequently used for this purpose. This model modifies the drain current dependence on V_{GS} by adding a velocity saturation model parameter b in the denominator as shown in Equation 1.230.

$$I_D = \left[\frac{\beta(V_{GS,i} - V_{T0})^2}{1 + b(V_{GS,i} - V_{T0})}\right](1 + \lambda V_{DS,i}) \tag{1.230}$$

This added term allows the drain current to be nearly square law in V_{GS} for small $V_{GS} - V_{T0}$, but it becomes almost linear when V_{GS} is large, effectively emulating the rapid rise in transconductance followed by saturation that is typical in short channel devices. Although the specific behavior of the drain current is sensitive to the vertical doping profile in the channel), Equation 1.230 is flexible enough to accommodate most short channel device characteristics with uniform or nonuniform channel doping. Another feature of short gate length FETs that this model predicts adequately is a saturation of I_D at $V_{DS,i} < V_{GS,i} - V_{T0}$. This early transition into the pinch-off region is also a consequence of velocity saturation and is widely observed.

1.3.2.5.2 Small-Signal Model

The small-signal model for the JFET in the pinch-off region is shown in Figure 1.53. The voltage dependent current source models the transconductance g_m as a constant which can be derived from the drain current equations above from

$$g_m = \frac{\partial I_D}{\partial V_{GS}} \tag{1.231}$$

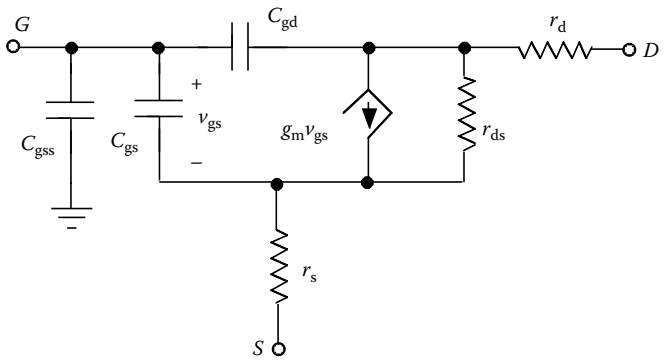

FIGURE 1.53 Small-signal model for the JFET in the pinch-off region.

The square-law current model (Equation 1.226) predicts a linearly increasing g_m with V_{GS}

$$g_m = -\frac{2I_{DSS}}{V_P}\left(1 - \frac{V_{GS}}{V_P}\right) \tag{1.232}$$

whereas a model which includes some velocity saturation effects such as Equation 1.230 would predict a saturation in g_m.

The small-signal output resistance, r_o, models the channel length modulation effect. This is also derived from the drain current equations through

$$r_o^{-1} = \frac{\partial I_D}{\partial V_{DS}} \tag{1.233}$$

For both models, r_o is determined by

$$r_o = \frac{1}{I_D \lambda} \tag{1.234}$$

The small-signal capacitors representing the nonlinear, voltage-dependent C_{gs}, C_{gd}, and C_{gss} are also shown in Figure 1.53. Parasitic source and drain resistances, R_S and R_D can also be included, as shown. If they are not included in the small-signal model, the effect of these parasitics can sometimes be produced in the intrinsic FET model by reducing the intrinsic g_m of the device.

The short-circuit current gain–bandwidth product, f_T, defined in Equation 1.235 is a high-frequency figure of merit for transistors. It is inversely proportional to the transit time τ of the channel charge, and it is increased by reducing the gate length. Reduced L also reduces the gate capacitance and increases transconductance. The material also affects f_T as higher drift velocity leads to higher g_m.

$$f_T = \frac{g_m}{2\pi\left(C_{gss} + C_{gs} + C_{gd}\right)} = \frac{1}{\tau} \tag{1.235}$$

1.3.2.6 Silicon JFET Technologies

The IC fabrication technology used to make JFETs depends primarily on the material. Discrete Si JFETs are available that provide f_T above 500 MHz and very low input rms noise currents through optimizing the channel design and minimizing parasitic capacitances, resistances, and gate diode leakage currents.

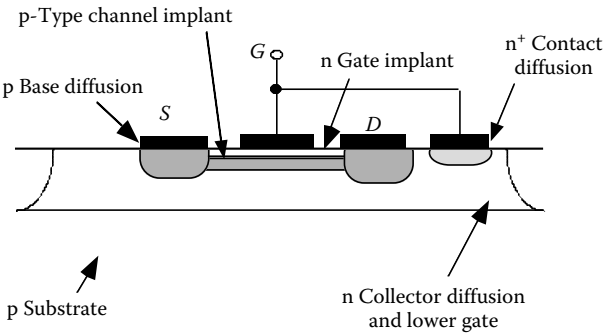

FIGURE 1.54 Cross section of an ion implanted silicon JFET (not to scale).

However, a silicon IC process is rarely designed to optimize the performance of the JFET; rather, the JFET is made to accommodate an existing bipolar process with as few modifications as possible [10]. Then, the extra circuit design flexibility and performance benefits of a relatively inexpensive mixed FET/BJT process (often called BiFET) can be obtained with small incremental cost.

In principle, it would be possible to build p-channel Si JFETs in a standard analog BJT process without additional mask steps if the base diffusion had suitable doping and thickness to give a useful pinch-off voltage when overlaid with the emitter diffusion. Unfortunately, this is usually not the case, since the emitter diffusion is too shallow, and the pinch-off voltage resulting from this approach would be too high (positive in the case of the p-channel device). Therefore, the channel of the JFET must be made thinner either through the use of an additional diffusion or by providing the channel and gate with ion implantations.

In analog ICs applications, silicon JFETs are passengers on a bipolar process; they must be compatible with the BJT process that they inhabit. Most flexibility in the JFET design is achieved using the ion implantation method. Figure 1.54 illustrates the cross section of an ion implanted JFET. In order to gain good control of the pinch-off voltage and transconductance, both the channel and the gate are formed by ion implantation. In addition, the forced compatibility with the BJT process requires use of the collector layer under the channel. This forms a lower gate electrode which is less heavily doped than the channel. Therefore, the depletion region at this interface extends primarily into the collector region, and the lower gate is less effective in contributing to the total transconductance of the JFET. It does add the parasitic capacitance C_{gss} to the device at the collector to substrate junction, limiting frequency response. In addition, the predeposition of channel and gate charge is much more repeatable with ion implantation than with earlier double diffusion methods, so device matching and reproducibility of pinch-off voltage is greatly improved. The f_T will be improved by the larger g_m per unit width and the slightly reduced gate capacitances, and the drain breakdown voltage will be increased as is often needed for an analog IC process. However, low-channel doping is not a good recipe for a high-frequency transistor with short gate length, so the f_T of these devices is still only 50 MHz or so.

1.3.3 Compound Semiconductor FET Technologies

An introduction to compound semiconductor materials will be presented in this section to establish the underlying rationale for using these materials for extremely high-performance MMIC and RFIC applications. The transport properties of typical III–V materials are compared with silicon and SiGe alloys.

There is no denying that silicon is the workhorse of the semiconductor industry. Large, high-quality substrates are relatively inexpensive, a highly stable oxide can be grown with low interface state density, and a highly advanced processing technology has enabled extremely large circuit density and extremely

fine lines to be achieved with low parasitic capacitances. Its greatest weakness for electronic device applications is the relatively low electron velocity and mobility. These intrinsic properties lead to higher transit times and access resistances, respectively, a limitation on high frequency device performance. The deeply scaled submicron technology has compensated for these deficiencies to some degree by aggressive reduction in gate length or base width. Also, p-SiGe has higher hole mobility than p-Si, so access resistance can be improved. And, using the strain induced by local depositions of SiGe in MOSFETs increases electron and hole mobilities. As good as Si IC technology is, there exist compound semiconductor materials whose intrinsic electron velocity and mobility are greatly superior to Si and so can potentially offer higher frequency, higher speed or higher power performance.

The III–V FET and bipolar device technology can provide the highest frequency and lowest noise circuit applications. Its main limitation is density. Device footprints are often significantly larger than those of similar Si devices. Thus, the high intrinsic performance of these devices is achieved in circuits of relatively low complexity.

1.3.3.1 Defining III–V Compound Semiconductors

The compound semiconductor family, as traditionally defined, is composed of the group III and group V elements shown in Table 1.3 [12]. Each semiconductor is formed from at least one group III and one group V element.

The main motivation for using the III–V compound semiconductors for device applications is found in their electronic properties when compared with those of the dominant semiconductor material, silicon. Figure 1.55 is a plot of steady-state electron velocity of several n-type semiconductors versus electric

TABLE 1.3 The Group II–VI Elements

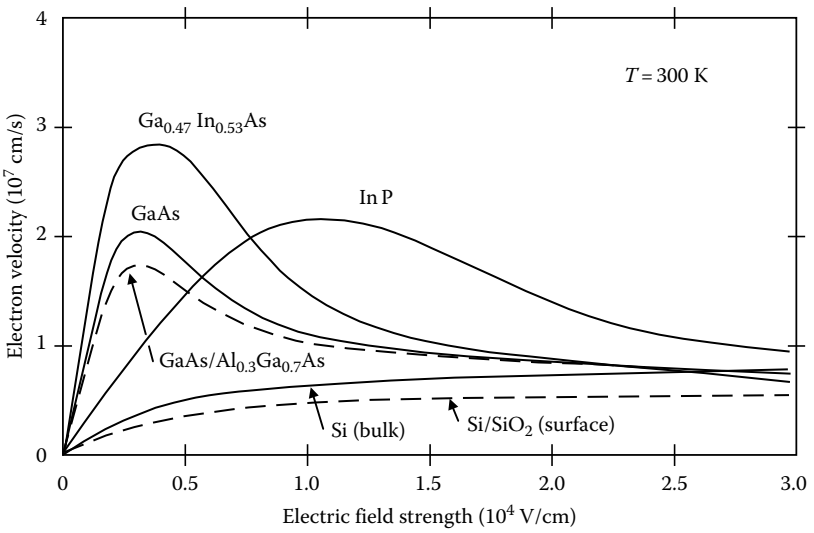

FIGURE 1.55 Electron velocity versus electric field for several n-type semiconductors.

field [12]. From this graph, we see that at low electric fields the slope of the III–V semiconductor curves (mobility) is higher than that of silicon. High mobility means that the semiconductor resistivity will be less for III–V n-type materials, and it therefore will be easier to achieve lower access resistance. Access resistance is the series resistance between the device contacts and the internal active region. An example would be the base resistance of a bipolar transistor or source resistance of a FET. Lower resistance will reduce some of the fundamental device time constants that often dominate device high frequency performance. Figure 1.55 also shows that the peak electron velocity is higher for the III–V's, and the peak velocity can be achieved at much lower electric fields. High velocity reduces transit time, the time required for a charge carrier to travel from its source to its destination, and improves device high-frequency performance. Achieving this high velocity at lower electric fields means that the devices will reach their peak performance at lower voltages, useful for low power, high-speed applications. Higher velocity of electrons also increases the current density of a device since current is the product of charge and velocity. Mobility and peak velocities of several semiconductors are compared in Table 1.4 [12].

The higher velocities are a consequence of the band structure of III–V materials. Since Si is an indirect bandgap material, conduction electrons reside in a high effective mass conduction band (CB). Mobility is dominated by the high effective mass. At high electric fields, the optical phonon generation process limits the maximum achievable electron drift velocity. GaAs, on the other hand, is direct gap, the electron mobility is high because of the lower energy, low effective mass CB where conduction electrons are confined at low fields. However, the average electron velocity will be reduced at higher electric fields due to scattering into the higher mass CB. This produces a saturated drift velocity less than the peak drift velocity, typical of the direct-gap III–V's.

To obtain significant transit velocity improvement over silicon, one must use a ternary III–III–V semiconductor such as InGaAs. The high effective mass CB is separated by 50% of the bandgap for InGaAs, whereas for GaAs it was only 20%. Thus, the peak velocity in InGaAs can be much higher than GaAs because more energy can be transferred to the conduction electrons before they begin scattering to the high mass CB. This results in higher peak velocity, 2.7×10^7 cm/s vs. 2×10^7 cm/s for GaAs.

Also shown in Table 1.4, p-type III–V semiconductors have rather poor hole mobility when compared with elemental semiconductor materials such as silicon or germanium. Holes also reach their peak velocities at much higher electric fields than electrons. Consequently, there has been very little use of p-channel III–V FET devices. The only reason to use compound semiconductor FETs is their superb high-frequency performance. The p-channel devices cannot provide this.

TABLE 1.4 Electronic Properties of Compound Semiconductors Compared with Si and Ge

Semiconductor	E_G (eV)	ε_r	Electron Mobility (cm^2/V-s)	Hole Mobility (cm^2/V-s)	Peak Electron Velocity (cm/s)
Si (bulk)	1.12	11.7	1,450	450	NA
Ge	0.66	15.8	3,900	1,900	NA
InP	1.35 D	12.4	4,600	150	2.1×10^7

GaN	3.39D	9.0	1,500	30	$2.5–2.7 \times 10^7$
SiC (4H)	3.26	9.8	500		2.2×10^7

Note: In bandgap energy column the symbol "D" indicates direct bandgap, otherwise it is indirect bandgap.

1.3.3.2 Heterojunctions

Heterojunctions provide an additional degree of freedom that is widely used to improve performance of compound semiconductor FET devices. The heterojunction formed by an atomically abrupt transition between AlGaAs and GaAs, shown in the energy band diagram of Figure 1.56 [12], creates discontinuities in the valence and CBs. The CB energy discontinuity is labeled ΔE_C and the valence band discontinuity, ΔE_V. Their sum equals the energy bandgap difference between the two materials. The potential energy steps caused by these discontinuities are used as barriers to electrons or holes. The relative sizes of these potential barriers depend on the composition of the semiconductor materials on each side of the heterojunction. In this example, an electron barrier in the CB is used to confine carriers into a narrow potential energy well with triangular shape. Quantum well structures such as these are used to improve device performance through two-dimensional charge transport channels, similar to the role played by the inversion layer in MOS devices. The structure and operation of heterojunctions in FETs will be described in Section 1.3.3.

The overall principle of the use of heterojunctions is summarized in a *Central Design Principle*:

> Heterostructures use energy gap variations in addition to electric fields as forces acting on holes and electrons to control their distribution and flow [13,14].

The energy barriers can control motion of charge both across the heterojunction and in the plane of the heterojunction. In addition, heterojunctions are most widely used in light emitting devices since the compositional differences also lead to either stepped or graded index of refraction, which can be used to confine, refract, and reflect light. The barriers also control the transport of holes and electrons in the light generating regions.

Figure 1.57 shows a plot of bandgap versus lattice constant for many of the III–V semiconductors [12]. Consider GaAs as an example. GaAs and AlAs have the same lattice constant (approximately 0.56 nm) but different band gaps (1.4 and 2.2 eV, respectively). An alloy semiconductor, AlGaAs, can be grown epitaxially on a GaAs substrate wafer using standard growth techniques. The composition can be selected by the Al to Ga ratio giving a bandgap that can be chosen across the entire range from GaAs to AlAs. Since both lattice constants are essentially the same, very low lattice mismatch can be achieved for any composition of $Al_xGa_{1-x}As$. Lattice matching permits low defect density, high quality materials to be grown that have good electronic and optical properties.

It quickly becomes apparent from Figure 1.57, however, that a requirement for lattice matching to the substrate greatly restricts the combinations of materials available to the device designer. For electron devices, the low mismatch GaAs/AlAs alloys, GaSb/AlSb alloys, and ternary combinations $GaAs/Ga_{0.49}In_{0.51}P$ and $InP/In_{0.53}Ga_{0.47}As/In_{0.52}Al_{0.48}As$ alone are available. Efforts to utilize

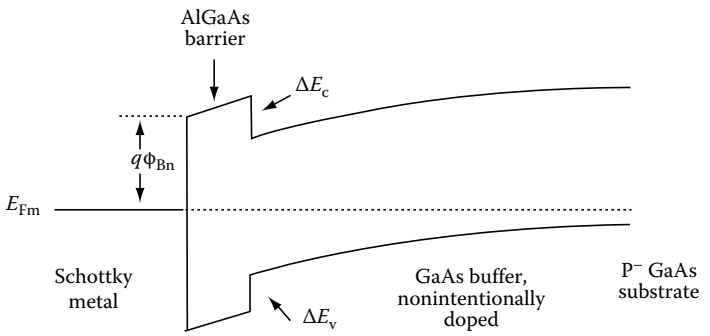

FIGURE 1.56 Energy band diagram of an abrupt heterojunction. Typical AlGaAs/GaAs HEMT band diagram.

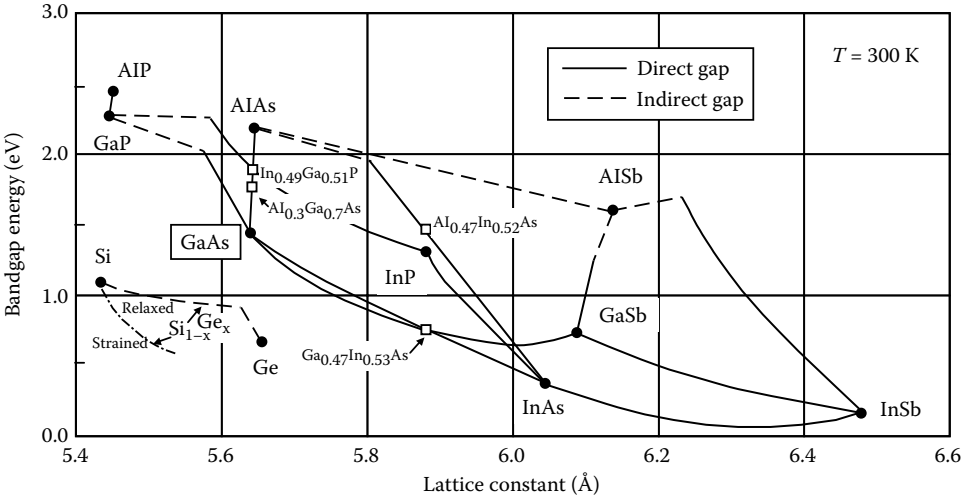

FIGURE 1.57 Energy bandgap versus lattice constant for compound semiconductor materials.

combinations such as GaP on Si or GaAs on Ge that lattice match have been generally unsuccessful because of problems with interface structure, polarization, and autodoping.

For several years, lattice matching was considered to be a necessary condition if mobility-damaging defects were to be avoided. This barrier was later broken when it was discovered that high quality semiconductor materials could still be obtained although lattice-mismatched if the thickness of the mismatched layer is sufficiently small [15,16]. This technique, called pseudomorphic growth, opened another dimension in III–V device technology, and allowed device structures to be optimized over a wider range of bandgap for better electron or hole dynamics and optical properties.

Two of the pseudomorphic systems that have been very successful in high performance millimeter-wave FETs are the InAlAs/InGaAs/GaAs and InAlAs/InGaAs/InP systems. The $In_xGa_{1-x}As$ layer is responsible for the high electron mobility and velocity which both improve as the In concentration x is increased. Up to $x = 0.25$ for GaAs substrates and $x = 0.80$ for InP substrates have been demonstrated and result in great performance enhancements when compared with lattice-matched combinations. [6]

InP substrates, however, are more expensive, smaller, and more easily broken than GaAs. And, the 3.8% lattice mismatch would seem to be too great for direct epitaxy of $In_{0.53}Ga_{0.47}As$ on GaAs substrates. It has been demonstrated, however, that good quality devices can be obtained using the metamorphic growth technique. A thick InP transition layer or a graded InGaP layer is grown directly upon a GaAs substrate. The defects caused by the lattice mismatch are largely contained in this layer, and low defect layers can be obtained when grown upon this transitional buffer layer [17,18].

1.3.3.3 Compound Semiconductor HEMT Devices

High performance GaAs MESFET* and HEMT† devices are constructed with a metal-to-semiconductor junction gate instead of a diffused or implanted pn junction gate. The metal gate forms a Schottky barrier diode directly on an n-type channel or on a wider bandgap barrier layer. In the case of the MESFET as shown in Figure 1.58 [19], the gate, directly on the n-type doped channel, forms a depletion layer which allows the channel height to be varied in the same manner as the JFET. No gate dielectric or p-type diffusion is necessary. Often the gate is deposited in a recess, etched below the surface of the channel. This allows for thicker and sometimes more highly doped regions at source and drain to be used to

* Metal–semiconductor FET.
† High electron mobility transistor.

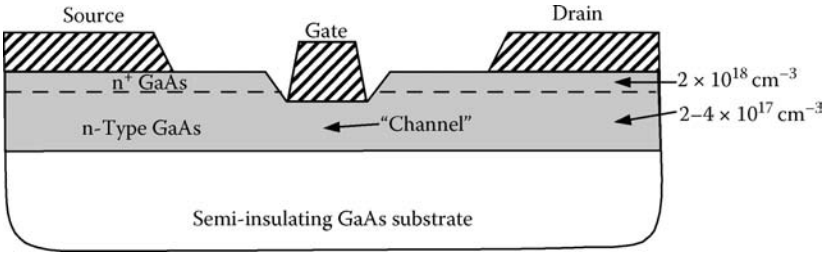

FIGURE 1.58 Cross section of recessed gate GaAs MESFET. (From Estreich, D., in *The VLSI Handbook*, CRC Press, Boca Raton, FL, 2006.)

reduce parasitic resistances. When gate cross sections are very small, for example less than 150 nm, the gate metal is taller than the width, and a thicker, wider region is often deposited on the top to reduce gate access resistance.

With the HEMT device, the gate potential modulates the height of a triangular potential well (Figure 1.56) thereby varying the channel charge available for source–drain conduction. The channel layer is confined by the triangular potential well formed at the interface between the higher bandgap barrier (InAlAs or AlGaAs) and channel (InGaAs or GaAs) as illustrated in the device cross sectional drawing in Figure 1.59 [19]. In some devices, the back side of the channel is also confined by a wide gap barrier. The confinement provided by these energy barriers provides large channel electron sheet concentrations, improving g_m and current density. The active region of the HEMT is formed by epitaxial growth of the channel and barrier region with molecular beam epitaxy.

In Figure 1.59, the device is also shown with a recessed gate. This type of structure enables the use of more highly doped, lower bandgap material on the surface to reduce parasitic source and drain resistances.

These compound semiconductor FETs are used as the primary active device in analog microwave and mm-wave monolithic integrated circuits (MMICs or RFICs). Extremely low noise figure and wide bandwidth have been obtained by the use of HEMT, p-HEMT (pseudomorphic HEMT), and m-HEMT (metamorphic HEMT) devices. These devices achieve their improved performance mainly through the high mobility, undoped InGaAs channel material. The electron velocity vs. electric field of $In_{0.53}Ga_{0.47}As$ is compared with GaAs and Si in Figure 1.55 where it can be seen that higher drift velocity is obtained in $In_{0.53}Ga_{0.47}As$ [20] than either GaAs [21] or Si [22]. The higher the In concentration in the InGaAs, the higher the mobility and velocity and the lower the noise.

Finally, the gate barrier heterojunction also enables good Schottky gate characteristics to be obtained even though the channel material itself has a low bandgap and would otherwise provide a poor barrier height if the metal were in direct contact.

270	35 nm	11.6	—	[6]
300	InP p-HEMT	6		

Excellent performance of HEMT, p-HEMT, and m-HEMT MMICs at microwave and millimeter wave frequencies has been reported. Table 1.5 presents a summary of some representative MMIC amplifiers where both narrowband and wideband amplifiers are reported. Gate lengths down to 35 nm have been successfully used for mm-wave and sub-mm-wave amplifiers.

GaAs HEMT devices also exhibit higher breakdown voltages (often 15 to 20 V) that make them suitable for power amplifier applications. In a recent article, a wideband distributed GaAs HEMT amplifier was reported that provided over 4 W of output power from 4 to 18 GHz at a 5 V drain bias with a power added efficiency of 23% [23]. Narrowband HEMT amplifiers can provide much higher efficiency and power.

1.3.3.4 Wide Bandgap Compound Semiconductors

In recent years there has been increasing interest in the wide bandgap compound semiconductors, SiC and GaN (and associated alloys of Al/In/Ga with N). The applications have been primarily for microwave power applications because the wider bandgap increases breakdown voltage while the band structure allows for high electron peak velocities in both materials [24,25]. Table 1.6 compares the fundamental physical properties of the wide-gap compound semiconductors with GaAs and Si [12]. It should be noted that there is not uniform agreement on the wide-gap parameter values from one reference to the next, but the numbers presented are representative of the current literature. As seen in Table 1.6, thermal conductivity is very high for both SiC and GaN, allowing for effective removal of heat from power devices. In fact, at room temperature, SiC has a higher thermal conductivity than any metal.

Figure 1.60 compares the electron velocity of GaN and SiC with GaAs and silicon [12,26]. The peak velocity of GaN is reached at electric fields above 150 kV/cm. Both SiC and GaN retain their good

TABLE 1.6 High Electron Mobility GaN

Material	Bandgap (eV)	Mobility (cm^2/V-s)	E_c (V/cm)	Saturation Drift Velocity (cm/s)	Thermal Conductivity (W/cm-K)
n-SiC (4H)	3.26	500	2.2×10^6	2×10^7	3.0–3.8
n-GaN	3.39	1500	3×10^6	1.5×10^7	2.2
n-GaAs	1.4	5000	3×10^5	0.6×10^7	0.45
n-Si	1.1	1300	2.5×10^5	1×10^7	1.45

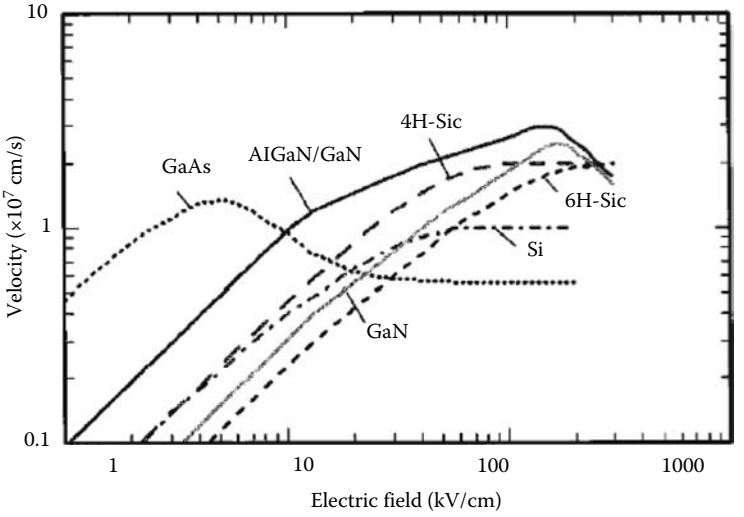

FIGURE 1.60 Electron velocity versus electric field of GaN and SiC compared with Silicon and GaAs. (From Trew, R.J., *Proc. IEEE*, 90, 1032, 2002. With permission.)

transport properties for high power applications. Table 1.6 shows that GaN has high electron mobility as well, which helps to reduce parasitic source resistance. Hole mobility for wide bandgap compound semiconductors is quite low, however, generally less than 50 $cm^2/V-s$.

There is significant lattice mismatch between a GaN channel in a heterojunction FET and the AlGaN barrier layer. However, the strain caused by this mismatch produces polarization and piezoelectric effects that induce large sheet charge densities, above $10^{13}\,cm^{-2}$ in the channel, beneficial for high current density operation of these devices [26]. This level of charge is about five times higher than what can be induced in GaAs channels in the AlGaAs/GaAs heterostructure.

Figures of merit are often employed when comparing materials for microwave power amplifier applications. Johnson's FOM [27]

$$\text{JFOM} = \frac{E_c v_{sat}}{2\pi} \tag{1.236}$$

has units of power–frequency. E_c is the maximum or critical electric field for breakdown and v_{sat} is the saturated drift velocity at high electric fields. This expresses the electronic merits of the material but neglects to consider thermal conductivity, also of importance for power electronics. Nevertheless, based on the electronic properties alone, GaN and SiC have a JFOM approximately 18 times greater than Si or GaAs. If the superior thermal conductivity is also considered, it becomes clear that these materials are extremely well suited for microwave power.

1.3.3.5 GaN HEMT Field Effect Transistors

The unusual electronic and thermal properties of the wide bandgap materials such as GaN are very attractive for applications requiring transistors with both high breakdown voltage and high frequency performance. This range of applications is focused especially on microwave power transistors. To understand why, consider first what is most desirable in a high power transistor's drain current–voltage characteristics. Figure 1.61 shows an idealized representation of this characteristic. To obtain the maximum output sinusoidal voltage and current amplitudes, one would like a device with high breakdown voltage, V_{break}, low "knee" voltage, V_{knee}, and high maximum current, I_{max}. The voltage swing is

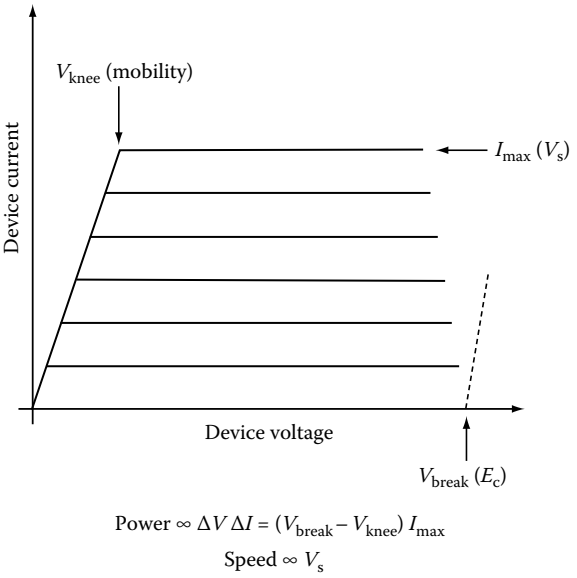

FIGURE 1.61 Idealized GaN HEMT drain current–drain voltage characteristic.

determined by $V_{break} - V_{knee}$, and the current swing by I_{max}. This combination provides high power density (W/mm) in a device, therefore requiring smaller device area. Power is proportional to

$$P_{OUT} \propto (V_{break} - V_{knee}) \times I_{max}.$$

DC to RF conversion efficiency, equally important in a power device, is proportional to

$$\text{Efficiency} \propto (1 - V_{knee}/V_{break}).$$

Thus, a large breakdown voltage is helpful for both power and efficiency.

But, Si LDMOS devices also have high breakdown voltage. So, why is GaN better? First, the current density is far higher in GaN. The high current density in the GaN HEMT is a result of the exceptionally high sheet charge, n_S, in the channel, typically 1×10^{13} cm^{-2} or higher. The high sheet charge density is a result of the static polarization that occurs at the interface between the GaN channel and the AlGaN barrier. To satisfy the charge balance at the interface, a high density of negative charge is required. A cross section of a GaN HEMT device is shown in Figure 1.62.

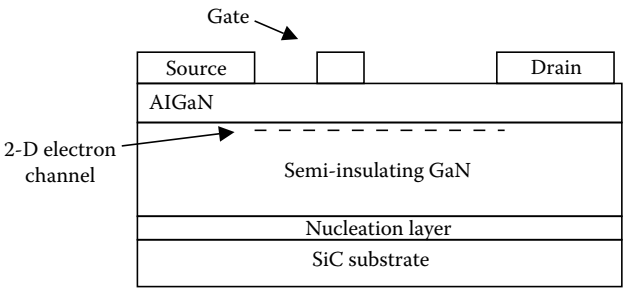

FIGURE 1.62 Cross section of GaN HEMT device structure.

Second, the high current and power density means that smaller device areas can be used to meet a particular power requirement. Smaller area translates into higher impedances because capacitances are proportional to device area. This simplifies the matching at the input and output, and therefore can lead to wider bandwidth and lower losses. The GaN devices are grown on a semi-insulating SiC substrate, thus the drain–source capacitance, C_{ds}, is small: typically about 0.25 pF/mm of device width. A 25 W device would require about 5 mm of channel width giving C_{ds} of about 1.25 pF. The Si device drain capacitance is generally quite high by comparison. For example, a 25 W LDMOS device designed for operation at 500 MHz has a C_{ds} of about 30 pF. This greatly limits the application of such devices for higher frequency or switching mode PA applications.

The current density and high frequency performance are also aided by the high saturated electron velocity in GaN. Refer once again to Figure 1.60 where electron velocity at high electric field in GaN is compared with other semiconductor materials. The electron transit time across the channel is inversely proportional to the carrier velocity; the current directly proportional.

The GaN HEMT gate structure often includes a field plate at the drain end of the gate as shown in Figure 1.63. The field plate distributes the electric field in the gate–drain region over a wider area leading to reduction in peak electric field and higher breakdown voltage. In addition, surface trap charge is less affected by potential variation on the surface, thus there is less depletion of channel charge by these traps leading to reduction in the low frequency dispersion effects.

Recent GaN HEMT microwave power amplifier performance highlights are presented in Table 1.7. Power outputs of several hundreds of watts have been obtained under low duty cycle pulsed operating conditions where thermal effects are less serious. CW output powers in the same range have been obtained by power combining of two or more amplifiers. Operation at 35 GHz was reported on MMIC PAs using devices with reduced gate length (0.15 μm) and smaller drain voltages.

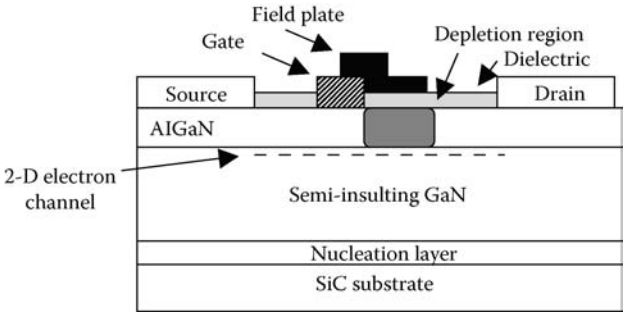

FIGURE 1.63 Cross section of GaN HEMT device structure with gate connected field plate.

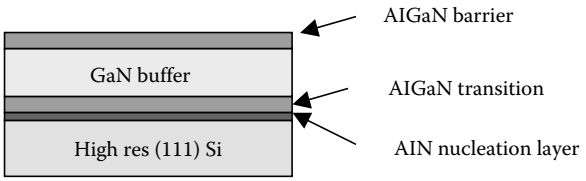

FIGURE 1.64 GaN on Si m-HEMT substrate.

GaN has also been successfully grown on high resistivity silicon substrates as illustrated by Figure 1.64. A thick nucleation layer leads to a metamorphic structure. Good power amplifier GaN on Si HEMT devices have been demonstrated to provide comparable performance in power and efficiency to those grown on Si [35,36]. The thermal conductivity of silicon is considerably less than that of SiC, however, so one would not expect the thermal resistance of the GaN on Si HEMT to be as low as the former.

1.3.4 Conclusion

While the mainstream semiconductor device and circuit technology is defined by silicon and its related materials, the superior electron transport properties of compound semiconductor materials offer unique advantages in applications requiring the highest frequency, speed and power or lowest noise figure. The range of device structural possibilities with compound semiconductor heterojunctions is far greater than what can be realized without this option, and this has led to high-performance FET structures, HEMT, p-HEMT, and m-HEMT, with excellent bandwidth, noise figure, and power.

1.4 Passive Components

Nhat M. Nguyen

1.4.1 Resistors

Resistors available in monolithic form are classified in general as semiconductor resistors and thin-film resistors. Semiconductor structures include diffused, pinched, epitaxial, and ion-implanted resistors. Commonly used thin-film resistors include tantalum, nickel–chromium (Ni–Cr), cermet (Cr–SiO), and tin oxide (SnO_2). Diffused, pinched, and epitaxial resistors can be fabricated along with other circuit elements without any additional processing steps. Ion-implanted and thin-film resistors require additional processing steps for monolithic integration but offer lower temperature coefficient, smaller absolute value variation, and superior high-frequency performance.

Resistor calculation. The simplified structure of a uniformly doped resistor of length L, width W, and thickness T is shown in Figure 1.65. The resistance is

$$R = \frac{1}{\sigma}\frac{L}{WT} = \left(\frac{\rho}{T}\right)\frac{L}{W} = R_{\mathrm{n}}\frac{L}{W} \tag{1.237}$$

where

σ and ρ are conductivity and resistivity of the sample, respectively
R_{N} is referred to as the *sheet resistance*

From the theory of semiconductor physics, the conductivity of a semiconductor sample is

$$\sigma = q\left(\mu_n n + \mu_p p\right) \tag{1.238}$$

where

q is the electron charge (1.6×10^{-19} C)
$\mu_n(\mathrm{cm}^2/\mathrm{V}\cdot\mathrm{s})$ is the electron mobility
$\mu_p(\mathrm{cm}^2/\mathrm{V}\cdot\mathrm{s})$ is the hole mobility
$n(\mathrm{cm}^{-3})$ is the electron concentration
$p(\mathrm{cm}^{-3})$ is the hole concentration
$\sigma(\Omega/\mathrm{cm})^{-1}$ is the electrical conductivity

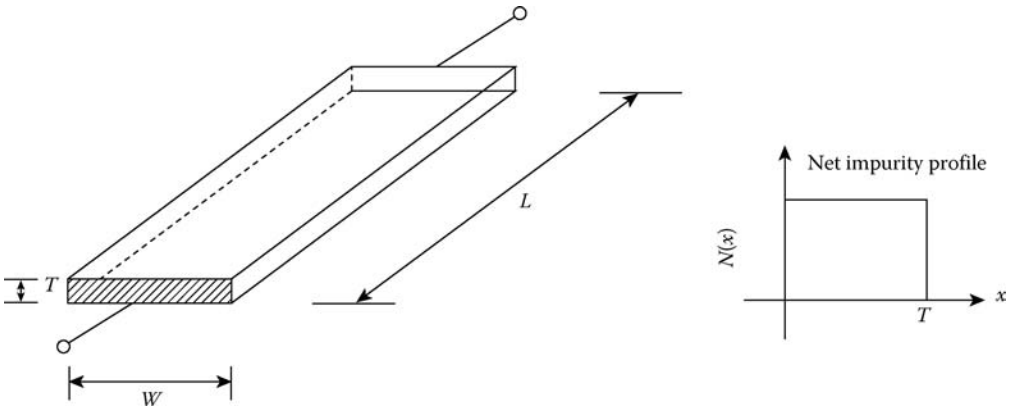

FIGURE 1.65 Simplified structure of a uniformly doped resistor.

For an n-type doped sample with a concentration $N_D(\text{cm}^{-3})$ of donor impurity atoms, the electron concentration n is approximately equal to N_D. Given the mass-action law $np = n_i^2$, the conductivity of an n-type doped sample is approximated by

$$\sigma = q\left(\mu_n N_D + \mu_p \frac{n_i^2}{N_D}\right) \approx q\mu_n N_D \tag{1.239}$$

where $n_i(\text{cm}^{-3})$ is the *intrinsic* concentration. For a p-type doped sample, the conductivity is

$$\sigma = q\left(\mu_n \frac{n_i^2}{N_A} + \mu_p N_A\right) \approx q\mu_p N_A \tag{1.240}$$

where $N_A(\text{cm}^{-3})$ is the concentration of p-type donor impurity atoms. The sheet resistance of an n-type uniformly doped resistor is thus

$$R_n = \left(\frac{1}{q\mu_n N_D T}\right) \tag{1.241}$$

For an n-type nonuniformly doped resistor as shown in Figure 1.66, where n-type impurity atoms are introduced into the p-type region by means of a high-temperature diffusion process, the sheet resistance [7] is

$$R_n = \left[\int_0^{x_j} q\mu_n N_D(x)\mathrm{d}x\right]^{-1} \tag{1.242}$$

where x_j is the distance from the surface to the edge of the junction depletion layer.

Measured values of electron mobility and hole mobility in silicon material as a function of impurity concentration are shown in Figure 1.67 [4]. The resistivity ρ (Ω-cm) of n-type and p-type silicon as a function of impurity concentration is shown in Figure 1.68 [12].

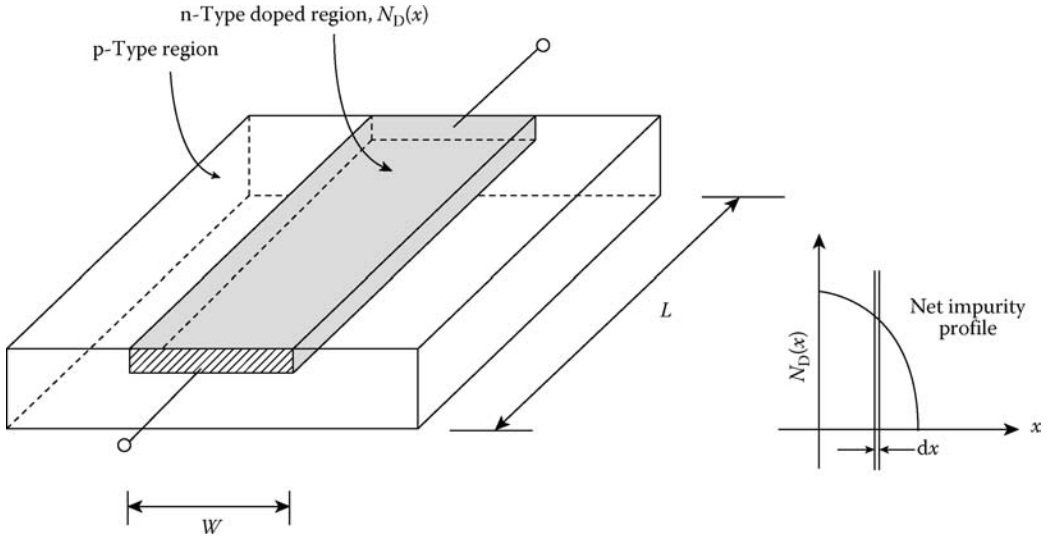

FIGURE 1.66 Simplified structure of an n-type nonuniformly doped resistor.

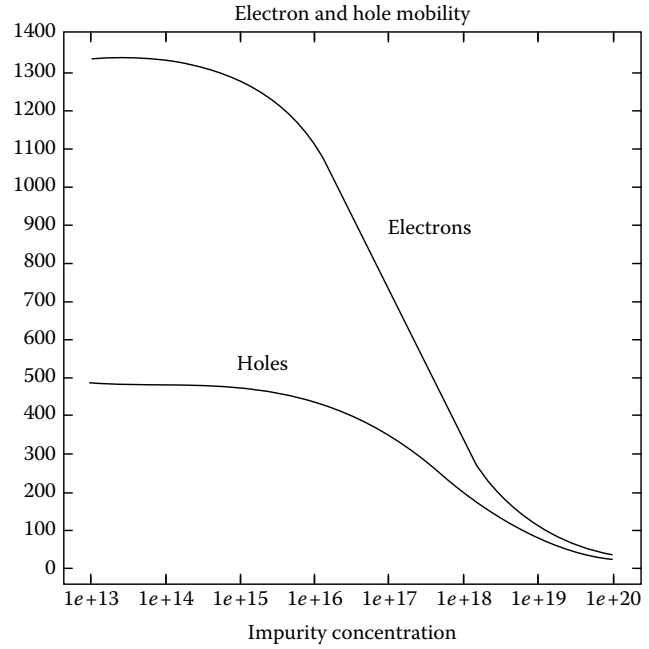

FIGURE 1.67 Electron and hole mobility vs. impurity concentration in silicon.

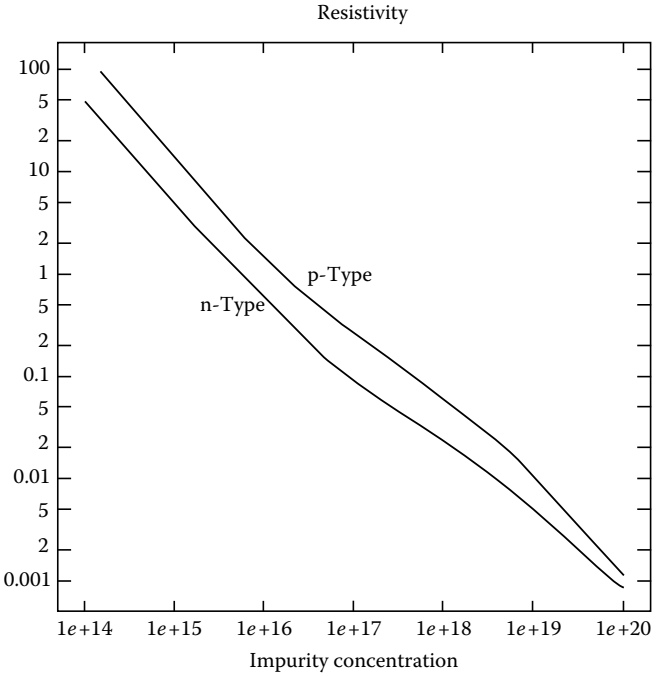

FIGURE 1.68 Resistivity of p-type and n-type silicon vs. impurity concentration.

The sheet resistance depends also on temperature since both electron mobility and hole mobility vary with temperature [17]. This effect is accounted for by utilizing a temperature coefficient quantity that measures the sheet resistance variation as a function of temperature. A mathematical model of the temperature effect is

$$R_v(T) = R_v(T_o)[(T - T_o)\text{TC}] \tag{1.243}$$

where

T_o is the room temperature

"TC" is the temperature coefficient

1.4.1.1 Diffused Resistors

In metal-oxide-semiconductor (MOS) technology, the diffused layer forming the source and drain of the MOS transistors can be used to form a diffused resistor. In silicon bipolar technology, the available diffused layers are base diffusion, emitter diffusion, active base region, and epitaxial layer.

Base-diffused resistors. The structure of a typical base diffused resistor is shown in Figure 1.69, where the substrate material is assumed of p-type silicon material. The diffused resistor is formed by using the p-type base diffusion of the npn transistors. The resistor contacts are formed by etching selected windows of the SiO_2 passivation layer and depositing thin films of conductive metallic material. The isolation region can be formed with either a p-type doped junction or a trench filled with SiO_2 dielectric material. The pn junction formed by the p-type resistor and the n-type epitaxial (epi) layer must be reverse biased

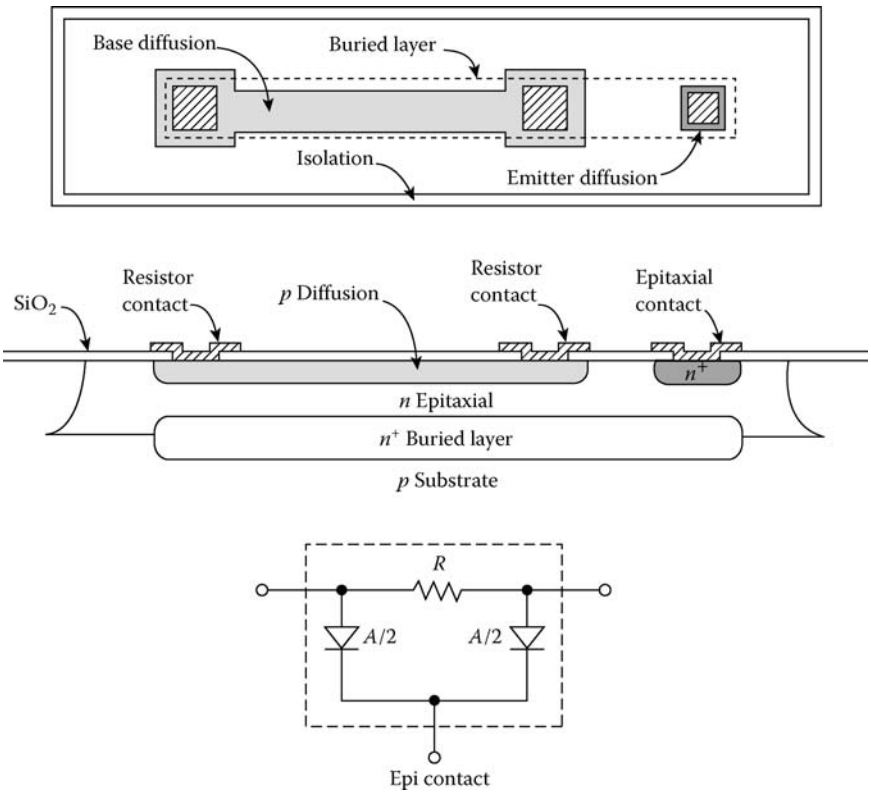

FIGURE 1.69 p-Type base-diffused resistor.

in order to eliminate the undesired dc current path through the pn junction. The impedance associated with a forward-biased pn junction is low and thus would also cause significant ac signal loss. To ensure this reverse bias constraint the epi region must be connected to a potential that is more positive than either end of the resistor contacts. Connecting the epi region to a relatively higher potential also eliminates the conductive action due to the parasitic pnp transistor formed by the p-type resistor, the n-type epi region, and the p-type substrate. When the base-diffused resistor is fabricated along with other circuit elements to form an integrated circuit (IC), the epitaxial contact is normally connected to the most positive supply of the circuit.

The resistance of a diffused resistor is given by Equation 1.237, where the diffused sheet resistance is between 100 and 200 Ω/N. Due to the lateral diffusion of impurity atoms, the effective cross-sectional area of the resistor is larger than the width determined by photomasking. This lateral or side diffusion effect can be accounted for by replacing the resistor width W by an effective width W_{eff}, where $W_{\text{eff}} \geq W$. The resistance from the two resistor contacts must also be accounted for, especially for small values of L/W [3]. Base-diffused resistors have a typical temperature coefficient between +1500 and +2000 ppm/°C.

The maximum allowable voltage for the base-diffused resistor of Figure 1.69 is limited by the breakdown voltage between the p-type base diffusion and the n-type epi. This voltage equals the breakdown voltage BV_{CBO} of the collector–base junction of the npn transistor and typically causes an *avalanche breakdown* mechanism across the base–epi junction. As the applied voltage approaches the breakdown voltage, a large leakage current flows from the epi region to the base region and can cause excessive heat dissipation.

For analog IC applications where good matching tolerance between adjacent resistors is required, the resistor width should be made as large as possible. Base-diffused resistors with 50 μm resistor widths can achieve a matching tolerance of ±0.2%. The minimum resistor width is limited by photolithographic consideration with typical values between 3 and 5 μm. Also, in order to avoid the self-heating problem of the resistor it is important to ensure a minimum resistor width for a given dc current level, with a typical value of about 3 μm for every 1 mA of current.

With respect to high-frequency performance, the reverse-biased pn junction between the p-type base diffusion and the n-type epi contributes a distributed depletion capacitance which in turn causes an impedance roll-off at 20 dB/decade. This capacitance depends on the voltage applied across the junction and the junction impurity-atom dopings. For most applications the electrical lumped model as shown in Figure 1.69 is adequate for characterizing this capacitive effect where the effective pn junction area is divided equally between the two diodes. Figure 1.70 shows a normalized impedance response as a function of the *RC* distributed stage. The frequency at which impedance value is reduced by 3 dB is given by

$$f_{-3\text{ dB}} = \begin{cases} \left(\dfrac{1}{2\pi}\right)\dfrac{2.0}{RC} & N = 1 \text{ (Circuit model of Figure 1.62)} \\ \left(\dfrac{1}{2\pi}\right)\dfrac{2.32}{RC} & N = 2 \\ \left(\dfrac{1}{2\pi}\right)\dfrac{2.42}{RC} & N = 3 \\ \left(\dfrac{1}{2\pi}\right)\dfrac{2.48}{RC} & N = 4 \end{cases} \tag{1.244}$$

Emitter-diffused resistors. Emitter-diffused resistors are formed by using the heavily doped n^+ emitter diffusion layer of the npn transistors. Due to the high doping concentration, the sheet resistance can be as low as 2 to 10 Ω/N with a typical absolute value tolerance of ±20%.

Figure 1.71 shows an emitter-diffused resistor structure where an n^+ diffusion layer is formed directly on top of the n-type epitaxial region and the ohmic contacts are composed of conductive

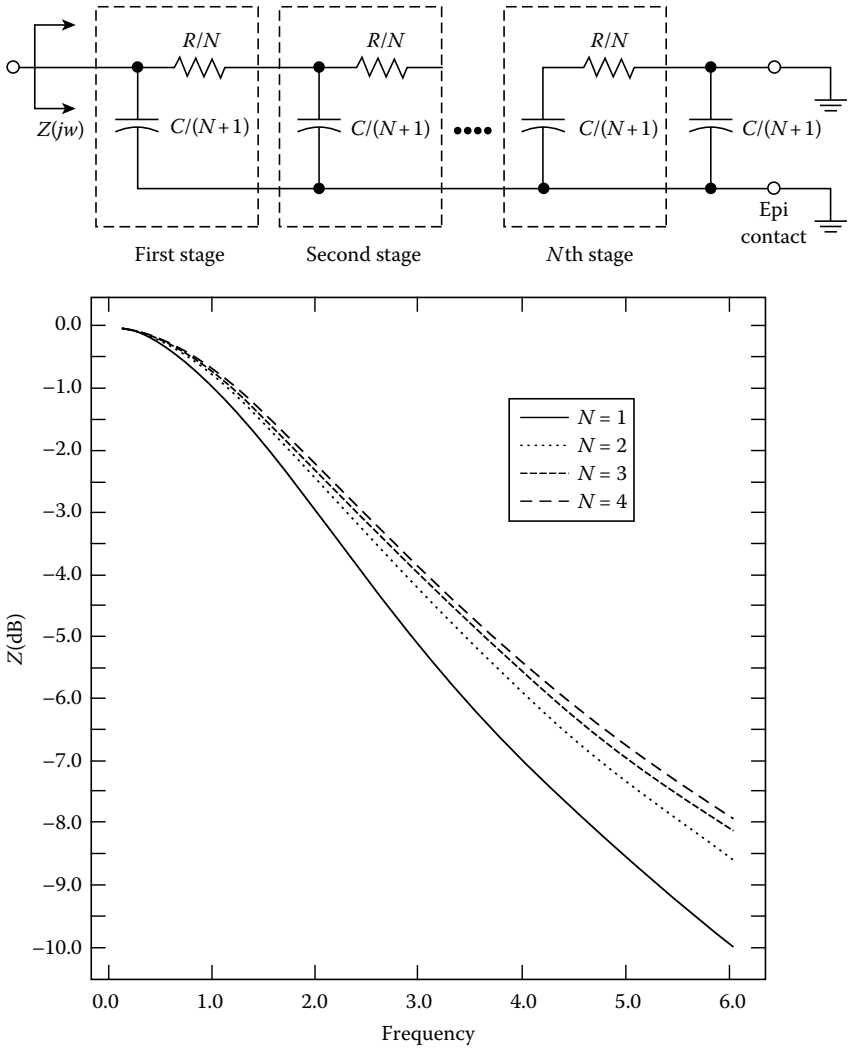

FIGURE 1.70 Normalized frequency response of a diffused resistor for $N = 1, 2, 3, 4$. The epi contact and one end of the resistor are grounded.

metal thin films. Since the resistor body and the epi layer are both n-type doped, they are electrically connected in parallel but the epi layer is of much higher resistivity due to its lower concentration doping, and thus the effective sheet resistance of the resistor structure is determined solely by the n^+ diffusion layer. The pn junction formed between the p-type substrate and the n-type epi region must always be reverse biased, which is accomplished by connecting the substrate to a most negative potential. Because of the common n-type epi layer, each resistor structure of Figure 1.71 requires a separate isolation region.

Figure 1.72 shows another emitter diffused resistor structure where the n^+ diffusion layer is situated within a p-type diffused well. Several such resistors can be fabricated in the same p-type well or in the same isolation region because the resistors are all electrically isolated. The p-type well and the n^+ diffusion region form a pn junction that must always be reverse biased for electrical isolation. In order to eliminate the conductive action due to the parasitic npn transistor formed by the n-type resistor body,

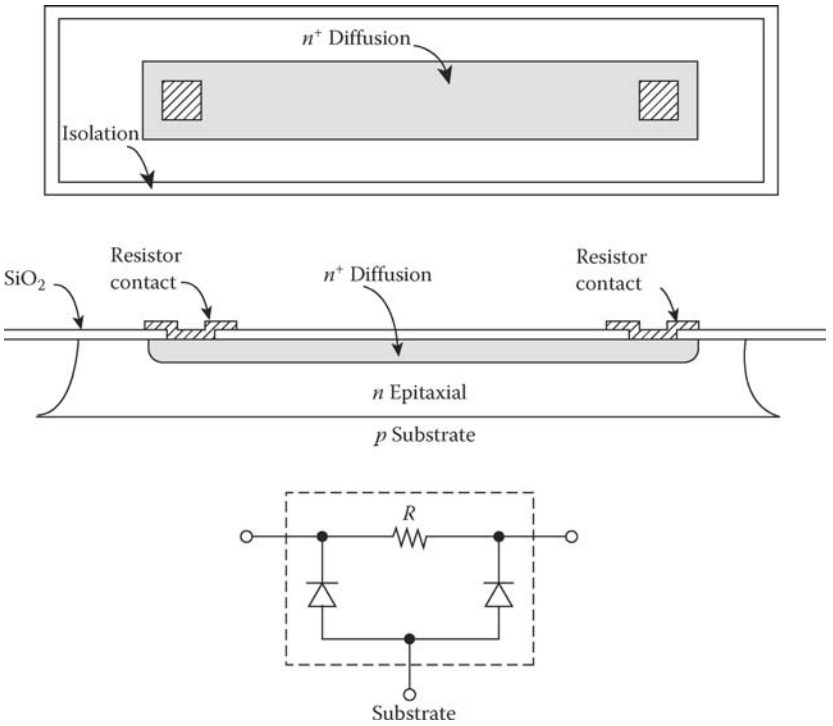

FIGURE 1.71 n-Type emitter-diffused resistor I.

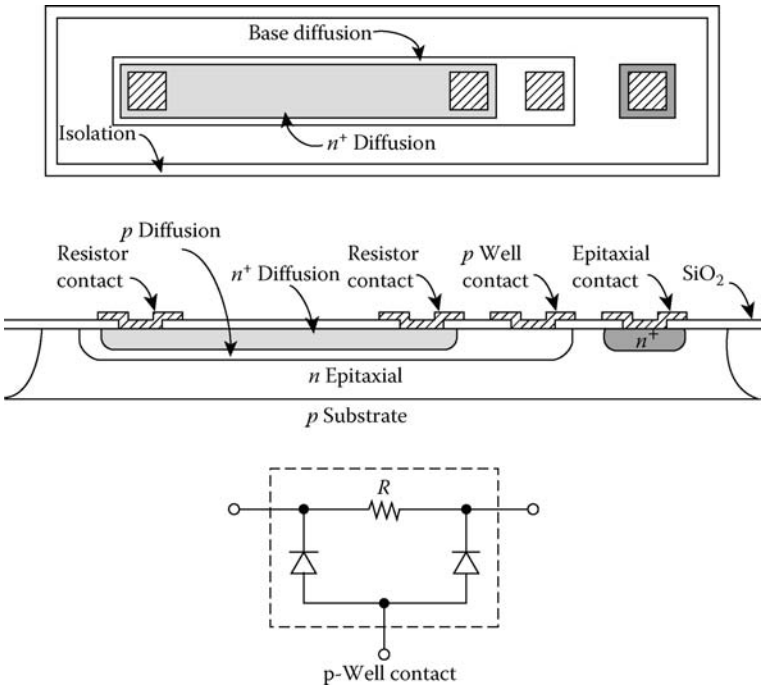

FIGURE 1.72 n-Type emitter-diffused resistor II.

the p-type well, and the n-type epi, the junction potential across the well contact and the epi contact must be either short-circuited or reverse-biased. The maximum voltage that can be applied across the emitter-diffused resistor of Figure 1.72 is limited by the breakdown voltage between the n^+ diffusion and the p-type well. This voltage equals the breakdown voltage BV_{EBO} of the emitter–base junction of the npn transistor, with typical values between 6 and 8 V.

1.4.1.2 Pinched Resistors

The active base region for the npn transistor can be used to construct pinched resistors with typical sheet resistance range from 2 to 10 KΩ/N. These high values can be achieved due to a thin cross-sectional area through which the resistor current traverses. The structure of a p-type base-pinched resistor is shown in Figure 1.73, where the p-type resistor body is ''pinched'' between the n^+ diffusion layer and the n-type epitaxial layer. The n^+ diffusion layer overlaps the p-type diffusion layer and is therefore electrically connected to the n-type epi. In many aspects the base-pinched resistor behaves like a p-channel JFET, in which the active base region functions as the p-channel, the two resistor contacts assume the drain and source, and the n^+ diffusion and the epi constitute the n-type gate. When the pn junction formed between the active base and the surrounding n^+ diffusion and n-epi is subject to a reverse bias potential, the carrier-free depletion region increases and extends into the active base region, effectively reducing the resistor cross section and consequently increasing the sheet resistance. Since the carrier-free depletion region varies with reverse bias potential, the pinched resistance is voltage controlled and is nonlinear.

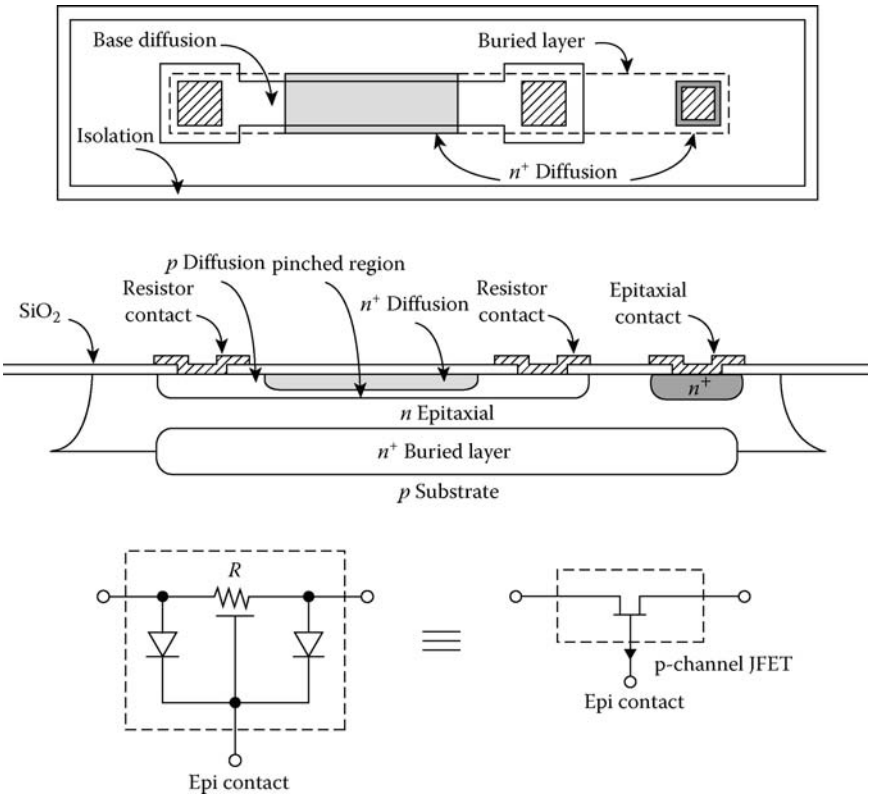

FIGURE 1.73 p-Type base-pinched resistor.

Absolute values for the base-pinched resistors can vary as much as ±50% due to large process variation in the fabrication of the active base region. The maximum voltage that can be applied across the base-pinched resistor of Figure 1.73 is restricted by the breakdown voltage between the n^+ diffusion layer and the p-type base diffusion. The breakdown voltage has a typical value around 6 V.

1.4.1.3 Epitaxial Resistors

Large values of sheet resistance can be obtained either by reducing the effective cross-sectional area of the resistor structure or by using a low doping concentration that forms the resistor body. The first technique is used to realize the pinched resistor while the second is used to realize the epitaxial resistor. Figure 1.74 shows an epitaxial resistor structure where the resistor is formed with a lightly doped epitaxial layer. For an epi thickness of 10 μm and a doping concentration of 10^{15} donor atoms/cm^3, this structure achieves a resistivity of 5 Ω-cm and an effective sheet resistance of 5 KΩ/N. The temperature coefficient of the epitaxial resistor is relatively high with typical values around +3000 ppm/°C. This large temperature variation is a direct consequence of the hole and electron mobilities undergoing more drastic variations against temperature at particularly low doping concentrations [13]. The maximum voltage that can be applied across the epitaxial resistor is significantly higher than that for the pinched resistor. This voltage

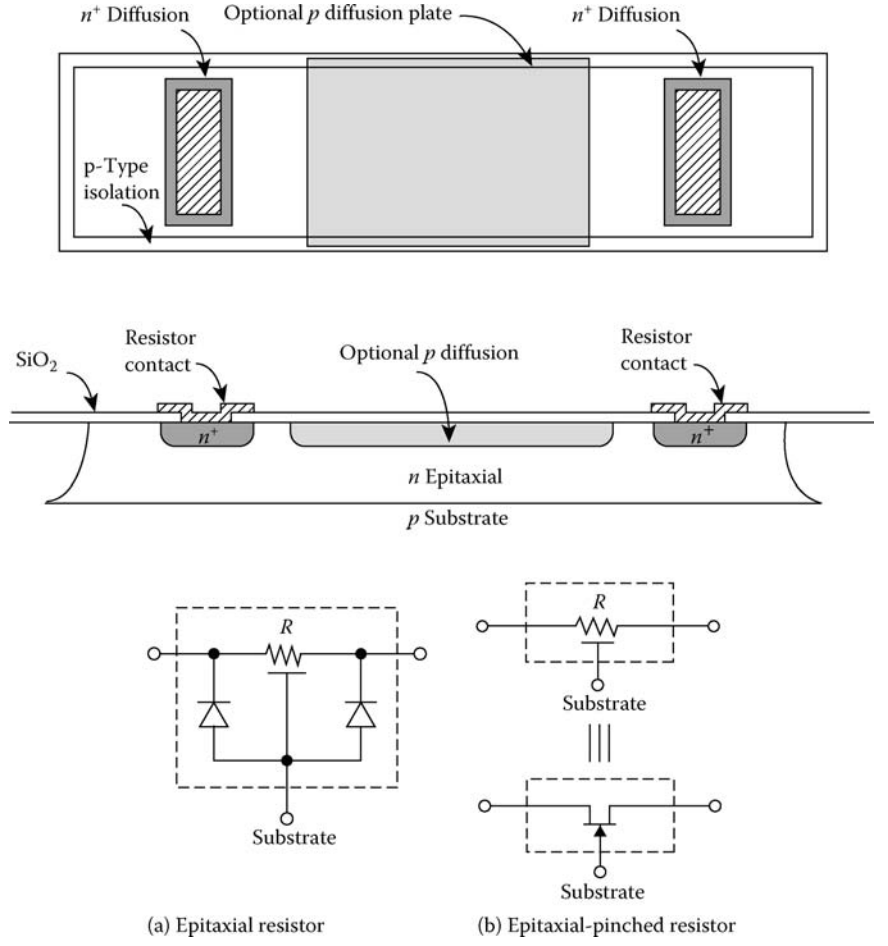

FIGURE 1.74 n-Type epitaxial and epitaxial-pinched resistors.

is set by the breakdown voltage between the n-type epi and the p-type substrate which varies inversely with the doping concentration of this pn junction.

Epitaxial-pinched resistors. By putting a p-type diffusion plate on top of the epitaxial resistor of Figure 1.74, even larger sheet resistance value can be obtained. The p-type diffusion plate overlaps the epi region and is electrically connected to the substrate through the p-type isolation. The epi layer is thus pinched between the p-type diffusion plate and the p-type substrate. When the n-type epi and the surrounding p-type regions is subject to a reverse bias potential, the junction depletion width extends into the epi region and effectively reduces the cross-sectional area. Typical sheet resistance values are between 4 and 5 KΩ/N. The epitaxial-pinched resistor behaves like an n-channel JFET, in which the effective channel width is controlled by the substrate voltage.

1.4.1.4 Ion-Implanted Resistors

Ion implantation is an alternative technique beside diffusion for inserting impurity atoms into a silicon wafer [17]. Commonly used impurities for implantation are the p-type boron atoms. The desired impurity atoms are first ionized and then accelerated to a high energy by an electric field. When a beam of these high-energy ions is directed at the wafer, the ions penetrate into exposed regions of the wafer surface. The penetration depth depends on the velocity at contact and is typically between 0.1 and 0.8 μm. The exposed regions of the wafer surface are defined by selectively etching a thick thermally grown SiO_2 layer that covers the wafer and functions as a barrier against the implanted ions. Unique characteristics of the ion-implantation technique include a precise control of the impurity concentration, uniformly implanted layers of impurity atoms, and no lateral diffusion. The structure of a p-type ion-implanted resistor is shown in Figure 1.75, where the p-type diffused regions at the contacts are used to achieve good ohmic contacts to the implanted resistor. The pn junction formed between the p-type implanted region and the n-type epitaxial layer must be reverse biased for electrical isolation. By connecting the epi region to a potential relatively more positive than the substrate potential, the conductive action due to the parasitic pnp transistor formed by the p-type implanted, the n-type epi, and the p-type substrate is also eliminated. Ion-implanted resistors exhibit relatively tight absolute value tolerance and excellent matching. Absolute value tolerance down to ±3% and matching tolerance of ±2% are typical performance.

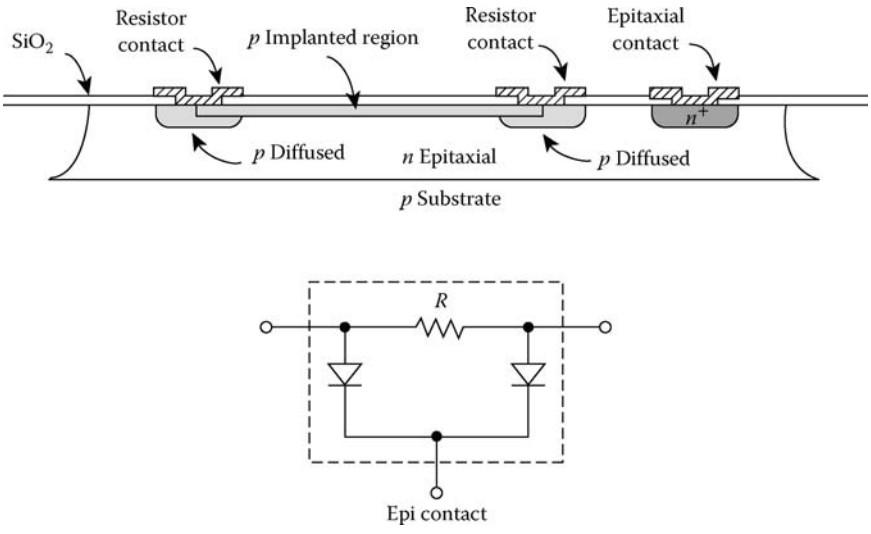

FIGURE 1.75 p-Type ion-implanted resistor.

TABLE 1.8 Typical Properties of Semiconductor Resistors

Resistor Type	Sheet ρ(Ω/N)	Absolute Tolerance (%)	Matching Tolerance (%)	Temperature Coefficient (ppm/°C)
Base-diffused	100–200	±20	±2 (5 μm wide)	+1500 to +2000
			±0.2 (50 μm wide)	—
Emitter-diffused	2–10	±20	±2	+600
Base-pinched	2–10 K	±50	±10	+2500
Epitaxial	2–5 K	±30	±5	+3000
Epitaxial-pinched	4–10 K	±50	±7	+3000
Ion-implanted	100–1000	±3	±2 (5 μm wide)	Controllable to ±100
			±0.15 (50 μm wide)

Table 1.8 provides a summary of the typical characteristics for the diffused, pinched, epitaxial, and ion-implanted resistors.

1.4.1.5 Thin-Film Resistors

Compared with diffused resistors, thin-film resistors offer advantages of a lower temperature coefficient, a smaller absolute value variation, and an excellent high-frequency characteristic. Commonly used resistive thin films are tantalum, Ni–Cr, Cr–SiO, and SnO_2. A typical thin-film resistor structure is shown in Figure 1.76, where a thin-film resistive layer is deposited on top of a thermally grown SiO_2 layer and a thin-film conductive metal layer is used to form the resistor contacts. The oxide layer functions as an insulating layer for the resistor. Various CVD techniques can be used to form the thin films [8]. The oxide passivation layer deposited on top of the resistive film and the conductive film protects the device surface from contamination. The electrical lumped model as shown in Figure 1.76 is adequate to characterize the high-frequency performance of the resistor. The parallel-plate capacitance formed

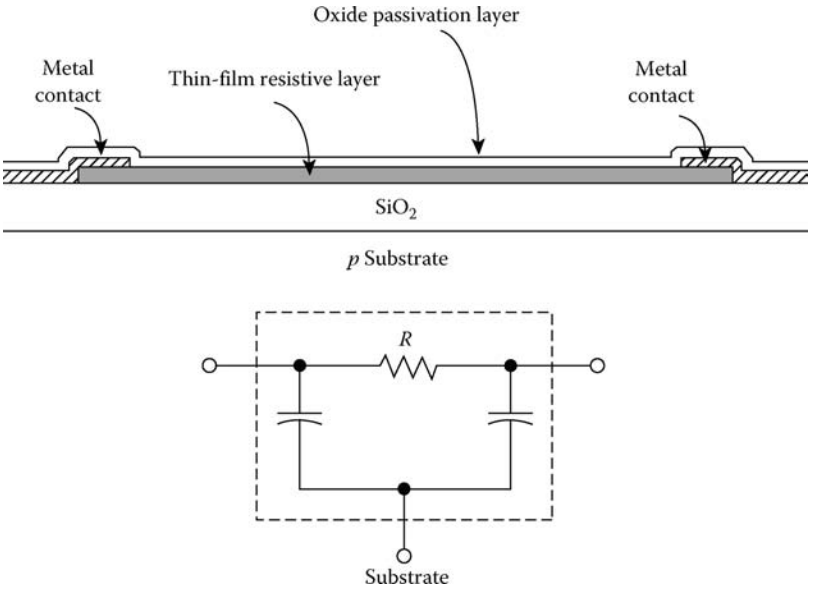

FIGURE 1.76 Thin-film resistor.

TABLE 1.9 Typical Characteristic of Thin-Film Resistors

Resistor Type	Sheet ρ(Ω/N)	Absolute Tolerance (%)	Matching Tolerance (%)	Temperature Coefficient (ppm/°C)
Ni–Cr	40–400	±5	±1	±100
Ta	10–1000	±5	±1	±100
SnO_2	80–4000	±8	±2	0–1500
Cr–SiO	30–2500	±10	±2	±50 to ±150

between the thin-film resistive and the substrate is divided equally between the two capacitors. Table 1.9 provides a summary of the characteristics for some commonly used thin-film resistors.

1.4.2 Capacitors

Monolithic capacitors are widely used in analog and digital ICs for functions such as circuit stability, bandwidth enhancement, ac signal coupling, impedance matching, and charge storage cells. Capacitor structures available in monolithic form include pn junction, MOS, and polysilicon capacitors. pn junctions under reverse-biased conditions exhibit a nonlinear voltage-dependent capacitance. MOS and polysilicon capacitors, on the other hand, closely resemble the linear parallel-plate capacitor structure as shown in Figure 1.77. If the insulator thickness T of the parallel-plate structure is small compared with the plate width W and length L, the electric field between the plates is uniform (fringing field neglected). Under this condition the capacitance can be calculated by

$$C = \frac{\kappa\varepsilon_0}{T} WL \tag{1.245}$$

where κ is the relative dielectric constant of the insulating material and ε_0 is the permittivity constant in vacuum (8.854×10^{-14} F/cm).

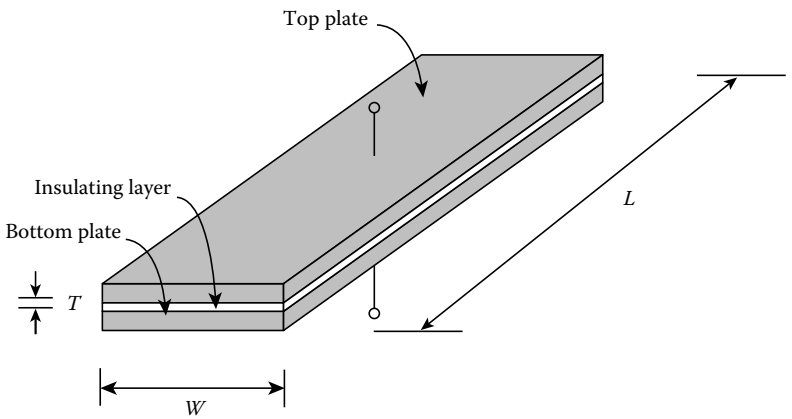

FIGURE 1.77 Structure of a parallel-plate capacitor.

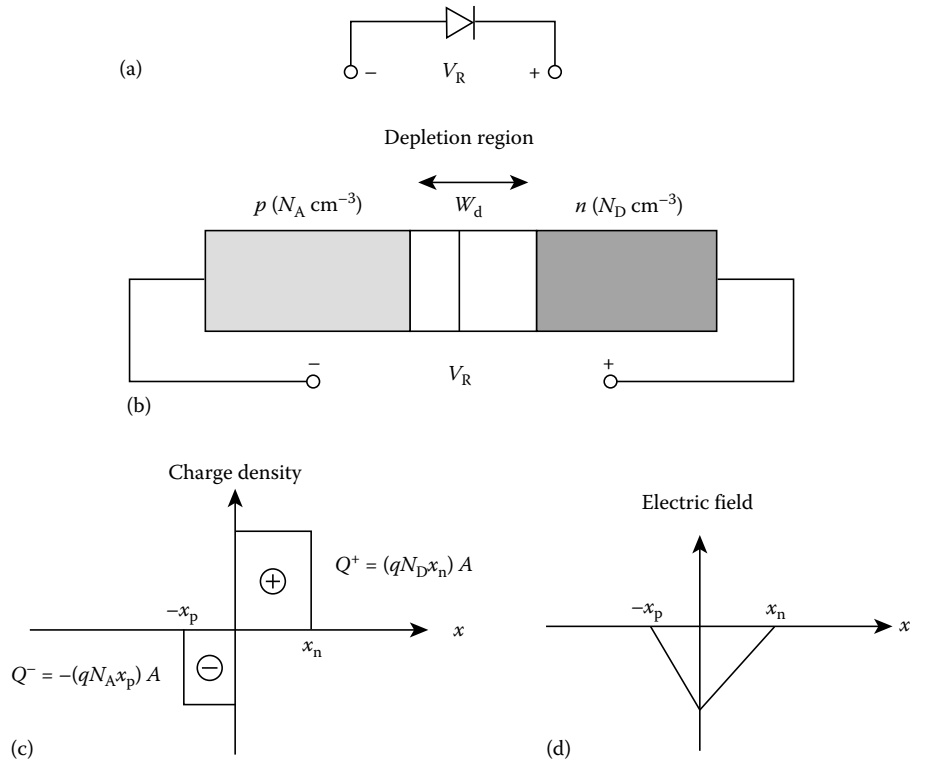

FIGURE 1.78 Abrupt p–n junction: (a) p–n junction symbol; (b) depletion region; (c) charge density within the depletion region; and (d) electric field.

1.4.2.1 Junction Capacitors

The structure of an *abrupt* pn junction is shown in Figure 1.78, where the doping is assumed uniform throughout the region on both sides. The acceptor impurity concentration of the p region is N_A atoms/cm^3 and the donor impurity concentration of the n region is N_D atoms/cm^3. When the two regions are brought in contact, mobile holes from the p region diffuse across the junction to the n region and mobile electrons diffuse from the n to the p region. This diffusion process creates a *depletion* region that is essentially free of mobile carriers (depletion approximation) and contains only fixed acceptor and donor ions. Ionized acceptor atoms are negatively charged and ionized donor atoms are positively charged. In equilibrium the diffusion process is balanced out by a drift process that arises from a *built-in* voltage ψ_o across the junction. This voltage is positive from the n region relative to the p region and is given by [17]

$$\psi_o = \frac{kT}{q} \ln \frac{N_A N_D}{n_i^2} \tag{1.246}$$

where

k is the Boltzmann constant (1.38×10^{-23} V · C/K)
T is the temperature in Kelvin (K)
q is the electron charge (1.60×10^{-19} C)
n_i(cm^{-3}) is the *intrinsic* carrier concentration in a pure semiconductor sample

For silicon at 300 K, $n_i \approx 1.5 \times 10^{10}$ cm^{-3}.

When the pn junction is subject to an applied reverse bias voltage V_R, the drift process is augmented by the external electric field and more mobile electrons and holes are pulled away from the junction. Because of this effect, the depletion width W_d and consequently the charge Q on each side of the junction vary with the applied voltage. A junction capacitor can thus be defined to correlate this charge–voltage relationship. The Poisson's equation relating the junction voltage $\phi(x)$ to the electric field $\xi(x)$ and the total charge Q is

$$\begin{aligned}\frac{d^2\varphi(x)}{dx^2} &= -\frac{d\xi(x)}{dx} = -\frac{q}{\varepsilon_S}(p - n + N_D - N_A) \\ &\approx \begin{cases} \dfrac{qN_A}{\varepsilon_S} & -x_p < x < 0 \\ -\dfrac{qN_D}{\varepsilon_S} & 0 < x < x_n \end{cases}\end{aligned} \tag{1.247}$$

where ε_S ($11.8\varepsilon_0 = 1.04 \times 10^{-12}$ F/cm) is the permittivity of the silicon material. The first integral of Equation 1.247 yields the electric field as

$$\xi(x) = \begin{cases} -\dfrac{qN_A}{\varepsilon_S}(x + x_p) & -x_p < x < 0 \\ -\dfrac{qN_D}{\varepsilon_S}(x_n + x) & 0 < x < x_n \end{cases} \tag{1.248}$$

The electric field is shown in Figure 1.78, where the maximum field strength occurs at the junction edge. This value is given by

$$|\xi_{max}| = \frac{qN_A}{\varepsilon_S}x_p = \frac{qN_D}{\varepsilon_S}x_n$$

The partial depletion width x_p on the p region and the partial depletion width x_n on the n region can then be related to the depletion width W_d as

$$\begin{aligned} x_p + x_n &= W_d \\ x_p &= \frac{N_D}{N_A + N_D}W_d \\ x_n &= \frac{N_A}{N_A + N_D}W_d \end{aligned}$$

Taking the second integral of Equation 1.247 yields the junction voltage

$$\varphi(x) = \begin{cases} \dfrac{qN_A}{\varepsilon_S}\left(\dfrac{x_p^2}{2} + x_p x + \dfrac{x^2}{2}\right) & -x_p < x < 0 \\ \dfrac{qN_D}{\varepsilon_S}\left(\dfrac{x_n x_p}{2} + x_n x - \dfrac{x^2}{2}\right) & 0 < x < x_n \end{cases} \tag{1.249}$$

where the voltage at x_p is arbitrarily assigned to be zero. The total voltage $\psi_0 + V_R$ can be expressed as

$$\psi_o + V_R = \varphi(x_n) = \frac{qN_D}{2\varepsilon_S}\left(1 + \frac{N_D}{N_A}\right)x_n^2$$

Finally, the depletion width W_d and the total charge Q in terms of the total voltage across the junction can be derived to be

$$W_d = \left[\frac{2\varepsilon_S}{q}(\psi_o + V_R)\left(\frac{1}{N_A} + \frac{1}{N_D}\right)\right]^{1/2}$$
$$|Q| = A(qN_A x_p) = A(qN_D x_n) = A\left[2q\varepsilon_S(\psi_o + V_R)\left(\frac{1}{N_A} + \frac{1}{N_D}\right)^{-1}\right]^{1/2} \tag{1.250}$$

The junction capacitance is thus

$$C_j = \left|\frac{dQ}{dV_R}\right| = A\left[\frac{q\varepsilon_S}{2}\left(\frac{1}{\psi_o + V_R}\right)\left(\frac{1}{N_A} + \frac{1}{N_D}\right)^{-1}\right]^{1/2}$$
$$= \frac{C_{jo}}{\left(1 + \frac{V_R}{\psi_o}\right)^{1/2}} \tag{1.251}$$

where

A is the effective cross-sectional junction area
C_{jo} is the value of C_j for $V_R = 0$

If the doping concentration in one side of the pn junction is much higher than that in the other, the depletion width and the junction capacitance can be simplified to

$$W_d = \left[\frac{2\varepsilon_S}{qN_L}(\psi_o + V_R)\right]^{1/2} \tag{1.252}$$

$$C_j = A\left[\frac{\varepsilon_S qN_L}{2}\left(\frac{1}{\psi_o + V_R}\right)\right]^{1/2} \tag{1.253}$$

where N_L is the concentration of the lightly doped side. Figure 1.79 displays the junction capacitance per unit area as a function of the total voltage $\psi_o + V_R$ and the concentration on the lightly doped side of the junction [3].

In silicon bipolar technology the base–emitter, the base–collector, and the collector–substrate junctions under reverse bias are often utilized for realizing a junction capacitance. The collector–substrate junction has only a limited use since it can only function as a shunt capacitor due to the substrate being connected to an ac ground.

Base–collector junction capacitor. A typical base–collector capacitor structure is shown in Figure 1.80 together with an equivalent lumped circuit model. A heavily doped n^+ buried layer is used to minimize the series resistance R_C. For the base–collector junction to operate in reverse bias, the n-type collector must be connected to a voltage relatively higher than the voltage at the p-type base. The junction breakdown voltage is determined by BV_{CBO} of the npn transistor, which has a typical value between 25 and 50 V.

Base–emitter junction capacitor. Figure 1.81 shows a typical base–emitter capacitor structure where the parasitic junctions D_{BC} and D_{SC} must always be in reverse bias. The base–emitter junction achieves the highest capacitance per unit area among the base–collector, base–emitter, and collector–substrate junctions due to the relatively higher doping concentrations in the base and emitter regions.

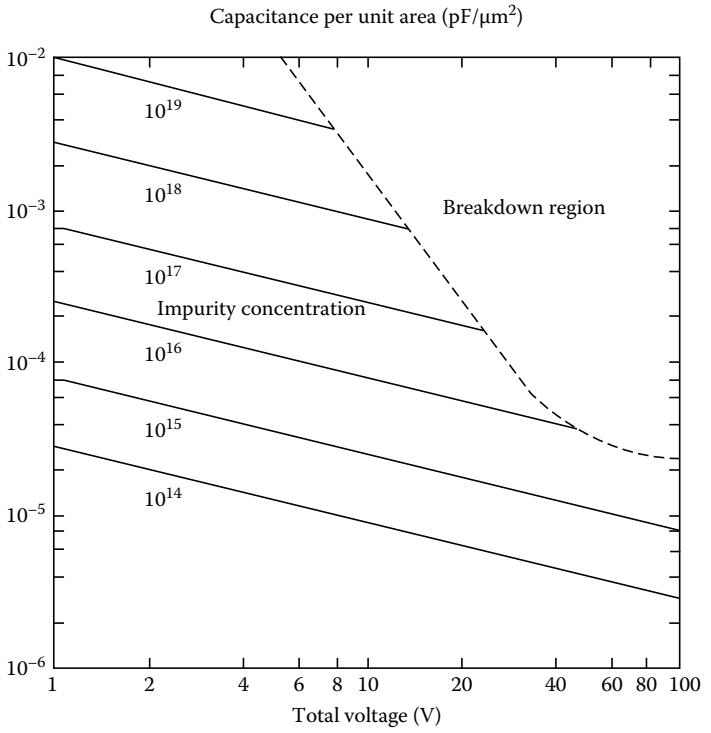

FIGURE 1.79 Junction capacitance as a function of the total voltage and the concentration on the lightly doped side.

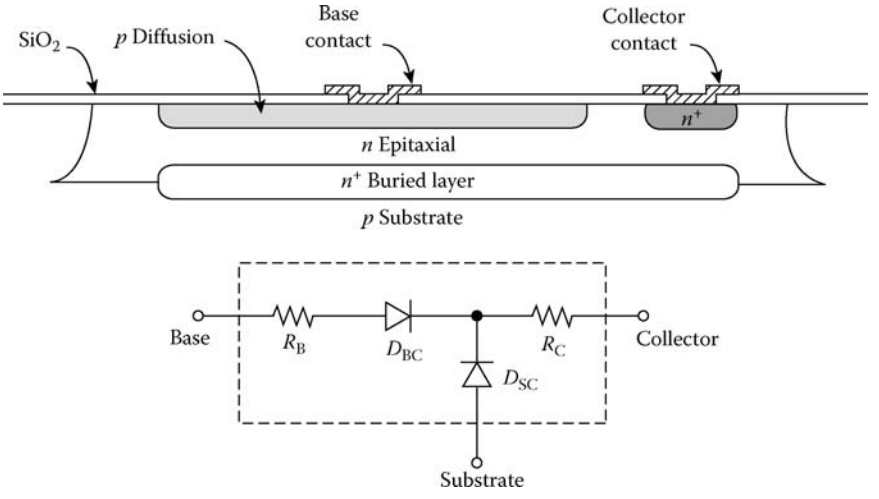

FIGURE 1.80 Base–collector junction capacitor.

For the base–emitter junction to operate in reverse bias, the n-type emitter must be connected to a voltage relatively higher than the voltage at the p-type base. The breakdown voltage of the base–emitter junction is relatively low, determined by the BV_{EBO} of the npn transistor, which has a typical value of about 6 V.

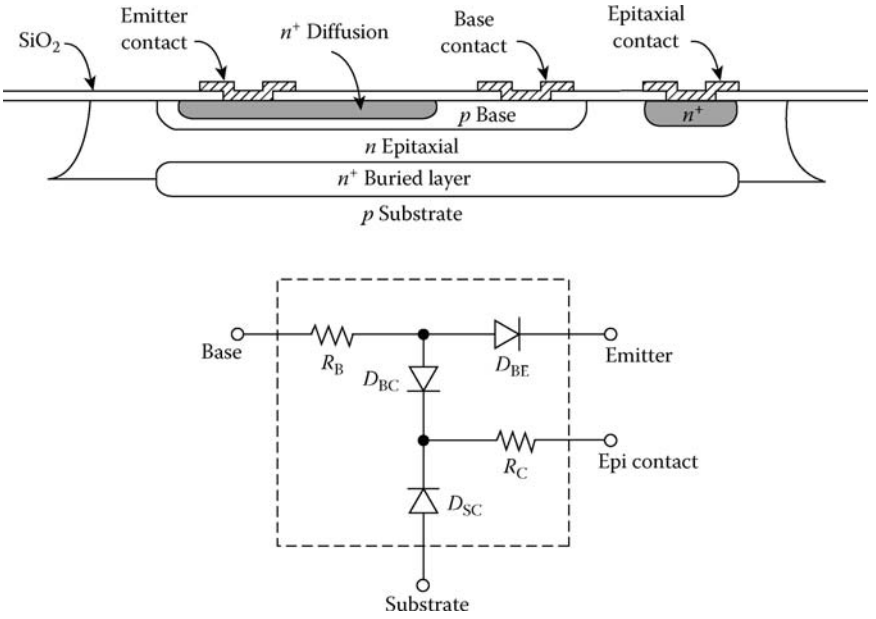

FIGURE 1.81 Base–emitter junction capacitor.

1.4.2.2 MOS Capacitors

MOS capacitors are preferable and commonly used in ICs since they are linear and not confined to a reverse-biased operating condition as in the junction capacitors. The structure of a MOS capacitor is shown in Figure 1.82, where by means of a local oxidation process a thin oxide layer is thermally grown on top of a heavily doped n^+ diffusion layer. The oxide layer has a typical thickness between 500 and 1500 Å (Å $= 10^{-10}$ m $= 10^{-4}$ μm) and functions as the insulating layer of the parallel-plate capacitor. The top plate is formed by overlapping the thin oxide area with a deposited layer of conductive metal. The bottom-plate diffusion layer is heavily doped for two reasons: to minimize the bottom-plate resistance and to minimize the depletion width at the oxide-semiconductor interface when the capacitor operates in the *depletion* and *inversion* modes [17]. By keeping the depletion width small, the effective capacitance is dominated by the parallel-plate oxide capacitance. The MOS capacitance is thus given by

$$C = \frac{\kappa_{ox}\varepsilon_0}{T} A \tag{1.254}$$

where

κ_{ox} is the relative dielectric constant of SiO_2 (2.7 to 4.2)
ε_0 is the permittivity constant
T is the oxide thickness
A is the area defined by the thin oxide layer

In practice, a thin layer of silicon nitride (Si_3N_4) is often deposited on the thin oxide layer and is used to minimize the charges inadvertently introduced in the oxide layer during oxidation and subsequent processing steps. These *oxide charges* are trapped within the oxide and can cause detrimental effect to the capacitor characteristic [17]. The silicon nitride assimilates an additional insulating layer and effectively

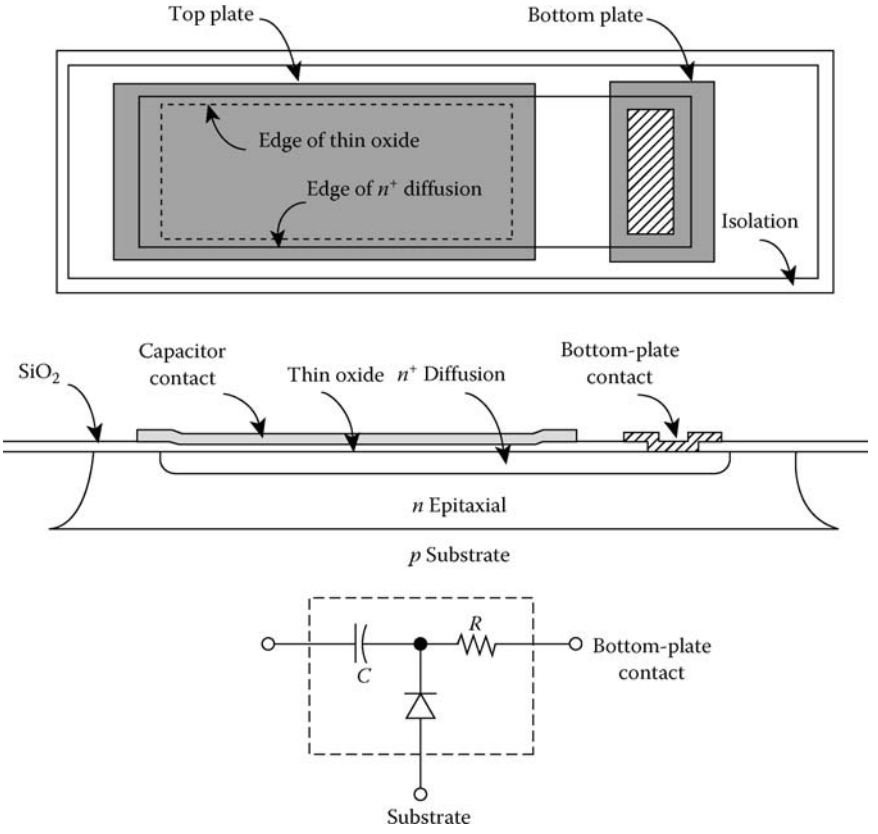

FIGURE 1.82 MOS capacitor.

creates an additional capacitor in series with the oxide capacitor. The capacitance for such a structure can be determined by an application of *Gauss's law*. It is given by

$$C = \frac{\varepsilon_o}{\left(\frac{T_{ni}}{\kappa_{ni}}\right) + \left(\frac{T_{ox}}{\kappa_{ox}}\right)} A \tag{1.255}$$

where

T_{ni} and T_{ox} are the thickness of the silicon nitride and oxide layers, respectively

κ_{ni} (2.7 to 4.2) and κ_{ni} (3.5 to 9) are the relative dielectric constant of oxide and silicon nitride, respectively

In the equivalent circuit model of Figure 1.82, the parasitic junction between the p-type substrate and the n-type bottom plate must always be reverse biased. The bottom-plate contact must be connected to a voltage relatively higher than the substrate voltage.

1.4.2.3 Polysilicon Capacitors

Polysilicon capacitors are conveniently available in MOSFET technology, where the gate of the MOSFET transistor is made of polysilicon material. Polysilicon capacitors also assimilate the parallel-plate capacitor. Figure 1.83 shows a typical structure of a polysilicon capacitor, where a thin oxide is deposited on top of a polysilicon layer and serves as an insulating layer between the top-plate metal layer and the

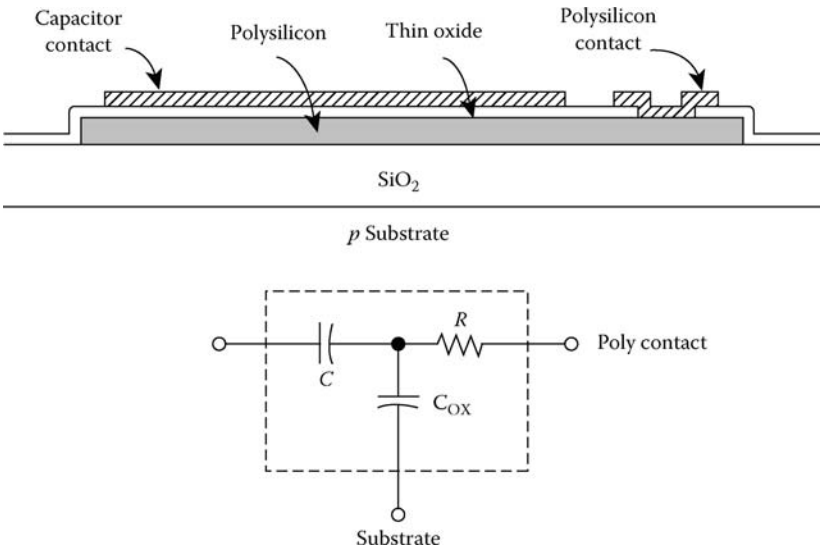

FIGURE 1.83 Polysilicon capacitor.

bottom-plate polysilicon layer. The polysilicon region is isolated from the substrate by a thick oxide layer that forms a parasitic parallel-plate capacitance between the polysilicon layer and the substrate. This parasitic capacitance must be accounted for in the equivalent circuit model. The capacitance of the polysilicon capacitor is determined by either Equation 1.254 or 1.255 depending on whether a thin silicon nitride is used in conjunction with the thin oxide.

1.4.3 Inductors

Planar inductors have been implemented using a variety of substrates such as standard PC boards, ceramic and sapphire hybrids, monolithic GaAs [24], and more recently monolithic silicon [18]. In the early development of silicon technology, planar inductors were investigated [26], but the prevailing lithographic limitations and relatively large inductance requirements (for low-frequency applications) resulted in excessive silicon area and poor performance. Reflected losses from the conductive silicon substrate were a major contribution to low inductor *Q*. Recent advances in silicon IC processing technology have achieved fabrication of metal width and metal spacing in the low micrometer range and thus allow many more inductor turns per unit area. Also, modern oxide-isolated processes with multilayer metal options allow thick oxides to help isolate the inductor from the silicon substrate. Practical applications of monolithic inductors in low-noise amplifiers, impedance matching amplifiers, filters and microwave oscillators in silicon technologies have been successfully demonstrated [19,20].

Monolithic inductors are especially useful in high-frequency applications where inductors of a few nano-Henrys of inductance are sufficient. Inductor structures in monolithic form include strip, loop, and spiral inductors. Rectangular and circular spiral inductors are by far the most commonly used structures.

1.4.3.1 Rectangular Spiral Inductors

The structure of a rectangular spiral inductor is shown in Figure 1.84, where the spiral loops are formed with the top metal layer M_2 and the connector bridge is formed with the bottom metal layer M_1. Using the top metal layer to form the spiral loops has the advantage of minimizing the parasitic metal-to-substrate

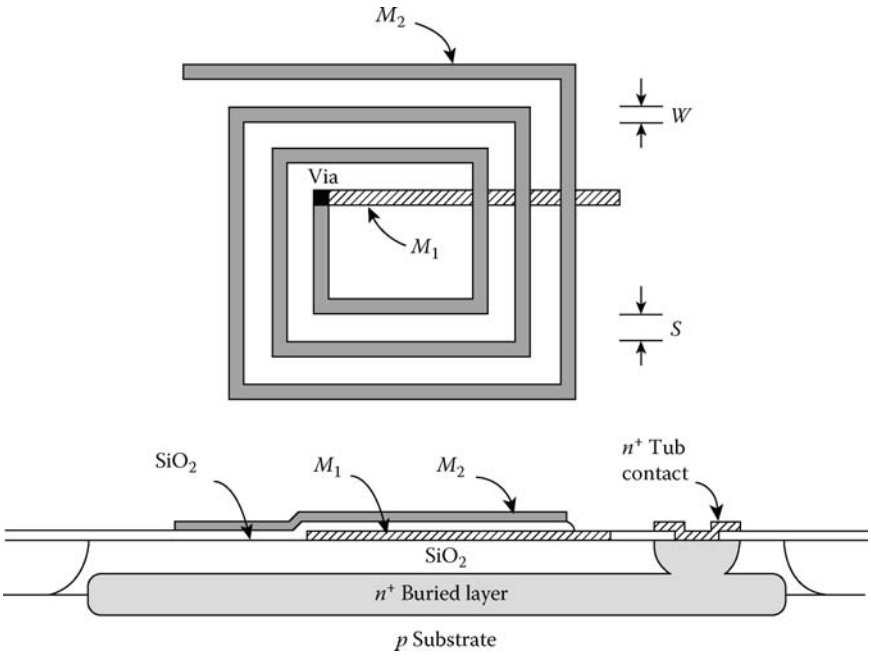

FIGURE 1.84 Rectangular spiral inductor.

capacitance. The metal width is denoted by W and the metal spacing is denoted by S. The total inductance is given by

$$L_T = \sum_{i=1}^{4N} L_S(i) + 2 \cdot \sum_{i=1}^{4N-1} \sum_{j=i+1}^{4N} L_M(ij) \tag{1.256}$$

where

N is the number of turns
$L_S(i)$ is the *self inductance* of the rectangular metal segment i
$L_M(ij)$ is the *mutual inductance* between metal segments i and j

The self-inductance is due to the magnetic flux surrounding each metal segment. The mutual inductance is due to the magnetic flux coupling around every two parallel metal segments and has a positive value if the currents applied to the metal conductors flow in the same direction and a negative value otherwise. Perpendicular metal segments have negligible mutual inductance.

The self-inductance and mutual inductance for straight rectangular conductors can be determined by the *geometric mean distance* method [10], in which the conductors are replaced by equivalent straight filaments whose basic inductive characteristics are well known.

Self-inductance. The self-inductance for the rectangular conductor of Figure 1.85 depends on the conductor length L, the conductor width W, and the conductor thickness T. The static self-inductance is given by [9,10].

$$L_S = 2L\left[\ln\left(\frac{2L}{GMD}\right) - 1.25 + \left(\frac{AMD}{L}\right) + \left(\frac{\mu_r}{4}\right)\zeta\right](nH) \tag{1.257}$$

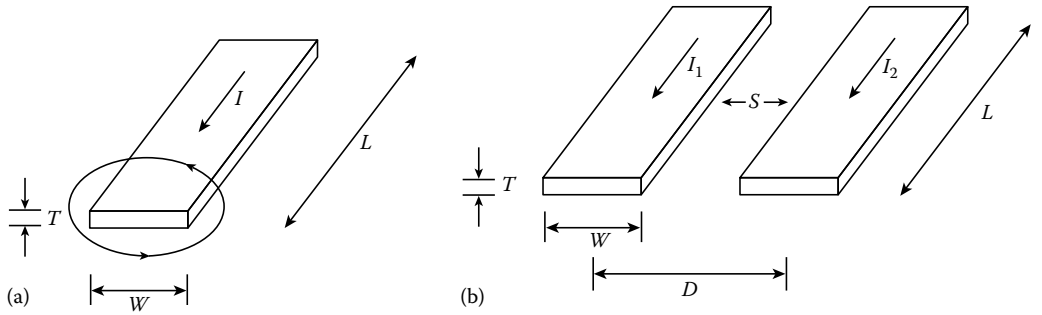

FIGURE 1.85 Calculation of (a) self-inductance and (b) mutual inductance for parallel rectangular conductors.

where

μ_r is the relative permeability constant of the conductor
GMD is the geometric mean distance
AMD is the arithmetic mean distance
ζ is a frequency-dependent parameter that equals 1 for direct and low-frequency alternating currents and approaches 0 for very high-frequency alternating currents

The AMD and GMD for the rectangular conductor of Figure 1.85 are

$$\text{AMD} = \left(\frac{W+T}{3}\right)$$
$$\text{GMD} = \begin{cases} 0.22313 \cdot (W+T) & T \to 0 \\ 0.22360 \cdot (W+T) & T = \text{W}/2 \\ 0.223525 \cdot (W+T) & T \to \text{W} \end{cases} \tag{1.258}$$

The rectangular dimensions L, W, and T are normalized to the centimeter in the preceding expressions.

Mutual inductance. The mutual inductance for the two parallel rectangular conductors of Figure 1.85 depends on the conductor length L, the conductor width W, and the conductor thickness T, and the distance D separating the conductor centers. The static mutual inductance is [10]

$$L_{\text{M}} = 2L\alpha(\text{nH}) \tag{1.259}$$

where

$$\alpha = \ln\left[\left(\frac{L}{\text{GMD}}\right) + \left[1 + \left(\frac{L}{\text{GMD}}\right)^2\right]^{1/2}\right] - \left[1 + \left(\frac{\text{GMD}}{L}\right)^2\right]^{1/2} + \left(\frac{\text{GMD}}{L}\right)$$

and

$$\text{GMD} = \exp(\ln D - \beta) \tag{1.260}$$

$$\beta = \begin{cases} \frac{1}{12}\left(\frac{D}{W}\right)^{-2} + \frac{1}{60}\left(\frac{D}{W}\right)^{-4} + \frac{1}{168}\left(\frac{D}{W}\right)^{-6} + \frac{1}{360}\left(\frac{D}{W}\right)^{-8} \\ + \frac{1}{660}\left(\frac{D}{W}\right)^{-10} + \cdots \\ 0.1137 \quad \text{for} \quad D = W \end{cases}$$

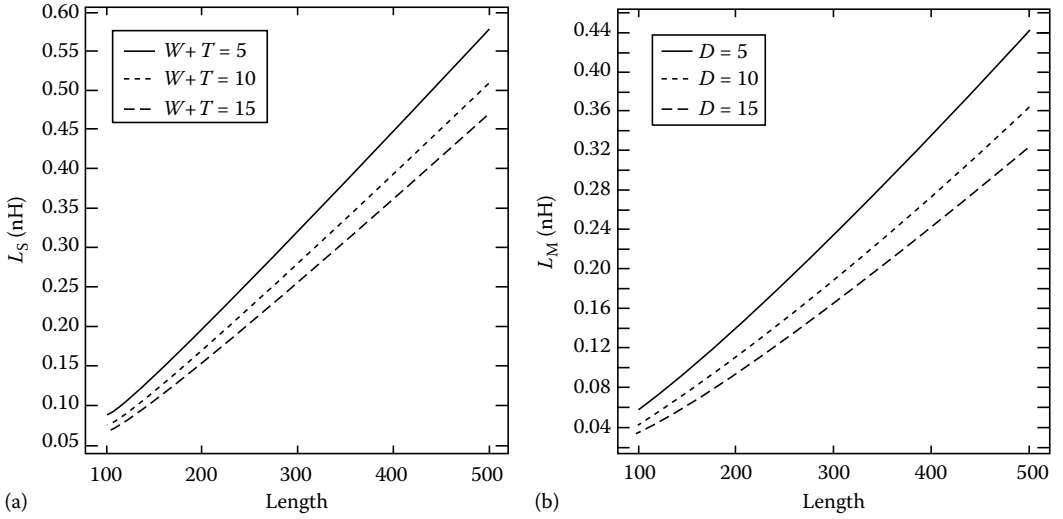

FIGURE 1.86 (a) Self-inductance as a function of width, thickness, and length for rectangular conductors. (b) Mutual inductance as a function of distance and length for rectangular conductors ($W = 5$, $T = 0$).

The GMD closed-form expression Equation 1.260 is valid for rectangular conductors with small thickness-to-width ratios T/W. As the thickness T approaches the width W, the GMD approaches the distance D and the GMD is no longer represented by the above closed-form expression. Figure 1.86 shows plots of the self inductance and the mutual inductance as expressed in Equations 1.257 and 1.259, respectively. The conductor dimensions are given in μm (μm $= 10^{-4}$ cm).

For the inductor structure of Figure 1.84 it is important to emphasize that since the spiral loops are of nonmagnetic metal material, the total inductance depends only on the geometry of the conductors and not on the current strength. At high-frequencies, especially those above the *self-resonant* frequency of the inductor, the *skin effect* due to current crowding toward the surface and the propagation delay as the current traverses the spiral must be fully accounted for [16,22]. The ground-plane effect due to the inductor image must also be considered regardless of the operation frequency.

An equivalent lumped model for the rectangular spiral inductor of Figure 1.84 is shown in Figure 1.87. This model consists of the total inductance L_T, the accumulated metal resistance R_S, the coupling

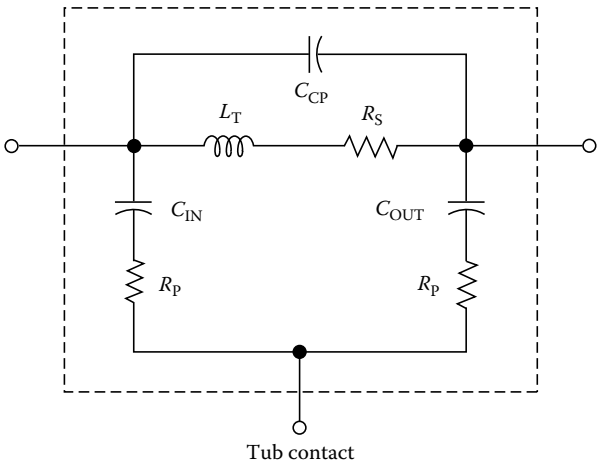

FIGURE 1.87 Electrical model for the spiral inductor.

capacitance C_{CP} between metal segments due to the electric fields in both the oxide region and the air region, the parasitic capacitances C_{IN} and C_{OUT} from the metal layers to the buried layer [2,11,15], and the buried-layer resistance R_P. Since the spiral structure of Figure 1.84 is not symmetrical, the parasitic capacitors C_{IN} and C_{OUT} are not the same, though the difference is relatively small. The self-resonant frequency can be approximated using the circuit model of Figure 1.87 with one side of the inductor being grounded. For simplicity, let $C_{IN} = C_{OUT} + C_P$ and neglect the relatively small coupling capacitor C_{CP}, the self-resonant frequency is given by

$$f_R = \frac{1}{2\pi} \frac{1}{\sqrt{L_T C_P}} \left[\frac{1 - R_S^2 \left(\frac{C_P}{L_T} \right)}{1 - R_P^2 \left(\frac{C_P}{L_T} \right)} \right]^{1/2} \tag{1.261}$$

Transformer structures. Transformers are often used in high-performance analog ICs that require conversions between single-ended signals and differential signals. In monolithic technology, transformers can be fabricated using the basic structure of the rectangular spiral inductor. Figure 1.88 shows a planar interdigitated spiral transformer that requires only two metal layers M_1 and M_2. The structure of Figure 1.89, on the other hand, requires three layers of metal for which the top metal layer M_3 is used for the upper spiral, the middle metal layer M_2 is used for the lower spiral, and the bottom metal layer M_1 is used for the two connector bridges. This structure can achieve a higher inductance per unit than that of Figure 1.88 due to a stronger magnetic coupling between the upper spiral and the lower spiral through a relatively thin oxide layer separating metal layers M_2 and M_3. An equivalent lumped model is

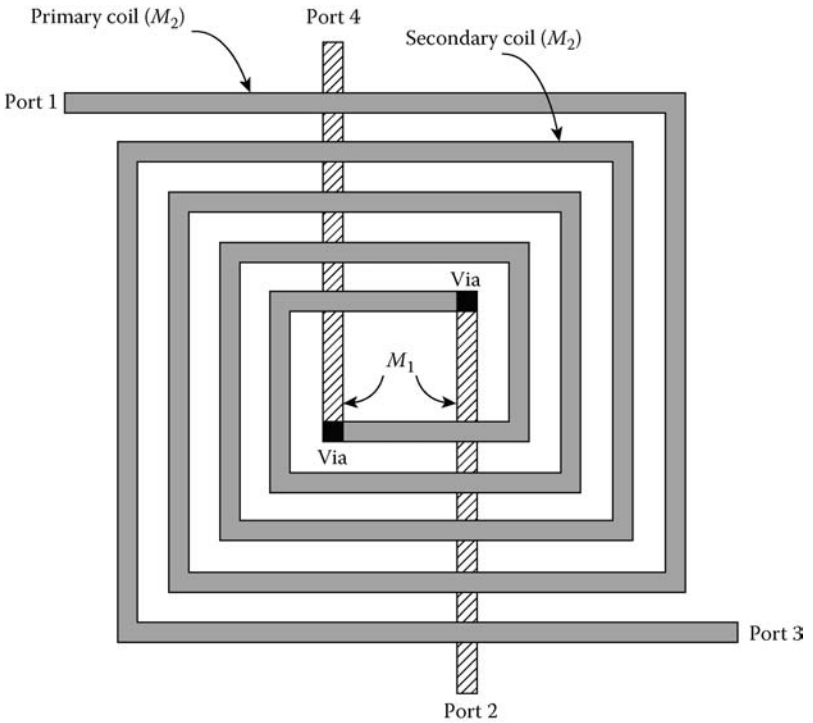

FIGURE 1.88 Rectangular spiral transformer I.

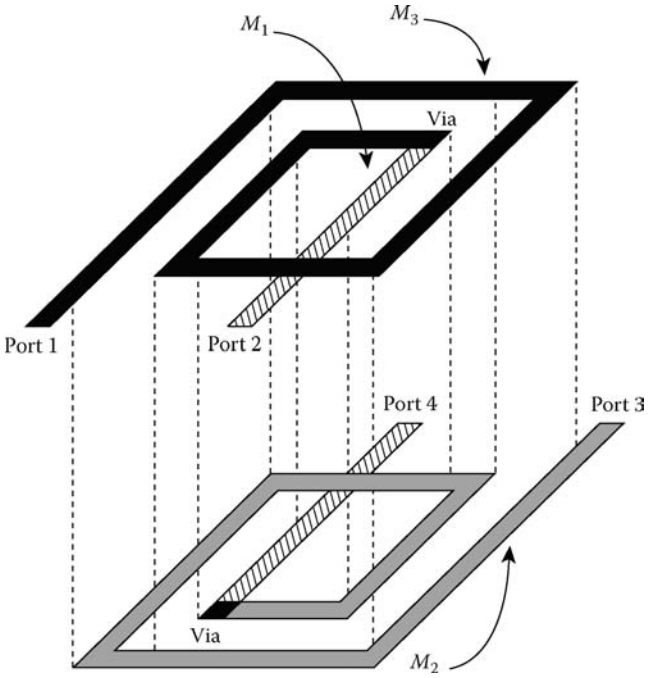

FIGURE 1.89 Rectangular spiral transformer II.

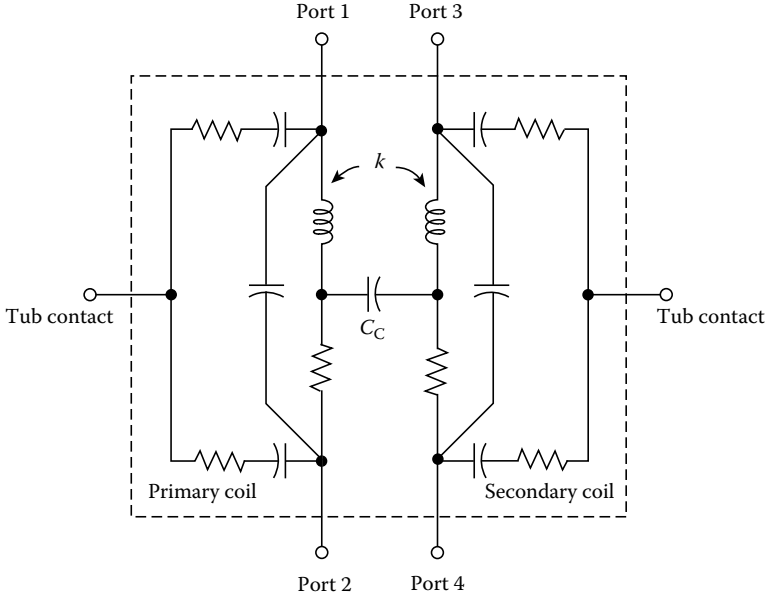

FIGURE 1.90 Electrical model for the spiral transformer.

shown in Figure 1.90. In addition to all the circuit elements of the two individual spiral inductors, there are also a magnetic coupling factor k and a coupling capacitance C_C between the primary and secondary coils.

1.4.3.2 Circular Spiral Inductors

The structure of a concentric circular spiral inductor is shown in Figure 1.91 where the circular loops share the same center point. The top metal layer M_2 is used for the circular conductors and the bottom metal layer M_1 is used for the connector bridge. The metal width is denoted by W and the spacing between two adjacent loops is denoted by S. The total inductance is given by

$$L_T = \sum_{i=1}^{N} L_S(i) + 2 \cdot \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} L_M(ij) \tag{1.262}$$

where

N is the number of circular turns
$L_S(i)$ is the *self-inductance* of the circular conductor i
$L_M(ij)$ is the *mutual inductance* between conductors i and j

Self-inductance. Consider the single circular conductor of Figure 1.92a that has a radius R and a width W. A current I applied to this conductor produces a magnetic flux encircled by the loop and another magnetic flux inside the conductor itself. The inductance associated with the former and the latter magnetic flux component is referred to as the *external* self-inductance and the *internal* self-inductance, respectively. The external self-inductance characterizing the change in the encircled magnetic flux to the change in current is [25].

$$L_S = \mu(2R - \delta)\left[\left(1 - \frac{k^2}{2}\right)K(k) - E(k)\right](\text{nH}) \tag{1.263}$$

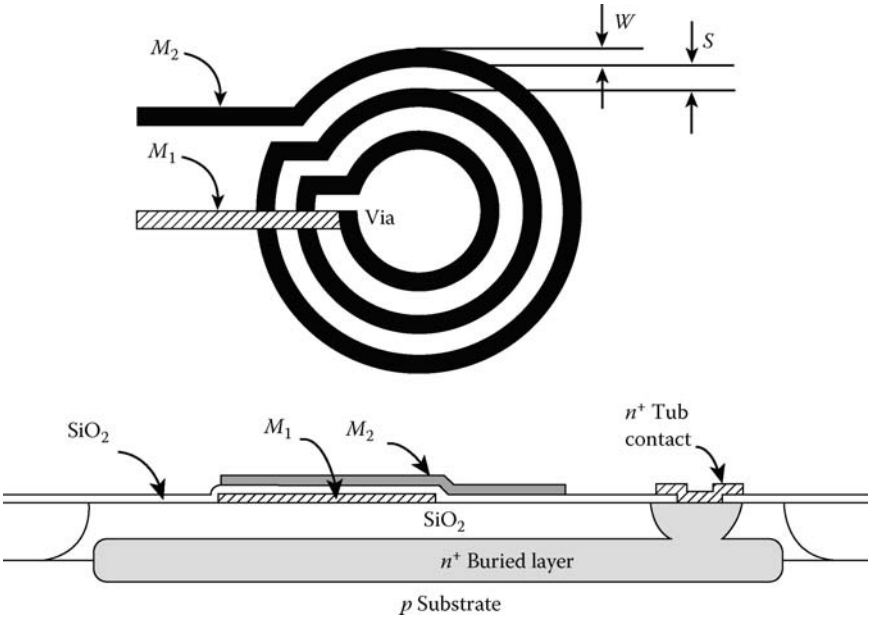

FIGURE 1.91 Concentric circular spiral inductor.

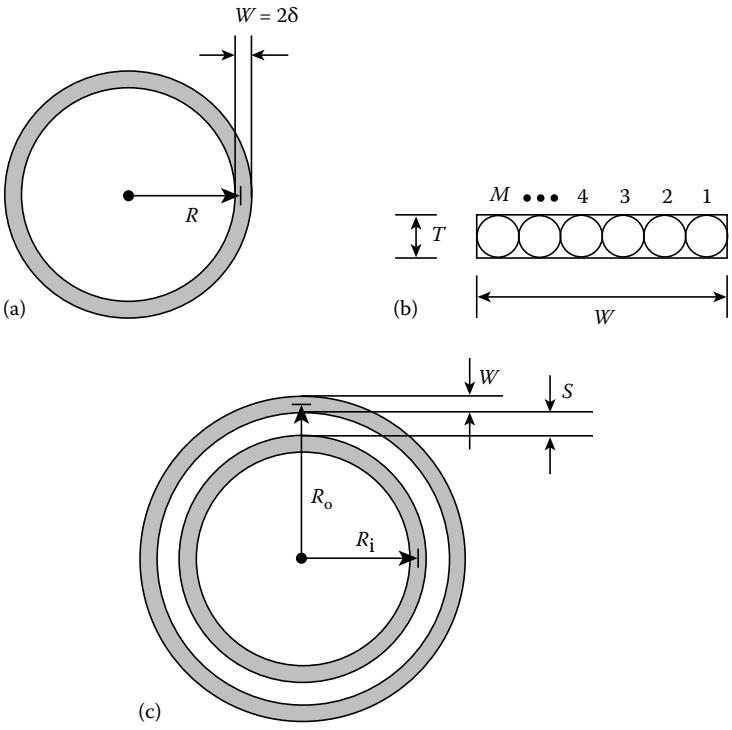

FIGURE 1.92 Calculation of self-inductance and mutual inductance for circular conductors. (a) External self-inductance; (b) internal self-inductance; and (c) mutual inductance.

where

$$k^2 = \frac{4R(R-\delta)}{(2R-\delta)^2} \tag{1.264}$$

and μ is the permeability of the conductor (equals 4π nH/cm for nonmagnetic conductors), and δ is one-half the conductor width W. $K(k)$ and $E(k)$ are the *complete elliptic integrals* of the first and second kind, respectively, and are given by

$$K(k) = \int_0^{\pi/2} \frac{d\phi}{\sqrt{1-k^2\sin^2\phi}}$$

$$E(k) = \int_0^{\pi/2} \sqrt{1-k^2\sin^2\phi}\, d\phi$$

The internal self-inductance is determined based on the concept of magnetic field energy. As shown in Figure 1.92b, the flat circular conductor is first approximated by an M number of round circular conductors [14] that are electrically in parallel and each conductor has a diameter equal to the thickness T of the flat conductor. The internal self-inductance of each round conductor is then determined as [25].

$$L = \frac{\mu}{8\pi}(\text{nH/cm})$$

The internal self-inductance of the flat conductor thus equals the parallel combination of these M components

$$L_S \approx \frac{\mu}{4}\left\{\sum_{i=1}^{M}[R - \delta + T(i - 0.5)]^{-1}\right\}^{-1}(\text{nH}) \tag{1.265}$$

where $R - \delta + T(i - 0.5)$ is the effective radius from the center of the loop to the center of the round conductor i. The typical contribution from the internal self-inductance of Equation 1.265 is less than 5% the contribution from the external self-inductance of Equation 1.263.

Mutual inductance. The mutual inductance of the two circular loops of Figure 1.92c depends on the inner radius R_i and the outer radius R_o. For any two adjacent loops of the circular spiral inductor, the outer radius is related to the inner radius by the simple relation $R_o = R_i + (W + S)$. The mutual inductance is determined based on the *Neumann's* line integral given as follows:

$$L_M = \frac{\mu}{4\pi}\int_C\int_C \frac{d\mathbf{l}_1 \cdot d\mathbf{l}_2}{D}$$

where

$d\mathbf{l}_1 \cdot d\mathbf{l}_2$ represents the dot product of the differential lengths
D is the distance separating the differential $\mathbf{l}_1$ vector and $\mathbf{l}_2$ vector

The static mutual inductance [25] is

$$L_M = \mu\sqrt{R_i R_o}\left[\left(\frac{2}{k} - k\right)K(k) - \frac{2}{k}E(k)\right](\text{nH}) \tag{1.266}$$

where

$$k^2 = \frac{4R_i R_o}{(R_i + R_o)^2} \tag{1.267}$$

Figure 1.93 shows plots of the external self-inductance and the mutual inductance as expressed in Equations 1.263 and 1.266, respectively. The conductor dimensions are given in μm.

As in the rectangular spiral inductor, the ground-plane effect and the retardation effect of the circular spiral inductor must be fully accounted for. The circuit model of Figure 1.87 can be used to characterize the electrical behavior of the circular inductor.

A comparison between the rectangular spiral of Figure 1.84 and the circular spiral of Figure 1.91 is shown in Figure 1.94, where the total inductance L_T is plotted against the turn number N. Both inductors have the same innermost dimension, the same conductor width, space, and thickness. The dimensions are given in μm, and the ground-plane effect and the retardation effect are not considered. For a given turn number, the rectangular spiral yields a higher inductance per semiconductor area than the circular spiral. Figure 1.95 shows a plot of the inductor Q vs. the total inductance of the same spiral inductors under consideration. Due to a higher inductance per length ratio, the Q of the circular inductor is higher than that of the rectangular inductor, about 10% for high inductance values.

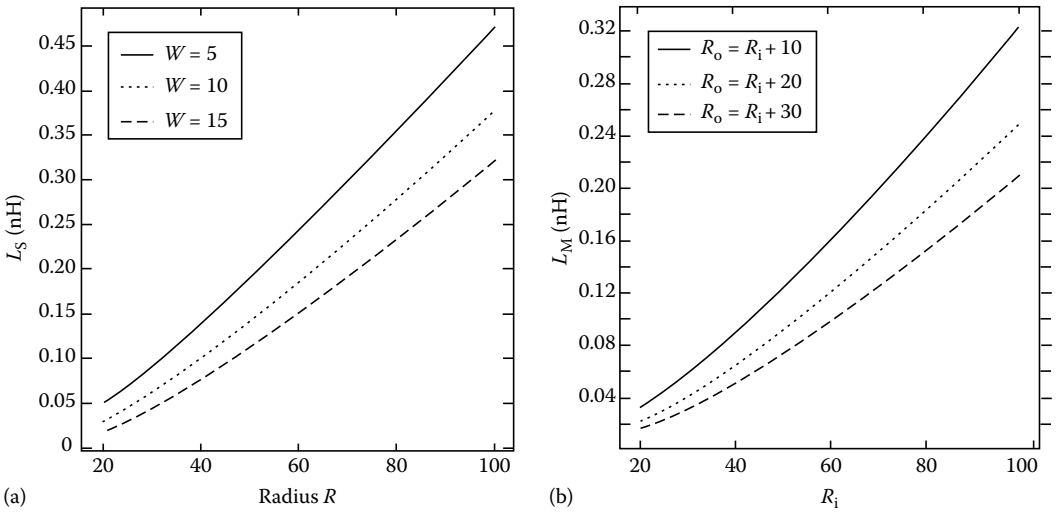

FIGURE 1.93 (a) External self-inductance as a function of radius and width for circular conductors. (b) Mutual inductance as a function of radii R_i and R_o for circular conductors.

1.5 Chip Parasitics in Analog Integrated Circuits

Martin A. Brooke

The parasitic elements in electronic devices and interconnect limit the performance of all ICs. No amount of improvement in device performance or circuit design can completely eliminate these effects. Thus, as circuit speeds increase, unaccounted for interconnect parasitics become a more and more common cause of analog IC design failure. Hence, the causes, characterization, and modeling of significant interconnect parasitics are essential knowledge for good analog IC design [1–4].

1.5.1 Interconnect Parasitics

The parasitics due to the wiring used to connect devices together on chip produce a host of problems. Unanticipated feedback through parasitic capacitances can cause unwanted oscillation. Mismatch due to differences in interconnect resistance contribute to unwanted offset voltages. For very-high-speed ICs, the inductance of interconnects is both a useful tool and a potential cause of yield problems.

Even the interactions between interconnect lines are both important and very difficult to model. So too are the distributed interactions of resistance, capacitance, and (in high-speed circuits) inductance that produce transmission line effects.

1.5.1.1 Parasitic Capacitance

Distributed capacitance of IC lines is perhaps the most important of all IC parasitics. It can lower the bandwidth of amplifiers, alter the frequency response of filters, and cause oscillations.

Physics. Every piece of IC interconnect has capacitance to the substrate. In the case of silicon circuitry, the substrate is conductive and connected to an ac ground, thus there is a capacitance to ground from every circuit node due to the interconnect. Figure 1.96 illustrates this substrate capacitance interconnect parasitic. The capacitance value will depend on the total area of the interconnect, and on the length of edge associated with the interconnect. This edge effect is due to the nonuniformity of the electric field at the interconnect edges. The nonuniformity of the electric field at edges is such that the capacitance value is larger for a given area of interconnect near the edge than elsewhere.

In addition to the substrate capacitance, all adjacent pieces of an interconnect will have capacitance between them. This capacitance is classified into two forms, overlap capacitance, and parallel line capacitance (also known as proximity capacitance). Overlap capacitance occurs when two pieces of interconnect cross each other, while parallel line capacitance occurs when two interconnect traces run close to each other for some distance.

When two lines cross each other, the properties of the overlapping region will determine that size of the overlap capacitance. The electric field through a cross section of two overlapping lines is illustrated in Figure 1.97. The electric field becomes nonuniform near the edges of the overlapping region, producing an edge-dependent capacitance term. The capacitance per unit area at the edge is always greater than elsewhere and, if the overlapping regions are small, the edge capacitance effect can be significant.

The size of parallel line capacitance depends on the distance for which the two lines run side by side and on the separation of the lines. Since parallel line capacitance occurs only at the edges of an interconnect, the electric field that produces it is very nonuniform. This particular nonuniformity, as illustrated in Figure 1.98, makes the capacitance much smaller for a given area of interconnect than either overlap or substrate capacitance. Thus, two lines must run parallel for some distance for this capacitance to be important. The nonuniformity of the electric field makes the dependence of the capacitance on line separation highly nonlinear, as a result the capacitance value decreases much more rapidly with separation than it would if it depended linearly on the line separation.

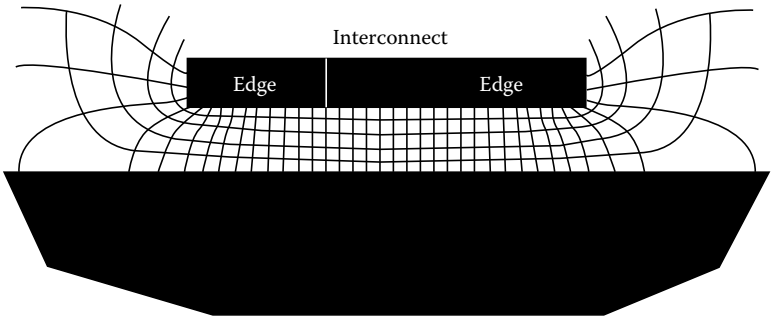

FIGURE 1.96 Substrate capacitance. The electric field distorts at the edges, making the capacitance larger there than elsewhere.

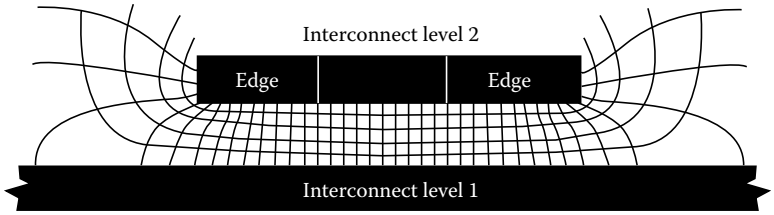

FIGURE 1.97 Overlap capacitance. The bottom interconnect level will have edges into and out of the page with distorted electric field similar to that shown for the top level of interconnect.

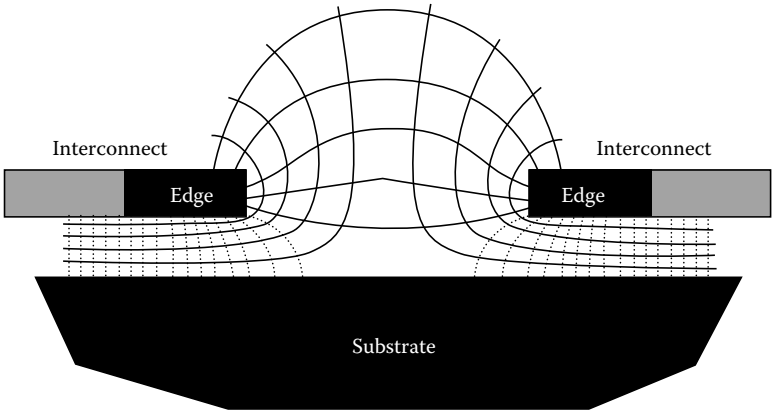

FIGURE 1.98 Parallel line capacitance. Only the solid field lines actually produce line-to-line capacitance, the dashed lines form substrate capacitance.

Modeling. In the absence of significant interconnect resistance effects, all of the parasitic capacitances can be modeled with enough accuracy for most analog circuit design applications by dissecting the interconnect into pieces with similar capacitance characteristics and adding up the capacitance of each piece to obtain a single capacitance term. For example, the dissected view of a piece of interconnect with substrate capacitance is shown in Figure 1.99. The interconnect has been dissected into squares that fall into three

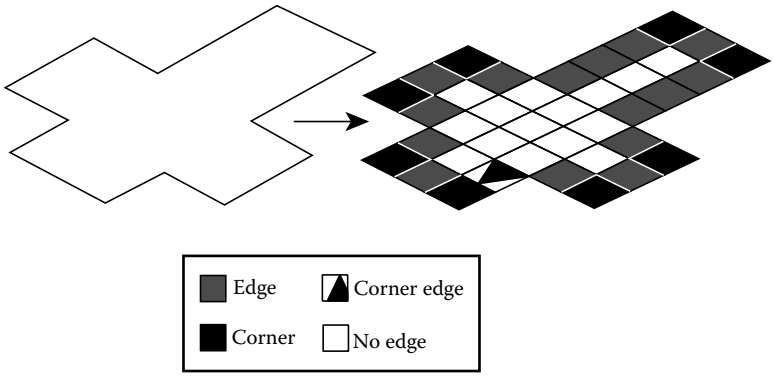

FIGURE 1.99 Determining substrate capacitance. The capacitance of each square in the dissected interconnect segment is summed.

classes: two types of edges, and one center type. The capacitance to the substrate for each of these squares in parallel and thus the total capacitance of the interconnect segment is simply the sum of the capacitance of each square. If the substrate capacitance contribution of each square has been previously measured or calculated, the calculation of the total interconnect segment substrate capacitance involves summing each type of squares capacitance multiplied by the number of squares of that type in the segment.

The accuracy of this modeling technique depends solely on the accuracy of the models used for each type of square. For example, in Figure 1.99, the accuracy could be improved by adding one more type of edge square to those that are modeled. One of these squares has been shaded differently in the figure and is called the corner edge square.

For the nonedge pieces of the interconnect the capacitance is approximately a parallel-plate capacitance and can be computed from Equation 1.268.

$$C = \frac{A \cdot \varepsilon_r \cdot \varepsilon_0}{t} \tag{1.268}$$

where

A is the area of the square or piece of interconnect
t is the thickness of the insulation layer beneath the interconnect
ε_r is the relative dielectric constant of the insulation material
ε_0 is the dielectric constant of free space

For silicon ICs insulated with silicon dioxide the parameters are given in Table 1.10.

The capacitance of edge interconnect pieces will always be larger than nonedge pieces. The amount by which the edge capacitance increases will depend on the ratio of the size of the piece of interconnect and the thickness of the insulation layer beneath the interconnect. If the interconnect width is significantly larger than the thickness of the insulation then edge effects are probably small and can be ignored. However, when thin lines are used in ICs the edge effects are usually significant. The factor by which the edge capacitance can increase over the parallel-plate approximation can easily be as high as 1.5 for thin lines.

The modeling of overlap capacitance is handled in the same fashion as substrate capacitance. The region where interconnect lines overlap is dissected into edges and nonedges and the value of capacitance for each type of square summed up to give a total capacitance between the two circuit nodes associated with each piece of interconnect that overlaps. The area of overlap between the two layers of interconnect can be used as A in Equation 1.268, while that separation between the layers can be used as t. The strong distortion of the electric fields will increase the actual value above this idealized computed value by a factor that depends on the thickness of the lines. This factor can be as high as 2 for thin lines.

Parallel line capacitance can also be handled in a manner similar to that used for substrate and overlap capacitance. However, we must now locate *pairs* of edge squares, one from each of the adjacent interconnect lines. In Figure 1.100, one possible pairing of the squares from adjacent pieces of interconnect is shown. The capacitance for each type of pair of squares is added together, weighted by the number of pairs of each type to get a single capacitance that connects the circuit nodes associated with each interconnect line.

The effect on the capacitance of the spacing between pairs must be either measured or computed for each possible spacing, and type of pair of squares. One approach to this is to use a table of measured or

TABLE 1.10 Parameters for Calculation of Substrate Capacitance in Silicon ICs Insulated with Silicon Dioxide

Parameter	Value
ε_r	3.9
ε_0	$8.854 \cdot 10^{-12}$ F/m
t	$1–5 \cdot 10^{-6}$ m

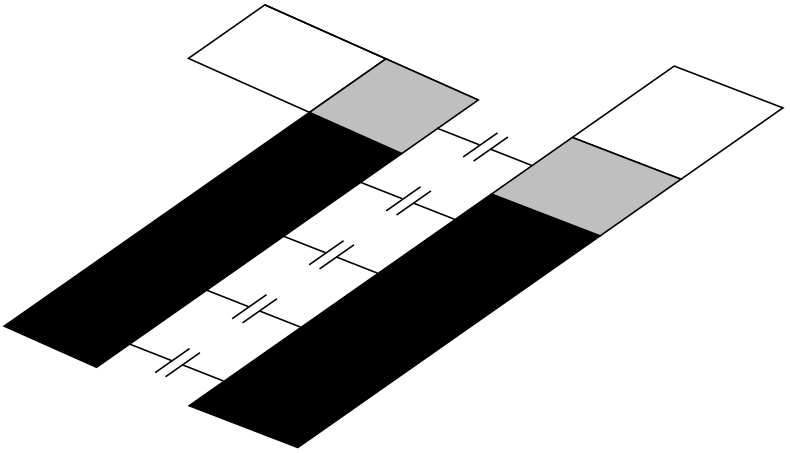

FIGURE 1.100 Determining parallel line capacitance. The differently shaded pairs of squares are different types and will each have a different capacitance between them.

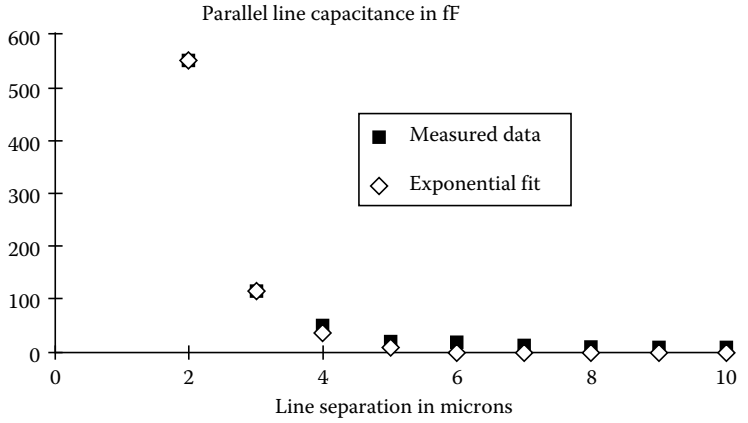

FIGURE 1.101 Parallel line capacitance measured from a silicon IC. The diamonds are an exponential fit to the data (using Equation 1.269). The fit is excellent at short separations when the capacitance is largest.

computed capacitances and separation distances. The measured parallel line capacitance between silicon IC lines for a variety of separations is presented in Figure 1.101. From the figure, we see that the capacitance value decreases exponentially with line separation. Thus an exponential fit to measured or simulated data is good choice for computing the capacitance [7,8].

Equation 1.269 can be used to predict the parallel line capacitance C for each type of pair of edge squares. L is the length of the edge of the squares, and the parameters C_c and S_d are computed or fit to measured coupling capacitance data like that in Figure 1.101.

$$C = C_c \cdot L \cdot e^{-(s/S_d)} \tag{1.269}$$

Effects on circuits. The effects that parasitic capacitances are likely to produce in circuits range from parametric variations, such as reduced bandwidth, to catastrophic failures, such as amplifier oscillation. Each type of parasitic capacitance produces a characteristic set of problems. Being aware of these typical problems will ease diagnosis of actual, or potential, parasitic capacitance problems.

Substrate capacitance usually causes lower than expected bandwidth in amplifiers and lowering of the poles in filters. The capacitance is always to ac ground and thus increases device and circuit capacitances to ground. Thus, circuit nodes that have a dominant effect on amplifier bandwidth, or filter poles, should be designed to have as little substrate capacitance as possible. Another, more subtle, parametric variation that can be caused by substrate capacitance is frequency-dependent mismatch. For example, if the parasitic capacitance to ground is different between the two inputs of a differential amplifier, then, for fast transient signals, the amplifier will appear unbalanced. This could limit the accuracy high-speed comparators, and is sometimes difficult to diagnose since the error only occurs at high speeds.

Overlap and parallel line capacitance can cause unwanted ac connections to be added to a circuit. These connections will produce crosstalk effects and can result in unstable amplifiers. The output interconnect and input interconnect of high-gain or high-frequency amplifiers must thus be kept far apart at all times. Care must be taken to watch for series capacitances of this type. For example, if the output and input interconnect of an amplifier both cross the power supply interconnect, unwanted feedback can result if the power supply line is not well ac grounded. This is a very common cause of IC amplifier oscillation. Because of the potential for crosstalk between parallel or crossing lines, great care should also be taken to keep weak (high-impedance) signal lines away from strong (low-impedance) signal lines.

1.5.1.2 Parasitic Resistance

For analog IC designers, the second most important interconnect parasitic is resistance. This unexpected resistance can cause both parametric problems, such as increased offset voltages, and catastrophic problems such as amplifier oscillation (for example, poorly sized power supply lines can cause resistive positive feedback paths in high gain amplifiers called ''ground loops''). To make matters worse, the resistivity of IC interconnect has been steadily increasing as the line widths of circuits have decreased.

Physics. Except for superconductors, all conductors have resistance. A length of interconnect used in an IC is no exception. The resistance of a straight section of interconnect is easily found by obtaining the resistance per square for the particular interconnect layer concerned, and then adding up the resistance of each of the series of squares that makes up the section. This procedure is illustrated in Figure 1.102.

For more complicated interconnect shapes the problem of determining the resistance between two points in the interconnect is also more complex. The simplest approach is to cut the interconnect up into rectangles and assume each rectangle has a resistance equal to the resistance per square of the interconnect material times the number of full and partial squares that will fit along the direction of current flow in the rectangle [5]. This scheme works whenever the direction of current flow is clear; however, for corners and intersections of interconnect the current flow is in fact quite complex. Figure 1.103 shows the kind of current flow that can occur in an interconnect section with complex geometry.

Modeling. To account for the effects of complex current flows the resistance of complex interconnect geometries must be determined by measurement or simulation. One simple empirical approach is to cut out sections of resistive material in the same shape as the interconnect shape to be modeled, and then

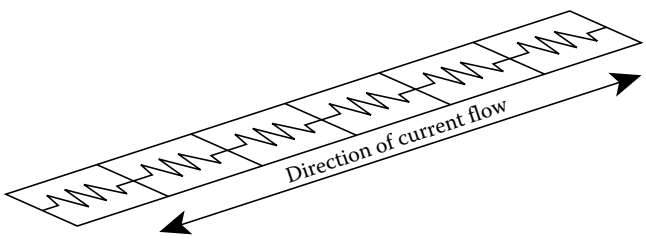

FIGURE 1.102 Determining the resistance of a length of interconnect. Each square has the same resistance regardless of size.

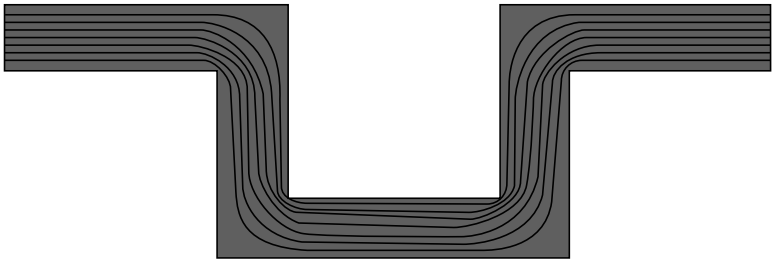

FIGURE 1.103 Current flow in a complex interconnect geometry.

measure the resistance. The resistance for other materials can be found by multiplying by the ratio of the respective resistances per square of the two materials.

Once the resistance has been found for a particular geometry it can be used for any linear scaling of that geometry. For most types of IC interconnect all complex geometries can be broken up into relatively few important subgeometries. If tables of the resistance of these subgeometries for various dimensions and connection patterns are obtained, the resistance of quite complex shapes can be accurately calculated by connecting the resistance of each subgeometry together and calculating the resistance of the connected resistances. This calculation can usually be performed quickly by replacing series and parallel connected resistor pairs with their equivalents. The process of breaking a complex geometry into subgeometries, constructing the equivalent connected resistance, and forming a single resistance for an interconnect section is illustrated in Figure 1.104.

Effects on circuits. The resistance of interconnect can have both parametric and catastrophic effects on circuit performance. Even small differences in the resistance on either input side of a differential amplifier can lead to increased offset voltage. Thus, when designing differential circuits care must be taken to make the interconnect identical on both input sides, as this ensures that the same resistance is present in both circuits.

The resistance of power supply interconnect can lead to both parametric errors in the voltages supplied and catastrophic failure due to oscillation. If power supply voltages are assumed to be identical in two parts of a circuit and, due to interconnect resistance, there is a voltage drop from one point to the next, designs that rely on the voltages being the same may fail. In high-gain and feedback circuits the resistance of the ground and power supply lines may become an unintentional positive feedback resistance which could lead to oscillation. Thus output and input stages for high-gain amplifiers will usually require separate ground and power supply interconnects. This ensures that no parasitic resistance is in a feedback path.

When using resistors provided in an IC process, the extra resistance provided by the interconnect may cause inaccuracies in resistor values. This would be most critical for small resistance values. The only solution in this case is to accurately compute the interconnect resistance. Since most resistance layers

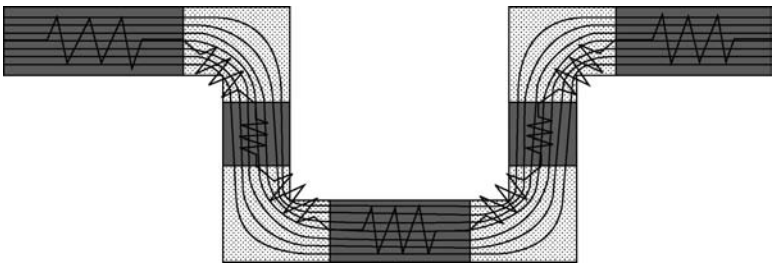

FIGURE 1.104 The process of breaking a complex geometry into subgeometries, constructing the equivalent connected resistance, and forming a single resistance for an interconnect section. In this example, only two subgeometries are used: a corner subgeometry and a basic rectangular subgeometry.

provided in analog IC processes are just a form of high resistivity interconnect, the methods described here for accurately computing the resistance of interconnect are also useful for predicting the resistance of resistors to be fabricated.

1.5.1.3 Parasitic Inductance

In high-speed ICs the inductance of long lines of interconnect becomes significant. In IC technologies that have an insulating substrate, such as gallium arsenide (GaAs) and silicon on insulator (SOI), reasonably high-performance inductive devices can be made from interconnect. In technologies with conductive substrates, resistive losses in the substrate restrict the application of interconnect inductance. High-frequency circuits are often tuned using interconnect inductance and capacitance (*LC*) to form a narrow bandpass filter or tank circuit, and *LC* transmission lines, or stubs, made from interconnect are useful for impedance matching. There is much similarity between this use of parasitic inductance and the design of microstripline-printed circuit boards. The major difference being that inductance does not become significant in IC interconnect until frequencies in the gigahertz are reached.

In order to make a good interconnect inductance, there are two requirements. First, there must not be any resistive material within range of the magnetic field of the inductance. If this occurs then induced currents flowing in the resistive material will make the inductor have high series resistance (low *Q* factor). This would make narrow bandwidth bandpass filters difficult to make using the inductance, and make transmission lines made from the interconnect lossy. The solution is to have an insulating substrate, or to remove the substrate from beneath the inductor.

The second requirement for large inductance is to form a coil or other device to concentrate the magnetic field lines. Within the confines of current IC manufacturing, spiral inductors, like that illustrated in Figure 1.105 are the most common method used to obtain useful inductances.

1.5.1.4 Transmission Line Behavior

Two types of transmission line behavior are important in ICs, *RC* transmission lines and *LC*/*RLC* transmission lines. For gigahertz operation inductive transmission lines are important. These can be lossy *RLC* transmission lines if a conductive substrate such as silicon is used, or nearly lossless *LC* transmission lines if an insulating substrate such as GaAs is used. The design of inductive transmission lines is very similar to designing microstripline-printed circuit boards. At lower frequencies of

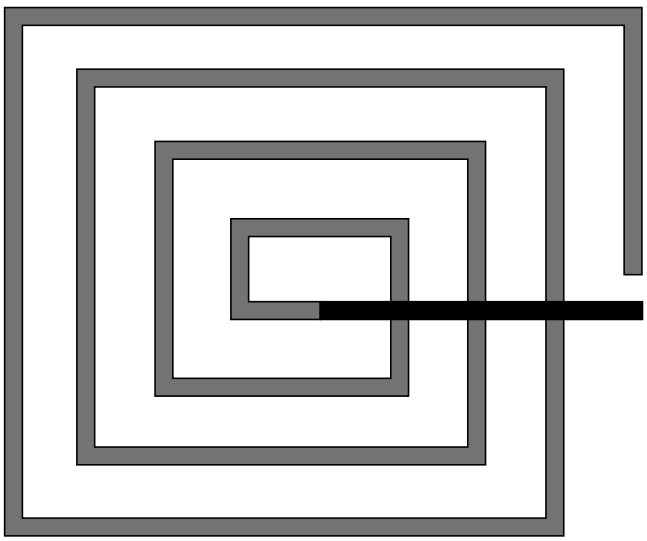

FIGURE 1.105 Spiral inductance used in insulated substrate ICs for gigahertz frequency operation.

10–1000 MHz resistive capacitive (*RC*) transmission lines are important for long low resistivity interconnect lines or short high resistivity lines.

RC transmission lines are of concern to analog circuit designers working in silicon ICs. When used correctly, an interconnect can behave as though it were purely capacitive in nature. However, when a higher resistivity interconnect layer, such as polysilicon or diffusion is used, the distributed resistance and capacitance can start to produce transmission line effects at relatively short distances. Similarly, for very long signal distribution lines or power supply lines, if they are not correctly sized, transmission line behavior ensues.

Physics. One method for modeling distributed transmission line interconnect effects is lumped equivalent modeling [6]. This method is useful for obtaining approximate models of complex geometries quickly, and is the basis of accurate numerical finite element simulation techniques. For analog circuit designers the conversion of interconnect layout sections into lumped equivalent models also provides an intuitive tool to understanding distributed transmission line interconnect behavior.

To be able to model a length of interconnect as a lumped *RC* equivalent, the error between the impedance of the interconnect when correctly treated as a transmission line, and when replaced with the lumped equivalent, must be kept low. If this error is *e*, then it can be shown that the maximum length of interconnect that can be modeled as a simple *RC T* or Π network is given in Equation 1.270. In the equation, *R* is the resistance per square of the particular type of interconnect used, *C* is the capacitance per unit area, and ω is the frequency of operation in radians per second.

$$D < \sqrt{\frac{3 \cdot e}{\omega \cdot R \cdot C}} \tag{1.270}$$

This length can be quite short. Consider the case of a polysilicon interconnect line in a 1.2 μm CMOS process that has a resistance per square of 40 Ω a capacitance per unit are of 0.1 fF/μm^2. For an error *e* of 10% the maximum line length of minimum width line that can be treated as a lumped T or Π network for various frequencies is given in Table 1.11. Longer interconnect lines than this must be cut up into lengths less than or equal to the length given by Equation 1.270.

Modeling. The accurate modeling of distributed transmission line effects in ICs is best performed with lumped equivalent circuits. These circuits can be accurately extracted by dissecting the interconnect geometry into lengths that are, at most, as long as the length given by Equation 1.270. These lengths are then modeled by either a *T* or Π lumped equivalent *RC* network. The extraction of the resistance and capacitance for these short interconnect sections can now follow the same procedures as were described in Sections 1.5.1.2 and 1.5.1.1. The resulting *RC* network is then an accurate transmission line model of the interconnect. Figure 1.106 shows an example of this process.

Effects on circuits. Several parametric and catastrophic problems can arise due to unmodeled transmission line behavior. Signal propagation delays in transmission lines are longer than predicted by a single lumped capacitance and resistance model of interconnect. Thus, ignoring the effects of transmission lines can result in slower circuits than expected. If the design of resistors for feedback networks

TABLE 1.11 The Maximum Length of Minimum Width Polysilicon Line That Can Be Modeled with a Single Lumped *RC T* or π Network and Remain 10% Accurate

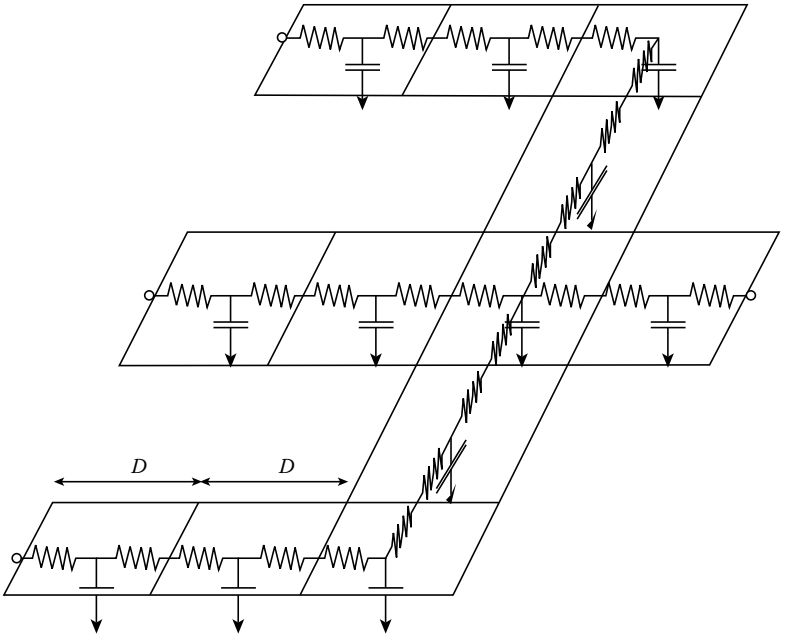

FIGURE 1.106 The extraction of an accurate *RC* transmission line model for resistive interconnect. The maximum allowable length D is computed from Equation 1.270.

results in long lengths of the resistive interconnect used to make the resistors, these resistors may in fact be *RC* transmission lines. The extra delay produced by the transmission line may well cause oscillation of the feedback loops using these resistors. The need for decoupling capacitors in digital and analog circuit power supplies is due to the *RC* transmission line behavior of the power supply interconnect. Correct modeling of the *RC* properties of the power distribution interconnect is needed to see whether fast power supply current surges will cause serious changes in the supply voltage or not.

1.5.1.5 Nonlinear Interconnect Parasitics

A number of types of interconnect can have nonlinear parasitics. These nonlinear effects are a challenge to model accurately because the effect can change with the operating conditions of the circuit. A conservative approach is to model the effects as constant at the worst likely value they can attain. This is adequate for predicting parameters, like circuit bandwidth, that need only exceed a specification value. If the specifications call for accurate prediction of parasitics then large nonlinear parasitics are generally undesirable and should be avoided.

Most nonlinear interconnect parasitics are associated with depletion or inversion of the semiconductor substrate. A diffusion interconnect is insulated from conducting substrates such as silicon by a reversed biased diode. This diode's depletion region width varies with the interconnect voltage and results in a voltage-dependent capacitance to the substrate. For example, the diffusion interconnect in Figure 1.107 has voltage-dependent capacitance to the substrate due to a depletion region. The capacitance value depends on the depletion region thickness, which depends on the voltage difference between the interconnect and the substrate.

$$C = C_0 \cdot \left(1 - \left(\frac{V_s}{\varphi_B}\right)\right)^M \tag{1.271}$$

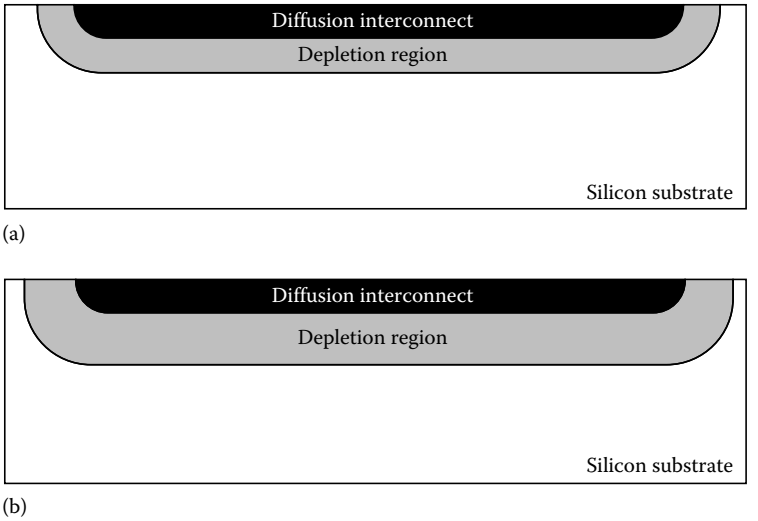

FIGURE 1.107 Diffusion interconnect has a voltage-dependent capacitance produced by the depletion region between the interconnect and the substrate. At low voltage difference between the interconnect and substrate (a), the capacitance is large. However, the capacitance decreases for larger voltage differences (b).

The typical equation for depletion capacitance is given in Equation 1.271. In this equation V_S is the voltage from the interconnect to the substrate, ϕ_B is the built-in potential of the semiconductor junction, M is the grading coefficient of the junction, while C_0 is the zero-bias capacitance of the junction. Since the capacitance is less than C_0 for reverse bias and the junction would not insulate for forward bias, we can assume that the capacitance is always less than C_0 and use C_0 as a conservative estimate of C. Because of the uncertainty in the exact structure of most semiconductor junctions φ_B and M are usually fit to measured capacitance versus voltage (CV) data.

Another common nonlinear parasitic occurs when metal interconnect placed over a conducting semiconductor substrate creates inversions at the semiconductor surface. This inversion layer increases the substrate capacitance of the interconnect and is voltage-dependent. To prevent this most silicon-IC manufacturers place an inversion-preventing implant on the surface of the substrate. The depletion between the substrate and n-type or p-type wells diffused into the substrate also creates a voltage-dependent capacitance. Thus use of the well as a high resistivity interconnect for making high value resistors will require consideration of a nonlinear capacitance to the substrate.

1.5.2 Pad and Packaging Parasitics

All signals and supply voltages that exit an IC must travel across the packaging interconnections. Just like the on-chip interconnect, the packaging interconnect has parasitic resistance, capacitance, and inductance. However, some of the packaging materials are significantly different in properties and dimension to those used in the IC, thus there are major differences in the importance of the various types of parasitics. Figure 1.108 is a typical packaged IC. The chief components of the packaging are the pads on the chip, the wire or bump bond used to connect the pad to the package, and then the package interconnect.

The pads used to attach wire bonds or bump bonds to ICs are often the largest features on an IC. The typical pad is 100 μm on a side and has a capacitance of 100 fF. In addition, protection diodes are often used on pads that will add a small nonlinear component to the pad capacitance.

The wire bonds that attach the pads to the package are typically very low resistivity and have negligible capacitance. Their major contribution to package parasitics is inductance. Typically, the

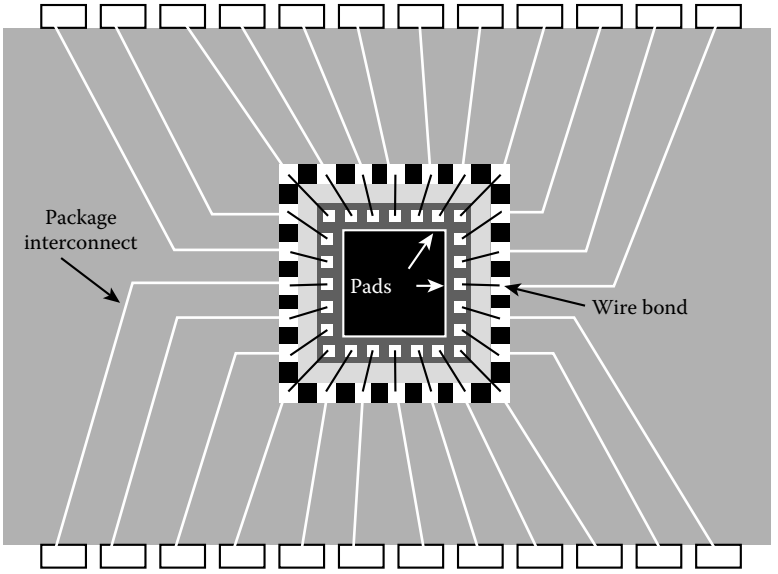

FIGURE 1.108 A packaged IC. The main sites of parasitics are the pad, bond, and package interconnect.

package interconnect inductance is greater than the wire bond inductance; however, when wire bonds are used to connect two ICs directly together, then the wire bond inductance is significant.

Often, the dominant component of package parasitics comes from the packaging interconnect itself. Depending on the package, there is inductance, capacitance to ground, and parallel line capacitance produced by this interconnect. Carefully made high-frequency packages do not exhibit much parallel line capacitance (at the expense of much capacitance to ground due to shielding), but in low-frequency packages with many connections this can become a problem.

Typical inductance and capacitance values for a high-speed package capable of output bandwidths around 5 GHz are incorporated into a circuit model for the package parasitics in Figure 1.109. When simulated with a variety of circuit source resistances (*RS*) this circuit reaches maximum bandwidth without peaking when the output resistance is 4 Ω. At lower output resistance, Figures 1.110 and 1.111 show that considerable peaking in the output frequency response occurs.

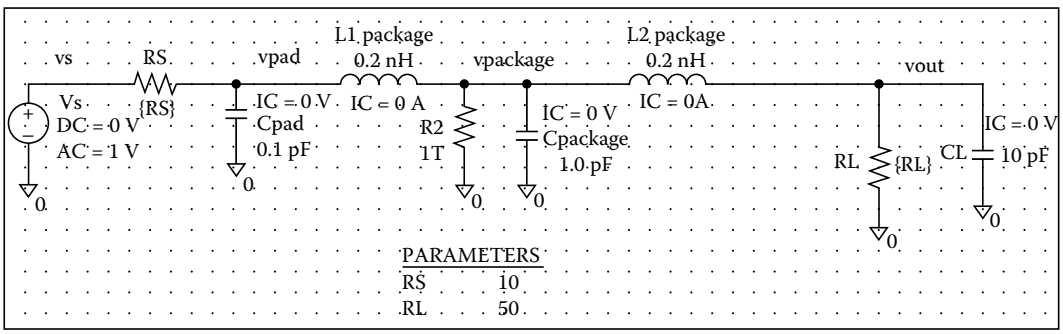

FIGURE 1.109 The circuit model of a high-frequency package output and associated parasitics. Cpad is the pad capacitance. L1package, Cpackage, R2, and L2package model the package interconnect. *RS* is the source resistance of the circuit. *RL* and *CL* are the external load.

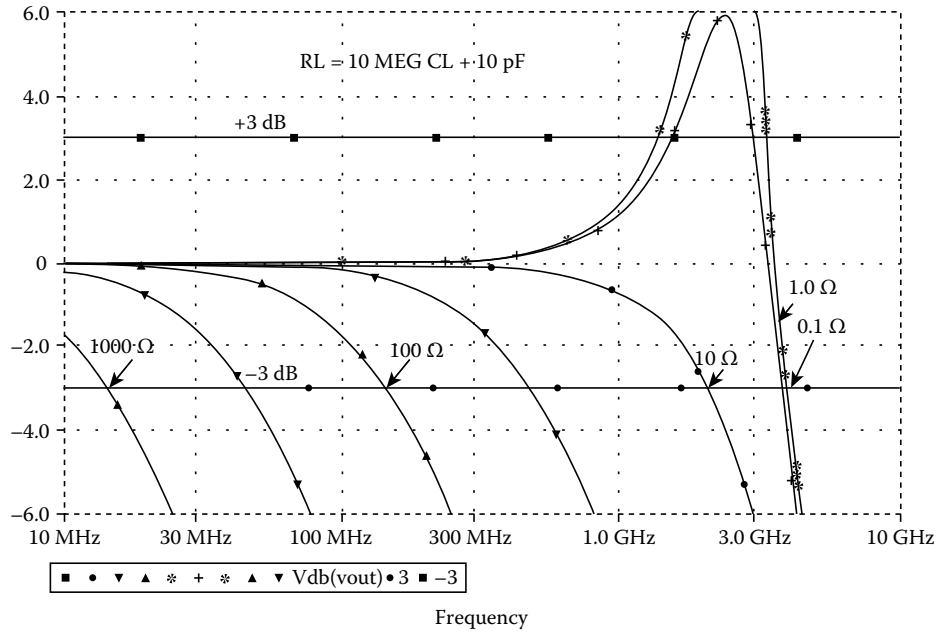

FIGURE 1.110 The PSPICE ac simulation of circuit in Figure 1.109 when the load resistance *RL* is 10 MΩ. This shows how the package inductance causes peaking for sufficiently low output resistance. In this case, peaking occurs for *RS* below 4 Ω and at about 2 GHz.

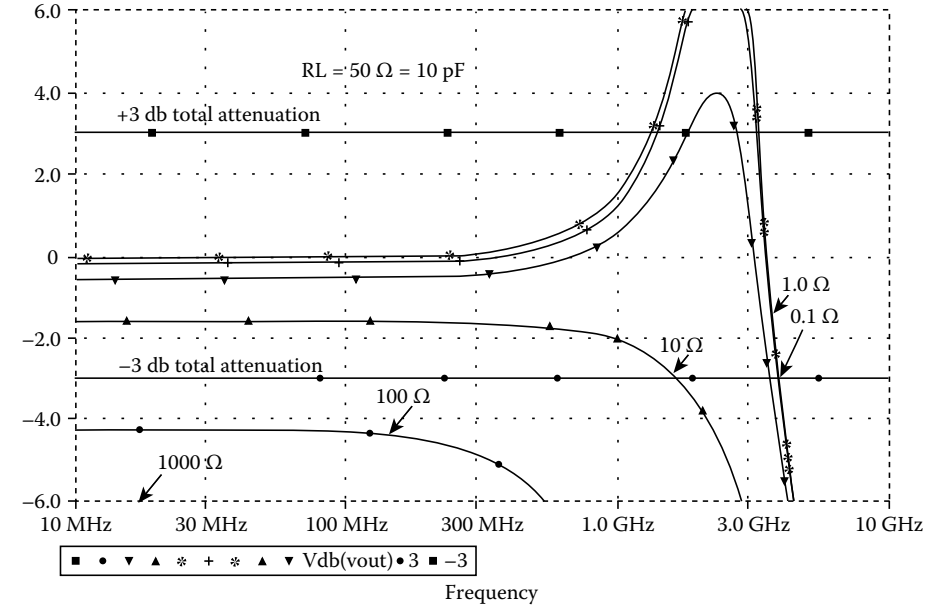

FIGURE 1.111 The PSPICE ac simulation of circuit in Figure 1.109 when the load is 50 Ω. The package inductance still causes peaking for *RS* below 4 Ω.

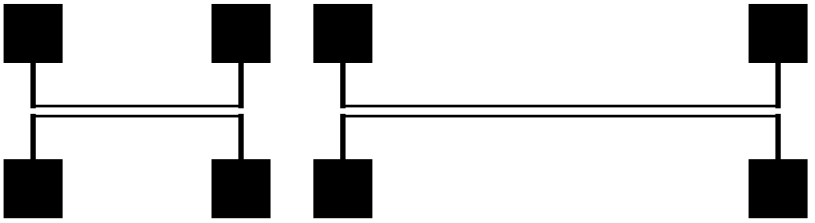

FIGURE 1.112 Test structures for measuring parallel line capacitance.

1.5.3 Parasitic Measurement

The major concern when measuring parasitics is to extract the individual parasitic values independently from measured data. This is normally achieved by exaggerating the effect that causes each individual parasitic in a special test structure, and then reproducing the structure with two or more different dimensions that will affect only the parasitic of interest. In this fashion, the effects of the other parasitics are minimized and can be subtracted from the desired parasitic in each measurement.

$$C_P = \frac{C_1 - C_2}{L_1 - L_2} \tag{1.272}$$

For example, to measure parallel line capacitance, the test structures in Figure 1.112 would be fabricated. These structures vary only in the length of the parallel lines. This means that if other parasitic capacitance ends up between the two signal lines used to measure the parasitic, then it will be a constant capacitance that can be subtracted from both measurements. The parallel line capacitance will vary in proportion to the variation of length between the two test structures. Thus the parallel line capacitance per unit length can be found from Equation 1.272. In this equation C_P is the parallel line capacitance per unit length, C_1 and C_2 are the capacitances measured from each test structure, and L_1 and L_2 are the length of the two parallel interconnect segments.

2.1 Bipolar Biasing Circuits

Kenneth V. Noren

Establishing bias currents and voltages for building blocks comprising an overall design is fundamental to the design of bipolar integrated circuits. These building blocks include single-stage and differential amplifiers, output stages, etc. Biasing often has a direct relationship to electrical characteristics, such as gain, signal-swing, slew-rate, etc., of the individual building blocks and hence to the overall design. Biasing circuits include current sources, voltage references, and level-shifters. Most often, it is desirable that the integrated circuit design be robust and independent of a variety of external factors that can affect circuit performance. These factors include variations in process parameters, supply voltage, and temperature. Efforts to improve the performance of current sources and voltage references have led to many refinements and developments that have started from simple beginnings. This section presents some of

the fundamental current sources and voltage references used for biasing in bipolar integrated circuit technologies and refinements of these circuits that have evolved over time.

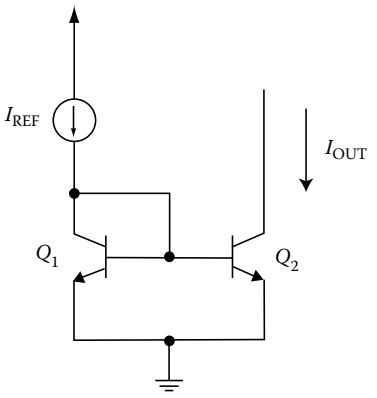

FIGURE 2.1 Simple current mirror.

2.1.1 Common Bipolar Junction Transistor (BJT) Biasing Circuits

2.1.1.1 Current Mirrors and Sources

The current mirror is a circuit that reproduces a reference current at one or more locations in larger circuit. A simple current mirror is depicted in Figure 2.1. Since $V_{BE1} = V_{BE2}$, $I_{OUT} \approx I_{REF}$, and the reference current I_{REF} is effectively mirrored to another location. In order to evaluate current mirrors and compare the properties of the many types of current mirrors to one another, we first define metrics for current mirrors and characteristics for an ideal current mirror. An ideal current mirror produces and output current that

1. Reproduces a reference current, exactly
2. Does not vary with loading (the output resistance [R_o] is infinite)
3. Is insensitive to process variations
4. Is insensitive to power supply variations
5. Is insensitive to temperature

2.1.1.1.1 Simple Current Mirror

The relationship between the output current and the reference current or the simple current mirror for matched transistors is

$$\frac{I_{OUT}}{I_{REF}} = \frac{1}{1 + (2/\beta)} \tag{2.1}$$

This equation does not include the effects of the early voltage, but does include the effects of nonzero base current often referred to as errors due to finite β. The error due to finite β results because I_{REF} must supply base current to Q_1 and Q_2. The key problem with this dependency of I_{OUT} on β is that β may vary from due to process variations, resulting in an I_{OUT} that varies due to process variations. Were it not for this dependency, I_{REF} could be adjusted to compensate for this and set I_{OUT} to a desired value. For $\beta \gg 2$, the fractional error is $-2/\beta$ percent.

A second error in I_{OUT} occurs due to finite output resistance. Performing a small-signal analysis for the circuit for Figure 2.1, it can be shown that the expression for R_o for the simple current source is equal to r_{o2}.

If the mirror in Figure 2.1 is configured with N output transistors and thus has N output currents, the transfer function becomes

$$\frac{I_{OUT}}{I_{REF}} = \frac{1}{1 + ((N+1)/\beta)} \tag{2.2}$$

2.1.1.1.2 Simple Current Mirror with Beta Helper

The β sensitivity of the simple current mirror can be improved by adding a third transistor to supply base current to Q_1 and Q_2 shown in Figure 2.2. Here, the base current of Q_1 and Q_2 is supplied by the emitter of Q_3 which draws the necessary current from I_{REF}, but reduced by a factor of $\beta + 1$. An analysis shows

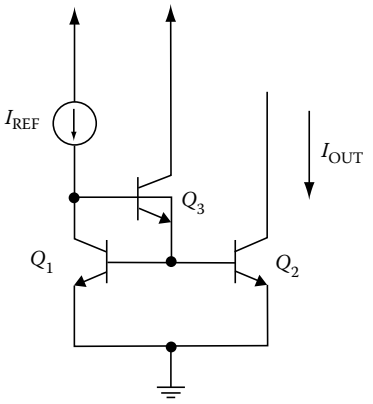

FIGURE 2.2 Simple current mirror with beta helper

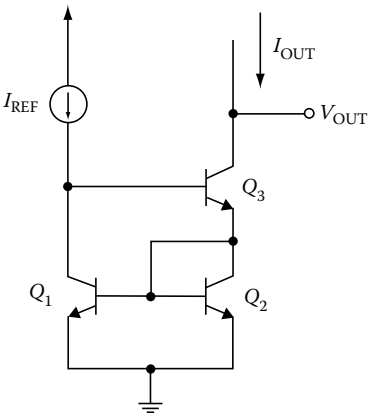

FIGURE 2.3 Wilson current mirror.

$$\frac{I_{OUT}}{I_{REF}} = \frac{1}{1 + (2/(\beta^2 + \beta))} \approx \frac{1}{1 + (2/\beta^2)} \tag{2.3}$$

This supports the argument that sensitivity to base current drain is reduced. It should be noted that the equation also depends on the betas of the transistors being matched as well. For $\beta \gg 2$, the fractional error is $-2/\beta^2$ percent. Thus, the fractional error is reduced by a factor of β. For this circuit $R_o = r_{o2}$, so there is no improvement in R_o.

2.1.1.1.3 Wilson Current Mirror

A current source that shows an improvement in R_o and has reduced β sensitivity is the Wilson current mirror shown in Figure 2.3 [1].

With this circuit, as with the simple current mirror with beta helper, the base current of Q_1 and Q_2 is supplied by emitter current of a third transistor, Q_3. A more rigorous analysis will show, neglecting the effects of the early voltage,

$$\frac{I_{OUT}}{I_{REF}} = \frac{1}{1 + (2/(\beta^2 + \beta))} \approx \frac{1}{1 + (2/\beta^2)} \tag{2.4}$$

For $\beta \gg 2$, the fractional error is $-2/\beta^2$. Thus, the fractional error is reduced by a factor of β.

The improvement in R_o is due to negative feedback present in the circuit due to the placement of Q_3. To see this, first consider the case for matched transistors and the effects of output voltage for all of the transistors, that an increase in V_{OUT} gives rise to an increase in output current. This, in turn, causes an increase in I_{C2}. Since Q_1 and Q_2 themselves form a simple current mirror, I_{C1} also increases which forces a decrease in I_{B3}, since I_{REF} is constant. This in turn reduces in I_{OUT}. A small-signal analysis to determine R_o shows

$$R_o \approx \frac{\beta}{2} r_o \tag{2.5}$$

R_o has been increased by a factor of $\beta/2$.

The Wilson current mirror can also be extended to N multiple outputs by placing additional transistors branches in parallel with Q_2 and Q_3. For this case, it can be shown that

$$\frac{I_{OUT}}{I_{REF}} = \frac{1}{N} \frac{1}{1 + (2/\beta^2)} \tag{2.6}$$

where N is the total number of output branches.

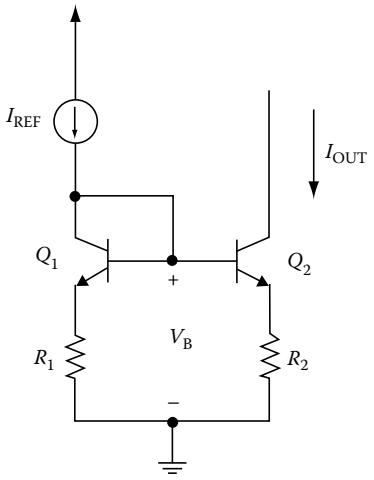

FIGURE 2.4 Simple current mirror with emitter degeneration.

2.1.1.1.4 Simple Current Mirror with Emitter Degeneration

Parameters and component values for fabricated devices usually exhibit deviation from some "nominal" value during the fabrication process. These variations may occur for across the die, from die-to-die, from wafer-to-wafer, or from lot-to-lot. An objective in designing circuits that are process insensitive is to minimize the effects of process variation. A good example of this is the simple current mirror with emitter degeneration shown in Figure 2.4. If I_{REF} and R_1 are such that the voltage drop across V_{BE1} is small in comparison, then the dominant voltage at V_B is approximately $I_{REF}R_1$. Likewise, if R_2 and I_{OUT} are such that the voltage drop across V_{BE2} can be neglected, then we have $I_{REF}R_1 \approx I_{OUT}R_2$ and

$$I_{OUT} = \frac{R_2}{R_1} I_{REF} \tag{2.7}$$

For the simple current mirror, neglecting β and considering the possibly of mismatched emitter areas, we have

$$I_{OUT} = \frac{A_2}{A_1} I_{REF} \tag{2.8}$$

Since resistors can be matched to ±0.1% and NPN matching for transistors can be as poor as ±1%, the current mirror with emitter degeneration is less susceptible to processing errors. The process insensitivity is made possible by having the relationship between I_{OUT} and I_{REF} dependent on resistor ratios.

2.1.1.1.5 Widlar Current Mirror

In bipolar integrated circuit design, it is sometimes desirable to create low currents levels, on the order of microamps, for example [2]. If either of the simple current mirrors or the Wilson current mirror is used, this has to be accomplished by creating a very small reference current and may require large values of resistors that may consume large amounts of area. The current mirror depicted in Figure 2.5 is capable of producing a small output current, from a nominal reference current and a reasonably sized resistor.

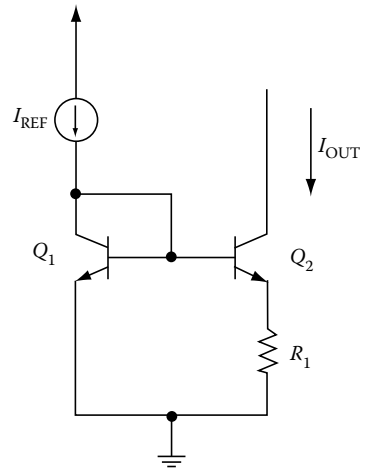

FIGURE 2.5 Widlar current mirror.

To analyze the circuit, recognize that I_{REF} is determines V_{BE1}. In the simple current mirror, all of V_{BE1} appears across V_{BE2}. In the Widlar current mirror, V_{BE1} is divided between the base–emitter junction of Q_2 and R_1, resulting in a smaller voltage for V_{BE2} than V_{BE1} and thus a smaller I_{OUT}. This suggests that with proper selection of R_1, the potential for generating very small currents exists. It can be shown, neglecting the effects of β, that

$$I_{OUT}R_1 = V_T \ln\left(\frac{I_{REF}}{I_{OUT}}\right) \tag{2.9}$$

where V_T is the thermal voltage.

For example, to create an I_{OUT} of 5 μA, from a reference of 1 mA, with $V_T = 26$ mV, we find $R_1 = 27$ kΩ. If the same 5 μA were desired from the simple current mirror, and we assume that the emitter areas of Q_1 and Q_2 are equal, we would need to generate a reference current of 5 μA. To do this, I_{REF} is replaced by a resistor, R_{REF}, tied to the positive supply voltage, V_{CC}, for example. Suppose for this example that V_{CC} is 5 V. Then, the voltage drop across R_{REF} is $V_{CC} - V_{BE}$. Taking $V_{BE} = 0.7$ V gives a value of $R_{REF} = (5 - 0.7)/5\mu = 860$ kΩ. This, of course, takes up much more chip real estate than for $R_1 = 27$ kΩ and is undesirable.

If the effects of β are included it is necessary to supply two base currents, though I_{B2} is less than I_{B1}. Equation 2.2 gives an upper bound for the error due to beta for the Widlar current mirror (the upper bound being the case where $I_{OUT} = I_{REF}$) and lower bound being $1/(1 + 1/\beta)$, supplying base current to only a single transistor. Thus, the errors due to base current drain are on the same order as that of the simple current mirror.

For the output resistance, R_1 provides negative feedback and thus increases the output resistance compared with that of the simple current mirror. It is identical to the increase in output resistance that results from emitter degeneration in a common-emitter amplifier. It can be verified that

$$R_o = (1 + g_m r_\pi R_1) r_o \tag{2.10}$$

2.1.1.1.6 Low-Bias Current Mirror

An alternative to the Widlar current source that also provides a low output current is the current source shown in Figure 2.6 [3,4]. Again, V_{BE1} is determined by I_{REF}. Applying Kirchhoff's voltage law,

$$V_{BE2} = V_{BE1} - I_{REF} R_1 \tag{2.11}$$

As with the Widlar current source voltage, the voltage V_{BE1} is divided between a resistor and the base emitter junction of Q_2, though in a less obvious manner. As a result, V_{BE2} must be smaller than V_{BE1} and effectively a fraction of I_{REF} is mirrored. A more exact equation that expresses the relationship between the output current and reference current can be derived from Equation 2.8, and this is

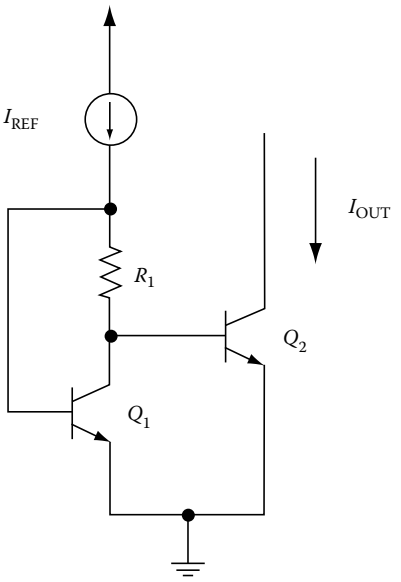

FIGURE 2.6 Current mirror for generating low-bias currents.

$$I_{OUT} = \frac{I_{REF}}{\exp(I_{REF} R_1 / V_T)} \tag{2.12}$$

or

$$R_1 = \frac{V_T \ln(I_{REF}/I_{OUT})}{I_{REF}} \tag{2.13}$$

In fact, this current source is capable of supplying even lower currents than the Widlar current source for a given I_{REF} and a lower bound for R_1. Consider the same example as was given for the Widlar current source. With $I_{REF} = 1$ mA, $I_{OUT} = 5$ μA, and $V_T = 26$ mV, we find that $R_1 = 137.75$ Ω. This is a substantial decrease in resistance from the Widlar current mirror example.

The price paid for this improvement is a reduced output resistance when compared to the Widlar current

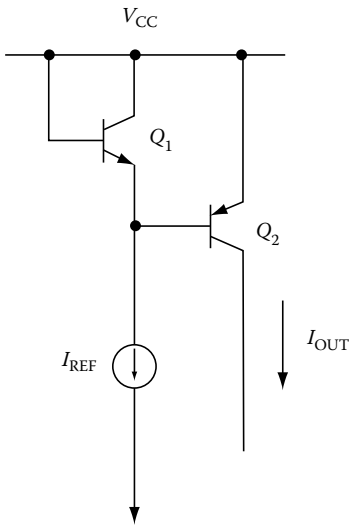

FIGURE 2.7 Current mirror for complementary bipolar design.

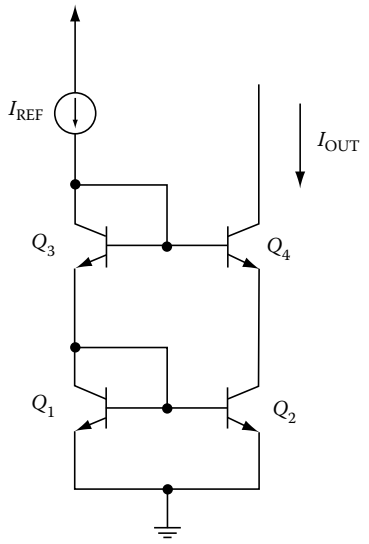

FIGURE 2.8 Cascode current mirror.

source. Negative feedback is not present in this topology and there are no improvements in output resistance when compared to the simple current mirror. For this current mirror, R_o is simply r_{o2}.

The basic current mirrors can be extended to complementary bipolar technology (CBT) as well. Figure 2.7 shows an example of a current mirror that can be found in a CBT. A problem that arises in the current mirrors used in bipolar technology results in the fact that PNP and NPN transistors have a different Gummel number [5]. This results in different base–emitter voltages (magnitudes) for equal collector currents. The effects of this can be deduced from Figure 2.7, where now ΔV_{BE} errors must be considered. Thus, care must be taken when biasing complementary bipolar designs. This issue of balancing and matching is a fundamental problem in this technology [5].

2.1.1.1.7 Cascode Current Mirror

The cascode current mirror is depicted in Figure 2.8. It derives its main advantage in an increased output resistance due to emitter degeneration as does the Widlar current source. In this case, r_{o2} replaces R_1 in the Widlar current source to provide the emitter degeneration. Though in theory the values of r_{o2} and R_1 may be on the same order, a large value for r_{o2} can be achieved using a transistor that takes up much less area than that of a resistor of the same value.

The complete expression for R_o is complicated. However, for the case where $I_{OUT} \approx I_{REF}$, the transistors are matched and $g_m r_o \gg 1$, $\beta \gg 2$, and $r_o \gg r_\pi$ (for any combination of transistors) the expression for the output resistance reduces to

$$R_o = \frac{\beta}{2} r_{o2} \tag{2.14}$$

2.1.1.1.8 V_{BE} Referenced Current Mirror

For many current mirrors, I_{REF} is determined by a resistor tied to the positive power supply. In the Widlar current mirror example, $I_{REF} = (V_{CC} - V_{BE})/R_{REF}$. The reference current is directly proportional to the supply voltage. In many situations, this is undesirable. One alternative is to replace V_{CC} by one of

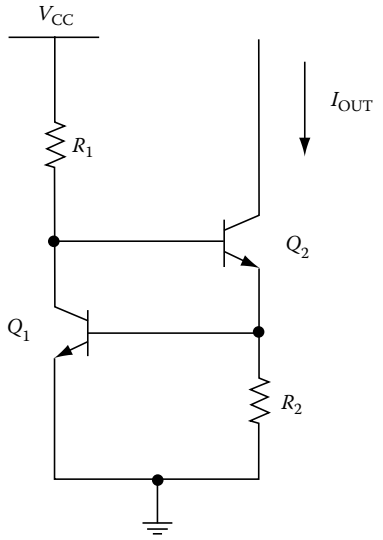

FIGURE 2.9 Current source that has reduced supply voltage dependency.

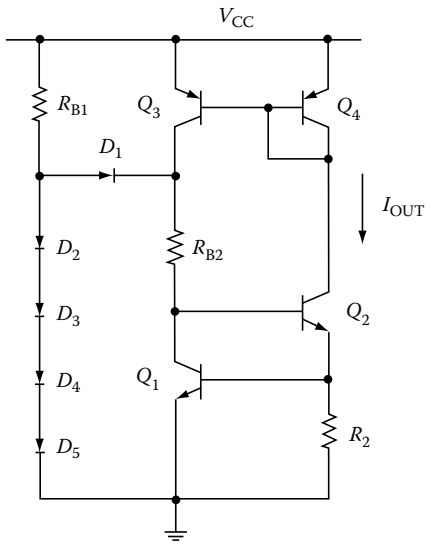

FIGURE 2.10 Self-biased V_{BE} referenced current source.

the many available circuits which provide a voltage reference that is independent of supply voltage. Another alternative is the V_{BE} referenced current mirror (Figure 2.9).

The basic principle of this current mirror is to establish a base–emitter voltage and to convert this voltage to a current using a resistor. Referring to Figure 2.9, the V_{BE} (V_{BE1}) drop is first established with V_{CC} and R_1. The voltage V_{BE1} and R_2 determines I_{OUT}. Neglecting finite betas for the transistors, this current is approximately equal to V_{BE1}/R_2. Since V_{BE1} is fairly constant, I_{OUT} is fairly constant. A complete derivation yields

$$I_{OUT} = \frac{V_T}{R_2} \ln\left(\frac{V_{CC}}{I_{S1}R_1}\right) \tag{2.15}$$

where I_{S1} is the saturation current of Q_1. Equation 2.13 shows the output current has a logarithmic variation with respect to V_{CC}, an improvement over the linear relationship found in other current mirrors.

2.1.1.1.9 Self-Biased V_{BE} Referenced Current Source

A self-biased V_{BE} referenced current source is depicted in Figure 2.10. Q_1, Q_2, Q_3, Q_4, and R_2 form the core of the current source. Q_1 and Q_2 form a V_{BE} referenced current mirror and the pair Q_3 and Q_4 form a simple current mirror. If current exists, then $I_{C1} = I_{C2}$, due to Q_3 and Q_4, and one valid solution to is $I_{C2} \approx V_{BE}/R_2$, independent of V_{CC}. However, a second valid solution is $I_{C2} = 0$ A (or practically, a value for I_{C2} on the order of leakage currents). For this reason, a start-up circuit is added to the circuit. D_{1-5}, R_{B1}, and R_{B2} form the start-up circuitry. If $I_{C1} = I_{C2} = 0$, the voltage at the cathode of D_1 is 0 V and D_1 turns on, injecting current into the core of the current source. Positive feedback in the circuit forces the current toward the condition where $I_{C2} \approx V_{BE}/R_2$. At some point, the voltage at the cathode of D_1 raises to a level that shuts D_1 off, thereby "disconnecting" the start-up circuitry from the current source core.

Once I_{C1} and I_{C2} have been established as a reference current for a larger circuit, the current can be mirrored to other parts of the circuit by placing transistors in parallel with Q_1 and Q_4, as shown with Q_5 and Q_6.

2.1.1.1.10 Self-Biased V_T Referenced Current Source

A second type of self-biased current source called self-biased V_T referenced current source is shown in Figure 2.11. In this circuit, Q_3 and Q_4 are current mirrors and force the condition that if current exists, then $I_{C1} = I_{C2}$. In general, the area of Q_2 (A_2) is set to be "N" times the area of Q_1 (A_1) and thus $I_{S2} = NI_{S1}$, where n is some integer. In practice, this is achieved by placing n transistors in parallel. This causes a difference in base–emitter voltages, $\Delta V_{BE} = V_{BE1} - V_{BE2} = nV_T \ln(N)$, and this difference is dropped across R_1. Thus,

$$I_{C1} = I_{C2} = \frac{nV_T \ln(N)}{R_1} \tag{2.16}$$

I_{C1} and I_{C2} can in turn be mirrored by placing transistors in parallel with Q_1 and Q_4 to form current mirrors.

2.1.1.2 Voltage References

Also fundamental to biasing in BJT circuits is the voltage reference. As with the current sources, we may define an ideal voltage source in order to have an adequate way of evaluating voltage references. An ideal voltage reference produces a voltage that

1. Does not vary with loading (zero output resistance)
2. Is insensitive to process variations
3. Is insensitive to power supply variations
4. Is insensitive to temperature

The simplest voltage reference is the zener diode reference, but it is well known that a zener diode exhibits temperature dependence and has a fairly high output resistance. Some of the modifications to a simple zener diode include placing a diode series with a zener, strings of diodes, and the common-collector stage. Figure 2.12 gives an example. Here it is assumed, but not always true, that V_{DZ} has a positive coefficient and V_{D1} has a negative temperature coefficient and provides some cancellation of the coefficients. Thus, this can produce a reference voltage that is insensitive to temperature. There are literally hundreds of deviations based on this fundamental principle.

A circuit that produces a voltage that is an arbitrary multiple of V_{BE} is the V_{BE} multiplier circuit shown in Figure 2.13. The circuit works on the principle that a current equal to V_{BE}/R_2 is generated and, neglecting base current, flows through R_1. Thus, the voltage across R_1 is $(V_{BE}/R_2)R_1$ and the total voltage can be written as

$$V_{REF} = \left(1 + \frac{R_2}{R_1}\right) V_{BE} \tag{2.17}$$

Many applications for biasing circuits demand that their performance remain constant through a wide range of temperatures. Thus, many circuits for temperature insensitive biasing have emerged. Ideally, a temperature insensitive output, voltage or current, would depend on a temperature insensitive element. Since all semiconductor components exhibit variation with temperature, most of the schemes for temperature independence involve some form of cancellation technique or compensation [6]. Instead of eliminating all of the sensitivity, the design techniques strive to minimize the errors. For example, a common solution is to place devices with positive temperature coefficients in series with devices with negative temperature coefficients, scaling some of these coefficients if necessary, to provide nearly zero sensitivity to temperature for an output is taken across the devices.

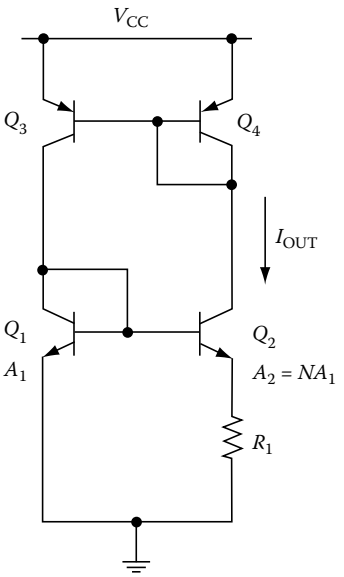

FIGURE 2.11 Self-biased VT referenced current source.

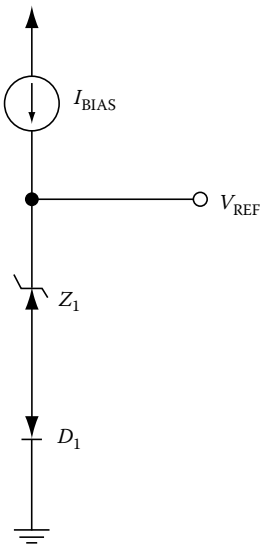

FIGURE 2.12 Zener-biased voltage reference.

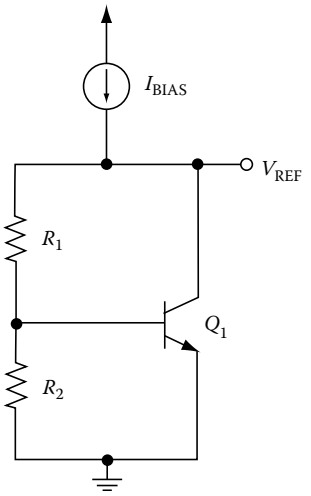

FIGURE 2.13 V_{BE} multiplier circuit.

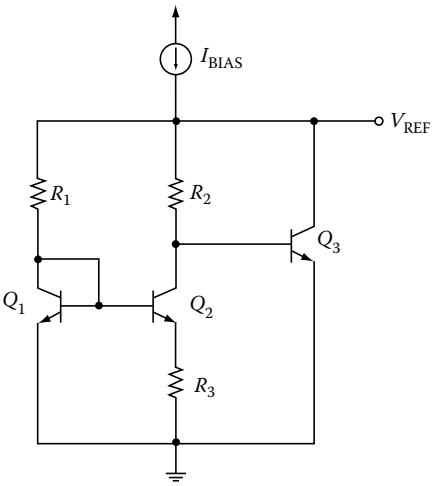

FIGURE 2.14 Simple bandgap reference.

A simple band-gap reference is depicted in Figure 2.14. Band-gap circuits also operate on a principle of cancellation of temperature coefficients. Generally, a voltage is developed which is a scaled value of V_T. This scaled value has a well-defined temperature coefficient which is the scaling constant times the temperature coefficient of V_T, which is positive. This voltage is added to a base–emitter voltage, which has a negative temperature coefficient. The scaling factor is chosen so that the sum of the temperature coefficients is zero. The output is then taken across the two voltages to produce a voltage with a temperature coefficient of approximately zero. Generally, the output voltage has the form

$$V_{REF} = V_{BE} + KV_T \tag{2.18}$$

If the temperature coefficient of V_{BE} is taken to be -2 mV/°C and the temperature coefficient of V_T is taken to be $k/q \approx +0.085$ mV/°C, this results in a value for K of about 23.52. This gives a value for V_{OUT} of about 0.7 V + 23.52(25.9 mV) = 1.3 V, close to the band-gap voltage of silicon, and gives rise to the nomenclature of band-gap references.

In the circuit in Figure 2.14, we assume that Q_1 and Q_2 operate at different current densities. This is done either by operating Q_1 and Q_2 at different collector current levels, with matched emitter areas, or by operating them at the same collector currents with emitter areas being mismatched. A voltage ΔV_{BE} is developed across R_3 and then current through R_3 and R_2, negecting the effects of β, is $\Delta V_{BE}/R_3$. This gives $V_{REF} = \Delta V_{BE} R_2/R_3 + V_{BE3}$. Since $\Delta V_{BE} = V_T \ln(J_1/J_2)$, this gives the constant K as being $R_2/R_3 \ln(J_1/J_2)$.

An improved band-gap reference is depicted in Figure 2.15. This reference forms a basic building block for several commercial voltage references. In this circuit, I_{C1} and I_{C2} are forced to be equal by the high-gain

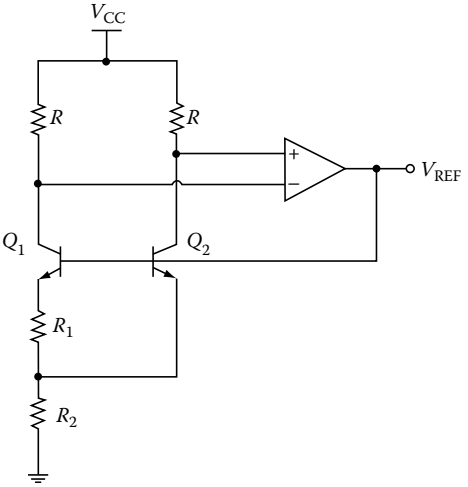

FIGURE 2.15 Improved bandgap reference.

amplifier operating with negative feedback. The current densities of Q_1 and Q_2 are made unequal by sizing the emitter areas of Q_1 and Q_2 differently. In this case, $A_1 = NA_2$. This means $\Delta V_{BE} = nV_T\ln(I_{S1}/I_{S2}) = V_T\ln(N)$. The voltage drop across R_2 is $\Delta V_{BE}R_2/R_1$. Finally, $V_{REF} = V_{BE} + V_T\ln(n)R_2/R_1$. Thus, in this case, $K = R_2/R_1\ln(n)$.

There is a wealth of information available in the literature on current sources and voltage references. Further depth into bias circuits behavior is provided in the accompanying references for this section.

2.2 Canonic Cells of Linear Bipolar Technology

John Choma, Jr. and J. Trujillo

2.2.1 Introduction

The circuit configurations of linear signal processors realized in bipolar technology are as diverse as the system operating requirements that these circuits are designed to satisfy. Despite topological diversity, most practical open-loop linear bipolar circuits are derived from interconnections of surprisingly few basic subcircuits. These subcircuits include the diode-connected bipolar junction transistor (BJT), the common-emitter amplifier, the common-base amplifier, the common-emitter–common-base cascode, the emitter follower, the Darlington connection, and the balanced differential pair. Because these open-loop subcircuits underpin linear bipolar circuit technology, they are rightfully termed the ''canonic cells'' of linear bipolar circuit design.

By examining the low-frequency performance characteristics of the canonic cells of linear bipolar technology, this section achieves two objectives. First, the forward gain, the driving point input resistance, and the driving point output resistance are cataloged for each canonic circuit. This information produces Thévenin and Norton I/O port equivalent circuits that expedite the analysis and design of multistage electronics. Second, the forthcoming work establishes a basis for prudent circuit design in that all analytical results are studied by highlighting the attributes and uncovering the limitations of each cell. The understanding that resultantly accrues paves the way toward systematic design procedures that yield optimal circuit architectures capable of circumventing observed subcircuit shortcomings.

2.2.2 Small-Signal Model

The fundamental tool exploited in the analyses that follow is the low-frequency small-signal equivalent circuit of a BJT shown in Figure 2.16a. This equivalent circuit, which applies to NPN and PNP discrete component and monolithic transistors, is derived from the low-frequency, large-signal NPN BJT model

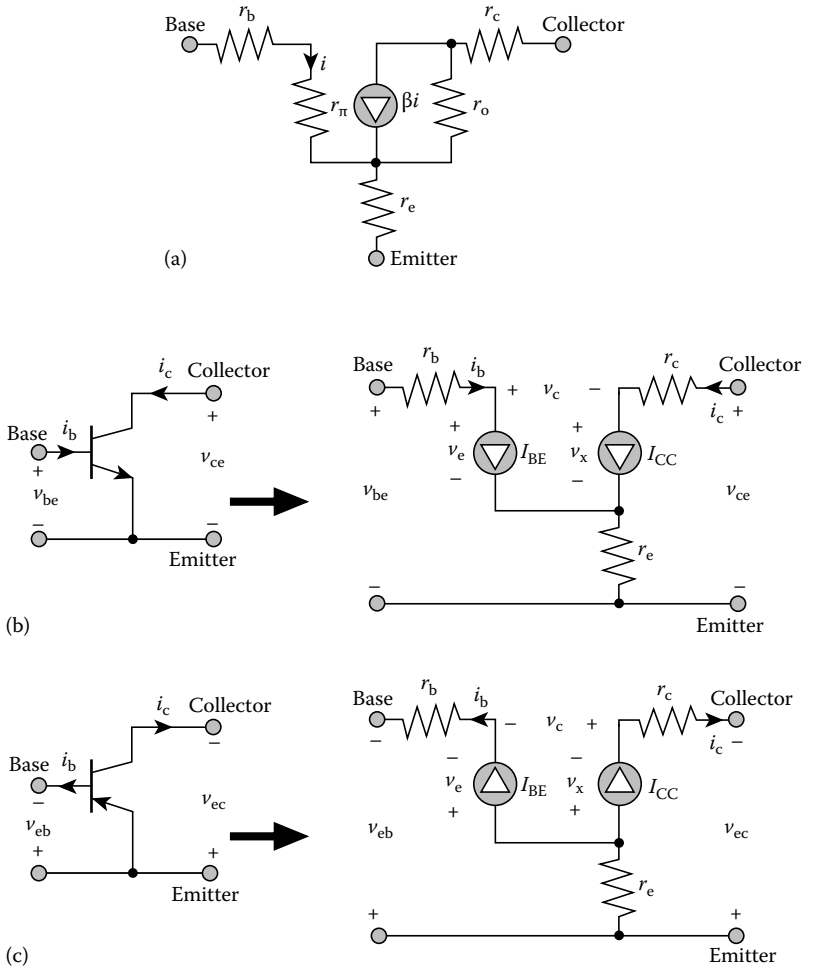

FIGURE 2.16 (a) Low-frequency, small-signal model of a BJT. (b) Low-frequency, large-signal model of an NPN BJT. (c) Low-frequency, large-signal model of a PNP BJT.

offered in Figure 2.16b [1,2]. As is depicted in Figure 2.16c, the PNP large-signal transistor model is topologically identical to its NPN counterpart. The only difference between the two models is a reversal in the direction of all controlled current sources and branch currents and a reversal in polarity of all assigned branch and port voltages.

The large-signal models in Figure 2.16b and c are simplified to reflect transistor biasing that assures nominally linear device operation for all values of applied input signal voltages. A necessary condition for linear operation is that the internal emitter–base junction voltage v_e be at least as large as the threshold voltage, say v_γ, of the junction for all time, that is,

$$v_e(t) \geq v_\gamma \quad \text{for all time } t \tag{2.19}$$

For silicon transistors, v_γ is typically in the neighborhood of 700–750 mV. A second condition underlying transistor operation in its linear regime is that the internal base–collector junction voltage v_c is never positive, that is,

$$v_c(t) \leq 0 \quad \text{for all time } t \tag{2.20}$$

In the models of Figure 2.16b and c, r_b represents the "effective base resistance" of a BJT, r_c is its net "internal collector resistance," and r_e is the net "internal emitter resistance." All three resistances, and particularly r_b, decrease monotonically with increasing quiescent base and collector currents, I_{BQ} and I_{CQ}, respectively [3,4]. The collector resistance also decreases with increase in the intrinsic collector–emitter voltage v_x. Large base, collector, and emitter resistances conduce reduced circuit gain, diminished gain-bandwidth product, and increased electrical noise. In view of these observations and in the interest of formulating a mathematically tractable analysis that produces conservative estimates of bipolar circuit performance, these resistances are usually interpreted as constants equal to their respective low-current, low-voltage values.

In a monolithic fabrication process, unacceptably large internal device resistances can be reduced by exploiting the fact that r_b, r_c, and r_e are inversely proportional to the emitter–base junction injection area. This area is a designable parameter chosen to ensure that the transistor in question conducts the proper density of collector current. Unfortunately, the engineering price potentially paid for a reduction of device resistances through increase in junction area is circuit response speed, since the capacitances associated with transistor junctions are directly proportional to device injection area.

The current I_{BE} in Figure 2.16b and c is given approximately by

$$I_{BE} = \frac{A_E J_S}{\beta_F} e^{v_e/n_f V_T} \tag{2.21}$$

where

A_E is the aforementioned emitter–base junction area
J_S is the density of transistor saturation current
β_F is the forward short-circuit current transfer ratio
n_f is the injection coefficient of the emitter–base junction
v_e is the internal junction voltage serving to forward bias the emitter–base junction

and

$$V_T = \frac{kT_j}{q} \tag{2.22}$$

is the Boltzmann voltage. In the last expression, k is Boltzmann's constant [1.38 (10^{-23}) J/K], T_j is the absolute temperature of the emitter–base junction, and q is the magnitude of electron charge [1.6 (10^{-19}) C].

The current I_{CC} is derived from [5]

$$I_{CC} = A_E J_S e^{v_e/n_f V_T} \left(1 - \frac{I_{CC}}{I_{KF}}\right)\left(1 + \frac{v_x}{V_{AF}}\right) \tag{2.23}$$

where

I_{KF}, which is proportional to A_E, is the "forward knee current" of the transistor [6]
V_{AF}, which is independent of A_E, is the "forward Early voltage" [7]

Note that the base current i_b is the current I_{BE}, while the collector current i_c is I_{CC}. Thus, the "static common-emitter current" gain (often referred to as the "DC beta"), h_{FE}, of a BJT is

$$h_{FE} = \frac{i_c}{i_b} = \frac{I_{CC}}{I_{BE}} = \beta_F \left(1 - \frac{i_c}{I_{KF}}\right)\left(1 + \frac{v_x}{V_{AF}}\right) \tag{2.24}$$

which is functionally dependent on both the collector current and the intrinsic collector–emitter voltage.

Unlike the base, collector, and emitter resistances, the resistance r_π in the small-signal model of Figure 2.16a is not an ohmic branch element. It is a mathematical resistance that arises from the Taylor series expansion of the current I_{BE} about the "quiescent-operating point," or "Q-point" of the transistor. In particular, r_π, which is known as the "emitter–base junction diffusion resistance," derives from

$$\frac{1}{r_\pi} = \left.\frac{\partial I_{BE}}{\partial v_e}\right|_Q \tag{2.25}$$

where it is understood that the indicated derivative is evaluated at the Q-point of the device. This Q-point is unambiguously defined by the "zero signal, or static," values of the base current I_{BQ}, the collector current I_{CQ}, and the internal collector–emitter voltage V_{XQ}. Using Equations 2.21 and 2.24, and the fact that $i_b + I_{BE}$,

$$r_\pi = \frac{h_{FE} n_f V_T}{I_{CQ}} \tag{2.26}$$

The inverse dependence of r_π on quiescent collector current renders r_π large at low collector current biases.

Similarly, r_o, the "forward Early resistance," derives from

$$\frac{1}{r_o} = \left.\frac{\partial I_{CC}}{\partial v_x}\right|_Q \tag{2.27}$$

It can be shown that

$$r_o = \frac{V_{XQ} + V_{AF}}{I_{CQ}\left(1 - \frac{I_{CQ}}{I_{KF}}\right)} \tag{2.28}$$

Like r_π, r_o is also large for low-level biasing.

Finally, the parameter β, which is the "low-frequency small-signal common-emitter short-circuit current gain" (often more simply referred to as the "AC beta") of the transistor, is

$$\beta = g_m r_\pi \tag{2.29}$$

where g_m, the "forward transconductance" of a BJT is

$$g_m = \left.\frac{\partial I_{CC}}{\partial v_e}\right|_Q \tag{2.30}$$

From Equations 2.23, 2.24, 2.26, and 2.29,

$$\beta = h_{FE}\left(1 - \frac{I_{CQ}}{I_{KF}}\right) \tag{2.31}$$

To the extent that $I_{CQ} \ll I_{KF}$, β is nominally independent of both Q-point collector current and emitter–base junction injection area.

2.2.3 Single-Input–Single-Output Canonic Cells

2.2.3.1 Diode-Connected Transistor

The simplest of the single-input–single-output, or "single-ended" canonic cells for linear bipolar circuits is the "diode-connected transistor" offered in Figure 2.17a. This transistor connection emulates the volt–ampere characteristics of a conventional PN junction diode. It can therefore be used in rectifier, voltage regulator, dc level shifting, and other applications that exploit conventional diodes. But unlike a conventional PN junction diode, the diode-connected transistor proves especially useful in current mirror biasing schemes. These and other similar circuits require that the base–emitter terminal voltage, v, of the diode track the base–emitter terminal voltage of a second, presumably identical transistor, over wide variations in junction-operating temperatures.

If the voltages dropped across the internal base, collector, and emitter resistances are small, the intrinsic emitter–base junction voltage, v_e, is approximately the indicated terminal voltage, v. Moreover, the intrinsic base–collector junction voltage, v_c, is essentially zero. It follows that for $v > v_\gamma$, the transistor in the diode connection operates in its linear regime.

In the subject diagram, the terminal voltage v is depicted as a superposition of a static voltage, V_Q, and a signal component, v_s. The resultant diode current, i, is a superposition of a quiescent current, I_Q, and a signal current, i_s. The quiescent components of diode voltage and current arise from static power supplied to the diode circuit to ensure that the diode-connected device operates in its linear regime. On the other hand, the signal components are established by a time-varying signal applied to the input port of the circuit in which the diode-connected transistor is embedded. In order to achieve reasonably linear processing of the applied input signal, the value of V_Q must be such as to ensure that $v = V_Q + v_s > v_\gamma$ for all values of the time-varying signal voltage v_s. Since v_s can be positive or negative at any instant of time, the requirement $V_Q + v_s > v_\gamma$ mandates that the amplitude of v_s be sufficiently small.

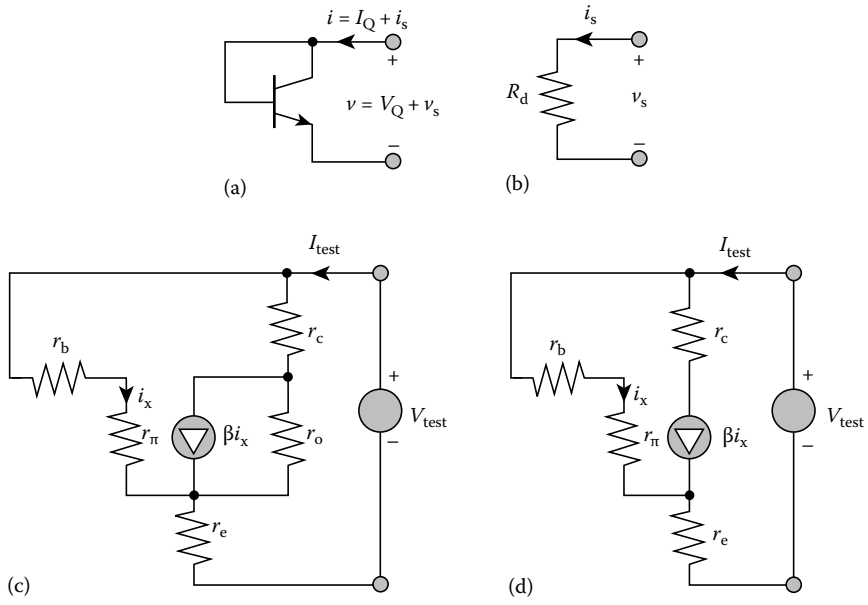

FIGURE 2.17 (a) Diode-connected BJT. (b) The small-signal equivalent circuit of the diode in (a). (c) Low-frequency, small-signal model of the diode-connected transistor in (a). The ratio V_{test}/I_{test} is the small-signal resistance R_d presented at the terminals of the diode-connected transistor. (d) The model in (c) approximated for the case of very large Early resistance.

The immediate impact of the small-signal condition corresponding to the linearity requirement $V_Q + v_s > v_\gamma$ is that the small-signal volt–ampere characteristics of the diode are linear. And since the diode is a two-terminal element, these characteristics can be modeled at low-signal frequencies by a simple resistance, say R_d, as suggested by the single-element macromodel offered in Figure 2.17b. The resistance in the latter figure can be determined by using the small-signal transistor model of Figure 2.16a to construct the small-signal equivalent circuit of the diode-connected transistor shown in Figure 2.17c. In this figure, the ratio of the test voltage, V_{test}, to the test current, I_{test}, is the desired resistance, R_d. A straightforward KVL analysis confirms that

$$R_d = \frac{V_{test}}{I_{test}} = r_e + \frac{(r_o + r_c) \| (r_b + r_\pi)}{1 + \frac{\beta r_o}{r_o + r_c + r_b + r_\pi}} \tag{2.32}$$

Typically, r_o is 25 kΩ or larger, r_c is smaller than 75 Ω, r_b is of the order of 100 Ω, and r_π is in the range of 1 kΩ for a minimal geometry device. It follows that $r_o \gg (r_c + r_b + r_\pi)$, and R_d can be approximated as

$$R_d \approx r_e + \frac{r_b + r_\pi}{\beta + 1} \tag{2.33}$$

Note that this terminal resistance is of the order of the low tens of ohms. For example, if $r_b = 100$ Ω, $r_\pi = 1.2$ kΩ, $r_e = 1$ Ω, and $\beta = 100$, $R_d = 13.9$ Ω. It is instructive to note that the approximation, $r_o \gg (r_c + r_b + r_\pi)$, collapses the model in Figure 2.17c to the structure in Figure 2.17d, from which Equation 2.33 follows immediately.

A variation of the diode scheme is the so-called V_{BE} "multiplier" depicted in Figure 2.18a. This circuit finds extensive use in regulator and level shifting applications that require either a series interconnection of more than one diode or a circuit branch voltage drop whose requisite value is a nonintegral multiple of the base–emitter terminal voltage of a single diode.

The circuit under consideration establishes a static terminal voltage, V_Q, whose value is a designable multiple of the static base–emitter terminal voltage, V_{BEQ}. To confirm this contention, observe that for static operating conditions, V_Q is

$$V_Q = R_Y(I_Q - I_{CQ}) + V_{BEQ} \tag{2.34}$$

where the voltage component V_{BEQ} of the net base–emitter terminal voltage v_{be} is

$$V_{BEQ} = R_X \left[I_Q - \left(\frac{h_{FE} + 1}{h_{FE}} \right) I_{CQ} \right] \tag{2.35}$$

The current, I_{CQ}, is the static component of the net collector current, i_c, and h_{FE} is the collector current to base current transfer ratio defined by Equation 2.24. An elimination of I_{CQ} from the foregoing two expressions leads to

$$V_Q = \left(1 + \frac{\alpha_{FE} R_Y}{R_X} \right) V_{BEQ} + \left(\frac{R_Y}{h_{FE} + 1} \right) I_Q \tag{2.36}$$

where

$$\alpha_{FE} = \frac{h_{FE}}{h_{FE} + 1} \tag{2.37}$$

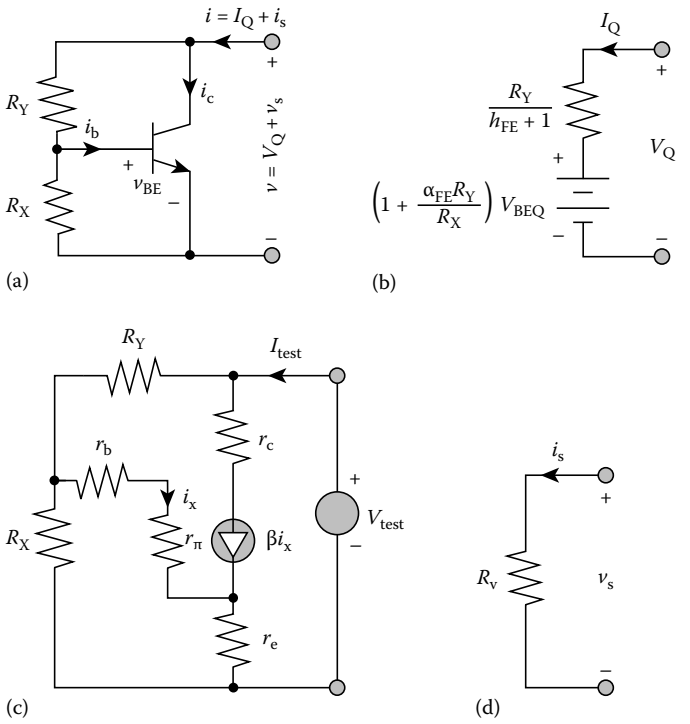

FIGURE 2.18 (a) Schematic diagram of V_{BE} multiplier. (b) DC macromodel of the multiplier in (a). (c) Low-frequency small-signal equivalent circuit of the Y_{BE} multiplier. (d) The small-signal equivalent resistance at the terminals of the V_{BE} multiplier.

is known as the ''static common-base current gain'' (often referred to as the ''DC alpha'') of a BJT. Equation 2.36 suggests that the static electrical behavior of the V_{BE} multiplier approximates a battery, whose voltage is controllable by the resistive ratio R_Y/R_X. The internal resistance of this effective battery is inversely dependent on $(h_{FE} + 1)$, and is therefore small. The macromodel in Figure 2.18b reflects the foregoing electrical interpretation. Note the for $R_Y = 0$ and R_X infinitely large, the circuit in Figure 2.18a collapses to the diode-connected transistor of Figure 2.17a, and V_Q understandably reduces to V_{BEQ}, the quiescent base–emitter terminal voltage of a diode-connected transistor.

For $V_Q + v_s > v_\gamma$, the transistor in the V_{BE} multiplier operates linearly. Accordingly, the pertinent small-signal terminal characteristics emulate a resistance, say R_V, which can be determined by applying the model of Figure 2.16a to the circuit in Figure 2.18a. The resultant equivalent circuit, simplified to reflect the realistic assumption of large r_o, is shown in Figure 2.18c while Figure 2.18d postulates the small-signal macromodel. An analysis of the circuit in Figure 2.18c reveals that

$$R_v \approx R_X \| R_d + R_Y \left[1 - \frac{\alpha R_X}{R_X + R_d}\right] \tag{2.38}$$

where

$$\alpha = \frac{\beta}{\beta + 1} \tag{2.39}$$

is the "low-frequency, small-signal, common-base, short-circuit current gain" (more simply referred to as the "ac alpha") of the transistor, and R_d is the resistance given by Equation 2.32. For $R_Y = 0$, $R_X = \infty$ reduces R_v to the expected result, $R_v \approx R_d$. Note further that for $\beta \gg 1$ (which makes $\alpha \approx 1$) and $R_d \gg R_X$, R_v is essentially the small-signal resistance presented at the terminals of a diode-connected transistor.

2.2.3.2 Common-Emitter Amplifier

The most commonly used single-ended canonic gain cell is the "common-emitter amplifier," whose NPN and PNP AC schematic diagrams are shown in Figure 2.19a and b, respectively. The AC schematic diagram delineates only the signal paths of a circuit. Thus, the biasing subcircuits required for linear operation of the transistors are not shown, thereby affording topological and analytical simplification. This simplification is accomplished without loss of engineering generality, for the results produced by an analysis of the AC schematic diagram reveal all salient performance traits of the common-emitter configuration.

The common-emitter amplifier is distinguished by the facts that signal is applied to the base of the transistor, and the resultant response is extracted as either the voltage, V_{OS}, or the current, I_{OS}, at the collector port. The effective load resistance terminating the collector to ground is indicated as R_{LT}, while the signal source is represented as a traditional Thévenin equivalent circuit. Alternatively, a Norton representation of the input source can be used, with the understanding that the Norton equivalent signal current, say I_{ST}, is simply the ratio of the Thévenin signal voltage, V_{ST}, to the Thévenin source resistance, R_{ST}.

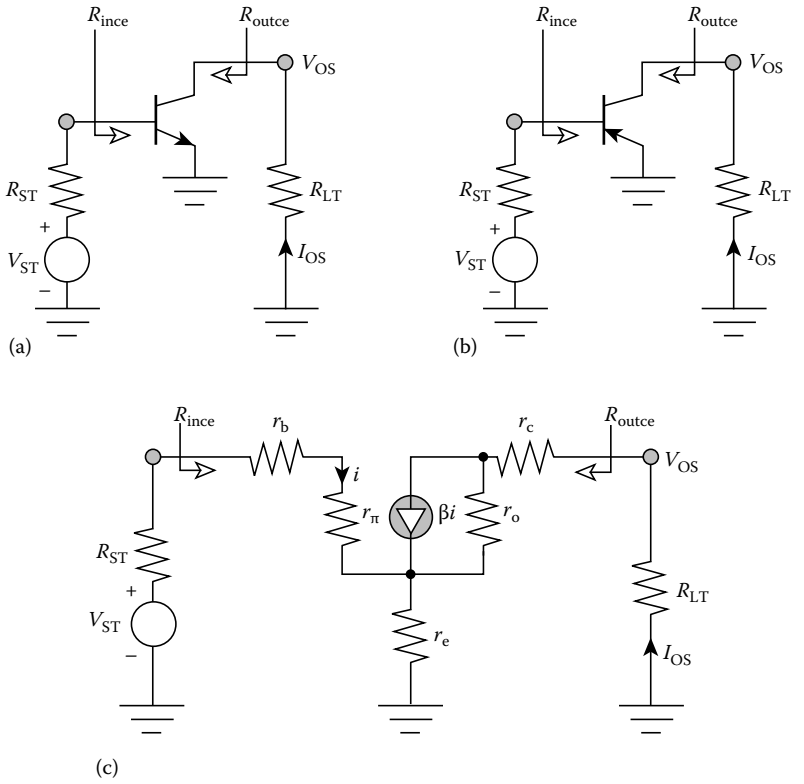

FIGURE 2.19 (a) AC schematic diagram of an NPN common-emitter amplifier. (b) AC schematic diagram of a PNP common-emitter amplifier. (c) Small-signal, low-frequency equivalent circuit of the common-emitter amplifier.

The common-emitter amplifier is capable of large magnitudes of voltage and current gains, moderately large input resistance, and very large driving point output resistance. An analytical confirmation of these contentions begins by drawing the small-signal equivalent circuit of the amplifier. This structure is given in Figure 2.19c and is valid for either the NPN or the PNP versions of the amplifier. An analysis of the small-signal model yields a voltage gain,

$A_{vce} = V_{OS}/V_{ST}$, of

$$A_{vce} = -\left\{\frac{(\beta - (r_e/r_o))(r_o/(r_o + r_c + r_e + R_{LT}))R_{LT}}{R_{ST} + r_b + r_\pi + ((\beta r_o/(r_o + r_c + R_{LT})) + 1)[r_e \| (r_o + r_c + R_{LT})]}\right\} \tag{2.40}$$

This relationship can be simplified by exploiting the fact that the internal resistance r_e of a transistor is small. Thus, $\beta \gg r_e/r_o$ and $r_e \gg (r_o + r_c + R_{LT})$, thereby implying

$$A_{vce} \approx -\frac{\beta_{eff} R_{LT}}{R_{ST} + r_b + r_\pi + (\beta_{eff} + 1)r_e} \tag{2.41}$$

where

$$\beta_{eff} \triangleq \beta\left[\frac{r_o}{r_o + r_c + R_{LT}}\right] \tag{2.42}$$

is an attenuated version of the AC beta for the utilized transistor. This effective beta approximates β itself, since $r_o \gg (r_c + R_{LT})$ is typical.

In concert with earlier arguments, Equation 2.41 confirms a diminished magnitude of gain for large internal device resistances. Note also that phase inversion, as inferred by the negative sign in either Equation 2.40 or 2.41 prevails between the Thévenin source voltage, V_{ST}, and the voltage signal response, V_{OS}. Finally, observe that large magnitudes of voltage gain are possible in the common-emitter orientation when β_{eff} is sufficiently large.

The driving point input resistance, R_{ince}, of the common-emitter amplifier can be determined as the ratio V_x/I_x for the test structure depicted in Figure 2.20a. It is easily shown that

$$R_{ince} = r_b + r_\pi + (\beta_{eff} + 1)[r_e \| (r_o + r_c + R_{LT})] \tag{2.43}$$

Since $r_e \ll (r_o + r_c + R_{LT})$, Equation 2.43 collapses to

$$R_{ince} \approx r_b + r_\pi + (\beta_{eff} + 1)r_e \tag{2.44}$$

Similarly, the driving point output resistance, R_{outce}, is derived as the V_x/I_x ratio of the equivalent circuit offered in Figure 2.20b. In particular,

$$R_{outce} = r_c + r_e \| (r_\pi + r_b + R_{ST}) + \left(\frac{\beta r_e}{r_e + r_\pi + r_b + R_{ST}} + 1\right) r_o \tag{2.45}$$

Since the model resistance r_π varies inversely with collector bias current, R_{ince} is moderately large when the common-emitter transistor is biased at low currents. On the other hand, R_{outce} is very large since Equation 2.45 confirms $R_{outce} > r_o$.

When the foregoing results are simplified to reflect the practical special case of a very large forward Early resistance, r_o, the cumbersome small-signal equivalent circuit of Figure 2.19c reduces to a ''small-signal macromodel'' useful for design-oriented circuit analysis of multistage amplifiers. To this end, note that a large r_o produces a driving point common-emitter input resistance that is independent of the

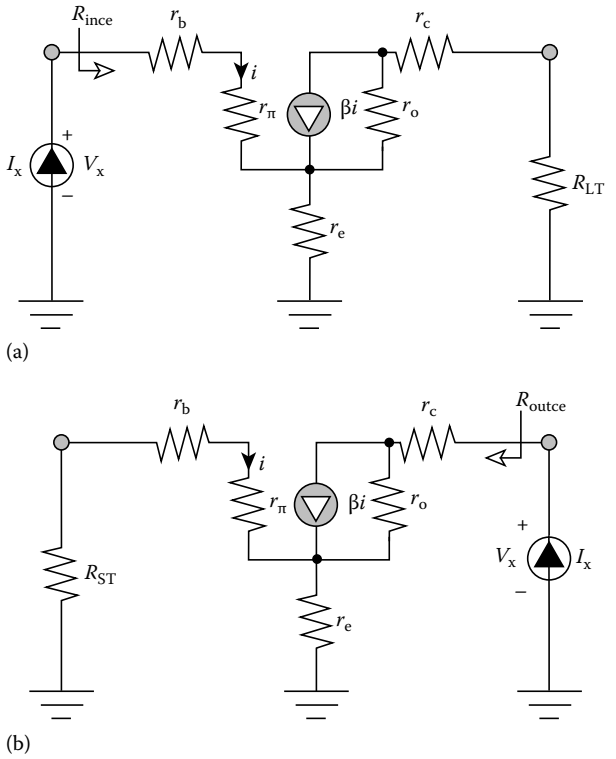

FIGURE 2.20 (a) Small-signal test structure used to determine the driving point input resistance of the common-emitter amplifier. (b) Small-signal test structure used to determine the driving point output resistance of the common-emitter amplifier.

terminating load resistance. Such independence implies no internal feedback from the output to input ports. It follows that the small-signal volt–ampere characteristics at the input port of a common-emitter amplifier can be modeled approximately by a simple resistance of value, R_{ince}, as defined by Equation 2.44. On the other hand, the large driving point output resistance R_{outce} suggests that a prudent output port model of a common-emitter stage is a Norton equivalent circuit. The Norton, or short-circuit, output current is proportional to the applied input signal voltage, V_{ST}, as depicted in Figure 2.21a. Alternatively, it can be expressed as a proportionality of the Norton input signal current, I_{ST}, as suggested in Figure 2.21b. In the former figure, the Norton current is

$$G_{fce}V_{ST} = \lim_{R_{LT}\to 0} I_{OS} = \lim_{R_{LT}\to 0}\left(-\frac{V_{OS}}{R_{LT}}\right) = \lim_{R_{LT}\to 0}\left(-\frac{A_{vce}V_{ST}}{R_{LT}}\right) \tag{2.46}$$

Subject to the assumption of large r_o,

$$G_{fce} = \lim_{R_{LT}\to 0}\left(-\frac{A_{vce}}{R_{LT}}\right) \approx \frac{\beta}{R_{ST} + r_b + r_\pi + (\beta+1)r_e} \tag{2.47}$$

Recalling Equation 2.29, this effective forward transconductance of the amplifier can be expressed in terms of the transconductance, g_m, of the transistor utilized in the amplifier. Specifically,

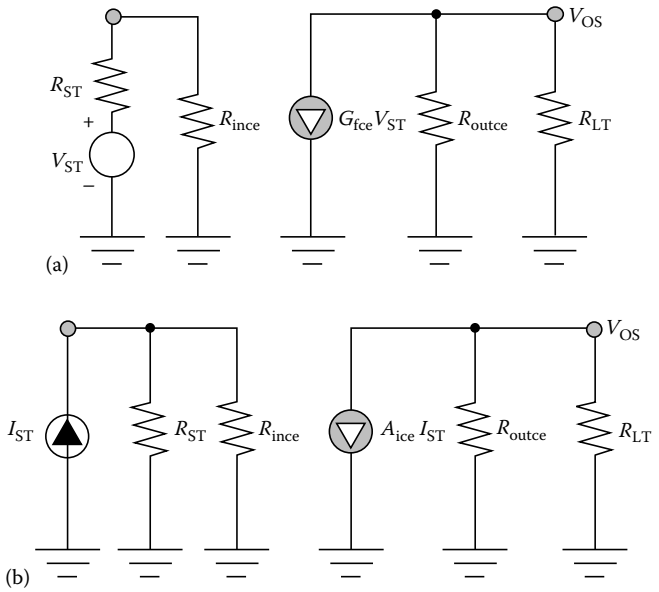

FIGURE 2.21 (a) Small-signal macromodel of a common-emitter amplifier in which the Norton output port circuit uses a voltage-controlled current source. (b) Small-signal macromodel of a common-emitter amplifier in which the Norton output port circuit uses a current-controlled current source.

$$G_{fce} \approx \frac{g_m}{1 = g_m r_e + ((r_e + r_b + R_{ST})/r_\pi)} \tag{2.48}$$

In the macromodel of Figure 2.21a, R_{outce} is very large by virtue of large r_o. Accordingly, the parallel combination of R_{outce} and R_{LT} is essentially R_{LT}, thereby implying an approximate common-emitter voltage gain of

$$A_{vce} \approx -G_{fce}R_{LT} \tag{2.49}$$

For the alternative macromodel in Figure 2.21b, the Norton current is

$$A_{ice}I_{ST} = A_{ice}\left(\frac{V_{ST}}{R_{ST}}\right) = \lim_{R_{LT}\to 0} I_{OS} = G_{fce}V_{ST} \tag{2.50}$$

Since $V_{ST} = R_{ST}I_{ST}$, it follows that A_{ice} is, for large r_o,

$$A_{ice} = G_{fce}R_{ST} \approx \beta\left[\frac{R_{ST}}{R_{ST} + r_b + r_\pi + (\beta + 1)r_e}\right] \tag{2.51}$$

Note that the Norton current proportionality A_{ice}, which is, in fact, the approximate ratio of the indicated output current, I_{OS}, to the Norton source current, I_{ST}, in the common-emitter configuration, is always smaller than β.

Example 2.1

Transistor Q_1 in the amplifier depicted in Figure 2.22a is fundamentally a common-emitter configuration since input signal is applied to its base terminal and the output voltage signal response is extracted at its

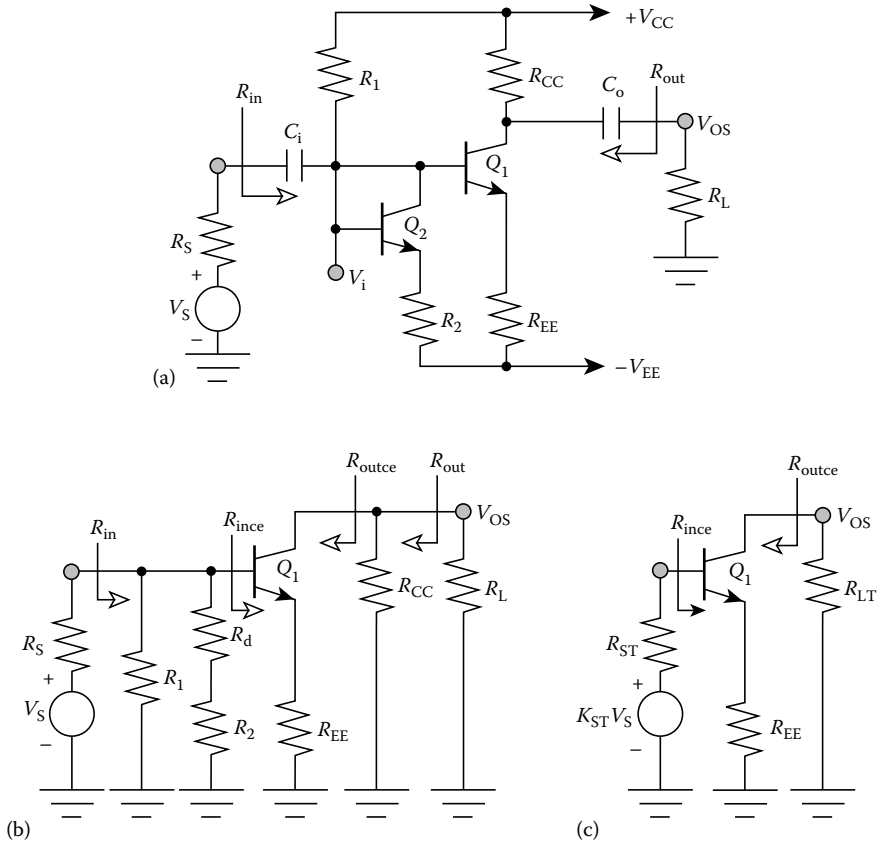

FIGURE 2.22 (a) Common-emitter amplifier with capacitively coupled input and output signal ports. (b) AC schematic diagram of the amplifier in (a). (c) Simplified AC schematic diagram of the amplifier in (a).

collector. The amplifier uses coupling capacitors C_i and C_o at its input and output ports. The input coupling capacitor, C_i, blocks the flow of static current in the source signal branch consisting of the series interconnection of the voltage, V_S, and the Thévenin source resistance, R_S. Accordingly, C_i, precludes R_S from affecting the biasing of both transistors used in the amplifier. Similarly, the output coupling capacitor, C_o, blocks the flow of static current in the external load resistance, R_L. Thus, both C_i and C_o can be viewed as open circuits for dc considerations. But simultaneously, these capacitors can be rendered transparent for AC situations by choosing them sufficiently large so that they emulate short circuits at the lowest frequency, say f_l, of signal-processing interest. In this problem, it is tacitly assumed that C_i and C_o, which are perfect DC open circuits, behave as good approximations of AC short circuits.

The subject amplifier utilizes a diode-connected transistor (Q_2) for temperature compensation of the static collector current conducted by transistor Q_1. For simplicity, assume that these two transistors have identical small-signal parameters of $r_b = 90\ \Omega$, $r_c = 55\ \Omega$, $r_\pi = 970\ \Omega$, $r_o = 42\ k\Omega$, and $\beta = 115$. Let the indicated circuit parameters be $R_1 = 2.2\ k\Omega$, $R_2 = 1.3\ k\Omega$, $R_{EE} = 75\ \Omega$, $R_{CC} = 3.9\ k\Omega$, $R_L = 1.0\ k\Omega$, and $R_S = 300\ \Omega$. Assuming that these circuit variables ensure linear operation of both devices, determine the small-signal voltage gain, $A_v = V_{OS}/V_S$, the driving point input resistance, R_{in}, and the driving point output resistance, R_{out}, of the amplifier. Finally, calculate the requisite minimum values of the input and output coupling capacitors, C_i and C_o, such that the lowest frequency f_l of interest is 500 Hz.

Solution

1. The first step of the solution process entails drawing the AC schematic diagram of the subject amplifier. By casting this diagram in the form of the canonic cell shown in Figure 2.19a, the gain and resistance expressions provided above can be exploited directly to assess the small-signal performance of the circuit at hand. Such a solution tack maximizes design-oriented understanding by avoiding the algebraic tedium implicit to an analysis of the entire small-signal equivalent circuit of the amplifier.

   To the foregoing end, observe that transistor Q_2 operates in its linear regime as a diode. It can therefore be viewed as the two terminal resistance R_d, given by Equation 2.32 or 2.33. Since the Early resistance is large, the latter expression can be used to arrive at $R_d = 10.64\ \Omega$.

   Since the power supply voltage, V_{EE}, is presumed ideal in the sense that it contains no signal component, the resultant series combination of R_d and R_2 returns base of transistor Q_1 to ground, as depicted in Figure 2.22b. Similarly, R_1 appears in shunt with the series interconnection of R_d and R_2, since V_{CC}, like V_{EE}, is also presumed to be an ideal constant (zero signal component) source of voltage. The AC schematic diagram of the input port is completed by noting that the AC short-circuit nature of the coupling capacitance C_i effectively connects the Thévenin representation of the signal source directly between the base of Q_1 and ground.

   At the output port of the amplifier, R_{CC} connects between the collector and ground since, as already exploited, V_{CC} is an AC short circuit. Moreover, the external load resistance, R_L, shunts R_{CC}, as shown in Figure 2.22b, because C_o behaves as an AC short circuit. The AC schematic diagram is completed by inserting the emitter degeneration resistance R_{EE} as a series element between ground and the emitter of transistor Q_1.
2. The diagram in Figure 2.22b can be straightforwardly collapsed to the simplified topology of Figure 2.22c. In the latter circuit, the effective load resistance, R_{LT}, is

$$R_{LT} = R_{CC} \| R_L = 795.9\ \Omega$$

   At the input port, the Thévenin resistance seen by the base of Q_1 is

$$R_{ST} = R_1 \| (R_d + R_2) \| R_S = 219.7\ \Omega$$

   while the corresponding Thévenin signal voltage can be expressed as $K_{ST}V_S$, where the voltage divider K_{ST} is

$$K_{ST} = \frac{R_1 \| (R_d + R_2)}{R_1 \| (R_d + R_2) + R_S} = 0.733$$

   The implication of this calculation is that, insofar as the active transistor Q_1 is concerned, the biasing resistances R_1 and R_2, cause a loss of more than 25% of the applied input signal.
3. The resultant AC schematic diagram in Figure 2.22c is virtually identical to the canonic topology in Figure 2.19a. Indeed, if the circuit resistance R_{EE} is absorbed into Q_1, where it appears in series with the internal emitter resistance r_e, the diagram is identical to the AC schematic diagram of the canonic common-emitter cell. Since $(r_e + R_{EE}) = 76.5\ \Omega$ is better than 560 times smaller than the resistance sum, $(r_o + r_c + R_{LT}) = 42.85\ \text{k}\Omega$, and $\beta = 115$ is more than 63,000 times larger than the resistance ratio $(r_e + R_{EE})/r_o = 0.00182$, the simplified expression in Equation 2.41 can be used to evaluate the voltage gain $V_{OS}/K_{ST}V_S$ in Figure 2.22c. From Equation 2.42, the effective small-signal beta is $\beta_{eff} = 112.7$. Then, with r_e replaced by $(r_e + R_{EE}) = 76.5\ \Omega$. Equation 2.41 gives

$$A_{vce} = \frac{V_{OS}}{K_{ST}V_S} = -8.99\ \text{V/V}$$

   It follows that the actual voltage gain of the amplifier in Figure 2.22a is

$$A_v = \frac{V_{OS}}{V_S} = K_{ST}A_{vce} = -6.59 \text{ V/V}$$

A better design, in the sense of achieving an adequate desensitization of circuit transfer characteristics with respect to parametric uncertainties, entails the use of a slightly larger emitter degeneration resistance R_{EE} selected to ensure that $(\beta_{eff}+1)(r_e+R_{EE}) \approx \beta_{eff} R_{EE} \gg (R_{ST}+r_b+r_\pi)$. For such a design, Equation 2.41 produces

$$A_v \approx -\frac{K_{ST}R_{LT}}{R_{EE}}$$

which is nominally independent of transistor parameters.

4. With r_e replaced by $(r_e+R_{EE}) = 76.5\ \Omega$, Equation 2.44 gives for the input resistance seen looking into the base of transistor Q_1 in Figure 2.22c, $R_{ince} = 9.76\ \text{k}\Omega$. It follows that the driving point input resistance seen by the source circuit in Figure 2.22b is

$$R_{in} = R_1 \| (R_d + R_2) \| R_{ince} = 757.6\ \Omega$$

5. The output resistance, R_{outce}, seen looking into the collector of transistor Q_1 in the diagram of Figure 2.22c is derived from Equation 2.45. With r_e replaced by $(r_e+R_{EE}) = 76.5\ \Omega$, $R_{outce} = 2.49\ \text{M}\Omega$. The resultant driving point output resistance seen by the load circuit in Figure 2.22b is

$$R_{out} = R_{CC} \| R_{outce} = 3894\ \Omega$$

The circuit output resistance is only a scant 6 Ω smaller than the collector biasing resistance R_{CC}, owning to the large value of R_{outce}. In turn, the value of the latter resistance is dominated by the last term on the right-hand side of Equation 2.45, which is proportional to the large forward Early resistance, r_o.

6. The input coupling capacitance, C_i, can be calculated with the help of the input port macromodel of Figure 2.23a. In this model, the subcircuit to the right of C_i in Figure 2.22a is replaced by its Thévenin equivalent circuit, which consists of the driving point input resistance, R_{in}, calculated previously. The voltage transfer function of this input port is

$$\frac{V_i(j\omega)}{V_S(j\omega)} = \left(\frac{R_{in}}{R_{in}+R_S}\right)\left[\frac{j\omega(R_{in}+R_S)C_i}{1+j\omega(R_{in}+R_S)C_i}\right]$$

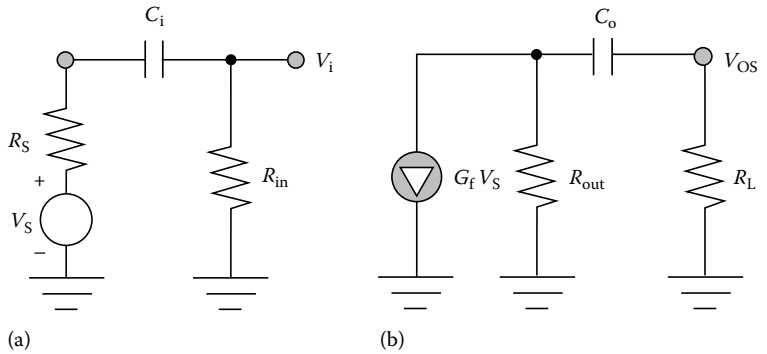

FIGURE 2.23 (a) Input port macromodel used in the calculation of the input coupling capacitor C_i. (b) Output port macromodel used to calculate the output coupling capacitor C_o.

An inspection of the foregoing relationship confirms that the dynamical effect of C_i on the voltage transfer function response is minimized if $\omega(R_{in} + R_s)C_i \gg 1$. At $\omega = 2\pi f_l$, the value of C_i that makes the left-hand side of this inequality equal to one is $C_i = 0.30$ μF. Observe that at $\omega_l(R_{in} + R_S)C_i = 1$,

$$\left|\frac{V_i(j\omega_1)}{V_S(j\omega_1)}\right| = \left(\frac{R_{in}}{R_{in} + R_S}\right)\left|\frac{j}{1+j}\right| = \frac{1}{\sqrt{2}}\left(\frac{R_{in}}{R_{in} + R_S}\right)$$

that is the magnitude of the input port voltage transfer function is a factor of the square root of two, or 3 dB, below the transfer function value realized at signal frequencies that are significantly higher than f_l. If this 3 dB attenuation is acceptable, $C_i = 0.30$ μF is appropriate to the design requirement.

7. The output coupling capacitance, C_o, is calculated analogously by exploiting the macromodel concepts overviewed in Figure 2.21a. To this end, the output port macromodel is offered in Figure 2.23b, where the effective forward transconductance, G_f, is such that $-G_f(R_{out}||R_L) = A_V$, as calculated in step 3. The voltage gain is seen to be

$$A_v(j\omega) = \frac{V_{OS}(j\omega)}{V_S(j\omega)} = -[G_f(R_{out}\|R_L)]\left[\frac{j\omega(R_{out} + R_L)C_o}{1 + j\omega(R_{out} + R_L)C_o}\right]$$

which has an algebraic form that is similar to the foregoing transfer relationship for the amplifier input port Thus, C_o is

$$C_o \geq \frac{1}{2\pi f_l(R_{out} + R_L)} = 0.065\ \mu F$$

Since the 0.30 μF input capacitor and the 0.065 μF output capacitor establish identical input and output port left-half-plane poles at the same frequency (f_1), the resultant attenuation at f_1 is actually larger than 3 dB. If this enhanced attenuation is unacceptable, the smaller of the two coupling capacitances can be made larger by a factor of three or so, thereby translating the associated pole frequency downward by a factor of three. In the present case, a plausible value of C_o is $C_o \geq (3)(0.065\ \mu F) = 0.2\ \mu F$.

It should be noted that the requisite two coupling capacitances are orders of magnitude too large for monolithic realization. Accordingly, if the subject amplifier is an integrated circuit, C_i and C_o are necessarily off-chip elements.

Example 2.2

When very large magnitudes of voltage gains are required, the output port of a common-emitter configuration can be terminated in an active load, as opposed to the passive resistive load encountered in the preceding example. Consider, for example, the complementary, NPN–PNP transistor amplifier whose schematic diagram appears in Figure 2.24a. The subcircuit containing transistors Q_1 and Q_2 is identical to that of the amplifier in Figure 2.22a. Indeed, for the purpose of this example, let the resistances, R_1, R_2, R_{EE}, and R_S, as well as small-signal parameters of transistors Q_1 and Q_2, remain at the values respectively stipulated for them in the preceding example. In the present diagram, the PNP transistor Q_3, along with its peripheral biasing resistances R_3, R_4, and R_5, supplants the resistance R_{CC} in the previously addressed common-emitter unit. Since no signal is applied to the base of Q_3, the subcircuit consisting of Q_3, R_3, R_4, and R_5 serves only to supply the appropriate biasing current to the collector of transistor Q_1. To the extent that this static current is invariant with temperature and the voltage signal response, V_{os}, established at the collector of Q_1, the Q_1 load circuit functions as a nominally constant current source. As a result, the effective load resistance, indicated as R_L in the subject figure,

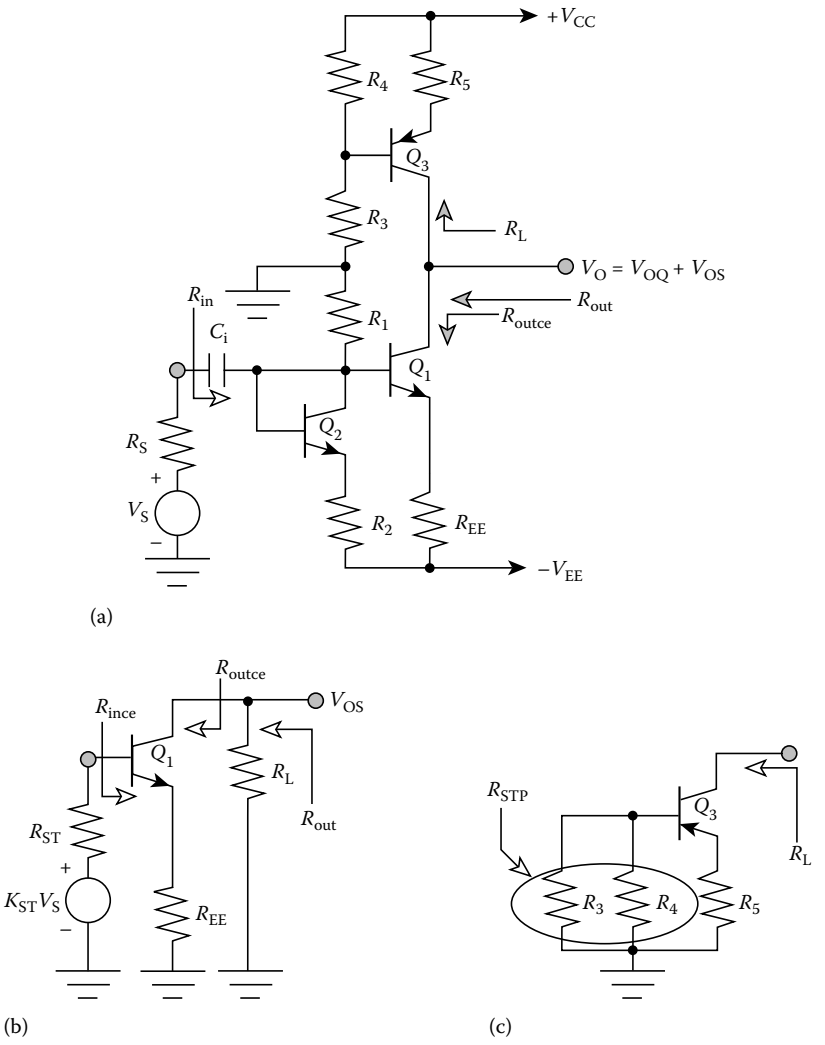

FIGURE 2.24 (a) Common-emitter amplifier with active current source load. (b) AC schematic diagram of the common-emitter unit. (c) AC schematic diagram of the active PNP transistor load.

seen by the collector of Q_1 is very large. In view of the absence of an external load appended to the output port, the resultant voltage gain of the amplifier is commensurately large.

Let $R_3 = 1.8$ kΩ, $R_4 = 3.3$ kΩ, and $R_5 = 100$ Ω. Moreover, let the small-signal parameters of the PNP transistor be $r_{bp} = 40$ Ω, $r_{cp} = 70$ Ω, $r_{ep} = 9$ Ω, $r_{\pi p} = 1100$ Ω, $r_{op} = 30$ kΩ, and $\beta_p = 60$. Assuming linear operation of all devices, determine the small-signal voltage gain $A_v = V_{OS}/V_S$, the driving point input resistance R_{in}, and the driving point output resistance R_{out} of the amplifier. As in the preceding example, the input coupling capacitance C_i can be presumed to act as an ac short circuit for the signal frequencies of interest.

Solution

1. The ac schematic diagram of the amplifier in Figure 2.24a is given in Figure 2.24b, where the PNP transistor load subcircuit is represented as an effective two terminal load resistance, R_L.

This representation is rendered possible by the fact that no signal is applied to the PNP load, which therefore acts only to supply biasing current to the collector of transistor Q_1. In the diagram, K_{ST}, R_{ST}, and R_{EE} (which effectively appears in series with r_e, the internal emitter resistance of Q_1) remain the same as in Example 2.1, namely, $K_{ST} = 0.733$, $R_{ST} = 219.7\ \Omega$, and $R_{EE} = 75\ \Omega$.

2. The AC schematic diagram of the Q_3 subcircuit alone appears in Figure 2.24c. A comparison of this figure with that shown in Figure 2.24b suggests that the subject diagram represents a PNP common-emitter amplifier under zero signal conditions. In particular, the Thévenin source resistance seen by the base of the PNP unit is $R_{STP} = R_3||R_4 = 1165\ \Omega$, while the emitter degeneration resistance of this subcircuit is $R_5 = 100\ \Omega$. It follows that the effective AC load resistance R_L terminating the collector port of Q_1 is the driving point output resistance of a common-emitter stage. With $r_c \triangleq r_{cp} = 70\ \Omega$, $r_b \triangleq r_{bp} = 40\ \Omega$, $r_e \triangleq (r_{ep} + R_5 = 109\ \Omega$, $r_\pi \triangleq r_{\pi p} = 1.1\ k\Omega$, $R_{ST} \triangleq R_{STP} = 1165\ \Omega$, $r_o \triangleq r_{op} = 30\ k\Omega$, and $\beta \triangleq \beta_p = 60$, (Equation 2.45) yields $R_{outce} \triangleq R_L = 111.5\ k\Omega$.
3. The voltage gain, input resistance, and output resistance of the actively loaded common-emitter amplifier can now be computed. For $r_c \triangleq r_{cn} = 55\ \Omega$, $r_b \triangleq r_{bn} = 90\ \Omega$, $r_e \triangleq (r_{en} + R_{EE} = 76.5\ \Omega$, $r_\pi \triangleq r_{\pi n} = 970\ k\Omega$, $R_{ST} \triangleq R_{STN} = 219.7\ \Omega$, $r_o \triangleq r_{on} = 42\ k\Omega$, $R_{LT} \triangleq R_L = 111.5\ k\omega$, and $\beta \triangleq \beta_n = 115$, Equation 2.42 gives an effective NPN transistor beta of $\beta_{eff} = 31.46$, and Equation 2.41 yields a voltage gain of $A_{vce} = V_{OS}/K_{ST}V_{ST} = -931.9$. It follows that the small-signal voltage gain of the stage at hand is $A_v = V_{OS}/V_S = K_{ST}A_{vce} = -682.6\ V/V$. It should be noted that this voltage gain is the ratio of only the signal component, V_{OS}, of the net output voltage, V_O (which contains a quiescent component of V_{OQ}) to the source signal voltage, V_S.
4. From Equation 2.43, the driving point input resistance seen looking into the base of transistor Q_1 in Figure 2.22b is $R_{ince} = 3.54\ k\Omega$. Then,

$$R_{in} = R_1||(R_d + R_2)||R_{ince} = 666.7\ \Omega$$

This input resistance differs slightly from the corresponding calculation in the preceding example owing to the reduction in the effective forward AC beta caused by the large active load resistance.

5. The resistance R_{outce} seen looking into the collector of transistor Q_1 remains the same as calculated in Example 2.1, namely, $R_{outce} = 2.49\ M\Omega$. It follows that the driving point output resistance of the amplifier under investigation is

$$R_{out} = R_L||R_{outce} = 106.7\ k\Omega$$

This large output resistance means that the actively loaded common-emitter configuration is a relatively poor voltage amplifier. In particular, an output buffer is mandated to couple virtually any practical external load resistance to the amplifier output port. In addition to reducing the output resistance, such a properly designed and implemented output buffer can reliably establish and stabilize the quiescent output voltage, V_{OQ}.

2.2.3.3 Common-Base Amplifier

The second of the canonic linear bipolar gain cells in the ''common-base amplifier,'' whose NPN and PNP AC schematic diagrams and corresponding small-signal equivalent circuit appear in Figure 2.25a and b, respectively. As it is confirmed below, the input resistance, R_{incb}, of this stage is very small and the output resistance, R_{outcb}, is very large. Accordingly, the common-base unit comprises a relatively poor voltage amplifier in the sense that its voltage gain, though potentially large, is a sensitive function of both the Thévenin source resistance R_{ST} and the Thévenin load resistance R_{LT}.

Although the common-base amplifier is not well suited for general voltage gain applications, it is an excellent ''current buffer,'' which is ideally characterized by zero input resistance, infinitely large output resistance, and unity current gain. When used for current buffering purposes, the common-base amplifier

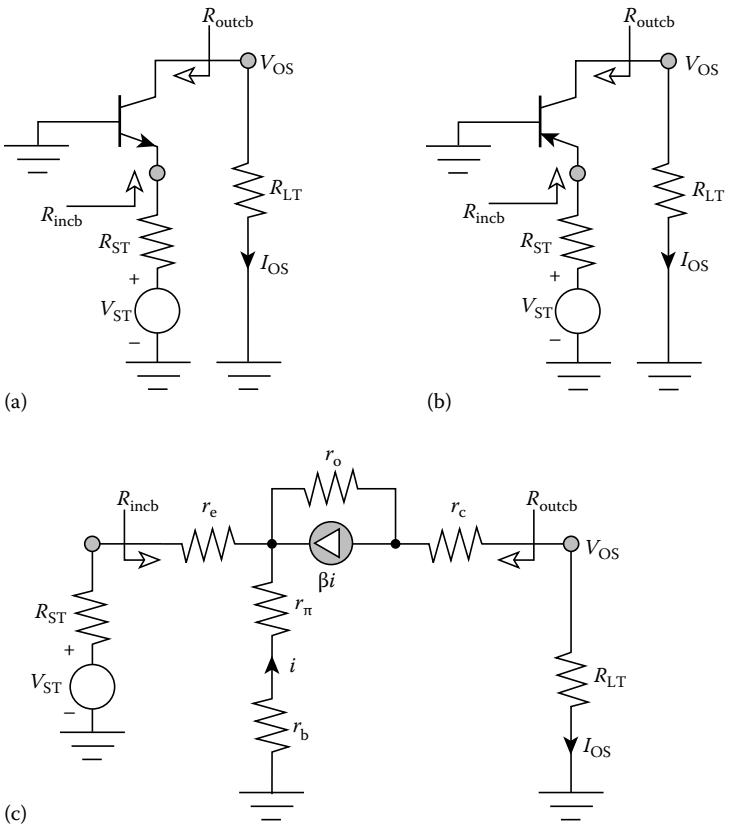

FIGURE 2.25 (a) AC schematic diagram of an NPN common-base amplifier. (b) AC schematic diagram of a PNP common-base amplifier. (c) Small-signal, low-frequency equivalent circuit of the common-base amplifier.

rarely appears as a stand alone single-stage amplifier, since signal excitations, particularly at the input and output ports of an electronic system are invariably formatted as voltages. Instead, it is invariably used in conjunction with an input voltage to current converter and/or an output current to voltage converter to achieve desired system performance characteristics.

The small-signal analysis of the common-base stage is considerably simplified if the assumption of large r_o is exploited at the outset. To this end, the equivalent circuit shown in Figure 2.25b reduces to the structure of Figure 2.26a. In the latter equivalent circuit, observe a signal emitter current i_{es} that relates to the indicated signal base current i in accordance with the Kirchhoff's current law constraint

$$i_{es} = -(\beta + 1)i \tag{2.52}$$

The signal component of the output current I_{OS} is therefore expressible as

$$I_{OS} = -\beta_i = \left(\frac{\beta}{\beta + 1}\right) i_{es} = \alpha i_{es} \tag{2.53}$$

where Equations 2.52 and 2.53 are used. The last result suggests the alternative model in Figure 2.26b, which is slightly more convenient version of the model in Figure 2.26a in that the current-controlled current source, αi_{es}, is dependent on the signal input port current i_{es}, as opposed to the signal current, i, that flows in the grounded base lead.

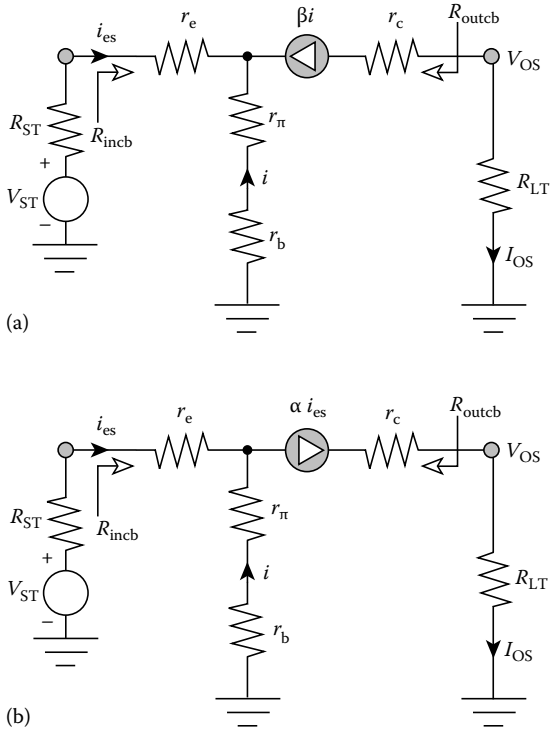

FIGURE 2.26 (a) The equivalent circuit of Figure 2.25c, simplified for the case of very large Early resistance r_o. (b) Modification of the circuit in (a) in which the current-controlled current source is rendered dependent on the input signal current i_{es}.

By inspection of the equivalent circuit in Figure 2.26b, the small-signal voltage gain A_{vcb} of the common-base cell is

$$A_{vcb} = \frac{\alpha R_{LT}}{R_{ST} + r_e + (1-\alpha)(r_\pi + r_b)} = \frac{\alpha R_{LT}}{R_{ST} + R_d} \tag{2.54}$$

where Equation 2.39 is used once again and R_d is the diode resistance defined by Equation 2.33. In contrast to the common-emitter cell, the common-base stage has no voltage gain phase inversion. But like the common-emitter configuration, the common-base voltage gain is directly proportional to the effective load resistance. It is also almost inversely proportional to the effective source resistance, given that the diode resistance R_d is small.

Although the voltage gain is vulnerable to uncertainties in the terminating load and source resistances, the common-base current gain, A_{icb}, is virtually independent of R_{LT} and R_{ST}. This contention follows from the fact that A_{icb}, which is the ratio of I_{OS} to the Norton equivalent source current, V_{ST}/R_{ST}, is

$$A_{icb} = \left(\frac{R_{ST}}{R_{LT}}\right) A_{vcb} = \frac{\alpha R_{ST}}{R_{ST} + R_d} \tag{2.55}$$

which is independent of R_{LT} (to the extent that the Early resistance r_o can indeed be ignored). Since the signal in a current-drive amplifier is likely to have a large source resistance, $R_{ST} \gg R_d$, which

implies $A_{icb} \approx \alpha$, independent of R_{LT} and R_{ST}. Note that this approximate current gain is essentially unity, since α as introduced by Equation 2.39 approaches one for the typically encountered circumstances of large β.

The input and output resistances of the common-base amplifier follow immediately from an analysis of the model in Figure 2.26b. In particular, the driving point input resistance, R_{incb}, is

$$R_{incb} = \left(\frac{V_{ST}}{i_{es}}\right)\Bigg|_{R_{ST}=0} = r_e + (1-\alpha)(r_\pi + r_b) = R_d \tag{2.56}$$

where the numerical value is of the order of only a few tens of ohms. On the other hand, the driving point output resistance, R_{outcb}, is infinitely large since $V_{ST} = 0$ constrains i_{es}, and thus αi_{es}, to zero. In turn, $\alpha i_{es}, = 0$ means that R_{LT} in Figure 2.26b faces an open circuit, whence $R_{outcb} = \infty$.

To the extent that the common-base amplifier is excited from a signal current source and that the forward Early resistance of the utilized transistor is very large, the common-base amplifier is seen to have almost unity current gain, very low input resistance, and infinitely large output resistance. Its transfer characteristics therefore approximate those of an ideal current buffer. Of course, the finite nature of the forward Early resistance renders the observable driving point output resistance of a common-base cell large, but nonetheless finite. The actual output resistance can be determined as the V_x to I_x ratio in the ac schematic diagram of Figure 2.27a. The requisite analysis is algebraically cumbersome owing to the presence of r_o in shunt with the current-controlled current source in the equivalent circuit of Figure 2.25c. Fortunately, however, an actual circuit analysis can be circumvented by a proper interpretation of cognate common-emitter results formulated earlier.

In order to demonstrate the foregoing contention, consider Figure 2.27b, which depicts the AC schematic diagram for determining the driving point output resistance R_{outce} of a common-emitter amplifier. The only difference between the two AC schematic diagrams in Figure 2.27 is the topological placement of the effective source resistance, R_{ST}. In the common-base stage, this source resistance is in series with the emitter of a transistor with a base that is grounded. On the other hand, R_{ST} appears in the common-emitter configuration as an element in series with the base of a transistor whose emitter is ground. It follows that Equation 2.45 can be used to deduce an expression for R_{outcb}, provided that in Equation 2.45 R_{ST} is set to zero and r_e is replaced by $(r_e + R_{ST})$.

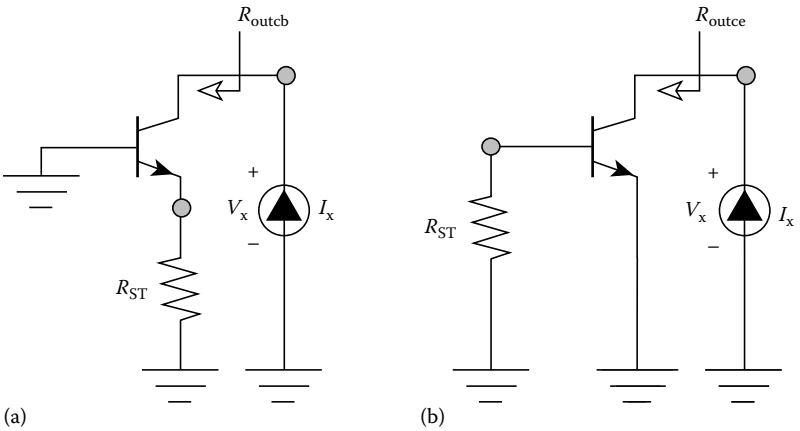

FIGURE 2.27 (a) AC schematic diagram appropriate to the computation of the driving point output resistance of a common-base amplifier. (b) AC schematic diagram pertinent to computing the driving point output resistance of a common-emitter amplifier.

The result is

$$R_{\text{outcb}} = r_c + (r_e + R_{ST}) \| (r_\pi + r_b) + \left[\frac{\beta(r_e + R_{ST})}{r_e + R_{ST} + r_\pi + r_b} + 1 \right] r_o \tag{2.57}$$

For large R_{ST} and large r_o, Equation 2.47 reduces to

$$R_{\text{outcb}} \approx (\beta + 1) r_o \tag{2.58}$$

which is an extremely large output resistance.

The common-base stage is generally used in conjunction with a common-emitter amplifier to form the "common-emitter-common-base cascode," whose schematic diagram is shown in Figure 2.28. In this application, the common-emitter stage formed by transistor Q_1, the emitter degeneration resistance, R_{EE}, and the biasing elements, R_1 and R_2, serves as a transconductor that converts the input signal voltage, V_S, to a collector current whose signal component is i_{1s}. Note that such conversion is encouraged by the fact that the effective load resistance, R_{Leff}, terminating the collector of Q_1, is the presumably low input resistance of the common-base stage formed by transistor Q_2 and the biasing resistances, R_3 and R_4. Since the current gain of a common-base stage is essentially unity, Q_2 translates the signal current in its emitter to an almost identical signal current flowing through the collector load resistance, R_L. The latter element acts as a current to voltage convert to establish the signal component, V_{OS}, of the net output voltage V_O.

The analysis of the common-emitter–common-base cascode begins by representing the collector port of the common-emitter configuration by its Norton equivalent circuit. Assuming that the input coupling

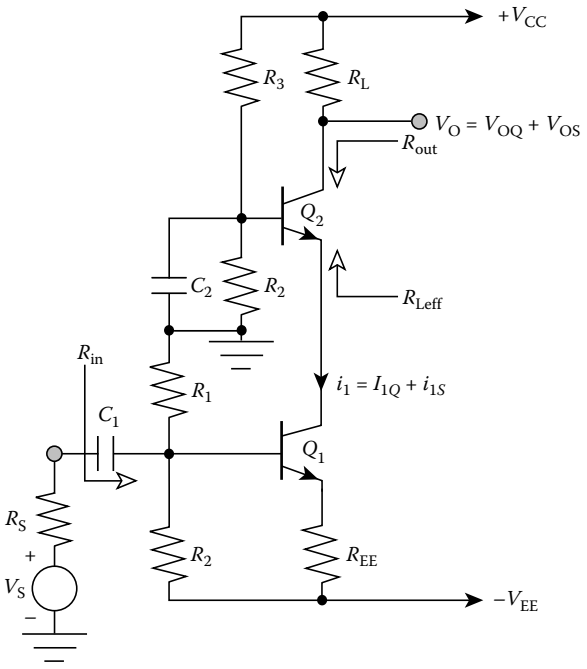

FIGURE 2.28 Schematic diagram of a common-emitter–common-base cascode. The common-emitter stage formed by transistor Q_1 and its peripheral elements acts as a voltage to current converter. Transistor Q_2 and its associated biasing elements function as a current amplifier, while the load resistance, R_L, acts as a current to voltage converter.

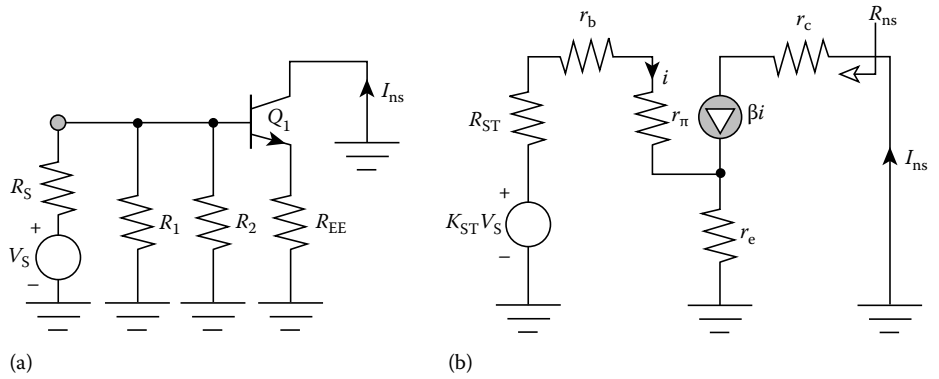

FIGURE 2.29 (a) AC schematic diagram used to calculate the Norton equivalent output circuit of the common-emitter subcircuit in the cascode configuration of Figure 2.28. (b) Small-signal model of the AC circuit in (a).

capacitor, C_1, is sufficiently large to enable its replacement by a short circuit over the signal frequency range of interest, the pertinent AC schematic diagram is the circuit in Figure 2.29a, where I_{ns} symbolizes the Norton, or short-circuit signal current conducted by the collector of transistor Q_1. The corresponding small-signal equivalent circuit appears in Figure 2.29b, where the Early resistance is tacitly ignored, the effective source resistance, R_{ST}, seen by the base of Q_1 is

$$R_{ST} = R_S \| R_1 \| R_2 \tag{2.59}$$

and the voltage divider K_{ST} is

$$K_{ST} = \frac{R_1 \| R_2}{R_1 \| R_2 + R_S} \tag{2.60}$$

Using the model in Figure 2.29b, it is a simple matter to show that

$$I_{ns} = \beta i = G_{ns} V_S \tag{2.61}$$

where G_{ns}, which can be termed the "Norton transconductance" of the common-emitter stage, is

$$G_{ns} = \frac{\beta K_{ST}}{R_{ST} + r_b + r_\pi + (\beta + 1) r_e} \tag{2.62}$$

The Norton output resistance R_{ns} is infinitely large by virtue of the assumption of infinitely large Early resistance.

The foregoing results permit drawing the AC schematic diagram of the common-base component of the common-emitter–common-base cascode in the topological form depicted in Figure 2.30a. From the corresponding small-signal equivalent circuit in Figure 2.30b, which assumes that the capacitor, C_2, behaves as an AC short circuit and which once again ignores transistor Early resistance, the voltage gain, say A_v, follows immediately as

$$A_v = \frac{V_{OS}}{V_S} = -\alpha G_{ns} R_L = -\frac{\alpha \beta K_{ST} R_L}{R_{ST} + r_b + r_\pi + (\beta + 1) r_e} \tag{2.63}$$

The driving point output resistance R_{out}, like the Norton output resistance of the common-emitter stage, is infinitely large. In fact, R_{out} is a good approximation of infinity. Its numerical value

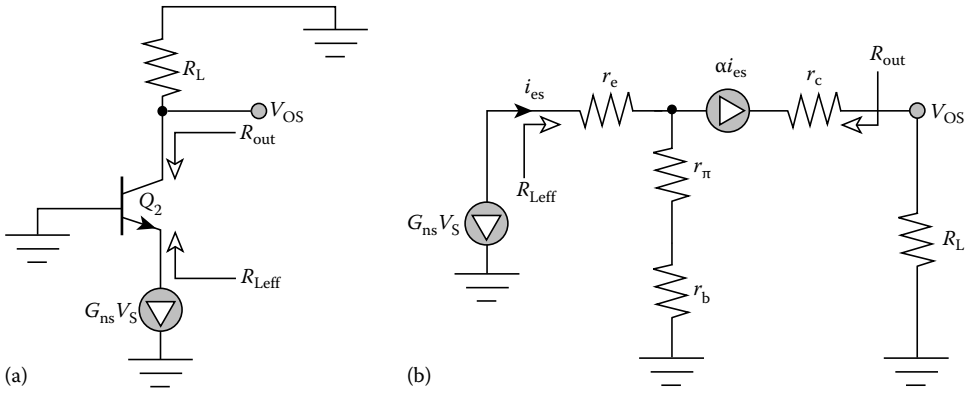

FIGURE 2.30 (a) The effective AC schematic diagram of the common-base component of the common-emitter–common-base cascode of Figure 2.28. (b) Small-signal model of the AC circuit in (a).

approaches $(\beta + 1)r_o$, since the terminating resistance, R_{ns}, seen in the emitter circuit of transistor Q_2 is of the order of r_o.

Equation 2.63 is similar in form to Equation 2.41 which defines the voltage gain of a simple common-emitter amplifier. A careful comparison of the two subject relationships suggests that the voltage gain of the common-emitter–common-base cascode of Figure 2.28 is equivalent to the voltage gain achieved by a simple common-emitter stage, whose output port is loaded in an effective load resistance of αR_L. Although α is close to unity, but nonetheless always less than one, an effective load of αR_L implies that the voltage gain of the cascode is slightly less than that achieved by the common-emitter stage alone, provided, of course, that the transistors utilized in both configurations have identical small-signal parameters. A question therefore arises as to the prudence of incorporating common-base signal processing in conjunction with a common-emitter unit stage.

In fact, no practical purpose is served by a common-emitter–common-base cascode if the load resistance R_L driven by the amplifier is very small. But if the load resistance imposed on the output port of a simple common-emitter amplifier is large, as it is when the load itself is realized actively, as per Example 2.2, the effective transistor beta defined by Equation 2.42 is appreciably smaller than the actual small-signal beta. The result is a degraded common-emitter amplifier voltage gain. In this situation, the insertion of a common-base stage between the output port of the common-emitter amplifier and R_L, as diagrammed in Figure 2.28, increases the degraded gain of the common-emitter amplifier alone by restoring the effective beta of the common-emitter transistor to a value that approximates the actual small-signal beta of the transistor. This observation follows from the fact that the effective load resistance, R_{Leff}, seen by the collector of the common-emitter transistor in the cascode topology is of the order of only a small diode resistance. It follows from Equation 2.42 that β_{eff} for $R_{LT} = R_{Leff}$ is likely to significantly larger than the value of β_{eff} that derives from the load condition, $R_{LT} = R_L$.

The reason for using common-base circuit technology in conjunction with a common-emitter amplifier is circuit broadbanding. In particular, a carefully designed common-emitter–common-base cascode configuration displays a 3 dB bandwidth and a gain-bandwidth product that are significantly larger than the bandwidth and gain-bandwidth product afforded by a common-emitter stage of comparable gain. The primary reason underlying this laudable attribute is the low effective load resistance presented to the collector of the common-emitter stage by the emitter of the common-base structure. This low resistance attenuates the magnitude of the phase-inverted voltage gain of the common-emitter circuit, thereby reducing the deleterious effects of Miller multiplication of the base-collector junction depletion capacitance implicit to the common-emitter transistor [8].

2.2.3.4 Common-Collector Amplifier

While the common-base configuration functions as a current buffer, the ''common-collector amplifier,'' or ''emitter follower,'' with AC schematic diagrams that appear in Figure 2.31a and b operates as a voltage buffer. It offers high input resistance, low output resistance, a voltage gain approaching unity, and a moderately large current gain. The small-signal model of the emitter follower is the circuit in Figure 2.31c.

Assuming infinitely large Early resistance, r_o, a straightforward analysis of the subject model reveals an emitter-follower voltage gain A_{vcc} of

$$A_{vcc} = \frac{V_{OS}}{V_S} = \frac{R_{LT}}{R_{LT} + R_d + (1-\alpha)R_{ST}} \tag{2.64}$$

where R_d is the diode resistance given by Equation 2.33. Observe that A_{vcc} is a positive less than unity number. The indicated gain approaches one for $R_{LT} \gg R_d + (1-\alpha)R_{ST}$. Although the voltage gain is less than one, the corresponding current gain, which is simply the voltage gain scaled by a factor of (R_{ST}/R_{LT}), can be substantially larger than one.

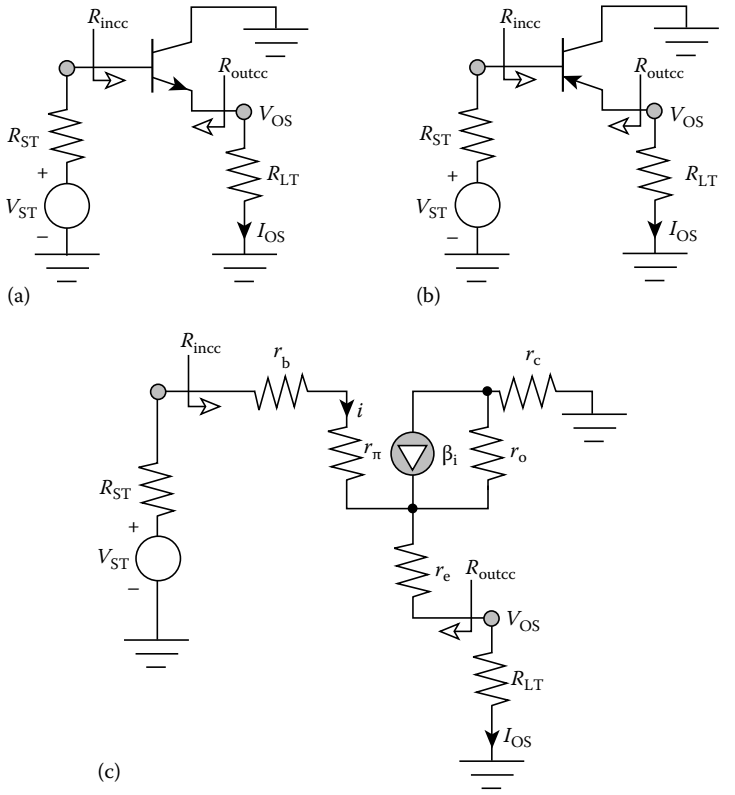

FIGURE 2.31 (a) AC schematic diagram of an NPN common-collector amplifier. (b) AC schematic diagram of PNP common-collector amplifier. (c) Small-signal low-frequency equivalent circuit of the common-collector amplifier, assuming that the Early resistance is sufficiently large to ignore.

It is simple to confirm that the driving point input resistance R_{incc} and the driving point output resistance R_{outcc} of the emitter follower are, respectively,

$$R_{incc} = r_b + r_\pi + (\beta + 1)(r_e + R_{LT}) = (\beta + 1)(R_d + R_{LT}) \tag{2.65}$$

and

$$R_{outcc} = r_e + \frac{r_\pi + r_b + R_{ST}}{(\beta + 1)} = R_d + (1 - \alpha)R_{ST} \tag{2.66}$$

It is interesting and instructive to note that the driving point input resistance, R_{incc}, of an emitter follower is of the same form as the driving point input resistance, R_{incc}, of a common-emitter stage. Indeed, if R_{LT} in the emitter follower is zero, $R_{incc} + R_{ince}$. This result is reasonable in view of the fact that for both the emitter-follower and common-emitter configurations, the input resistance is, as suggested by the test circuits in Figure 2.32a and b, the Thévenin resistance presented to the source circuit by the base of the subject transistor. Moreover, the common-collector output resistance R_{outcc} mirrors the driving point input resistance R_{incb} for the common-base amplifier. In fact, $R_{incb} + R_{outcc}$ if the base of a common-base amplifier is terminated to ground in a resistance of value R_{ST}. Once again, the latter observation is

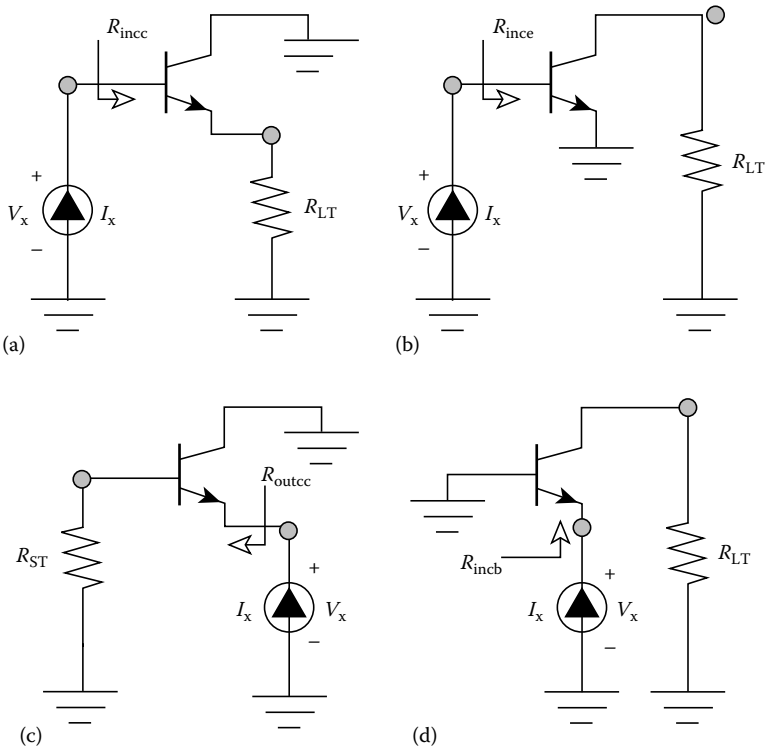

FIGURE 2.32 (a) Test circuit for determining the driving point input resistance R_{incc} of a common-collector amplifier. (b) Test circuit for determining the driving point input resistance R_{ince} of a common-emitter amplifier. Note that $R_{incc} = R_{ince}$ if R_{LT} in the common-collector unit is zero. (c) Test circuit for determining the driving point output resistance R_{outcc} of a common-collector amplifier. (d) Test circuit for determining the driving point input resistance R_{incb} of a common-base amplifier. Note that $R_{outcc} = R_{incb}$ if R_{ST} in the common-collector unit is zero.

intuitively correct, for, as depicted in Figure 2.32c and d, the emitter of the transistor comprises the input terminal for the common-base amplifier and the output terminal of an emitter follower.

An inspection of Equation 2.64 confirms a common-collector voltage gain that tends toward unity for progressively larger Thévenin load resistances, R_{LT}. Correspondingly, the driving point input resistance of an emitter follower increases dramatically with increasing R_{LT}. These observations are often pragmatically exploited by supplanting the passive load in the schematic diagram of Figure 2.31a with an active load, as suggested in Figure 2.33a. Since the effective AC load resistance must be large to achieve a near unity voltage gain, this active load must function as a sink of nominally constant current. To this end, the active load in question is shown conducting a net current that consists of a static current component I_{CS} and a signal current component I_{OS}, where the constant current sink nature of the load implies $I_{CS} \gg I_{OS}$.

The subject active load can be represented by its Norton equivalent circuit, as diagrammed in Figure 2.33b, where I_{CS} is depicted as a constant current source and I_{OS} is made to flow through a resistance, R_{cs}. The latter branch element represents the dynamic resistance presented to the emitter-follower output port by the two terminal active termination. Note that $R_{cs} = \infty$ yields $I_{os} = 0$, which implies an active load that behaves as an ideal constant current sink. The corresponding AC schematic

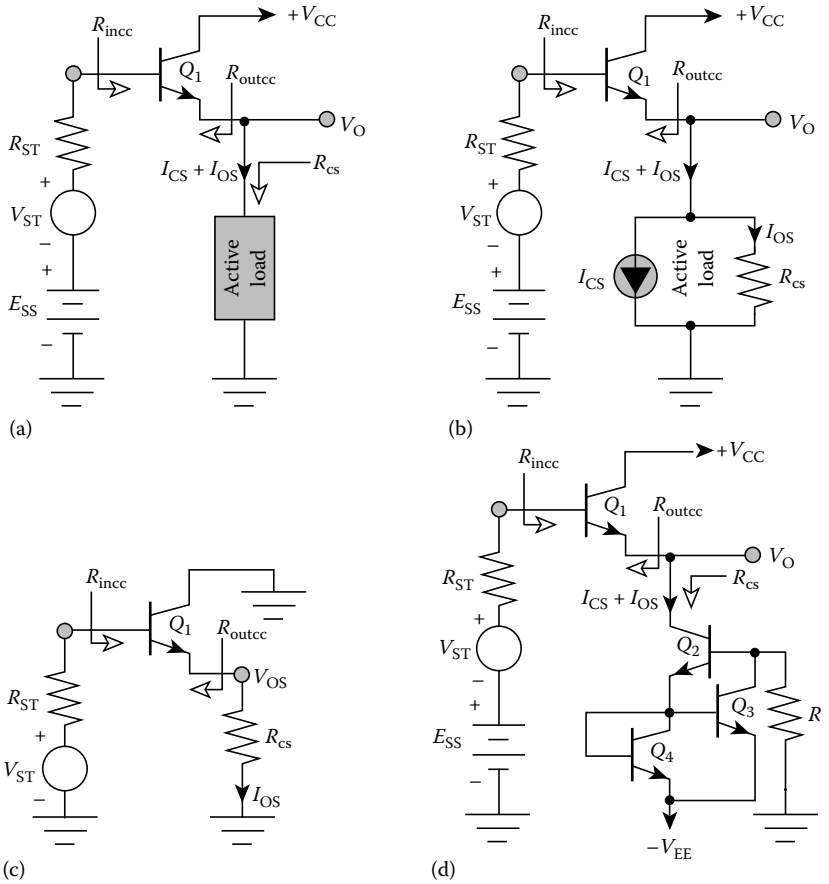

FIGURE 2.33 (a) Emitter follower with active load that conducts a static current I_{CS} and a signal component I_{OS}. (b) The Norton equivalent circuit of the active load. (c) AC schematic diagram of the actively loaded emitter follower. (d) Wilson current mirror realization of the active load.

diagram, which is offered in Figure 2.33c, is derived from Figure 2.33b by setting I_{CS} to zero, since I_{CS} itself is a constant current that is devoid of any signal component. Additionally, the biasing sources, V_{CC}, V_{EE}, and E_{SS} are presumed ideal and are therefore set to zero as well.

The AC schematic diagram in Figure 2.33c is identical to that in Figure 2.31a, subject to the proviso that $R_{LT} = R_{cs}$. But since R_{cs} is presumably a large resistance, substituting $R_{LT} = R_{cs}$ into Equation 2.66 to evaluate the voltage gain of the actively loaded emitter follower is at least theoretically inappropriate because the subject gain equation is premised on the assumption of a large Early resistance, r_o; specifically Equation 2.64 reflects the assumption $R_{LT} \ll r_o$. A voltage gain expression, more accurate than Equation 2.64, derives from an analysis of the model in Figure 2.31c. If r_o is included in this analysis, but if r_e and r_c are sufficiently small to justify their neglect, the result for $R_{LT} = R_{cs}$ is

$$A_{vcc} = \frac{V_{OS}}{V_S} \approx \frac{r_o \| R_{cs}}{(r_o \| R_{cs}) + R_d + (1 - \alpha) R_{ST}} \tag{2.67}$$

where the algebraic form collapses to Equation 2.64 if $R_{cs} \ll r_o$. Similarly, the revised expression for the driving point input resistance is

$$R_{incc} \approx r_b + r_\pi + (\beta + 1)(r_o \| R_{cs}) \tag{2.68}$$

The output resistance R_{outcc} remains as stipulated by Equation 2.66.

The active load appearing in Figure 2.33a can be realized as any one of a variety of NPN current sources [9]. Figure 2.33d offers an examples of such a realization in the form of the Wilson current mirror formed of transistors Q_2, Q_3, and Q_4, and the current setting resistor, R [10]. This subcircuit establishes an extremely high dynamic resistance between the collector of transistor Q_2 and the signal ground. In particular, if β_2 and r_{o2} symbolize the AC beta and forward Early resistance, respectively, of transistor Q_2, it can be shown that

$$R_{cs} \approx \frac{\beta_2 r_{o2.}}{2} \tag{2.69}$$

Note further that the static current, I_{CS}, conducted by the Wilson mirror flows through the emitter lead of the emitter-follower transistor Q_1. Thus, the biasing stability of Q_1 is determined by the thermal sensitivity of the static current that flows in the Wilson subcircuit.

Example 2.3

In order to dramatize the voltage buffering property of an emitter follower, return to the amplifier addressed analytically in Example 2.1 and drawn schematically in Figure 2.22a. Let the two coupling capacitors remain large enough to approximate them as AC short circuits over the signal frequency range of interest, and let the small-signal parameters of the two transistors remain at $r_b = 90\ \Omega$, $r_c = 55\ \Omega$, $r_e = 1.5\ \Omega$, $r_\pi = 970\ \Omega$, $r_o = 42\ k\Omega$, and $\beta = 115$. The circuit parameters also remain the same; namely, $R_1 = 2.2\ k\Omega$, $R_2 = 1.3\ k\Omega$, $R_{EE} = 75\ \Omega$, $R_{CC} = 3.9\ k\Omega$, and $R_S = 300\ \Omega$. But instead of $R_L = 1.0\ k\Omega$, consider an external load termination of $R_L = 300$. Reevaluate the small-signal voltage gain, $A_v = V_{OS}/V_S$, for the subject amplifier. Compare this result to the voltage gain achieved when an emitter follower is inserted between the collector of transistor Q_1 and the 300 Ω load termination, as depicted in Figure 2.34a. Assume that the small-signal parameters of the emitter-follower transistor Q_3 and those of the two transistors that comprise the diode-compensated current sink load of the follower are identical to the model parameters of transistors Q_1 and Q_2.

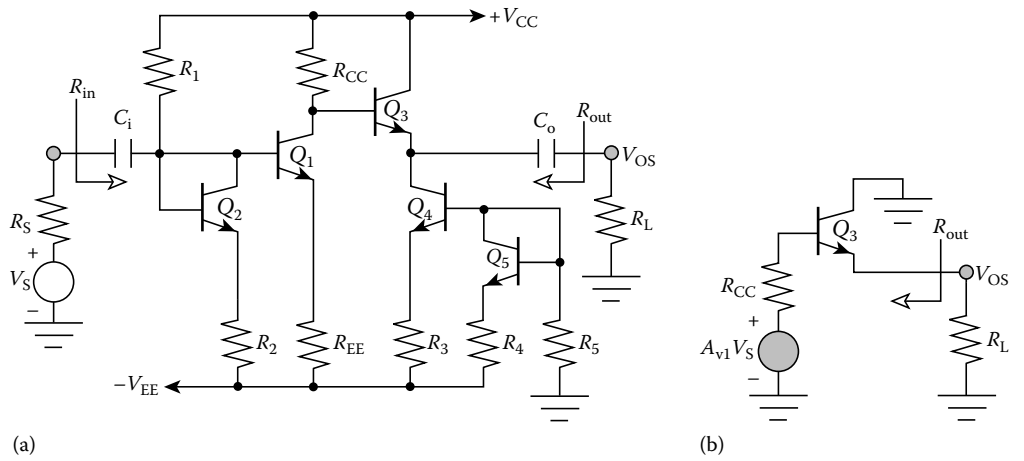

FIGURE 2.34 (a) The amplifier of Figure 2.22, but with an emitter-follower buffer inserted between the gain stage and the terminating load resistance. (b) AC schematic diagram of the amplifier in (a).

Solution

1. With reference to Figure 2.22 and Example 2.1, the Thévenin load resistance R_{LT} is now

$$R_{LT} = R_{CC} \| R_L = 278.6\ \Omega$$

The parameters R_{ST} and K_{ST} in Figure 2.22c remain unchanged at the previously computed values of $R_{ST} = 219.7\ \Omega$ and $K_{ST} = 0.733$. Then, ignoring the effects of the finite, but large, Early resistance r_o, the voltage gain is

$$A_v = \frac{V_{OS}}{V_S} \approx -\frac{\beta K_{ST} R_{LT}}{R_{ST} + r_b + r_\pi + (\beta + 1)(r_e + R_{EE})}$$

whence $A_v = -2.31$ V/V.

2. Consider now the amplifier modification shown in Figure 2.34a. Transistor Q_3 functions as an emitter follower to buffer the terminating load resistance R_L effectively seen by the gain stage formed of transistor Q_1 and its peripheral elements. Transistors Q_3 and Q_4 form a diode-compensated current sink that comprises the active load presented to the emitter-follower output port under static operational conditions. To the extent that r_o can be tacitly ignored, this current sink comprises an infinitely large dynamic resistance. Accordingly, the AC schematic diagram seen to the right of the collector of transistor Q_1 is the structure identified in Figure 2.34b.
3. The source circuit that drives the base of transistor Q_3 in Figure 2.34b is the Thévenin equivalent circuit established at the collector of transistor Q_1 in Figure 2.34a. The signal voltage associated with this source circuit is the open circuit voltage developed at the Q_1 collector; that is, it is the voltage at the Q_1 collector with the load formed of transistor Q_3 and its peripheral elements removed. Since the circuit to the left of the base of transistor Q_3 is a linear network, this Thévenin voltage is necessarily proportional to the input signal V_S. The indicated constant of proportionality in Figure 2.34b, A_{v1}, can rightfully be termed the open-circuit voltage gain of the first stage of the subject amplifier. This is to say that A_{v1} is A_v, as determined in step 1 above, but with R_L removed and therefore, R_{LT} set equal to R_{CC}. It follows that

$$A_{v1} = -\frac{\beta K_{ST} R_{CC}}{R_{ST} + r_b + r_\pi + (\beta + 1)(r_e + R_{EE})}$$

or $A_{v1} = -32.38$ V/V. Since r_o is taken to be infinitely large, the resistance seen looking into the collector of transistor Q_1 is likewise infinitely large. As a result, the Thévenin resistance associated with the source circuit in the AC diagram of Figure 2.34b is $R_{CC} = 3.9$ kΩ.

4. Recalling Equation 2.64, the voltage gain of the circuit in Figure 2.22b is

$$A_{vcc} = \frac{V_{OS}}{A_{v1} V_S} = \frac{R_L}{R_L + R_d + (1 - \alpha) R_{CC}} = 0.871 \text{ V/V}$$

The resultant overall circuit gain is

$$A_v = \frac{V_{OS}}{V_S} = A_{v1} A_{vcc}$$

or $A_v = -28.21$ V/V. Recalling the results of step 1 of this computational procedure, the effect of the emitter follower is to boost the gain magnitude of the original configuration by a factor of about 12.2.

5. From Equation 2.66, the driving point output resistance of the buffered amplifier is

$$R_{out} = R_d + (1 - \alpha) R_{CC}$$

or $R_{out} = 44.3$ Ω. Note that for the original nonbuffered case, the output resistance is $R_{CC} = 3.9$ kΩ.

2.2.3.5 Darlington Connection

In the Darlington connection, whose basic schematic diagram is abstracted in Figure 2.35a, the emitter of one transistor Q_1 is incident with the base of a second transistor Q_2 and the two transistor collector leads are connected. The output signal is extracted as either the current flowing in the collector of transistor Q_2 or the voltage developed at the emitter of Q_2. In the former case, the indicated Darlington connection functions as a transconductance amplifier. In the latter case, an output signal voltage at the emitter of Q_2 renders the connection functional as a voltage follower, or buffer. In both applications, the small-signal driving point input resistance, R_{ind}, seen looking into the base of transistor Q_1 is large. On the other hand, the driving point output resistance, R_{outed}, seen at the emitter is small and virtually independent of the source resistance R_S. The output resistance, R_{outcd}, presented to the node at which the two transistor collectors are incident is large. At the expense of forward transconductance, R_{outcd} can be enhanced by returning the collector of Q_1 to the $+V_{CC}$ bus, instead of to the collector of transistor Q_2. For a nonzero collector load resistance, R_{LC}, this alternate connection, which is diagrammed in Figure 2.35b eliminates Miller multiplication of the base–collector junction capacitance of transistor Q_1, thereby resulting in an improved transconductance frequency response.

A fundamental problem that plagues both of the foregoing Darlington connections is the fact that the static emitter current conducted by Q_1 is identical to the static base current drawn by Q_2. Accordingly, the emitter current of Q_1 is likely to be much smaller than the biasing current commensurate with optimal gain-bandwidth product in this device. Moreover, this emitter current cannot be predicted accurately since it is inversely proportional to the Q_2 static beta, whose numerical value is an unavoidable uncertainty. This poor biasing translates into an unreliable delineation of the static and small-signal parameters for Q_1. In turn, potentially significant uncertainties shroud the forward transfer and driving point resistance characteristics of the Darlington configuration.

To remedy the situation at hand, an additional current path, usually directed to signal ground, is provided at the junction of the Q_1 emitter and the Q_2 base, as suggested in Figure 2.35c and d.

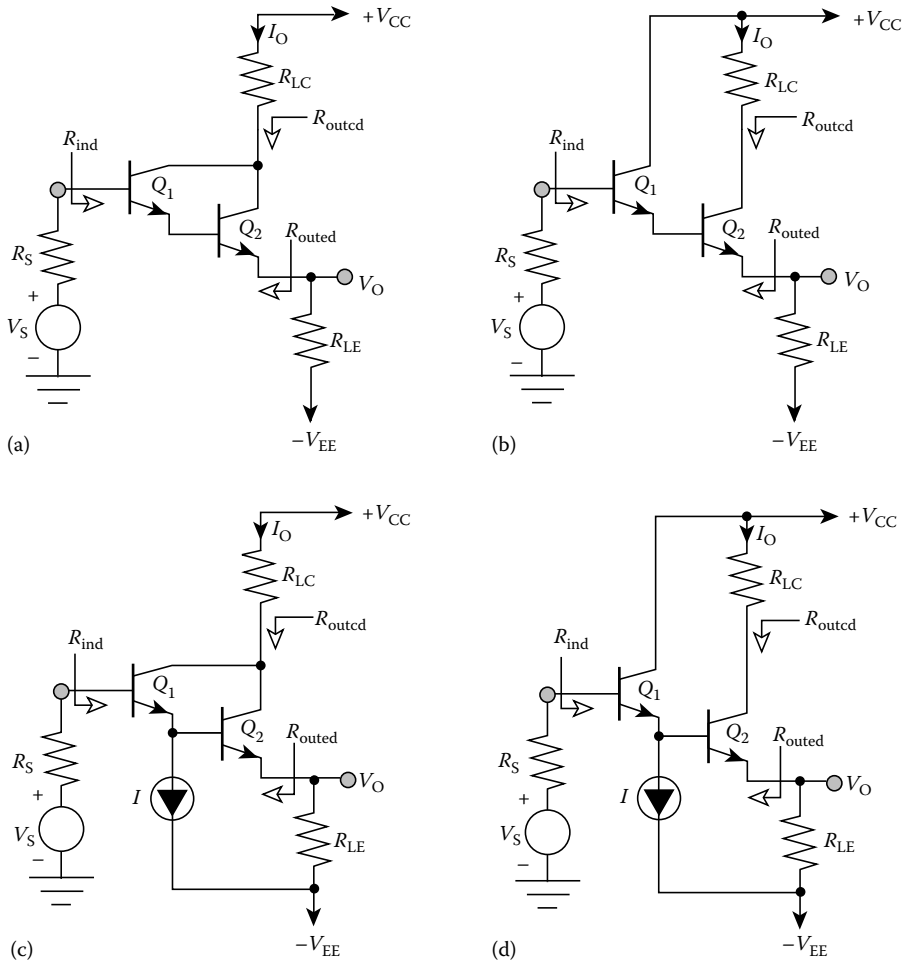

FIGURE 2.35 (a) The basic Darlington connection. (b) Alternative Darlington connection for wide-band transconductance response. (c) Darlington connection with input transistor current compensation. (d) Alternative Darlington connection with input transistor current compensation.

The appended current path can be a simple two terminal resistance, although care must be exercised to ensure that this resistance is sufficiently large to avoid seriously compromising the large driving point input resistance afforded by the basic Darlington connection in either of the preceding diagrams. Since large resistance and realistic biasing currents may prove to be conflicting design requirements, the appended current path is often an active current sink, such as the Wilson mirror load explored earlier in conjunction with the common-collector amplifier. Note in the latter two diagrams that the current, indicated as I, conducted by the appended passive or active current path is essentially the emitter current of transistor Q_1, provided that I is much larger than the base currents of Q_2.

The small-signal BJT equivalent circuit of Figure 2.16a can be used to deduce the transfer and driving point resistance characteristics of any of the Darlington connections depicted in Figure 2.35. An analysis is provided herewith for only the configuration in Figure 2.35c, since this topology is the most commonly encountered Darlington circuit and the others are amenable to very straightforward analyses. To this end, the model for the subject structure is offered in Figure 2.36, where it is assumed that both transistors are biased so that their corresponding small-signal parameters are nominally identical. Moreover, the Early

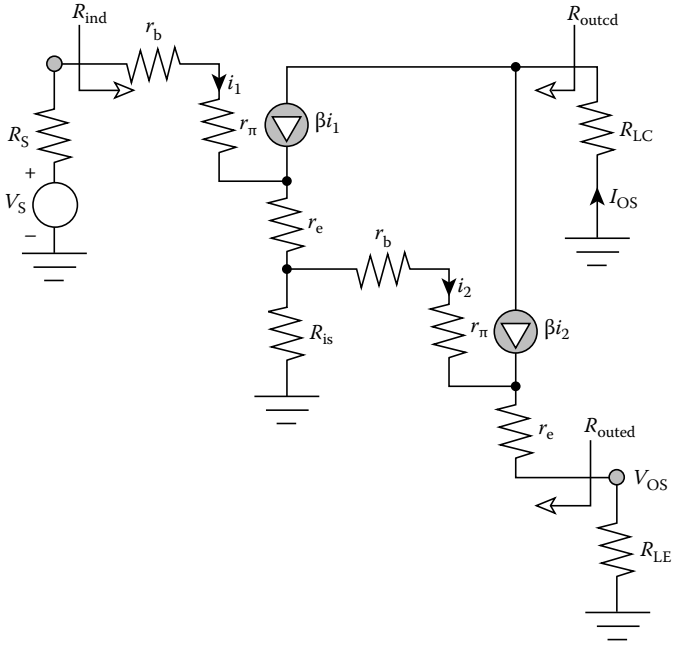

FIGURE 2.36 Small-signal equivalent circuit of the Darlington connection in Figure 2.35c. The Early resistance is ignored, and both transistors are presumed to have identical corresponding small-signal parameters. The resistance, R_{is}, represents the terminal AC resistance associated with the appended current path conducting current I in Figure 2.35c.

resistance of each transistor is presumed to be sufficiently large to warrant its neglect, and a resistance, R_{is}, is included to account for the terminal resistance of the appended current path discussed above. Letting

$$k_{is} \triangleq \frac{R_{is}}{R_{is} + (\beta + 1)(R_d + R_{LE})} \tag{2.70}$$

denote the small-signal current divider between the appended current path and the base circuit of transistor Q_2, it can be shown that the driving point input resistance R_{ind} is

$$R_{ind} = (\beta + 1)[R_d + (\beta + 1)k_{is}(R_d + R_{LE})] \tag{2.71}$$

For large ac beta,

$$R_{ind} \approx (\beta + 1)^2 k_{is}(R_d + R_{LE}) \tag{2.72}$$

which is maximal for $k_{is} \approx 1$. From Equation 2.70, the latter constraint mandates that the appended current path be designed so that its small-signal terminal resistance satisfies the inequality $R_{is} \gg (\beta + 1)(R_d + R_{LE})$.

The voltage gain, A_{vd}, from the signal source to the emitter port is

$$A_{vd} = \frac{V_{OS}}{V_S} = \frac{(\beta + 1)^2 k_{is} R_{LE}}{R_S + (\beta + 1)R_d + (\beta + 1)^2 k_{is}(R_d + R_{LE})} \tag{2.73}$$

where V_{OS} is the signal component of the net output voltage V_O. Equation 2.53 reduces to

$$A_{vd} \approx \frac{R_{LE}}{R_d + R_{LE}} \tag{2.74}$$

for large ac beta. The corresponding driving point output resistance, R_{outed}, is

$$R_{outed} = R_d + \frac{R_d}{(\beta + 1)k_{is}} + \frac{R_S}{(\beta + 1)^2 k_{is}} \approx R_d \tag{2.75}$$

At the collector port, the driving point output resistance, R_{outcd}, is infinitely large to the extent that the Early resistance r_o of both transistors can be ignored. For finite r_o, this resistance is of the order of, and slightly larger than, $(r_o/2)$. Finally, the model in Figure 2.36 yields a forward transconductance, G_{fd}, from the signal source to the collector port of

$$G_{fd} = \frac{I_{OS}}{V_S} = \frac{\beta[1 + (\beta + 1)k_{is}]}{R_S + (\beta + 1)R_d + (\beta + 1)^2 k_{is}(R_d + R_{LE})} \tag{2.76}$$

where I_{OS} is the signal component of the net output current I_O. Equation 2.76 collapses to

$$G_{fd} \approx \frac{\alpha}{R_d + R_{LE}} \tag{2.77}$$

for large AC beta.

2.2.4 Differential Amplifier

The ''differential amplifier'' is a four-port network, as suggested in Figure 2.37a. Source signals represented by the voltages, V_{S1} and V_{S2}, which have Thévenin resistances of R_{S1} and R_{S2}, respectively, are applied to the two amplifier input ports. The two output ports are terminated in three load resistances. Two of these loads, R_{L1} and R_{L2}, are ''single-ended terminations'' in that they provide a signal path to ground from each of the two output terminals. A third load resistance, R_{LL}, is differentially connected between the two output terminals. In response to the two applied source signals, two ''single-ended output'' voltages, V_{O1} and V_{O2}, are generated across R_{L1} and R_{L2}, and a ''differential output voltage,'' V_{DO}, is established across R_{LL}. This third output response is the difference between V_{O1} and V_{O2}; that is,

$$V_{DO} = V_{O1} - V_{O2} \tag{2.78}$$

The salient features of a differential amplifier are unmasked by the concepts of ''differential- and common-mode'' excitation and response. To this end, let the ''differential input source voltage,'' V_{DI}, be defined as

$$V_{DI} \triangleq V_{S1} - V_{S2} \tag{2.79}$$

and let the ''common-mode input voltage,'' V_{CI}, be

$$V_{CI} \triangleq \frac{1}{2}(V_{S1} + V_{S2}) \tag{2.80}$$

The differential input voltage is seen as the difference between the two applied source excitations. On the other hand, the common-mode input voltage is the arithmetic average of the two source voltages.

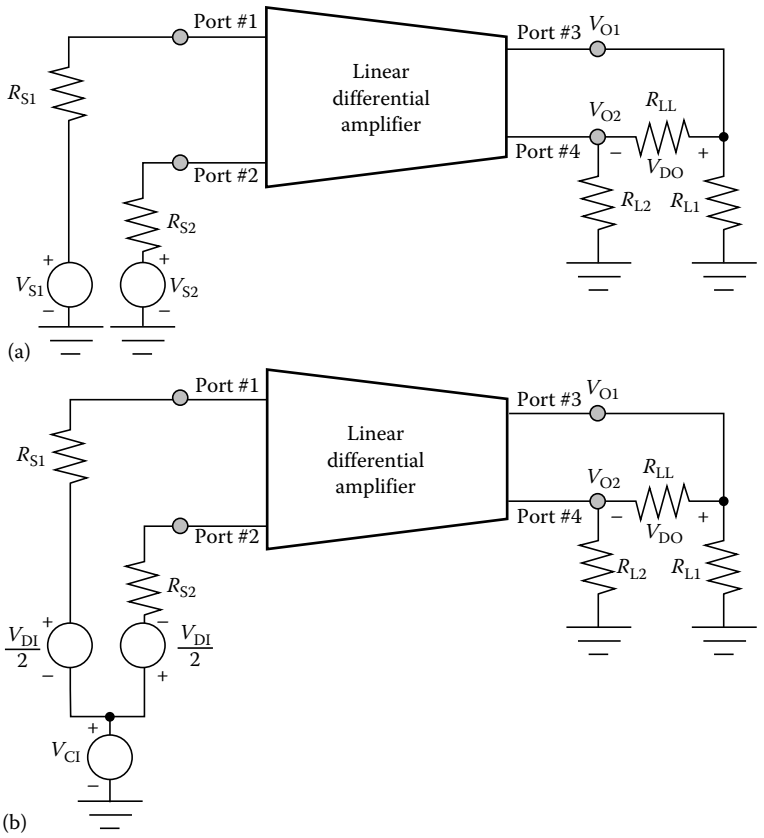

FIGURE 2.37 (a) System-level diagram of a differential amplifier. (b) System-level diagram that depicts the electrical implications of the common-mode and the differential-mode input source voltages.

When solved for V_{S1} and V_{S2}, Equations 2.79 and 2.80 give

$$V_{S1} = V_{CI} + \frac{1}{2}V_{DI} \tag{2.81a}$$

$$V_{S2} = V_{CI} - \frac{1}{2}V_{DI} \tag{2.81b}$$

The preceding two expressions allow the diagram of Figure 2.37a to be drawn in the form shown in Figure 2.37b. This alternative representation underscores the fact that the Thévenin voltage applied to either input port is the superposition of a common-mode source voltage and a component proportional to the differential-mode source voltage. The common-mode component raises both of the open-circuit input terminals to a voltage that lies above ground by an amount, V_{CI}. Superimposed with V_{CI} at the open circuit terminals of port 1 is a differential-mode voltage, $V_{DI}/2$. Simultaneously, a voltage of $-V_{DI}/2$ superimposes with V_{CI} at the open-circuit terminals of port 2.

The fact that two general source excitations applied to a four-port system can be separated into a voltage component that appears only differentially across the two system input ports and a single-ended common-mode voltage component that is simultaneously incident with both of the system input ports makes it possible to achieve signal discrimination in a differential circuit. In particular, a differential amplifier can be designed so that it amplifies the differential component of two source signals while

rejecting (in the sense of amplifying with near zero gain) their common-mode component. Signal discrimination is useful whenever an electronic system must process low-level electrical signals that are contaminated by spurious inputs, such as the voltage ramifications of electromagnetic interference or the biasing perturbations induced by temperature. If the two input ports of a differential amplifier are geometrically proximate and have matched driving point input impedances, these spurious excitations impact the two input ports identically. The undesired inputs are therefore common-mode excitations that can be rejected by a differential amplifier that is well designed in the sense of producing output port responses that are sensitive to only differential inputs.

If the differential amplifier in Figure 2.37 is linear, superposition theory gives

$$V_{O1} = A_{11}V_{S1} + A_{12}V_{S2} \tag{2.82a}$$

$$V_{O2} = A_{21}V_{S1} + A_{22}V_{S2} \tag{2.82b}$$

where the A_{ij} are constants, independent of V_{S1} and V_{S2}. When Equation 2.81a and b are inserted into the last two relationships, the single-ended output voltages are expressible as

$$V_{O1} = (A_{11} + A_{12})V_{CI} + (A_{11} - A_{12})\frac{V_{DI}}{2} \tag{2.83a}$$

$$V_{O2} = (A_{22} + A_{21})V_{CI} - (A_{22} - A_{21})\frac{V_{DI}}{2} \tag{2.83b}$$

It follows that the differential output voltage is

$$V_{DO} = (A_{11} - A_{22} + A_{12} - A_{21})V_{CI} + (A_{11} + A_{22} - A_{12} - A_{21})\frac{V_{DI}}{2} \tag{2.84}$$

Since the common-mode output voltage is

$$V_{CO} \triangleq \frac{1}{2}(V_{O1} + V_{O2}) \tag{2.85}$$

Equation 2.83a and b yield

$$V_{CO} = \left(\frac{A_{11} + A_{22} + A_{12} + A_{21}}{2}\right)V_{CI} + \left(\frac{A_{11} - A_{22} - A_{12} + A_{21}}{2}\right)\frac{V_{DI}}{2} \tag{2.86}$$

The ability of a differential amplifier to process differential excitations is measured by the ''differential-mode voltage gain,'' A_D. This performance index is defined as the ratio of the differential output voltage to the differential input voltage, under the condition of zero common-mode input voltage. From Equation 2.84,

$$A_D \triangleq \left[\frac{V_{DO}}{V_{DI}}\right]\Bigg|_{V_{CI}=0} = \frac{A_{11} + A_{22} - A_{12} - A_{21}}{2} \tag{2.87}$$

On the other hand, the ''common-mode voltage gain,'' A_C, is a measure of the common-mode signal rejection characteristics of a differential amplifier. It is the ratio of the common-mode output voltage to the common-mode input voltage, under the condition of zero differential input voltage. Using Equation 2.86,

$$A_C \triangleq \left[\frac{V_{CO}}{V_{CI}}\right]\Bigg|_{V_{DI}=0} = \frac{A_{11} + A_{22} + A_{12} + A_{21}}{2} \tag{2.88}$$

A measure of the degree to which a differential amplifier rejects common-mode excitation is the "common-mode rejection ratio ρ," which is the ratio of the differential-mode voltage gain to the common-mode voltage gain. From Equations 2.87 and 2.88

$$\rho \triangleq \frac{A_D}{A_C} = \frac{A_{11} + A_{22} - A_{12} - A_{21}}{A_{11} + A_{22} + A_{12} + A_{21}} \tag{2.89}$$

A common-mode gain of zero indicates that no common-mode output results from the application of common-mode input signals. Therefore, a practical design goal is the realization of a differential amplifier that has the largest possible magnitude of common-mode rejection ratio.

2.2.4.1 Balanced Differential Amplifier

Most differential amplifiers are "balanced." Two operating requirements are satisfied by balanced differential systems. First, with zero common-mode input voltage, the two single-ended output voltages are mutually phase inverted, but otherwise identical. By Equation 2.83a and b, the balance requirement implies the parametric constraint.

$$A_{11} - A_{12} = A_{22} - A_{21} \tag{2.90}$$

Second, equal single-ended output voltages result when the differential-mode input voltage is zero. Using Equation 2.83a and b once again, this stipulation requires

$$A_{11} + A_{12} = A_{22} + A_{21} \tag{2.91}$$

Equations 2.90 and 2.91 combine to deliver the balanced operating requirement

$$\left.\begin{aligned} A_{11} &= A_{22} \\ A_{12} &= A_{21} \end{aligned}\right\} \tag{2.92}$$

From Equations 2.87 through 2.89, the differential-mode voltage gain, the common-mode voltage gain, and the common-mode rejection ratios of a balanced differential amplifier are

$$A_D = A_{11} - A_{12} \tag{2.93}$$

$$A_C = A_{11} + A_{12} \tag{2.94}$$

$$\rho = \frac{A_{11} - A_{12}}{A_{11} + A_{12}} \tag{2.95}$$

Moreover, the single-ended output voltages in Equation 2.83a and b become

$$V_{O1} = A_C V_{CI} + A_D \frac{V_{DI}}{2} = \frac{A_D}{2}\left(1 + \frac{2V_{CI}}{\rho V_{DI}}\right) V_{DI} \tag{2.96a}$$

$$V_{O2} = A_C V_{CI} - A_D \frac{V_{DI}}{2} = -\frac{A_D}{2}\left(1 - \frac{2V_{CI}}{\rho V_{DI}}\right) V_{DI} \tag{2.96b}$$

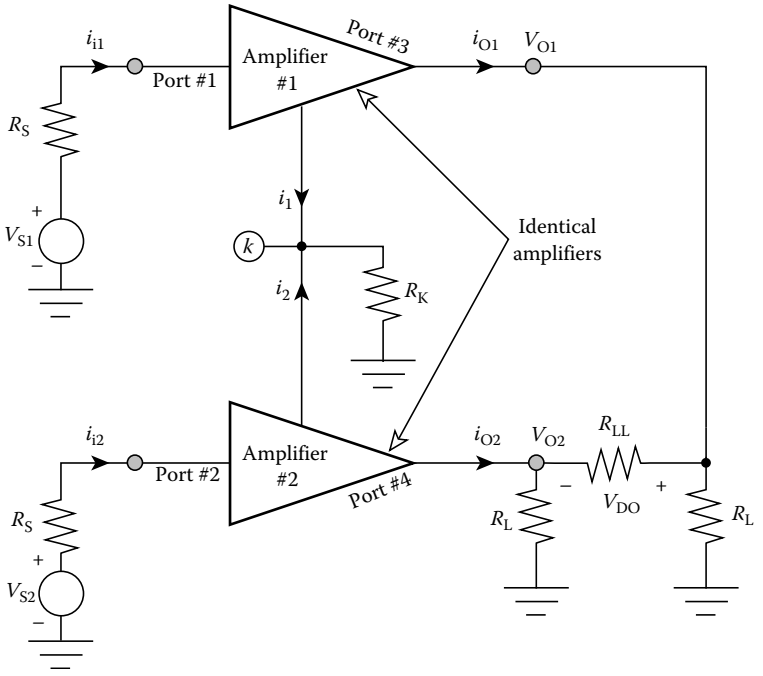

FIGURE 2.38 Generalized system diagram of a balanced differential system. The topology is an AC schematic diagram in that requisite biasing subcircuits of either amplifier are not shown.

which give rise to a differential response of

$$V_{DO} = V_{O1} - V_{O2} = A_D V_{DI} \tag{2.97}$$

Equation 2.96a and b shows that a balanced differential amplifier having a very large common-mode rejection ratio produces single-ended outputs that are nominally phase-inverted versions of one another and approximately independent of the common-mode input voltage. On the other hand, the differential output voltage of a balanced system is independent of the common-mode input signal, regardless of the value of the common-mode rejection ratio.

Figure 2.38 depicts the most straightforward way to implement balance in a differential configuration. In this abstraction, two identical single-ended amplifiers, such as those discussed in earlier subsections, are interconnected to establish signal flow paths between single-ended input and single-ended output ports. This topology boasts integrated circuit practicality, since it exploits the inherent ability of a mature monolithic fabrication process to produce well-matched equivalent components. The two single-ended amplifiers in the subject figure are topologically identical, and they incorporate matched active devices that are biased at the same quiescent-operating points. Thus, amplifiers 1 and 2 have small-signal two-port equivalent circuits that are reflective of one another. In order to ensure balanced operation, the single-ended output ports of each amplifier are terminated to ground in equal load resistances R_L. Similarly, the Thévenin source resistances are equivalent. Observe that balance implies that the upper half of the circuit in Figure 2.38 is a mirror image of the lower half of the system schematic diagram. This interpretation begets the common reference to a balanced differential amplifier as a ''differential pair.''

The balance condition entails the following engineering constraints:

1. Under the case of differential-mode excitation, which implies $V_{S1} = -V_{S2} = V_{DI}/2$ and hence, $V_{CI} = 0$, the currents indicated in Figure 2.38 are such that $i_{i1} = -i_{i2}$, $i_{01} = -i_{02}$, and $i_1 = -i_2$.

Since the resistance, R_K, conducts a current equal to the sum of i_1 and i_2, $i_1 = -i_2$ clamps node k to signal ground potential for exclusively differential-mode inputs. Moreover, Equation 2.96a and b confirm $V_{01} = -V_{02} = A_D\ V_{DI}/2$, which produces a signal current through the differential load resistance R_{LL} of

$$\frac{V_{O1} - V_{O2}}{R_{LL}} = \frac{V_{O1}}{R_{LL}/2}$$

Since the single-ended response voltage, V_{O1}, is referred to signal ground, the midpoint of the differential load resistance is effectively grounded for differential inputs.

The foregoing disclosures imply the circuit diagram of Figure 2.39a, which is the so-called "differential-mode half-circuit equivalent" [11,12] of the differential amplifier. For a balanced differential pair driven by exclusively differential inputs, the branch currents, branch voltages, and node voltages computed from an analysis of the structure in Figure 2.39a are precisely the negative of the corresponding circuit variables in the remaining half of the system.

2. Under the case of common-mode inputs, which implies $V_{SI} = V_{S2} = V_{CI}$ and hence, $V_{DI} = 0$, the currents delineated in Figure 2.38 satisfy the constraints, $i_{i1} = i_{i2}$, $i_{01} = i_{02}$, and $i_1 = i_2$. Since the resistance, R_K, conducts a current equal to the sum of i_1 and i_2, $i_1 = i_2$ establishes a voltage at node k of

$$R_K(i_1 + i_2) = (2R_K)i_1$$

that is, the signal voltage developed at node k corresponds to an amplifier 1 current of i_1 flowing through a resistance whose value is twice R_K. Additionally, $V_{O1} = V_{O2} = V_{CO}$, which means that no signal current flows through R_{LL} under exclusively common-mode excitation.

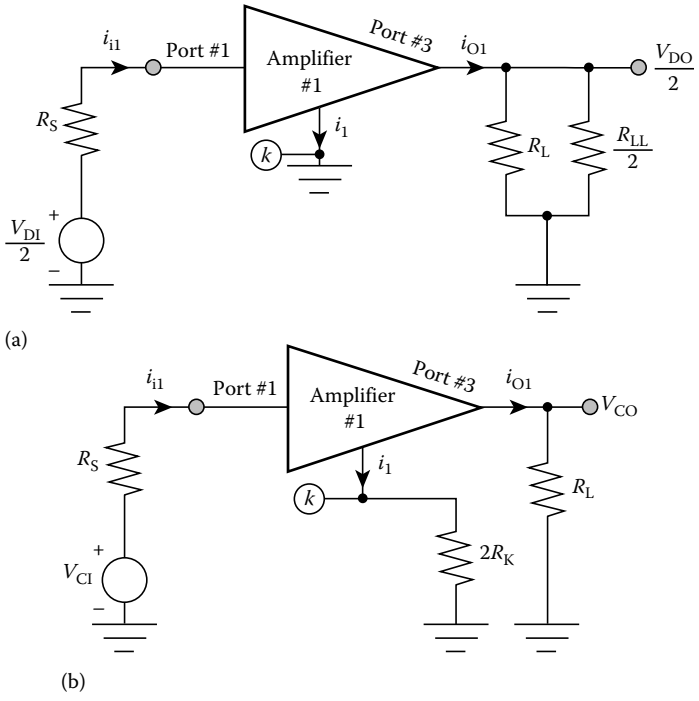

FIGURE 2.39 (a) Differential-mode half-circuit equivalent of the balanced differential amplifier. (b) Common-mode half-circuit equivalent of the balanced differential amplifier.

It follows that the "common-mode half-circuit equivalent" of the differential amplifier is as drawn in Figure 2.39b. For a balanced differential pair driven by exclusively common-mode input signals, the branch currents, branch voltages, and nodal voltages computed for the structure in Figure 2.39b are identical to the corresponding circuit variables in the other half of the circuit.

2.2.4.2 Thévenin Equivalent I/O Circuits

Because the two input ports of a differential amplifier electrically interact with one another, the Thévenin equivalent circuit seen by the two signal sources in Figure 2.37a is itself a two-port network. The branch elements of the Thévenin model are defined in terms of a "differential-mode input resistance," R_{DI}, and a "common-mode input resistance," R_{CI}.

Consider the test circuit of Figure 2.40a, which is configured to formulate the Thévenin equivalent input circuit. This structure is analogous to that of Figure 2.37a, except that the linear differential unit is presumed balanced. Furthermore, the original source circuits are supplanted by the test voltages, V_{tl} and V_{t2}, which establish the input port currents I_{t1} and I_{t2}. Because no signals other than V_{tl} and V_{t2} are applied to the differential pair, the Thévenin equivalent circuit seen between ports 1 and 2 is a resistance, say R_{XI}. Similarly, a second resistance, R_{XX}, is introduced to terminate port 1 to ground. System balance implies that a resistance of the same value terminates the second input port. The hypothesized Thévenin equivalent input circuit is given in Figure 2.40b.

The application of Kirchhoff's current and voltage laws to the model is Figure 2.40b produces

$$I_{t1} - \frac{V_{t1}}{R_{XX}} = \frac{V_{t2}}{R_{XX}} - I_{t2} \tag{2.98a}$$

$$V_{t1} - V_{t2} = R_{XI}\left(I_{t1} - \frac{V_{t1}}{R_{XX}}\right) \tag{2.98b}$$

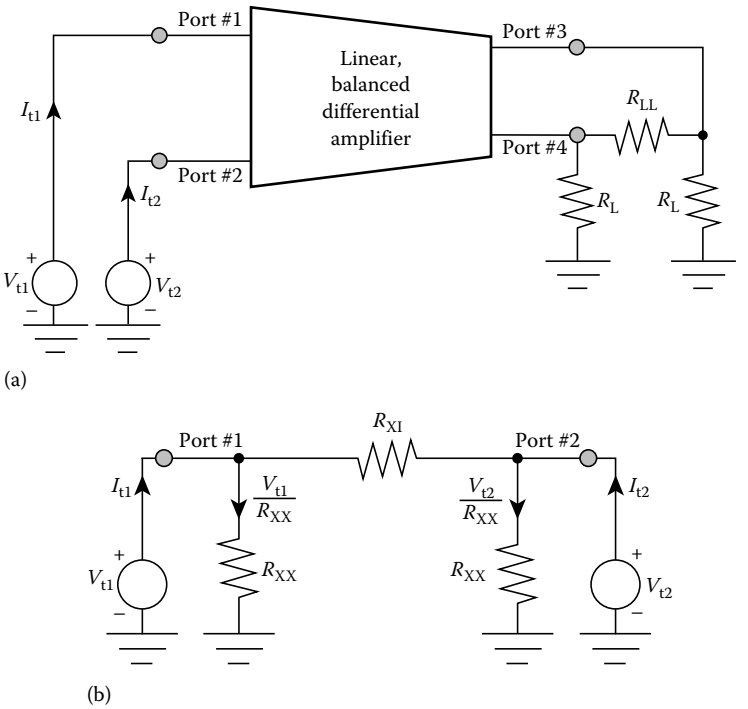

FIGURE 2.40 (a) Test circuit used to evaluate the Thévenin input equivalent circuit of a balanced differential amplifier. Note the connection of balanced loads at ports 3 and 4. (b) Hypothesized Thévenin equivalent input circuit.

If the test voltages, V_{t1} and V_{t2}, are decomposed into their differential (V_{Dt}) and common mode (V_{Ct}) components in accordance with

$$V_{t1} = V_{Ct} + \frac{V_{Dt}}{2} \tag{2.99a}$$

$$V_{t2} = V_{Ct} - \frac{V_{Dt}}{2} \tag{2.99b}$$

Equation 2.98a and b lead to

$$I_{t1} = \frac{V_{Ct}}{R_{XX}} + \frac{V_{Dt}}{R_{XI} \| (2R_{XX})} \tag{2.100a}$$

$$I_{t2} = \frac{V_{Ct}}{R_{XX}} - \frac{V_{Dt}}{R_{XI} \| (2R_{XX})} \tag{2.100b}$$

Equation 2.100a and b implicitly define the common-mode and differential-mode components of the currents I_{t1} and I_{t2} resulting from the test voltages V_{t1} and V_{t2}. Accordingly, the common-mode driving point input resistance, R_{CI}, is

$$R_{CI} = R_{XX} \tag{2.101}$$

On the other hand, the differential-mode driving point input resistance, R_{DI}, is

$$R_{DI} = R_{XI} \| (2R_{CI}) \tag{2.102}$$

where use has been made of Equations 2.100a, b, and 2.101. Note that the model resistance, R_{XI}, is related to the differential input resistance, R_{DI}, of the amplifier by

$$R_{XI} = \frac{2R_{CI}R_{DI}}{2R_{CI} - R_{DI}} \tag{2.103}$$

The test circuits for measuring the common-mode and the differential-mode driving point input resistances derive directly from Equation 2.100a and b. For a differential input test voltage, V_{Dt} of zero, V_{t1} and V_{t2} are identical to the common-mode input test voltage V_{Ct}, whence

$$I_{t1} = \frac{V_{t1}}{R_{XX}} = \frac{V_{t1}}{R_{CI}} \equiv I_{t2} \tag{2.104}$$

It follows that the circuit of Figure 2.41a is appropriate to the measurement (or calculation) of R_{CI} as the Ohm's law ratio of the common-mode test voltage to the resultant common-mode test current. Observe that half circuit analysis measures apply, wherein R_{CI} is the resistance seen looking into port 1, with port 3 terminated to ground in the resistance R_L. For differential testing, $V_{t1} = -V_{t2} = V_{Dt}/2$, whence

$$I_{t1} = \frac{2V_{t1}}{R_{XI} \| (2R_{CI})} = \frac{2V_{t1}}{R_{DI}} = -I_{t2} \tag{2.105}$$

The pertinent test cell is shown in Figure 2.41b. For half-circuit analysis, care should be exercised to recognize that the ratio of the test voltage, V_{t1}, to the corresponding test current, I_{t1}, is one-half of the driving point differential input resistance, R_{DI}. In addition, the subcircuit connecting port 2 to port 4

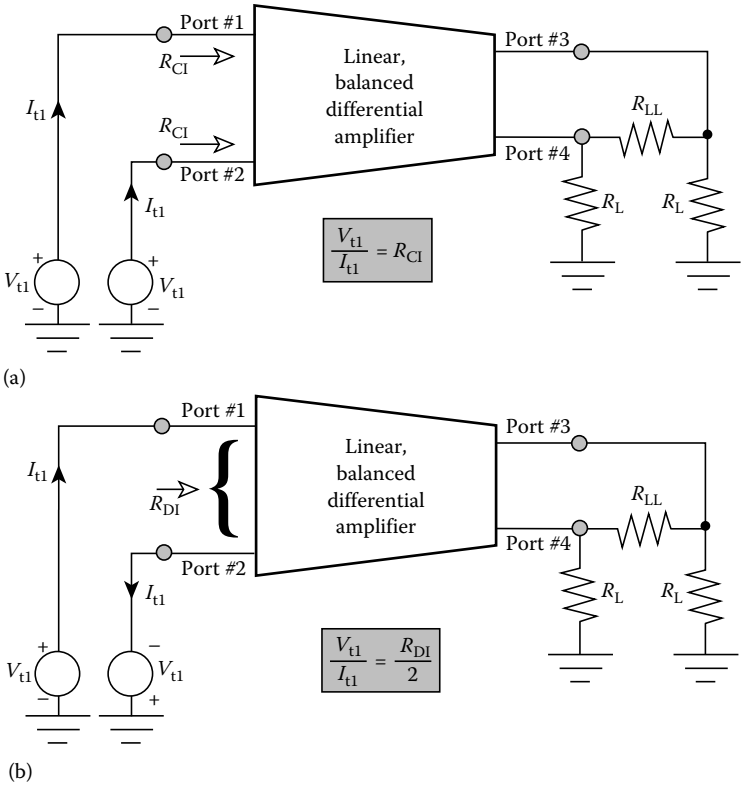

FIGURE 2.41 (a) Test circuit used to evaluate the driving point common-mode input resistance of a linear, balanced differential pair. (b) Test circuit used to evaluate the driving point differential-mode input resistance of a linear, balanced differential pair.

must be removed, and port 3 must be terminated to ground by the shunt interconnection of the resistances, R_L and $R_{LL}/2$.

Just as a Thévenin model can be constructed for the input ports of a balanced differential pair, a Thévenin equivalent circuit can be developed for the output ports. Under zero input conditions, this output model, which is presented in Figure 2.42, is topologically identical to the equivalent circuit in Figure 2.40b. In a fashion that reflects the computation of the resistance parameters for the input equivalent circuit, Figure 2.43a is the test circuit for evaluating the driving point common-mode output resistance, R_{CO}. Figure 2.43b is the test structure for calculating the driving point differential-mode output resistance, R_{DO}. Following Equation 2.103, R_{XO} in Figure 2.42 is given by

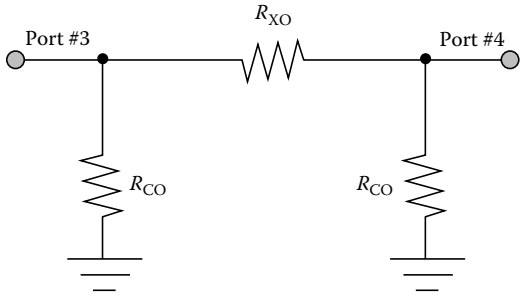

FIGURE 2.42 Thévenin equivalent output circuit of the balanced differential amplifier for the case of zero input signal excitation.

$$R_{XO} = \frac{2R_{CO}R_{DO}}{2R_{CO} - R_{DO}} \tag{2.106}$$

Two electrically interactive output ports are included in the differential system of Figure 2.37a. Thus, two Thévenin voltage V_{th1} and V_{th2},

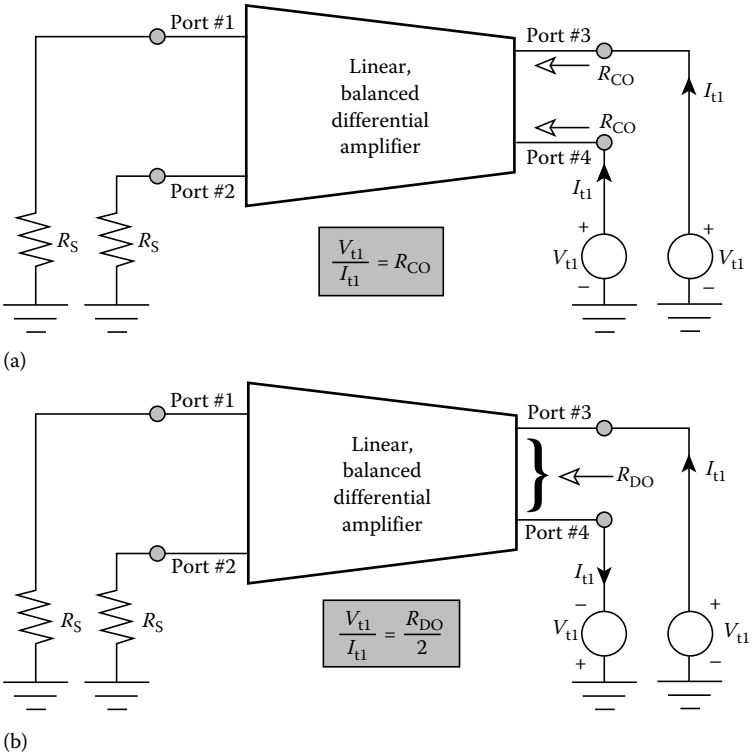

FIGURE 2.43 (a) Test circuit used to evaluate the driving point common-mode output resistance of a linear, balanced differential pair. (b) Test circuit used to evaluate the driving point differential-mode output resistance of a linear, balanced differential pair.

each of which is linearly dependent on the differential-mode and the common-mode components of the applied source signals must be evaluated. These Thévenin output responses derive from open-circuited load conditions, as indicated in Figure 2.44a. With $R_{S1} = R_{S2} = \Delta R_S$, balance prevails, and V_{th1} and V_{th2} are characterized by differential and common-mode components, analogous to the characterization of the terminated outputs, V_{O1} and V_{O2}.

The Thévenin voltages in question derive from an analysis of the equivalent circuit in Figure 2.44b, which represents the model of Figure 2.42 modified to account for nonzero source excitation. The proportionality constants, k_c and k_d, are related to the previously determined common-mode and differential-mode voltage gains. It is a simple matter to confirm that

$$V_{thl},\ V_{th2} = k_c V_{CI} \pm \left(\frac{k_d R_{XO}}{2R_{CO} + R_{XO}}\right)\frac{V_{DI}}{2} \tag{2.107}$$

The first term on the right-hand side of this relationship is the open-circuit common-mode output voltage, while the second term is the open-circuit differential-mode output voltage. It follows that k_c represents the open-circuit common-mode voltage gain, A_{CO}; that is

$$k_c = \lim_{\substack{R_L \to \infty \\ R_{LL} \to \infty}} (A_C) \triangleq A_{CO} \tag{2.108}$$

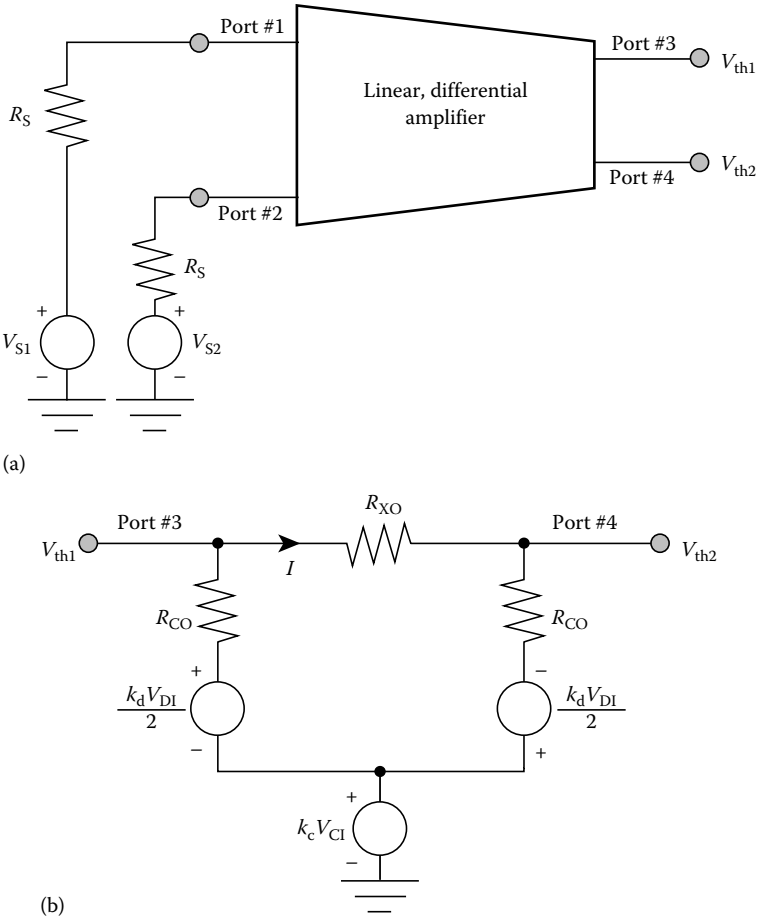

FIGURE 2.44 (a) System schematic diagram used to define the Thévenin voltages at the output ports of a balanced differential amplifier. (b) Thévenin equivalent circuit for the output ports of a balanced differential pair.

On the other hand, the open-circuit differential-mode gain, A_{DO}, is

$$\frac{k_d\ R_{XO}}{2R_{CO} + R_{XO}} = \lim_{\substack{R_L \to \infty \\ R_{LL} \to \infty}} (A_D) \triangleq A_{DO} \tag{2.109}$$

Using Equation 2.53, the Thévenin model parameter, k_d, in the last expression can be cast as

$$k_d = \left(\frac{2R_{CO}}{R_{DO}}\right) A_{DO} \tag{2.110}$$

Figure 2.45 summarizes the foregoing modeling results [13].

Example 2.4

Consider the balanced circuit of Figure 2.46 which is operated as a single-ended input–single-ended output amplifier. The input voltage signal, which is capacitively coupled to the base of transistor Q_1, is

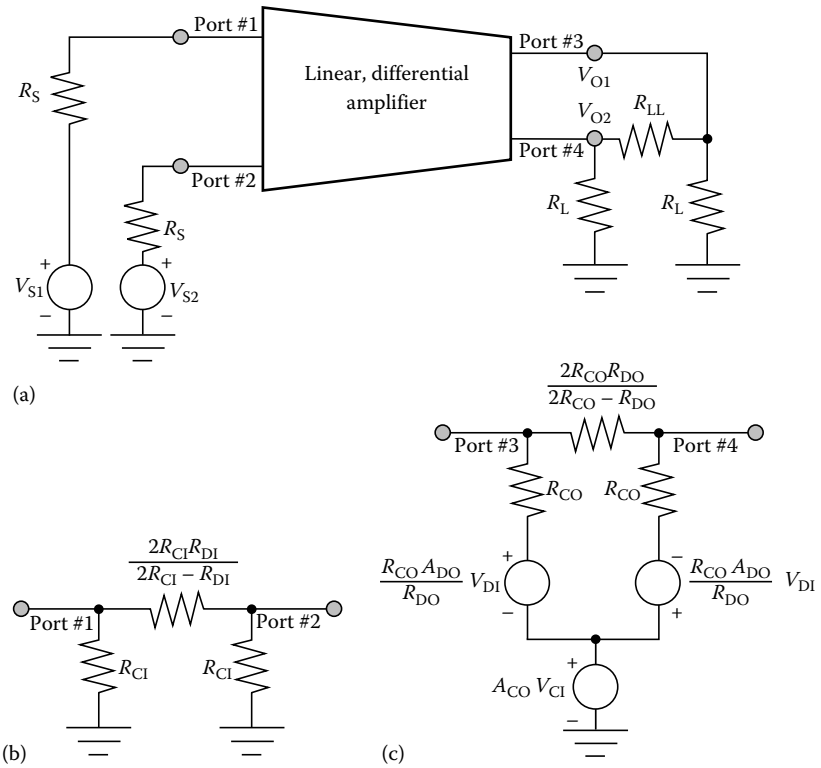

FIGURE 2.45 (a) System schematic diagram of a linear, balanced differential amplifier. (b) Thévenin equivalent input circuit. (c) Thévenin equivalent output circuit. The parameters, A_{DO} and A_{CO}, represent the open-circuit values of the differential- and common-mode voltage gains, respectively, of the balanced pair in (a).

represented as a Thévenin equivalent circuit consisting of the source voltage, V_S, in series with a source resistance, R_S. In order to preserve electrical balance, the base of transistor Q_2 is capacitively returned to ground through a resistance whose value is also equal to R_S. The capacitors can be presumed to act as AC short circuits over the signal frequency range of interest. For the parameters delineated in the inset to Figure 2.46, a computer-aided circuit simulation of the subject amplifier indicates that both transistors have the small-signal parameters $r_b = 33.5\ \Omega$, $r_\pi = 1.22\ k\Omega$, and $\beta = 81.1$. Determine the small-signal voltage gain $A_v = V_{OS}/V_S$, driving point input resistance R_{in}, and driving point output resistance R_{out}.

Solution

1. The AC schematic diagram of the differential-mode half circuit of the balanced amplifier in Figure 2.46 is shown in Figure 2.47a. In concert with earlier arguments, note that the junction of the two emitter degeneration resistances, R_{EE}, is grounded, as are the mid-point of the resistance, R_{LL}, and the node at which R_1, R_2, and the two resistances labeled R are incident. Using the bipolar model of Figure 2.16a, with r_o and r_e ignored, the voltage gain of this structure is the differential-mode voltage gain of the differential pair. Moreover, the driving point input resistance of the circuit at hand is one-half of the differential input resistance of the original pair, while its driving point output resistance is one-half of the differential-mode output resistance. Analysis confirms

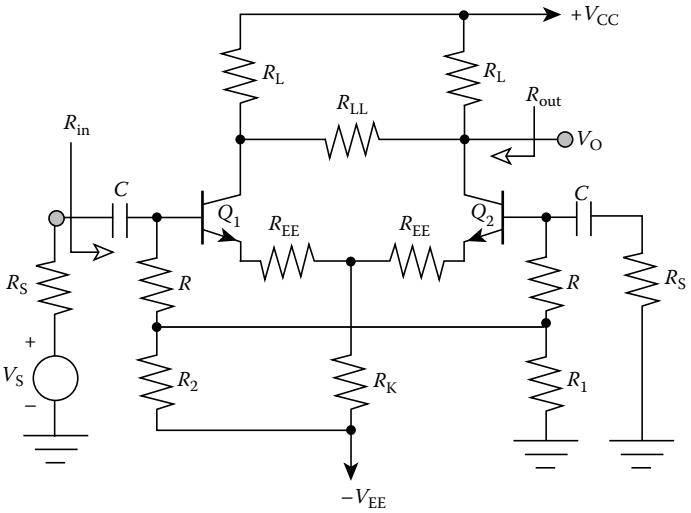

FIGURE 2.46 A balanced bipolar differential amplifier used in a single-ended input–single-ended output mode.

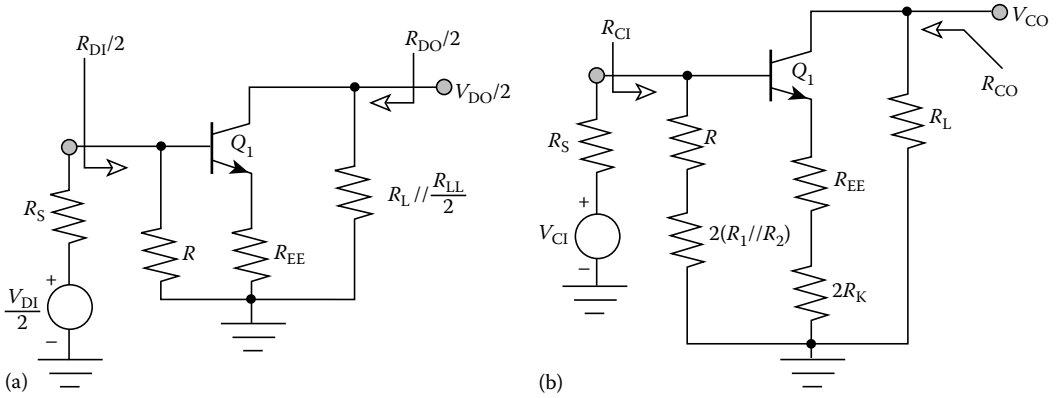

FIGURE 2.47 (a) Differential-mode half-circuit ac equivalent schematic of the differential amplifier shown in Figure 2.46. (b) Common-mode half-circuit ac equivalent schematic of the differential amplifier shown in Figure 2.46.

$$A_D = \frac{V_{DO}/2}{V_{DI}/2} = -\frac{\beta\left(\frac{R}{R+R_S}\right)\left(R_L \| \frac{R_{LL}}{2}\right)}{(R_S \| R) + r_b + r_\pi + (\beta+1)R_{EE}}$$

$$\frac{R_{DI}}{2} = R \| [r_b + r_\pi + (\beta+1)R_{EE}]$$

$$\frac{R_{DO}}{2} = R_L \| \frac{R_{LL}}{2}$$

Numerically, $A_D = -10.09$, $R_{DI} = 5971\ \Omega$, and $R_{DO} = 1875\ \Omega$.

2. The AC schematic diagram of the pertinent common-mode half circuit is given in Figure 2.47b. The input signal voltage is now the common-mode input voltage, V_{CI}, which produces the common-mode output response, V_{CO}. Using the bipolar model of Figure 2.16a, with r_o and r_e ignored, it is easily shown that

$$A_C = \frac{V_{CO}}{V_{CI}} = -\frac{\beta\left(\frac{R+2(R_1\|R_2)}{R+2(R_1\|R_2)+R_S}\right)R_L}{\{R_S\|[R+2(R_1\|R_2)]\}+r_b+r_\pi+(\beta+1)(R_{EE}+2R_K)}$$

$$R_{CI} = [R+2(R_1\|R_2)]\|[r_b+r_\pi+(\beta+1)(R_{EE}+2R_K)]$$

$$R_{CO} = R_L$$

   Numerically, $A_C = -923.3\ (10^{-3})$, $R_{CI} = 5493\ \Omega$, and $R_{CO} = 1500\ \Omega$. The common-mode rejection ratio $p = A_D/A_C$ 10.93 is small owing to the relatively small value of the resistance R_K.
3. As the output voltage is extracted at the collector of transistor Q_2, Equation 2.96b is the applicable equation for determining the output signal voltage, V_{OS}. With only a single source voltage, V_S, applied, the differential input voltage is V_S, and the common-mode input voltage is $V_S/2$. It follows that

$$V_{OS} = A_C V_{CI} - \left(\frac{A_D}{2}\right)V_{DI} = \left(\frac{A_C - A_D}{2}\right)V_S$$

   whence a voltage gain of

$$A_v = \frac{V_{OS}}{V_S} = \frac{A_C - A_D}{2}$$

   These analyses give $A_v = 4.583$.
4. In order to evaluate the driving point input and output resistances, the parameters, R_{XI} and R_{XO} must be calculated. From Equations 2.103 and 2.106, $R_{XI} = 13.08\ \text{k}\Omega$, and $R_{XO} = 5.0\ \Omega$.

The two-port model for calculating the driving point input resistance R_{in} is given in Figure 2.45b. Recall that a circuit resistance, whose value is numerically equal to the internal signal source resistance, R_S, is connected between ground and the node to which the base of transistor Q_2 is incident. By inspection,

$$R_{in} = R_{CI}\|[R_{XI}+(R_{CI}\|R_S)]$$

or $R_{in} = 3.87\ \text{k}\Omega$.

The output port model that emulates the driving point output resistance is given in Figure 2.45c. This model is analogous to that of Figure 2.45a, except that no external loads are connected between signal ground and the node to which the collector of transistor Q_1 is incident. Clearly,

$$R_{out} = R_{CO}\|(R_{XO}+R_{CO})$$

which produces $R_{out} = 1219\ \Omega$.

2.3 MOSFET Biasing Circuits

David G. Haigh, Bill Redman-White, and Rahim Akbari-Dilmaghani

2.3.1 Introduction

CMOS technology is finding a very wide range of applications in analog and analog-digital mixed-mode circuit implementations in addition to its traditional role in digital circuits. In mixed-mode circuits compatibility of analog circuits with digital very large scale integration (VLSI) is important, particularly in cost-sensitive areas and situations where low power consumption is required. Such CMOS circuits require a range of biasing circuits and it is this topic that is the main subject of this section, although the subject is mentioned elsewhere in this text, where particular designs are covered.

The requirements for biasing circuits in CMOS circuit design can be divided into the requirements for voltage and for current sources. These sources can be further subdivided into two additional categories, high precision and noncritical. High-precision voltage or current sources are essential components in data converters, both analog-to-digital and digital-to-analog and the precision required depends on the overall target precision of the data converter. For a large number of bits, the precision required could be very great indeed and would need to be maintained over a specified temperature and supply voltage range and in the presence of on-chip, chip-to-chip and wafer-to-wafer component parameter variations. Precision sources are also required in other applications such as dc pedestals for video signals in video systems.

Noncritical voltage sources are generally required for setting up an internal analog ground or for biasing the gates of FETs in common-gate configuration, as in a cascode FET. In these cases, the sensitivity of overall circuit performance parameters to the bias voltage would generally not be high and moderate precision circuit techniques would be acceptable. The main considerations would be to
