maintain correct operation, especially in terms of signal headroom, overall variations in process, power supply, and temperature conditions. The requirement for current sources for biasing CMOS analog and mixed-mode circuits is very considerable. The reason for this is that most circuits, such as an operational amplifier, consist of several stages, each of which requires biasing. In discrete circuits, the tendency is to use resistors for biasing, for reasons of cost and the poor sample-to-sample tolerances on discrete active device parameters. In integrated circuit implementation, on the other hand, relatively well-matched devices on the same chip are available and the use of current source biasing minimizes gain loss due to loading effects. Furthermore, using a multioutput current mirror to supply different parts of the circuit allows stabilization of the current against temperature and power supply voltage variations to be performed at one location only (on or off the chip) and the stabilized current can be distributed throughout the chip or subcircuit using current mirror circuits. This also produces significant immunity to localized power supply fluctuation and noise. Full or partial stabilization of bias currents with operating and environmental changes is desirable in order to minimize the range of operating current for which design must be specified, allowing higher design performance targets to be achieved.

In many cases, CMOS circuits have their power supplies derived from an off-chip bipolar regulator (with its own internal bandgap). In these situations, a reasonable voltage reference can sometimes be obtained from the power supply voltage via a potential divider. A voltage obtained in this way can be applied to an external low tolerance resistor to obtain a current reference of moderate precision. The value of realizing a reference on chip is that the cost of the external reference can be avoided. For example, in battery supplied equipment, a large degree of supply voltage immunity is required in the presence of a widely varying battery voltage. It is possible to use an on-chip voltage regulator or an on-chip, switched-mode power supply. In CMOS technology, high-precision voltage references are difficult to design, although a reference with good power supply rejection is possible. BiCMOS technology overcomes many of the problems experienced with CMOS technology since well-controlled bipolar devices for very high-precision references are available on-chip.

Many references to biasing appear in this text under the heading of the circuit concerned and only some general guidelines and principles, together with some example circuits will be given here. We begin this section on CMOS biasing circuits by considering the devices available for biasing in a CMOS-integrated circuit including parasitically realized bipolar junction devices. Some useful simplified models of these devices and a brief examination of the variability of the relevant model parameters will be presented. We then consider different types of references and biasing circuits. Since voltage and current references are closely interrelated, they are dealt with concurrently. The material is presented according to a gradually increasing level of sophistication and achievable precision, starting with simple circuits with only minor supply voltage, temperature, and process independence and leading to fully curvature-compensated bandgap references. This is followed by a consideration of references based on less usual devices that may not be available or usable in every process but that offer potentially attractive solutions. We then illustrate the application of some biasing techniques in the context of simple operational amplifier circuits. Finally, we consider the biasing of amplifiers for very low supply voltages, where rail-to-rail optimized performance is required, and dynamic biasing techniques. The topic of CMOS biasing circuits is sufficiently large to warrant an entire book and we include a list of references that will help provide the reader with more detailed information.

2.3.2 Device Types and Models for Biasing

2.3.2.1 Devices

The principal devices of CMOS technology are the enhancement-mode N-channel and P-channel MOSFET, which are shown schematically in Figure 2.48a and b for N-well and P-well technologies, respectively. Currently, N-well technology is more widely available than P-well. Depletion-mode devices

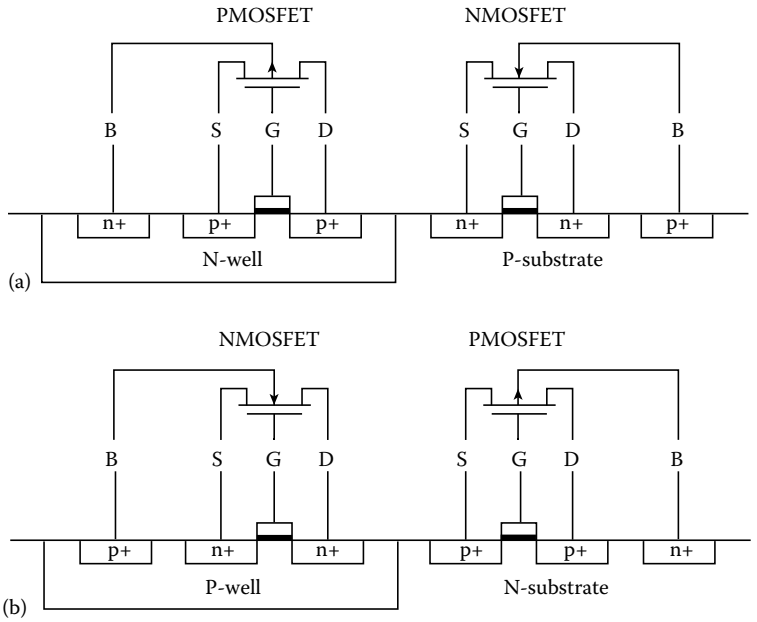

FIGURE 2.48 Realization of NMOS and PMOS FETs in CMOS technology. (a) N-well process. (b) P-well process.

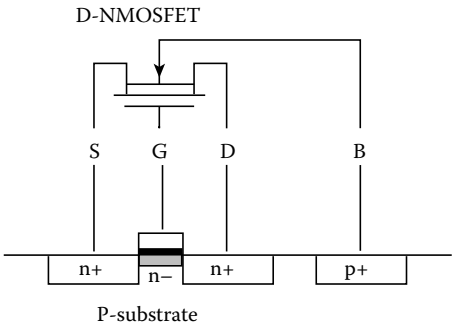

FIGURE 2.49 Realization of NMOS depletion-mode FET in N-well CMOS technology.

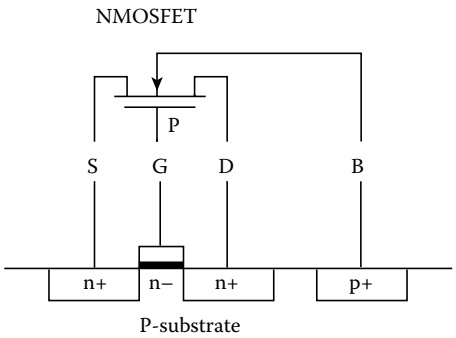

FIGURE 2.50 NMOS enhancement-mode FET with P-doped polysilicon gate.

are not routinely provided in CMOS (in contrast with NMOS), but they are available in some processes [23] and they can be used to realize reference circuits [4,5,23]. They are produced by an additional implementation under the gate region (N-type for NMOS and P-type for PMOS). The NMOS depletion-mode symbol is shown schematically in Figure 2.49.

In most processes, the MOSFET gate material is highly N-doped polysilicon. In some processes [8], P-doped gates are available, and these can be used to realize reference circuits. The symbol of an N-channel enhancement MOSFET with P-type doped base is shown in Figure 2.50.

In order to realize temperature and process desensitized biasing of CMOS circuits, the special properties of BJTs are advantageous. BJT devices can be realized in CMOS technology as parasitic devices with certain restrictions. Two classes of such device are available, namely, vertical and lateral. For the vertical device [13], the restrictions are that an N-well process can realize PNP devices with the collectors connected to the substrate (most negative supply rail) and that a P-well process can realize

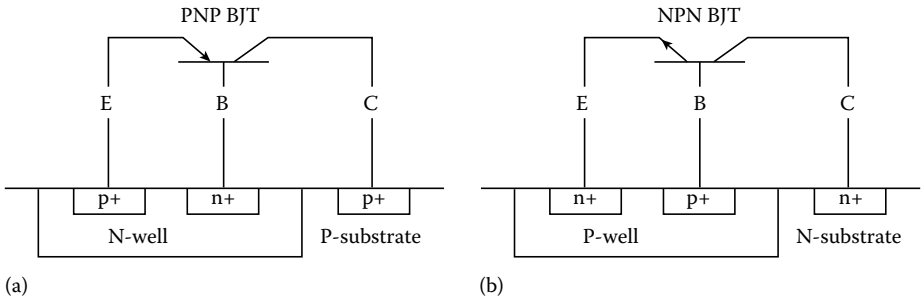

FIGURE 2.51 Realization of vertical BJT devices in CMOS technology. (a) N-well process. (b) P-well process.

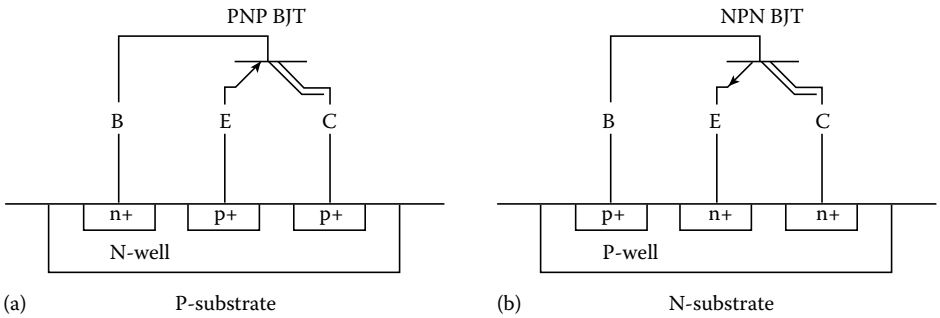

FIGURE 2.52 Realization of lateral BJT devices in CMOS technology. (a) N-well process. (b) P-well process.

NPN devices with the collectors connected to the substrate (most positive supply rail). The realization of these vertical devices in the case of N-well and P-well processes is shown schematically in Figure 2.51a and b, respectively. The devices can have typical current gains of around 100 and may have high leakage, and certain precautions have to be taken in the layout. One problem is that the control on the parameters of these devices in production is minimal. Nevertheless, such devices are adequate to realize moderate-to-high precision bias and reference circuits.

The restriction on the collector connections of the vertical BJT devices in CMOS technology is effectively removed in lateral BJT devices [16]. The realization of these devices in the case of N-well and P-well processes is illustrated in Figure 2.52a and b, respectively. It should be noted that β_∂ for lateral bipolar transistors is not related to α_∂ in the usual way due to substrate currents. For both vertical and lateral parasitic bipolar devices, it is often the case that the foundry will not provide detailed characterization and models, and also that the parameters of the devices will not be well controlled.

Apart from MOSFETs and BJTs, the remaining component needed to realize bias circuits are resistors and in some cases capacitors. In the case of precision bias circuits, the realized variable (voltage or current) would be dependent on resistor ratios rather than on absolute values. On-chip resistors may be realized using polysilicon, or as N- or P-well diffusion, as illustrated in Figure 2.53. Diffused resistors are sensitive to substrate potential and thus they are not suitable for precision potential dividers. In some cases, voltages or currents on a chip that are required to have high stability are referred to an off-chip highly stable and accurate discrete resistor. In some advanced processes, film resistors (usually nichrome) are available and they have excellent temperature stability, a wide range of values and can sometimes be laser-trimmed.

Capacitors, both on-chip and external, are used for decoupling bias and reference voltages and are especially valuable where low noise is critically important. On-chip capacitors also provide the basic components used for dynamic biasing.

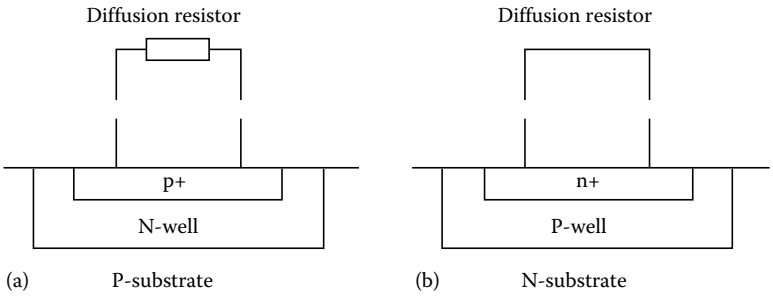

FIGURE 2.53 Realization of diffusion resistors in CMOS technology. (a) N-well process. (b) P-well process.

2.3.2.2 Device Models and Parameter Variability

The MOSFETs in Figure 2.48 may be very approximately described by [13,15]

$$I_d = \beta(V_{gs} - V_t)^2(1 + \lambda V_{ds}) \tag{2.111}$$

where

$$\beta = \mu C_{ox} W/L \tag{2.112}$$

and

$$V_t = V_{to} + \gamma\left[(2\phi_{fb} - V_{bs})^{0.5} - 2\phi_{fb}^{0.5}\right] \tag{2.113}$$

with

$$\phi_{fb} = \left(\frac{kT}{q}\right)\ln\left(\frac{N_{sub}}{n_i}\right) \tag{2.114}$$

and

$$\mu \propto T^{-\eta} \tag{2.115}$$

The parameters in Equations 2.111 through 2.115 are defined in Table 2.1. As a result of Equations 2.111 through 2.115, MOSFET parameters show considerable temperature dependence. In particular, threshold voltage varies with temperature according to

$$\frac{\partial V_t}{\partial T} = \frac{2}{T}\left(\phi_F - \frac{E_{go}}{2q}\right)\left(1 + \frac{\gamma}{2(2\phi_{fb} - V_{bs})}\right) \tag{2.116}$$

which amounts typically to about −2 mV/°C (Ego is the bandgap of silicon at 0 K) [15]. Transconductance varies according to

$$\frac{\partial g_m}{\partial T} = \frac{g_m}{2}\left(-\frac{\eta}{T} + \frac{1}{I_d}\frac{\partial I_d}{\partial T}\right) \tag{2.117}$$

The temperature and process dependencies of MOS devices have led to the exploitation of some properties of combinations of less usual MOS devices. It has been observed that the difference between

TABLE 2.1 Device Parameters

Symbols	Parameters
I_d	Drain current
β	Transconductance parameter
V_{gs}	Gate–source voltage
V_t	Threshold voltage
λ	Output conductance parameter
V_{ds}	Drain–source voltage
μ	Mobility
C_{ox}	Oxide capacitance per unit area
W	Gate width
L	Gate length
V_{to}	Zero substrate bias threshold voltage
γ	Body factor
ϕ_{fb}	Fermi potential
V_{bs}	Substrate–source voltage
K	Boltzmann's constant
T	Absolute temperature in K
Q	Electronic charge
N_{sub}	Substrate doping density
n_i	Intrinsic carrier density
$\acute{\eta}$	Mobility temperature coefficient
V_{FB}	Flat-band voltage
Q_{SS}	Surface charge per unit area
ϕ_P	Bulk potential
Q_d	Charge per unit area in inversion layer
ϕ_{bi}	Channel to substrate built-in potential
Q_i	Implanted charge per unit area
C_{impl}	Capacitance defined by implanted channel depth
ϕ_G	Bandgap voltage for silicon
ϕ_{GO}	Bandgap voltage for silicon at 0 K

the threshold voltages of an enhancement- and depletion-mode FET pair is relatively temperature independent. The threshold voltages for enhancement- and depletion-mode MOSFETs may be written

$$V_{t(enh)} = V_{FB} - \frac{Q_{SS}}{C_{ox}} + 2|\phi_P| + \frac{|Q_d|}{C_{ox}} \tag{2.118}$$

$$V_{t(depl)} = V_{FB} - \frac{Q_{SS}}{C_{ox}} + \phi_{bi} + (|Q_d| - |Q_i|)\left(\frac{1}{C_{ox}} + \frac{1}{C_{impl}}\right) \tag{2.119}$$

where the meaning of the parameters is given in Table 2.1 [4]. Many of the parameters in Equations 2.118 and 2.119 show considerable temperature dependence. The difference between the threshold voltages is given by

$$\begin{aligned} V_{t(diff)} &= V_{t(enh)} - V_{t(depl)} \\ &= 2|\phi_P| - \phi_{bi} - |Q_i|\left(\frac{1}{C_{ox}} + \frac{1}{C_{impl}}\right) \end{aligned} \tag{2.120}$$

assuming that $1/C_{ox} \gg 1/C_{impl}$, which is true in practice. In practice, it is also the case that $2|\phi_{P|} \approx \phi_{bi}$. Since the implanted charge Q_i is controllable and independent of temperature to first order [4], the threshold voltage difference exhibits temperature independence to first order.

The difference between the threshold voltages of two N-channel FETs with polysilicon gates of opposite doping polarity (P and N) also shows relative insensitivity to temperature variations [8]. To a first approximation, the threshold voltage difference is given by

$$\Delta V_G = \phi_G = 1.12 \text{ V (room temperature)} \tag{2.121}$$

which is the bandgap voltage for silicon [8]. A more detailed analysis [1] gives

$$\Delta V_G(T) = \phi_{GO} - \frac{\alpha T^2}{T + \beta} \tag{2.122}$$

where $\alpha = 7.02 \times 10^{-4}$ V/K, $\beta = 1109$ K and the meaning of the remaining parameters is given in Table 2.1. In practice, the degree of temperature independence obtained provides useful reference circuits [8]. The exploitation of both the enhancement–depletion FET threshold difference and the N–P-doped polysilicon gate threshold voltage difference for the design of references will be described later.

The strong temperature dependence of conventional MOS device parameters means that for stable biasing circuits, MOS devices are mainly useful where the critical variable depends on a ratio of parameters of similar devices. Even in this case, the matching is not as good as for bipolar devices. The matching of the gate–source voltages of two similar devices with nominally identical drain currents is inversely proportional to the square root of the gate area and is typically of the order of 10 mV, which limits the minimum offset voltage of a CMOS op-amp. Since op-amps form key components in many voltage and current reference circuits, this is a serious limitation.

In contrast to the rather complex dependence of MOS device parameters with temperature, the situation in the case of BJT devices is relatively straightforward [15,17,26]. The BJT may be described by

$$I_c = I_s e^{V_{be} q/kT} \tag{2.123}$$

where the additional parameters are defined in Table 2.1. Equation 2.123 may alternatively be written

$$V_{be} = \frac{kT}{q} \ln \frac{I_c}{I_s} \tag{2.124}$$

For two devices with an emitter area ratio of A

$$A = \frac{I_{s1}}{I_{s2}} \tag{2.125}$$

We have

$$\begin{aligned} \Delta V_{be} &= V_{be1} - V_{be2} \\ &= \frac{kT}{q} \ln \frac{I_{c1}}{I_{c2}} \frac{1}{A} \\ &= V_T \ln \frac{1}{A} \quad (\text{for } I_{c1} = I_{c2}) \end{aligned} \tag{2.126}$$

Thus, the difference between the V_{be}s of two BJTs with different current densities is proportional to the thermal voltage V_T, which is proportional to absolute temperature (PTAT). The positive temperature coefficient of V_T can be effectively used to cancel the negative temperature coefficient of V_{be} [13]. This is referred to as the bandgap principle.

Resistors are also key elements in MOS biasing circuits and they may be realized using diffusion, polysilicon and, in some advanced processes, using film techniques. Polysilicon and diffused resistors suffer from a high temperature coefficient that is positive for diffusion. The resistivity of gate polysilicon is typically rather low at about 20 Ω/square and its initial value tolerance is quite high. Film resistors have a very low temperature coefficient.

2.3.3 Voltage and Current Reference and Bias Circuits

2.3.3.1 Supply-Voltage-Referenced Voltage and Current References

When the supply voltages to a chip are well-regulated off-chip, then a voltage reference, acceptable in some cases, can be realized by a simple potential divider from the power supply voltage, as shown in Figure 2.54. An external decoupling capacitor may be used if needed and the voltage dividing elements may be resistors (Figure 2.54a) or MOSFETs (Figure 2.54b). If the power supply voltages are well-controlled off-chip, using an external regulator circuit, then a simple current reference can be realized by the arrangement in Figure 2.55, where the reference current is defined by applying a well-defined fraction of the controlled supply voltage to a well-controlled external resistor.

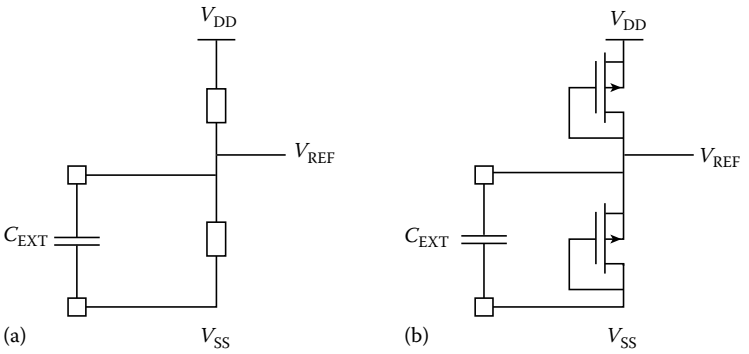

FIGURE 2.54 Voltage reference obtained via potential divider from regulated power supply: (a) using resistors; (b) using MOSFETs.

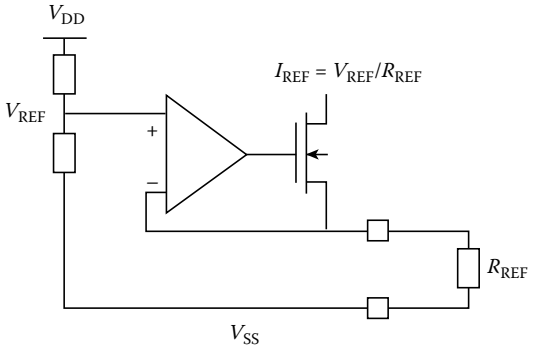

FIGURE 2.55 Current source realized using potential divider.

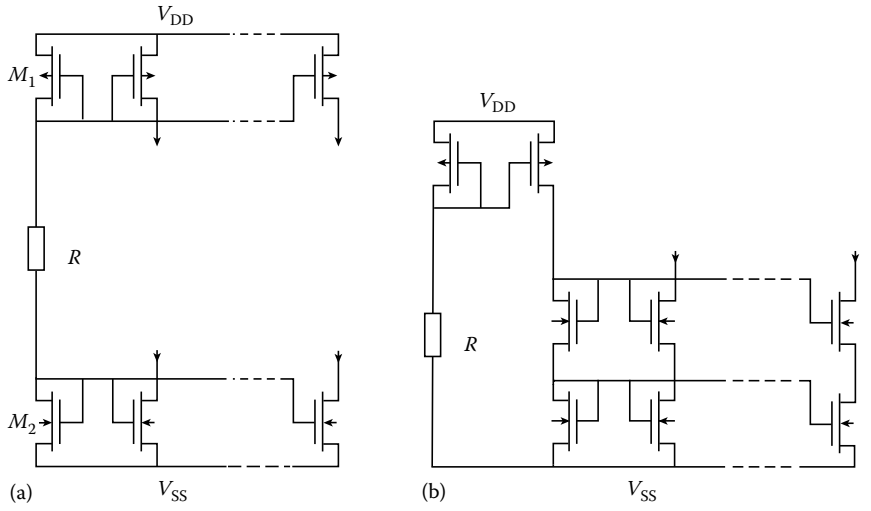

FIGURE 2.56 Resistor/current mirror bias circuits: (a) simple; (b) cascode.

A very simple biasing circuit proving multiple current sources and sinks, as required in CMOS analog signal-processing circuits, is shown in Figure 2.56a [13]. Assuming large FET W/L ratios, the voltage across the resistor is approximately $V_{dd} - V_{ss} - 2V_t$. The current in R is mirrored in the output MOSFETs where the W/L ratios may be chosen to provide required current magnitudes. The resistor R may have to be realized off-chip as a precision film component with narrow tolerance and small temperature coefficient. In practice, the voltage across the diode-connected MOSFETs M_1 and M_2 will be greater than V_t and have some dependence on MOSFET β as well as V_t.

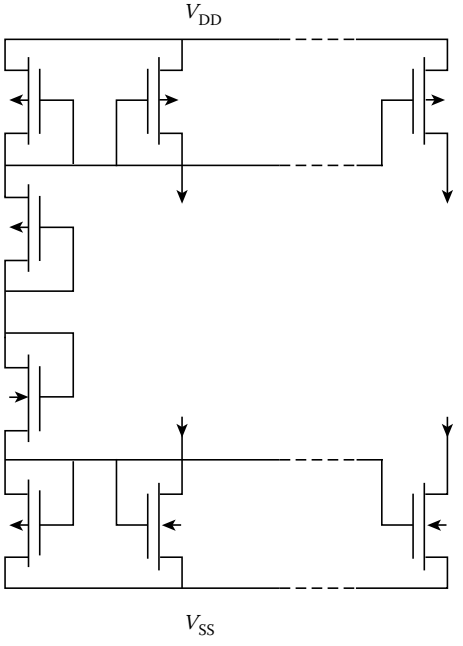

FIGURE 2.57 FET/current mirror bias circuit.

For the circuit in Figure 2.56a, the source conductance is equal to the MOSFET g_{ds}, which might not be sufficiently low for some applications. This disadvantage can be overcome by introducing cascode FETs as in Figure 2.56b. Nevertheless, the supply voltage dependence of the circuit in Figure 2.56 remains.

For uncritical applications where the current source is to be realized entirely on-chip, the resistor R in Figure 2.56a may be replaced by a chain of diode-connected P- and N-channel MOSFETs, as shown in Figure 2.57 [13]. The number of these devices and their W/L ratios may be chosen according to the supply voltage and the value of the current to be realized. Since the diode-connected MOSFETs are effectively realizing the resistor in the basic current source of Figure 2.56a, the power supply voltage dependence of the current remains. In addition, the effective resistance realized depends on MOSFET β and V_t, both of which have large tolerances and high temperature coefficients.

2.3.3.2 MOSFET Threshold Voltage-Based References

A current reference with reduced power supply voltage dependence is shown in Figure 2.58 [13]. By choosing W/L for M_1 to be large, the gate–source voltage of M_1 can be made close to the device threshold voltage V_t. Since the gate–source voltage of M_1 appears across the resistor R, the current in R is approximately V_t/R, which is ideally independent of power supply voltage. The W/L ratios of MOSFETs M_3 and M_4 are chosen to define a fixed ratio for the currents in M_1 and R. The combination of MOSFETs M_2, M_3, and M_4 constitute a positive feedback loop and it is important to choose the W/L ratios so that the loop gain is less than unity to avoid oscillation. Many reference circuits have a stable state with all currents zero. In such cases, it is necessary to provide a start-up circuit [13] to prevent the reference circuit locking into an undesired operating point. A source follower can be introduced at the gate of M_2 such that in this condition a current is injected into the circuit. The added components must be such that in the normal operating point, they are switched off and therefore do not influence operation. In practice, the currents realized by the circuit in Figure 2.58 will have some supply voltage dependence due to channel length modulation in the MOSFETs. This effect can be reduced by introducing cascode devices appropriately. Although the currents realized can be made substantially independent of supply voltage, the dependence on resistance R remains. For high precision and temperature independence, R may need to be realized as an off-chip film resistor. It must be borne in mind that the device threshold voltage on which the current depends is rather variable (typically 0.5–0.8 V) and also rather temperature dependent. Solution of this problem requires the introduction of alternative techniques based on BJT or unconventional CMOS devices, which will be discussed.

An alternative circuit to that in Figure 2.58 is shown in Figure 2.59 [25]. This circuit regulates the MOSFET drain currents with the result that MOSFET transconductance is proportional to $1/R$. This circuit also relies on positive feedback and care must be taken in the design to avoid instability. It has been shown in Ref. [21] that a practical stable design results from the choice $(W/L)_4 = (W/L)_3$ and $(W/L)_2 = 4(W/L)_1$, giving $g_m = 1/R$. In processes where R can be realized as a film resistor on-chip, this circuit can stabilize transconductances to within 3% over a 100°C temperature range [25].

2.3.3.3 BJT V_{be}-Based References

The problem that MOSFET threshold voltage is not very well controlled from chip sample to chip sample leads to the idea of using the V_{be} of a parasitic bipolar transistor [13]. Such a V_{be}-referenced circuit is

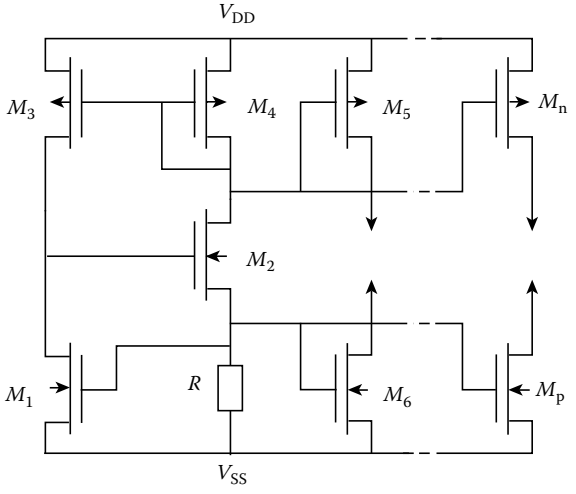

FIGURE 2.58 V_t-referenced current bias circuit.

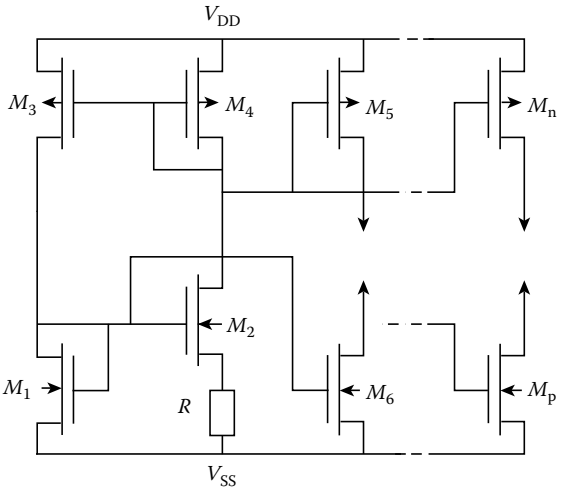

FIGURE 2.59 g_m-R tracking current reference circuit.

shown in Figure 2.60 for the case of an N-well process, where the BJT is PNP [13]. The W/L ratios for M_1 and M_2 are made large so that the V_{be} of T_1 appears substantially across R. In order to achieve high precision and temperature independence, R would need to be an off-chip film resistor. However, the V_{be} has a process-dependent tolerance of about 5% and a dependence with temperature of about -2 mV/°C.

2.3.3.4 BJT V_T-Based References

The temperature dependence of V_{be} in the circuit of Figure 2.60 can be overcome in the V_T-based circuit of Figure 2.61 [13]. The emitter areas of the BJTs Q_1 and Q_2 are scaled in the ratio 1:n and the MOS current mirrors force the emitter currents to be equal. The difference between the V_{be} of Q_1 and Q_2 given by Equation 2.121 appears across the resistor R, hence defining the current. The positive temperature coefficient of V_T can be used to counteract the positive temperature coefficient of the resistor R to obtain

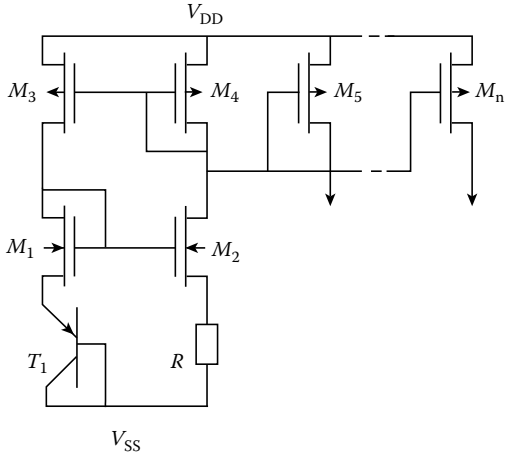

FIGURE 2.60 V_{be}-referenced current bias circuit.

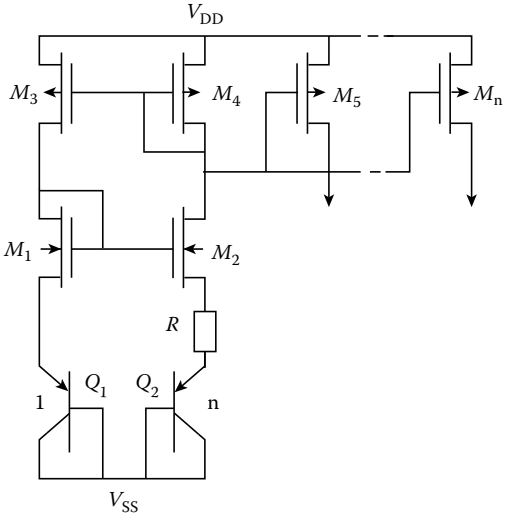

FIGURE 2.61 V_T-referenced current bias circuit.

a stable current. In the circuit of Figure 2.61, M_1 and M_2 must have large W/L to minimize the effect of MOSFET process variability. Also, cascoding of the current mirrors may be required to reduce the effect of channel length modulation.

2.3.3.5 Bandgap References

Precision voltage sources are key requirements for the realization of precision data converters and have received much attention [2,3,7,10,12–14,20,22]. The requirements for high precision and very low temperature and supply voltage dependence have led to the development of the bandgap principle [2,3,7,10,13]. The bandgap principle was originally developed for bipolar technology and a typical architecture is shown in Figure 2.62a. As described previously, the difference between the V_{be}s of two BJTs with different current densities is proportional to the thermal voltage V_T and is PTAT. In Figure 2.62a, the difference between the V_{be}s appears across R_3 and in scaled form across R_2. Thus the output voltage is equal to the V_{be} of Q_1 plus the scaled version of ΔV_{be}. Thus R_2/R_3 may be chosen so that the opposite temperature coefficients of V_{be} and ΔV_{be} cancel. The ratio R_1/R_2 determines the ratio of the currents in Q_1 and Q_2. The circuit in Figure 2.62a is incompatible with implementation using CMOS technology with vertical parasitic bipolar devices because the collectors are not grounded. This can be overcome using the architecture in Figure 2.62b. However, there is the further problem that the offset voltage of the operational amplifier is multiplied by the internal gain of the feedback loop and added to the output. Offset is worse for CMOS than for bipolar operational amplifiers. This problem has been overcome in various ways. In Refs. [12,22], use is made of a discrete time offset compensated differential amplifier, which can have very low offset. Another approach is to make use of lateral bipolar devices, which do not suffer from the topological restrictions of their vertical counterparts [16]. Thus the architecture of Figure 2.62a or an equivalent topology may be implemented.

A typical example of a current reference based on a bandgap voltage reference is shown in Figure 2.63 [13]. The current in the resistor xR is V_T-referenced as in Figure 2.61 and therefore has a negative temperature coefficient (the BJTs are vertical parasitic devices). This current is converted to a voltage and weighted by the resistor xR before being added to the V_{be} of Q_3, which has a negative temperature coefficient. The parameter x is chosen to obtain an overall zero temperature coefficient for the output current, which is given by V_{REF}/R_0. Clearly, R_0 needs to be a high-precision resistor and could be external to the chip. The current mirrors need to be very well matched as any offset is amplified. The operational amplifier needs to have a low offset voltage since this is added to the reference voltage. Further current mirroring may be used to change the sign of the current or to increase the permissible range of the output voltage, referred to as compliance.

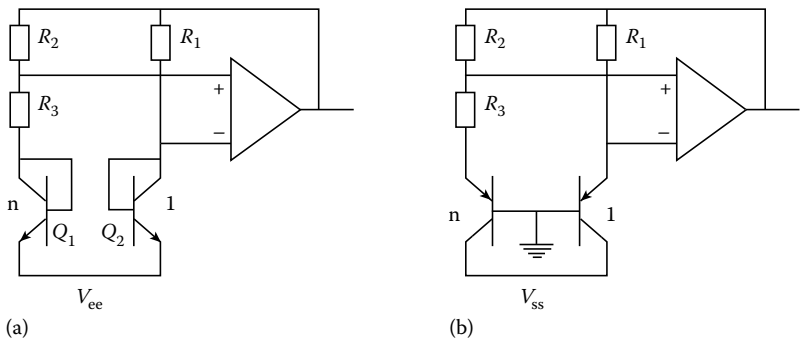

FIGURE 2.62 Basic bandgap circuits. (a) Classical bandgap circuit. (b) Modified form with grounded-collector PNP transistors, assuming an N-well process.

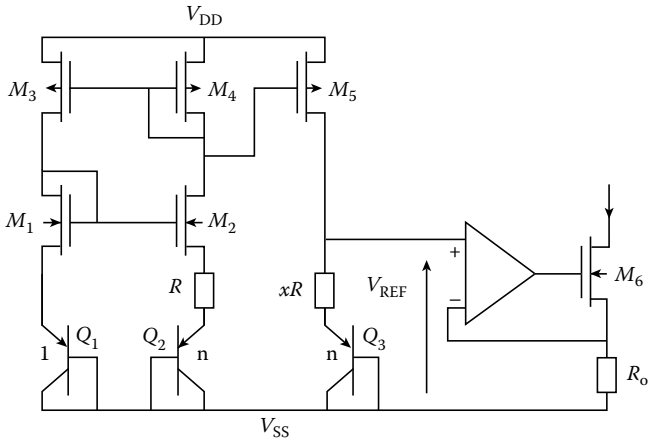

FIGURE 2.63 Bandgap current bias circuit.

2.3.3.6 Curvature-Compensated Bandgap References

The bandgap reference principle can provide a zero temperature coefficient at a single temperature, leaving a temperature dependence that is dominated by a second-order temperature dependence. Very sophisticated techniques have been developed [12,24] to eliminate this second-order dependence to leave a typically much smaller third-order dependence. This technique is referred to as curvature compensation. An example of a curvature-compensated current reference [24] is shown in Figure 2.64. This circuit can achieve precisions of the order of 5 ppm/°C for supply voltages over 5–15 V.

2.3.3.7 Discrete Time Bandgap References

The voltage reference in Ref. [12] provides curvature compensation and achieves a drift of the order of 13 ppm/°C over the commercial temperature range. The design is based on a comprehensive analysis of nonideal effects in the basic bandgap circuit including finite β and base resistance of the bipolar devices, operational amplifier offset, and bias current variation. This leads to a system involving a very low offset switched capacitor differential amplifier and a system of injecting a differential pair of currents into the

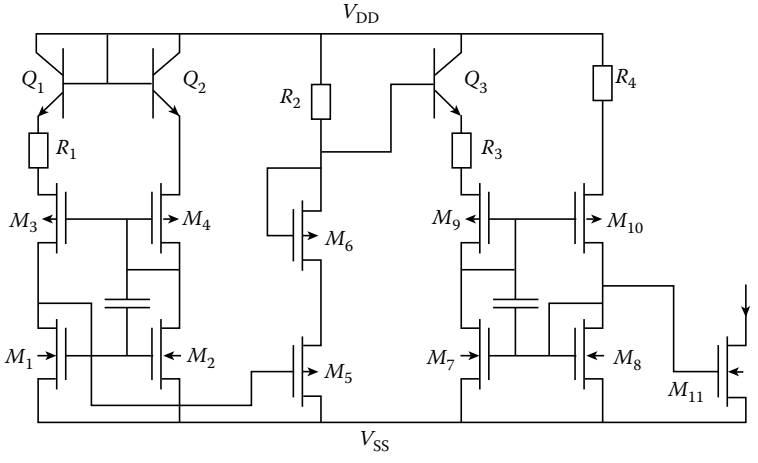

FIGURE 2.64 Curvature-compensated current bias circuit.

emitters of the bipolar devices to provide curvature compensation. The offset cancellation of the switched capacitor differential amplifier is accompanied by techniques for cancellation of the effect of base currents and base resistance in the bipolar devices. Base currents can sometimes be a severe problem due to the available current gains of parasitic bipolar devices. The design is fully compatible with a digital IC process and achieves an equivalent precision of 12 b. Room temperature trims are necessary for a zero temperature coefficient and for curvature compensation. Although low-frequency power supply rejection is good, it falls with increasing frequency.

In Ref. [22], a floating voltage reference for signal-processing applications with a good power supply rejection ratio of at least 85 dB maintained up to 500 MHz is realized. Over a temperature range of -40 to $+85$°C, voltage dependence is 40 ppm/°C and supply voltage dependence $\pm 5\%$. The circuit has the important advantage that trimming is not required.

2.3.4 Voltage and Current References Based on Less Usual Devices

2.3.4.1 Use of Device in Subthreshold Region

An alternative approach to current reference making use of MOSFETs in the subthreshold region is reported in Ref. [19]. The principle of the approach is illustrated in Figure 2.65a, where for thermal stabilization the voltage source is required to be PTAT. The PTAT voltage source is realized as a cascade of 5 of the PTAT voltage sources shown in Figure 2.65b, which rely on the subthreshold mode operation of the devices. In practice, cascoding of the current mirrors and current sources is required and a start-up circuit is needed. A current accuracy of 3% with temperature stability of 3% over 0–80°C can be achieved with this approach [19].

2.3.4.2 Voltage Reference Circuits Using Lateral Bipolar Devices

The circuit diagram of a bandgap voltage reference making use of lateral bipolar devices is shown in Figure 2.66 [16]. The circuit is designed to be insensitive to low β and α of the bipolar devices. It is also insensitive to offsets and mismatch. A single trim at room temperature is required and a high power supply rejection ratio, at least at low frequencies, is obtained. The output voltage is stable to within 2 mV over a wide temperature range.

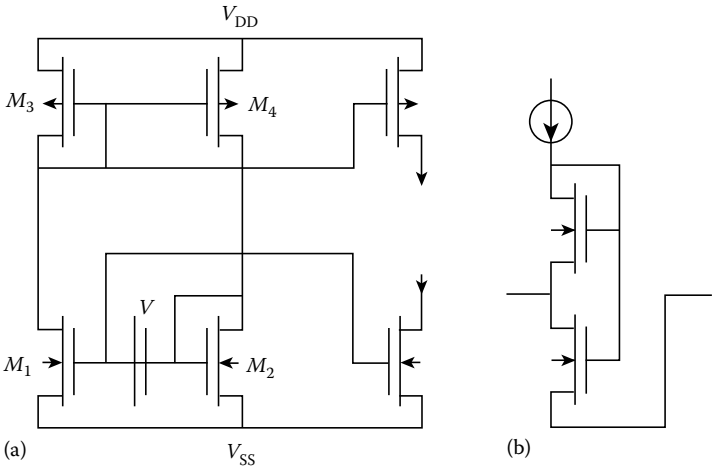

FIGURE 2.65 MOS current bias circuit based on weak inversion operation: (a) basic circuit; (b) voltage source cell.

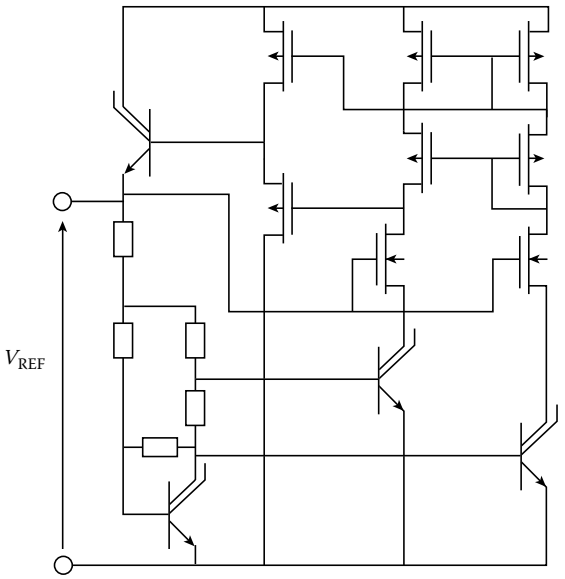

FIGURE 2.66 Voltage reference using lateral bipolar devices.

2.3.4.3 Voltage References Based on Enhancement and Depletion-Mode Threshold Voltage Difference

The topology restrictions and imperfections of the BJT devices available in CMOS technology have led to the development of alternative techniques for designing references without needing bipolar devices. In one technique, the fact that the difference between the threshold voltage of depletion-mode and enhancement-mode devices is relatively temperature independent has been exploited [4,5,23].

The section on device models and parameter variability demonstrated that the difference in threshold voltages of an enhancement- and depletion-mode MOSFET is relatively insensitive to temperature. Since the threshold voltage of the depletion-mode device is negative, this approach leads to a reference voltage of the order of 2 V, which is higher than the bandgap voltage, and this can be an advantage. A basic scheme for exploiting this principle for a voltage reference is shown in Figure 2.67. The op amp adjusts the gate voltage of the enhancement-mode FET to keep the drain voltages the same and the resistor values can be used to adjust the ratio of the currents in the two FETs. The operational amplifier may be implemented at device level [4]. The gate voltage of the depletion-mode FET may be connected to the output of a buffer amplifier whose output voltage may be adjusted using polysilicon fuses to typically 3.15 ± 0.02 V [5].

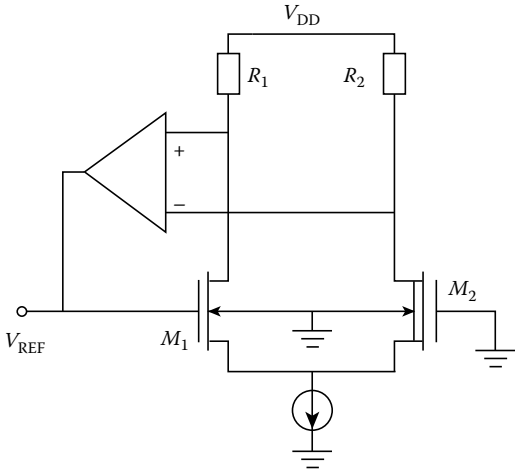

FIGURE 2.67 Basic reference based on enhancement–depletion threshold difference.

Higher reference voltages may be obtained by replicating the enhancement- and depletion-mode MOSFETs. In Figure 2.68, the reference voltage is the difference between the threshold voltages of the three enhancement-mode MOSFETs M_1–M_3 and the three depletion-mode MOSFETs

M_4–M_6 [23]. M_7–M_{10} are providing the necessary bias currents. In Ref. [23], the variation of V_{REF} with temperature is 1.5 mV/°C, which is useful for many biasing situations and the reference voltage is of the order of 3 V in spite of low threshold voltage devices.

2.3.5 Voltage References Based on N- and P-Doped Polysilicon Gate Threshold

2.3.5.1 Voltage Difference

In CMOS technology, the gate material is usually polysilicon with N-type doping. In some processes, selective doping to provide P-type doping of the polysilicon gate is also available and the presence of both types of doping has been exploited for reference circuit design [8].

The basic principle of a voltage reference based on the difference between the threshold voltages of N- and P-doped polysilicon gate MOSFETs is illustrated in Figure 2.69. M_1 has a P-doped gate and a higher threshold voltage than M_2. M_1 and M_2 are in different P-wells but have the same effective dimensions and bias currents.

A full transistor-level implementation of the basic circuit in Figure 2.69 is shown in Figure 2.70 [8]. M_1 and M_2 are the reference MOSFETs. M_3 has a very long channel and its current is the same as that in M_1 by virtue of the current mirror M_4: M_5. Thus the current in M_1 adjusts itself to the crosspoint of the characteristics of M_1 and M_3. M_7, M_8, and M_9 ensure that the currents in M_1 and M_2 are identical. M_6 is a start-up device. When the power supply is switched on, M_6 comes on but within 1 ms is switched off by the reverse leakage resistance of the polysilicon diode D. In Ref. [8], M_1 and M_2 can have a W/L of 100/20 μm; supply voltage sensitivity of $<10^{-3}$ is obtained for V_{DD} between 2 and 9 V [8]. Digital tuning using polysilicon fuses to reference voltages other than the polysilicon gate work function difference can be obtained and a further level of temperature compensation applied [8].

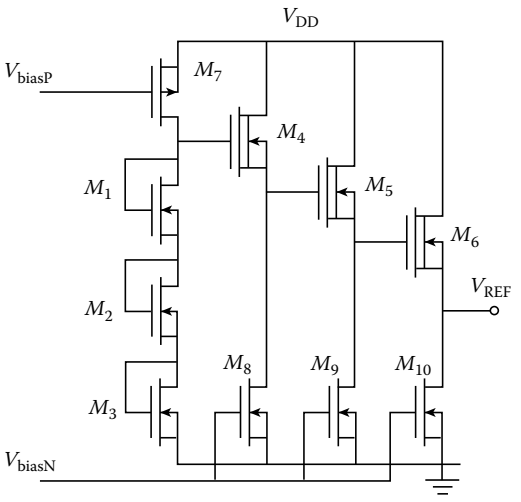

FIGURE 2.68 High-output enhancement–depletion threshold difference reference.

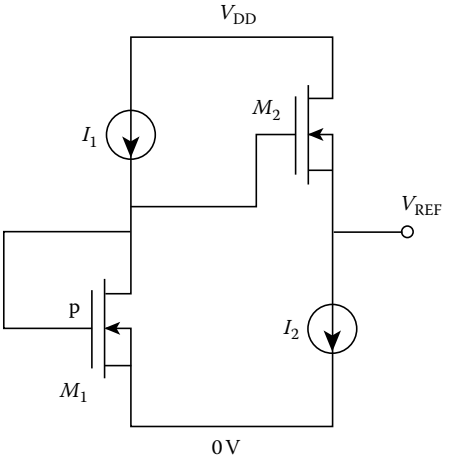

FIGURE 2.69 Basic reference based on polysilicon work function difference.

2.3.6 Biasing of Simple Amplifiers and Other Circuits

2.3.6.1 Simple Amplifiers

In traditional two-stage amplifier design, the bias for the whole circuit is easily set up from one reference current and no critical voltage differences have to be set up. It is only necessary to ensure that the operating currents, and hence the transconductance, of each device have a required value. A typical example of the biasing of a two-stage amplifier is shown in Figure 2.71 [13]. The ratio of currents between

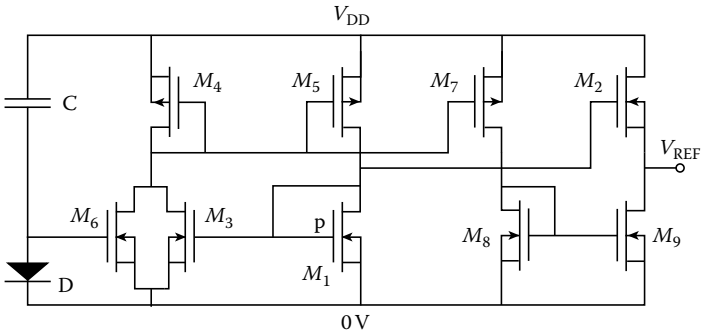

FIGURE 2.70 Example of reference based on polysilicon work function difference.

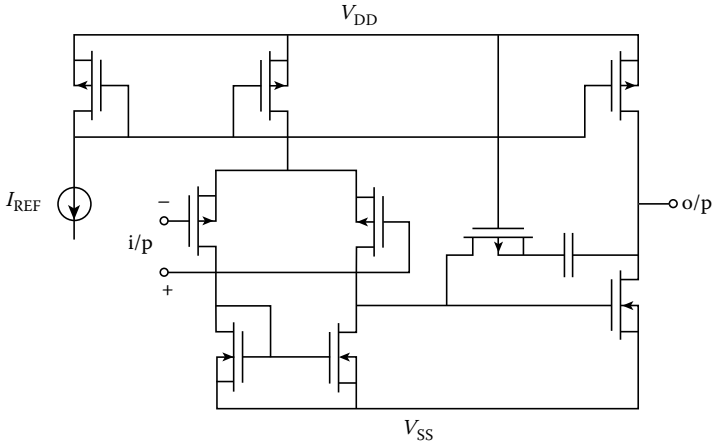

FIGURE 2.71 Two-stage amplifier.

the first- and second-stage controls the separation of the poles and also the systematic offset. The internal biasing circuit consists simply of a set of current mirrors.

2.3.6.2 Cascode Amplifiers

In cascode amplifiers [13], the idea is to raise the amplifier output impedance in order to increase the gain. An important requirement, especially in a low supply voltage environment, is to obtain maximum output voltage swing, or compliance, in the cascode amplifier. This requirement makes the biasing of the cascode devices critical.

A simple amplifier designed for cascode loads is shown in Figure 2.72. Only a single current mirror from the main current reference is needed to control all the bias currents. For reasonable low-frequency gains of say >60 dB, the output impedance must be made high while keeping component parameters practical. Use of very long channel output FETs is undesirable because of poor bandwidth and the chip area requirement. Therefore, the cascode technique, as shown in Figure 2.73, is the ideal solution. This raises output impedance by approximately $g_{m(M11)}r_{ds(M11)}$ and $g_{m(M12)}r_{ds(M12)}$ on each side. However, the maximum output voltage swing, or compliance, of the circuit has now been reduced by at least the saturation voltages of M_{11} and M_{12}. The cascode devices must be biased so that the voltage across M_8 and M_9 is just above V_{dsat}.

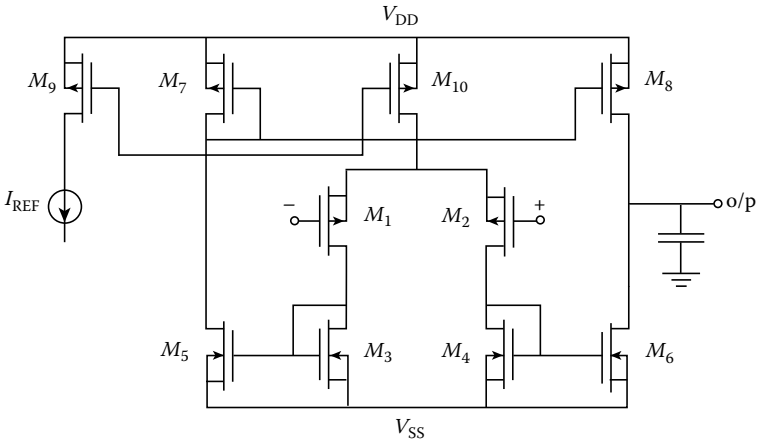

FIGURE 2.72 Simple single-stage amplifier.

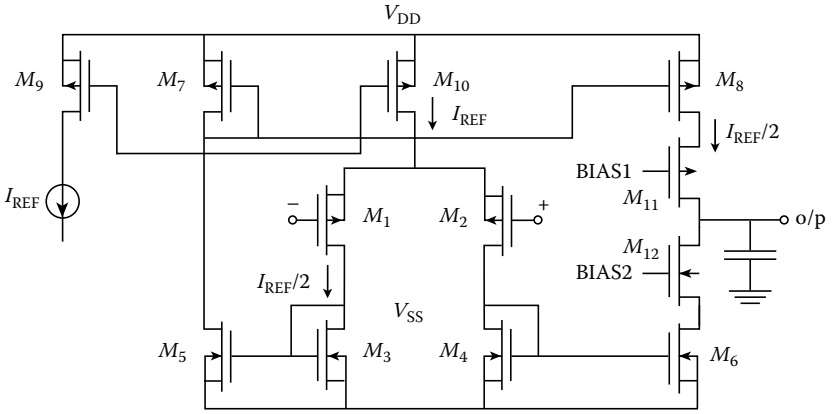

FIGURE 2.73 Simple single-stage amplifier with cascoded output FETs.

The usual way of achieving this is to arrange that a current is passed through an FET with a scaled width so that one obtains a voltage $V_{TN} + V_{Dsat(M6)} + V_{Dsat(M12)}$ for the N-channel side and $V_{TP} + V_{Dsat(M8)} + V_{Dsat(M11)}$ for the P-channel side. If the saturation voltage of the driver FET (M_6) and the cascode FET (M_{12}) are the same, then this requires a bias FET with a current density four times higher. In reality, the body effect in M_{12} and tolerance considerations mean that this factor will have to be somewhat higher than 4 [13].

Hence, there is a requirement for more replicas of the incoming reference current. The whole scheme develops to the configuration shown in Figure 2.74, where the circuit is represented in its simplest ideal form. Note that all FET scaling is applied to device widths; the lengths are the same throughout. In practice, this circuit would have a large offset due to the unequal drain voltages in the various current mirrors, and balancing dummy FETs would be needed.

2.3.6.3 Folded Cascode Amplifiers

A common problem in modern CMOS design is the basing of folded cascode amplifier stages [13]. Folded cascode amplifiers are much used to get reasonable common-mode and output range in low power supply voltage situations. A typical example of a folded cascode amplifier is shown in Figure 2.75.

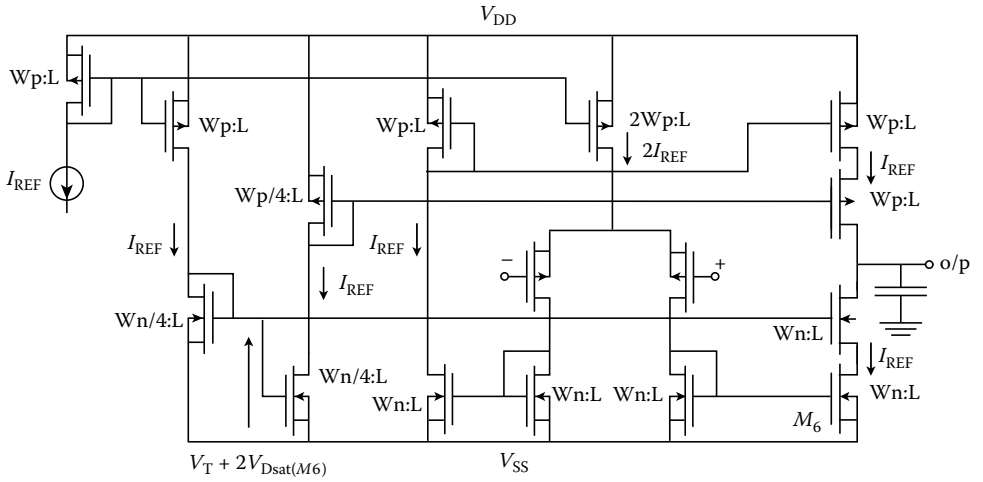

FIGURE 2.74 Cascode simple single-stage amplifier with biasing circuits.

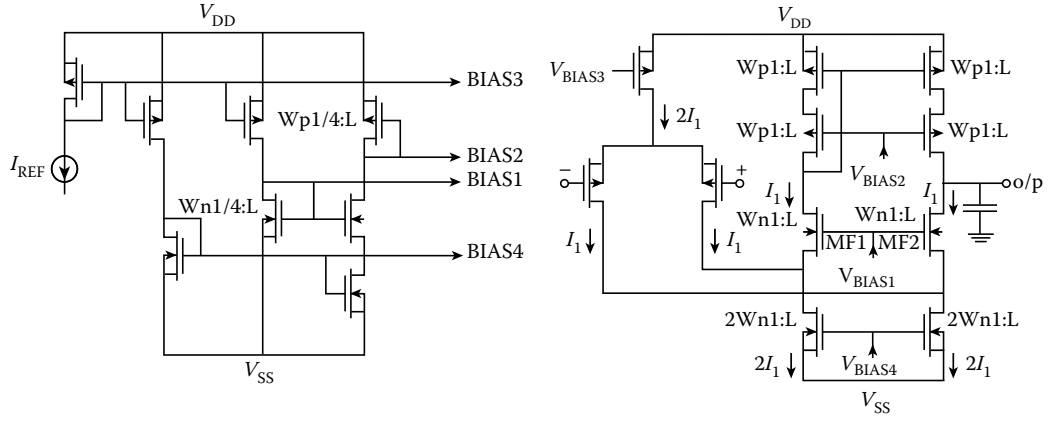

FIGURE 2.75 Folded cascode amplifier with biasing circuits.

The biasing of the folded cascode architecture is basically similar to that of a nonfolded cascode provided that correct current densities are maintained in the FETs. This is important because the folding current source (*MF*1, *MF*2) and the cascode will have different current levels and the bias must allow for this and set the cascode FET to the minimum safe operating bias. A ratio of 1:4 in width for the same current density gives the ideal bias for equal saturation voltages. Differing values of saturation voltage must be summed and the bias FET scaled accordingly.

2.3.6.4 Current Mirrors

The folded cascode amplifier of Figure 2.75 includes the current mirror of Figure 2.76 [18]. This circuit is a high compliance current mirror featuring low input voltage and low minimum output voltage. The cascode devices embedded in it are biased from an FET of width ratio running at the same quiescent current as the mirror. A width ratio of 1:4 is predicted by simple theory for equal saturation voltages in the mirror.

2.3.7 Biasing of Circuits with Low Power Supply Voltage

The topic of low-voltage analog MOS circuits is an important one because of the requirement for battery operation and also for compatibility with advanced digital IC processes with low power supply voltages. In order to maintain a reasonably high dynamic range in low supply voltage analog circuits, it is essential that the circuits operate with signal swings that are a very large fraction of the total supply voltage. Since operational amplifiers are key components in analog circuits, this has led to the design of operational amplifiers with "rail-to-rail" input common-mode voltage and output voltage capability. The design of such an input stage requires new approaches to biasing and we shall give brief details of an example of one such circuit [27].

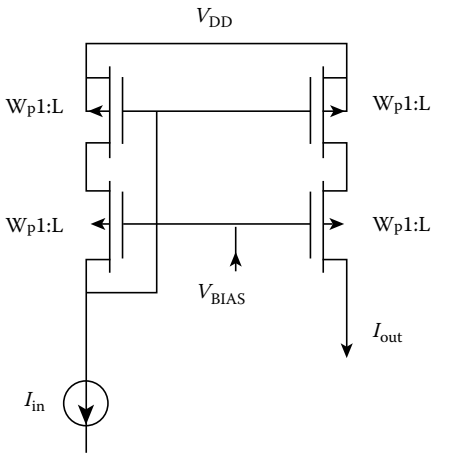

FIGURE 2.76 High-compliance current mirror.

A conventional differential pair of N- or P-channel MOSFETs would not provide sufficient input voltage common-mode range. This is because the input FET pair and the FET realizing the tail current source would tend to come out of saturation at one extreme of input common-mode voltage (negative for NMOS, positive for PMOS). This is overcome by combining an NMOS and PMOS differential pair as shown in Figure 2.77. However, this circuit has the disadvantage that the effective transconductance varies widely with common-mode input voltage since in the middle range, both differential pairs are conducting but at the extremes, only one differential pair is conducting. This produces a common-mode voltage dependence of amplifier dynamic performance and makes it difficult to optimize the dynamic performance for all input conditions.

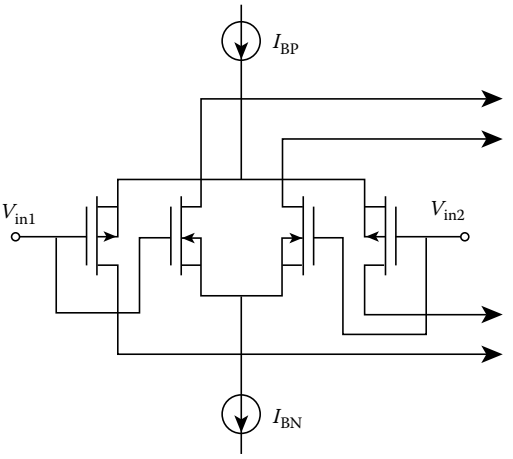

FIGURE 2.77 Op-amp input stage for rail-to-rail operation.

An elegant solution to this problem is reported in Ref. [27]. Assuming that the drain current of a MOSFET can be described by a square-law relationship, then transconductance is proportional to the square root of bias current. Since the overall effective transconductance of the input stage in Figure 2.77 is the sum of the effective transconductance of each pair, it follows that the condition when the overall transconductance is independent of common-mode input voltage is

$$\sqrt{I_{BN}} + \sqrt{I_{BP}} = \text{Constant} \tag{2.127}$$

Bias currents satisfying this relationship can be implemented using the MOS translinear circuit principle [27]. This principle applies to circuits where the gate–source ports of MOSFETs form a closed loop. Assuming that the devices are describable by a square-law drain–current relationship, the sum of the square roots of the drain currents of the MOSFETs whose ports are connected in a clockwise fashion equals the sum of the square roots of the drain currents of the counterclockwise-connected MOSFETs.

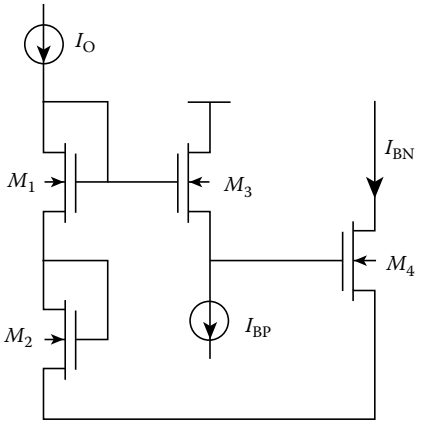

FIGURE 2.78 Bias circuit based on MOS translinear principle.

The application of the basic idea to implement bias currents according to Equation 2.127 is shown in Figure 2.78. Since the clockwise-connected MOSFETs M_1 and M_2 have a constant drain current I_o, the translinear principle implies that the drain current in M_3 and M_4 satisfy Equation 2.127. The development of the schematic bias circuit in Figure 2.78, the input stage in Figure 2.77, and a class *AB* output stage into a fully operational amplifier is described in Ref. [27]. The circuit operates with a minimum power supply of 2.5 V.

2.3.8 Dynamic Biasing

Dynamic biasing is a technique that is applicable to amplifiers in sampled data systems, such as switched capacitor filters and data converters [6,9]. Such amplifiers are required to meet two key requirements. These are fast settling time in order to allow high switching rates and high gain in order to obtain precision performance [13]. Fast settling time is obtained for maximum effective device transconductance and device transconductance g_m is approximately proportional to, $\sqrt{I_B}$, where I_B is bias current. Gain is given by g_m/g_o, where g_o is output conductance. Since g_o is proportional to bias current, gain is "inversely" proportional to $\sqrt{I_B}$. Thus maximum settling time requires a high bias current and maximum gain requires a low bias current. The dynamic bias technique reconciles these two requirements.

Figure 2.79 shows a typical switched capacitor integrator, which is a basic building block for implementing high-order switched capacitor systems. The switches are controlled by two-phase nonoverlapping clock signals ϕ and $\bar{\phi}$. The operational amplifier would generally have a first stage comprising a differential MOSFET pair with constant current source bias. The equivalent of this with dynamic biasing is shown in Figure 2.80, where the constant current source has been replaced by the combination of capacitor *C* and switches S1 and S2. We refer to the integrator of Figure 2.79. During phase ϕ, the capacitor C_1 is being charged up to the input voltage and the amplifier is inactive. Meanwhile, in the dynamically biased amplifier of Figure 2.80, the capacitor *C* is being discharged. In phase $\bar{\phi}$, capacitor C_1 in Figure 2.79 is connected to the input of the amplifier, where the output voltage is required to change to absorb the incoming charge. At the same time, capacitor *C* in Figure 2.80 is connected to the differential pair and immediately starts to conduct a high current. The high current through the amplifier MOSFETs provides a high effective amplifier slew rate and fast initial settling time, although the gain of the amplifier during this initial part of the clock phase is low. As time progresses, capacitor *C* becomes charged and the current in the amplifier MOSFETs reduces. This increases the gain of the amplifier leading to a high precision of the amplifier output voltage.

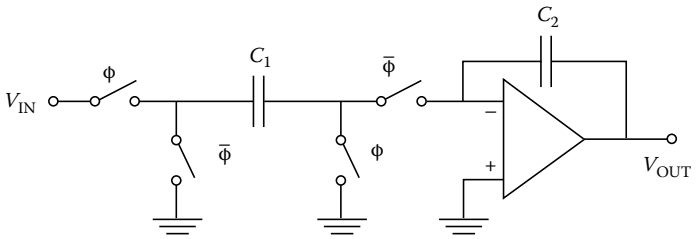

FIGURE 2.79 Typical switched capacitor integrator.

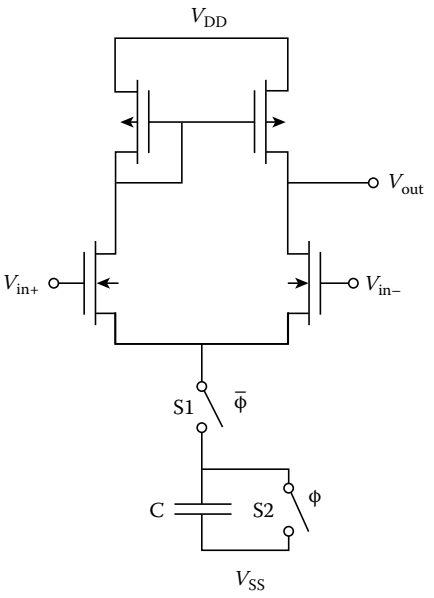

FIGURE 2.80 Simple op-amp with dynamic biasing.

Eventually, the amplifier current falls to zero with the output voltage at this required level. If, as would usually be the case, it is required to sample the amplifier output voltage in both phases, then the dynamic current source comprising capacitor *C* and the two switches S1 and S2 in Figure 2.80 would need to be duplicated with opposite switch phasing. This technique considerably increases the gain available from an amplifier since the effective gain depends on the low bias current condition and is very high. Dynamic biasing may, however, be easily applied to both stages of a two-stage amplifier if required [9]. Also, efficient schemes are available for the dynamic biasing of several amplifiers in a circuit.

Dynamic biasing is well worth considering in sampled date applications, such as switched capacitor filters and data converters. It can maximally exploit a given low power consumption to obtain good dynamic circuit performance. A variant of this approach [11] is adaptive biasing in which the input differential signal is sensed and the bias current is increased for large differential input signals to speed up the slewing response.

2.3.9 Conclusions

The task of designing voltage and current references and bias circuits is an important one. The requirements are very diverse, ranging from high precision, as required in data converters, to moderate, as required in general biasing situations. In these sections, space has been sufficient only to discuss some outstanding work in the area and some of the main principles. It is hoped that the reader will consult the references for more detailed information.

2.4 Canonical Cells of MOSFET Technology

Mohammed Ismail, Shu-Chuan Huang, Chung-Chih Hung, and Trond Saether

Analog integrated circuits have long been designed in technologies other than CMOS. But modern analog and mixed-signal VLSI applications in areas such as telecommunications, smart sensors, battery-operated consumer electronics, and artificial neural computation require CMOS analog design solutions. In recent years, analog CMOS circuit design has shown signs of dramatic change. Field programmable analog arrays and modular analog VLSI circuits [1] are representatives of emerging analog design philosophies leading to a whole new generation of analog circuit and layout design methodologies.

This section discusses basic cells used in contemporary CMOS analog integrated circuits. The performance of a CMOS (bipolar) circuit can often be improved further by incorporating a limited

number of bipolar (CMOS) transistors on the same substrate. The resulting circuits are called BiCMOS circuits. BiCMOS circuits that are predominantly CMOS will also be discussed. First, we discuss primitive analog cells. These cells may or may not require device matching for proper operation. Second, we introduce modern and simple circuit techniques to mitigate nonideal effects and significantly improve circuit performance, and finally, we discuss basic voltage amplifier circuits. The presented cells will help in the systematic design of analog integrated circuits and could constitute an efficient analog VLSI cell library. Throughout this section, MOS transistors are assumed to be biased in strong inversion.

2.4.1 Matched Device Pairs

Figure 2.81 shows basic MOS transistors pairs [2] operating in the saturation region, where only NMOS transistors pairs are shown. Figure 2.81a shows a differential pair with no direct connection between the two transistors. The resultant differential pair is characterized by the difference in the drain currents (using the simple square-law equation); that is

$$\begin{aligned} I_{a1} - I_{a2} &= \frac{K}{2}(V_{G1} - V_{S1} - V_T)^2 - \frac{K}{2}(V_{G2} - V_{S2} - V_T)^2 \\ &= \frac{K}{2}[(V_{G1} - V_{G2}) - (V_{S1} - V_{S2})] \\ &\quad \times [(V_{G1} + V_{G2}) - (V_{S1} + V_{S2}) - 2V_T] \end{aligned} \tag{2.128}$$

where $K(=\mu C_{ox}W/L)$ and V_T are the transconductor parameter and the threshold voltage of the transistor, respectively. Figure 2.81b is a common-source or source-coupled differential pair, a special case of circuit (a) with $V_{S1} = V_{S2} = V_S$, and the differential current is

$$I_{b1} - I_{b2} = \frac{K}{2}(V_{G1} - V_{G2})[(V_{G1} + V_{G2}) - 2V_S - 2V_T] \tag{2.129}$$

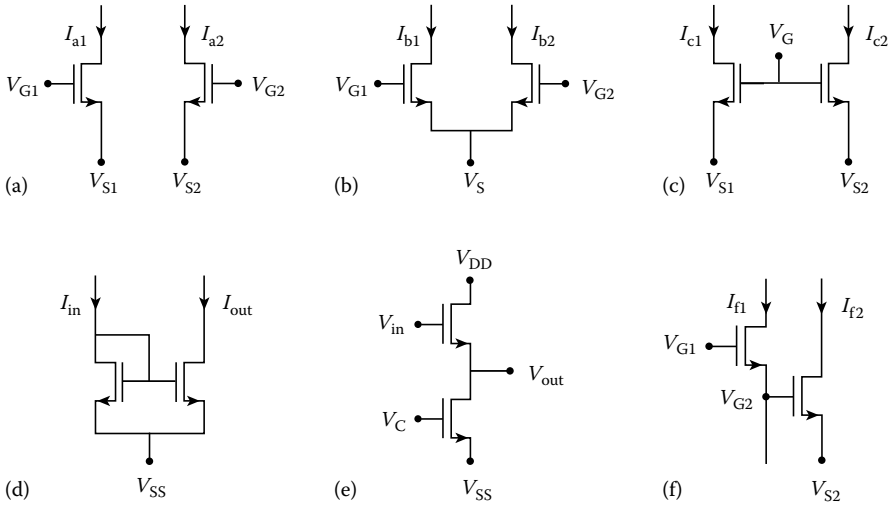

FIGURE 2.81 Matched primitive cells operating in the saturation region. (a) A differential pair with no direct connection between the two transistors, (b) is a common source or source coupled differential pair, (c) a common-gate differential pair, (d) a well-known simple current mirror, (e) a voltage follower, and (f) a rearranged transistor pair.

Figure 2.81c is a common-gate differential pair with $V_{G1} = V_{G2} = V_G$ in circuit (a), and the differential current is obtained as

$$I_{c1} - I_{c2} = -\frac{K}{2}(V_{S1} - V_{S2})[2V_G - (V_{S1} + V_{S2}) - 2V_T] \tag{2.130}$$

Differential pairs are essential building blocks of circuits such as op-amps, differential difference amplifiers and operational transconductance amplifiers. Several linear *V–I* converters built by these cells have been developed.

Current mirrors are usually used as loads for amplifier stages. Moreover, current mirrors are essential building blocks in modern current-mode analog integrated circuits. Figure 2.81d shows a well-known simple current mirror. Ideally, the input current I_{in} is equal to the output current I_{out} for matched transistors. In practice, a nonunity I_{out} to I_{in} ratio occurs due to finite output resistance resulting from channel length modulation effects. The output resistance can be increased by Wilson or cascode current mirrors at the expense of a limited output swing, which is not desired in low-voltage applications. A regulated current mirror can improve both the output resistance and swing but increase circuit complexity. Detail analysis and comparison are discussed in Ref. [3].

A voltage follower is shown in Figure 2.81e. Since the same current flows in both transistors, their gate–source voltages are the same. That is,

$$V_{in} - V_{out} = V_C - V_{SS} \tag{2.131}$$

and therefore

$$V_{out} = V_{in} - V_C + V_{SS} \tag{2.132}$$

Alternatively, a transistor pair can be arranged as the circuit shown in Figure 2.81f, which is used as a basic cell for composite MOSFET (COMFET) circuits [4]. The differential current is given by

$$\begin{aligned} I_{f1} - I_{f2} &= \frac{K}{2}(V_{G1} - V_{G2} - V_T)^2 - \frac{K}{2}(V_{G2} - V_{S2} - V_T)^2 \\ &= \frac{K}{2}(V_{G1} - V_{S2} - 2V_T)(V_{G1} - 2V_{G2} + V_{S2}) \end{aligned} \tag{2.133}$$

With proper biasing, linear *V–I* conversion can be achieved by this transistor cell.

Transistor pairs operating in the triode region are found mostly in simulating linear transconductors and resistors, for example, those in MOSFET-C filters. Figure 2.82 shows three popular examples, where the nonlinear terms in the drain current equations are canceled. A simple drain current equation in the triode region is

$$I_D = K\left[(V_G - V_T)(V_D - V_S) - \frac{1}{2}\left(V_D^2 - V_S^2\right)\right] \tag{2.134}$$

$$= \frac{K}{2}(V_G - V_S - V_T)^2 - \frac{K}{2}(V_G - V_D - V_T)^2 \tag{2.135}$$

Equation 2.135 gives another form of the triode current equation. In some cases, circuit analysis can be performed more easily with this form than using Equation 2.134. The resulting current equations of the equivalent ''MOS resistors'' are now obtained.

For the circuit shown in Figure 2.82a, a two-transistor transconductor, the current difference is given by [5]

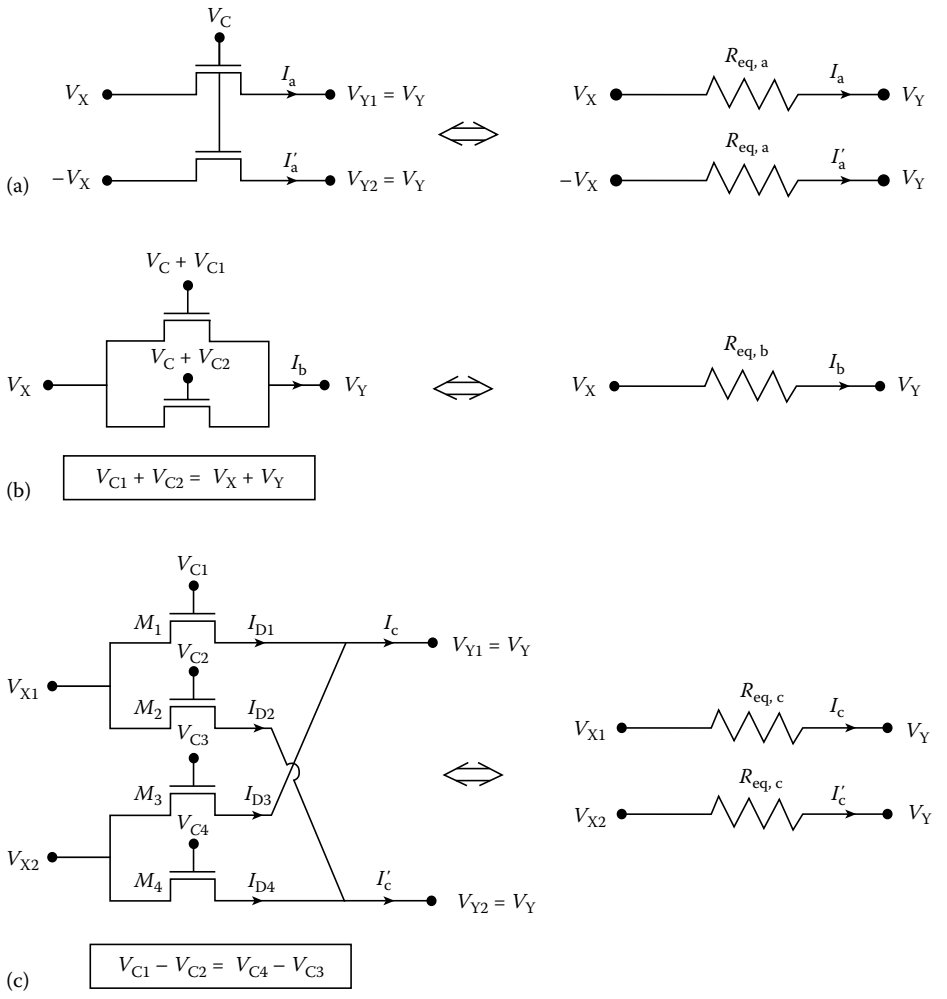

FIGURE 2.82 Matched primitive cells operating in the triode region. Three popular examples: (a) a two-transistor transconductor, (b) a realized floating resistor, and (c) a four-transistor transconductor.

$$\begin{aligned} I_a - I'_a &= K\left[(V_C - V_T)(V_X - V_Y) - \frac{1}{2}\left(V_X^2 - V_Y^2\right)\right] \\ &\quad - K\left[(V_C - V_T)(-V_X - V_Y) - \frac{1}{2}\left(V_X^2 - V_Y^2\right)\right] \\ &= 2K(V_C - V_T)V_X \end{aligned} \tag{2.136}$$

and the equivalent resistance is obtained as

$$R_{eq,a} = \frac{2V_X}{I_a - I'_a} = \frac{1}{K(V_C - V_T)} \tag{2.137}$$

The circuit shown in Figure 2.82b realizes a floating resistor [5], where

$$
\begin{aligned}
I_b &= K\left[(V_C + V_{C1} - V_T)(V_X - V_Y) - \frac{1}{2}\left(V_X^2 - V_Y^2\right)\right] \\
&\quad + K\left[(V_C + V_{C2} - V_T)(V_X - V_Y) - \frac{1}{2}\left(V_X^2 - V_Y^2\right)\right] \\
&= K\left[(2V_C - 2V_T + V_X + V_Y)(V_X - V_Y) - \left(V_X^2 - V_Y^2\right)\right] \\
&= 2K(V_C - V_T)(V_X - V_Y)
\end{aligned} \tag{2.138}
$$

and the equivalent resistance is

$$
R_{eq,b} = \frac{V_X - V_Y}{I_b} = \frac{1}{2K(V_C - V_T)} \tag{2.139}
$$

An implementation with $V_{C1} = V_{C2} = (V_X + V_Y)/2$ has been described in Ref. [6].

The circuit shown in Figure 2.82c, a four-transistor transconductor [7], gives the following current equation:

$$
\begin{aligned}
I_c - I_c' &= K\left[(V_{C1} - V_T)(V_{X1} - V_Y) - \frac{1}{2}\left(V_{X1}^2 - V_Y^2\right)\right] \\
&\quad - K\left[(V_{C2} - V_T)(V_{X1} - V_Y) - \frac{1}{2}\left(V_{X1}^2 - V_Y^2\right)\right] \\
&\quad + K\left[(V_{C3} - V_T)(V_{X2} - V_Y) - \frac{1}{2}\left(V_{X2}^2 - V_Y^2\right)\right] \\
&\quad - K\left[(V_{C4} - V_T)(V_{X2} - V_Y) - \frac{1}{2}\left(V_{X2}^2 - V_Y^2\right)\right]
\end{aligned} \tag{2.140}
$$

$$
\begin{aligned}
&= K(V_{C1} - V_{C2})(V_{X1} - V_{X2}) \\
&= K(V_{C4} - V_{C3})(V_{X1} - V_{X2})
\end{aligned} \tag{2.141}
$$

and

$$
R_{eq,c} = \frac{V_{X1} - V_{X2}}{I_c - I_c'} = \frac{1}{K(V_{C1} - V_{C2})} = \frac{1}{K(V_{C4} - V_{C3})} \tag{2.142}
$$

Note that I_c and I_c' are taken at the V_Y nodes. It is very interesting to know that nonlinearity cancellation is also achieved with the four transistors operating in the saturation region [2].

Figure 2.82a and c are usually used together with op-amps to simulate resistors, where the virtual short property of op-amps makes $V_{Y1} = V_{Y2}$.

2.4.2 Unmatched Device Pairs

Figure 2.83 shows primitive cells that do not require matching, unless specified. Figure 2.83a and b are parallel and series composite NMOS transistors, respectively, which are very useful in laying out very wide or long transistors, respectively. The equivalent device transconductance parameter K_{eq} is calculated as follows:

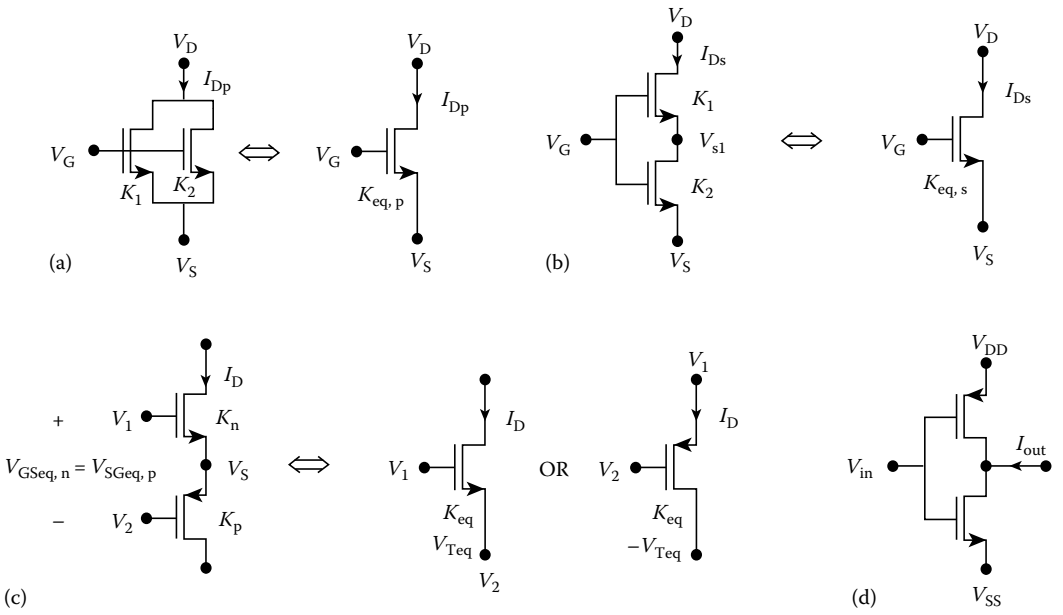

FIGURE 2.83 Unmatched primitive cells. (a) A parallel composite NMOS transistor, (b) a series composite NMOS transistor, (c) a CMOS composite transistor, and (d) a CMOS inverter.

For the parallel composite transistor, the drain current is written as

$$\begin{aligned} I_{Dp} &= \frac{K_{eq,p}}{2}(V_G - V_S - V_T)^2 \\ &= \frac{K_1}{2}(V_G - V_S - V_T)^2 + \frac{K_2}{2}(V_G - V_S - V_T)^2 \end{aligned} \tag{2.143}$$

That is,

$$K_{eq,p} = K_1 + K_2 \tag{2.144}$$

or alternatively

$$\left(\frac{W}{L}\right)_{eq,p} = \left(\frac{W}{L}\right)_1 + \left(\frac{W}{L}\right)_2 \tag{2.145}$$

Using the same channel length L, it can be simplified as

$$W_{eq,p} = W_1 + W_2 \tag{2.146}$$

As a result, a wider transistor can be realized by parallel connection of two or more narrower transistors.

For the series composite transistor, note that the lower transistor is always operating in the triode region due to the requirement $V_G - V_{S1} > V_T$, to turn on the upper transistor. The resultant drain current is given by

$$I_{Ds} = \frac{K_{eq,s}}{2}(V_G - V_S - V_T)^2 \tag{2.147}$$

$$= \frac{K_1}{2}(V_G - V_{S1} - V_T)^2 \tag{2.148}$$

$$= \frac{K_2}{2}\left[(V_G - V_S - V_T)^2 - (V_G - V_{S1} - V_T)^2\right] \tag{2.149}$$

From the preceding equations, we have

$$(V_G - V_S - V_T)^2 = \frac{2I_{Ds}}{K_{eq,s}} \tag{2.150}$$

$$(V_G - V_{S1} - V_T)^2 = \frac{2I_{Ds}}{K_1} \tag{2.151}$$

Substituting the preceding equations into Equation 2.149, we obtain

$$I_{Ds} = \frac{K_2}{2}\left(\frac{2I_{Ds}}{K_{eq,s}} - \frac{2I_{Ds}}{K_1}\right) \tag{2.152}$$

That is,

$$\frac{1}{K_{eq,s}} = \frac{1}{K_1} + \frac{1}{K_2} \tag{2.153}$$

or

$$\left(\frac{L}{W}\right)_{eq,s} = \left(\frac{L}{W}\right)_1 + \left(\frac{L}{W}\right)_2 \tag{2.154}$$

Similarly, with fixed channel width W, the above equation is simply obtained as

$$L_{eq,s} = L_1 + L_2 \tag{2.155}$$

which indicates that the equivalent transistor can be used to realize a long-channel device with shorter channel ones.

Figure 2.83c is a CMOS composite transistor, which can be seen as equivalent to either an NMOS or a PMOS transistor operating in the saturation region. In contrast, the composite transistors shown in Figure 2.83a and b can operate in both saturation and triode regions. The main advantage of the equivalent composite transistor shown in Figure 2.83c is that both their equivalent gate and source nodes have high input impedances, which is desired in some circuits. The equivalent K and V_T are obtained by the equations of the gate–source voltages.

$$\begin{aligned} V_1 - V_2 &= V_{GSn} + V_{SGp} \\ &= \sqrt{\frac{2I_D}{K_n}} + \sqrt{\frac{2I_D}{K_p}} + V_{Tn} - V_{Tp} \\ &= \sqrt{\frac{2I_D}{K_{eq}}} + V_{Teq} \end{aligned} \tag{2.156}$$

which give

$$\frac{1}{\sqrt{K_{eq}}} = \frac{1}{\sqrt{K_n}} + \frac{1}{\sqrt{K_p}} \tag{2.157}$$

and

$$V_{Teq} = V_{Tn} - V_{Tp} \tag{2.158}$$

Finally, Figure 2.83d shows a CMOS inverter, which could be used as a transconductor [8]. Its output current is

$$\begin{aligned} I_{out} &= \frac{K_n}{2}(V_{in} - V_{SS} - V_{Tn})^2 - \frac{K_p}{2}(V_{DD} - V_{in} + V_{Tp})^2 \\ &= a(V_{in} - V_{Tn})^2 + bV_{in} + c \end{aligned} \tag{2.159}$$

where

$$\begin{aligned} a &= \frac{1}{2}(K_n - K_p) \\ b &= -K_n V_{SS} + K_P(V_{DD} - V_{Tn} + V_{Tp}) \\ c &= \frac{K_n}{2}\left(2V_{SS}V_{Tn} + V_{SS}^2\right) + \frac{K_p}{2}\left[V_{Tn}^2 - (V_{DD} + V_{Tp})^2\right] \end{aligned}$$

2.4.3 Composite Transistors

The body effect of a transistor is due to nonzero source to bulk voltage (V_{SB}), which widens the depletion region between the source and bulk and therefore increases the absolute value of its threshold voltage. The threshold voltage (referred to the source) is dependent on V_{SB} and is given by

$$\begin{aligned} V_{Tn} &= V_{Tno} + \gamma\left(\sqrt{2|\phi_F| + V_{SB}} - \sqrt{2|\phi_F|}\right) \quad \text{for NMOS} \\ V_{Tp} &= V_{Tpo} - \gamma\left(\sqrt{2|\phi_F| + V_{SB}} - \sqrt{2|\phi_F|}\right) \quad \text{for PMOS} \end{aligned}$$

where $2|\phi_F|$ is the potential required for strong inversion and γ is the body effect parameter.

Usually, bulk regions of an NMOS transistor and a PMOS transistor are tied to the most negative voltage (V_{SS}) and the most positive voltage (V_{DD}) respectively to turn off the parasitic diodes associated with source-bulk and drain-bulk. In some cases, bulk regions are directly connected to transistor sources ($V_{SB} = 0$) to eliminate the body effect; for example, in the follower of Figure 2.81e, the bulk must be connected to the source in each transistor to ensure equal threshold voltages. This is achieved by putting each device in a separated well, which must be the P-well for NMOS devices. However, separate wells require large layout areas. Besides, unless twin-tub processes are used, only one type of transistor (either NMOS or PMOS depending on the process) can be connected this way.

Due to the body effect, the equivalent threshold voltage of a CMOS composite transistor would be large (two threshold voltages plus extra voltage resulting from the body effect), which would render it unsuitable for low-voltage applications. The equivalent threshold voltage could be reduced by replacing one of the MOS transistors with a BJT, as shown in Figure 2.84 [9]. For the stacked composite BiCMOS transistors, the equivalent threshold voltage is given by $V_{Teq} \approx |V_T| + 0.7$ V, where V_T is the threshold

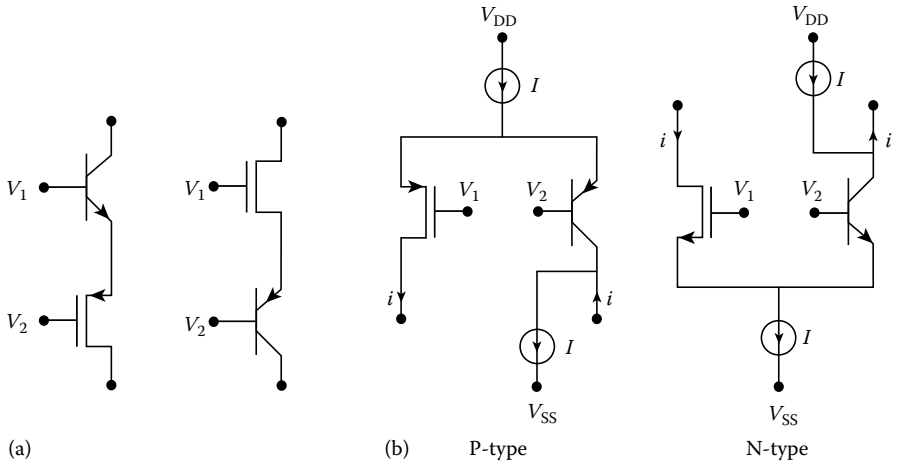

FIGURE 2.84 BiCMOS composite transistors: (a) stacked version and (b) folded version.

voltage of the NMOS or PMOS transistor, and 0.7 V is the BJT turn-on voltage V_{BE}, which is not subject to body effects. It can be further reduced by the folded arrangement as shown in Figure 2.84b, where $V_{Teq} \approx |V_T| - 0.7$ V. An all-MOS-folded composite transistor can be implemented in a similar manner as shown in Figure 2.85 [10], where $K_2 \gg K_1$. As a result,

$$K_{eq} \approx K_1$$

$$V_{Teq} = V_T - V_{GS2} \tag{2.160}$$

$$\approx -\sqrt{\frac{2I}{K_2}} \tag{2.161}$$

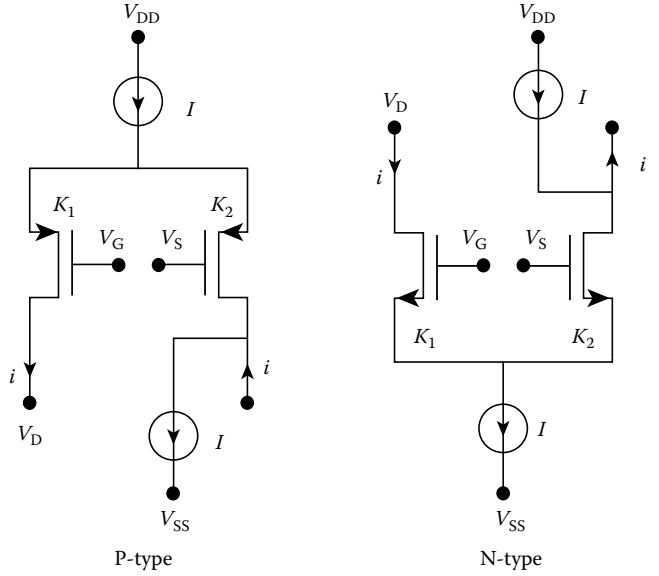

FIGURE 2.85 MOS-folded composite transistors.

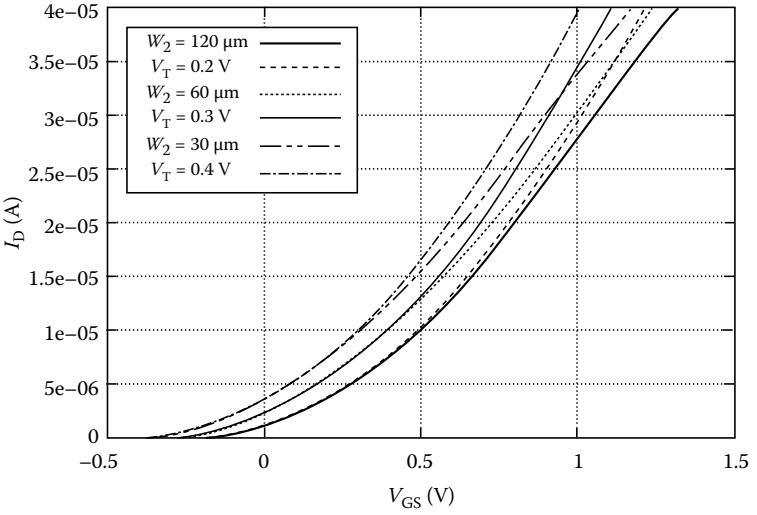

FIGURE 2.86 I_D curves for a folded N-type transistor with various W_2 and a single transistor with various V_T.

where $V_{GS2} \approx \sqrt{(2I)/K_2} + V_T$. Simulation program with integrated circuit emphasis (SPICE) simulation results for the N-type folded transistors ($W_1 = L_1 = L_2 = 3$ μm) operating in the saturation region ($V_{DG} = 0$) with various W_2 are compared with a single NMOS depletion transistor ($W = L = 3$ μm) with various V_T shown in Figure 2.86. It can be seen that a smaller K_2 results in a smaller V_{Teq} (more negative), but with a larger K_2 the composite transistor behaves more like a single transistor having a smaller $|V_{Teq}|$, which could be useful in low-voltage applications.

Forcing $V_{SB} = 0$ to eliminate the body effect is usable only for MOS circuits conducting currents in a single direction. For the circuits shown in Figure 2.82, since resistors operate bidirectionally, the bulk regions of each transistor must be connected to the rail to assure that parasitic diodes are turned off when currents flow in either direction. In fact, the transistors are operating in the triode region symmetrically between drain and source and biased at $V_{DS} \approx 0$. It would, however, result in nonzero V_{SB} and increase the threshold voltage, which increases the equivalent resistance, in Figure 2.82a and b, but introduces nonlinearities. To overcome this problem, one may configure two transistors into one composite transistor as shown in Figure 2.87a, where the bulks of the transistors are interconnected to node V_{S1}. Due to symmetry, this composite transistor can be operated in either direction. Its physical cross section is shown in Figure 2.87b, where the diodes represent the p–n junctions composed by bulk and source/drain nodes. This configuration is equivalent to Figure 2.87c, and one can find that the parasitic diode connected between V_{S1} and V_S would turn on when $V_{S1} - V_S$ is larger than the turn-on voltage of the parasitic diode. However, this is undesired, but fortunately the diode current is restricted by the drain current of M_2. This effect can be illustrated more clearly through the comparison of transistors with various bulk connections, as shown in Figure 2.88, where Figure 2.88d and e are composite transistors (same as Figures 2.87 and Figure 2.83b, respectively), which simulate single transistors. With $V_{DG} = 0$ (diode connection), $V_S = 0$ and $V_{SS} = -5$ V, Figure 2.89 gives simulation results of drain currents for the circuits, shown in (a) and (c)–(e), where the transistor sizes for the circuits, shown in (a)–(c), (d), and (e) are 20/3 μm, 30/3 μm, and 36/3 μm, respectively. One can observe that the curve (c) shown in Figure 2.89 completely departs from curve (a), due to the body effect. Curve (e) fits perfectly to curve (a). Although behaving slightly differently from curve (a), circuit (d) approximates a single transistor as well.

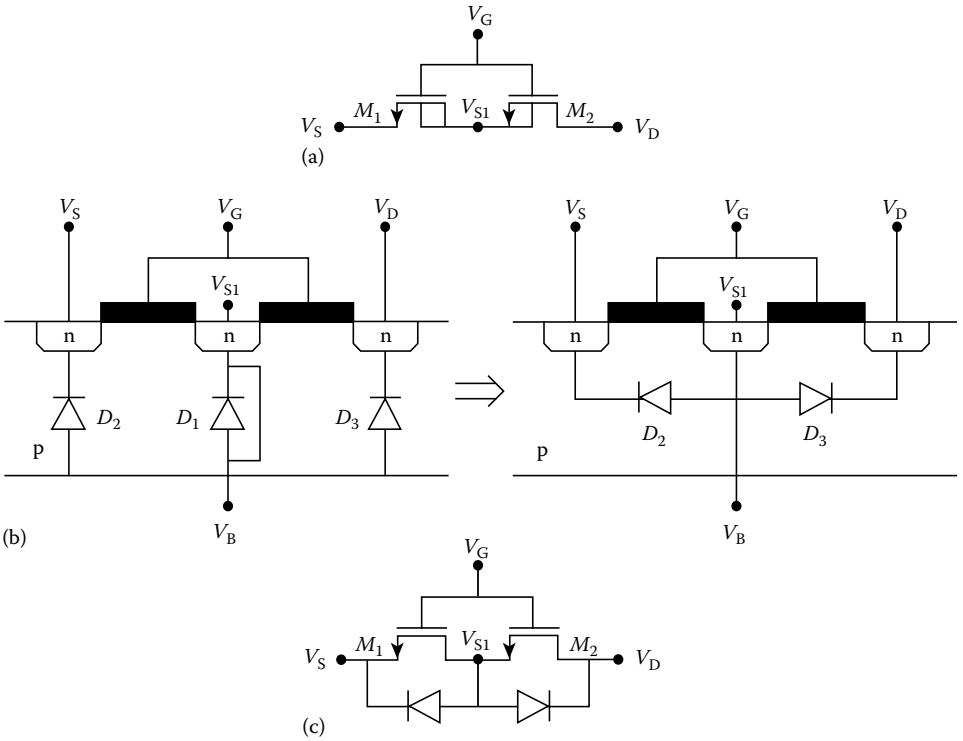

FIGURE 2.87 (a) Composite bidirectional transistor with reduced body effect. (b) Cross-sectional view of the physical device, where the short connection across D_1 is, in effect, placing D_2 and D_3 back-to-back between V_D and V_S and forming a parasitic symmetrical bipolar device. (c) Equivalent circuit of (a). FIGURE 2.88 Transistors with various bulk connections.

Figure 2.90 shows the drain current for the circuit labeled (b), whose current is much larger than those of the rest of the circuits shown in Figure 2.88. Since the bulk of the circuit shown in Figure 2.88b is connected to its drain and the parasitic diode between the drain and bulk is on, the current is dominated by the diode current due to its exponential nature. By using it as in Figure 2.88d, the diode current is limited to the current level of an MOS transistor. This can be seen from Figure 2.91, showing V_{S1} of the

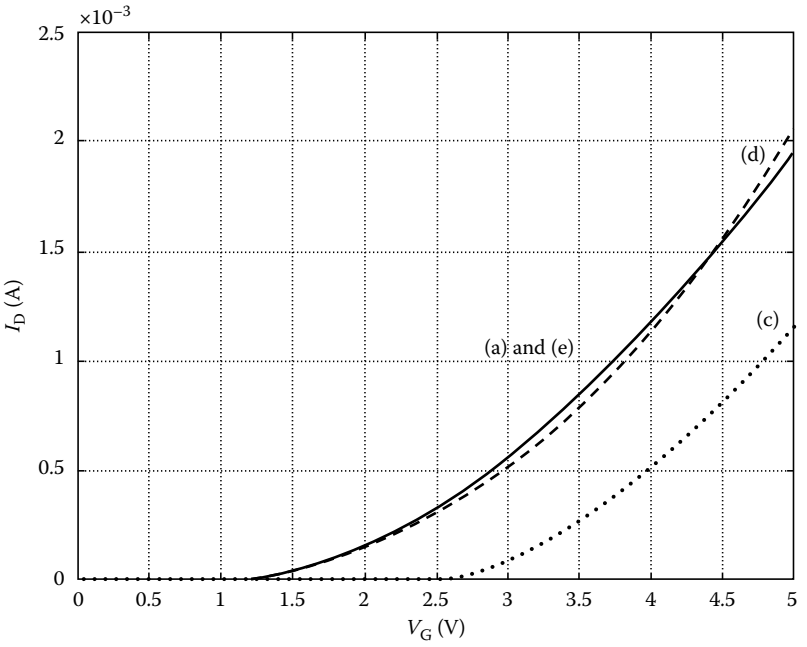

FIGURE 2.89 I_D curves for transistors with various bulk connections.

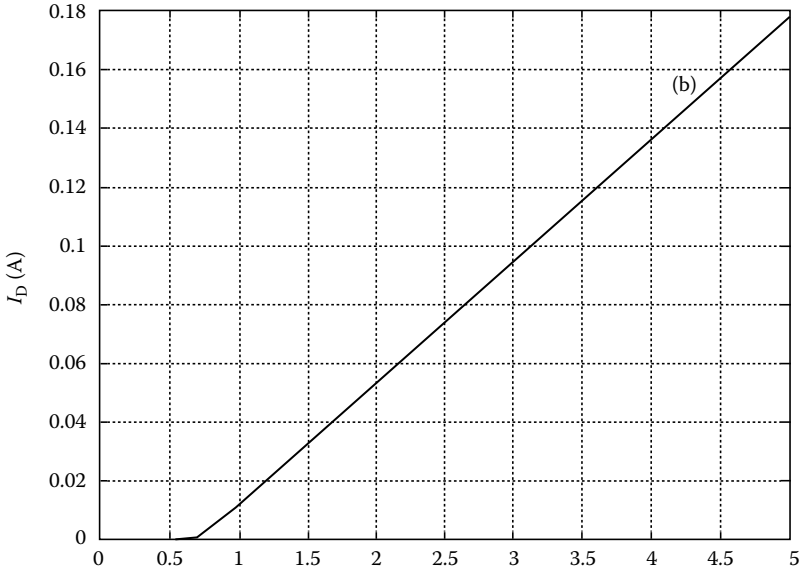

FIGURE 2.90 I_D curve for transistor with bulk connected to drain.

circuit (d) saturated at a voltage ∼0.7 V, which is close to the turn-on voltage of a p–n junction diode. The transistor sizes of the circuits labeled (d) and (e) are adjusted to achieve the same K value of the single transistor (a). According to Equation 2.153, $1/K_{eq,s} = 1/K_1 + 1/K_2$. That is, to achieve $K_{eq,s} = K$, K_e $(= K_1 = K_2)$ is given by

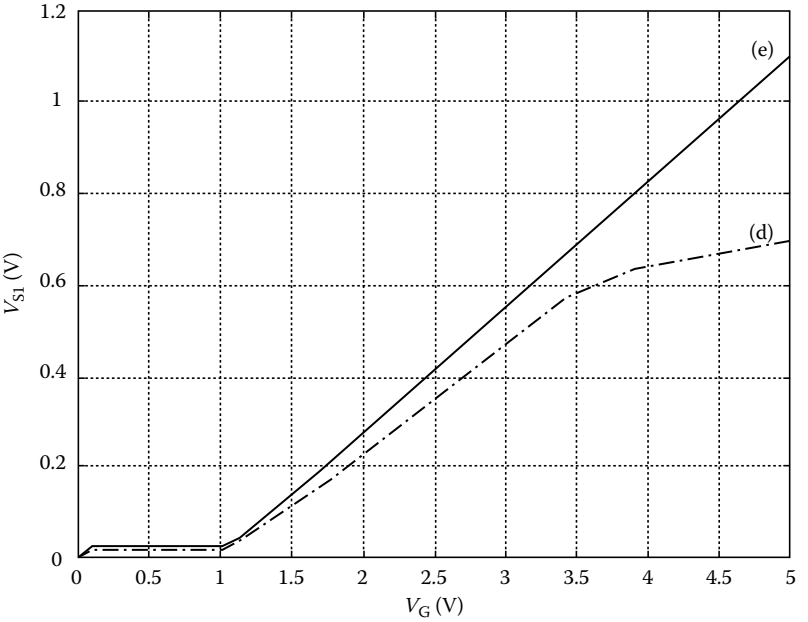

FIGURE 2.91 V_{S1} curves for composite transistors, labeled (d) and (e).

$$K_e = 2K \tag{2.162}$$

For circuit (d), K_d is obtained by rewriting Equation 2.149, which follows that

$$\begin{aligned} I_{Ds} &= \frac{K}{2}(V_G - V_S - V_T)^2 \\ &= \frac{K_d}{2}(V_G - V_{S1} - V_T)^2 \\ &= \frac{K_d}{2}\left[(V_G - V_S - V_T)^2 - (V_G - V_{S1} - V_T)^2\right] + I_s e^{(V_{S1}-V_S)/U_T} \end{aligned}$$

where I_s is the leakage current of the diode and U_T is the thermal voltage. Therefore,

$$\begin{aligned} I_{Ds} &= \frac{K_d}{2}\left(\frac{2I_{Ds}}{K} - \frac{2I_{Ds}}{K_d}\right) + I_s e^{(V_{S1}-V_S)/U_T} \\ &= I_{Ds}\left(\frac{K_d}{K} - 1\right) + I_s e^{(V_{S1}-V_S)/U_T} \end{aligned} \tag{2.163}$$

Divided by I_{Ds}, the preceding equation becomes

$$\begin{aligned} 1 &= \frac{K_d}{K} - 1 + \frac{I_s}{I_{Ds}} e^{(V_{S1}-V_S)/U_T} \\ 2K &= K_d + K\frac{I_s}{I_{Ds}} e^{(V_{S1}-V_S)/U_T} \end{aligned} \tag{2.164}$$

and hence

$$K_d < 2K \tag{2.165}$$

due to the parasitic diode. A SPICE level 2 model is used in the simulation and its higher order effects result in using a device size of 36/3 μm($K_e \neq 2K$), instead of 40/3 μm.

2.4.4 Super MOS Transistors

The channel length modulation effect models the channel shortening effect in the saturation region due to the increase in the depletion width near the drain when increasing V_{DS}. It is modeled as

$$I_D = \frac{K}{2}(V_{GS} - V_T)^2(1 + \lambda V_{DS}) \tag{2.166}$$

where λ is the channel length modulation parameter. The effect results in a finite output impedance of a transistor, since the output impedance is given by

$$r_o = \left(\frac{\partial I_D}{\partial V_{DS}}\right)^{-1} = \frac{1}{\lambda \frac{K}{2}(V_{GS} - V_T)^2} \simeq \frac{1}{\lambda I_D} \tag{2.167}$$

As mentioned previously, this effect would cause inaccuracy in the single current mirror shown in Figure 2.81d, and can be mitigated by using cascode, improved Wilson, or regulated current mirrors as shown in Figure 2.92 [3]. These are based on the gain-boosting principle as shown in Figure 2.93 [11], where for the cascode stage in (a) (used in the cascode and the Wilson current mirrors) the output impedance is given by

$$r_{o,a} = (g_{m2}r_{o2} + 1)r_{o1} + r_{o2} \tag{2.168}$$

where g_{mi} and r_{oi} are, respectively, the small-signal transconductance and output impedance for transistor M_i. An addition gain stage A_{dd}, as in Figure 2.93b (implemented in the regulated current mirror by M_{add}) increases the output impedance almost by a factor of $(A_{dd} + 1)$ and gives

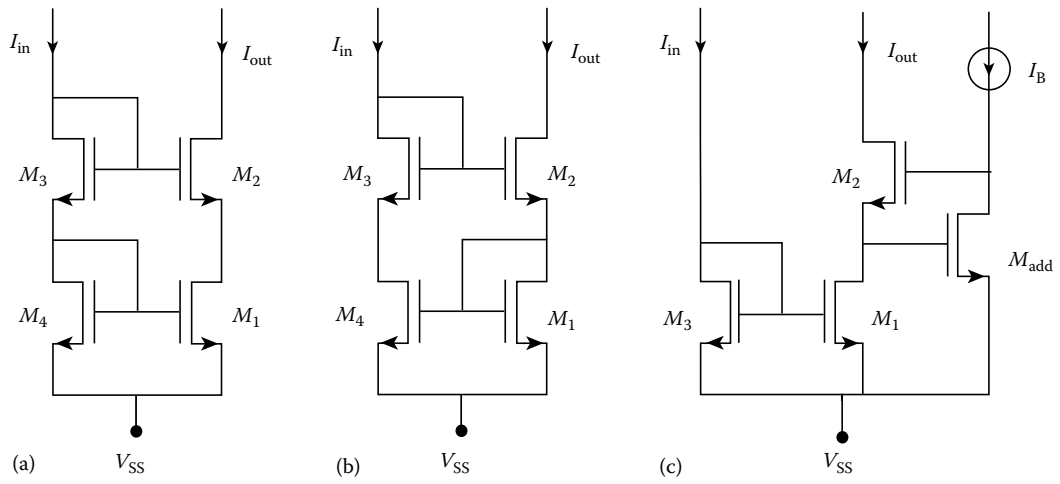

FIGURE 2.92 (a) Cascode, (b) improved Wilson, and (c) regulated current mirrors.

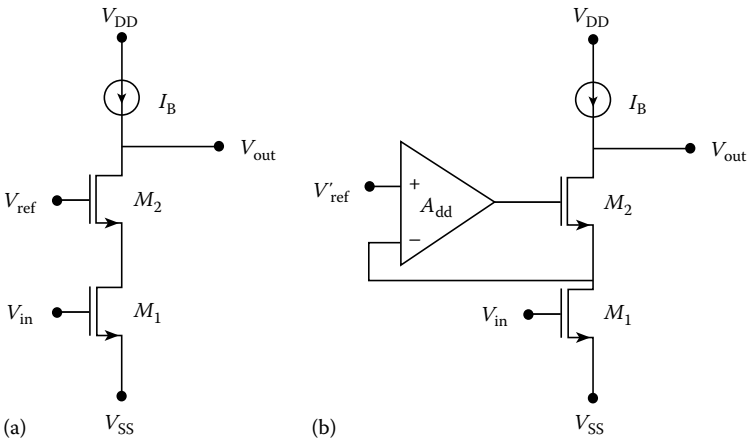

FIGURE 2.93 (a) Cascode stage and (b) cascode stage with an additional gain stage.

$$r_{o,b} = [g_{m2}r_{o2}(A_{dd} + 1) + 1]r_{o1} + r_{o2} \tag{2.169}$$

As a result, composite transistors with high output impedances can be obtained as shown in Figure 2.94 [10]. Figure 2.94a is directly obtained from the regulated current mirror, where M_{N1} and M_{N2} are cascoded and M_{P2} and M_{N4} compose an additional gain stage. The drain-source voltage of M_{N1} biased by I_1 is given by

$$V'_{DS,a} = \sqrt{\frac{2I_1}{K_4}} + V_T \tag{2.170}$$

Figure 2.94b, a modified version of (a), employs the biasing technique in Ref. [12], biasing V_{DS} for a triode-mode V–I converter. The resultant $V'_{Ds,b}$ is given by

$$V'_{DS,b} = \sqrt{\frac{2I_1}{K_4}} - \sqrt{\frac{2I_2}{K_5}} \tag{2.171}$$

Therefore, unlike the circuit shown in Figure 2.93a, where $V'_{Ds,a}$ is larger than V_T, M_{N1} can be biased at the edge of saturation by properly choosing currents I_1 and I_2 or K_4 and K_5 In addition, V_F provides a low impedance node for folded cascode configurations. Figure 2.94c, also called the super-MOS transistor [11], uses a similar concept. The CMOS cascode gain stage, composed by M_{P2}, M_{P4}, M_{N4}, and M_{N6}, gives a higher gain than the previous two circuits. Since M_{N8} in the series composite transistor (constituted by M_{N7} and M_{N8}) is always operating in the triode region, V_{DS} of M_{N8} can be very small, and M_{N1} can also be biased at the edge of saturation. However, due to its circuit complexity, the input range for V_{GS} is limited. The drain currents of the circuits shown in Figure 2.94b versus V_{DS} with various V_{GS} are compared to those obtained from a single transistor and are given in Figure 2.95. It can be seen that the output impedance of the composite transistor is significantly larger than that of a single one. The use of super MOS transistors in the design of high-gain operational amplifiers is discussed in Ref. [11].

2.4.5 Basic Voltage Gain Cells

In this subsection, we discuss simple voltage amplifier circuits implemented in NMOS, CMOS, and BiCMOS technologies.

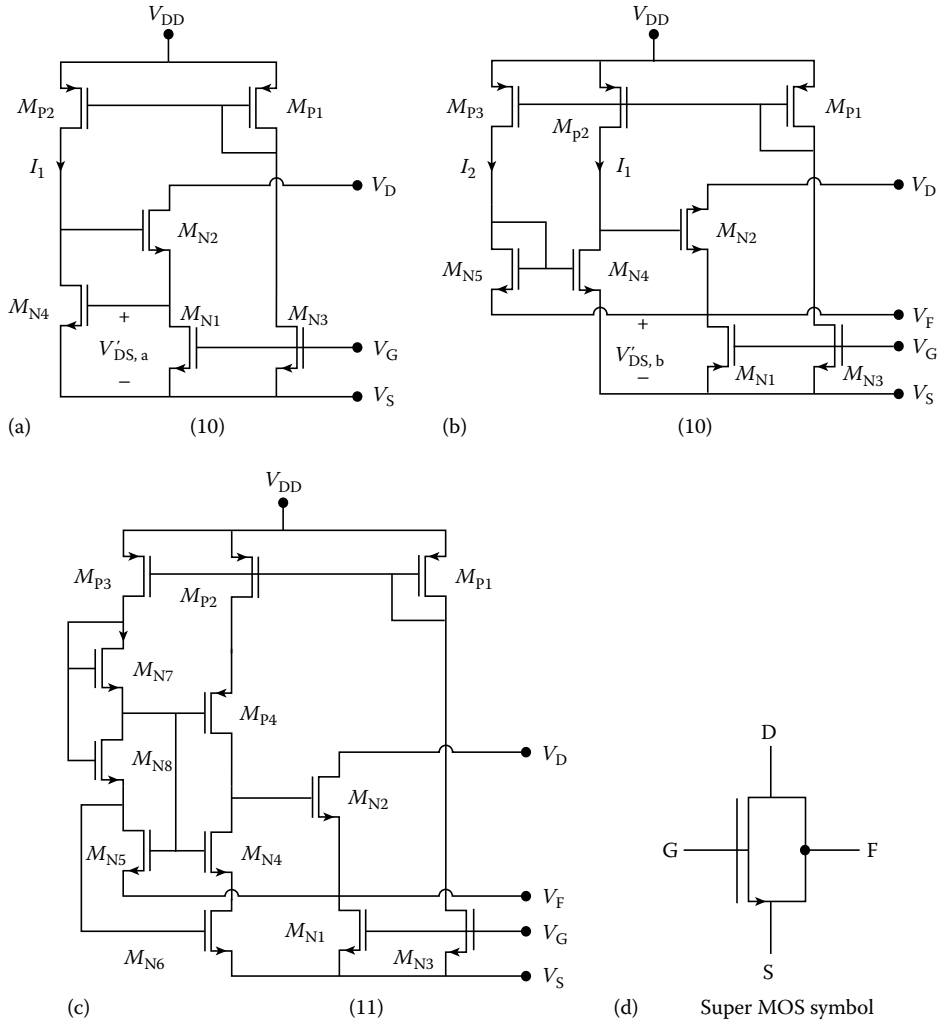

FIGURE 2.94 Composite super NMOS transistors. (a, b) (From Huang, S.-C., Systematic design solutions for analog VLSI circuits, PhD dissertation, Department of Electrical Engineering, Ohio State University, 1994.) (c) (From Bult, K. and Geelen, G.J., *J. Analog Integrat. Circuits Signal Process.*, 1, 119, 1991.)

2.4.5.1 NMOS Amplifier

Figure 2.96a shows an enhancement common-source NMOS amplifier with an enhancement load. M_1 is the driving (amplifying) transistor and the diode-connected transistor M_2 is the load device. The large-signal transfer characteristics of the amplifier is shown in Figure 2.96b and displays three well-defined regions. In region I, M_1 is off since $v_I < V_{T1}$. M_2, however, is always in the saturation region and is conducting a small current. The voltage across it is V_{T2} and hence the output voltage, v_o, is $V_{DD} - V_{T2}$. In region II, M_1 is conducting and is operating in saturation and the transfer curve is linear. Finally in region III, M_1 leaves the saturation region and enters the triode region. For the circuit to operate as an amplifier, the dc operating point must be located in the linear region (region II). Assuming that both M_1 and M_2 have the same threshold voltage V_T, but different values of K (K_1 and K_2) and neglecting both channel length modulation and body effects, we write

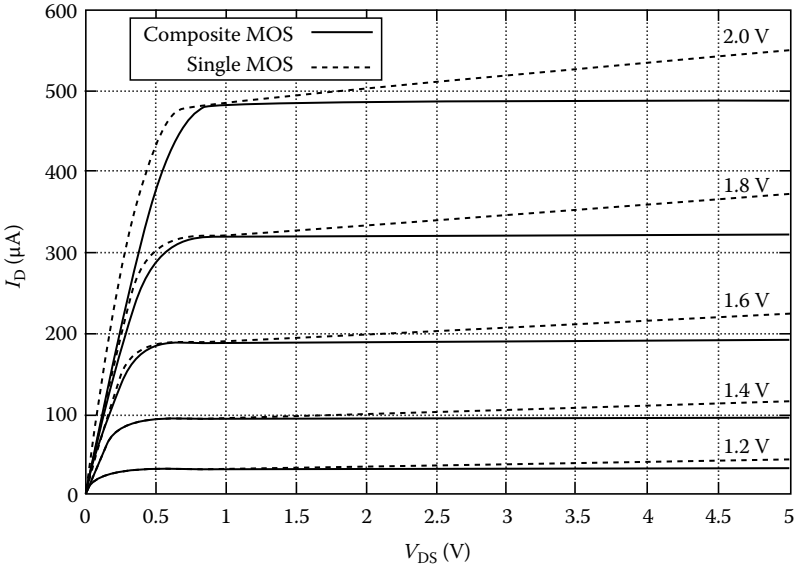

FIGURE 2.95 Simulated I_D curves for the high-output impedance composite transistor shown in Figure 2.94b and for a single transistor.

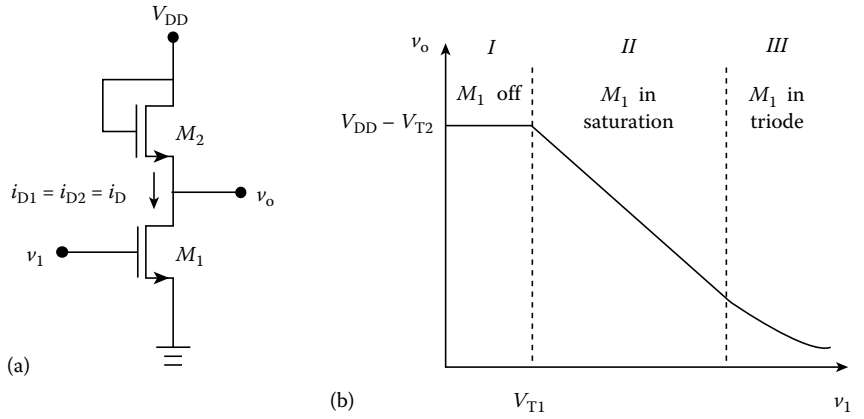

FIGURE 2.96 (a) The NMOS amplifier. (b) Transfer characteristics.

$$i_{D1} = i_{D2} = i_D = \frac{K_1}{2}(v_1 - V_T)^2 \tag{2.172}$$

and

$$\begin{aligned} i_D &= \frac{K_2}{2}(v_{GS2} - V_T)^2 \\ &= \frac{K_2}{2}(V_{DD} - v_o - V_T)^2 \end{aligned} \tag{2.173}$$

Combining Equations 2.172 and 2.173 and with some manipulations, we obtain

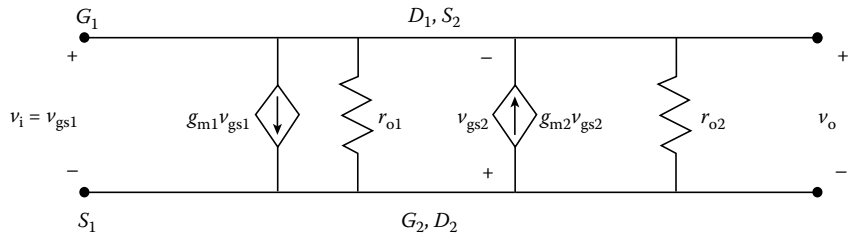

FIGURE 2.97 Small-signal equivalent circuit of the NMOS amplifier.

$$v_o = \left(V_{DD} - V_T + \sqrt{\frac{K_1}{K_2}}V_T\right) - \sqrt{\frac{K_1}{K_2}}v_I \tag{2.174}$$

which is a linear equation between v_o and v_I. This is obviously the equation of the straight-line portion (region II) of the transfer curve.

The first term in Equation 2.174 represents the dc component of the output voltage V_o. The second term represents the small-signal component and thus the ac small-signal gain of the amplifier A_v is

$$A_v = \frac{v_o}{v_i} = -\sqrt{\frac{K_1}{K_2}} = -\sqrt{\frac{(W/L)_1}{(W/L)_2}} \tag{2.175}$$

The small-signal equivalent circuit of the amplifier in Figure 2.96a is shown in Figure 2.97. Since D_2 and G_2 are connected in M_2, the voltage across the controlled current–source $g_{m2}v_{gs2}$ is v_{gs2}. Therefore, the controlled current–source can be represented by a resistance $1/g_{m2}$. Since $v_{gs1} = v_i$, we obtain the voltage gain as follows:

$$A_v = \frac{v_o}{v_i} = -\frac{g_{m1}}{g_{m2} + (1/r_{o1}) + (1/r_{o2})} \tag{2.176}$$

Now, if r_{o1} and r_{o2} are much larger than $(1/g_{m2})$, the gain reduces to $A_v \simeq -g_{m1}/g_{m2}$, which can easily be shown to lead to the expression in Equation 2.175. Note that the gain can also be determined by inspection from the circuit in Figure 2.96a as $-g_{m1}$ multiplied by the equivalent small-signal resistance seen at the drain of M_1, which is $(1/g_{m2}||r_{o1}||r_{o2})$.

Practically, M_1 and M_2 share the same substrate, which is normally connected to the most negative supply voltage in the circuit (ground in this case). It follows that M_2 suffers from body effect, which is modeled in the small-signal equivalent circuit by a controlled current-source $g_{mb2}v_{bs2}$ connected between the two output terminals in Figure 2.97, where $v_{bs2} = v_{gs2}$ and $g_{mb2} = \chi g_{m2}$ and χ is a function of the dc source–body voltage V_{SB} and lies in the range 0.1–0.3 [13]. Taking the body effect of M_2 into account, the amplifier gain becomes

$$A_v = -\frac{g_{m1}}{g_{m2} + g_{mb2}} = -\frac{g_{m1}}{g_{m2}}\frac{1}{1+\chi} \tag{2.177}$$

2.4.5.2 CMOS Amplifier

In CMOS technology, both n-channel and p-channel devices are available, and are usually fabricated in a way that eliminates the body effect. The basic CMOS amplifier is shown in Figure 2.98. Here, M_2 and M_3 in Figure 2.98c are a pair of PMOS devices operating as a current source active load and implement the

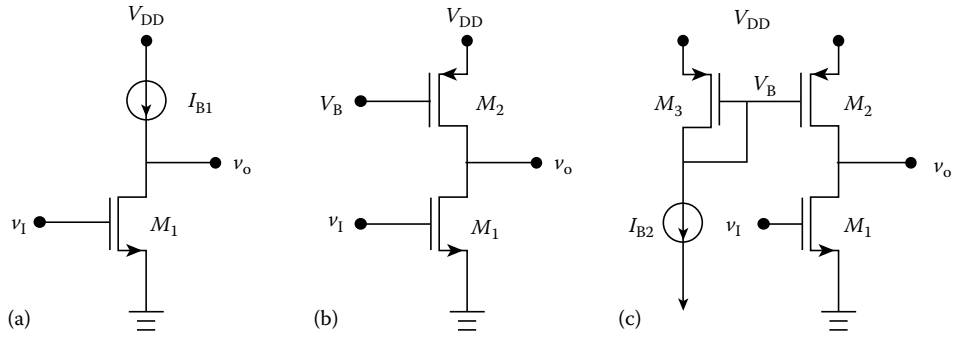

FIGURE 2.98 CMOS amplifier: (a) basic circuit, (b and c) CMOS implementations.

current source I_{B1} in Figure 2.98a. M_2 is biased in the saturation region and when M_1 is operating in the saturation region, the small-signal voltage gain will be equal to $-g_{m1}$, multiplied by the total resistance seen between the output and ground which is $(r_{o1}||r_{o2})$.

Cascode versions of the amplifier as shown previously in Figure 2.93 can be used to boost the gain significantly. For instance, the cascode amplifier in Figure 2.93a has a gain equal to the effective transconductance $-g_{meff}$, multiplied by $r_{o,a}$ given by Equation 2.168, where g_{meff} is given by [14]

$$g_{meff} = g_{m1}\frac{g_{m2}r_{o1} + (r_{o1}/r_{o2})}{g_{m2}r_{o1} + (r_{o1}/r_{o2}) + 1} \tag{2.178}$$

2.4.5.3 BiCMOS Amplifiers

A BiCMOS technology combines bipolar and CMOS transistors on a single substrate. A bipolar transistor has the advantage over an MOS of a much higher transconductance (g_m) for the same dc bias current. Also, bipolar transistors have better high-frequency performance than their MOS counterparts. On the other hand, the practically infinite input resistance at the gate of a MOSFET makes it possible to design amplifiers with extremely high input resistance and an almost zero input bias current. For these reasons, there has been an increasing interest in BiCMOS technologies for implementing high-performance integrated circuits. While most BiCMOS processes offer high-quality NMOS, PMOS, and NPN transistors, advanced BiCMOS processes offer PNP transistors as well.

Figure 2.99 shows three basic folded-cascode single-ended high-performance BiCMOS amplifiers [15]. The main features of these amplifiers are a high gain-bandwidth product and extremely high dc input

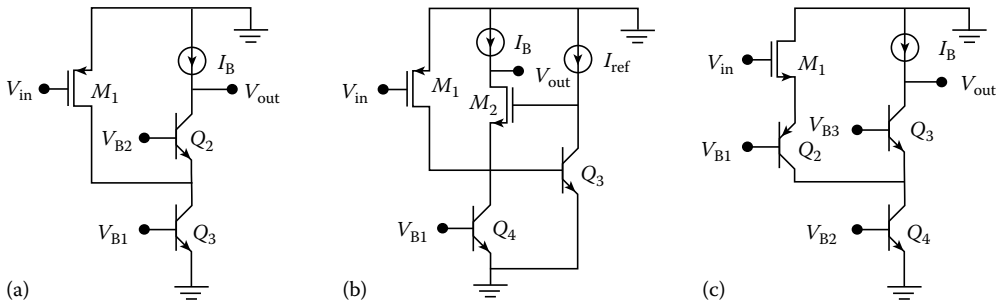

FIGURE 2.99 BiCMOS basic amplifier circuits: (a) common-source, common-base, (b) common-source, common-gate with active-feedback, and (c) common-drain, common-base, common-base.

impedance. The high gain is achieved by cascoding transistors in the signal path (M_1, Q_2 in Figure 2.99a, M_1, M_2 in Figure 2.99b, and M_1, Q_2, Q_3, in Figure 2.99c). The high bandwidth is achieved by exploiting the exponential nature of the current–voltage characteristics of bipolar transistors. For instance, let us consider the amplifier circuit in Figure 2.99a. The internal node in the signal path at the emitter of Q_2 has an extremely low impedance. This is due to the fact that while the emitter current can change significantly with the input signal, the emitter voltage remains almost constant. The same argument can be made about the internal nodes in the signal paths of the other two amplifiers (the base of Q_3 in Figure 2.99b and the emitters of Q_2 and Q_3 in Figure 2.99c). The low impedance of internal nodes in the signal path places nondominant poles at very high frequencies.

2.4.5.4 Differential Amplifier

The amplifier circuits discussed previously are of the single-ended type. A single-ended amplifier has both input and output voltage signals referred to ground. In most IC applications, a differential amplifier is utilized. In this case, the amplifier has a differential input and may also have a differential output, in which case it is called a fully differential amplifier. It is usually easy and straightforward to convert single-ended amplifiers to differential architectures.

The most widely used differential amplifier is based on the common-source or common-gate differential pairs shown respectively in Figure 2.81b and c. The common-source pair is shown here again in Figure 2.100. The only difference here is that the circuit is biased by a constant current source I that is usually implemented using a current-mirror circuit (see Figure 2.81d).

Assuming that M_1 and M_2 are identical and neglecting both channel length modulation and body effect, we write

$$i_{D1} = \frac{K}{2}(v_{GS1} - V_T)^2 \tag{2.179}$$

$$i_{D2} = \frac{K}{2}(v_{GS2} - V_T)^2 \tag{2.180}$$

Taking the square root of both sides in each of the two equations above and defining the differential input as $v_{id} = v_{GS1} - v_{GS2}$, we get

$$\sqrt{i_{D1}} - \sqrt{i_{D2}} = \sqrt{\frac{K}{2}}\, v_{id} \tag{2.181}$$

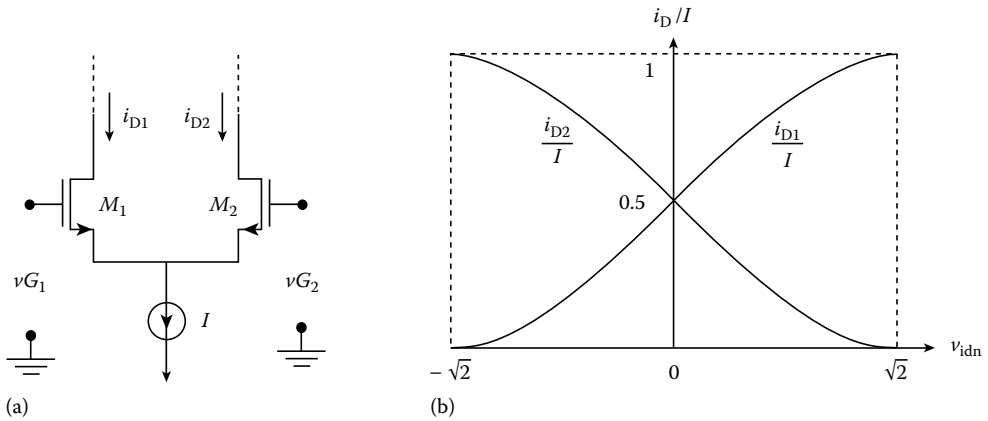

FIGURE 2.100 MOS differential pair: (a) the circuit and (b) the transfer characteristic.

But since the current–source bias imposes the constraint that $i_{D2} + i_{D2} = I$, one can easily show that

$$i_{D1,2} = \frac{I}{2} \pm \sqrt{KI}\left(\frac{v_{id}}{2}\right)\sqrt{1 - \frac{(v_{id}/2)^2}{(I/K)}} \tag{2.182}$$

At the bias point, the small-signal differential input voltage v_{id} is zero,

$$v_{GS1} = v_{GS2} = V_{GS} \quad \text{and} \quad i_{D1} = i_{D2} = I/2$$

This can be used to rewrite the preceding equation as follows:

$$i_{D1,2} = \frac{I}{2} \pm \left(\frac{I}{V_{GS} - V_T}\right)\left(\frac{v_{id}}{2}\right)\sqrt{1 - \left(\frac{v_{id}/2}{V_{GS} - V_T}\right)^2} \tag{2.183}$$

And for $v_{id}/2 \ll V_{GS} - V_T$ (small-signal approximation),

$$i_{D1,2} \simeq \frac{I}{2} \pm \left(\frac{I}{V_{GS} - V_T}\right)\left(\frac{V_{id}}{2}\right) \tag{2.184}$$

The differential pair tranconductance g_m, defined as $g_m = (i_{D1} - i_{D2})/v_{id}$ is then given by $I/(V_{GS} - V_T)$. We recall that a single MOS transistor biased at a drain current I_D has a transconductance $2I_D/(V_{GS} - V_T)$. Thus, we see that each transistor in the pair has a transconductance $2(I/2)/(V_{GS} - V_T)$, which is equal to the differential pair transconductance, g_m. Equations 2.183 and 2.184 indicate that for small-signal inputs, the current in M_1 increases by i_d and that in M_2 decreases by i_d. From Equation 2.183, we can find v_{id} at which current steering between M_1 and M_2 occurs that is $i_{D1} = I$ and $i_{D2} = 0$ or vice versa for negative v_{id}. Equating the second term in Equation 2.183 to $I/2$, we get

$$|v_{id}|\,\max = \sqrt{2}(V_{GS} - V_T) \tag{2.185}$$

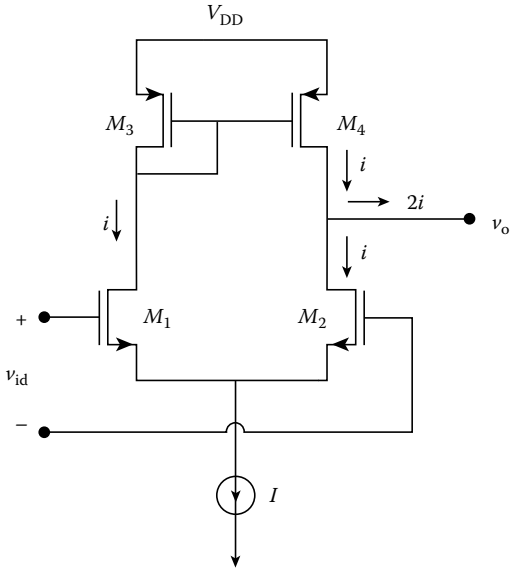

FIGURE 2.101 Simple differential-input, single-ended output CMOS amplifier.

Figure 2.100b shows plots of the normalized currents i_{D1}/I and i_{D2}/I versus the normalized differential input voltage $v_{idn} = v_{id}/(V_{GS} - V_T)$.

A simple CMOS differential amplifier is shown in Figure 2.101, where the PMOS pair is used as an active load. The small-signal current i is given by $g_m(v_{id}/2)$, where $g_m = I/(V_{GS} - V_T)$. The small-signal output voltage is given by $v_o = 2i(r_{o2}||r_{o4})$ and the voltage gain is $A_v = v_o/v_{id} = g_m((r_{o2}||r_{o4})$.

When $v_{id} = 0$, the bias current I does not actually split equally between M_1 and M_2. This is due to mismatches in K, ΔK, and V_T, ΔV_T, which contribute to a dc offset voltage that is usually larger than that in differential amplifiers implemented with bipolar transistors. For instance, modern silicon-gate MOS technologies have ΔV_T as high as 2 mV [13]. Note that ΔV_T has no counterpart in BJTs.

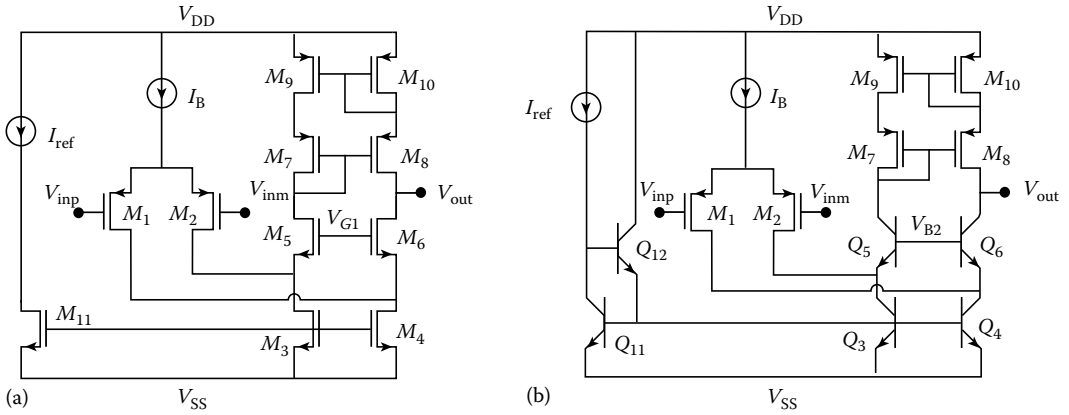

FIGURE 2.102 Folder-cascode amplifier: (a) common-source, common-gate and (b) common-source, common-base.

2.4.5.5 Folded-Cascode Operational Amplifier

The folded-cascode operational amplifier (op-amp) is a basic building block in modern analog-integrated circuits. Figure 2.102 shows two folded-cascode op-amp circuits in CMOS and BiCMOS technologies [15]. Actually, several combinations of bipolar and CMOS devices could be used in the design of this amplifier. Here, we assume that PNP bipolar transistors are not available, which implies a BiCMOS process having less complexity. The input common-source MOS pair is of the PMOS type. The cascode common-gate or common-base pair (M_5 and M_6 in Figure 2.102a and Q_5 and Q_6 in Figure 2.102b) is ''folded'' and, therefore, is implemented with devices of the opposite type to that used in the input pair. This is unlike the basic ''unfolded'' cascode amplifier in Figure 2.93, where both input and cascode devices are of the same type.

The greater values of transconductance associated with the common-base bipolar devices in the BiCMOS op-amp place the nondominant parasitic poles at much higher frequencies. Note that the BiCMOS op-amp circuit is based on the single-ended amplifier shown in Figure 2.99a. The BiCMOS op-amp combines the increased bandwidth the advantages of an MOS input stage; namely a nearly infinite input impedance, a zero input bias current, and a higher slew rate [13].

2.4.6 Conclusion

Analog design is more complicated and less systematic than digital design and involves many trade-offs to meet certain design specifications. It strongly relies on human heuristics. The transfer of these human experiences into a computer-aided design environment is essential to the success of analog design in the context of VLSI of both analog and mixed analog/digital integrated circuits. This transfer, however, requires the development of systematic approaches to the analysis and design of analog integrated circuits. To this end, understanding the basic operations of the analog cells discussed here is critical. The use of these cells in the systematic design of analog VLSI systems, such as filters and data converters, is discussed in Ref. [10].

3.1 Broadband Bipolar Networks

Chris Toumazou, Alison Payne, and John Lidgey

3.1.1 Introduction

Numerous textbooks have presented excellent treatments of the design and analysis of broadband bipolar amplifiers. This chapter is concerned with techniques for integrated circuit amplifiers, and is written mainly as a tutorial aimed at the practicing engineer.

For broadband polar design, it is first important to identify the key difference between lumped and distributed design techniques. Basically when the signal wavelengths are close to the dimensions of the integrated circuit, then characteristic impedances become significant, lines become lossy, and we essentially need to consider the circuit in terms of transmission lines. At lower frequencies where the signal

wavelength is much larger than the dimensions of the circuit, the design can be considered in terms of lumped components, allowing some of the more classical low-frequency analog circuit techniques to be applied. At intermediate frequencies, we enter the realms of hybrid lumped/distributed design. Many radio-frequency (RF) designs fall into this category, although every day we see new technologies and circuit techniques developed that increase the frequency range for which lumped approaches are possible. In broadband applications, integrated circuits (ICs) are generally designed without the use of special microwave components, so broadband techniques are very similar to those employed at lower frequencies. However, several factors still have to be considered in RF design: all circuit parasitics must be identified and included to ensure accurate simulation; feedback can generally only be applied locally as phase shifts per stage are significant; the cascading of several local feedback stages is difficult since alternating current (ac) coupling is often impractical; the NPN bipolar transistor is the main device used in silicon, since it has potentially a higher f_t than PNP bipolar or MOSFET devices; active PNP loads are generally avoided due to their poor frequency and noise performance and so resistive loads are used instead.

The frequency performance of an RF or broadband circuit will depend on the frequency capability of the devices used, and no amount of good design can compensate for transistors with an inadequate range. As a rule, designs are kept as simple as possible, since at high frequencies all components have associated parasitics.

3.1.2 Miller's Theorem

It is important to describe at the outset a very useful approximation that will assist in simplifying the high-frequency analysis of some of the amplifiers to be described. The technique is known as Miller's theorem and will be briefly discussed here. A capacitor linking input to output in an inverting amplifier results in an input-referred shunt capacitance that is multiplied by the voltage gain of the stage, as shown in Figure 3.1. This increased input capacitance is known as the Miller capacitance.

It is straightforward to show that the input admittance looking into the inverting input of the amplifier is approximately $Y_{in} = j\omega C_f(1 + A)$. The derivation assumes that the inherent poles within the amplifier are at a sufficiently high frequency so that the frequency response of the circuit is dominated by the input of the amplifier. If this is not the case, then Miller's approximation should be used with caution as it will be discussed later. From the preceding model, it is apparent that the Thévenin input signal sources see an enlarged capacitance to ground. Miller's approximation is often a useful way of simplifying circuit analysis by assuming that the input dominant frequency is given by the simple low-pass *RC* filter in Figure 3.1. However, the effect is probably one of the most detrimental in broadband amplifier design, affecting both frequency performance and/or stability.

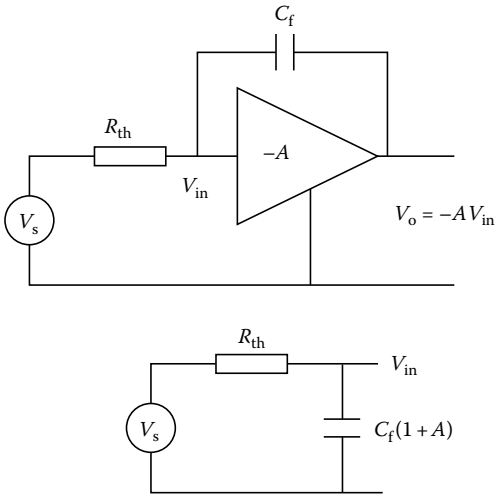

FIGURE 3.1 Example of the Miller effect.

3.1.3 Bipolar Transistor Modeling at High Frequencies

In this section, we consider the high-frequency small-signal performance of the bipolar transistor. The section assumes that the reader has some knowledge of typical device parameters, and has some familiarity with the technology. For small-signal analysis, the simplified hybrid-π model shown in Figure 3.2 is used,

where

r_b is the base series resistance
r_c is the collector series resistance
r_π is the dynamic base–emitter resistance
r_o is the dynamic collector–emitter resistance

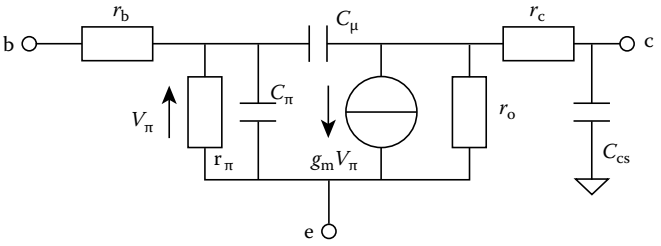

FIGURE 3.2 Hybrid π model of BJT.

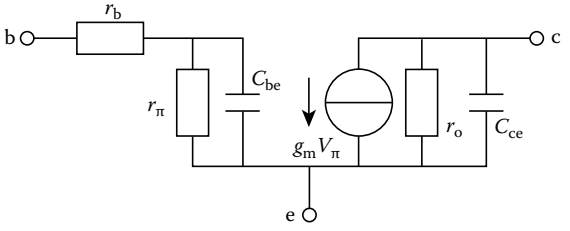

FIGURE 3.3 Simplified Miller-approximated hybrid π model of BJT.

C_π is the base–emitter junction capacitance
C_μ is the collector–base junction capacitance
C_{cs} is the collector–substrate capacitance
g_m is the small-signal transconductance

At low frequencies, the Miller approximation allows the hybrid-π model to be simplified to the circuit shown in Figure 3.3, where the net input capacitance now becomes $C_{be} = C_\pi + C_\mu (1 - A_v)$, the net output capacitance becomes $C_{ce} = C_\mu(1 - 1/A_v)$, where A_v is the voltage gain given by $A_v = (V_{ce}/V_{be}) \approx -g_m R_1$ where R_1 is the collector load resistance. r_c and C_{cs} have been neglected. Thus, $C_{be} \approx C_\pi + g_m R_1 C_\mu$ and $C_{ce} \approx C_\mu$. The output capacitance C_{ce} is often neglected from the small-signal model. The approximation $A_v = -g_m R_1$ assumes that $r_\pi \gg r_b$, and that the load is purely resistive. At high frequencies, however, we cannot neglect the gain roll-off due to C_π and C_μ, and even at frequencies as low as 5% of f_t the Miller approximation can introduce significant errors.

A simplified hybrid-π model that takes the high-frequency gain roll-off into account is shown in Figure 3.4. C_μ is now replaced by an equivalent current source $sC_\mu(V_\pi - V_{ce})$.

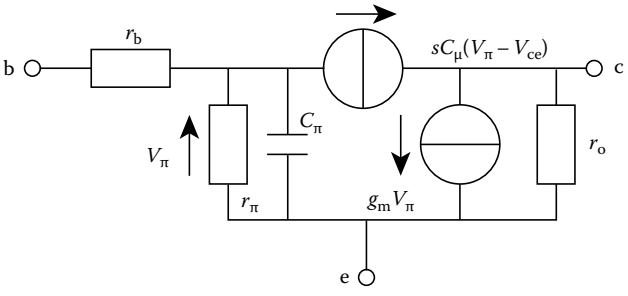

FIGURE 3.4 Simplified high-frequency model.

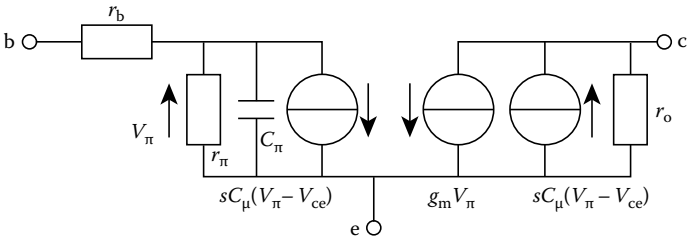

FIGURE 3.5 Split current sources.

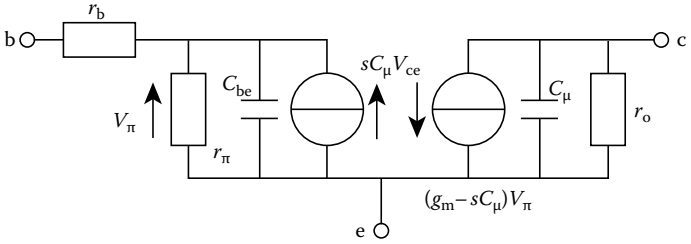

FIGURE 3.6 Modified equivalent circuit.

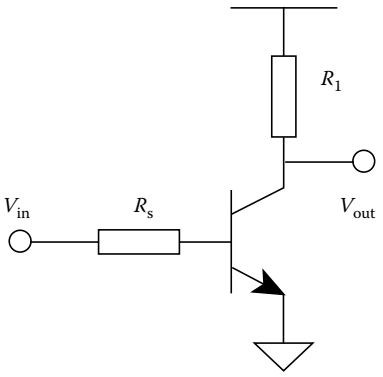

FIGURE 3.7 CE amplifier.

A further modification is to split the current source between the input and output circuits as shown in Figure 3.5.

Finally, the input and output component terms can be rearranged leading to the modified equivalent circuit shown in Figure 3.6, which is now suitable for broadband design. From Figure 3.6, the transconductance $(g_m - sC_\mu)$ shows the direct transmission of the input signal through C_μ. The input circuit current source $(sC_\mu V_{ce})$ shows the feedback from the output to the input via C_μ. Depending on the phase shift between V_{ce} and V_{be}, this feedback can cause high-frequency oscillation. At lower frequencies, $sC_\mu \ll g_m$ and $V_{ce}/V_\pi \approx -g_m R_1$, which is identical to the Miller approximation. The model of Figure 3.6 is the most accurate for broadband amplifier design, particularly at high frequencies.

3.1.4 Single-Gain Stages

Consider now the high-frequency analysis of single-gain stages.

3.1.4.1 Common-Emitter (CE) Stage

Figure 3.7 shows a CE amplifier with load R_1 and source R_s. External biasing components are excluded from the circuit.

First analysis using the Miller approximation yields the small-signal high-frequency model shown in Figure 3.8,

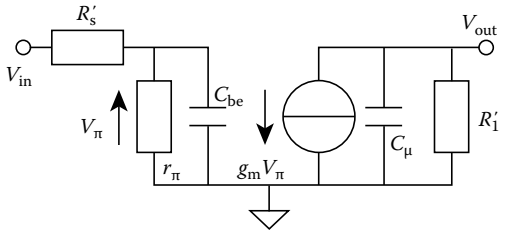

FIGURE 3.8 High-frequency model of the CE.

where

$$\begin{aligned} &R_{1'} = (R_1 \| r_0), \quad R_{s'} = R_s + r_b \quad \text{and} \quad C_{be} = C_\pi + g_m R_{1'} C_\mu \\ &\frac{V_\pi}{V_{in}} = \left(\frac{r_\pi}{r_\pi + R_{s'}}\right)\left(\frac{1}{1 + s(r_\pi \| R_{s'})C_{be}}\right) \\ &\frac{V_{out}}{V_\pi} = \frac{-g_m R_{1'}}{1 + sC_\mu R_{1'}} \end{aligned} \tag{3.1}$$

and thus

$$\frac{V_{out}}{V_{in}} = -\left(\frac{g_m R_{1'} r_\pi}{r_\pi + R_{s'}}\right)\left(\frac{1}{(1 + sC_\mu R_{1'})(1 + s(r_\pi \| R_{s'})C_{be})}\right) \tag{3.2}$$

This approximate analysis shows

- "Ideal" voltage gain $= -g_m R_1$
- Input attenuation caused by $R_{s'}$ in series with r_π
- Input circuit pole p_1 at $s = 1/C_{be}(r_\pi/R_{s'}) \approx 1/C_{be}R_{s'}$
- Output attenuation caused by r_0 in parallel with R_1
- Output circuit pole p_2 at $s = 1/C_\mu R_{1'}$

The input circuit pole is generally dominant, and thus the output pole p_2 can often be neglected. With a large load capacitance C_1, $p_2 \approx 1/C_1 R_{1'}$, and the gain and phase margin will be reduced. However, under these conditions the Miller approximation will no longer be valid, since the gain roll-off due to the load capacitance is neglected.

If we now consider analysis using the broadband hybrid-π model of Figure 3.6, then the equivalent model of the CE now becomes that shown in Figure 3.9, where

$$C_{be} = C_\pi + C_\mu, \quad R_{s'} = R_s + r_b \quad \text{and} \quad R_{1'} = R_1 \| r_0$$

From the model, it can be shown that

$$\frac{V_{out}}{V_\pi} = \frac{-(g_m - sC_\mu)R_{1'}}{1 + sC_\mu R_{1'}} \tag{3.3}$$

$$(V_{in} - V_\pi)/R_{s'} + sC_\mu V_{out} = V_\pi/r_\pi + sC_{be}V_\pi \tag{3.4}$$

and

$$V_{in} r_\pi + V_{out} sC_\mu r_\pi R_{s'} = V_\pi(r_\pi + R_{s'})(1 + sC_{be}(r_\pi \| R_{s'})) \tag{3.5}$$

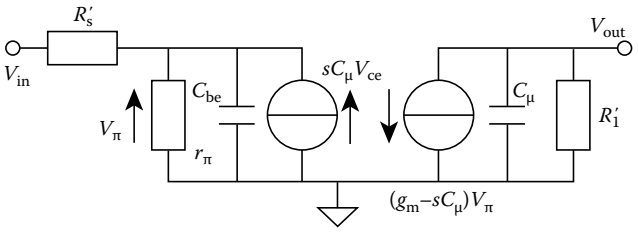

FIGURE 3.9 Equivalent circuit model of the CE.

Rearranging these equations yields

$$\frac{V_{out}}{V_{in}} = -\left(\frac{g_m R_{1'} r_\pi}{r_\pi + R_{s'}}\right) \times \left(\frac{1 - sC_\mu/g_m}{(1 + sC_{be}R_{s'})(1 + sC_\mu R_{1'}) + sC_\mu g_m R_{1'} R_{s'} - s^2 C_\mu^2 R_{s'} R_{1'}}\right) \tag{3.6}$$

This analysis shows that there is a right-hand-plane (RHP) zero at $s = 1/(C_\mu r_e)$, which is not predicted by the Miller approximation. Assuming $R_\pi \gg R_{s'}$ and $C_\pi \gg C_\mu$, the denominator can be written as

$$1 + s\left(R_{s'}\left(C_\pi + C_\mu g_m R_{1'}\right) + C_\mu R_{1'}\right) + s^2 C_\mu C_\pi R_{1'} R_{s'} \tag{3.7}$$

which can be described by the second-order characteristic equation

$$1 + s(1/p_1 + 1/p_2) + s^2/p_1 p_2 \tag{3.8}$$

By comparing coefficients in Equations 3.7 and 3.8, the sum of the poles is the same as that obtained in Equation 3.2 using the Miller approximation, but the pole product $p_1 p_2$ is greater. This means that the poles are farther apart than predicted by the Miller approximation. In general, the Miller approximation should be reserved for analysis at frequencies of operation well below f_t, and for situations where the capacitive loading is not significant. The equivalent circuit of Figure 3.9 therefore gives a more accurate result for high-frequency analysis. For a full understanding of RF behavior, computer simulation of the circuit including all parasitics is essential.

Since the CE stage provides high current and voltage gain, oscillation may well occur. Therefore, care must be taken during layout to minimized parasitic coupling between the input and output. The emitter should be at ground potential for ac signals, and any lead inductance from the emitter to ground will generate phase-shifted negative feedback to the base, which can result in instability.

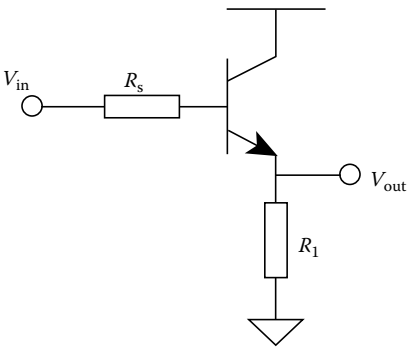

FIGURE 3.10 Common-collector amplifier.

3.1.4.2 Common-Collector (CC) Stage

The CC or emitter follower shown in Figure 3.10 is a useful circuit configuration since it generally serves to isolate a high-gain stage from a load. The high-frequency performance of this stage must be good enough not to degrade the frequency performance or stability of the complete amplifier. An equivalent high-frequency small-signal model of the CC is shown in Figure 3.11.

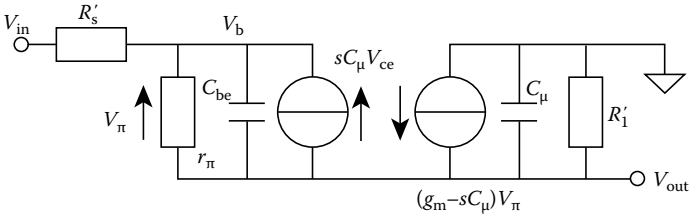

FIGURE 3.11 Equivalent circuit of the CC.

The following set of equations can be derived from Figure 3.11:

$$(V_{in} - V_b)/R_{s'} = V_\pi/r_\pi + sC_{be}V_\pi + sC_\mu V_{out}, \quad V_b = V_{out} + V_\pi \tag{3.9}$$

and

$$V_\pi/r_\pi + sC_{be}V_\pi + sC_\mu V_{out} + (g_m - sC_\mu)V_\pi - sC_\mu V_{out} - V_{out}/R_{1'} = 0 \tag{3.10}$$

Rearranging these equations yields

$$\frac{V_{out}}{V_{in}} = \frac{R_{1'}(1 + g_m r_\pi + sC_\pi r_\pi)}{(R_{s'} + r_\pi)(1 + s(R_{s'} \| r_\pi)C_{be}) + R_{1'}(1 + sC_\mu R_{s'})(1 + g_m r_\pi + sC_\pi r_\pi)} \tag{3.11}$$

The preceding expression can be simplified by assuming $R_\pi \gg R_{s'}$, $g_m r_\pi \gg 1$, $C_\pi \gg C_\mu$ to,

$$\frac{V_{out}}{V_{in}} = \left(\frac{r_\pi}{r_\pi + R_{s'}}\right)\left(\frac{1 + sC_\pi/g_m}{(1 + sC_\mu R_{s'})(1 + sC_\pi/g_m) + (1 + sC_\pi R_{s'})/g_m R_{1'}}\right) \tag{3.12}$$

This final transfer function indicates the presence of a left-half-plane zero at $s = (g_m/C_\pi) = \omega_t$. The denominator can be rewritten as approximately

$$(1 + 1/g_m R_{1'}) + s(C_\mu R_{s'} + C_\pi/g_m + C_{be}R_{s'}/g_m R_{1'}) + s^2 C_\mu C_\pi R_{s'}/g_m \tag{3.13}$$

which simplifies to

$$1 + s(C_\pi r_e + C_\mu R_{s'} + (C_\mu + C_\pi) r_e R_{s'}/R_{1'}) + s^2 C_\mu C_\pi R_{s'} R_{1'} \tag{3.14}$$

Assuming a second-order characteristic form of $1 + s(1/p_1 + 1/p_2) + s^2/p_1 p_2$, if $p_1 \ll p_2$, the above reduces to $1 + s/p_1 + s^2/p_1 p_2$. If $(R_{s'}/R_{1'}) \ll 1$, then $p_1 \approx 1/(C_\pi r_e)$, and this dominant pole will be approximately canceled by the zero. The frequency response will then be limited by the nondominant pole $p_2 \approx 1/C_\mu R_{s'}$.

The frequency response of a circuit containing several stages is thus rarely limited by the CC stage, due to this dominant pole-zero cancellation. For this analysis to be valid, $R_{s'} \ll R_{1'}$. As $R_{s'}$ increases the poles will move closer together, and the pole-zero cancellation will degrade. In practice, the CC stage is often used as a buffer, and is thus driven from a high source resistance into a low value load resistance.

A very important parameter of the common-collector stage is output impedance. It is generally assumed that the output impedance of a CC is low, also that there is good isolation between a load and the amplifying stage, and that any amount of current can be supplied to the load. Furthermore, it is assumed that capacitive loads will not degrade the frequency performance since the load will be driven by an almost short circuit. While this may be the case at low frequencies, it is a different story at high frequencies. Consider the following high-frequency analysis. We first assume that the small-signal model shown in Figure 3.12 is valid.

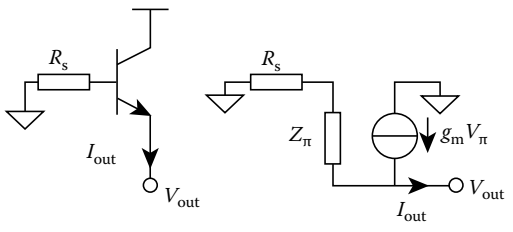

FIGURE 3.12 Equivalent circuit of the CC output stage.

From the Figure 3.12, the output impedance can be approximated as

$$\frac{V_{out}}{I_{out}} = \frac{Z_\pi + R_{s'}}{1 + g_m Z_\pi} \tag{3.15}$$

where $Z_\pi = (r_\pi \| C_{be})$ and $R_{s'} = R_s + r_b$. At very low frequencies ($\omega \to 0$):

$$R_{out} = \frac{r_\pi + R_{s'}}{1 + g_m r_\pi} \approx 1/g_m + R_{s'}/g_m r_\pi \approx r_e + R_{s'}/\beta \tag{3.16}$$

At very high frequencies ($\omega \to \infty$):

$$R_{out} = \frac{1/sC_{be} + R_{s'}}{1 + g_m/sC_{be}} \approx R_{s'} \tag{3.17}$$

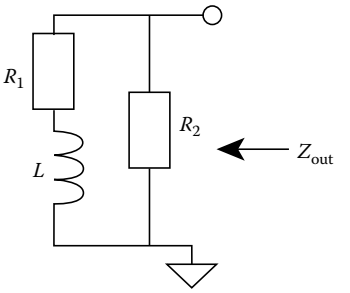

FIGURE 3.13 Equivalent high-frequency model of CC output stage.

If $r_e > R_{s'}$, then the output impedance decreases with frequency, that is, Z_{out} is capacitive. If $R_{s'} > r_e$, then Z_{out} increases with frequency, and so Z_{out} appears inductive. It is usual for an emitter follower to be driven from a high source resistance, thus the output impedance appears to be inductive and can be modeled as shown in Figure 3.13, where

$$R_1 = r_e + R_{s'}/\beta, \quad R_2 = R_{s'}, \quad L = R_{s'}/\omega_t$$

The inductive behavior of the CC stage output impedance must be considered in broadband design since any capacitive loading on this stage could result in peaking or instability. The transform from base resistance to emitter inductance arises because of the 90° phase shift between base and emitter currents at high frequencies, due principally to C_π. This transform property can be used to advantage to simulate an on-chip inductor by driving a CC stage from a high source resistance. Similarly, by loading the emitter with an inductor, we can increase the effective base series resistance $R_{s'}$ without degrading the noise performance of the circuit. A capacitive load will also be transformed by 90° between the base and emitter; for example, a capacitive loading on the base can look like a negative resistance at the emitter.

3.1.4.3 Common-Base (CB) Stage

The CB amplifier shown in Figure 3.14 offers the highest frequency performance of all the single-stage amplifiers. When connected as a unity gain current buffer, the CB stage operates up to the f_t of the transistor.

Using the simplified hybrid π model of Figure 3.3, it follows that

$$\frac{I_{out}}{I_{in}} \approx \frac{\beta}{\beta + 1} \quad \text{where} \quad \beta = \frac{\beta_o}{1 + s/\omega_o} \tag{3.18}$$

$$\frac{I_{out}}{I_{in}} \approx \frac{a_o}{1 + s/\omega_t} \quad \text{where} \quad a_o = \beta_o/(\beta_o + 1) \quad \text{and} \quad \omega_t = \beta_o \omega_o \tag{3.19}$$

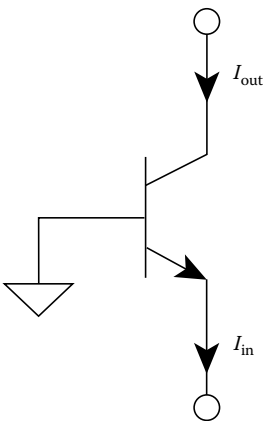

FIGURE 3.14 CB configuration.

The CB stage thus provides wideband unity current gain. Note that the input impedance of the CB stage is the same as the output impedance of the CC stage, and thus can appear inductive if the base series resistance is large.

In many situations, the CB stage is connected as a voltage amplifier, an example of this being the current-feedback amplifier, which will be discussed in a later section. Consider the following high-frequency analysis of the CB stage being employed as a voltage gain amplifier. Figure 3.15 shows the circuit together with a simplified small-signal model. From the equivalent model, the gain of the circuit can be approximated as

$$\frac{V_{out}}{V_{in}} = \frac{kR_1}{R_s}\left(\frac{1 - sC_\mu/g_m}{1 + s(C_\pi/g_m)(kR_{s'}/R_s)}\right) \tag{3.20}$$

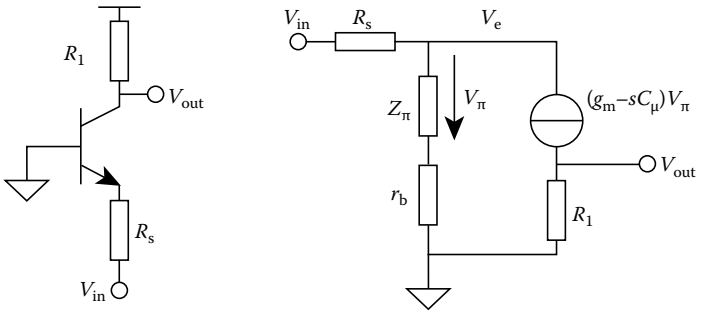

FIGURE 3.15 CB stage as a voltage amplifier.

where

$$R_{s'} = R_s + r_b, \quad \text{and} \quad k \approx \frac{R_s}{R_s + 1/g_m}$$

If $R_s \gg 1/g_m$, then $k \approx 1$ and so

$$\frac{V_{out}}{V_{in}} = \frac{R_1}{R_s}\left(\frac{1 - sC_\mu/g_m}{1 + s(C_\pi/g_m)(1 + r_b/R_s)}\right) \tag{3.21}$$

Thus, it can be seen that the circuit has an RHP zero at $s = 1/(r_e\ C_\mu)$, since $r_e = 1/g_m$ and a pole at $1/C_\pi r_e(1 + r_b/R_s) = \omega_t/(1 + r_b/R_s)$. Note that in the case of a current source drive ($R_s \gg r_b$), the pole is at the ω_t of the transistor. However, this does assume that the output is driven into a short circuit. Note also that there is an excellent isolation between the input and output circuits, since there is no direct path through C_μ and so no Miller effect.

3.1.5 Neutralization of C_μ

Many circuit techniques have been developed to compensate for the Miller effect in amplifiers and hence extend the frequency range of operation. The CE stage provides the highest potential power gain, but the bandwidth of this configuration is limited since the amplified output voltage effectively appears across the collector–base junction capacitance resulting in the Miller capacitance multiplication effect. This bandwidth limiting due to C_μ can be overcome by using a two-transistor amplifying stage such as the CE–CB cascode stage or the CC–CE cascade. Consider now a brief qualitative description of each in turn. The circuit diagram of the CE–CB cascode is shown in Figure 3.16.

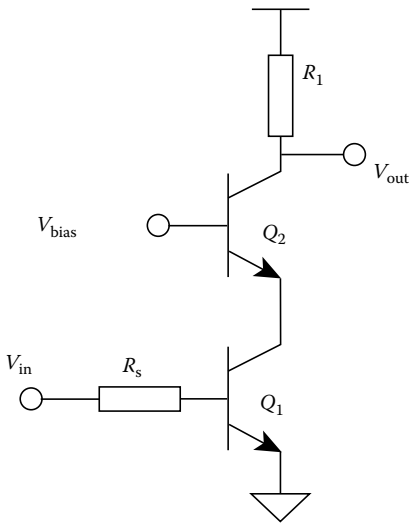

FIGURE 3.16 CE–CB cascode.

The CE transistor Q_1 provides high current gain of approximately β and a voltage gain of $A_{v1} \approx -g_{m1}R_1 = -g_{m1}r_{e2}$, which in magnitude will be close to unity. Therefore, the Miller multiplication of C_μ is minimized, and the bandwidth of Q_1 is maximized. The CB transistor Q_2 provides a voltage gain $A_{v2} \approx R_1/r_{e2}$. The total voltage gain of the circuit can be approximated as $A_v \approx -g_{m1}R_1$, which is equal to that of a single CE stage. The total frequency response is given by the cascaded response of both stages. Since both transistors exhibit wideband operation, then the dominant poles of each stage may be close in frequency. As a result, the total phase shift through the cascode

configuration is likely to be greater than that obtained with a single device, and care should be taken when applying negative feedback around the pair.

Consider now the CC–CE stage of Figure 3.17. In this case, voltage gain is provided by the CE stage transistor Q_2 and is $A_{v2} \approx -g_{m2}R_1$. This transistor is being driven from the low-output impedance of Q_1 and so the input pole frequency of this device ($\approx 1/C_{be2}R_{s2}$) is maximized. The CC stage transistor Q_1 is effectively a buffer that isolates C_μ of Q_2 from the source resistance R_s. The low-frequency voltage gain of this circuit is reduced when compared with a single-stage configuration because the input signal effectively appears across two base–emitter junctions.

The two-transistor configurations help to maintain a wideband frequency response by isolating the input and output circuits. In integrated circuit design, another method of neutralizing the effect of C_μ is possible when differential gain stages are used.

For example, Figure 3.18 shows a section of a differential input amplifier. If the inputs are driven differentially, then the collector voltages V_{c1} and V_{c2} will be 180° out of phase. The neutralization capacitors C_n thus inject a current into the base of each transistor that is equal and opposite to that caused by the intrinsic capacitance C_μ. Consequently, the neutralization capacitors should be equal to C_μ in order to provide good signal cancellation, and so they may be implemented from the junction capacitance of two dummy transistors with identical geometries to Q_1 and Q_2 as shown in Figure 3.19.

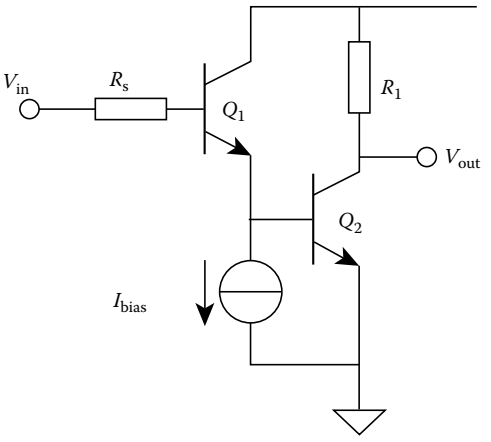

FIGURE 3.17 CC–CE stage.

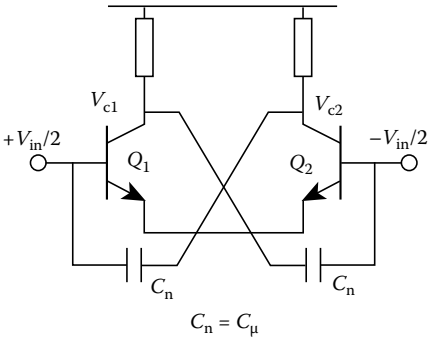

FIGURE 3.18 Differential gain stage.

3.1.6 Negative Feedback

Negative feedback is often employed around high-gain stages to improve the frequency response. In effect, the gain is reduced in exchange for a wider, flatter bandwidth. The transfer function of a closed-loop system can be written

$$H(s) = \frac{A(s)}{1 + A(s)B(s)} \tag{3.22}$$

where $A(s)$ is the open-loop gain and $B(s)$ is the feedback fraction. If the open-loop gain $A(s)$ is large, then $H(s) \approx 1/B(s)$. In RF design, compound or cascaded stages can produce excessive phase shifts that result in instability when negative feedback is applied. To overcome this problem, it is generally accepted to apply local negative feedback around a

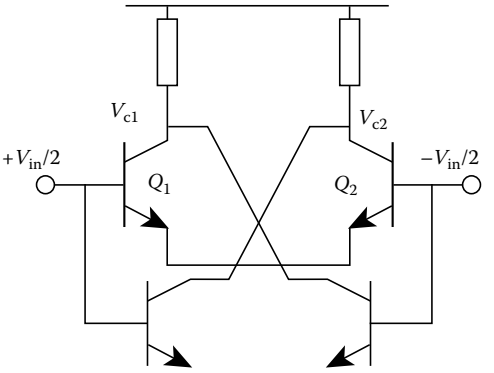

FIGURE 3.19 Implementation of neutralization capacitors.

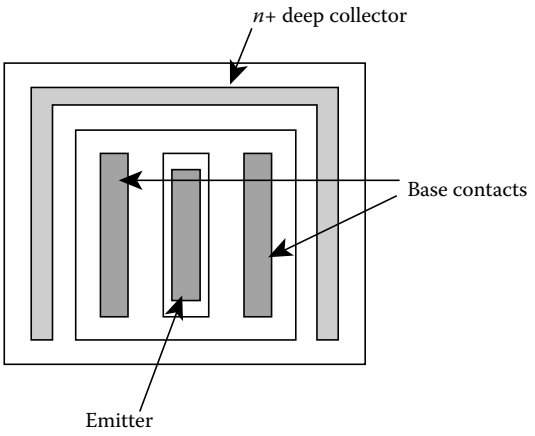

FIGURE 3.20 Stripe geometry.

single stage only. However, the open-loop gain of a single stage is usually too low for the approximation $H(s) = 1/B(s)$ to hold.

3.1.7 RF Bipolar Transistor Layout

When laying out RF transistors, the aim is to

- Minimize C_μ and C_π
- Minimize base width to reduce the forward transit time t_∂ and thus maximize ∂_t
- Minimize series resistance r_b and r_c

To minimize junction capacitance, the junction area must be reduced; however, this will tend to increase the series resistance. Transistors are generally operated at fairly high currents to maximize ∂_t. However, if the emitter gets too crowded, then the effective value of β will be reduced. The requirements given above are generally best met by using a stripe geometry of the type shown in Figure 3.20.

The stripe geometry maximizes the emitter area-to-periphery ratio, which reduces emitter crowding while minimizing the junction capacitance. The length of the emitter is determined by current-handling requirements. The base series resistance is reduced by having two base contacts and junction depths are minimized to reduce capacitance. The buried layer, or deep collector, reduces the collector series resistance. High-power transistors are produced by paralleling a number of transistors with interleaving "fingers," as shown in Figure 3.21. This preserves the frequency response of the stripe geometry while increasing the total current-handling capability.

3.1.8 Bipolar Current-Mode Broadband Circuits

Recently there has been strong interest in applying so-called current-mode techniques to electronic circuit design. Considering the signal operating parameter as a current and driving into low-impedance nodes has allowed the development of a wealth of circuits with broadband properties. Many of the following circuit and system concepts date back several years; it is progress in integrated circuit technology that has given a renewed impetus to "practical" current-mode techniques.

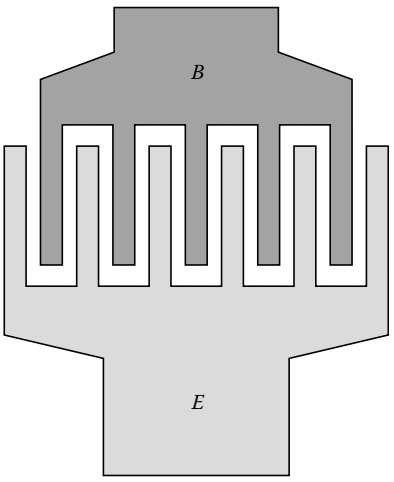

FIGURE 3.21 Transistor layout with interleaving fingers.

The NPN bipolar transistor, for example, is used predominantly in analog IC design because electron mobility is greater than hole mobility in silicon. This means that monolithic structures are typically built on P-type substrates, because vertical NPN transistors are then relatively easy to construct and to isolate from each other by reverse biasing the substrate.

Fabricating a complementary PNP device on a P-type substrate is less readily accomplished. An N type substrate must be created locally and the PNP device placed in this region. Early bipolar processes created PNP devices as lateral transistors and engineers dealt with their inherently poor, low-frequency characteristics by keeping the PNP transistors out of the signal path whenever possible.

However, high-speed analog signal-processing demands symmetrical silicon processes with fully complementary BJTs.

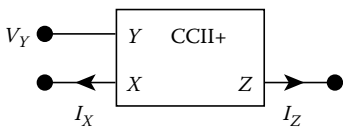
Newer, advanced processes have dielectrically isolated transistors rather than reversed-biased pn junction isolation. These processes are able to create separate transistors, each situated in a local semiconductor region. Then, both PNP and NPN devices are vertical and their performance characteristics are much more closely matched.

Dielectric isolation processes have revolutionized high-speed analog circuit design and have been key in making high-performance current-conveyor and current-feedback op-amp architectures practical. In the following sections, we will briefly review the development of the current-conveyor and current-feedback op-amp.

3.1.8.1 Current Conveyor

The current conveyor is a versatile broadband analog amplifier that is intended to be used with other circuit components to implement many analog signal-processing functions. It is an analog circuit building block in much the same way as a voltage op-amp, but it presents an alternative method of implementing analog systems that traditionally have been based on voltage op-amps. This alternative approach leads to new methods of implementing analog transfer functions, and in many cases the conveyor-based implementation offers improved performance when compared to the voltage op-amp-based implementation in terms of accuracy, bandwidth, and convenience. Circuits based on voltage op-amp are generally easy to design since the behavior of a voltage op-amp can be approximated by a few simple design rules. This is also true for current conveyors, and once the appropriate design rules are understood, the application engineer is able to design conveyor-based circuits just as easily.

The first-generation current conveyor (CCI) was proposed by Smith and Sedra in 1968 [1] and the more versatile second-generation current conveyor (CCII) was introduced by the same two authors in 1970 [2], as an extension of the CCI. The CCII, is without doubt the more valuable and adaptable building block of the two, and we will concentrate mostly on this device. Figure 3.22a shows the voltage–current describing matrix for the CCII, while Figure 3.22b shows the schematic normally used for the CCII with the power supply connections omitted.



The voltage at the low-impedance input node X follows that at the high-impedance input node Y, while the input current at node X is mirrored or "conveyed" to the high-impedance output node Z. The $\pm$ sign indicates the polarity of the output current with respect to the input current; by convention, a positive sign indicates that both the input and output currents simultaneously flow into or out of the device, thus Figure 3.22b illustrates a CCII+. For the CCI, the input current at node X was reflected to input Y, that is the two inputs had equal currents. In the case of the second-generation conveyor input, Y draws no current, and this second generation, or CCII formulation, has proved to be much more adaptable and versatile than its first-generation predecessor. Because of the combined voltage and current following properties, CCIIs may be used to synthesize a number of analog circuit functions that are not so easily or accurately realizable using voltage op-amps.

Some of these application areas are shown in Figure 3.23. As current-conveyors become more readily available and circuits designers become more familiar with the versatility of this device, it is certain that further ingenious uses will be devised.

The ideal transistor and the current-conveyor. So far a transistor-level realization of the CCII has not been discussed. The current–voltage transfer relationship for the CCII+ is given by

$$\begin{bmatrix} I_Y \\ V_X \\ I_Z \end{bmatrix} = \begin{bmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & \pm 1 & 0 \end{bmatrix} \begin{bmatrix} V_Y \\ I_X \\ V_Z \end{bmatrix}$$

(a)

(b)

FIGURE 3.22 The CCII current conveyor. (a) I–V describing matrix. (b) Schematic.

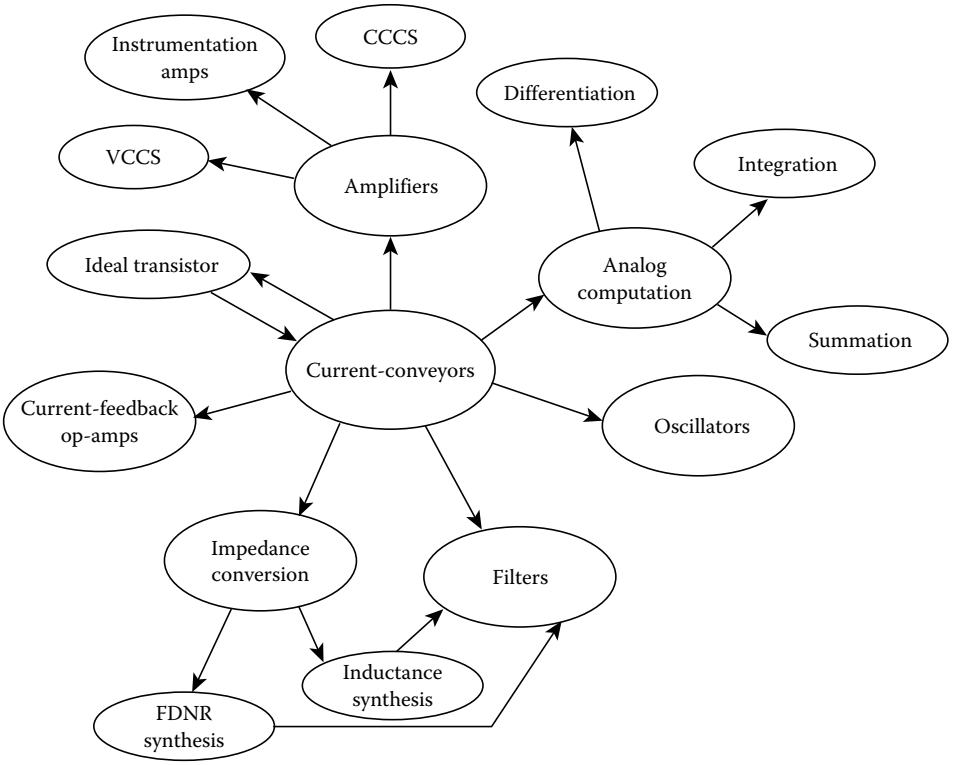


FIGURE 3.23 Current-conveyor applications.

$$V_X = V_Y, \quad I_Y = 0, \quad \text{and} \quad I_Z = I_X \tag{3.23}$$

These equations show that a simple voltage-following action exists between input node Y and output node X, and that there is a simple current-following action between input node X and output node Z. Also, these characteristic equations tell us that the impedance relationship for the ideal current conveyor is

$$Z_{\text{in}Y} = \infty, \quad Z_X = 0, \quad \text{and} \quad Z_{\text{out}Z} = \infty \tag{3.24}$$

Figure 3.24 shows a schematic representation of a CCII—built with a single BJT and on reflection it is clear that the current conveyor is effectively an ideal transistor, with infinite β and infinite g_m.

Driving into the base of a BJT gives almost unity voltage gain from input base to output emitter, with high input impedance and low-output impedance, and driving into the emitter of a BJT gives almost unity current gain from emitter input to collector output, with low input impedance and high output impedance. Drawing the comparison further, the high-input-impedance Y node corresponds to the base (or gate) of a transistor, the low-input-impedance X node corresponds to the emitter (or source) of a transistor, and the high-output-impedance Z node corresponds to the collector (or drain) of a transistor. Clearly, one transistor cannot function alone as a complete current conveyor since an unbiased single transistor at best can only handle unipolar signals and the high-accuracy unity voltage and unity current gain required for a high-performance current conveyor cannot be obtained. However, the generic relationship between the current conveyor and an ideal transistor is valid, and it provides valuable insight into the development and operation of monolithic current conveyors described in the next section.

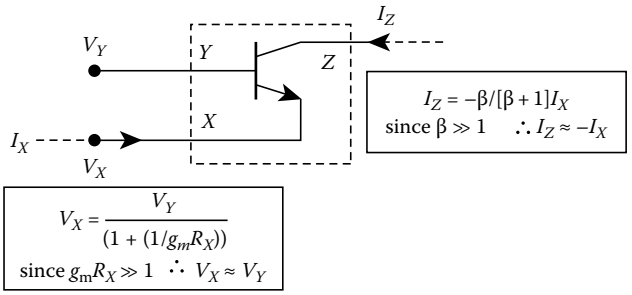

FIGURE 3.24 Single BJT CCII–.

Supply-current sensing. Many of the current-conveyor theories and applications have been tested out in practice using "breadboard" conveyor circuits, due to the lack of availability of a commercial device. Some researchers have built current conveyors from matched transistor arrays, but the most common way of implementing a fairly high-performance current conveyor has been based on the use of supply-current sensing on a voltage op-amp [3,4], as shown in Figure 3.25. The high-resistance op-amp input provides the current-conveyor *Y* node, while the action of negative feedback provides the low-resistance *X* node. Current-mirrors in the op-amp supply leads copy the current at node *X* to node *Z*.

Using this type of architecture, several interesting features soon became apparent. Consider the two examples shown in Figure 3.26. In Figure 3.26b, R_s represents the output resistance of the current source. The open-loop gain of an op-amp can generally be written

$$\frac{V_{out}}{V_{in}} = \frac{A_o}{1 + j(f/f_o)} \tag{3.25}$$

where A_o is the open-loop direct current (dc) gain magnitude and ∂_o is the open-loop -3 dB bandwidth. Since $A_o \gg 1$, the transfer function of the voltage follower of Figure 3.26a can be written as

$$\frac{V_{out}}{V_{in}} \approx \frac{1}{1 + j(f/GB)} \tag{3.26}$$

where $GB = A_o \partial_o$. From Equation 3.26, the -3 dB bandwidth of the closed-loop voltage follower is equal to the open-loop gain-bandwidth product or *GB* of the op-amp. If the op-amp is configured instead to give a closed-loop voltage gain *K*, it is well known that the closed-loop bandwidth correspondingly reduces by the factor *K*.

The transfer function for the current-follower circuit of Figure 3.26b, as shown in Ref. [4], is given by

$$\frac{I_{out}}{I_{in}} \approx \lambda \frac{1 + j(f/GB)}{1 + j(f/kGB)} \tag{3.27}$$

where λ is the current transfer ratio of the current mirrors and $k = (R_s + r_o/A_o)/(R_s + r_o)$, and r_o represents the output resistance of the op-amp. Since $A_o \gg R_s \gg r_o$, then $K \approx 1$, and the pole and zero in Equation 3.27 almost

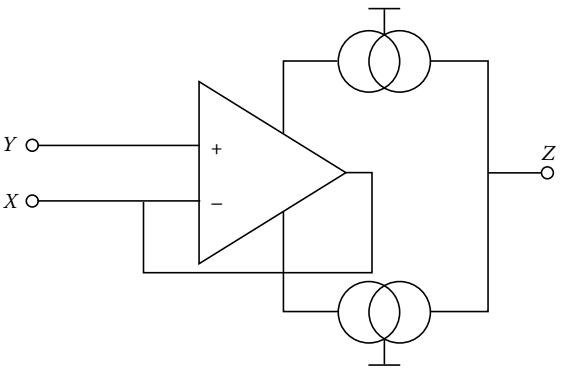

FIGURE 3.25 Supply-current sensing on a voltage op-amp.

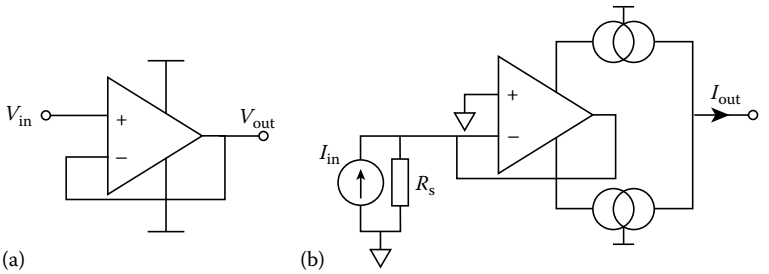

FIGURE 3.26 (a) Voltage follower. (b) Current follower.

cancel. The current-follower circuit thus operates well above the gain-bandwidth product *GB* of the op-amp, and the −3 dB frequency of this circuit will be determined by higher frequency parasitic poles within the current mirrors.

This "extra" bandwidth is achieved because the op-amp is being used with input and output nodes held at virtual ground. The above example is generic in the development of many of the circuits that follow. It demonstrates that reconfiguring a circuit topology to operate with current signals can often result in a superior frequency performance.

First-generation current conveyors. Smith and Sedra's original paper presenting the first-generation CCI current conveyor showed a transistor-level implementation based on discrete devices, shown in Figure 3.27. Assuming that transistors Q_3–Q_5 and resistors R_1–R_3 are matched, then to first order the currents through these matched components will be equal. Transistors Q_1 and Q_2 are thus forced to have equal currents, and equal V_{be}s. Input nodes *X* and *Y* therefore track each other in both voltage and current. In practice, there will be slight differences in the collector currents in the different transistors, due to the finite β of the devices. These differences can be reduced, for example, by using more elaborate current mirrors. The polarity of the output current at node *Z* can be inverted easily by using an additional mirror stage, and the entire circuit can also be inverted by replacing NPN transistors with PNPs, and vice versa. Connecting two complementary current conveyors, as shown in Figure 3.28, results in a class *AB* circuit capable of bipolar operation. Note that in practice this circuit may require additional components to guarantee start-up.

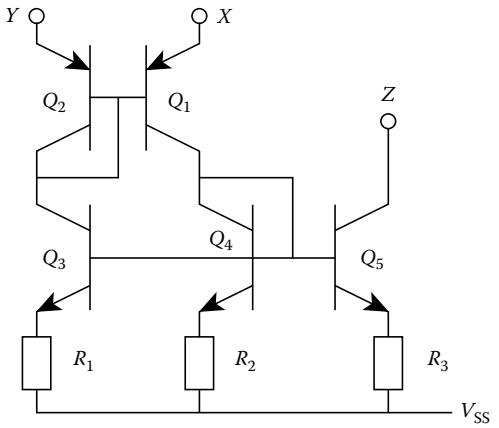

FIGURE 3.27 First-generation current conveyor.

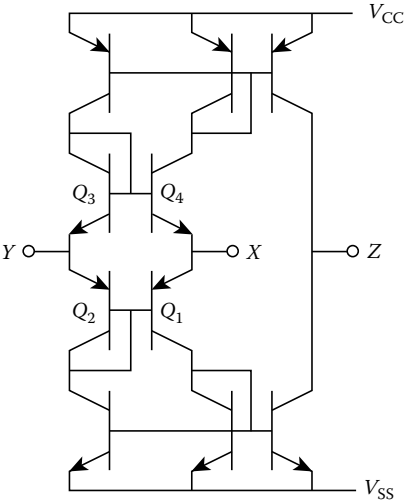

FIGURE 3.28 Class *AB* current conveyor.

An integrated current conveyor based on the architecture shown in Figure 3.27 is commercially available as the PA630 [5], and the basic topology of this device is shown in Figure 3.29. An NPN Wilson mirror (Q_1–Q_3) and a PNP Wilson mirror (Q_4–Q_6) are used to provide the current and voltage following properties between inputs X and Y, similar to the circuit of Figure 3.27. Taking a second output from the PNP current mirror to provide the Z output would destroy the base-current compensation scheme of the Wilson mirror. Therefore, a second NPN Wilson mirror (Q_7–Q_9) is used to perform a current-splitting action and so the combined emitter current of Q_7 and Q_8 is divided in two, with one half being shunted via Q_9 to the supply rail, and the other half driving an output PNP Wilson mirror (Q_{10}–Q_{12}). This results in an output current at node Z that to first order is virtually equal to that at the X and Y inputs. Q_{13} is included to ensure that the device always starts up when turned on. The complete architecture of the PA630 CCI also includes frequency compensation to ensure stability, and modified output current mirrors that use the ''wasted'' collector current of Q_9 to effectively double the output resistance at node Z. A full description of the architecture and operation of this device can be found in Ref. [6].

The current-conveyor architecture shown in Figure 3.29 includes both NPN and PNP transistors in the signal path, and thus the bandwidth and current-handling capability of this device will be poor if only lateral PNPs are available. The development of complementary bipolar processes, with vertical PNP as well as NPN transistors, has made possible the implementation of high-performance integrated circuit current conveyors.

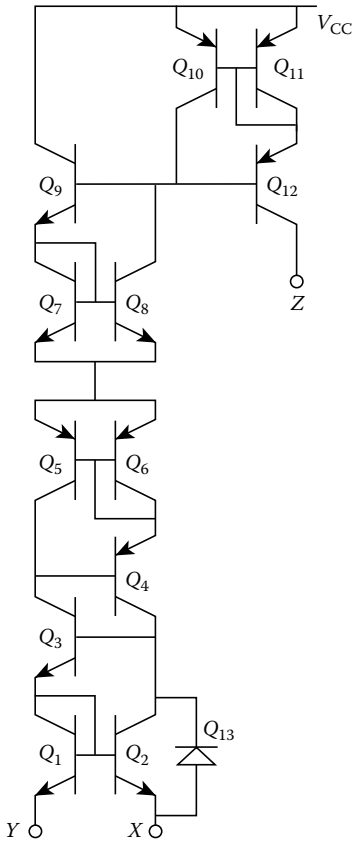

FIGURE 3.29 Simplified PA630 current conveyor.

Second-generation current conveyors. A CCII can also be simply implemented on a complementary bipolar process, by replacing the diode at the CCI Y input with a transistor, and taking the input from the high resistance base terminal, as shown in Figure 3.30a. This can be extended to a class AB version, as shown in Figure 3.30b. Referring to Figure 3.30b, transistors Q_1–Q_4 act as a voltage buffer that transfers the voltage at node Y to node X. The current source and sink ($I_{B1} = I_{B2} = I_B$) provide the quiescent bias current for these input transistors. Any input current (I_x) at node X is split between Q_2 and Q_3, and is copied by current mirrors CM_1 and CM_2 to the output node Z. This CCII architecture forms the basis of the commercially available CCII01 current conveyor [7]. As we shall see later, it is also used as the basic input stage of the current-feedback op-amp, which has emerged as a high-speed alternative to the more conventional voltage op-amp [8].

The simple CCII architecture of Figure 3.30b will clearly exhibit a quiescent voltage offset between nodes X and Y due to the mismatch between the V_{be}s of the NPN and PNP transistors Q_1/Q_2 and Q_3/Q_4, as

$$\begin{aligned} V_Y - V_X &= V_{BE}(p) - V_{BE}(n) \\ &= V_T \ln\left(I_{sp}/I_{sn}\right) \end{aligned} \tag{3.28}$$

where I_{sp} and I_{sn} are the reverse saturation currents of the PNP and NPN transistors, respectively, and V_T is the thermal voltage. This process-dependent voltage offset can be reduced by including additional matching diodes in the input stage, as shown in Figure 3.31. Referring to this diagram,

$$\begin{aligned} V_Y - V_X &= V_{BE}(Q_1) + V_{D_2} - V_{BE}(Q_2) - V_{D_1} \\ V_Y - V_X &= [V_{BE}(Q_1) - V_{D_1}] - [V_{BE}(Q_2) - V_{D_2}] \end{aligned} \tag{3.29}$$

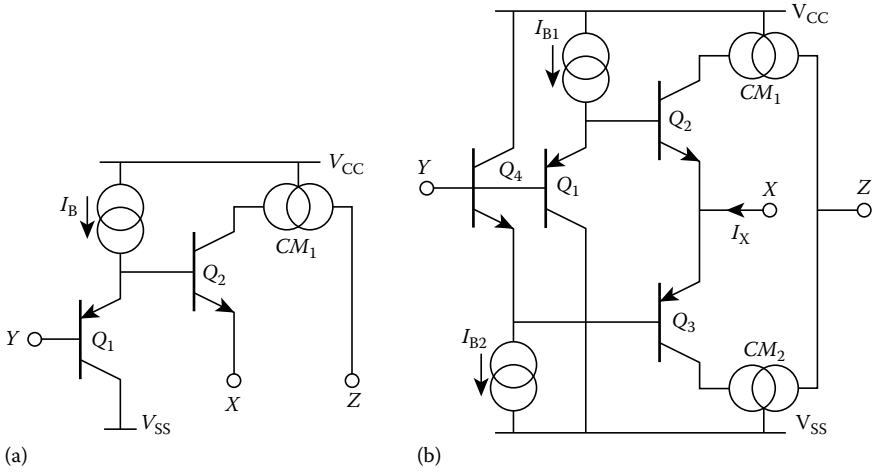

FIGURE 3.30 (a) Class *A* CCII. (b) Class *AB* CCII.

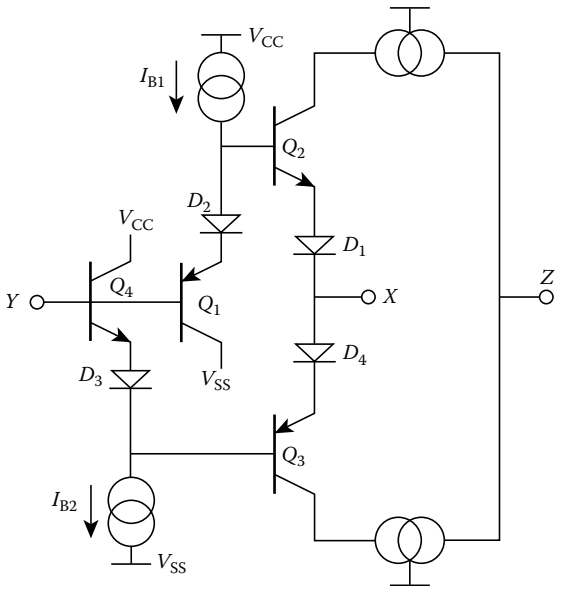

FIGURE 3.31 CCII with input matching diodes.

Inclusion of these diodes clearly reduces the quiescent input voltage offset, provided that D_1 is matched to Q_1, D_2 is matched to Q_2, etc. However, the addition of diodes D_1 and D_2 has several disadvantages. First, the input voltage dynamic range of the circuit will be reduced by the forward voltage across the additional diode. Second, the small-signal input resistance seen looking into node X will be double that for the basic architecture given in Figure 3.30b. This nonzero input resistance at node X (R_x) will compromise the performance of the current conveyor, especially in applications where a nonzero input voltage is applied at node Y. The effect of the small-signal input resistance R_x is to produce a signal-dependent voltage offset V_d between nodes X and Y, where

$$V_{\dot{a}} = R_x I_x \tag{3.30}$$

Since the value of R_x is determined by the small-signal resistance $(r_{e2} + r_{d2})$ in parallel with $(r_{e3} + r_{d3})$, its value could be reduced by increasing the value of the quiescent bias current I_B. However, an increase in bias current will lead to an increase in the total power consumption, as well as a possible increase in offsets, and so is certainly not an ideal solution. Further techniques for CCII implementation are discussed in Ref. [14].

The previous conveyor is typical of commercial conveyor architectures [7], which are generally built on a high-speed dielectric isolation (fully complementary) bipolar process. Such devices feature an equivalent slew rate of some 2000 V/μs and a bandwidth of around 100 MHz.

Until high-performance current conveyors are widely available, these devices will continue to be used in research laboratories rather than in the applications arena. Process technologies and design techniques

have now advanced to the stage where the implementation of an integrated current conveyor is both desirable and viable, and a whole host of applications are waiting for its arrival.

3.1.8.2 Current-Feedback Operations Amplifier

In this section, the design and development of a high-gain wide-bandwidth transimpedance or current-feedback operational amplifier is considered. The design of conventional operational amplifiers has remained relatively unchanged since the introduction of the commercial operational amplifier in 1965. Recently, a new amplifier architecture, called a current-feedback operational amplifier, has been introduced. This amplifier architecture is basically a transimpedance amplifier, or a current-controlled voltage source, while the classical voltage-feedback operational amplifier is a voltage-controlled voltage source.

The current-feedback operational amplifier has two major advantages, compared to its voltage-feedback counterpart. First, the closed-loop bandwidth of the current-feedback amplifier is larger than that of classical voltage-feedback design for comparable open-loop voltage gain. Second, the current-feedback operational amplifier is able to provide a constant closed-loop bandwidth for closed-loop voltage gains up to about 10. A further advantage of the current-feedback architecture is an almost unlimited slew rate due to the class-*AB* input drive, which does not limit the amount of current available to charge up the compensation capacitor as is the case in the conventional voltage-feedback op-amp. This high-speed performance of the current-feedback operational amplifier is extremely useful for analog signal-processing applications within video and telecommunication systems.

The generic relationship between the CCII+ and the current-feedback op-amp is extremely close and several of the features offered by the CCII are also present in the current-feedback op-amp. The basic structure of the current-feedback op-amp is essentially that of a CCII+ with the Z node connected directly to an output voltage follower, as shown in Figure 3.32. Any current flowing into the low-impedance inverting input is conveyed to the gain node (Z_T), and the resulting voltage is buffered to the output. Z_T is thus the open-loop transimpedance gain of the current-feedback op-amp, which in practice is equal to the parallel combination of the CCII+ output impedance, the voltage buffer input impedance and any additional compensation capacitance at the gain node. Generally, in current-feedback op-amps, the gain node is not connected to an external pin, and so the Z node of the CCII+ cannot be accessed.

Current-feedback op-amp architecture. In the following sections, we review the basic theory and design of the current-feedback op-amp and will identify the important features and mechanisms that result in broadband performance. We will begin by reviewing the voltage-feedback op-amp and comparing it with the current-feedback op-amp in order to see the differences clearly.

A schematic of the classical voltage-feedback op-amp comprising a long-tail pair input stage is shown in Figure 3.33a, which contrasts a typical current-feedback architecture, which is shown in Figure 3.33b. In both circuits, current mirrors are represented by two interlocking circles with an arrow denoting the input side of the mirror.

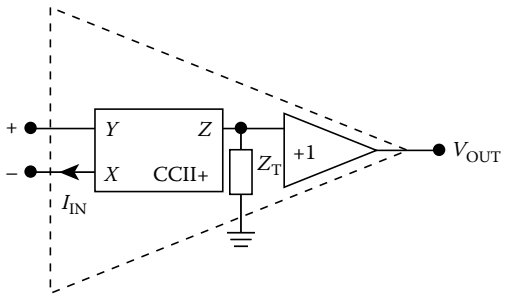

FIGURE 3.32 Current-feedback op-amp structure.

The current-feedback op-amp of Figure 3.33b shows that the noninverting input is a high-impedance input that is buffered to a low-impedance inverting terminal via a class *AB* complementary common-collector stage (Q_1, Q_2, D_1, D_2). Note that this classical input buffer architecture is used here for simplicity. In practice, a higher performance topology such as that described in Figure 3.31 would more likely be employed. The noninverting input is a voltage input; this voltage is then buffered to the inverting low-impedance current input to which feedback is applied. In contrast, both the noninverting and

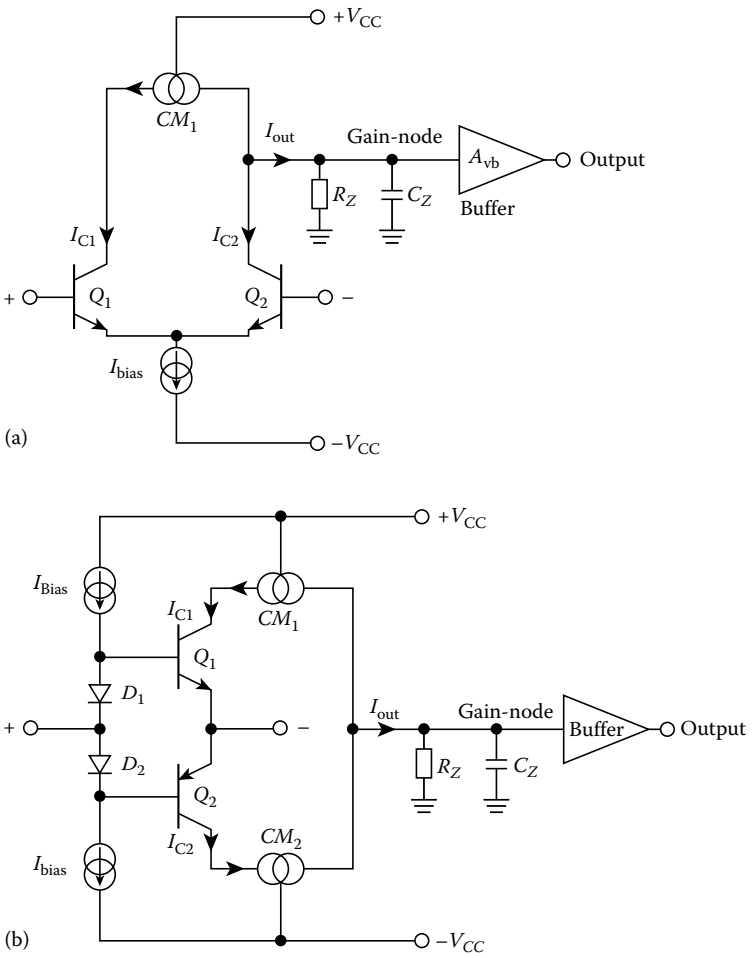

FIGURE 3.33 (a) Simplified classic voltage-feedback op-amp architecture. (b) Typical current-feedback op-amp architecture.

inverting input of the voltage-feedback op-amp are high-impedance voltage inputs at the bases of transistors Q_1 and Q_2.

In both architectures, the collector currents of Q_1 and Q_2 are transferred by the current mirror to a high-impedance node represented by resistance R_Z and capacitance C_Z. This voltage is then transferred to the output by voltage buffers that have a voltage gain A_{vb}, providing the necessary low-output impedance for current driving. In the case of the current-feedback op-amp, the output buffer is usually the same topology as the input buffer stage shown in the Figure 3.33b, but with slightly higher output current bias levels and larger output devices to provide an adequate output drive capability. Ideally, the bias currents I_{CQ1} and I_{CQ2} will be canceled at the gain node giving zero offset current.

Differential-mode operation of the current-feedback op-amp. A schematic diagram of the current-feedback op-amp with a differential input voltage applied at the noninverting and inverting input is shown in Figure 3.34.

The positive input voltage is applied to the base of transistor Q_1 (NPN) via D_1, and the negative input voltage is applied to the emitter of Q_1, causing the V_{BE} of Q_1 to increase and the V_{BE} of Q_2 to

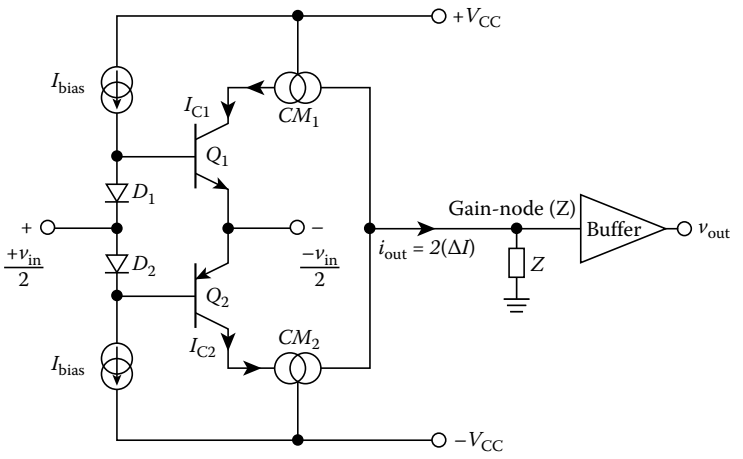

FIGURE 3.34 Current-feedback op-amp with differential input voltage applied.

reduce. I_{C1} will therefore increase by an amount ΔI and so I_{C2} will decrease by the same amount $-\Delta I$. A net current of $2\Delta I$ is therefore sourced out of the high-impedance node (Z) giving rise to a positive voltage ($2\Delta IZ$). This voltage is then buffered to the output.

With negative feedback applied around the current-feedback op-amp, the low-impedance inverting input will sense the current "feedback" from the output via the feedback network. This feedback current flowing into the inverting input is given by

$$i_{in-} = I_{C2} - I_{C1} \tag{3.31}$$

The difference between the collector current I_{C1} and I_{C2}, i_{in-}, will thus be driven into gain node Z, giving rise to the output voltage

$$V_{out} = Zi_{in-} \tag{3.32}$$

It is clear that the output voltage is dependent on the current that flows into the inverting input, hence the amplifier has a high open-loop transimpedance gain Z.

Closed-loop noninverting operation of the current-feedback op-amp. A schematic diagram of the current-feedback op-amp connected with negative feedback as a noninverting amplifier is shown in Figure 3.35. For a positive input voltage v_{in}, the output voltage v_{out} will swing in the positive direction and the inverting input current i_{in-} will flow out:

$$i_{in-} = \frac{v_{in-}}{R_1} - \frac{(v_{out} - v_{in-})}{R_2} \tag{3.33}$$

The input stage is simply a voltage follower and so ideally, $v_{in+} = v_{in-} = v_{in}$. Because $v_{out} = Zi_{in-}$, then substituting for v_{in-} and i_{in-} in Equation 3.33 yields

$$\frac{v_{out}}{Z} = \frac{v_{in}}{R_1} - \frac{(v_{out} - v_{in})}{R_2} \tag{3.34}$$

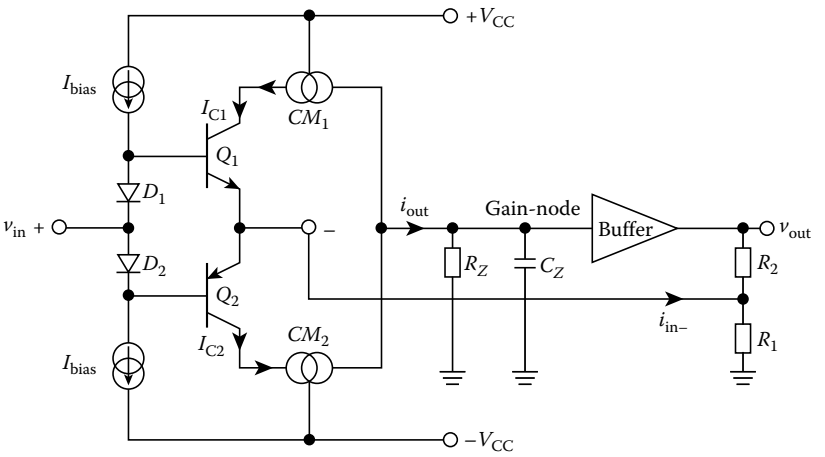

FIGURE 3.35 Noninverting current-feedback op-amp.

rearranging for v_{out}/v_{in}

$$v_{out}\left(\frac{1}{R_2}+\frac{1}{Z}\right)=v_{in}\left(\frac{1}{R_1}+\frac{1}{R_2}\right) \tag{3.35}$$

$$\frac{v_{out}}{v_{in}}=\left(1+\frac{R_2}{R_1}\right)\left(\frac{1}{1+(R_2/Z)}\right) \tag{3.36}$$

This result shows that the closed-loop noninverting gain of the current-feedback op-amp is similar to that of a classical voltage-feedback op-amp. From Equation 3.36, the open-loop transimpedance gain Z must be as large as possible to give good closed-loop gain accuracy. Since v_{out}/Z represents the error current i_{in-}, then maximizing the Z term will minimize the inverting error current. Note that at this stage it is only the R_2 term in the denominator of the second term in Equation 3.36 that sets the bandwidth of the amplifier; the gain-setting resistor R_1 has no effect on the closed-loop bandwidth.

Closed-loop inverting operation of current-feedback op-amp. A current-feedback op-amp connected as an inverting amplifier is shown in Figure 3.36. The low-impedance inverting input samples the input current and drives the output until the voltage at its terminal is at a virtual ground because of negative feedback. Ideally the closed-loop gain is given by

$$A_{CL}=-\frac{R_2}{R_1} \tag{3.37}$$

From Figure 3.36, application of Kirchhoff's current law to the current i_1, i_{in-}, and i_2 gives

$$i_{in-}+i_2=i_1$$
$$i_{in-}-\frac{v_{out}}{R_2}=\frac{v_{in}}{R_1}$$

because $v_{out}/Z=-i_{in-}$, then

$$-\frac{v_{out}}{Z}-\frac{v_{out}}{R_2}=\frac{v_{in}}{R_1}$$

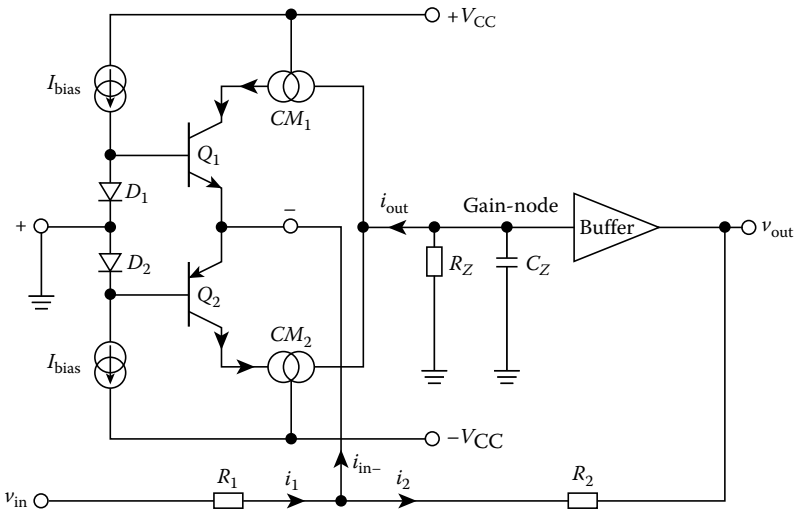

FIGURE 3.36 Inverting current-feedback op-amp amplifier.

which can be rearranged as

$$\frac{v_{\text{out}}}{v_{\text{in}}} = -\frac{R_2}{R_1}\left(\frac{1}{1+\frac{R_2}{Z}}\right) \tag{3.38}$$

Again, the high-Z term is required to provide good closed-loop gain accuracy.

More detailed analysis of the current-feedback op-amp. A simplified macromodel of the current-feedback architecture configured as a noninverting amplifier is shown in Figure 3.37. The input stage is represented by a semi-ideal voltage buffer to the inverting input. The output resistance of the input stage buffer R_{inv} is included since it has a significant effect on the bandwidth of the amplifier, as will be shown later. The current that flows out from the inverting terminal i_3 is transferred to the gain node, which is represented by R_Z and C_Z, via a current mirror that has a current gain K. The voltage at the gain node is transferred to the output in the usual way by a voltage buffer, with voltage gain A_{vb}. The net transfer function is given by

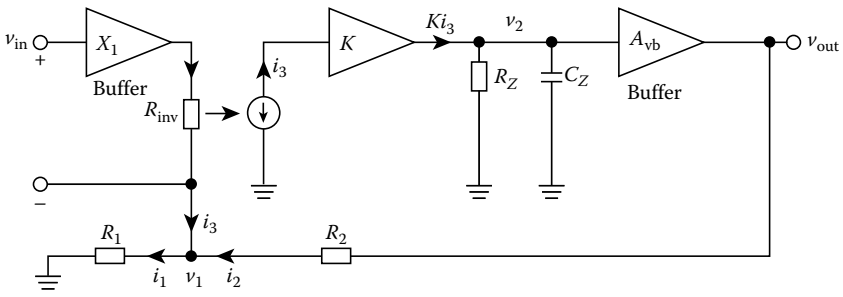

FIGURE 3.37 Inverting amplifier with current-feedback op-amp macromodel.

$$\frac{v_{out}}{v_{in}} = \frac{1 + \dfrac{R_2}{R_1}}{1 + j\omega C_Z \left[\dfrac{R_{inv}\left(1 + \dfrac{R_2}{R_1}\right) + R_2}{A_{vb}K} \right]} \tag{3.39}$$

Hence, the pole frequency is also given by

$$f_{-3dB} = \frac{A_{vb}K}{2\pi C_Z \left[R_{inv}\left(1 + \dfrac{R_2}{R_1}\right) + R_2 \right]} \tag{3.40}$$

(A full derivation of this transfer function is given in Appendix A.)

To compare this result to the classical voltage-mode op-amp architecture, a simplified schematic diagram of the voltage-feedback op-amp configured as a noninverting amplifier is shown in Figure 3.38.

Again from a full analysis, given in Appendix B, the transfer function obtained is

$$\frac{v_{out}}{v_{in}} = \frac{1 + \dfrac{R_2}{R_1}}{1 + j\omega \left[\dfrac{R_z C_Z}{1 + \dfrac{g_m A_{vb} R_Z}{\left(1 + \dfrac{R_2}{R_1}\right)}} \right]} \tag{3.41}$$

The pole frequency is given by

$$f_{-3dB} = \frac{1 + \dfrac{g_m A_{vb} R_Z}{\left(1 + \dfrac{R_2}{R_1}\right)}}{2\pi R_Z C_Z} \tag{3.42}$$

Pole frequency comparison. If one compares the closed-loop pole frequency Equations 3.40 and 3.42 for the current-feedback and voltage-feedback op-amp, respectively, it is clear that the bandwidth of the voltage-feedback op-amp is dependent on the closed-loop gain $(1 + R_2/R_1)$ resulting in the well-known constant gain-bandwidth product $f_{max} = (A_v)_{CL} f_T$. This means that an increase in the closed-loop gain results in a decrease in the bandwidth by the same factor as illustrated in Figure 3.39. In contrast, the pole

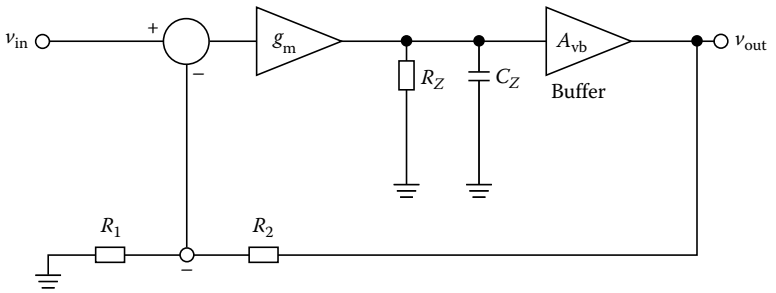

FIGURE 3.38 Noninverting amplifier with voltage-feedback op-amp macromodel.

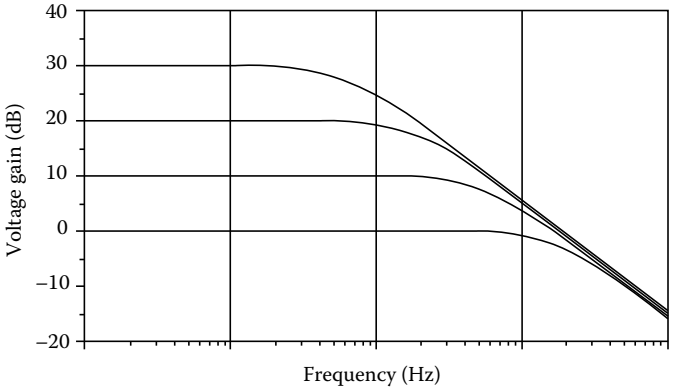

FIGURE 3.39 Frequency response of voltage-feedback op-amp amplifier for various closed-loop gains.

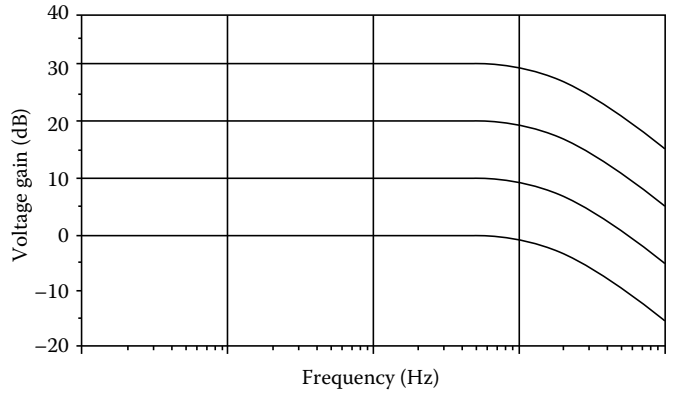

FIGURE 3.40 Frequency response of current-feedback op-amp amplifier for various closed-loop gains.

frequency of the current-feedback op-amp is directly dependent on R_2 and can be set almost independently of the closed-loop gain. Thus, the closed-loop bandwidth is almost independent of closed-loop gain as shown in Figure 3.40, assuming that R_{inv} is close to zero. Intuitively, this is the case since the feedback error current that is set by the feedback resistor R_2 is the current available to charge up the compensation capacitor. However, if one considers Equation 3.40 in some detail it can be seen that for high closed-loop gains and a nonzero R_{inv}, then the R_{inv} term starts to dictate and so the bandwidth will become more dependent on the closed-loop gain.

Slow rate of the current-feedback op-amp. As mentioned earlier, one other advantage of the current-feedback op-amp over the classical voltage-feedback op-amp is the high slew rate performance. For the classical long-tail, or emitter-coupled pair input stage shown in Figure 3.41, the maximum current available to charge up the compensation capacitor C_Z at the gain node is I_{bias}, and this occurs when Q_1 or Q_2 is driven fully on. The resulting transconductance plot shown in Figure 3.42 limits the slew rate of the amplifier.

In contrast, the slew rate of the current-feedback op-amp is virtually infinite, as can be seen from the input stage schematic shown in Figure 3.43. Referring to Figure 3.43, a change in the input voltage ΔV_{in} at $V(+)$ will be copied by the input buffer to $V(-)$. When connected as noninverting amplifier, the current through R_1 will change by $\Delta V_{in}/R_1$, while the current through R_2 will change by $\Delta V_{in}/R_2$, since

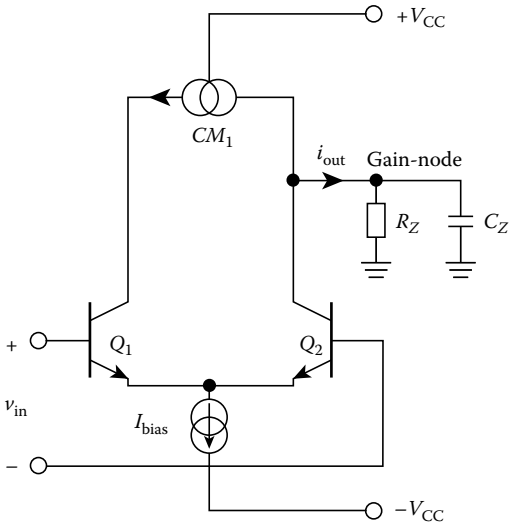

FIGURE 3.41 Long-tail pair input stage.

the output voltage at this point remains stationary. The total change in current through R_1 and R_2 must be supplied by the internal input buffer, and will be $\Delta I(-) = \Delta V_{in}((R_2 + R_1)/(R_2 \times R_1))$. This large input error current causes a rapid change in the output voltage, until V_{out} is again at the value required to balance the circuit once more, and reduce $I(-)$ to zero. The larger the input voltage slew rate, the larger the change in input error current, and thus the faster the output voltage slew rate. Current-feedback op-amps theoretically have no slew-rate limit. A typical current-feedback op-amp will exhibit a slew rate of between 500 and 2000 V/μS.

An analysis of this input stage (see Appendix C) shows that the transconductance follows a sinh(x) type function, as shown in Figure 3.44. In theory, this characteristic provides nearly unlimited slew-rate capability [9]. However, in practice a maximum slew rate will be limited by the maximum current drive into the gain node, which depends on the power dissipation of the circuit, the ability of power supply to deliver sufficient current, and the current-handling capability of the current mirrors.

Wideband and high-gain current-feedback op-amp. Previously, we have shown that the bandwidth of the current-feedback op-amp is almost independent of the closed-loop gain setting. Therefore, the closed-loop gain-bandwidth GB increases linearly with the closed-loop gain. However, the bandwidth of the practical current-feedback op-amp starts decreasing with high gain as a result of the finite inverting-input impedance [10], as shown by Equation 3.40. This is because for high gain, $R_{inv}(1 + R_2/R_1) > R_2$, and so the $R_{inv}(1 + R_2/R_1)$ term dominates the expression for closed-loop bandwidth, resulting in a direct conflict between gain and bandwidth.

At low gains when $R_2 > R_{inv}(1 + R_2/R_1)$, the closed-loop pole frequency is determined only by the compensation capacitor and the feedback resistor R_2. Thus, the absolute value of the feedback resistor R_2 is important, unlike the case of the voltage-feedback op-amp. Usually, the manufacturer species a minimum value of R_2 that will maximize bandwidth but still ensure stability. Note that because of the

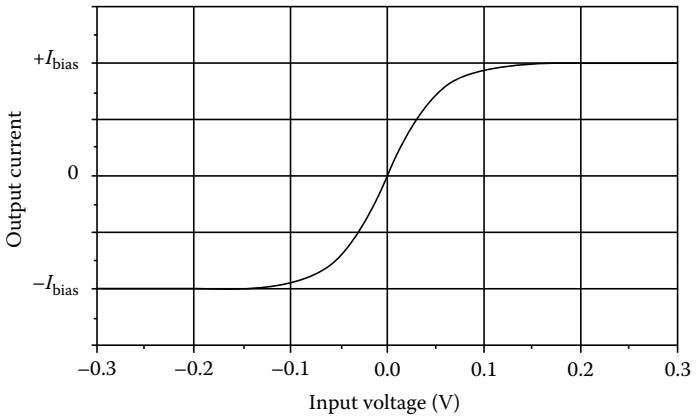

FIGURE 3.42 Long-tail pair input transconductance.

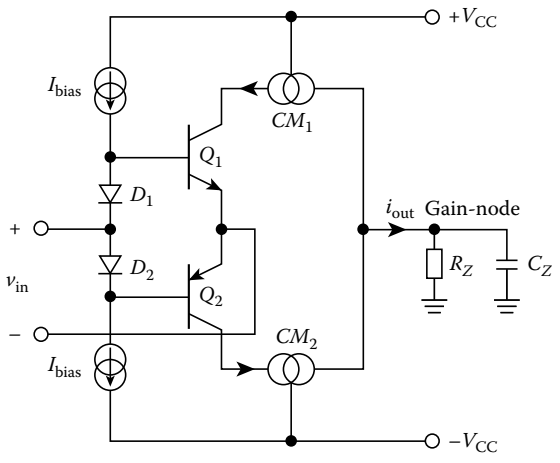

FIGURE 3.43 Current-feedback op-amp input stage.

inherent architecture a very high bandwidth can be achieved with the current-feedback design for a given value of R_2.

In practice, for gains higher than about 10, the $R_{inv}(1 + R_2/R_1)$ term in Equation 3.40 becomes dominant and the amplifier moves toward constant gain-bandwidth product behavior. The *GB* can be increased by reducing R_2 [11] but this will compromise stability and/or bandwidth, or alternatively, C_Z can be reduced. The latter option is limited since the minimum value of C_Z is determined by the device parameters and layout parasitics. Two possible ways of improving the high-gain constant bandwidth capability of the current-feedback op-amp can be seen by inspection of Equation 3.40. Either the K factor, which represents current gain in the current mirrors at the Z-node can be increased from unity to increase the bandwidth as it rolls off with high gain, or the inverting input impedance of the amplifier should be reduced toward zero. In the following section we consider the design of a suitable broadband variable-gain current-mirror circuit with a possible application being to improving the maximum bandwidth capability of current-feedback op-amps.

Basic current mirror. A typical current-feedback op-amp circuit is shown in Figure 3.45. It includes a complementary common-collector input stage (Q_1–Q_4) and a similar output buffer (Q_5–Q_8), with linking cascode current mirrors setting the Z-node impedance (Q_{12}–Q_{14}, Q_9–Q_{11}). The cascoded mirror provides unity current gain. Any attempt to increase the current gain via emitter degeneration usually results in much poorer current-mirror bandwidth. Consider now the development of a suitable broadband, variable gain current mirror.

A schematic diagram of a simple Widlar current mirror and its small-signal equivalent circuit are shown in Figures 3.46 and 3.47, respectively. For simplicity, we will assume that the impedance of the diode-connected transistor Q_1 is resistive and equal to R_D. The dc transfer function of the mirror is derived in Appendix D and is given by

$$\frac{I_{out}}{I_{in}} = \frac{\beta}{\beta + 2} \tag{3.43}$$

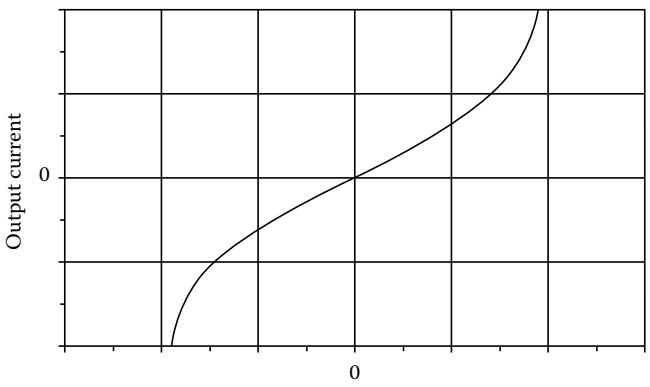

FIGURE 3.44 Input-stage transconductance of the current-feedback op-amp.

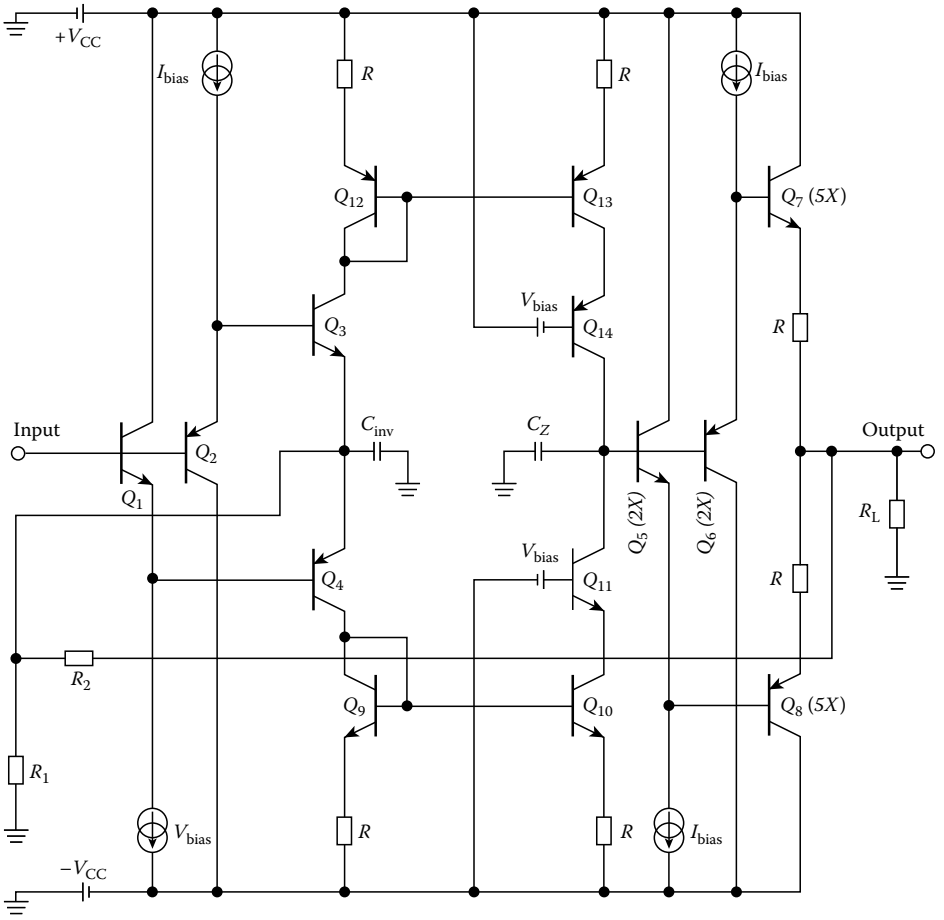

FIGURE 3.45 Transistor-level schematic of a typical current-feedback op-amp. $x =$ Unit transistor area.

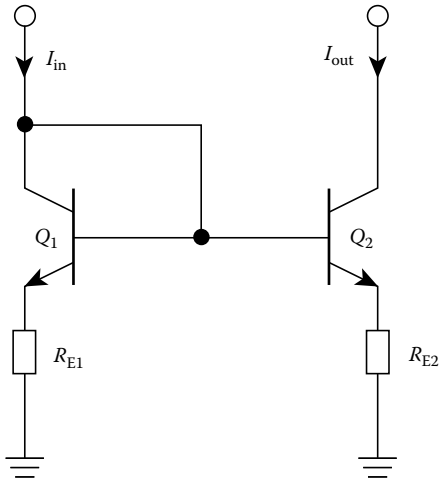

FIGURE 3.46 Simple Widlar current mirror with emitter degeneration.

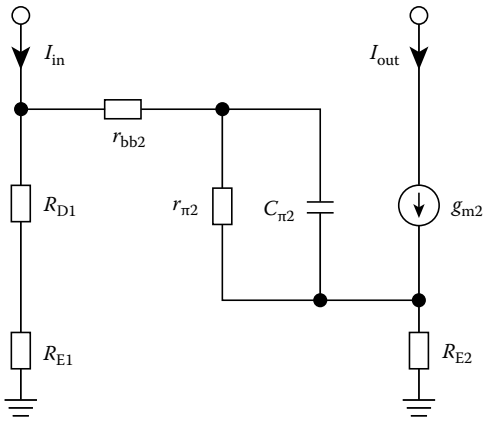

FIGURE 3.47 Small-signal equivalent circuit of Figure 3.46 current mirror.

and the −3 dB bandwidth is given by

$$f_{-3\text{ dB}} = \frac{1}{2\pi C_\pi \left\{ \dfrac{r_{\pi 2}(r_{\text{bb2}} + R_D)}{r_\pi + r_{\text{bb2}} + R_D} \right\}} \tag{3.44}$$

In order to increase the current gain it is usual to insert an emitter-degeneration resistor R_{E1} in the emitter of Q_1. The dc transfer function, derived in the Appendix E, is then

$$I_{\text{in}} R_{\text{E1}} = V_{\text{T}} \ln \frac{I_{\text{out}}}{I_{\text{in}}} \tag{3.45}$$

and the ac small-signal current gain is given by

$$\frac{i_{\text{out}}}{i_{\text{in}}} = (R_{\text{E1}} + R_{\text{D1}}) g_{\text{m2}} \tag{3.46}$$

where

$$R_{\text{D1}} = \frac{I_{\text{in}}}{\frac{KT}{q}} \tag{3.47}$$

The −3-dB bandwidth now becomes

$$f_{-3\text{dB}} = \frac{1}{2\pi C_{\pi 2} \left\{ \dfrac{r_{\pi 2}(r_{\text{bb2}} + R_{\text{D1}} + R_{\text{E1}})}{r_{\pi 2} + r_{\text{bb2}} + R_{\text{D1}} + R_{\text{E1}}} \right\}} \tag{3.48}$$

It can be seen that increasing R_{E1} to increase the gain results in a reduction in the mirror bandwidth. The method of increasing the area of Q_2 to increase the current gain is not advantageous because the capacitance $C_{\pi 2}$ increases simultaneously, and so again, the bandwidth performance is compromised. We can conclude that this approach, though apparently well founded, is flawed in practice.

Improved broadband current mirror. A current mirror with current gain is shown in Figure 3.48 and the small-signal equivalent circuit is shown in Figure 3.49. In this current mirror Q_1 and Q_2 are connected as diodes in series with R_{E1}. Q_3 is connected as a voltage buffer with the bias current source I_{EQ3}. Q_4 is the output transistor with degeneration resistor R_{E4} for current gain setting. The basic idea is to introduce the CC Q_3 to buffer the output from the input and hence isolate gain setting resistor R_{E4} from the bandwidth determining capacitance of the input. The dc transfer function is given by

$$I_{\text{in}} R_{\text{E1}} - I_{\text{out}} R_{\text{E4}} + V_{\text{T}} \ln \frac{I_{\text{in}}^2}{I_{\text{CQ3}} I_{\text{out}}} = 0 \tag{3.49}$$

and the ac small-signal current gain is given by

$$\frac{i_{\text{out}}}{i_{\text{in}}} = \frac{(R_{\text{E1}} + R_{\text{D1}} + R_{\text{D2}}) g_{\text{m4}}}{1 + g_{\text{m4}} R_{\text{E4}}} \tag{3.50}$$

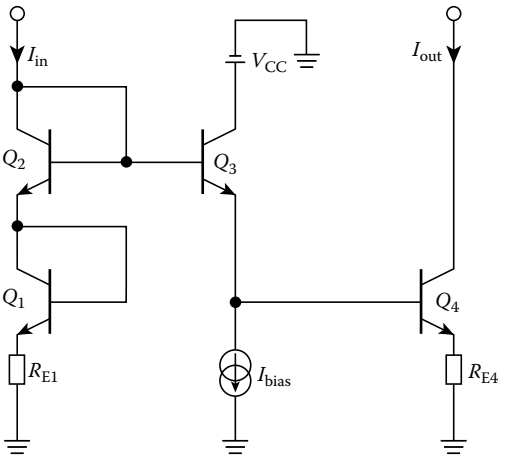

FIGURE 3.48 Improved current mirror with current gain.

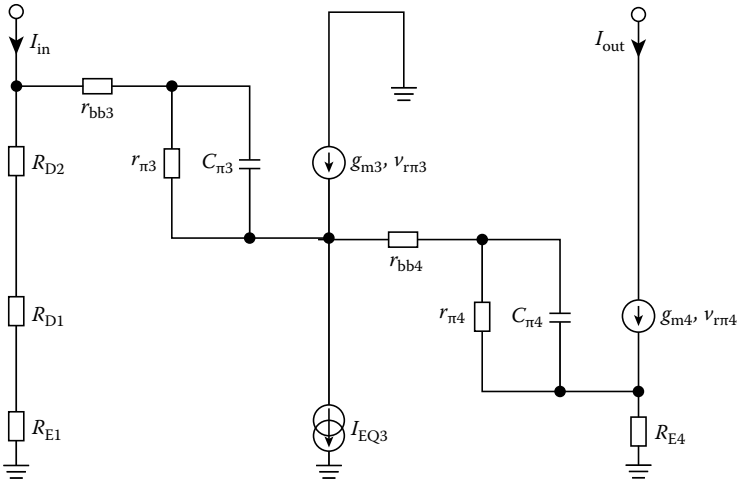

FIGURE 3.49 Equivalent circuit of improved current mirror with current gain.

and the −3 dB bandwidth now becomes

$$f_{-3\text{ dB}} = \frac{1}{2\pi C_{\pi 4}\left(\dfrac{r_{\pi 4}R_x}{r_{\pi 4}+R_x}\right)} \tag{3.51}$$

where

$$R_x = r_{bb4} + \frac{r_{\pi 3} + r_{bb3} + R_{D1} + R_{D2} + R_{E1}}{\beta_3} \tag{3.52}$$

It can be seen clearly that the dominant pole Equation 3.51 of the current mirror with current gain is now only slightly decreased when we increase the current gain by increasing R_{E1}. However, the nondominant pole at the input node is increased, and this will marginally effect the resultant overall stability performance if employed in a current-feedback op-amp. This current mirror with current gain has been employed successfully in current-feedback op-amp design for increased gain-bandwidth capability [12].

Phase linearity. The internal signal path in a current-feedback op-amp is very linear due largely to the symmetrical architecture. Consequently, these devices have a very linear phase response. Furthermore, all the frequency components of a signal are delayed by the same amount when passing through the amplifier, and so the waveform is reproduced accurately at the output. Current-feedback op-amps typically exhibit differential phase error of around ±1° at frequencies of approximately half the bandwidth.

Choosing the value of R_2. From Equation 3.40, we can see that for a fixed value of C_z, a smaller feedback resistor R_2 will give a higher closed-loop bandwidth. It might be expected that the maximum bandwidth would be obtained with the minimum feedback resistance; that is, with $R_2 = 0$. In practice, current-feedback op-amps are generally unstable when their feedback resistance is reduced below a particular value. The reason for this is that the dominant closed-loop pole at frequency of $f \approx 1/2\pi C_z R_2$ must be significantly lower than any nondominant parasitic pole frequency within the op-amp, so that a reasonable gain and phase margin is maintained. If the value of R_2 is reduced, then this dominant pole will move upward in frequency toward the parasitic poles, reducing the gain and phase margin, and eventually leading to instability. Obviously, the "correct" value for R_2 will depend on the internal value of C_z and the location of any parasitic poles within the device. These are the sort of parameters

that are known to the manufacturer, but are generally not listed in a data sheet. Therefore, the manufacturer of a particular device will generally recommend a value of R_2 that guarantees stability, while maintaining a reasonably wide bandwidth. Reducing R_2 below this recommended or optimum value will tend to lead to peaking and instability, while increasing R_2 above the optimum value will reduce the closed-loop bandwidth. If band limiting is required, then a larger value of R_2 than the optimum can be chosen to limit the bandwidth as required.

Since a current-feedback op-amp requires a minimum value of R_2 to guarantee stability, these devices cannot be used with purely capacitive feedback because the reactance of a capacitor reduces at high frequencies. This means that the conventional voltage op-amp integrator cannot be implemented using a current-feedback op-amp.

Practical considerations for broadband designs.

1. *Ground planes.* The purpose of a ground plane is to provide a low-impedance path for currents flowing to ground, since any series impedance in the ground connections will mean that not all ground nodes are at the same potential. In addition, the inductance of a printed circuit track is approximately inversely proportional to the track width, and so the use of thin tracks can result in inductive ground loops, leading to ringing or even oscillations. The use of an unbroken ground plane on one side of the circuit board can minimize the likelihood of inductive loops within the circuit. However, any particularly sensitive ground-connected nodes in the circuit should be grounded as physically close together as is possible.
2. *Bypass capacitors.* Power supply lines often have significant parasitic inductance and resistance. Large transient load currents can therefore result in voltage spikes on the power supply lines, which can couple onto the signal path within the device. Bypass capacitors are therefore used to lower the impedance of the power supply lines at the point of load, and thus short out the effect of the supply line parasitics. The type of bypass capacitor to use is determined by the application and frequency range of interest. High-speed op-amps work best when their power supply pins are decoupled with RF-quality capacitors.

   Manufacturers often recommend using a composite large-small parallel bypass capacitor with something like a 4.7 uF tantalum capacitor on all supply pins, with a parallel 100 nF ceramic to ensure good capacitive integrity at higher frequencies, where the tantalum becomes inductive. However, a note of caution here: This large-small double capacitor technique relies on the large capacitor having sufficiently high ESR so that at resonance the two capacitors do not create a high-Q parallel filter. In surface-mount designs, a single bypass capacitor may well be better than two due to the inherent high-Q of surface-mount capacitors.

   All bypass capacitor connections should be minimized, since track lengths will simply add more series inductance and resistance to the bypass path. The capacitor should be positioned right next to the power supply pin, with the other lead connected directly to the ground plane.
3. *Sensitive nodes.* Certain nodes within a high-frequency circuit are often sensitive to parasitic components. A current-feedback op-amp, for example, is particularly sensitive to parasitic capacitance at the inverting input, since any capacitance at this point combines with the effective resistance at that node to form a second nondominant pole in the feedback loop. The net result of this additional pole is a reduced phase margin, leading to peaking and even instability. Clearly, great care must be taken during layout to reduce track lengths, etc., at this node. In addition, the stray capacitance to ground at $V(-)$ can be reduced by putting a void area in the ground plane at this point. If the op-amp is used as an inverting amplifier, then the potential of the inverting input is held at virtual ground, and any parasitic capacitance will have less effect. Consequently, the current-feedback op-amp is more stable when used in the inverting rather than the noninverting configuration.
4. *Unwanted oscillations.* Following the preceding guidelines should ensure that your circuit is well behaved. If oscillations still occur, a likely source is unintentional positive feedback due to poor

layout. Output signal paths and other tracks should be kept well away from the amplifier inputs to minimize signal coupling back into the amplifier. Input track lengths should also be kept as short as possible for this same reason.

3.1.9 Broadband Amplifier Stability

Operational amplifiers are generally designed with additional on-chip frequency compensation capacitance in place. This is done to present the applications engineer with an op-amp that is simple to use in negative feedback, with minimal chance of unstable operation. In theory, all will be well, but for three main reasons, op-amps become unstable in the real world of analog electronic circuit design. This section outlines the three main causes for unstable operation of broadband amplifiers and shows practical ways of avoiding these pitfalls.

3.1.9.1 Op-Amp Internal Compensation Strategy

Before dealing with specific stability problems in broadband amplifiers and how to solve them, we will look briefly at the internal frequency compensation strategy used in op-amp design. Generally, op-amps can be classified into two groups, those with two high-voltage gain stages and those with only one stage. The two-stage design provides high open-loop gain but relatively low bandwidth, while the higher speed signal-stage amplifier provides lower open-loop gain but much higher usable bandwidth. Insight into the internal op-amp architecture and the type of compensation used will give the designer valuable information on how to tame the unstable op-amp.

3.1.9.2 Review of the Classical Feedback System

Analyzing the classical feedback system in Figure 3.50 gives the well-known expression for the closed-loop gain, A_c:

$$A_c = A/[1 + B \cdot A] \tag{3.53}$$

where A is the open-loop gain of the amplifier and B the feedback fraction. $T = B \times A$ is referred to as the loop-gain, and the behavior of T over frequency is a key parameter in feedback system design. Clearly, if $T \gg 1$ or $A \gg A_c$, then the closed-loop gain is virtually independent of the open-loop gain A, thus

$$A_c \approx B^{-1} \tag{3.54}$$

This is the most important and desirable feature of negative feedback systems. However, the system will not necessarily be stable as, at higher frequencies, phase lag in the open-loop gain A may cause the feedback to become positive.

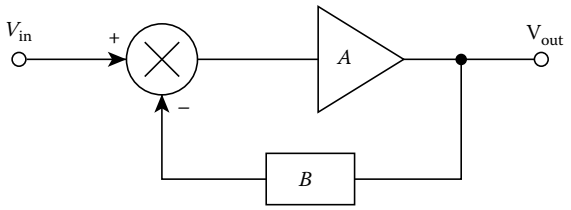

FIGURE 3.50 Classical feedback system.

3.1.9.3 Stability Criteria

Though negative feedback is desirable, it results in potential instability when the feedback becomes positive. The loop-gain T is the best parameter to test whether an amplifier is potentially unstable. The phase margin Φ_M is a common feature of merit used to indicate how far the amplifier is from becoming an oscillator:

$$\Phi_M = 180^\circ + \Phi(|BA| = 1) \tag{3.55}$$

When $\Phi_M = 0°$, the phase of the loop gain, $T = B \times A$ is exactly $-180°$ for $|B \times A| = 1$. The closed-loop gain A_c will become infinite and we have got an oscillator! Clearly, what is required is that $\Phi_M > 0$ and generally the target is to make $\Phi_M \geq 45°$ for reasonably stable performance. However, excessive Φ_M is undesirable if settling time is an important parameter in a particular application.

An op-amp is a general purpose part and so the IC designer strives to produce a maximally versatile amplifier by ensuring that even with 100% feedback, the amplifier circuit will not become unstable. This is done by maintaining a $\Phi_M > 0$ for 100% feedback, that is, when $B = 1$. If the feedback network B is taken to be purely resistive, then any additional phase lag in the loop gain must come from the open-loop amplifier A. Tailoring the phase response of A so that the phase lag is less than 180° up to the point at which $|A| < 1$ or 0 dB ensures that the amplifier is "unconditionally stable"; that is, with any amount of resistive feedback, stable operation is "guaranteed."

Most open-loop op-amps, whether single-stage or two-stage, will exhibit a two-pole response. The separation of these two poles whether at low frequency or high frequency will have a major effect on the stability of the system and it is the op-amp designer's objective to locate these open-loop poles to best advantage to achieve maximum bandwidth, consistent with versatile and stable performance.

3.1.9.4 Two-Stage Op-Amp Architecture

A schematic of the standard two-stage op-amp topology is shown in Figure 3.51. The input differential pair T_1/T_2 provides high gain, as does the second gain stage of T_3/T_4 Darlington pair CE. A high-voltage gain is achieved with this structure, so that output stage is usually a unity voltage gain common-collector output buffer to provide a useful load current drive capability.

The amplifier structure in Figure 3.51 has two internal high-impedance nodes, node X and node Y. These high-impedance nodes are responsible for introducing two dominant poles into the frequency response and their relative location is critical in determining the stability of the amplifier. Each pole contributes a low-pass filter function to the open-loop gain expression of the form

$$[1 + jf/f_P]^{-1} \tag{3.56}$$

Each pole introduces 45° of phase lag at the pole frequency f_P and an additional 45° at $f \approx 10 \times f_P$. With a two-pole amplifier, the open-loop gain A is given by

$$A = A_0/[1 + jf/f_{P1}][1 + jf/f_{P2}] \tag{3.57}$$

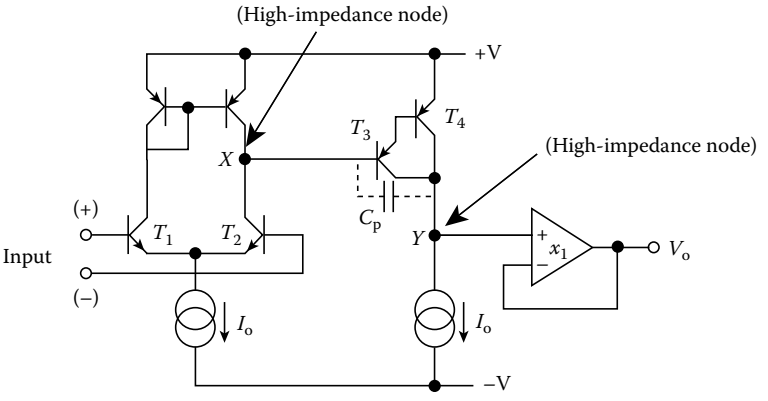

FIGURE 3.51 Architecture of the standard two-stage op-amp.

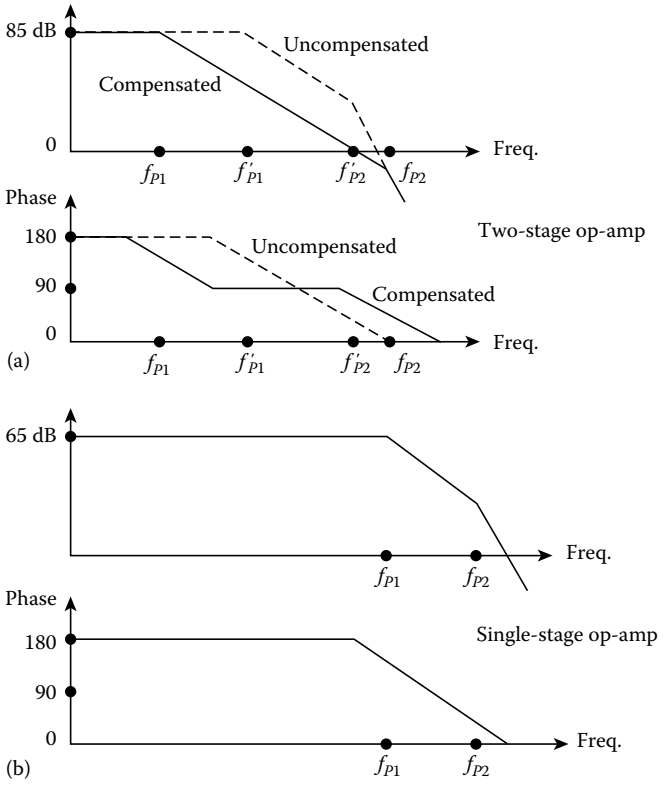

FIGURE 3.52 Pole frequency and phase response for (a) two-stage op-amp and (b) single-stage op-amp.

where A_0 is the dc open-loop gain and f_{P1} and f_{P2} are the two-pole frequencies. A typical plot of A versus f is shown in Figure 3.52a. At low frequencies, where $f \ll f_{P1}$ the gain is flat, and at f_{P1} the gain begins to fall at a rate increasing to −20 dB/decade. The roll-off steepens again at f_{P2} to a final gradient of −40 dB/decade.

It is generally the case that $f_{P1} \ll f_{P2}$ as shown in Figure 3.52a. Turning our attention to the phase plot in Figure 3.52a, at $f = f_{P1}$ the output lags the input by 45°, and as the frequency rises toward f_{P2} the phase lag increases through 135° at f_{P2} to 180° at $f \approx 10 \times f_{P2}$. To ensure unconditionally stable performance, the second pole must be sufficiently far from the first so that the phase margin is large enough.

Figure 3.53 shows curves of the dc value of open-loop gain A_0 versus the ratio N of the pole frequencies ($N = f_{P2}/f_{P1}$) for different values of phase margin. For a given value of $A_0 = 1000$ or +60 dB, the ratio of the pole frequencies must be $N \approx 700$ to obtain a phase margin of 45°.

3.1.9.5 Miller Compensation and Pole Separation

Without any added compensation capacitance, the two open-loop poles of the op-amp are invariably too close to make the amplifier unconditionally stable. The most common compensation method is to add a capacitor between the base and collector of the Darlington pair, shown as C_p in Figure 3.51. This is known as Miller compensation because this strategy makes use of the Miller capacitance multiplication effect discussed earlier. The net result is that the two poles now become significantly far apart, with f_{P1} reducing and f_{P2} increasing, and so the phase margin can be increased to make the op-amp unconditionally stable. However, the penalty of this method is poorer bandwidth and also lower slew rate because of the large capacitance needed, which in practice may be 20 pF or more.

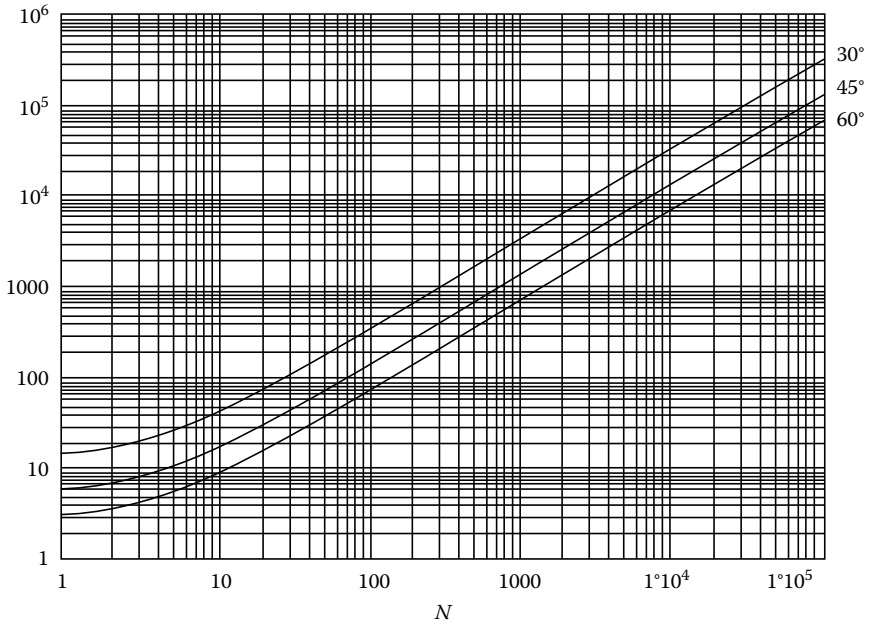

FIGURE 3.53 Low-frequency gain A_0 versus $N\ (=f_{P2}/f_{P1})$ for a two-pole amplifier.

3.1.9.6 Single-Stage Op-Amp Compensation

Figure 3.54 shows a typical simplified circuit schematic of a single-stage op-amp. The input is a differential emitter-coupled pair followed by a folded cascode transistor and an output complementary common-collector buffer. The key difference between this architecture and the two-stage design shown earlier is that X is a low-impedance node, and so the only high-impedance node in the circuit is node Y. Interestingly, the higher frequency nondominant pole of the two-stage amplifier has now become the dominant frequency pole of the single-stage design, as indicated by the second set of curves in Figure 3.52b, which leads to several advantages:

1. The frequency performance off the amplifier is extended. This frequency extension does not lead to a deterioration in phase margin, but simply means that the phase margin problem is shifted up in the frequency domain.

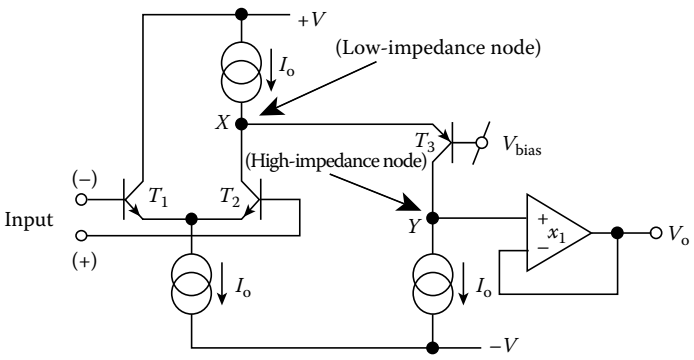

FIGURE 3.54 Architecture of single-stage op-amp.

2. Capacitance at the high-impedance Y node reduces bandwidth, but now improves phase margin.
3. A single value of a few pFs of grounded capacitor at Y will now act as a satisfactory compensation capacitor, unlike the large Miller capacitor required in the two-stage design.
4. The slewing capability of this single-stage structure is very good as a result of the much smaller compensation capacitor.
5. Clearly, it is much more straightforward to develop a stable amplifier for high-frequency applications if it has essentially only one voltage gain stage and so high-frequency op-amp designers generally opt for a single gain stage architecture.

3.1.9.7 Grounded Capacitor Compensation

Typical A_{OL} versus f responses of two single-stage op-amps are shown in Figure 3.55, indicating one high-frequency pole and its proximity to the nondominant pole.

The curves are taken from data for (a) a 2 GHz gain-bandwidth product voltage-feedback op-amp and (b) a 150 MHz current-feedback op-amp. In both cases, the phase characteristics demonstrate the expected 45° lag at the pole frequency, and the slow roll-off in phase at high frequency due to the presence of the very-high-frequency poles.

Both single-stage and two-stage op-amps can be approximated by the two-pole macromodel shown in Figure 3.56. Transconductance G_M and output resistance R_0 represent the gain per stage of $G_M \times R_0$. The difference between the two-stage and single-stage op-amp models is that R_{01} of the single-stage is of the order of $[G_M]^{-1}$ and the dominant compensation capacitor is C_2. C_P in the case of the single stage will

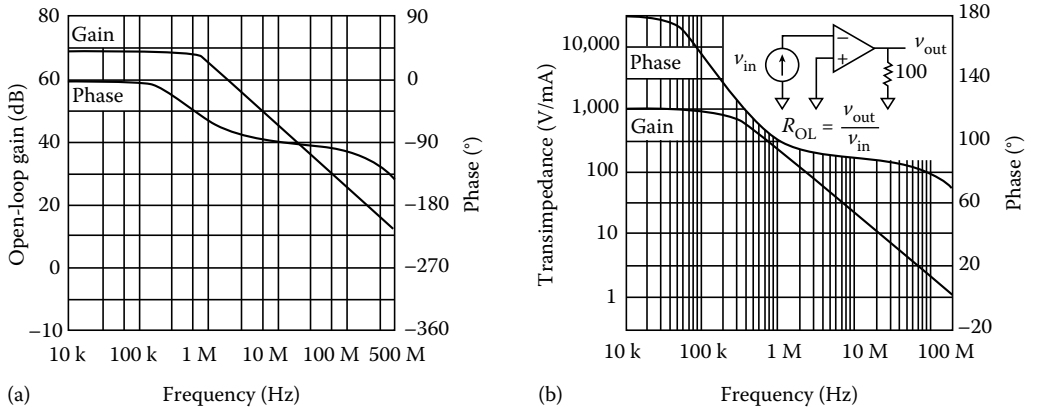

FIGURE 3.55 Single-pole op-amps; open-loop gain and phase frequency characteristics. (a) Voltage feedback. (b) Current feedback.

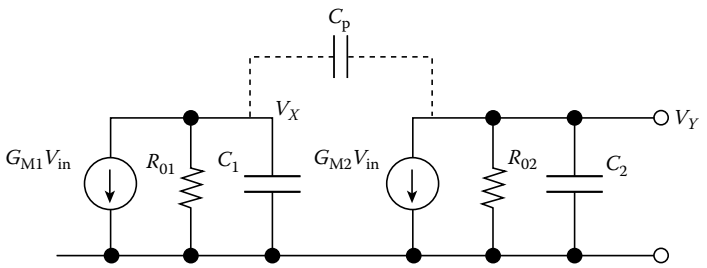

FIGURE 3.56 Partial equivalent circuit of two-pole op-amp.

simply be a feedback parasitic capacitor, while in the case of a two-stage it will be the dominant Miller compensating capacitor. This simple model is an excellent first-cut tool for determining pole locations, and the value of compensation capacitor for a desired bandwidth and stability.

3.1.9.8 High-Frequency Performance

Although the bandwidth in a single-stage design is significantly extended, circuit parasitics become more important. We are confronted with the problem of potential instability, since at higher frequencies the "working environment" of the op-amp becomes very parasitic sensitive; in other words, now op-amp-embedded parasitics cannot be neglected.

An op-amp in closed-loop can be considered at three levels, as shown schematically in Figure 3.57. The inner triangle is the ideal op-amp, internally compensated by the op-amp designer for stable operation using the circuit techniques outlined earlier. High-frequency amplifiers are sensitive to parasitics of the surrounding circuit. The key parasitics within the outer triangle include power supply lead inductance, stray capacitance between power supply pins, and input to ground capacitance. The effect of these parasitics is to destabilize the amplifier, and so the designer is confronted with the task of reestablishing stable operation. The approach needed to achieve this parallels the work of the op-amp designer. The parasitics almost always introduce additional extrinsic nondominant poles, which need to be compensated. The task of compensation cannot be attempte without considering the outer or third level, which includes the closed-loop gain defining components together with the load impedance. Again, stray reactance associated with these components will modify the loop gain, and so to guarantee stable operation of the closed-loop amplifier it is necessary to compensate the complete circuit.

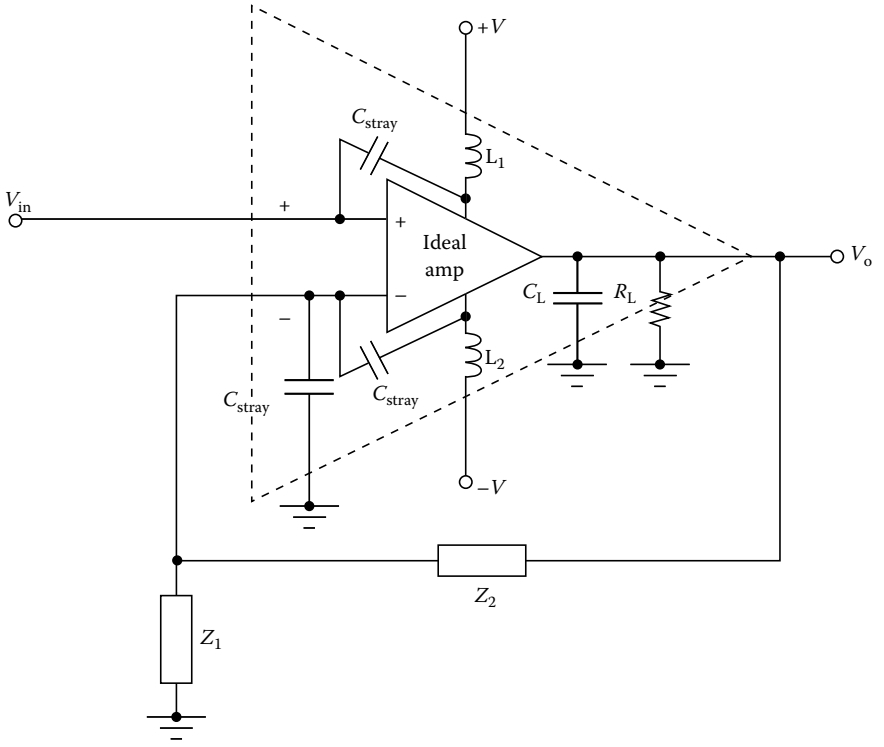

FIGURE 3.57 Real feedback amplifier.

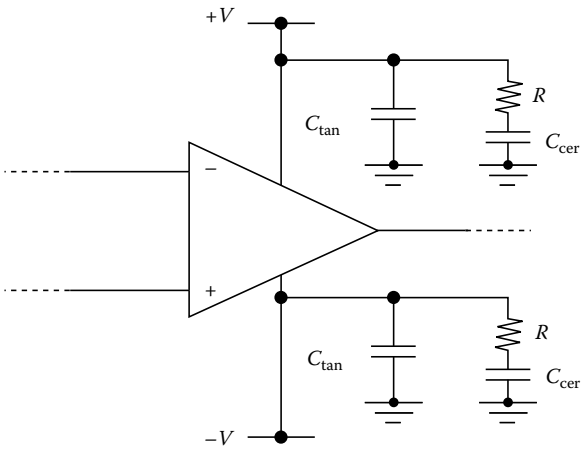

FIGURE 3.58 Supply decoupling circuitry (C_{CER} = ceramic capacitor and C_{TAN} = tantalum).

3.1.9.9 Power Supply Impedance

In this section, we consider the ways in which the impedance of the power supply can affect the frequency response of the amplifier. First, some important rules are

1. There is no such thing as an ideal zero-impedance power supply.
2. Real power supplies have series *R–L* impedance and at high frequencies the inductance matters most.
3. Power supply inductance causes "bounce" on the power supply voltage, generating unwanted feedback via parasitic capacitive links to the inputs. Power supply "bounce" increases with increasing load current.
4. Supply decoupling capacitors act as "short-term local batteries" to maintain power supply integrity, and it is important that they are placed as close as possible to the power supply pins of the op-amp.

Large electrolytic capacitors are fine at low frequencies but are inductive at high frequencies. Figure 3.58 shows commonly used decoupling circuitry. Small-sized tantalum electrolytics are preferred, while a parallel ceramic capacitor with low series inductance takes over the decoupling role at high frequencies. The added series *R* prevents the inductance of the electrolytic resonating with the ceramic capacitor. The waveforms in Figure 3.59 illustrate the benefits of good decoupling.

3.1.9.10 Effects of Resistive and Capacitive Loads

The load presented to an amplifier is likely to have both resistive and capacitive components, as illustrated previously in Figure 3.57. Increasing the load current causes power supply ripple, so good power supply decoupling is vital.

A closed-loop amplifier with voltage-sampled negative feedback results in a very-low output impedance, so it is natural to think that the effects of any load would be shunted out by this low impedance. In reality, the load has an important effect on the amplifier and must not be overlooked. Resistive loads, for example, cause two main effects. First, as a voltage divider with the open-loop output resistance of the op-amp r_0, the open-loop gain is reduced. This effect is small unless the load resistance approaches r_0. Second, the load current is routed to the output pin via the supply pins, and as the load current increases,

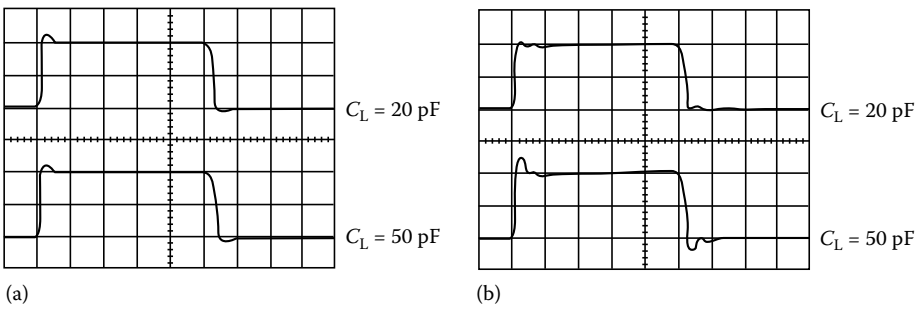

FIGURE 3.59 High-speed voltage buffer: (a) with and (b) without supply decoupling.

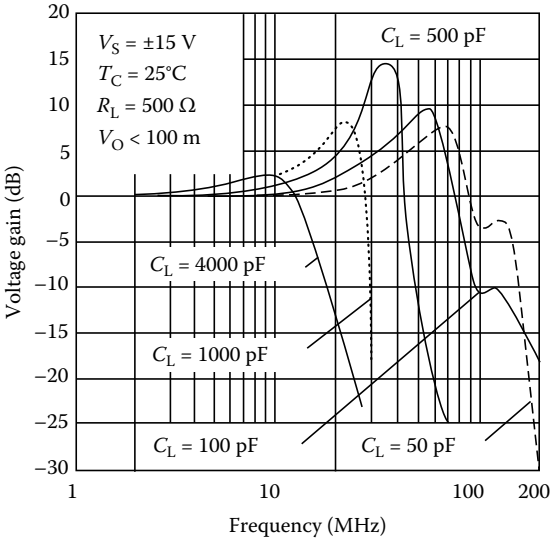

FIGURE 3.60 Load capacitance causes gain peaking.

the supply pin voltage is modulated. This effect is more important, since the integrity of the power supply will be degraded. Again, good supply decoupling is essential to minimize this effect.

Capacitive load current is proportional to the derivative of output voltage, and the maximum capacitive output current demand occurs when dV_{out}/dt is a maximum. Though not directly a stability issue, the designer must remember that a capacitive load demands high-output current at high frequencies and at high amplitude, that is,

$$I_{max} = C_L \cdot 2\pi f_{max} \cdot V_{outpeak} \tag{3.58}$$

Figure 3.60 illustrates the effect of load capacitance on the loop gain.

C_1 together with the equivalent output resistance of the op-amp adds an additional pole into the loop gain of the form

$$V_F/V_{out} = B = 1/[1 + jf/f_L] \quad \text{where } f_L = 1/2\pi r_0 \cdot C_L \tag{3.59}$$

The load resistance has a minor influence on the loop gain compared to the effects of load capacitance by slightly reducing the value of dc open-loop gain by factor K, where $K = R_L/[r_0 + R_L]$, as described above. Since the effective output resistance reduces to $r_{0'} = r_0/R_L$, then f_L changes to $f_{L'} = 1/2\pi r_{0'} C_L$.

3.1.9.11 Neutralizing the Phase Lag

To compensate for high-frequency phase lag, the simplest technique is to add a series resistance R between the output of the op-amp and the load connection point, as shown in Figure 3.61.

The series resistor adds a zero into the V_F/V_{out} equation, which changes to

$$V_F/V_{out} = K \cdot [1 + jf/f_Z]/[1 + jf/f_P] \tag{3.60}$$

where $K = [R + R_L]/[r_0 + R + R_L]$, $f_P = 1/[2\pi(r_0 + R)/R_L \cdot C_L]$ and $f_Z = 1/[2\pi R_{L//R} \cdot C_L] = f_P \cdot [1 + r_0/R]$, so clearly; $f_P < f_Z$.

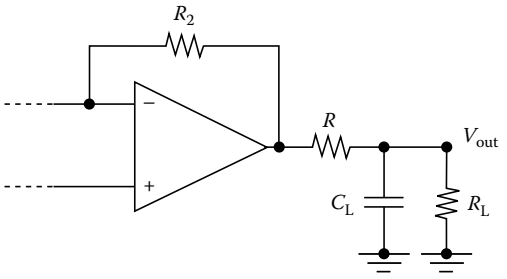

FIGURE 3.61 Load capacitance neutralization.

The phase lag introduced by the pole is compensated by the phase lead of the zero at higher frequencies. The maximum phase lag is limited if the zero is close to the pole, almost eliminating the effects of the load capacitor. Maximum phase lag in V_F/V_{out} occurs at $f = f_M$, where f_M is given by

$$f_M = [f_P \cdot f_Z]^{1/2} = f_P \times (1 + r_0/R)^{1/2} \tag{3.61}$$

and at f_M the phase lag $\Phi = \Phi'$ is given by

$$\begin{aligned} \Phi' &= 90^\circ - 2 \cdot \tan^{-1}[f_M/f_P] = 90^\circ - 2 \cdot \tan^{-1}\left[(1 + r_0/R)^{1/2}\right] \\ \Phi' &\approx -19.5^\circ \quad \text{for} \quad R = r_0 \\ \Phi' &\approx -8.2^\circ \quad \text{for} \quad R = 2 \cdot r_0 \\ \Phi' &\approx -6.4^\circ \quad \text{for} \quad R = 3 \cdot r_0 \end{aligned} \tag{3.62}$$

These values show that the added lag Φ' is not excessive as long as $R > r_0$. The disadvantage with this method is that the series resistor is in direct line with the output current, increasing the output resistance of the amplifier and limiting the output current drive capability. The output impedance also goes inductive at high frequencies.

An alternative way of solving the problem of capacitive load is to view the closed-loop output resistance of the op-amp as being inductive, since the closed-loop output impedance of the op-amp is essentially the open-loop output resistance divided by the loop gain. As the loop gain falls with frequency, the output impedance rises, and thus appears inductive. Adding a load capacitor generates a resonant circuit. The solution is to "spoil" the Q of the resonator, therefore minimizing the added phase lag of C_L.

Adding a so-called series R–C "snubber," as in Figure 3.62, effects a cure. The resistor R is ac coupled by the capacitor at high frequencies and spoils the Q. Effectively, C_L resonates with the inductive output impedance, and at this frequency leaves the R–C snubber as a "new" load. The equivalent circuit is therefore close to the previous compensation method shown in Figure 3.61, but with the added advantage that now the load current is not carried by the series resistance. To select the snubber component values, make $R = 1/2\pi f_0 C$, where f_0 is the resonant frequency, which can simply be determined experimentally from the amplifier without the snubber in place. The value of the series capacitance is a compromise: too big and it will increase the effective load capacitance. Choosing $C = C_L$ works reasonably well in practice.

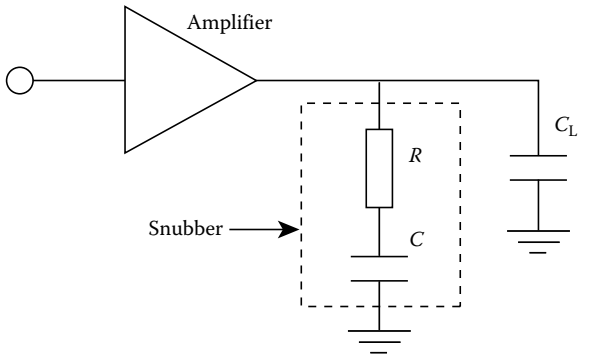

FIGURE 3.62 Snubber cures capacitive load peaking.

3.1.9.12 Inverting Input Capacitance to Ground

With most broadband bipolar op-amps, parasitic capacitance to ground adds an additional pole (and hence phase lag) into the feedback path, which threatens stability. Stray capacitance C_1 at the inverting input pin (shown previously in Figure 3.57) modifies B and adds phase lag in the loop-gain T, compromising stability.

Solving for B with C_1 taken into account will clarify the problem. It is simple to show that

$$B = V_F/V_{out} = Z_1/[Z_1 + Z_2] \tag{3.63}$$

where $Z_1 = R_1/[1 + j\omega R_1 C_1]$ and $Z_2 = R_2$. Substituting, we get

$$B = K/[1 + jf/f_C] \tag{3.64}$$

where $K = R_1\ [R_1 + R_2]$ and $f_C = 1/[2\pi C_1 R_1/R_2]$.

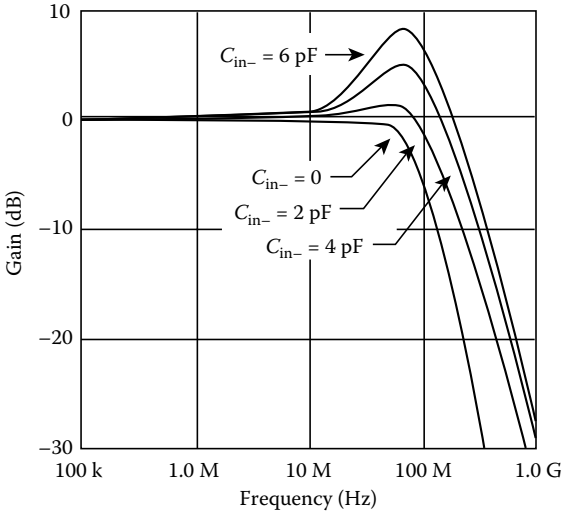
The additional pole at $f = f_C$ will now give the circuit a very undesirable three-pole loop gain, which could cause significant gain peaking, as shown in Figure 3.63. f_C could be made high by choosing relatively low values of $R_1 // R_2$ but the additional pole can be eliminated by adding a feedback capacitor C_2 across resistor R_2 to give pole-zero cancellation.

$$Z_1 = R_1/[1 + j\omega R_1 C_1] \quad \text{and} \quad Z_2 = R_2/[1 + j\omega R_2 C_2] \tag{3.65}$$

If $R_1C_1 = R_2C_2$, then $B = Z_1/[Z_1 + Z_2] = R_1/[R_1 + R_2]$, making B frequency independent. The design equation for C_2 is then

$$C_2 = C_1 \cdot R_1/R_2 \tag{3.66}$$

If the open-loop phase margin Φ_M needs to be increased for the desired value of closed-loop gain, and the inverting capacitance C_1 has its inevitable high-frequency influence, then the optimum solution for C_2 would be to locate the zero on the second pole of the loop-gain response following the procedure given above.



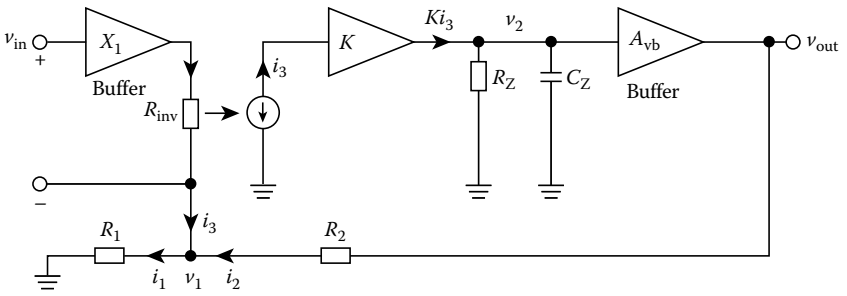


FIGURE 3.63 Stray input capacitance causes gain peaking.

3.1.10 Conclusions

This chapter hopefully serves to illustrate some of the modern techniques the practicing engineer will encounter when designing broadband bipolar amplifiers. It focuses mainly upon key generic building blocks and methodologies for broadband design. Many circuits and design techniques have not been covered, but analysis techniques described should serve as a foundation for the analysis of other broadband designs. Furthermore, comprehensive analytical treatment of many alternative broadband bipolar circuits can be found in the texts [6,13–15].

Appendix A: Transfer Function and Bandwidth Characteristic of Current-Feedback Operational Amplifier

$$-i_1 + i_2 + i_3 = 0 \tag{3.67}$$

$$i_1 = \frac{v_1}{R_1} \tag{3.68}$$

$$i_2 = \frac{v_{out} - v_1}{R_2} \tag{3.69}$$

$$i_3 = \frac{v_{in} - v_1}{R_{inv}} \tag{3.70}$$

$$v_2 = \frac{Ki_3R_Z}{1 + j\omega R_Z C_Z} \tag{3.71}$$

$$v_{out} = A_{vb}v_2 \tag{3.72}$$

Substituting Equations 3.68 through 3.70 into Equation 3.67 yields

$$-\frac{v_1}{R_1} + \frac{v_{out} - v_1}{R_2} + \frac{v_{in} - v_1}{R_{inv}} = 0$$

Rearranging for v_1 gives

$$v_1 = \frac{v_{in}R_2/R_{inv} + v_{out}}{1 + (R_2/R_1) + (R_2/R_{inv})}$$

From Equations 3.71 and 3.72, it is clearly seen that

$$v_{\text{out}} = \frac{A_{\text{vb}} K i_3 R_Z}{1 + j\omega R_Z C_Z} \tag{3.73}$$

Substituting for i_1 and i_2 from Equations 3.68 and 3.69 into Equation 3.67 gives

$$i_3 = v_1\left(\frac{1}{R_1} + \frac{1}{R_2}\right) - \frac{v_{\text{out}}}{R_2}$$

Substitute for v_1:

$$i_3 = \left[\frac{v_{\text{in}} R_2/R_{\text{inv}} + v_{\text{out}}}{1 + (R_2/R_1) + (R_2/R_{\text{inv}})}\right]\left(\frac{1}{R_1} + \frac{1}{R_2}\right) - \frac{v_{\text{out}}}{R_2}$$

Substitute for i_3 from Equation 3.73:

$$\frac{v_{\text{out}}(1 + j\omega R_Z C_Z)}{A_{\text{vb}} K R_Z} = \left\{\left[\frac{v_{\text{in}} R_2/R_{\text{inv}} + v_{\text{out}}}{1 + (R_2/R_1) + (R_2/R_{\text{inv}})}\right]\left(\frac{1}{R_1} + \frac{1}{R_2}\right) - \frac{v_{\text{out}}}{R_2}\right\}$$

rearranging

$$v_{\text{out}}\left[\frac{(1 + j\omega R_Z C_Z)}{A_{\text{vb}} K R_Z} - \frac{(1/R_1 + 1/R_2)}{1 + (R_2/R_1) + (R_2/R_{\text{inv}})} + \frac{1}{R_2}\right] = \frac{(v_{\text{in}} R_2/R_{\text{inv}})(1/R_1) + (1/R_2)}{1 + (R_2/R_1) + (R_2/R_{\text{inv}})}$$

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1 + (R_2/R_1)}{\frac{R_{\text{inv}}(1 + (R_2/R_1) + (R_2/R_{\text{inv}}))(1 + j\omega R_Z C_Z)}{A_{\text{vb}} K R_Z} - R_{\text{inv}}((1/R_1) + (1/R_2)) + \frac{R_{\text{inv}}(1 + (R_2/R_1) + (R_2/R_{\text{inv}}))}{R_2}}$$

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1 + (R_2/R_1)}{\frac{R_{\text{inv}}(1 + (R_2/R_1)) + R_2}{A_{\text{vb}} K R_Z} + \frac{(R_{\text{inv}}(1 + (R_2/R_1)) + R_2) j\omega R_Z C_Z}{A_{\text{vb}} K R_Z} + 1}$$

Factorize the denominator

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1 + (R_2/R_1)}{\left[1 + \frac{R_{\text{inv}}(1 + (R_2/R_1)) + R_2}{A_{\text{vb}} K R_Z}\right]\left[1 + \frac{\frac{(R_{\text{inv}}(1 + (R_2/R_1)) + R_2) j\omega R_Z C_Z}{A_{\text{vb}} K R_Z}}{1 + \frac{R_{\text{inv}}(1 + (R_2/R_1)) + R_2}{A_{\text{vb}} K R_Z}}\right]}$$

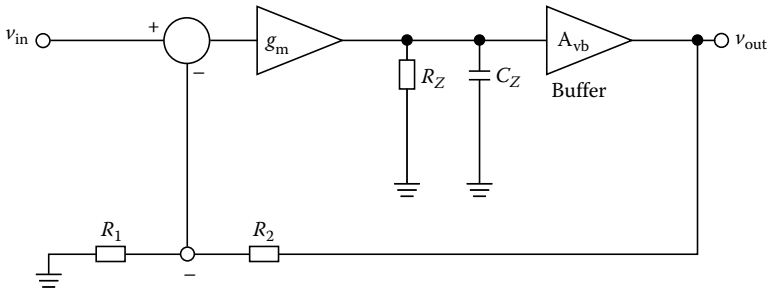
$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1 + (R_2/R_1)}{\left[1 + \frac{R_{\text{inv}}(1 + (R_2/R_1)) + R_2}{A_{\text{vb}} K R_Z}\right]\left[1 + j\omega C_Z\left\{\frac{R_{\text{inv}}(1 + (R_2/R_1)) + R_2}{A_{\text{vb}} K + \frac{R_{\text{inv}}(1 + (R_2/R_1)) + R_2}{R_Z}}\right\}\right]}$$

If we assume that R_Z is very large, then

$$\frac{R_{\text{inv}}(1 + (R_2/R_1)) + R_2}{R_Z} \approx 0$$

and the transfer function becomes

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1 + (R_2/R_1)}{1 + j\omega C_Z\left[\frac{R_{\text{inv}}(1 + (R_2/R_1)) + R_2}{A_{\text{vb}} K}\right]}$$



The pole frequency is given by

$$f_{-3\ \mathrm{dB}} = \frac{A_{\mathrm{vb}}K}{2\pi C_Z[R_{\mathrm{inv}}(1+(R_2/R_1))+R_2]}$$

The gain-bandwidth product is given by

$$GBW = \frac{A_{\mathrm{vb}}K[1+(R_2/R_1)]}{2\pi C_Z[R_{\mathrm{inv}}(1+(R_2/R_1))+R_2]}$$

Appendix B: Transfer Function and Bandwidth Characteristic of Voltage-Feedback Operational Amplifier

$$\begin{aligned}
v_{\mathrm{out}} &= \left(v_{\mathrm{in}} - \frac{R_1}{R+R_2 v_{\mathrm{out}}}\right)\frac{g_{\mathrm{m}}R_Z A_{\mathrm{vb}}}{1+j\omega R_Z C_Z} \\
v_{\mathrm{out}}&\left[1+\frac{R_1 g_{\mathrm{m}}A_{\mathrm{vb}}R_Z}{(R_1+R_2)(1+j\omega R_Z C_Z)}\right] = v_{\mathrm{in}}\frac{g_{\mathrm{m}}A_{\mathrm{vb}}R_Z}{1+j\omega R_Z C_Z} \\
\frac{v_{\mathrm{out}}}{v_{\mathrm{in}}} &= \frac{g_{\mathrm{m}}A_{\mathrm{vb}}R_Z/(1+j\omega R_Z C_Z)}{1+\frac{R_1 g_{\mathrm{m}}A_{\mathrm{vb}}R_Z}{(R_1+R_2)(1+j\omega R_Z C_Z)}}
\end{aligned} \tag{3.74}$$

Multiply the numerator and denominator by $(1+j\omega R_Z C_Z)/g_{\mathrm{m}}\ A_{\mathrm{vb}}\ R_Z$

$$\begin{aligned}
\frac{v_{\mathrm{out}}}{v_{\mathrm{in}}} &= \frac{1}{\frac{1+j\omega R_Z C_Z}{g_{\mathrm{m}}A_{\mathrm{vb}}R_Z}+\frac{R_1}{(R_1+R_2)}} \\
\frac{v_{\mathrm{out}}}{v_{\mathrm{in}}} &= \frac{1+(R_2/R_1)}{\left[\frac{1+j\omega R_Z C_Z}{g_{\mathrm{m}}A_{\mathrm{vb}}R_Z}\right][1+(R_2/R_1)]+1} \\
\frac{v_{\mathrm{out}}}{v_{\mathrm{in}}} &= \frac{1+(R_2/R_1)}{\frac{1+(R_2/R_1)}{g_{\mathrm{m}}A_{\mathrm{vb}}R_Z}+\frac{j\omega R_Z C_Z(1+(R_2/R_1))}{g_{\mathrm{m}}A_{\mathrm{vb}}R_Z}+1}
\end{aligned}$$

get $1+[1+(R_2/R_1)/g_{\mathrm{m}}\ A_{\mathrm{vb}}\ R_Z]$ out of the denominator

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1 + (R_2/R_1)}{\left[1 + \frac{1 + (R_2/R_1)}{g_m A_{vb} R_Z}\right]\left[1 + \frac{\frac{j\omega R_Z C_Z (1 + (R_2/R_1))}{g_m A_{vb} R_Z}}{1 + \frac{1 + (R_2/R_1)}{g_m A_{vb} R_Z}}\right]}$$

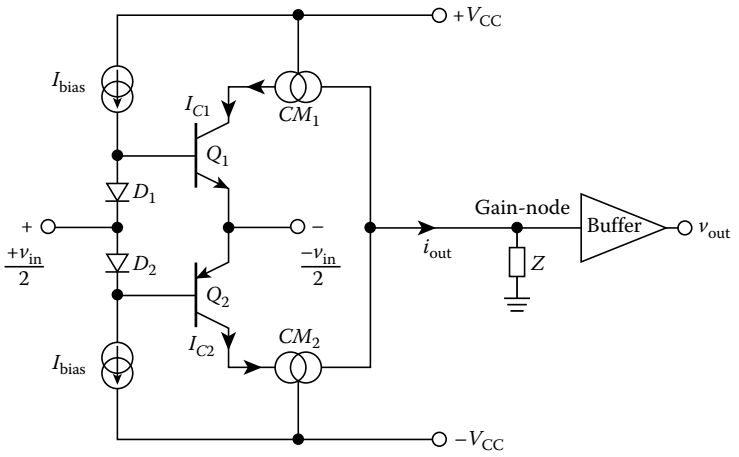
multiply the denominator bracket by $g_m\, A_{vb}\, R_z/[1 + (R_2/R_1)]$

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1 + (R_2/R_1)}{\left[1 + \frac{1 + (R_2/R_1)}{g_m A_{vb} R_Z}\right]\left[1 + \frac{j\omega R_Z C_Z (1 + (R_2/R_1))}{g_m A_{vb} R_Z + (1 + (R_2/R_1))}\right]}$$

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1 + (R_2/R_1)}{\left[1 + \frac{1 + (R_2/R_1)}{g_m A_{vb} R_Z}\right]\left[1 + \frac{j\omega R_Z C_Z}{1 + \frac{g_m A_{vb} R_Z}{1 + (R_2/R_1)}}\right]}$$

assuming that $g_m\, A_{vb} R_Z$ is much larger than $1 + R_2/R_1$, then

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1 + (R_2/R_1)}{1 + j\omega\left[\frac{R_Z C_Z}{1 + \frac{g_m A_{vb} R_Z}{1 + (R_2/R_1)}}\right]}$$



The pole frequency is given by

$$f_{-3\text{ dB}} = \frac{1 + \frac{g_m A_{vb} R_Z}{1 + (R_2/R_1)}}{2\pi R_Z C_Z}$$

The gain-bandwidth product is given by

$$GBW = \frac{(1 + (R_2/R_1))\left[1 + \frac{g_m A_{vb} R_Z}{(1 + (R_2/R_1))}\right]}{2\pi R_Z C_Z}$$

Appendix C: Transconductance of the Current-Feedback Op-Amp Input Stage

$$v_{\text{in}} = v_1 - v_2$$

$$i_{\text{out}} = I_{CI} - I_{C2}$$

$$I_{C1} = I_{S1} e^{\frac{v_{BE1}}{v_T}}$$

$$I_{C2} = I_{S2} e^{\frac{v_{BE2}}{v_T}}$$

$$V_{BE1} = V_{DQ1} + v_{\text{in}}$$

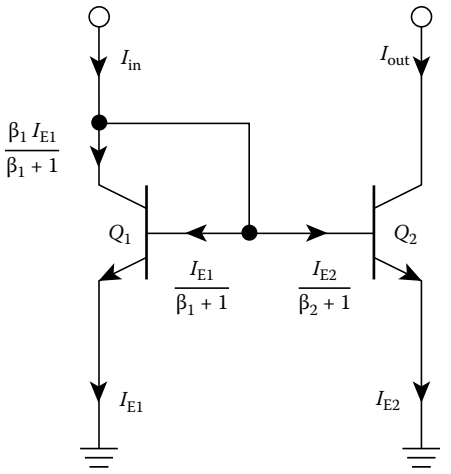
$$V_{BE2} = v_{\text{in}} - V_{DQ2}$$

$$I_{C1} = I_{S1} e^{\left(\frac{V_{DQ1}}{V_T} + \frac{v_{\text{in}}}{v_T}\right)}$$

$$I_{C2} = I_{S2} e^{\left(\frac{V_{DQ1}}{V_T} - \frac{v_{\text{in}}}{v_T}\right)}$$

$$I_{C1} = I_{CQ1} e^{\frac{v_{\text{in}}}{v_T}}$$

$$I_{C2} = I_{CQ2} e^{-\frac{v_{\text{in}}}{v_T}}$$



Assuming matched transistors then, $I_{\text{CQ1}} = I_{\text{CQ2}} = I_{\text{CQ}}$

$$i_{\text{out}} = I_{\text{C1}} - I_{\text{C2}} = I_{\text{CQ}} \left[e^{+\left(\frac{v_{\text{in}}}{v_{\text{T}}}\right)} - e^{-\left(\frac{v_{\text{in}}}{v_{\text{T}}}\right)} \right]$$

$$\frac{i_{\text{out}}}{I_{\text{CQ}}} = y = \left[e^{x} - e^{-x}\right] = 2 \sinh(x)$$

where $x = + v_{\text{in}}/V_{\text{T}}$.

Appendix D: Transfer Function of Widlar Current Mirror

$$I_{in} = I_{E1} + \frac{I_{E2}}{\beta_2 + 1}$$

$$I_{in} = \frac{I_{E1}(\beta_2 + 1) + I_{E2}}{\beta_2 + 1}$$

$$I_{out} = \beta_2 I_{B2}$$

$$I_{out} = \frac{\beta_2 I_{E2}}{\beta_2 + 1}$$

$$\frac{I_{out}}{I_{in}} = \frac{(\beta_2 I_{E2})(\beta_2 + 1)}{(\beta_2 + 1)[I_{E1}(\beta_2 + 1) + I_{E2}]}$$

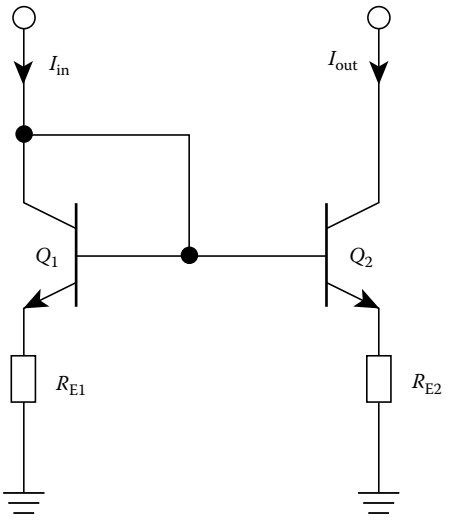
$$\frac{I_{out}}{I_{in}} = \frac{\beta_2 I_{E2}}{I_{E1}(\beta_2 + 1) + I_{E2}}$$

$$\frac{I_{out}}{I_{in}} = \frac{1}{\frac{I_{E1}(\beta_2 + 1)}{I_{E2}\beta_2} + \frac{1}{\beta_2}}$$

For

$$\frac{I_{E1}}{I_{E2}} = \frac{I_{S1}\left(\frac{\beta_1 + 1}{\beta_1}\right) e^{\frac{v_{BE1}}{V_T}}}{I_{S2}\left(\frac{\beta_2 + 1}{\beta_2}\right) e^{\frac{v_{BE2}}{v_T}}}$$

Then, as $V_{BE1} = V_{BE2}$,



$$\frac{I_{E1}}{I_{E2}} = \frac{I_{S1}(\beta_1 + 1/\beta)}{I_{S2}(\beta_2 + 1/\beta_2)}$$

$$\frac{I_{out}}{I_{in}} = \frac{1}{\frac{I_{S1}(\beta_1 + 1)}{I_{S2}\beta_1} + \frac{1}{\beta_2}}$$

Assume $\beta_1 = \beta_2 = \beta$, $I_{S1} = I_{S2}$. Then

$$\frac{I_{out}}{I_{in}} = \frac{\beta}{\beta + 2}$$

Appendix E: Transfer Function of Widlar Current Mirror with Emitter Degeneration Resistors

Assuming that $\beta \gg 1$, then

$$V_{BE1} + I_{in}R_1 = V_{BE2} + I_{out}R_2$$

$$I_{out} = \frac{I_{in}R_1}{R_2} + \frac{(V_{BE1} - V_{BE2})}{R_2}$$

$$\frac{I_{out}}{I_{in}} = \frac{R_1}{R_2} + \frac{(V_{BE1} - V_{BE2})}{I_{in}R_2}$$

$$\frac{I_{out}}{I_{in}} = \frac{R_1}{R_2} + \frac{V_T \ln\left(\frac{I_{in}}{I_{S1}}\frac{I_{S2}}{I_{out}}\right)}{I_{in}R_2}$$

$$\frac{I_{out}}{I_{in}} = \frac{R_1}{R_2} + \frac{V_T(\ln(I_{in}/I_{out}) + (\Delta V_{BE}/V_T))}{I_{in}R_2}$$

$$\frac{I_{out}}{I_{in}} = \frac{R_1}{R_2} + \frac{V_T(\ln(I_{in}/I_{out}))}{I_{in}R_2} + \frac{\Delta V_{BE}}{I_{in}R_2}$$

Assuming that the term $V_T[\ln(I_{in}/I_{out})]/I_{in}R_2$ is small compared with the other terms, then

$$\frac{I_{out}}{I_{in}} = \frac{R_1}{R_2} + \frac{\Delta V_{BE}}{I_{in}R_2}$$

3.2 Bipolar Noise

Alicja Konczakowska and Bogdan M. Wilamowski

Bipolar transistors and other electronic devices generate inherent electrical noise. This limits the device operation at a small-signal range. There are a few different sources of noise, such as thermal noise, shot noise, generation–recombination, $1/f$ (flicker noise), and $1/f^2$ noise, burst noise or random telegraph signal noise (RTS noise), and avalanche noise [1,6].

3.2.1 Thermal Noise

Thermal noise is created by random motion of charge carriers due to the thermal excitation [1]. This noise is sometimes known as the Johnson noise. In 1905 Einstein presented his theory of fluctuating movement of charges in thermal equilibrium. This theory was experimentally verified by Johnson in 1928. The thermal motion of carriers creates a fluctuating voltage on the terminals of each resistive element. The average value of this voltage is zero, but the power on its terminals is not zero. The internal noise voltage source or current source is described by Nyquist equation

$$\overline{v_{\mathrm{n}}^2} = 4kTR\Delta f, \quad \overline{i_{\mathrm{n}}^2} = \frac{4kT\Delta f}{R} \tag{3.75}$$

where
k is the Boltzmann constant
T is absolute temperature
$4kT$ is equal to 1.61×10^{-20} V · C at room temperature

The thermal noise is proportional to the frequency bandwidth Δf. It can be represented by the voltage source in series with resistor R, or by the current source in parallel to the resistor R. The maximum noise

power can be delivered to the load when $R_L = R$. In this case maximum noise power in the load is $kT\Delta f$. The noise power density $dP_n/df = kT$, and it is independent of frequency. Thus, the thermal noise is the white noise. The RMS noise voltage and the RMS noise current are proportional to the square root of the frequency bandwidth Δf. The thermal noise is associated with every physical resistor in the circuit. In a bipolar transistor, the thermal noise is generated mainly by series base, emitter, and collector resistances.

Spectral density of the equivalent voltage and currant thermal noise are given by

$$S_{vR} = 4kT_kR \tag{3.76}$$

or

$$S_{iG} = 4kT_kG \tag{3.77}$$

These spectral noise densities are constant up to 1 THz and it is proportional to temperature and to resistance of elements and as such can be used to indirectly measure:

- The device temperature
- Series distributed resistances of bipolar transistors (primarily base resistance)
- Quality of contacts and connections

3.2.2 Shot Noise

Shot noise is associated with a discrete structure of electricity and the individual carrier injection through the *pn* junction. In each forward biased junction, there is a potential barrier which can be overcome by the carriers with higher thermal energy. This is a random process and the noise current is given by

$$\overline{i_n^2} = 2qI\Delta f \tag{3.78}$$

Spectral density of the shot noise is temperature independent and it is proportional to the junction current:

$$S_{is} = 2qI \tag{3.79}$$

where

q is the electron charge
I is the forward junction current

Shot noise is usually considered as a current source connected in parallel to the small-signal junction resistance. The measurement of shout noise in modern nanoscale devices is relatively difficult since measured values of current are in the range of 100 fA.

Shot noise has to be proportional to the current and any deviation from this relation can be used to evaluate parasitic leaking resistances. It can be used for diagnosis of photodiodes, Zener diodes, avalanche diodes, and Schottky diodes.

3.2.3 Generation–Recombination Noise

The generation–recombination noise is caused by the fluctuation of number of carriers due to existence of the generation–recombination centers. Variation of number of carriers leads to changes of device conductance. This type of noise is function of both temperature and biasing conditions. The spectral density of the generation–recombination noise is described by

$$\frac{S_{g-r}(f)}{N^2} = \frac{(\overline{\Delta N})^2}{N^2} \cdot \frac{4\tau}{1 + (2\pi f \cdot \tau)^2} \tag{3.80}$$

where
$(\overline{\Delta N})^2$ is the variance of the number of carriers N
τ is the carrier lifetime

Spectral density is constant up to the frequency $f_{g-r} = 1/(2\pi\tau)$, and after that is decreasing proportionally to $1/f^2$.

In the case when there are several types of generation–recombination centers with different carrier life time the resultant noise spectrum will be a superposition of several distributions described by Equation 3.80. Therefore the spectral distribution of noise can be used to investigate various generation–recombination centers. This is an alternative method to deep level transient spectroscopy (DLTS) to study generation–recombination processes in semiconductor devices.

3.2.4 *1/f* Noise

The *1/f* noise is the dominant noise in the low-frequency range and its spectral density is proportional to *1/f*. This noise is present in all semiconductor devices under biasing. This noise is usually associated with material failures or with imperfection of a fabrication process. Most of research results conclude that this noise exists even for very low frequencies up to 10^{-6} Hz (frequency period of several weeks). This noise is sometimes used to model fluctuation of device parameters with time. There are two major models of *1/f* noise:

- Surface model developed by McWhorter in 1957 [7]
- Bulk model developed by Hooge in 1969 [8]

The simplest way to obtain $1/f$ characteristics is to superpose many different spectra of generation–recombination noises, where free carriers are randomly trapped and released by centers with different life times. This was the basic concept behind McWhorter model where it was assumed that

- In the silicon oxide near the silicon surface there are uniformly distributed trap centers
- Probability of the carrier penetration to trap centers is decreasing exponentially with the distance from the surface.
- Time constants of trap centers increases with the distance from the surface
- Trapping mechanisms by separate centers are independent

The resulted noise spectral density is given by

$$S_{1/f} \propto (\overline{\Delta N})^2 \int_{\tau_1}^{\tau_2} \frac{1}{\tau} \frac{4\tau}{1 + \omega\tau^2} \cdot d\tau = (\overline{\Delta N})^2 \cdot \frac{1}{f} \quad \text{for } 1/\tau_2 \ll \omega \ll 1/\tau_1 \tag{3.81}$$

The spectral density is constant up to frequency $f_2 = 1/(2\pi\tau_2)$, then is proportional to $1/f$ between f_2 and $f_1 = 1/(2\pi\tau_1)$, from frequency f_1 is proportional to $1/f^2$. The McWhorter model is primarily used for MOS devices.

For bipolar transistor Hooge bulk model is more adequate. In this noise model Hooge uses in the carrier transport two scattering mechanisms of carries: scattering on the silicon lattice and scattering on impurities. He assumed that only scattering on the crystal lattice is the source of the *1/f* noise, while scattering on the impurities has no effect on noise level. All imperfections of the crystal lattice leads to large *1/f* noise.

The noise spectral density for the Hooge model is

$$S_{1/f} = \frac{\alpha_H \cdot I^{\beta}}{f^{\gamma} \cdot N} \tag{3.82}$$

where
$\alpha_H = 2 \cdot 10^{-3}$ is the Hooge constant [8]
β and γ are material constants
N is the number of carriers

Later [9] Hooge proposed to use α_H as variable parameter, which in the case of silicon devices may vary from $5 \cdot 10^{-6}$ to $2 \cdot 10^{-3}$.

The $1/f$ noise is increasing with the reduction of device dimensions and as such is becoming a real problem for devices fabricated in nanoscale. The level of *1/f* noise is often used as the measure of the quality of devices and its reliability. Devices fabricated with well-developed technologies usually have much smaller level of *1/f* noise. The *1/f* noise (flicker noise) sometimes is considered to be responsible for the long term device parameter fluctuation.

3.2.5 Noise $1/f^2$

The noise $1/f^2$ is a derivative of *1/f* noise and it is observed mainly in metal interconnections of integrated circuits. It has become more evident for very narrow connections where there is a possibility of electromigration due to high current densities. In aluminum the electromigration begins at current densities of 200 $\mu A/\mu m^2$ and noise characteristics changes from $1/f^2$ to $1/f^{\gamma}$, where $\gamma > 2$. Also the noise level increases proportionally to the 3rd power of the biasing current:

$$S_{1/f^2}(f) = \frac{C \cdot J^{\beta}}{f^{\gamma} \cdot T} \cdot \exp(-E_a/k \cdot T) \tag{3.83}$$

where
$\beta \geq 3$, $\gamma \geq 2$
C is experimentally found constant
E_a activation energy of the electromigration
$k = 8.62 \cdot 10^{-5}$ eV/K is the Boltzmann constant

The degeneration of metallic layer is described by

$$\nu_d \propto J^n \exp(-E_a/k \cdot T) \tag{3.84}$$

Since Equations 3.83 and 3.84 have a similar character therefore the $1/f^2$ noise can be used as the measure of the quality of metal interconnections. This is a relatively fast and accurate method to estimate reliability of metal interconnections.

3.2.6 Burst Noise—RTS Noise

The burst noise is another type of noise at low frequencies [3,4]. Recently this noise is described as RTS noise. With given biasing condition of a device the magnitude of pulses is constant, but the switching time is random. The burst noise looks, on an oscilloscope, like a square wave with the constant magnitude, but with random pulse widths (see Figure 3.64). In some cases the burst noise may have not two but several different levels.

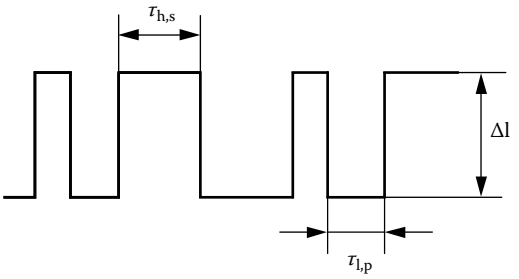

FIGURE 3.64 Example of RTS noise waveform.

Spectral density of the RTS noise has similar form like generation–recombination noise:

$$S_{\mathrm{RTS}} = C\frac{4\cdot(\Delta I)^2}{1+(2\pi f/f_{\mathrm{RTS}})^2} \tag{3.85}$$

where

$$C = \frac{1}{(\overline{\tau_{\mathrm{l}}}+\overline{\tau_{\mathrm{h}}})\cdot f_{\mathrm{RTS}}^2}$$

$f_{\mathrm{RTS}} = \frac{1}{\tau} = \frac{1}{\tau_{\mathrm{l}}} + \frac{1}{\tau_{\mathrm{h}}} = \frac{\overline{\tau_{\mathrm{l}}}+\overline{\tau_{\mathrm{h}}}}{\overline{\tau_{\mathrm{h}}}\cdot\overline{\tau_{\mathrm{l}}}}$ is the corner frequency, below this frequency spectrum of the RTS noise is flat
$\overline{\tau_{\mathrm{l}}}$ is the average time of pulses at low level
$\overline{\tau_{\mathrm{h}}}$ is the average time of pulses at high level

$$\overline{\tau_{\mathrm{l}}} = \frac{1}{P}\sum_{i=1}^{P}\tau_{\mathrm{l,p}}$$

$$\overline{\tau_{\mathrm{h}}} = \frac{1}{S}\sum_{j=1}^{S}\tau_{\mathrm{h,s}}$$

The intensity of the RTS noise depends on the location of the trap center with the reference to the Fermi level. Only centers in the vicinity of Fermi levels are generating the RTS noise. These trapping centers, which are a source for RTS noise, are usually the result of silicon contamination with heavy metals or lattice structure imperfections.

In the SPICE program the burst noise is often approximated by

$$\overline{i_{\mathrm{n}}^2} = K_{\mathrm{B}}\frac{I_{\mathrm{D}}^{A_{\mathrm{B}}}}{1+\left(\frac{f}{f_{\mathrm{RTS}}}\right)^2}\Delta f \tag{3.86}$$

where K_{B}, A_{B}, and f_{RTS} are experimentally chosen parameters, which usually vary from one device to another. Furthermore, a few different sources of the burst noise can exist in a single transistor. In such a case, each noise source should be modeled by separate Equation 3.85 with different parameters (usually different corner frequency f_{RTS})

Kleinpenning [10] showed that RTS noise exists with devices with small number of carriers, where a single electron can be captured by a single trapping center. RTS noise is present in submicrometer MOS transistors and in bipolar transistors with defected crystal lattice. It is present in modern SiGe transistors.

This noise has significant effect at low frequencies. It is function of temperature, collector current, induced mechanical stress, and also radiation. In audio amplifiers the burst noise sounds as random shoots, which are similar to the sound associated with making popcorn. Obviously, bipolar transistors with large burst noise must not be used in audio amplifiers and in other analog circuitry. The burst noise was often observed in epiplanar bipolar transistors with large β coefficients. It is now assumed that devices fabricated with well developed and established technologies do not generate the RTS noise. This is unfortunately not true for modern nanotransistors and devices fabricated with other than silicon materials.

3.2.7 Avalanche Noise

The avalanche noise is another noise component, which can be found in bipolar transistors. For large reverse voltages on the collector junction, the collector current can be multiplied by the avalanche

phenomenon. Carriers in the collector–base junctions gain energies in high electrical field, then lose this energy during collision with the crystal lattice. If the energy gained between collisions is large enough, then during collision another pair of carriers (electron and hole) can be generated. This way the collector current can be multiplied. This is a random process and obviously the noise source is associated with the avalanche carrier generation. The magnitude of the avalanche noise is usually much larger than any other noise component. Fortunately, the avalanche noise exists only in the *pn* junction biased with a voltage close to the breakdown voltage. The avalanche phenomenon is often used to build the noise sources [5].

Spectral density of the avalanche noise is frequency independent

$$S_{\mathrm{I}}(f) = \frac{2qI}{(2\pi f \cdot \tau)^2} \tag{3.87}$$

where I is an average value of the reverse biasing current.

3.2.8 Noise Characterization

Many different methods are used in literature for noise characterization. Sometimes the noise is characterized by an equivalent noise resistance, sometimes by an equivalent noise temperature, sometimes by an equivalent RMS noise voltage or current or sometimes by a noise figure.

3.2.8.1 Equivalent Noise Voltage and Current

The equivalent noise voltage or current is the most commonly used method for modeling the noise in semiconductor devices. The equivalent diagram of the bipolar transistor, including various noise components, is shown in Figure 3.65. The noise components are given by

$$\overline{i_{\mathrm{B}}^2} = \frac{4kT\Delta f}{r_{\mathrm{B}}}, \quad \overline{i_{\mathrm{E}}^2} = \frac{4kT\Delta f}{r_{\mathrm{E}}}, \quad \text{and} \quad \overline{i_{\mathrm{C}}^2} = \frac{4kT\Delta f}{r_{\mathrm{C}}} \tag{3.88}$$

$$\overline{i_{\mathrm{C}}^2} = 2qI_{\mathrm{C}}\Delta f \tag{3.89}$$

$$\overline{i_{\mathrm{B}}^2} = 2qI_{\mathrm{B}}\Delta f + K_{\mathrm{F}}\frac{I_{\mathrm{B}}^{A_{\mathrm{F}}}}{f}\Delta f + K_{\mathrm{B}}\frac{I_{\mathrm{B}}^{A_{\mathrm{B}}}}{1+(f/f_{\mathrm{B}})^2}\Delta f \tag{3.90}$$

Thermal noise is associated with physical resistors only, such as base, emitter, and collector series resistances. The small-signal equivalent resistances, such as r_π and r_o, do not exhibit thermal noise.

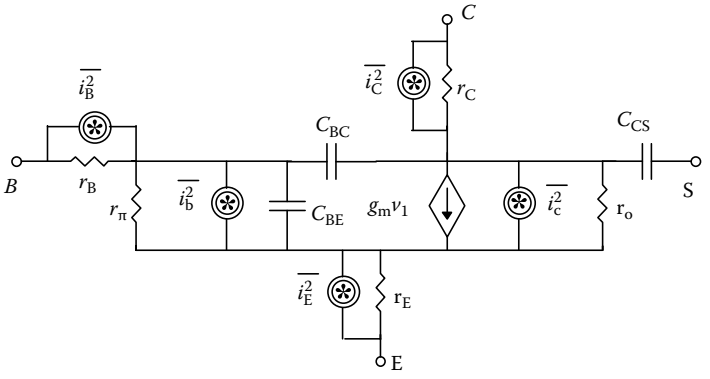

FIGURE 3.65 Equivalent diagram of the bipolar transistor which includes noise sources.

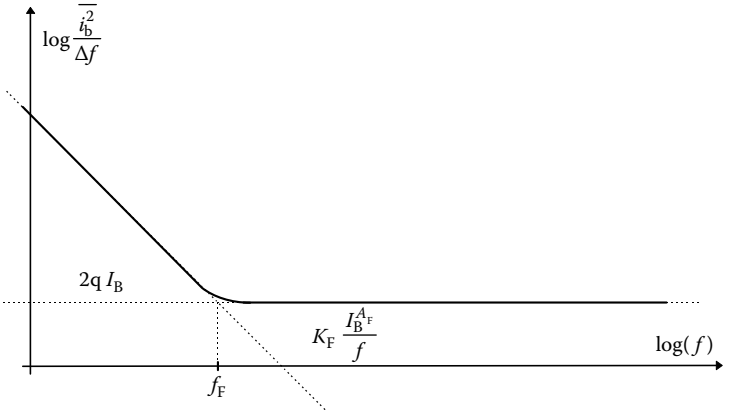

FIGURE 3.66 Bipolar transistor noise as a function of frequency.

The shot noise is associated with both collector and base currents. It was found experimentally that the $1/f$ noise and the burst noise are associated with the base current. The typical noise characteristic of a bipolar transistor is shown in Figure 3.66. The corner frequency of the $1/f$ noise can vary form 10 Hz to 1 MHz.

3.2.8.2 Equivalent Noise Resistance and Noise Temperature

The noise property of a two-port element can be described by a noise current source connected in parallel to the output terminals as Figure 3.67a shows. Knowing that noise current can be expressed as the shot noise of the DC device current the two-port noise can be expressed by means of an equivalent DC noise current

$$I_{eq} = \frac{\overline{i_n^2}}{2q\Delta f} \tag{3.91}$$

Another way to model the two-port noise in the two-port is to use the thermal noise at the input. This can be done using an additional "noisy" resistor connected to the input as Figure 3.67b shows

$$R_n = \frac{\overline{v_{n1}^2}}{4kT\Delta f} = \frac{\overline{v_{n2}^2}}{A_V^2 4kT\Delta f} \tag{3.92}$$

where

A_V is the voltage gain of the two-port

v_{n1}^2 and v_{n2}^2 are equivalent noise voltage sources at the input and the output, respectively

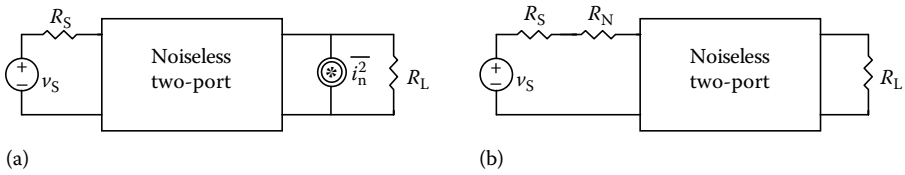

FIGURE 3.67 Noise characterization for two-ports, (a) using the noise source at the output, (b) using noise resistance R_n at the input.

The equivalent noise resistance is not a very convenient way to represent the noise property of the two-port. This additional resistance R_n must not be on the circuit diagram for small-signal analysis. To overcome this difficulty the concept of the equivalent noise temperature was introduced. This is a temperature increment of the source resistance required to obtain the same noise magnitude at the output if this source resistance is the only noise source. The noise temperature can be calculated from the simple formula

$$T_n = \frac{R_n}{R_s} 290^\circ \text{ K} \tag{3.93}$$

where R_n and R_s are shown in Figure 3.67b. It is customary to use 290° K as the reference room temperature for the noise temperature calculations.

3.2.8.3 Noise Figure

The noise figure is the ratio of the output noise of the actual two-port to the output noise of the ideal noiseless two-port when the resistance of the signal source R_s is the only noise source.

$$F = 10 \log \left(\frac{\text{total output noise}}{\text{output noise due to the source resistance}} \right) \tag{3.94}$$

The noise figure F is related to the noise resistance and the noise temperature in the following way

$$F = 10 \log \left(1 + \frac{R_n}{R_s} \right) = 10 \log \left(1 + \frac{T_n}{290^\circ \text{K}} \right) \tag{3.95}$$

The noise figure F is the most common method of noise characterization.

4.1 Introduction

During the last decade of last century, the world of wireless communications started to grow rapidly. Today, cellular handsets are the largest consumer market in the world. The main trigger was the introduction of digital coding and digital signal processing in wireless communications. The aggressive scaling of CMOS process technology driven by the memory and microprocessor market made CMOS a logical choice for integration of digital signal processing in wireless applications. The development of these high performance, low-cost CMOS technologies allowed integration of enormous amount of digital functionality on one chip. This enabled the use of sophisticated modulation schemes, complex demodulation algorithms, and high-quality error detection and correction to produce high data rate communication channels bringing the Shannon limit in sight [1].

The radio frequency (RF) front-ends are the interface between the antenna and the digital modem of the wireless transceiver. They have to detect very weak signals (μV) that come in at a very high frequency (10 GHz), and at the same time transmit high-power levels (up to several watts) at the same high frequencies. This requires high-performance analog circuits, like filters, amplifiers, and mixers that translate the incoming modulated data between the antenna and the A/D conversion and digital signal processing. Consumer electronic markets are mainly driven by low-cost and low-power consumption. This makes the RF front-ends the bottleneck for future wireless applications. Low-cost and low-power are both linked to high integration level. A high level of integration renders a significant space, cost, weight, and power reduction. A higher degree of integration requires less discrete components reducing the bill of materials cost. Keeping signals on chip greatly reduces power consumption since less I/O drivers are needed. Many

different techniques to obtain a higher degree of integration have been presented over the years [2–5]. This chapter introduces and analyzes some advantages and disadvantages and their fundamental limitations.

Parallel to the trend for further integration, there is the trend to integrate RF circuitry in CMOS technologies. While digital baseband processing has already been implemented in CMOS technology in several product generations, CMOS RF has only recently made its pace forward. For long time, many design houses believed complicated Mixed-Signal RF CMOS chips were impossible to realize. The main objective against CMOS RF was the lack of high-Q passive components and its poor noise performance. It took the persistence of some academic institutions and some pioneering firms to prove them wrong. It is clear that RF CMOS full potential would not have been unfold if only stand-alone radios were developed. CMOS RF systems on chip today implement all radio building blocks including phase-locked-loop (PLL), low-noise amplifier (LNA), power amplifier (PA), up- and down-conversion mixers, filters, and antenna switch. Furthermore, they include all digital baseband processing circuitry and ROM memory [6,7]. This reveals the real strength of CMOS RF over other ''better-suited'' technologies like Si Bipolar, BiCMOS, and Silicon Germanium (SiGe). Putting together RF and baseband in one chip permits compensation of lower radio performance with less expensive digital signal processing circuits, making its performance competitive with SiGe radios. Together with a possible 75% reduction of discrete components, RF CMOS offers the cheapest solution if one pursues the ultimate goal: A single chip including the physical layer (PHY) as well as the media access control (MAC) together with an MAC processor, memory, and I/O such as USBports or peripheral component interconnect (PCI) interfaces.

RF CMOS is not a matter of just replacing bipolar transistors with their CMOS counterpart. It requires a whole range a new architectures, techniques, and a high integration level. When compared with CMOS, SiGe requires less power for a certain gain and achieves a lower noise figure. The biggest drawback of CMOS is its inferior 1/f noise performance. This will only increase with the introduction of high-K dielectric materials in the gate of future CMOS technology nodes. CMOS design engineers therefore went looking for new topologies to reduce the impact of 1/f noise on the radio performance. Another problem that had to be overcome was the lack of high-Q passive components in CMOS technology. Extra processing steps as well as innovative layout and design techniques solved this problem. First, this chapter will analyze some concepts, trends, limitations, and problems posed by technology for high frequency design. Next we will discuss a variety of architectures used in modern RF CMOS transceivers. In the rest of the chapter, we will take a closer look at the different building blocks that appear in a typical RF transceiver. We will split this up between down-conversion, up-conversion, and frequency synthesis.

In the final section, we will take a look at RF CMOS's last barrier: RF power transmission. As CMOS gate lengths shrink, lower voltages are tolerated at the transistor terminals. High-quality impedance converters must therefore be placed between the antenna and the transistor's drain for high power transmissions. These are not available yet in integrated form. One of the major bottlenecks in CMOS PAs is combining high efficiency with high linearity. For high power transmission, designers are obliged to bias the PA high in its saturation region where linearity is low. Therefore, todays integrated PAs are limited to constant envelope modulation schemes like GSM. High efficient PAs still remain out of reach for modulation schemes with large peak-to-average power ratios like orthogonal frequency division modulation (OFDM). This chapter discusses some circuit techniques to circumvent this bottleneck bringing the ultimate goal of a single-chip CMOS solution that is compatible with all standards and is capable of adapting itself a step closer to reality.

4.2 System Level RF Design

4.2.1 General Overview

One of the main challenges facing the RF design engineer originates from the transmission medium used by RF systems. RF systems communicate through AIR by means of electromagnetic waves. Using air as transmission medium has one huge advantage: it gives the transceiver the ability to be mobile. However, there are some disadvantages to this high degree of freedom. There exists only one medium air, which is

consequently used by numerous applications. An overview of these applications and the part of the spectrum they use can be found on the Website of the National Telecommunications and Information Administration (NTIA) [8]. As a result, RF systems operate in a filled spectrum. Receivers will not only detect the wanted signals own to the application, but will also pick up other signals that will consequently be amplified and detected. These unwanted detected signals are called interferes. If the interferer is sufficiently large, it can corrupt the wanted signals preventing them to be properly demodulated and understood. On the transmit side of the application, unwanted signals are generated and transmitted. They are picked up by other applications and can distort their performance. These unwanted transmitted signals are called spurious signals. It is the designer's responsibility to keep these interferers and spurious signals as low as possible. Based on the earlier discussion, it is clear that one needs a regulator to manage this spectrum use. In the United States, this is done using a dual organizational structure; NTIA manages the federal government's use of the spectrum while the Federal Communications Commission (FCC) [9] manages all other uses.

Signals traveling through air also suffer from attenuation. There are several mechanisms causing attenuation such as free-space dispersion, fading, and multipath. These mechanisms depend heavily on the distance between transmitter and receiver, the frequency of transmission, and the environment. Discussion of these mechanisms, however, is beyond the scope of this text. More information concerning these topics can be found in Refs. [10,11]. As a result of these mechanisms, one can expect the received signal power to have a large variation since the distance between transmitter and receiver can change considerably due to the mobility. Performance of RF communication systems is also degraded by thermal noise. Noise is, like in other communication systems, the limiting factor when dealing with weak signals. The noise energy consists of two contributors. First, there is thermal noise which is determined by temperature and bandwidth and is out of control of the designer. On the other hand, there is system noise. This kind of noise can, within limits, be controlled by the designer to allow a certain minimum level of signal power to be detected by the system.

In the next sections, we will take a closer look at the challenges described in the earlier discussion. First, we will take a brief look at the tools and metrics RF designers use to describe and control the performance of their system in the presence of interferers and noise. We will end this section with a discussion of some commonly used transceiver architectures.

4.2.2 RF System Performance Metrics

As described in Section 4.2.1, the lowest signal power level that can be detected correctly by a receiver is limited by noise. The lowest power level that can be detected is usually called the receiver sensitivity. The receiver sensitivity is related to the signal-to-noise ratio (SNR) at the end of the receive chain (baseband). The SNR at baseband is determined by the bit error rate (BER) required by the application. It is usually expressed in terms of E_b/N_o. E_b is the energy per received bit and N_o is the noise power density received together with the bit. The relation between E_b/N_o and BER depends on the modulation scheme used in the application (e.g., Gaussian minimum shift keying (GMSK) in global system for mobile communications (GSM)) and is beyond the scope of this text. More information can be found in Ref. [12]. The SNR can be expressed in function of E_b/N_o as follows:

$$\mathrm{SNR} = \frac{S}{N} = \frac{E_b}{N_o} \times \frac{f_b}{B} \tag{4.1}$$

where

f_b is the bit rate

B is the receiver noise bandwidth

Note that the overall system noise at baseband N is the sum of thermal and circuit noise. This leads to a figure of merit that describes the circuit's performance. It is called noise figure when expressed in decibels and noise factor otherwise. Noise factor or figure is a measure for the excess noise that is contributed by

the circuit to the overall noise and is defined as the ratio between the SNR at the input of the receiver (SNR_i) and the SNR at the output of the receiver (SNR_o)

$$NF = \frac{\mathrm{SNR_i}}{\mathrm{SNR_o}} = \frac{(S/N)_\mathrm{i}}{(S/N)_\mathrm{o}} \tag{4.2}$$

If the receiver consists of different building blocks, one may want to know the noise figures of the different blocks and not only the overall noise figure. One can prove that in case of a series connection [12]

$$\mathrm{NF_{total}} = \mathrm{NF_1} + \frac{\mathrm{NF_2} - 1}{G_1} + \frac{\mathrm{NF_3} - 1}{G_1 G_2} + \cdots \tag{4.3}$$

where

NF_i are the noise factors of successive building blocks
G_i is their respective power gain

One can easily conclude from Equation 4.3 that building blocks earlier in the receive chain have a larger contribution to the overall noise figure than blocks at the end of the chain. This is the reason behind the use of an LNA at the input of an RF receiver. The large power gain combined with a low-noise figure will relax the noise specifications for the following blocks. The principle is explained in Figure 4.1. If an LNA is omitted and the mixer is put directly behind the antenna, the signal is drowned in the mixer noise and the sensitivity will be low. The power gain of the LNA, however, pushes the antenna signal above the noise floor of the mixer. As long as the output noise of the LNA is greater than the input noise of the mixer, the sensitivity is fully determined by the NF of the LNA.

RF systems often operate in an interference limited environment. Interference can also reduce receiver sensitivity. It is therefore more correct to describe the receiver sensitivity by its signal-to-noise plus interference ratio $S/(N+I)$ also known as the signal-to-noise and distortion ratio (SNDR). One of the mechanisms by which interference limits the performance is nonlinearity. It can reduce the signal power as well as increase interference. Large signals can saturate the receiver resulting in a gain compression, which reduces the signal power S. On the other hand, two large interfering signals can, due to non linearity, produce cross-product terms that fall on top of the wanted signal increasing the interference I. This cross-product generation is called intermodulation distortion (IMD). Nonlinearity performance is typically characterized by small signal linearity described by second-and third-order intercept points

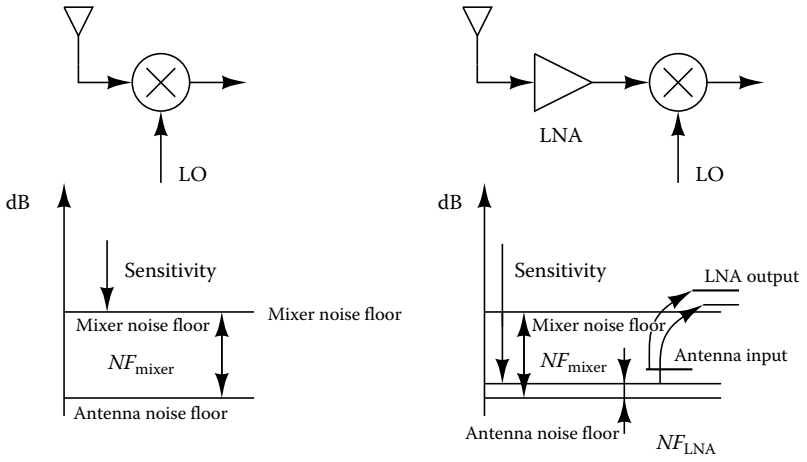

FIGURE 4.1 The benefit of using an LNA.

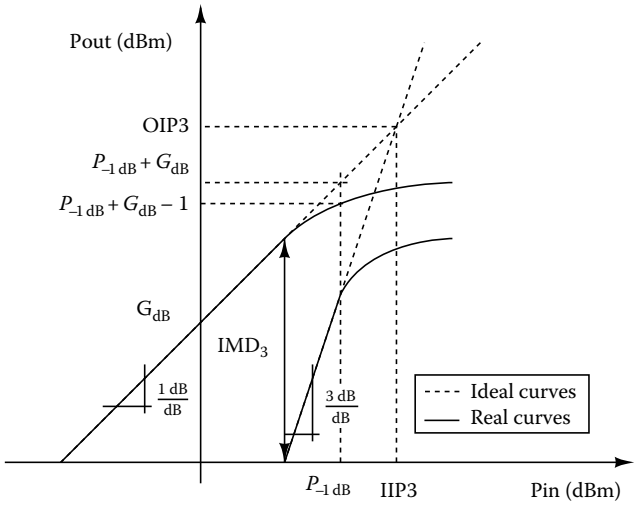

FIGURE 4.2 First- and third-order intermodulation as a function of the input power.

(IP2 and IP3) and large signal linearity described by the 1 dB compression point. Usually balanced topologies are used attenuating the second-order harmonics. Consequently, third-order nonlinearity will become the limiting factor. These concepts will be explained with the help of Figure 4.2. Gain compression is characterized by the 1 dB compression point ($P_{-1\ \mathrm{dB}}$) and is used to evaluate the ability of the system to cope with strong input or interference signals often referred to as blockers. It is defined as the input power for which the gain drops by 1 dB. By identifying the strongest signals at each stage of the design, one can calculate the required 1 dB compression point for each block in a receiver chain. As mentioned earlier, nonlinearity not only causes gain compression, but also generates IMD. This is produced by any pair of blockers that lie near the wanted signal. If two tones at f_1 and f_2 are applied to a nonlinear block, frequencies are produced not only at f_1 and f_2 but also at $2f_1 - f_2$, $2f_2 - f_1$, $3f_1$, $3f_2$, and so on. $f_1, f_2, 3f_1$, and $3f_2$ are not important since they lie far outside the frequency band of interest and can therefore be filtered out. $2f_1 - f_2$ and $2f_2 - f_1$, however, are potential problems as they can fall on top of the wanted signal band and remain unaffected by filtering. The ratio of any of the two cross products is called third-order IMD3. The output power of the intermodulation products grows at a faster rate than that of the wanted signal itself. Therefore, it follows that at a certain input power, the output power of the intermodulation signals will surpass the wanted signal. The input power level where this takes place is called the input-referred third-order intercept point (IIP3). The output power at this point is called the output-referred third-order intercept point (OIP3). Note that this is an imaginary point since gain compression occurs before this point is reached. If the receiver consists of different building blocks, one may want to know the contribution of the different building blocks to the overall linearity performance. One can prove that in case of a cascaded system

$$\frac{1}{\mathrm{IIP3}_{total}} = \frac{1}{\mathrm{IIP3}_1} + \frac{G_1}{\mathrm{IIP3}_2} + \frac{G_1 G_2}{\mathrm{IIP3}_3} + \cdots \tag{4.4}$$

where

$\mathrm{IIP3}_i$ are the input-referred third-order IPs of the successive building blocks
G_i is their respective power gain

One can conclude that, contrary to noise (see Equation 4.3), the last blocks in the receive chain has the largest influence on the overall linearity of the receiver. Equations 4.3 and 4.4 reveal a first trade-off. High gain at the input reduces noise constraints in the rest of the chain but increases the linearity requirements.

A last origin of distortion is due a nonideal local oscillator (LO) signal driving the mixers. In practice, the spectrum of an oscillator is never pure. There is always a certain amount of energy present close to the ideal LO frequency at $\omega_0 + \Delta\omega$. This can translate nearby frequency signals on top of the wanted signal also deteriorating the SNDR of the system. A figure of merit to describe this nonideal LO behavior is called the LO phase noise and is defined as the ratio of the power present in a 1 Hz band at a certain offset frequency $\Delta\omega$ from the carrier frequency ω_0 to the carrier power:

$$\mathcal{L}\{\Delta\omega\} = 10\log\left(\frac{\text{noise power in a 1 Hz band at } \omega_0 + \Delta\omega}{\text{carrier power}}\right) \tag{4.5}$$

4.2.3 RF Transceiver Architectures

In this section, a brief overview of some common transceiver structures will be discussed and contrasted to one another. The discussion will be restricted to the heterodyne transceiver, the zero-IF or direct conversion transceiver, and the low-IF transceiver. There exist numerous other types of transceivers but their properties can be understood by looking at these three structures as they are all variations or combinations of these three structures. First, the different receiver architectures will be discussed followed by there transmitter equivalent.

The heterodyne receiver has been the dominant choice in RF systems for many decades. The reason behind this is its high performance and adaptability to different standards. Figure 4.4 shows the operation of a heterodyne receiver. The broadband antenna signal is first fed to a highly selective RF filter (band select filter) that suppresses all interferers outside the wanted application band. An LNA boosts the wanted signal above the mixer noise floor and an LO generates a signal located at an offset frequency f_{IF} from the wanted signal. The result is that the following signals are down-converted by the mixer to f_{IF}

$$f_{wanted} = f_{LO} - f_{IF} \tag{4.6}$$

$$f_{image} = f_{LO} + f_{IF} \tag{4.7}$$

Not only the wanted signal is mapped onto IF (intermediate frequency), but also another signal called the image or mirror signal. This signal can corrupt the information content in such a way that the information is irreparable. To avoid this, an image reject filter is inserted before the mixer. This way, a highly attenuated version of the image signal is folded on top of the wanted signal, preventing the irreparable corruption of the information content of the signal. Figure 4.3 summarizes this operation. From Equation 4.6 and 4.7, one can see that the center of the image signal is located at a distance $2f_{IF}$ from the wanted signal. The choice of f_{IF} therefore determines the requirements for the image reject filter. If a very low f_{IF} is chosen, a very high-quality filter is needed to suppress the image frequency. To relax the filter specifications, f_{IF} is usually chosen relatively high and a series of down-conversion steps are performed. The heterodyne structure is then referred to as the superheterodyne receiver.

The heterodyne or superheterodyne receiver features a single path topology. Mismatch between different parts is not a issue here. Also LO feedthrough in the mixer is not a problem, since the wanted signal is never close to the LO frequency. In Figure 4.4, it can also be seen that the channel selection is done before the AGC-A/D structure. They will therefore only need to handle a limited dynamic range.

A drawback of the structure, however, is that all critical functions are realized with passive devices. Due to the high demands posed upon these structures, they are mostly implemented off-chip. The integratability of the heterodyne transceiver is therefore rather low. This induces an additional material cost. Moreover, the insertion loss of the passive filters needs to be compensated by a higher gain on-chip to keep the required SNR. Since the filters need to be driven at low impedance (e.g., 50 Ω), one has the choice between using complex impedance transformation structures or using low-output impedance

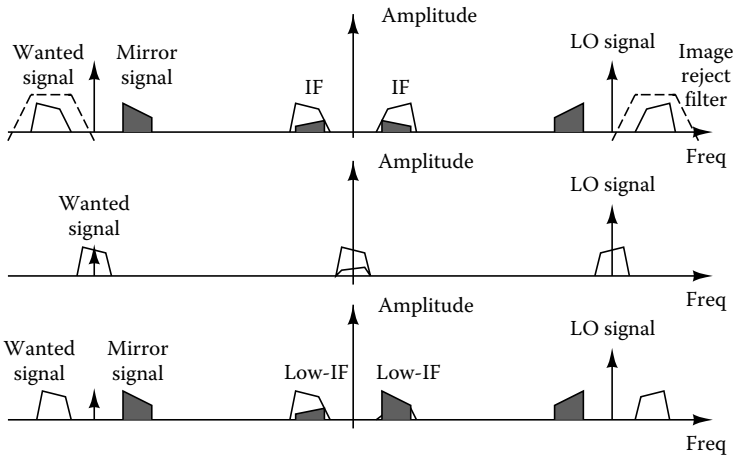

FIGURE 4.3 The down-conversion process in an IF, zero-IF, and a low-IF receiver.

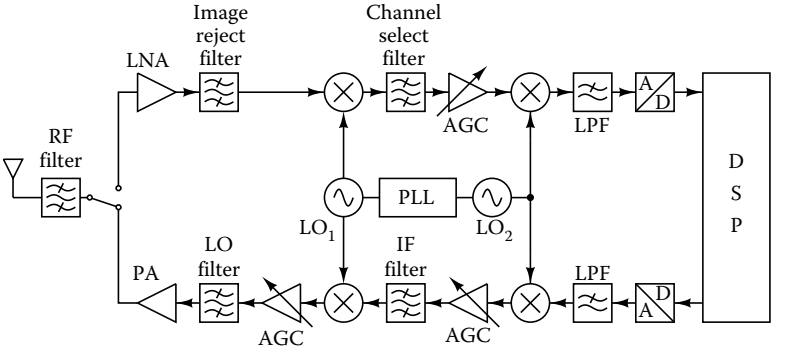

FIGURE 4.4 Heterodyne transceiver architecture.

buffers. Using low output impedance drivers, however, comes at the cost of an extra amount of extra power consumption.

The integratability however can dramatically be improved if one could find a way of getting rid of the external high-quality filters. This means looking for a way of suppressing the image frequency without filters. A first solution to this problem is obvious. Make the image signal the wanted signal or choose $f_{IF} = 0$. This solution is called the zero-IF receiver or direct-conversion receiver [13,14]. Another solution is related to the first one and is called the low-IF topology [3]. This topology takes advantage of the fact that the channels in the direct neighborhood of the wanted channel—the adjacent channels—are usually much weaker than the wanted signal and the signals laying further away. Furthermore, these frequency bands are usually regulated in the application specifications or by the FCC. So, if an IF-frequency is chosen so that the image frequency falls into this lower power bands, less image rejection is needed to keep the required SNR. Figure 4.5 shows the architecture of both a direct or zero-IF receiver and a low-IF receiver. The only difference between both can be found in the choice of IF-frequency. In a zero-IF receiver, the wanted channel is converted to DC and a mirrored version of the channel itself is superimposed onto the clean version of the signal. In a low-IF receiver, the wanted signal is down-converted to a low, nonzero IF, e.g., half the channel bandwidth, such that the mirror signal is the adjacent channel. The antenna signal is first passed through a band select filter. An LNA boosts the signal

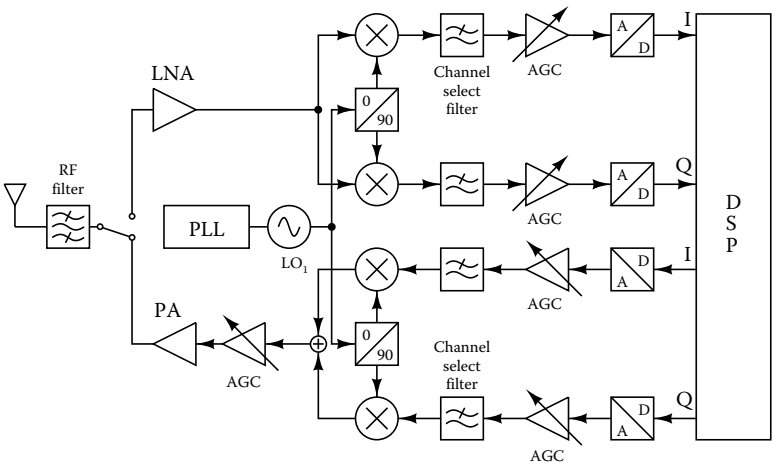

FIGURE 4.5 Direct transceiver architecture.

above the mixer noise floor. So far, there is no difference with the heterodyne receiver. After the LNA, however, the signal is fed to two different signal paths. The two signal paths are then down-converted by two mixers that are steered by two LO signals that are spaced 90° apart. The interstage filter has now become obsolete since the mirror signal will be neutralized by recombining the two signal paths after down conversion. This type of down conversion is called quadrature down conversion. Since the image signal and the wanted signal are separated in the digital signal processor (DSP), the real channel selection and image rejection are done in the digital back-end. This is a positive thing, since the digital domain is the natural biotope of CMOS. Since the image rejection and channel selection no longer rely on high-quality filtering, no external filters are required; therefore, one does not have to cope with their inevitable loss and one does not need low impedance drivers. This allows low power operation. However, the spreading of the signal over two independent signal paths has some drawbacks. The topology relies heavily on the symmetry between the two paths, every mismatch between the two paths will lead to a deterioration of the image suppression and an increased corruption of the wanted information content. Although one could think that that image rejection requirements are more relaxed for a zero-IF receiver since the image signal is a mirrored version of the wanted signal, this is not exactly true. For low-IF receivers, the image signal can be considered as noise for the wanted signal, since there is no correlation at all between the two bands. For zero-IF receivers, there is a strong correlation between image and wanted signal leading to a distortion of the wanted signal. The required image suppression is therefore dependent on the type of modulation that is used in the system. When a quadrature amplitude modulation (QAM) type modulation is used, one can calculate that the required image rejection for zero-IF is 20–25 dB while 32 dB rejection is required for low-IF systems [15]. As the wanted signals in both receivers are located at low frequencies (dc in case of zero-IF), the signal is susceptible to 1/f noise and dc-offset. Complicated feedback structures can get rid of the dc-offset; however, due to the finite time-constants in those loops, part of the signal is also canceled by the feedback. This can corrupt the signal in an unacceptable way. Low-IF topologies are less vulnerable. As long as the dc-offset does not saturate the A/D converters, there is no signal degradation. Due to the absence of filtering in the RF part, the A/D converters, however, have to deal with larger dynamic ranges. Fortunately, as the signals are at low frequencies, oversampled converters can be used which allow higher accuracies.

The same topologies exist for the transmitter side of the transceiver. The heterodyne as well as the direct up-conversion transmitter will be discussed. They are depicted in Figures 4.4 and 4.5. The early up-conversion architectures were in fact multistage architectures. They employed a number of mixing stages

and intermediate frequencies. The main advantage of this type of systems is that only one D/A converter is needed. Quadrature modulated signals are therefore generated in the digital domain. This topology puts high demands on the D/A converter since it must deliver signals at a higher IF frequency. The DSP on the other hand must be able to deliver perfectly matched I/Q signals. This approach requires the use of high-quality passives, multiple LOs. The same conclusions can be drawn as in the receiver. Due to the large number of external components, integratability is limited and power consumption will be high. Another implementation of this multistage architecture includes the use of two D/A converters. Quadrature modulated signals are then generated in the analog domain. Since they are generated at low frequencies, quadrature matching is superior. However, multiple RF filters are still needed, giving rise to a higher cost and power consumption. The topology, however, is not vulnerable to one of the main problems in the direct conversion architecture, oscillator pulling caused by the PA due to the fact that the PA output spectrum is far away from the voltage-controlled oscillator (VCO) frequency. Hereby the main problem in direct up-conversion circuits is addressed. In direct conversion transmitters, the transmitted carrier frequency is equal to the LO frequency. As can be seen in Figure 4.5, modulation and up conversion occur in the same circuit. The I/Q quadrature modulator takes the baseband (or low-IF) input signal and up-converts it directly to the desired RF frequency. This eliminates the need for RF passives and limits the number of amplifiers, mixers, and LOs. The simplicity of the architecture makes it an obvious choice when high integration levels are demanded. However, as mentioned before, the circuit suffers from one major drawback, the disturbance of the LO by the PA. This phenomenon is explained in detail in Refs. [16,17]. As the LO frequency lies in the transmit band, high demands are put on the LO/RF isolation. The system is also susceptible to I/Q mismatch errors, even the least phase mismatch or amplitude difference between I and Q path will result in distortion in the spectrum. However, the elimination of the IF stage in the transmitter leads to large saving in material cost and increases the robustness of the system as the number of discrete components that could fail is reduced. There is not only a cost saving in material cost, the direct up-converter architecture also allows a reduction in equipment size. This makes the circuit first choice for applications with stringent space constraints [18].

4.3 Technology

4.3.1 Active Devices

Since all high level or system level designs in the end need to be implemented in terms of actual active and passive components, it is no surprise that the transistor performance is of major importance for the overall system performance. It is therefore imperative to know the performance limitations of the technology one is working in and to be aware of the shortcomings of the model one is using. It is clear that conformity between measurements and simulation results will strongly depend on the accuracy of the models used with respect to the actual behavior of the devices. Although several compact models exist to describe MOSFET transistors, the BSIM [19] is considered as the de facto standard because it is the model that is generally provided by silicon foundries. Most models are quite accurate for low frequencies; however, most models fail when higher frequencies are to be modeled. ''High frequency'' means operating frequencies around 1/10th of the transistor's cutoff frequency f_t. Figure 4.6 gives an overview of f_t for different technology nodes. For a standard 0.18 μm technology with an f_t of around 50 GHz, this means 5 GHz is considered to be a high frequency. Another parameter is plotted in Figure 4.6, $f_{3\,dB}$ reflects the speed limitation of a transistor in a practical configuration. It is defined as the 3 dB point of a diode connected transistor [20] and takes into account the parasitic speed limitation due to overlap capacitances, drain-bulk junction, and gate-source capacitance while f_t only models the parasitic effect of the gate-source capacitance. In Ref. [21], an extended transistor model is presented that can be used for circuit simulation at RF frequencies. It is shown in Figure 4.7. All the extrinsic components are pulled out of the MOS transistor model, so that the MOS transistor symbol only represents the intrinsic part of the device. This allows to have access to internal nodes and model extrinsic components such as series

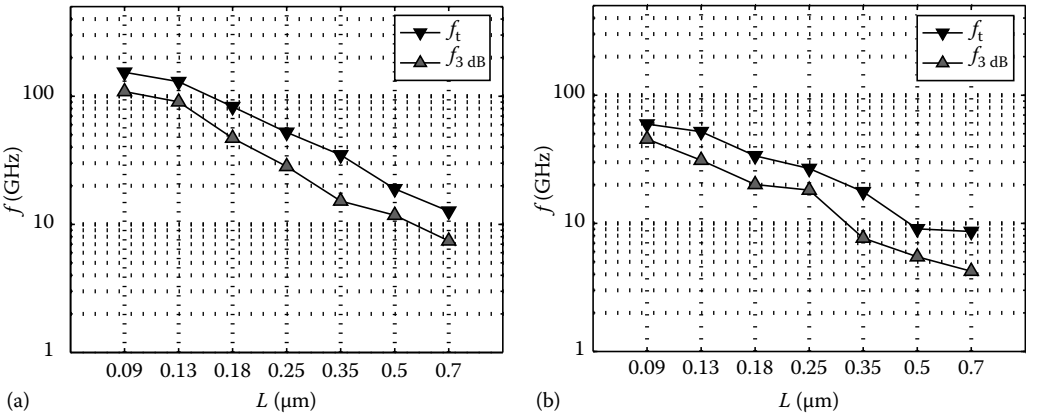

FIGURE 4.6 Maximum operating frequencies for different technology nodes.

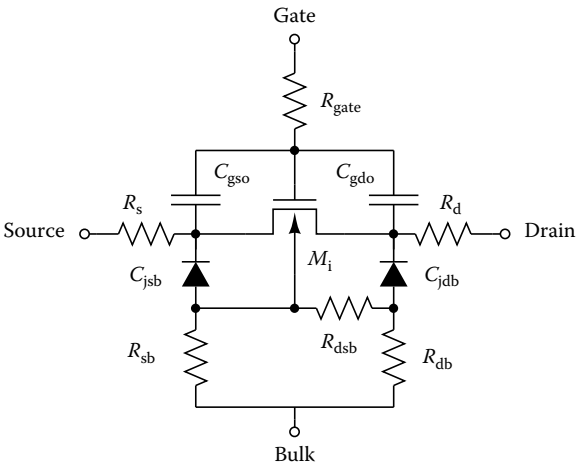

FIGURE 4.7 Extended RF transistor model.

resistances and overlap capacitances in a different way than what is available in the complete model. The source and drain series resistors are added outside the MOS model since the series resistances internal to the compact model are only used in the calculation of the I–V characteristic to account for the dc voltage drop across the source and drain. They do not add any poles and are therefore invisible for ac simulation. The gate resistance is usually not part of a MOSFET model, but plays a fundamental role in RF circuits and is therefore of outmost importance. The substrate resistors R_{dsb}, R_{sb}, and R_{db} have been added to account for the signal coupling through the substrate. Apart from the extra components added in the extended transistor model presented in Ref. [21], another point deserves some attention. The classical transistor model is based on the so-called quasi-static assumption. This means that any positive (negative) change in charge at the gate is immediately compensated by a negative (positive) change of charge in the channel. In reality, however, there will always be a delay in the charge buildup in the channel. Individual electrons (holes) will need a finite time to travel from bulk to the channel. This effect is called the non-quasi-static effect and has been described in Ref. [22–24]. This effect can be modeled by adding a resistance in series with the gate-source capacitance, introducing an extra time constant in the model.

$$\tau_{gs} = \frac{C_{gs}}{5g_m} = \frac{1}{5\omega_t} \tag{4.8}$$

This model is valid in strong innversion and within the long channel approximation. Although one could think that this effect is neglectable at realistic operating frequencies much lower than f_t, in bandpass applications, the gate-source capacitance can be tuned away by an inductor making the input impedance of the transistor purely resistive.

4.3.2 Passive Devices

For a long time, CMOS RF integration was believed to be impossible due to the poor quality of passive devices. Smaller CMOS geometries and innovative design and layout [25–27], however, have enabled high-quality passive components at high frequency to be integrated on chip. Four passive devices (resistors, inductors, capacitors, and varactors) will be discussed. First, one needs of figure of merit to qualify these passive devices. In general, the Q-factor is used for this purpose. Although there exist several definitions for the Q-factor, the most fundamental definition is based on the ratio between the maximum energy storage and the average power dissipation during one cycle in the device.

$$Q = \frac{\omega W_{\max}}{P_{\text{diss}}} \tag{4.9}$$

For an overview of other definitions of the Q-factor, the reader is referred to Ref. [28]. For a purely reactive element (capacitor or inductor), current through the element and voltage over the element are 90° out of phase. Hence, no power is dissipated in it. In real live, however, a certain amount of power will always be dissipated. Power dissipation supposes the presence of a resistance and a resistance always generates thermal noise. The Q-factor consequently is also a way of describing the pureness of a reactive device. Figure 4.8 shows some very common structures used in the modeling of reactive components used in RF circuits together with their Q-factor according to Equation 56.9. Low-Ohmic resistors are commonly available now in all CMOS technologies and their parasitic capacitance is such that they allow for more than high enough bandwidth. A more important passive device is the capacitor. In RF circuits, capacitors can be used for AC coupling. This enables DC-level shifting between different stages resulting in an extra degree of freedom enabling an optimal design of each stage. It also offers the possibility of lowering the power supply voltages. Another field, although not completely RF, where capacitors are commonly used is to implement switched capacitor circuits or arrays. This is favorable to using common resistors since capacitors in general offer better matching properties than resistors. The quality of an integrated capacitor is mainly determined by the ratio between the capacitance value and the value of the parasitic capacitance to the substrate. Too high a parasitic capacitor loads the transistor stages, thus reducing their bandwidth, and it causes an inherent signal loss due to a capacitive division.

The passive device, however, that got the most attention in the past is the inductor. It was long believed that high-quality integrated inductors were simply impossible in standard CMOS processes [29] and

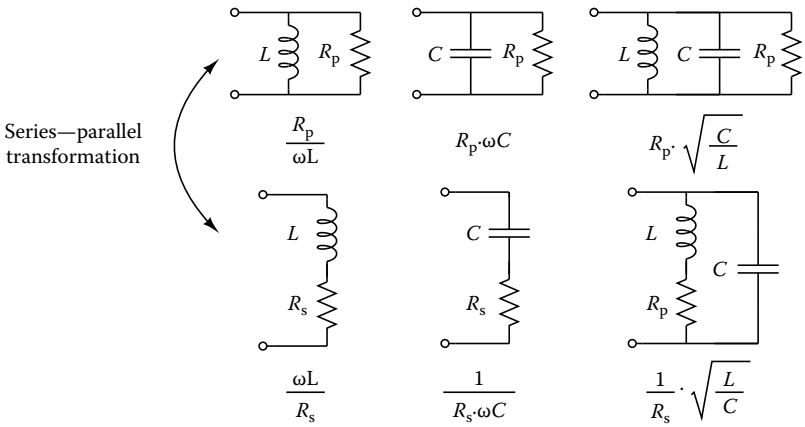

FIGURE 4.8 Quality factors of some common circuits.

could better be avoided if possible. However, due to the use of hollow spiral inductors and slightly altered process technology (thick top metal layer), one is now able to produce high-Q inductors in CMOS. The use of inductors on chip allows a further reduction of the power supply and offers compensation for parasitic capacitors by tuning them away resulting in higher operating frequencies. To be able to use integrated inductors in actual designs, an accurate model is needed. Reference [30] introduces such a model. One of the problems faced when modeling an inductor is how to model the substrate. One of the major drawbacks of inductors is the losses introduced by the substrate underneath the coil by capacitive coupling and eddy currents. This reduces the quality factor of the inductor.

A last passive component that is often encountered in RF CMOS designs is the varactor. It is mostly used for implementing tunable RF filters and VCOs. The different varactor types can be put in two classes: junctions and MOS capacitors. The latter can be used in accumulation and in inversion mode. For all cases, the devices have to be placed in a separate well to be able to use the well potential as the tuning voltage. For a standard NWELL process, the available configurations are therefore limited to p^+/n^- junction diodes and PMOS capacitors. When comparing the different varactor types, one should look at the following specifications: the varactor should offer a high Q-factor, the tuning range over which the capacitance can be varied should be compatible with the supply voltages used in the design, the physical structure should be as compact as possible to limit the area and its capacitance variation should be uniform over the complete tuning range as this makes feedback design easier. For an extended discussion about the different varactor types and their performance, the reader is referred to Ref. [27].

4.4 Receiver

4.4.1 LNA

The importance of the LNA has been explained earlier. The LNA is used to boost the received signal above the mixer noise floor. It is therefore critical that the LNA itself produces little noise. The noise figure of an LNA embedded in a 50 Ω system is defined as

$$\mathrm{NF} = 10 \log_{10} \left(\frac{\text{LNA output noise}}{\text{LNA output noise if the LNA itself was noiseless}} \right) \tag{4.10}$$

that is the real output noise power (dv^2/Hz) of the LNA (consisting of the amplified input noise power and all noise contributions generated in the LNA itself) divided by the amplified input power. Figure 4.9 shows some common input structures. Figure 4.9a shows a nonterminated common source input stage. Figure 4.9b shows the same input stage but now with an impedance matching at the input. Figure 4.9c shows the common gate input structure and finally Figure 4.9d shows a transimpedance amplifier

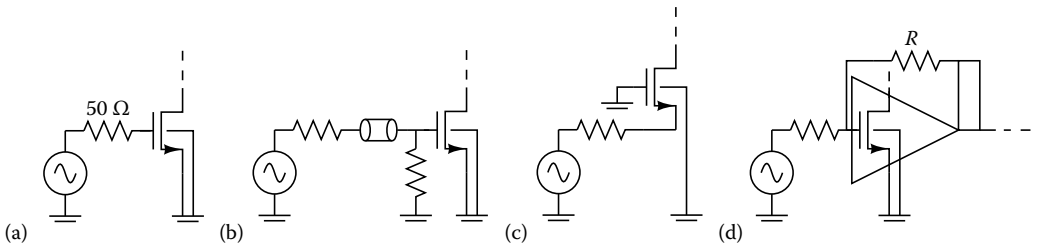

FIGURE 4.9 Some common LNA topologies.

structure that is commonly used for wideband applications. Their respective noise figures can be approximated with the following equations:

$$\text{Common source nonterminated (Figure 4.9a):} \quad \text{NF} = 1 + \frac{1}{50 \cdot g_m} \tag{4.11}$$

$$\text{Common source terminated (Figure 4.9b):} \quad \text{NF} = 2 + \frac{1}{50 \cdot g_m} \tag{4.12}$$

$$\text{Common gate (non)terminated (Figure 4.9c):} \quad \text{NF} = \left[\frac{1 + 50 \cdot g_m}{50 \cdot g_m}\right]^2 + \frac{1}{50 \cdot g_m} \tag{4.13}$$

$$\text{Common source transimpedance (Figure 4.9d):} \quad \text{NF} = 1 + \frac{1}{50 \cdot g_m} \cdot \left[\frac{R + 50}{R}\right]^2 + \frac{50}{R} \tag{4.14}$$

Figure 4.10 compares the noise figures of the different topologies. It is clear that the transimpedance structure and the not terminated common source circuit are far superior compared to the other structures as far as noise is concerned. For those circuits, the NF can be approximated as

$$\text{NF} - 1 \approx \frac{1}{50 \cdot g_m} = \frac{(V_{gs} - V_T)}{2 \cdot 50 \cdot I} \tag{4.15}$$

indicating that a low noise figure requires a large transconductance in the first stage. To generate this transconductance with high power efficiency, we need to bias the transistor in the region with a large transconductance efficiency, i.e., low $V_{gs} - V_T$. This, however, will result in a large gate-source capacitance limiting the bandwidth of the circuit. Together with the 50 Ω source resistance, the achievable bandwidth is limited by

$$f_{3\ \text{dB}} = \frac{1}{2\pi 50 C_{gs}} \tag{4.16}$$

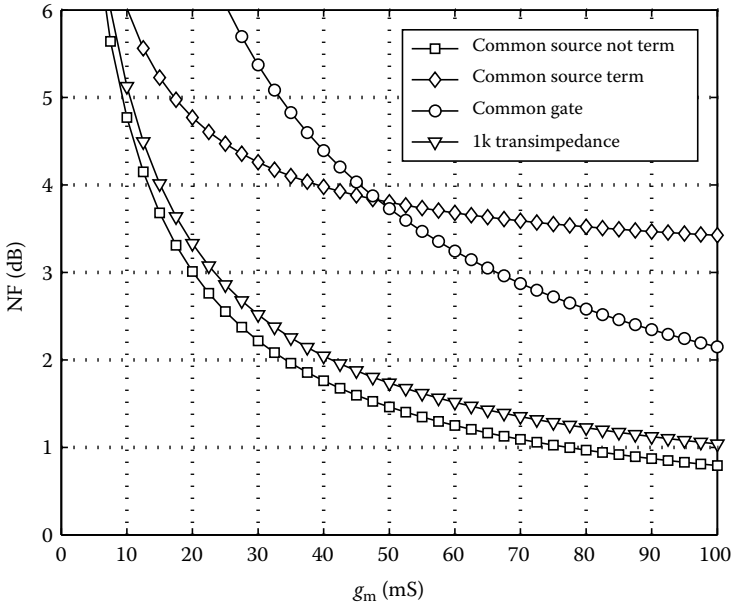

FIGURE 4.10 LNA input structure performance comparison.

When using the well-known approximative expression for the cutoff frequency of a transistor f_T

$$f_T = \frac{g_m}{2\pi C_{gs}}$$

one can conclude that

$$NF - 1 = \frac{f_{3\ dB}}{f_T} \tag{4.17}$$

This means that a low noise figure can only be achieved by making a large ratio between the frequency performance of a transistor, represented by f_T and the theoretical bandwidth $f_{3\ dB}$ of the circuit. Note that the $f_{3\,dB}$ used here is not the same as the one used in Section 4.3. Since f_T is proportional with $V_{gs} - V_T$, a low noise figure requires a large $V_{gs} - V_T$ and associated with it a large power drain. Only by going to deep submicron technologies will f_T become large enough to achieve low noise figures for gigahertz operation with low power consumption. In practice, the noise figure is further optimized by using noise and source impedance matching. These matching techniques often rely on inductors to cancel out parasitics by creating resonant structures. This boosts the maximum operation frequency to higher frequencies. More information concerning the design and optimization of common source LNAs can be found in Refs. [15,31].

At high antenna input powers, the signal quality mainly degrades due to in-band distortion components that are generated by third-order intermodulation in the active elements. Long channel transistors are generally described by a quadratic model. Consequently, a one transistor device ideally only suffers from second-order distortion and produces no third-order intermodulation products. As a result, high IIP3 values should easily be achieved. When transistor lengths shrink, however, third-order intermodulation becomes more important.

To start the analysis of the main mechanisms behind third-order intermodulation, one needs an approximate transistor model. A drain current equation that is strongly related to the SPICE level 2 and level 3 model is

$$I_{ds} = \frac{\mu_0 C_{ox}}{2n} \cdot \frac{W}{L} \cdot \frac{(V_{gs} - V_T)^2}{1 + \Theta \cdot (V_{gs} - V_T)} \tag{4.18}$$

with

$$\Theta = \theta + \frac{\mu_0}{L_{eff} \cdot v_{max} \cdot n} \tag{4.19}$$

where

- θ stands for the mobility degradation due to transversal electrical fields (surface scattering at the oxide–silicon interface)
- $\mu_0/(L_{eff} \cdot v_{max} \cdot n)$ models the degradation due to longitudinal fields (electrons reaching the thermal saturation speed)

As the θ-term is small in todays technologies, it can often be neglected relative to the longitudinal term. It can be seen from Equation 4.18 that for large values of $V_{gs} - V_T$, the current becomes a linear function of $V_{gs} - V_T$. The transistor is then conducting in the velocity saturation region. For smaller values of $V_{gs} - V_T$, the effect of Θ consists apparently in linearizing the quadratic relationship, but in reality, the effect results in an intermodulation behavior that is worse than in the case of quadratic transistors. The second-order modulation will be lower, but it comes at the cost of a higher third-order intermodulation. The following equations can be found by calculating the Taylor expansions of the drain current around a certain $V_{gs} - V_T$ value [32]:

$$\text{IIP2} \cong 10 + 20\log_{10}\left(\left(V_{gs} - V_T\right) \cdot (1 + r) \cdot (2 + r)\right) \tag{4.20}$$

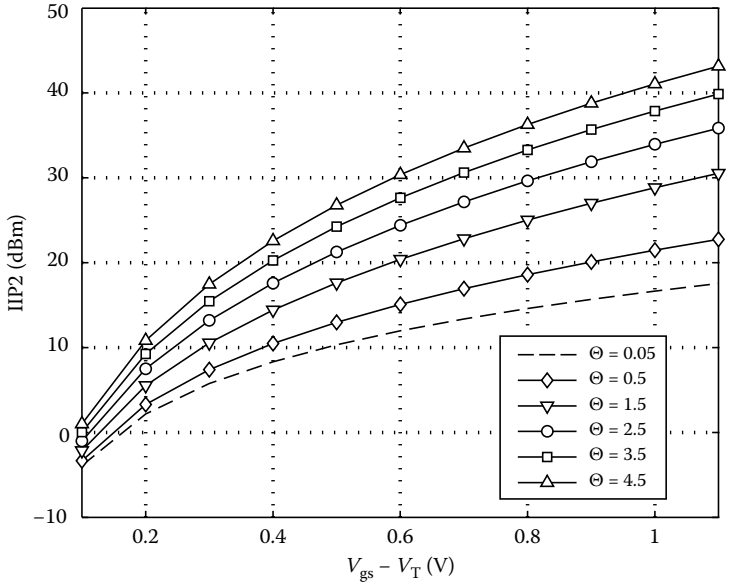
$$\text{IIP3} \cong 11.25 + 10\log_{10}\left(\left(V_{gs} - V_T\right) \cdot V_{sv} \cdot (1 + r)^2 \cdot (2 + r)\right) \tag{4.21}$$

where

$$V_{sv} = \frac{1}{\Theta} \tag{4.22}$$

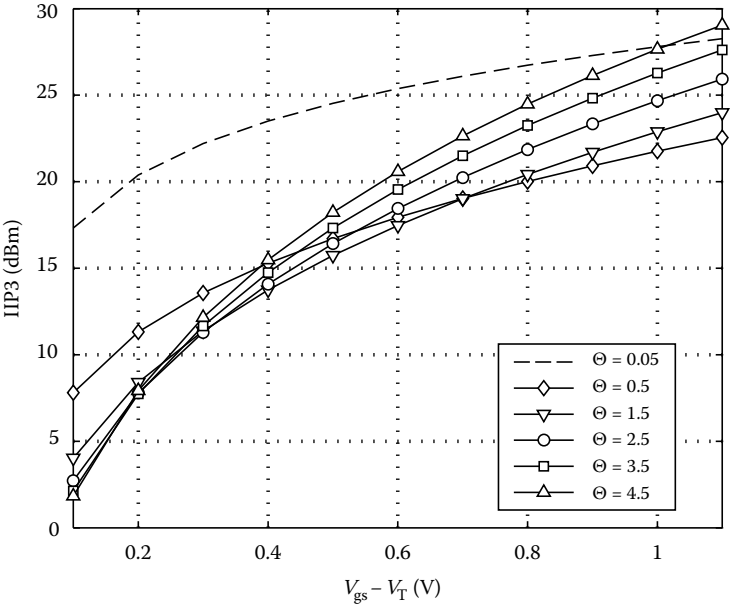
represents the transit voltage between strong inversion and velocity saturation and

$$r = \frac{V_{gs} - V_T}{V_{sv}} \equiv \Theta \cdot \left(V_{gs} - V_T\right) \tag{4.23}$$



denotes the relative amount of velocity saturation. The transit voltage V_{sv} depends only on technology parameters. For deep submicron processes, this voltage becomes even smaller than 300 mV, which is very close to the $V_{gs} - V_T$ at the boundary of strong inversion. The expressions for IIP2 and IIP3 are normalized to 0 V dBm, the voltage that corresponds to a power of 0 dB in a 50 Ω resistor. For a given L_{eff}, the IIP3-value of a transistor is only a function of the gate overdrive voltage. Figure 4.11 plot the IIP2 and IIP3 in function of the gate overdrive voltage for different values of Θ. It can be seen that for a certain value of $V_{gs} - V_T$, the IIP2 increases for increasing Θ (decreasing gate lengths) which proves former statements. The picture becomes a bit more complicated when looking at the IIP3 plot. For practical values of Θ, one can distinguish two regions in the $V_{gs} - V_T$ domain. For high gate overdrive voltages, deep submicron transistors clearly exhibit better linearity because the saturation voltage becomes lower and the transistor will reach velocity saturation earlier. Short channel transistors therefore offer a maximum amount of linearity at a given power supply and require minimum $V_{gs} - V_T$ for a given IIP3. On the other hand, for low overdrive voltages, short channel transistors perform worse. Thus, to ensure a certain amount of linearity, one has to bias the transistors at a high enough overdrive voltage or apply some linearizing feedback technique (e.g., source degeneration). It can be shown that for the same equivalent g_m and the same distortion level, the required dc current is lower when local feedback is provided at the source. It comes, however, at the cost of a larger transistor and this can compromise the amplifier bandwidth.

4.4.2 Down Converter



The most often used topology for a multiplier is the multiplier with cross-coupled variable transconductance differential stages. The use of this topology or related topologies (e.g., based on the square law) in CMOS is limited for high-frequency applications. Two techniques are used in CMOS: the use of the MOS transistor as a switch and the use of the MOS transistor in the linear region.

The technique often used in CMOS downconversion for its ease of implementation is subsampling on a switched-capacitor amplifier [33,34]. Here, the MOS transistor is used as a switch with a high input bandwidth. The wanted signal is commutated via these switches. Subsampling is used in order to be able to implement these structures with a low frequency op-amp. The switches and the switched capacitor circuit run at a much lower frequency (comparable to an IF frequency or even lower). The clock jitter must, however, be low so that the high frequency signals can be sampled with a high enough accuracy. The disadvantage of subsampling is that all signals and noise on multiples of the sampling frequency are folded upon the wanted signal. The use of a high-quality HF filter in combination with the switched capacitor subsampling topology is therefore absolutely necessary.

In Ref. [3], a fully integrated quadrature down-converter is presented. The circuit requires no external components, nor does it require tuning or trimming. It uses a double-quadrature structure, which renders a very high performance in quadrature accuracy. The down-converter topology is based on the use of MOS transistors in the linear region. By creating a virtual ground, a low frequency op-amp can be used for down conversion. The MOS transistor in the linear region results in a very high linearity for both the RF and the LO signal.

(a) Second-order intermodulation point

(b) Third-order intermodulation point

FIGURE 4.11 Linearity as a function of the gate overdrive voltage.

4.5 Synthesizer

One fundamental building block in every RF transceiver is the frequency synthesizer. The frequency synthesizer is responsible for generating the LO signal. The signal generated by the frequency synthesizer needs to be clean since low oscillator noise is crucial for the quality and reliability of the information

transfer. The signal should also be programmable and fast switching to be able to address all frequency channel within the specified time frame.

4.5.1 Topology

Synthesizers can usually be divided into three categories: table look-up synthesizer, the direct synthesizer, and the indirect or PLL synthesizer. In a table look-up synthesizer, the required sinusoidal frequency is created piece by piece using digital representations stored in memory of the amplitude at different time points of the sinusoidal waveform. The required building blocks are an accumulator that keeps track of the time, a memory containing a sine, a digital-to-analog converter (DAC), and a low-pass-filter to perform interpolation of the waveform to remove high frequency spurs. This type of synthesis is limited in frequency due to the access time of the memory and due to the maximum operation frequency of the high accuracy DAC. Moreover, high frequency spurs, generated due to the sampling behavior of the system, tend to corrupt the spectral purity of the signal. The direct frequency synthesizer employs multiplication, division, and mixing to generate the wanted frequency from a single reference. By repeatedly mixing and dividing, any accuracy is possible. The output spectrum is as clean as the reference frequency spectrum. Very fast frequency hopping is possible. The main disadvantages of this type of system is the difficult layout of the system, the high power consumption due to the numerous components, and the spectral purity can be corrupted by cross-coupling between stages. For generating high frequencies, the indirect or PLL type of frequency synthesizer often is the best choice. In a PLL, the synthesized frequency is generated by locking a locally generated frequency to an external frequency. The external frequency originates from a low frequency high quality crystal oscillator. To generate to local signal in the PLL, a VCO is used. A simple PLL topology is shown in Figure 4.12. A PLL includes following the building blocks: a VCO, a phase/frequency detector (PD/PFD), a loop filter, and a frequency divider or prescaler. The last building block is needed to derive a low frequency signal from the LO. This allows the signal to be locked to the external frequency through means of the PD. The PD is a circuit that compares the external frequency phase with the locally generated frequency phase and outputs an error voltage proportional to the phase difference. After filtering, this error signal is fed back to the VCO. This constitutes a control system. Under lock conditions, the external frequency and the locally generated frequency have a constant phase relationship.

$$F_{\text{out}} = N \cdot F_{\text{ref}} \tag{4.24}$$

The two signals are locked to each other, hence the name PLL. Even when a low-quality LO signal is generated, a high-quality signal can be synthesized. Due to the phase relationship between the input and the output frequency, the output signal will have the same spectral purity as the input high-quality signal. This is due to the fact that the loop remains locked to the input phase and therefore follows the phase deviations of that signal thus taking over its phase noise. This, however, is only true as long as the loop dynamics can follow the input signal. The loop dynamics are mainly determined by the bandwidth of the loop. For offset frequencies below the loop bandwidth, the phase noise is determined by the phase noise of the reference signal, for frequency offsets above the loop bandwidth, the output phase noise will be determined by the phase noise of the locally generated signal.

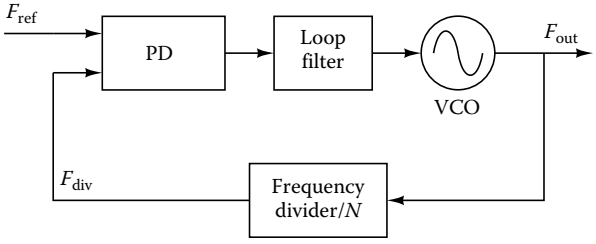


FIGURE 4.12 PLL-based frequency synthesizer.

When a programmable frequency divider is used in the loop, one can see that a set of frequencies can be synthesized. Suppose that the frequency by which the output signal is divided can be varied between N_1 and N_2, the output becomes

$$F_{\text{out}} = N_1 \cdot F_{\text{ref}},\ (N_1 + 1) \cdot F_{\text{ref}}, \ldots, N_2 \cdot F_{\text{ref}} \tag{4.25}$$

The PLL synthesizer is inherently slower than the other two types of synthesizers. The switching speed between two frequencies in Equation 4.25 is mainly determined by the loop bandwidth. Fast switching is only possible if a high loop bandwidth is implemented. Note that the loop bandwidth will also determine the phase noise performance. One, however, cannot indefinitely enlarge the loop bandwidth for stability reasons. A rule of thumb is that the loop bandwidth may not exceed 10% of the reference frequency to maintain stability. The loop bandwidth will also be limited by phase noise constraints. Spurious suppression and in-band phase noise levels will ultimately determine the loop bandwidth. When a low bandwidth has to be implemented, large capacitors will be needed. The total capacitance value is mainly determined by the need for implementing a stabilizing low frequency zero in the loop filter. This makes integration difficult as it will blow up silicon area and therefore increases the cost. One must therefore find ways to implement small bandwidth without having to use large capacitors. One obvious way of doing this is creating a low frequency pole through the use of a large resistance. This, however, will increase the phase noise. Other techniques, however, exist. In Ref. [35], a dual path loop filter is used. The filter consists of one active path and one passive path. Combining both will create a low frequency zero without the need for an extra resistor and capacitor. In Ref. [36], another technique is used to create the low frequency zero. It is created in the digital domain. The signal in the loop filter is combined with a sampled delayed version of itself. If the required switching speed is not achieved with a PLL configuration, one can make a combination of the direct synthesizer with the indirect synthesizer. In this topology, a number of PLLs are implemented and the outputs of all are combined with mixers. In this way, it is possible to synthesize a wide frequency range with a fast switching speed. This technique has recently been adopted for use in ultrawide band systems [37]. The major drawback of this technique, however, is that single sideband mixers have to be used. This requires accurate quadrature phases in all PLLs, low harmonic distortion, and well-matched mixers.

4.5.2 Oscillator

As it was mentioned above, the VCO is the main source of the phase noise outside the loop bandwidth. Therefore, its design is one of the critical parts of a PLL design. For the design of sub-gigahertz VCO, two oscillator types are often used: ringoscillators and oscillators based on a resonant tank composed of an inductor and a capacitor. The last type is referred to as an LC-tank VCO. The inductor in an LC-tank VCO can be implemented in two ways: an active implementation and a passive implementation. It can be shown [38,39] that the phase noise is inversely proportional to the power consumption. In LC-tank VCOs, the power consumption is proportional to the quality factor of the tank. Equations 4.26 through 4.28 show this relationship.

$$\text{Ring Osc. [39]}: \quad \mathcal{L}\{\Delta\omega\} \sim kTR \cdot \left(\frac{\omega}{\Delta\omega}\right)^2 \quad \text{with} \quad g_m = \frac{1}{R} \tag{4.26}$$

$$\text{Active LC [38]}: \quad \mathcal{L}\{\Delta\omega\} \sim \frac{kT}{2\omega C} \cdot \left(\frac{\omega}{\Delta\omega}\right)^2 \quad \text{with} \quad g_m = 2\omega C \tag{4.27}$$

$$\text{Passive LC [38]}: \quad \mathcal{L}\{\Delta\omega\} \sim kTR \cdot \left(\frac{\omega}{\Delta\omega}\right)^2 \quad \text{with} \quad g_m = R(\omega C)^2 \tag{4.28}$$

It is clear that for high frequency, a low power solution is only viable with an LC-tank VCO with a passive inductor. The use of a passive inductor, however, comes at a severe area penalty. Moreover, as it was discussed in Section 4.3, high-quality integrated inductors are difficult to make. For extremely low phase noise VCOs, bond wire inductors have been investigated [38]. The main drawback of using bondwires as inductors lies in reliability and yield. It is very difficult to make two bondwires exactly the same and reproduce this several times.

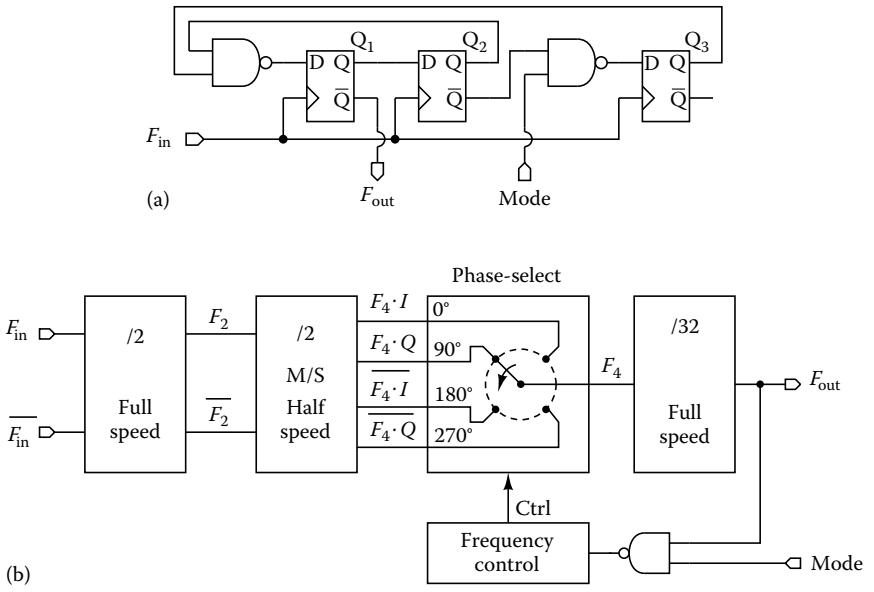

FIGURE 4.13 Dual modulus prescaler architecture: (a) D-flipflop based and (b) phase select topology. (From Craninckx, J. and Steyaert, M. *IEEE J. Solid-State Circuits*, 30(12), 1474, 1995.)

4.5.3 Prescaler

Several structures can be used as programmable divider. Programmable counters are the easiest solutions and are available in standard cell libraries. They are, however, limited in operation frequency. When high frequencies need to be synthesized, one can use a so-called prescaler. A prescaler divides by a fixed ratio and can therefore operate at high frequencies because they do not have to allow for delays involved with counting and presetting. A few high speed prescaller stages lower the speed used in the following counter stages. The disadvantage is that for a certain frequency resolution, the reference frequency has to be lowered. This slows the loop down as a lower bandwidth has to be implemented to maintain stability in the loop. A solution to this resolution problem is the use of dual- or multi-modulus prescalers. This circuit extends the prescaler with some extra logic to allow the prescaler to divide by N and $N+1$ in case of a dual-modulus prescaler and by N to $N+x$ in case of a multi-modulus prescaler. The speed decrease of this extra circuitry can usually be kept limited. Figure 4.13 shows two possible implementations of a dual-modulus prescaler. Implementation given by Figure 4.13a is a straightforward implementation based on d-flipflops. The critical path consists of a NAND gate and a d-flipflop. Implementation given by Figure 4.13b is a more complex implementation. It is based on the 90° phase relationship between the outputs of a master/slave toggle flipflop. It contains no additional logic in the high frequency path. The dual-modulus prescaler is as fast as an asynchronous fixed divider.

4.5.4 Fractional-*N* Synthesis

As it can be concluded from Equation 4.25, the minimal frequency resolution that can be achieved when using the topologies described previously is equal to F_{ref}. In GSM, e.g., the channels are 200 kHz spaced apart, this means that we need a frequency resolution of 200 kHz and therefore a low reference frequency. This results in high division ratios. The in-band phase noise of a PLL, however, is proportional to the division ratio, large ratios mean high in-band noise. As it is already explained, a low reference frequency will also result in a low PLL bandwidth and therefore a slow loop. Therefore, we need a technique that enables us to use a high reference frequency and still achieve the required frequency resolution. Fractional-N synthesizers solve this problem. Figure 4.14 makes things clearer. A basic fractional-N

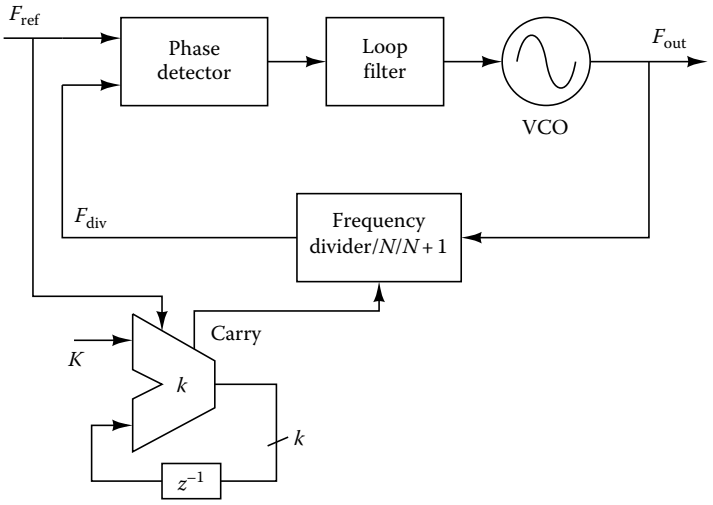

FIGURE 4.14 Fractional-N principle.

synthesizer consists, besides the standard PLL building blocks, of an accumulator and a dual modulus prescaler. By switching fast between the two division ratios, fractional divisions can be synthesized. The accumulator increases its value every reference clock cycle with a certain amount $K = n \cdot 2^k$. The dual-modulus prescaler is controlled by the accumulator overflow bit. If the accumulator overflows, the division ratio is $N+1$, otherwise it is N. On average, the dual-modulus prescaler divides K times by $N+1$ and $2^k - K$ times by N, resulting in a synthesized frequency of

$$N_{\text{frac}} = \frac{(2^k - K) \cdot N + K \cdot (N+1)}{2^k} = N + \frac{K}{2^k} = N + n \tag{4.29}$$

This means that also non-integer ratios can be synthesized and the above-mentioned limitations on the reference frequency is not applicable. There are, of course, drawbacks to the technique. The major one is the generation of spurs in the output spectrum due to pattern noise in the overflow signal. A detailed study of fractional-N synthesis, however, is beyond the scope of this chapter and the reader is referred to the open literature for further information. A thorough study of fractional-N synthesizers and their simulation can be found in Ref. [41].

4.6 Transmitter

Most RF communication systems are based on bidirectional data traffic. This means that apart from the receiver section, also a transmitter section must be implemented to complete a full transceiver. As explained in Section 4.2, a transmitter commonly includes a number of mixers, LO, and a PA. The LO is covered in a previous section; this section will therefore only describe the mixer and the PA used in up-conversion or transmitter systems.

4.6.1 Up versus Down Conversion

Although a huge amount of literature exists concerning the down-conversion process, up conversion has long time been neglected. This is rather surprising. When looking in Figure 4.5, one immediately notices

the parallelism between the receiver and the transmitter. The same functionality occurs. Both paths contain an amplifier (LNA, PA), both contain an interface to the digital domain (A/D, D/A), both contain a mixer and both are steered by the same LO system. The nature of the signals in both paths (input and output) has a huge influence on the circuit implementation. This seems logical for the LNA/PA analogy or the A/D and D/A-converter. Both have completely different topologies. Although the mixers in the up-conversion path and the down-conversion path face the same signals, there is typically not a great difference between the up- and down-conversion mixer topology. Most implementations are variations on the four-quadrant mixer topology, better known as the Gilbert-cell [42]. There are, however, fundamental differences between up conversion and down conversion. The first fundamental difference is located in the input signals of the mixer. In case of a down-conversion mixer, the input usually is a high-frequency, low-power signal surrounded by large blocking signals. In case of an up conversion, the input signal is a locally generated large baseband signal with a clean spectrum. At the output side, the situation is the opposite. A down-converted signal is a low frequency signal. It is, therefore, relatively easy to filter or apply feedback to cope with unwanted signals. At the transmitter side, however, a large and linear signal has to be processed within the technology dependend limited frequency range. Every extra building block placed between the mixer and the PA has to deal with high-frequency signals. Filtering is, therefore, impossible behind the up-conversion mixer as it will require large amount of power. Therefore LO leakage and other unwanted signals like intermodulation products have to be limited. A last, but not least difference lies within one of the design specifications of a mixer, the conversion gain G_c. It is defined as the ratio between the input power of the mixer and the output power. At the receiver side, the mixer input power is a design constraint as it is determined by the application. At the transmitter side, both input and output power are design variables. They can both be chosen freely. As it is easier and more power friendly to amplify a low-frequency signal, a large baseband signal is preferred.

4.6.2 CMOS Mixer Topologies

4.6.2.1 Switching Modulators

Many mixer implementations are based on the traditional variable transconductance multiplier with cross-coupled differential modulator stages [42]. It is depicted in Figure 4.15. The circuit was originally implemented in a bipolar technology and therefore based on its inherent translinear behavior. The MOS counterpart, however, can only be effectively used in switching mode. This induces the use of large LO driving signals and result in large LO feedthrough and power consumption. Moreover, when using a square-wave type modulation signal, a lot of energy is located at the third harmonic.

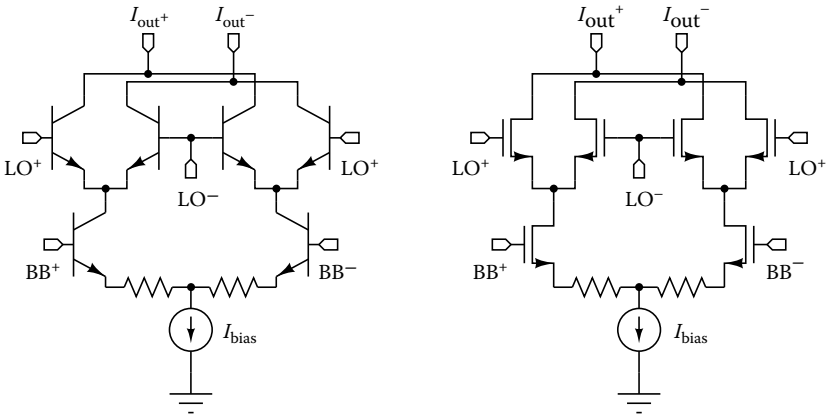

FIGURE 4.15 Bipolar and CMOS version of the Gilbert cell mixer.

This unwanted signal can only be filtered out by an extra blocking filter at the output. In CMOS the variable transconductance is typically implemented using a differential pair biased in the saturation region. To avoid distortion problems, large $V_{gs} - V_T$ values or a large source degeneration resistor is needed. This results in a large power consumption and noise problems. For upconversion, one also has to be aware that the high frequency current has to run through the modulating transistors. The source degeneration is therefore limited by bandwidth constraints. These problems can be circumvented by replacing the bottom differential pair with a pseudo-differential topology biased in the linear region [43].

4.6.2.2 Linear MOS Mixers

Figure 4.16 presents a linear CMOS mixer topology together with an output driver [44,45]. The circuit implements a real single-ended output topology avoiding the use of external combining. Some basic design ideas and some guidelines to optimize the circuit will be presented. The circuit is based on an intrinsically linear mixer topology. The circuit feature four mixer transistors biased in the linear region. Each mixer converts a quadrature LO voltage and a baseband signal to a linearly modulated current. The expression for the source-drain current for an MOS transistor in the linear region is given by

$$I_{DS} = \beta\left[(V_{GS} - V_T)V_{DS} - \frac{V_{DS}^2}{2}\right] \tag{4.30}$$

This equation can be rewritten in terms of a DC and an AC term:

$$\begin{aligned} I_{DS} &= \beta(V_{DS} + v_{ds}) \cdot \left(V_{GS} - V_T - \frac{V_D - V_S}{2} + v_g - \frac{v_d + v_s}{2}\right) \\ &= \underbrace{\beta V_{DS}\left(V_{GS} - V_T - \frac{V_D - V_S}{2}\right)}_{\text{DC component}} \\ &\quad + \underbrace{\beta v_{ds}\left(V_{GS} - V_T - \frac{V_D - V_S}{2}\right) + \beta V_{DS}\left(v_g - \frac{v_d + v_s}{2}\right) + \beta v_{ds}\left(v_g - \frac{v_d + v_s}{2}\right)}_{\text{AC component}} \end{aligned} \tag{4.31}$$

Two signal have to be applied to a mixer transistor, the low frequency baseband signal, and the high frequency LO signal. Applying these signals may only result in the wanted high-frequency currents. Based on Equation 4.31, some conclusions can be drawn.

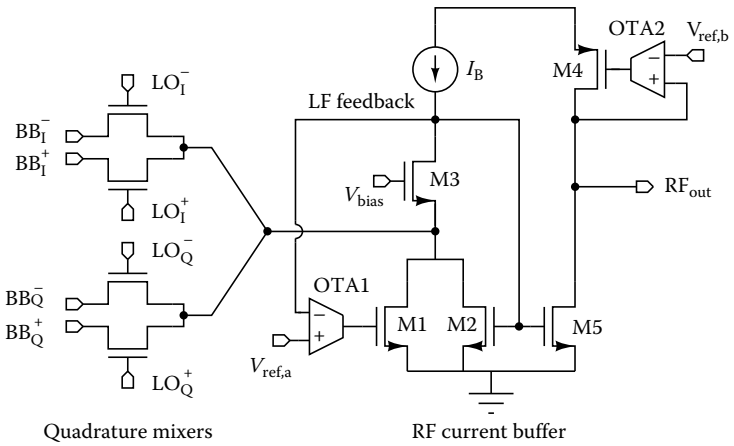

FIGURE 4.16 Schematic of a linear up-conversion mixer with output driver.

If the LO signal is applied to the drain/source of the mixer transistor, a product term

$$\beta v_{ds} \cdot \left(V_{GS} - V_T - \frac{V_D - V_S}{2} \right)$$

is formed. As this contains the product of a DC voltage with the oscillator signal, this component is located at LO frequency. It is preferable to avoid this frequency component to be formed. Therefore, the LO signal should not be applied to this node. Applying the LO signal to the gate of the mixer transistors results in the wanted behavior. According to Equation 4.31, only the high-frequency components are formed by

$$\beta v_g \cdot (V_{DS} + v_{ds})$$

By applying a zero-DC voltage between source and drain, only the high frequency mixer product is generated. The voltage to current conversion is perfectly balanced. The current of the four mixer paths is immediately added at the output of the mixers at a common node. This requires a virtual ground at that point that is achieved due to the low impedance input of the buffer stage (Figure 4.16). The total current flowing into the output buffer is given by

$$I_{MIX} = \beta \left(v_{bb_I}^2 + v_{bb_Q}^2 + 2 \cdot v_{LO_I} v_{bb_I} + 2 \cdot v_{LO_Q} v_{bb_Q} \right) \tag{4.32}$$

Equation 4.32 shows two frequency components in the modulated waveform. $\beta v_{LO} v_{bb}$ is the wanted signal. To prevent intermodulation products of the low frequency baseband signal $\beta v_{bb_I}^2$ with the wanted RF signal, the LF signal has to be suppressed at the current summing node. This is achieved by a low frequency feedback loop in the output buffer.

The low frequency feedback loop consists of OTA1 and transistors M1 and M3. It suppresses the low frequency signals resulting in a higher dynamic range of the output stage and decreases unwanted intermodulation products. It also lowers the input impedance of the output stage at low frequencies. The structure in fact separates the high- and low-frequency components of the input current and prevents the low frequency component to be mirrored to the output stage. The RF current buffer also ensures a low impedance at high frequencies at the mixer current summing node and therefore provides the necessary virtual ground.

4.6.2.3 Nonlinearity and LO Feedthrough Analysis

The difficulty to integrate IF filters is one of the reasons to implement direct conversion transmitters. This implies the the LO is at the same frequency as the RF signal and cannot be filtered out. To minimize the spurious signal components at the LO frequency, one has to isolate the origins of the unwanted frequency components. They can be categorized in three topics: capacitive feedthrough due to gate-source and gate-drain, parasitic overlap capacitances, and intrinsic nonlinearity of the mixers, mixer products due to a nonideal virtual ground.

When an ideal virtual ground is provided at the output of the mixer, capacitive LO feedthrough is canceled. This cancellation is never perfect, however, due to technology mismatch. The capacitive LO feedthrough for a single mixer transistor, biased in the linear region, is therefore given by

$$I_{LO} = 2\pi f \cdot v_{LO} \cdot WL \cdot \left(\frac{C_{ox}}{2} + \frac{C_{ov}}{L} \right) \tag{4.33}$$

where

c_{ox} is the oxide capacitance
C_{ov} is the gate-drain/source overlap capacitance
v_{LO} is the amplitude of the LO signal
f is its frequency

Based on Equations 4.32 and 4.33, the ratio between the LO feedthrough current and the modulated current is given by

$$\frac{i_{\text{signal}}}{\Delta(i_{\text{LO}})} = \frac{2\mu C_{\text{ox}} \frac{W}{L} v_{\text{bb}} v_{\text{LO}}}{\delta(i_{\text{LO}}) \cdot 2\pi f \cdot v_{\text{LO}} \cdot WL \cdot \left(\frac{C_{\text{ox}}}{2} + \frac{C_{\text{ov}}}{L}\right)} = \frac{\mu C_{\text{ox}} v_{\text{bb}}}{\delta(i_{\text{LO}}) \cdot \pi f \cdot L^2 \cdot \left(\frac{C_{\text{ox}}}{2} + \frac{C_{\text{ov}}}{L}\right)} \tag{4.34}$$

where $\delta(i_{\text{LO}})$ accounts for the relative difference in LO feedthrough for the different mixer transistors due to mismatch. Equation 4.34 shows that the ratio between the modulated current and the LO feedthrough current is independent from the LO amplitude and from the transistor width. Feedthrough will be less if shorter transistor lengths are used. The relative matching between the different mixer transistor will become worse, however, when shorter lengths are used [46]. One must therefore use Equation 4.34 with care. The δ will increase for smaller transistor length. With proper design and optimization, one should, however, be able to achieve a 30 dBC signal to LO feedthrough ratio even if two LO feedthrough currents are added instead of being canceled by the virtual ground ($\delta(i_{\text{LO}} = 1)$). When more realistic numbers of mismatch are considered (e.g., 10%), 50 dBC is easily achieved. The presented equations can, therefore, be used by the experienced designer to estimate the matching requirements and check if these requirements are realistic.

Another problem one faces is a possible DC-offset between the source and drain terminal of the mixer transistor. Equation 4.31 explains the problem. Ideally, no DC is present. The mixer then shows the required behavior. When a DC is present, however, one can see that components are generated at DC, the LO frequency due to multiplication with v_{g} and a component at baseband. While the low frequency components can be filtered out by the low frequency feedback in the output buffer, the component at the LO frequency remains. This component will, therefore, set the requirements for the tolerated DC-offset. A possible solution for this problem is measuring the DC-offset between source and drain. The offset is then controllable. The offset requirement is translated into an offset specification on the op-amps used in the feedback loops in the output buffer.

If the common mixer node is not a ideal virtual ground, the modulated current will be converted to a voltage dependent on the impedance seen on that node. The spectrum of the modulated signal will therefore be a combination of the modulated current spectrum and the frequency dependence of the impedance. When an impedance Z_{c} is considered at the common mixer node, the modulated current is given as the result of a second-order equation

$$\left(\beta Z_{\text{c}}^2\right) \cdot I^2 - (1 + 2\beta Z_{\text{c}} \cdot (V_{\text{GS}} - V_{\text{T}})) \cdot I + 2\beta v_1 v_{\text{g}} + \beta v_1^2 = 0 \tag{4.35}$$

It can be noticed that when $Z_{\text{c}} = 0$, Equation 4.35 is reduced to Equation 4.32. As Equation 4.35 is a second-order equation, it is a possible origin of distortion and therefore has to be taken into account. One side note should be made to the previous. Only currents that are not canceled out by the differential character of the mixer are converted in a voltage. This advantage of a balanced structure, however, is not valid for a nonideal voltage source at the input of the mixer transistors. If a nonideal voltage source is used at this node, each frequency component of the modulated current will be converted in a voltage according to the specific frequency-dependent impedance. These voltages are then similar to the baseband signal up-converted to the LO frequency. It is therefore essential to keep this node as low-impedance as possible.

Equation 4.32 is only valid if a very low impedance is seen at the source and drain terminals of the mixer transistors. If this condition is fulfilled, no unwanted high-frequency mixing components are present in the modulated signal. However, both in measurements and in simulations, a significant unwanted signal is noticed at $f_{\text{LO}} \pm 3f_{\text{bb}}$. One expects this component to originate from a $v_{\text{LO}} v_{\text{bb}}^3$ product term. However, Equation 4.35 only shows a second-order relationship. The observed product term must therefore find its origin in another effect. It is proved to be a result of short channel effects in an

MOS transistor. Both the effective mobility and the threshold voltage are affected by the gate-source and drain-source voltage. The calculated impact of the threshold voltage modulation cannot explain the observed effect; it is therefore assumed that it is a result of the mobility modulation. After some calculations, one can prove that the effective mobility is

$$\mu_{\text{eff}} = \frac{\mu_0}{1 + \theta \cdot (V_{\text{GS}} - V_{\text{T}})_{\text{dc}} + \theta \cdot \left(v_{\text{LO}} - \frac{v_{\text{bb}}}{2}\right) + \frac{\mu_0}{V_{\max} \cdot L} + \frac{\theta}{2} \cdot |v_{\text{bb}}|} \tag{4.36}$$

Substituting v_{bb} with $A\sin(\omega_{\text{bb}}t)$ and making a Fourier series expansion of $|v_{\text{bb}}|$ results in

$$\mu_{\text{eff}} = \frac{\mu_0}{B\left(1 + \frac{\theta}{B} v_{\text{LO}} - \frac{\theta A}{2B} \sin(\omega_{\text{bb}}t) + C\cos(2\omega_{\text{bb}}t) + D\cos(4\omega_{\text{bb}}t) + \cdots\right)} \tag{4.37}$$

with

$$\begin{aligned} A\sin(\omega_{\text{bb}}t) &= \text{the baseband signal} \\ B &\approx 1 + (V_{\text{GS}} - V_{\text{T}}) \\ C &= \frac{A}{B} \cdot \frac{4}{3\pi} \cdot \left(\frac{\mu_0}{V_{\max} \cdot L} + \frac{\theta}{2}\right) \\ D &= \frac{A}{B} \cdot \frac{4}{5 \cdot 3\pi} \cdot \left(\frac{\mu_0}{V_{\max} \cdot L} + \frac{\theta}{2}\right) \end{aligned}$$

Equation 4.37 shows that a second-order baseband frequency component $\cos(2\omega_{\text{bb}}t)$ appears. In the DC reduction factor B, the third term is an order of magnitude smaller than 1. Hence it appears that the magnitude C of the second-order component has a first order relationship to the baseband signal amplitude A. In the voltage to current relationship, μ_{eff} is multiplied with $v_{\text{LO}}v_{\text{bb}}$. As a result a mixing component at $f_{\text{LO}} \pm 3f_{\text{bb}}$ occurs. In the amplitude C of this distortion component, $\mu_0/(V_{\max} \cdot L)$ is dominant to $\theta/2$ for most submicron technologies. It is also important to notice that the distortion is inversely proportional to the gate length. This indicates that this effect will become even more apparent as gate lengths continue to scale down.

4.6.3 Power Amplifier

4.6.3.1 CMOS Power Amplification

The integration of PAs in a CMOS technology is impeded by the low supply voltage of the current deep-submicron and nanometer technologies. Apart from this, the relative high parasitic capacitances of the MOS transistor, at least compared to GaAs or SiGe transistors, and the relative low quality factor of on-chip inductors, further hinders the integration. On the other hand, the digital MOS transistor is optimized for switching and as such a lot of switching amplifiers have been integrated in CMOS with great success recently [47–53]. Furthermore, CMOS RF amplifiers are capable to break the 1 W barrier of output power performance [54]. In this section, the topic of switching RF amplifier is discussed first. In the second part, some linearization techniques will be discussed.

4.6.3.2 Switching Class E Amplifier

The Class E amplifier was invented in 1975 [55], but the first implementation of this amplifier in CMOS was reported in 1997 [47]. In contrast to the Class A, B, C, and F amplifiers, the Class E is designed in the time-domain. In theory, the Class E amplifier is capable to achieve an efficiency of 100%. In order to achieve this, the transistor and output network are designed in such a way that the drain through the transistor is separated in time from the voltage across the transistor. This avoids power dissipation in the transistor, a necessary requirement to achieve a high efficiency. If all other elements are assumed to be

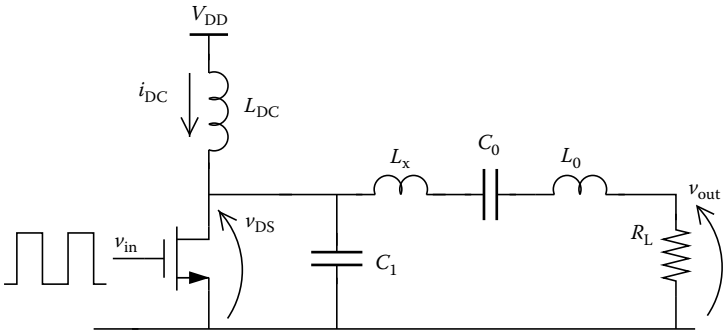

FIGURE 4.17 Basic Class E PA.

lossless, the amplifier is then indeed capable to achieve an efficiency of 100%. Figure 4.17 depicts the basic circuit of a CMOS Class E amplifier. The nMOS transistor should act as a switch and therefore it is driven by a square wave between zero and the maximum permissible gate voltage, which is normally equal to V_{DD}, the supply voltage of the technology. As such the nMOS transistor can be modeled by an ideal switch with a series resistance R_{on}. Inductor L_1 can be seen as the DC feed inductance, and in the original Class E theory, this inductor is assumed to be very large, and can be replaced by an ideal current source. Finally, inductor L_x and capacitor C_1 are the two crucial elements that create the Class E waveform at the drain of the nMOS transistor.

In a fully integrated CMOS implementation, the DC feed inductor L_1 cannot be made very large. First, this would require a huge silicon area, but more important, the relative high power loss of CMOS integrated inductors does not allow for such a large value. As such, the value of L_1 has to be reduced, and the current through the latter will not be a constant. The amplifier can still be designed to meet the Class E conditions, even with a small value of L_1. In fact, reducing the value of L_1 will result in a larger value for C_1 and a smaller value for L_x.

The capacitor C_1 and inductor L_x are constrained by the two Class E requirements, given below.

$$\text{Class E} \Leftrightarrow \begin{cases} v_{DS}(t = t_1) & = & 0 \\ \left.\dfrac{dv_{DS}(t)}{dt}\right|_{t=t_1} & = & 0 \end{cases}$$

In Figure 4.18, the drain voltage and current for Class E operation are shown. Solving the two Class E equations will give a value for C_1 and L_x. Finally, the value of the load resistance is constrained by the required output power. To achieve sufficient output power in a low voltage CMOS technology, an impedance matching network is required between the 50 Ω load or antenna impedance and the Class E amplifier. The on resistance of the nMOS transistor can be written as

$$r_{on} = \frac{L}{\mu_n C_{ox} W (V_{GS} - V_T)} \tag{4.38}$$

The lower the on resistance, the higher the efficiency of the amplifier, and thus it is beneficial to increase the width of the nMOS transistor. However, that large transistor cannot be directly connected to the up-conversion mixer, and several amplifying stages are needed between them. If the nMOS transistor has a large gate width, more power will be consumed by the driver stages and thus the overall efficiency of the amplifier, defined as

$$\eta_{oa} = \frac{P_{out}}{P_{DC,PA} + P_{DC,DRV}} \tag{4.39}$$

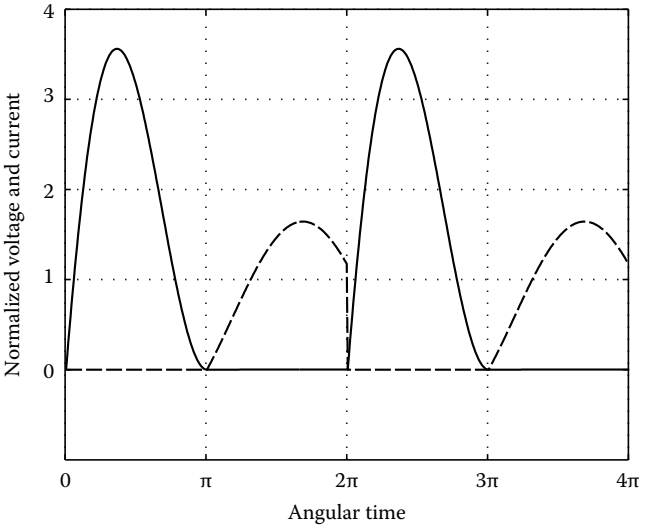

FIGURE 4.18 Voltage (solid line) and current (dashed line) of the Class E PA.

will have a maximum value for a specific transistor width. The overall efficiency is not always a good figure to compare PAs, since that figure can never reach 100%, even if each of the stages has a conversion efficiency of 100%. After all, the power consumed by the driver stages will never flow to the output load, but is only needed to switch on and of the next stage in line.

The power added efficiency (PAE) defined as

$$\text{PAE} = \frac{P_{\text{out}} - P_{\text{in}}}{P_{\text{DC}}} \tag{4.40}$$

is a useful definition for stand-alone PAs that have an input matched to 50 Ω. However, one should be aware whether the DC power consumption of the driver stages is included in P_{DC}.

Another important aspect of switching amplifiers is the reliability. A drawback of the Class E amplifier, at least compared to the Classes B and F, is that the drain voltage goes up to several times the supply voltage of the amplifier. This might cause reliability problems. On the other hand, the switching nature of the amplifier alleviates this. After all, due to the switching, voltage and current are separated in time. In other words, the high voltage peaks are not accompanied by a drain current, and when the drain current is high, the voltage across the switch is low. This is a big advantage compared to other types of amplifiers.

Figure 4.17 depicts another benefit of the Class E amplifier. For Class E operation, a shunt capacitance C_1 is required at the drain. However, in CMOS, there is already a large parasitic drain capacitance, and this capacitance can now become part of the amplifier. In Classes B and F amplifiers, that parasitic capacitance will create a low impedance for the harmonics that are crucial for the high efficiency of Classes B and F. Therefore, CMOS seems to be the natural habitat of the Class E amplifier.

4.6.3.3 Linearization of CMOS RF PAs

Switching amplifiers only have phase linearity, and therefore are only useful for constant envelope systems like Bluetooth and GSM. However, modern RF communication systems like UMTS, CDMA-2000, and WLAN allow amplitude modulation to increase the datarate of a wireless link. The only way to recover or restore the amplitude linearity of a switching amplifier is by modulating the supply voltage or by combining two nonlinear amplifiers. Systems that modulate the supply voltage of a switching

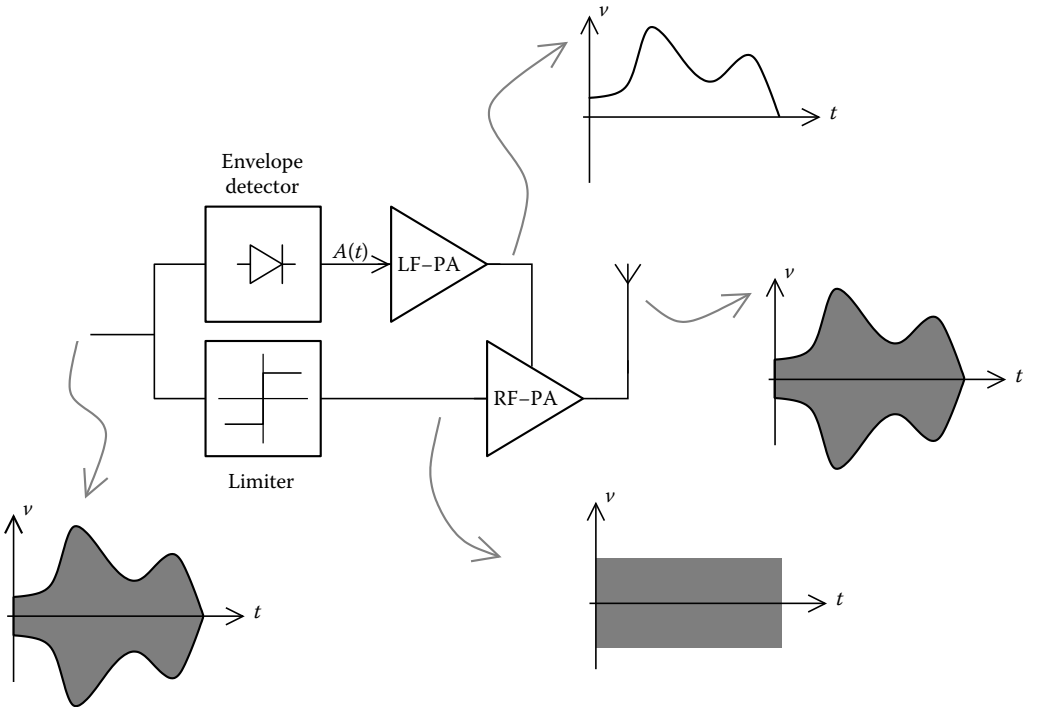

FIGURE 4.19 Kahn technique linearized PA.

amplifier are denoted as ''envelope elimination and restoration,'' ''polar modulation,'' or ''supply modulation.'' They originate from the Kahn technique (see Figure 4.19) that was already employed in vacuum tube amplifiers. In CMOS, one can make use of the availability of digital signal processing to directly create the amplitude and phase signal, and as such, the limiter and envelope detector of Figure 4.19 can be avoided. Furthermore, AM-AM and AM-PM predistortion is relative easy to implement. The general picture of polar modulation is shown in Figure 4.20. An another advantage of polar-modulated amplifiers is that the entire phase path carries a constant envelope signal and thus one can use nonlinear or saturated blocks in the upconversion path. Furthermore, amplitude and phase feedback are relatively easy to implement. Another group of techniques combine the output of two constant envelope amplifiers that have a different in phase. The two amplifiers are combined through a transformer, a power combiner, or through transmission lines, and the output is, in general, the sum of the two amplifiers. These systems are called ''outphasing'' or ''LINC,'' depending on the used combiner. Depending on their phase difference, the resulting output envelope can be higher or lower, and thus has amplitude modulation, as shown in Figure 4.21. The major drawback of these techniques is the difficulty to implement the power combiner in CMOS. Also, feedback is not as easy to implement in these systems. On the other hand, these systems allow to efficiently amplify signals that have a very high modulation bandwidth.

Apart from the two groups discussed in this section, several other techniques exist to amplify an amplitude-modulated signal. There is no ''ideal'' solution for CMOS integration. An alternative solution or approach is to use a linear amplifier with an efficiency improvement technique, such as the Doherty amplifier or the bias adoption technique. However, the linearization of nonlinear amplifiers has the advantage that switching or nonlinear amplifiers can be used, which are easier to implement in CMOS. Furthermore, the RF driver stages and all the blocks preceding the RF amplifier can be nonlinear as well. Needless to say, this is a huge advantage in low voltage technologies.

5.1 Introduction

5.1.1 What Is and Why Phase-Locked?

Phase-locked loop (PLL) is a circuit architecture that causes a particular system to track with another one. More precisely, PLL synchronizes a signal (usually a local oscillator output) with a reference or an input signal in frequency as well as in phase.

Phase locking is a useful technique that can provide effective synchronization solutions in many data transmission systems such as optical communications, telecommunications, disk drive systems, and local networks, in which data are transmitted in baseband or passband. In general, only data signals are transmitted in most of these applications, namely, clock signals are not transmitted in order to save hardware cost. Therefore, the receiver should have some mechanisms to extract the clock information from the received data stream in order to recover the transmitted data. The scheme is called a timing recovery or clock recovery.

The cost of electronic interfaces in communication systems raises as the data rate gets higher. Hence, high-speed circuits are the critical issue of the high data rate systems implementation, and the advanced very large scale integration (VLSI) technology plays an important role in cost reduction for the high-speed communication systems.

5.1.2 Basic Operation Concepts of PLLs

Typically, as shown in Figure 5.1, a PLL consists of three basic functional blocks: a phase detector (PD), a loop filter (LF), and a voltage-controlled oscillator (VCO). PD detects the phase difference between the VCO output and the input signal, and generates a signal proportional to the phase error. The PD output

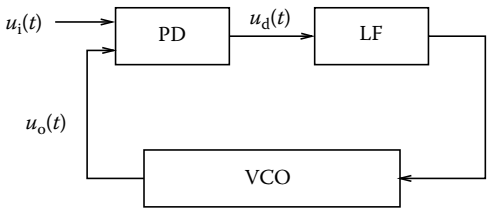

FIGURE 5.1 Basic block diagram of the PLL.

contains a direct current (DC) component and an alternative current (AC) component, the former is accumulated and the latter is filtered out by the LF. The LF output that is near a DC signal is applied to the VCO. This almost DC control voltage changes the VCO frequency toward a direction to reduce the phase error between the input signal and the VCO. Depending on the type of LF used, the steady-state phase error will be reduced to zero or to a finite value.

PLL has an important feature, which is the ability to suppress both the noises superimposed on the input signal and generated by the VCO. In general, the more narrow bandwidth the PLL has, the more effectively the filtering of the superimposed noises can be achieved. Although a narrow bandwidth is better for rejecting large amounts of the input noise, it also prolongs the settling time in the acquisition process. Then, the error of the VCO frequency cannot be reduced rapidly. So there is a trade-off between jitter filtering and fast acquisition.

5.1.3 Classification of PLL Types

Different PLL types have been built from different classes of building blocks. The first PLL integrated circuit (IC) appeared around 1965 and consisted of purely analog devices. In the so-called linear PLLs (LPLLs), an analog multiplier (four-quadrant) is used as the PD, the LF is built of a passive or an active RC filter, and the VCO is used to generate the output signal of the PLL. In most cases, the input signal to this LPLL is a sine wave, whereas the VCO output signal is a symmetrical square wave.

The classical digital PLL (DPLL) uses a digital PD such as an exclusive OR (XOR) gate, a JK-flipflop, or a phase-frequency detector (PFD). The remaining blocks are still the same as LPLL. In many aspects, the DPLL performance is similar to the LPLL.

The function blocks of the all digital PLL (ADPLL) are implemented by purely digital circuits, and the signals within the loop are digital, too. Digital versions of the PD are the same as DPLL. The digital LF is built of an ordinary up/down counter, N-before-M counter or K-counter [1]. The digital counterpart of the VCO is the digital-controlled oscillator [2,3].

In analogy to filter designs, PLLs can be implemented by software such as a microcontroller, microcomputer, or digital signal processing (DSP); this type of PLL is called software PLL (SPLL).

5.2 PLL Techniques

5.2.1 Basic Topology

A PLL is a feedback system that operates and minimizes the phase difference between two signals. Referring to the basic function block diagram of a PLL as shown in Figure 5.1, it typically consists of a PD, an LF, and a VCO. The PD works as a phase error detector and an amplifier. It compares the phase of the VCO output signal $u_o(t)$ with the phase of the reference signal $u_i(t)$ and develops an output signal $u_d(t)$ that is proportional to the phase error θ_e. Within a limited range, the output signal can be expressed as

$$u_d(t) = k_d \theta_e \tag{5.1}$$

where k_d with the unit of V/rad represents the gain of the PD.

The output signal $u_d(t)$ of the PD consists of a DC component and a superimposed AC component. The latter is undesired and removed by the LF. In general, the LF is a low-pass filter (LPF) to generate an almost DC control voltage for the VCO to oscillate at the frequency equal to the input frequency.

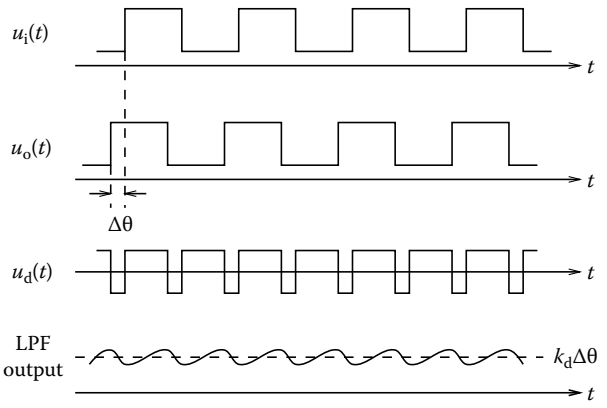

FIGURE 5.2 Waveforms in a PLL.

How the building blocks of a basic PLL work together will be explained below. At first, assume both the waveforms of input signal and VCO output are rectangular. Furthermore, it is assumed that the angular frequency ω_i of the input signal $u_i(t)$ is equivalent to the central frequency ω_o of the VCO signal $u_o(t)$. Now a small positive frequency step is applied to $u_i(t)$ at $t = t_0$ (shown in Figure 5.2). $u_i(t)$ accumulates the phase increments faster than $u_o(t)$ of VCO does. If the PD can response wider pulses increasingly, a higher DC voltage is accordingly generated at the LF output to increase the VCO frequency. Depending on the type of the LF that will be discussed later, the final phase error will be reduced to zero or a finite value.

It is important to note from the descriptions above that the loop locks only after the two conditions are satisfied: (1) ω_i and ω_o are equal and (2) the phase difference between the input $u_i(t)$ and the VCO output $u_o(t)$ settles to a steady-state value. If the phase error varies with time so fast that the loop is unlocked, the loop must keep on the transient process, which involves both "frequency acquisition" and "phase acquisition."

To design a practical PLL system, it is required to know the status of the responses of the loop if (1) the input frequency is varied slowly (tracking process), (2) the input frequency is varied abruptly (lock-in process), and (3) the input and the output frequencies are not equal initially (acquisition process). Using LPLL as an example, these responses will be shown in Sections 5.2.3 through 5.2.5.

5.2.2 Loop Orders of the PLL

Figure 5.3 shows the linear model of a PLL. According to the control theory, the closed-loop transfer function of PLL can be derived as

$$H(s) \triangleq \frac{\theta_o(s)}{\theta_i(s)} = \frac{k_d k_o F(s)}{s + k_d k_o F(s)} \tag{5.2}$$

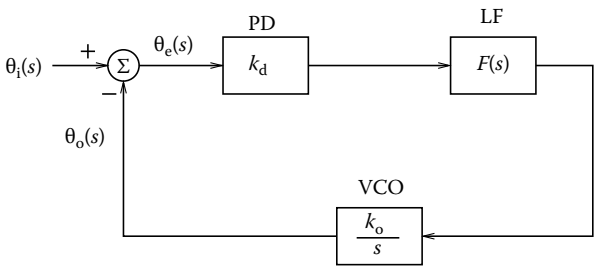

FIGURE 5.3 Linear model of PLL.

where

k_d with units V/rad is called the PD gain

k_o is the VCO gain factor and has units rad/(s-V)

In addition to the phase transfer function, a phase-error transfer function $H_e(s)$ is derived as follows:

$$H_e(s) \triangleq \frac{\theta_e(s)}{\theta_i(s)} = \frac{s}{s + k_d k_o F(s)} \tag{5.3}$$

The loop order of the PLL depends on the characteristics of the LF. Therefore the LF is a key component that affects the PLL dynamic behavior. A PLL with an LF consisted of simple amplifier or attenuator is called a first-order PLL. As shown in Figure 5.3, set $F(s) = 1$ and the closed-loop transfer function can be derived as

$$H(s) = \frac{k}{s + k} \tag{5.4}$$

where the DC loop gain $k = k_d k_o$. If fast tracking is required, a high DC loop gain k is necessary for the bandwidth of the PLL being wide enough because the DC loop gain k is the only parameter available. Such a design is not suitable for noise suppression. Therefore, fast tracking and narrow bandwidth are incompatible in a first-order loop.

A commonly used LF is the passive lag filter. The transfer function is

$$F(s) = \frac{1}{1 + s\tau} \tag{5.5}$$

The closed-loop transfer function can be derived as

$$H(s) = \frac{k_d k_o/\tau}{s^2 + (1/\tau)s + k_d k_o/\tau} = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \tag{5.6}$$

where

$\omega_n = \sqrt{\frac{k_d k_o}{\tau}}$ is the "natural frequency"

$\zeta = \frac{1}{2}\sqrt{\frac{1}{\tau k_d k_o}}\,\omega_n$ is the "damping factor"

These two parameters are important to characterize a PLL. Now, a second-order PLL is obtained and there are two parameters (τ and $k = k_o k_d$) available to achieve fast tracking as well as the noise suppression. Then three loop parameters (ω_n, ζ, k) must be determined. In addition, the phase-error transfer function $H_e(s)$ can be further derived as follows:

$$H_e(s) = \frac{s(s + 1/\tau)}{s^2 + (1/\tau)s + k_d k_o/\tau} \tag{5.7}$$

5.2.3 Tracking Process

The linear model of a PLL shown in Figure 5.3 is suitable for analyzing the tracking performance of a PLL that is almost in lock, that is, only with a small phase error. If the phase error changes too abruptly, the PLL fails to lock, and a large phase error is induced even though the change happens only momentarily. The unlock condition is a nonlinear process that cannot be analyzed via the linear model. The acquisition process will be described in Section 5.2.5.

At first, consider that a step phase error expressed as $\theta_i(t) = \Delta\theta u(t)$ is applied to the input. The Laplace transform of the input is $\theta_i(s) = \frac{\Delta\theta}{s}$ that is substituted into Equation 5.7 to get

$$\theta_e(s) = \frac{\Delta\theta}{s} \frac{s(s + 1/\tau)}{s^2 + (1/\tau)s + k_d k_o/\tau} \tag{5.8}$$

According to the final value theorem of the Laplace transform,

$$\lim_{t\to\infty} \theta_e(t) = \lim_{s\to 0} s\theta_e(s) = \frac{\Delta\theta}{k_d k_o}$$

In another word, the loop will eventually track on the step phase change with a steady-state phase error proportional to the DC loop gain. If it is necessary to have a high DC loop gain in order to reduce the steady-state phase error and a very narrow bandwidth for improving the noise suppression, the loop will be severely underdamped and the transient response will be poor.

When a step change of frequency $\Delta\omega$ is applied to the input, the input phase change is a ramp, that is, $\theta_i(t) = \Delta\omega t$, therefore $\theta_i(s) = \frac{\Delta\omega}{s^2}$. Substituting $\theta_i(s)$ in Equation 5.7 and applying the final value theorem, then

$$\begin{aligned} \theta_v &= \lim_{t\to\infty} \theta_e(t) = \lim_{s\to 0} s\theta_e(s) \\ &= \lim_{s\to 0} \frac{\Delta\omega}{s^2} \frac{s(s + 1/\tau)}{s^2 + (1/\tau)s + (k_d k_o/\tau)} \end{aligned} \tag{5.9}$$

where θ_v is called the "velocity error" or "static phase error" [4]. In practice, the input frequency almost never agrees exactly with the VCO free-running frequency, that is, usually there is a frequency difference $\Delta\omega$ between the two. From Equation 5.9, the velocity error will be infinite while there is a frequency difference $\Delta\omega$. Another commonly used LF is the active lead-lag LF with the transfer function $F(s)$ described as follows:

$$F(s) = k_a \frac{1 + s\tau_2}{1 + s\tau_1} \tag{5.10}$$

where τ_1, τ_2, and k_a are the two time constants and DC gain of an active lead-lag LF, respectively. Substituting $\theta_i(s)$ in Equation 5.3 and applying the final value theorem, then

$$\begin{aligned} \theta_v &= \lim_{s\to 0} s\theta_e(s) = \lim_{s\to 0} \frac{\Delta\omega}{s + k_d k_o F(s)} \\ &= \frac{\Delta\omega}{k_d k_o F(0)} = \frac{\Delta\omega}{k_v} \end{aligned} \tag{5.11}$$

From Equation 5.11, if the PLL has a high DC loop gain, that is, $k_d k_o F(0) \gg \Delta\omega$, the steady-state phase error corresponding to a step frequency error input approaches to zero. This is the reason that a high gain loop has a good tracking performance. Now the advantage of a second-order loop using an active LF with high DC gain is evident. The active lead-lag LF with a high DC gain will make the steady-state phase error approach to zero and the noise bandwidth be narrow simultaneously, which is impossible in a first-order loop.

If the input frequency is changed linearly with time at a rate of $\Delta\omega$, that is $\theta_i(t) = \frac{1}{2}\Delta\omega\ t^2$, $\theta_i(s) = \frac{\Delta\omega}{s^3}$. Using an active LF with high DC gain and applying the final value theorem of Laplace transform, it is derived that

$$\theta_a = \lim_{t\to\infty} \theta_e(t) = \lim_{s\to 0} s\theta_e(s) = \frac{\Delta\omega}{\omega_n^2} \tag{5.12}$$

where θ_a is called an "acceleration error" (sometimes calls "dynamic tracking error" or "dynamic lag") [4].

In some applications, PLL needs to track an accelerating phase error without static tracking error. When frequency ramp is applied, the static phase error will be

$$\theta_e(s) = \lim_{s \to 0} \frac{\Delta\omega}{s(s + k_d k_o F(s))} \tag{5.13}$$

In order to have θ_e zero, it is necessary to make $F(s)$ be a form of $\frac{G(s)}{s^2}$, where $G(0) \neq 0$. $\frac{G(s)}{s^2}$ implies that the LF has two cascade integrators. This results in a third-order loop. In order to eliminate the static acceleration error, a third-order loop is very useful for some special applications such as satellite and missile systems.

Based on Equation 5.12, a large natural frequency ω_n is used to reduce the static tracking phase error in a second-order loop; however, a wide natural frequency has an undesired noise filtering performance. In the contrast, the zero tracking phase error for a frequency ramp error is concordant with a small loop bandwidth in a third-order loop. In practice, there are three basic types of LF: passive lead-lag filter, active lead-lag filter, and active proportional and integral (PI) filter. The characteristics of the three types of LF and their effects on the PLL will be described in Section 5.3.3. Besides, a high-order filter is used for critical applications because it provides better noise filtering, initial acquisition, and fast tracking. However it is difficult to design a high-order loop due to some problems such as loop stability.

All the preceding analysis on the tracking process is under the assumption that the phase error is relatively small and the loop is linear. If the phase error is large enough to make the loop drop out of lock, the linear assumption is invalid. For a sinusoidal-characteristic PD, the exact phase expression of Equation 5.11 should be

$$\sin\theta_v = \frac{\Delta\omega}{k_v} \tag{5.14}$$

The sine function has solutions only when $\Delta\omega \leq k_v$. However, there is no solution if $\Delta\omega > k_v$. This is the case the loop loses lock and the output of the PD will be beat notes signal rather than a DC control voltage. Therefore, k_v can be used to define the ''hold range'' of the PLL, that is

$$\Delta\omega_H = \pm k_v = k_o k_d F(0) \tag{5.15}$$

The hold range is the frequency range in which a PLL is able to maintain lock ''statically.'' Namely, if input frequency offset exceeds the hold range statically, the steady-state phase error would drop out of the linear range of the PD and the loop loses lock. k_v is the function of k_o, k_d, and $F(0)$. The DC gain $F(0)$ of the LF depends on the filter type. Therefore, it is important to make an LF have a high DC gain for extending the hold range. Referring to the characteristics of the three basic types of LF described in Section 5.3.3, the hold range $\Delta\omega_H$ can be $k_o k_d$, $k_o k_d k_a$, and ∞ for passive lead-lag filter, active lead-lag filter, and active PI filter, respectively. The hold range expressed in Equation 5.15 is not correct when some other components in PLL are saturated earlier than the PD. When the PI filter is used, the real hold range is actually determined by the control range of the VCO.

Considering the dynamic phase error θ_a in a second-order loop, the exact expression for a sinusoidal characteristic PD is

$$\sin\theta_a = \frac{\Delta\omega}{\omega_n^2} \tag{5.16}$$

which implies that the maximum change rate of the input frequency is ω_n^2. If the rate exceeds ω_n^2, the loop will fall out of lock.

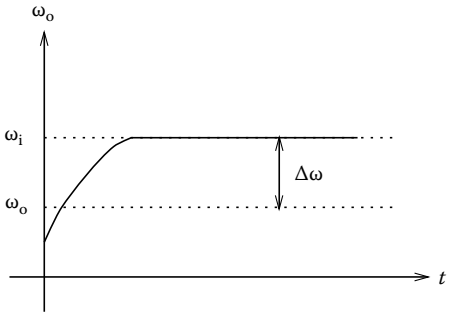

FIGURE 5.4 Lock-in process of the PLL.

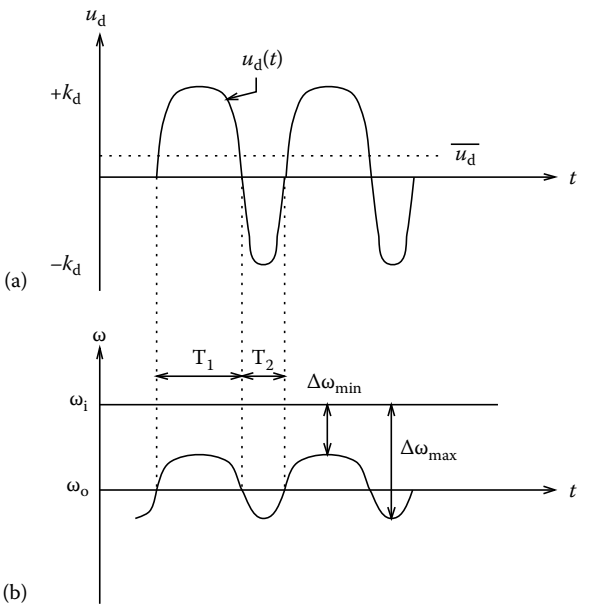

FIGURE 5.5 Pull-in process of the PLL.

5.2.4 Lock-In Process

The "lock-in" process is defined as PLL locks within one single beat note between the input and the output (VCO output) frequency. The maximum frequency difference between the input and the output that PLL can lock within one single beat note is called the "lock-in range" of the PLL.

Figure 5.4 shows a case of PLL lock-in process that a frequency offset $\Delta\omega$ is less than the lock-in range, and the lock-in process happens. Then PLL will lock within one single beat note between ω_i and ω_o. In Figure 5.5b, the frequency offset $\Delta\omega$ between input (ω_i) and output (ω_o) is larger than the lock-in range, hence the lock-in process will not take place, at least not instantaneously.

Suppose the PLL is unlocked initially. The input frequency ω_i is $\omega_o + \Delta\omega$. If the input signal $v_i(t)$ is a sine wave and given by

$$v_i(t) = A_i \sin(\omega_o t + \Delta\omega t) \tag{5.17}$$

And the VCO output signal $v_o(t)$ is usually a square wave written as a Walsh function [5]

$$v_o(t) = A_o W(\omega_o t) \tag{5.18}$$

$v_o(t)$ can be replaced by the Fourier series,

$$v_o(t) = A_o \left[\frac{4}{\pi}\cos(\omega_o t) + \frac{4}{3\pi}\cos(3\omega_o t) + \cdots\right] \tag{5.19}$$

So the PD output v_d is

$$\begin{aligned} v_d(t) = v_i(t)v_o(t) &= A_i A_o \left[\frac{2}{\pi}\sin(\Delta\omega t) + \cdots\right] \\ &= k_d \sin(\Delta\omega t) + \text{high} - \text{frequency terms} \end{aligned} \tag{5.20}$$

The high frequency components can be filtered out by the LF. The output of the LF is given by

$$v_f(t) \approx k_d |F(\Delta\omega)| \sin(\Delta\omega t) \tag{5.21}$$

The peak frequency deviation based on Equation 5.21 is equal to $k_d k_o |F(\Delta\omega)|$. If the peak deviation is larger than the frequency error between ω_i and ω_o, the lock-in process will take place. Hence the lock-in range is consequently given by

$$\Delta\omega_L = k_d k_o |F(\Delta\omega_L)| \tag{5.22}$$

The lock-in range is always larger than the corner frequency $\frac{1}{\tau_1}$ and $\frac{1}{\tau_2}$ of the LF in practical cases. An approximation of the LF gain $F(\Delta\omega_L)$ is shown as follows:

For the passive lead-lag filter

$$F(\Delta\omega_L) \approx \frac{\tau_2}{\tau_1 + \tau_2}$$

For the active lead-lag filter

$$F(\Delta\omega_L) \approx k_a \frac{\tau_2}{\tau_1}$$

For the active PI filter

$$F(\Delta\omega_L) \approx \frac{\tau_2}{\tau_1}$$

τ_2 is usually much smaller than τ_1, the $F(\Delta\omega_L)$ can be further approximated as follows:

For the passive lead-lag filter

$$F(\Delta\omega_L) \approx \frac{\tau_2}{\tau_1 + \tau_2}$$

For the active lead-lag filter

$$F(\Delta\omega_L) \approx k_a \frac{\tau_2}{\tau_1}$$

For the active PI filter

$$F(\Delta\omega_L) \approx \frac{\tau_2}{\tau_1}$$

Substituting above equations in Equation 5.22 and assuming a high gain loop,

$$\Delta\omega_L \approx 2\zeta\omega_n \tag{5.23}$$

can be gotten for all three types of LF shown in Figure 5.12.

5.2.5 Acquisition Process

Suppose that the PLL does not lock initially, the input frequency is $\omega_i = \omega_o + \Delta\omega$, where ω_o is the initial frequency of VCO. If the frequency error $\Delta\omega$ is larger than the lock-in range, the lock-in process will not happen. Consequently the output signal $u_d(t)$ of the PD shown in Figure 5.5a is a sine wave that has the frequency of $\Delta\omega$. The AC PD output signal $u_d(t)$ passes through the LF. Then the output $u_f(t)$ of the LF modulates the VCO frequency. As shown in Figure 5.5b, when ω_o increases, the frequency difference between ω_i and ω_o becomes smaller and vice versa. Therefore, the PD output $u_d(t)$ becomes asymmetric when the duration of positive half-periods of the PD output is larger than the negative ones. The average value $\overline{u_d(t)}$ of the PD output therefore goes positive slightly. Then the frequency of VCO will be pulled up until it reaches the input frequency. This phenomenon is called a ''pull-in process.''

Because the pull-in process is a nonlinear behavior, the mathematical analysis is quite complicated. According to the results of [1], the pull-in range and the pull-in time depend on the type of LF. For an active lead-lag filter with a high gain loop, the pull-in range is

$$\Delta\omega_P \approx \frac{4\sqrt{2}}{\pi}\sqrt{\zeta\omega_n k_o k_d} \tag{5.24}$$

and the pull-in time is

$$T_P \approx \frac{\pi^2}{16}\frac{\Delta\omega_0^2 k_a}{\zeta\omega_n^3} \tag{5.25}$$

where $\Delta\omega_0$ is the initial frequency error. Equations 5.24 and 5.25 should be modified for different types of PDs [1].

5.2.6 Aided Acquisition

The PLL bandwidth is always too narrow to lock a signal with large frequency error. Furthermore, the frequency acquisition is slow and impractical. Therefore, there are aided frequency-acquisition techniques to solve this problem such as the frequency locked-loop (FLL) and the bandwidth-widening methods.

The FLL, which is very much similar to a PLL, is composed of a frequency discriminator, an LF, and a VCO. PLL is a coherent mechanism to recover a signal buried in noise. An FLL, in contrast, is a noncoherent scheme that cannot distinguish the phase error between input signal and VCO signal. Therefore an FLL can only be useful to provide the signal frequency which exactly synchronizes with the reference frequency source.

The major difference between PLL and FLL is the PD and the frequency discriminator. The frequency discriminator is the frequency detector in the FLL. It generates a voltage proportional to the frequency difference between the input and the VCO. The frequency difference will be driven to zero in a negative feedback fashion. If a linear frequency detector is employed, it can be shown that the frequency-acquisition time is proportional to the logarithm of the frequency error [6]. In the literature, some frequency detectors-like quadricorrelator [7], balance quadricorrelator [8], rotational frequency detector [9], and frequency delimiter [10] are disclosed.

5.2.7 PLL Noise Performance

In high-speed data recovery applications, a better performance of the VCO and the overall PLL itself is desired. In a consequence, the random variations of the sampling clock, so-called jitter, is the critical performance parameter.

Jitter sources of PLL in the case of using a ring VCO mainly come from the input and the VCO itself. The ring oscillator jitter is associated with the power supply noise, the substrate noise, $1/f$ noise, and the thermal noise. The former two noise sources can be reduced by fully differential circuit structure. $1/f$ noise, on the other hand, can be rejected by the tracking capability of the PLL. Therefore, the thermal noise is the worst noise source. From the analysis of [18], the one stage RMS timing jitter error of the ring oscillator normalized to the time delay per stage can be shown as

$$\frac{\Delta\tau_{rms}}{t_d} \approx \sqrt{\frac{2KT}{C_L}}\left(\sqrt{1+\frac{2}{3}a_v}\right)\frac{1}{V_{pp}} \tag{5.26}$$

where

C_L is the load capacitance

$\sqrt{1+\frac{2}{3}a_v}$ is called the noise contribution factor ζ

a_v is the small-signal gain of the delay cell

V_{pp} is the VCO output swing

From Equation 5.26, for a fixed output bandwidth, higher gain contributes larger noise.

Because the ring oscillator is a feedback architecture, the noise contribution of a single delay cell may be amplified and filtered by the following stage. To consider two successive stages, Equation 5.26 can be rearranged as [18]

$$\frac{\Delta\tau_{rms}}{t_d} \approx \sqrt{\frac{2KT}{C_L}}\frac{1}{(V_{gs}-V_t)}\zeta \tag{5.27}$$

Therefore, the cycle-to-cycle jitter of the ring oscillator in a PLL can be predicted by [18]

$$\overline{(\Delta\tau_N)^2} = \frac{KT}{I_{ss}}\frac{a_v\zeta^2}{(V_{gs}-V_t)}T_o \tag{5.28}$$

where

I_{ss} is the rail current of the delay cell

T_o is the output period of the VCO

Based on Equation 5.28, designing a low jitter VCO ($V_{gs}-V_t$) should be as large as possible. For fixed delay and fixed current, a lower gain of each stage is better for jitter performance, but the loop gain must satisfy the Barkhausen criterion. From the viewpoint of VCO jitter, a wide bandwidth of PLL can correct the timing error of the VCO rapidly [14]. If the bandwidth is too wide, the input noise jitter may be so large that dominates the jitter performance of the PLL. Actually this is a trade-off.

For a PLL design, the natural frequency and the damping factor are the key parameters to be determined by designers. If the input signal-to-noise ratio $(SNR)_i$ is defined, then the output signal-to-noise ratio $(SNR)_o$ can be obtained [4]

$$(SNR)_o = (SNR)_i\frac{B_i}{2B_L} \tag{5.29}$$

where

B_i is the bandwidth of the prefilter

B_L is the noise bandwidth

Hence the B_L can be derived using Equation 5.29. And the relationship of B_L with ω_n and ζ is

$$B_L = \frac{\omega_n}{2}\left(\zeta+\frac{1}{4\zeta}\right) \tag{5.30}$$

Therefore the ω_n and ζ can be designed to satisfy the $(SNR)_o$ requirement.

Besides the system and the circuit designs, jitter can be reduced in the board level design. Board jitter can be alleviated by better layout and noise decoupling schemes such as appending proper decouple and bypass capacitances.

5.3 Building Blocks of PLL Circuit

5.3.1 Voltage-Controlled Oscillators

The function of a VCO is to generate a stable and periodic waveform whose frequency can be varied by an applied control voltage. The relationship between the control voltage and the oscillation frequency

depends upon the circuit architecture. A linear characteristic is generally preferred because of its wider applications. As a general classification, VCO can be categorized roughly into two types by the output waveforms: (1) harmonic oscillators that generate nearly sinusoidal outputs and (2) relaxation oscillators that provide square or triangle outputs.

In general, a harmonic oscillator is composed of an amplifier that provides an adequate gain and a frequency-selective network that feeds a certain output frequency range back to the input. LC tank oscillators and crystal oscillators belong to this type. Generally, the harmonic oscillators have the following advantages: (1) superior frequency stability while the conditions of temperature, power supply, and noise are included; and (2) good frequency accuracy control due to that the oscillation frequency is determined by a tank circuit or a crystal.

Essentially, harmonic oscillators are not compatible with monolithic IC technology and their frequency tuning range is limited. On the contrary, relaxation oscillators are easy to be implemented in monolithic ICs. Since frequency is normally proportional to a controlled-current or -voltage and inversely proportional to timing capacitors, the frequency of oscillation can be varied linearly over a very wide range. On the other hand, the ease of frequency tuning brings in drawbacks, such as poor frequency stability and frequency inaccuracy.

Relaxation oscillators are the most commonly used oscillator configuration in monolithic IC design because they can operate in a wide frequency range with a minimum number of external components. According to the mechanism of the oscillator topology employed, relaxation oscillators can be further categorized into three types: (1) grounded capacitor VCO [20], (2) emitter-coupled VCO, and (3) delay-based ring VCO [21]. The operation of the first two oscillators are similar in the sense that the time duration spent in each state is determined by the timing components and the charge/discharge currents. The ring oscillator is one of the relaxation oscillators and has received considerable attentions recently in high frequency PLL applications for clock synchronization and timing recovery. Because the ring oscillator can provide high frequency oscillation with simple digital-like circuits that are compatible with digital technology, it is suitable for VLSI implementations.

In order to achieve high rejection of power supply and substrate noises, both the signal path and the control path of a VCO must be fully differential. A common ring oscillator topology in monolithic PLLs is shown in Figure 5.6. The delay-based ring VCO operates quite differently since the timing relies on the delay in each gain stages that are connected in a ring configuration. The loop oscillates with a period equal to $2NT_d$, where T_d is the delay of each stage. The oscillation can be obtained when the total phase shift is zero and the loop gain is greater or equal to unity at a certain frequency. To vary the frequency of oscillation, the effective number of stages or the delay of each stage must be changed. The first approach is called ''delay interpolating'' VCO [21], where a shorter delay path and a longer delay path are used in parallel. The total delay is tuned by increasing the gain of one path and decreasing the other, and the total delay is a weighted sum of the two delay paths. The second approach is to vary the delay time of each stage to adjust the oscillation frequency. The delay of each stage is tuned by varying the capacitance or the resistance seen at the output node of each stage.

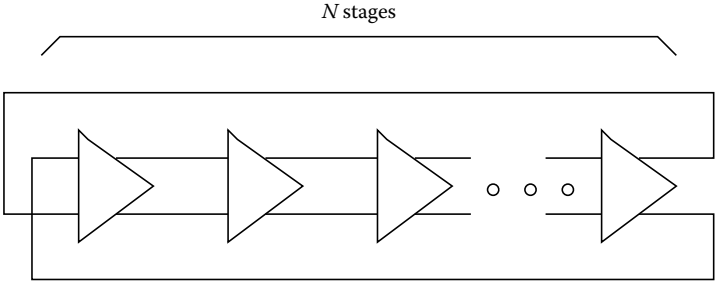

FIGURE 5.6 Ring oscillator.

Because the tuning range of the capacitor is small and the maximum oscillation frequency is limited by the minimum value of the load capacitor, the ''resistive tuning'' is a better alternative technique. Resistive tuning method provides a large, uniform frequency tuning range and leads itself easily to a differential control. In Figure 5.7a, the on-resistance of the triode PMOS loads is adjusted by V_{cont}. The more V_{cont} decreases, the more the delay of the stage drops because the time constant at the output node is decreased. However, the small-signal gain decreases as well when V_{cont} decreases. The circuit eventually fails to oscillate when the loop gain at the oscillation frequency is less than unity. In Figure 5.7b, the delay of gain stage is tuned by adjusting the tail current, but the small-signal gain remains constant. So the circuit is better than Figure 5.7a. As shown in Figure 5.7c [22], the PMOS current source with a pair of cross-coupled diode loads provides a differential load impedance that is independent of common-mode voltage. This makes the cell delay insensitive to common-mode noise. Figure 5.7d is a poor delay cell for a ring oscillator because the tuning range is very small.

The minimum number of stages that can be used while maintaining a reliable operation is an important issue in a ring oscillator design. When the number of stages decreases, the required phase

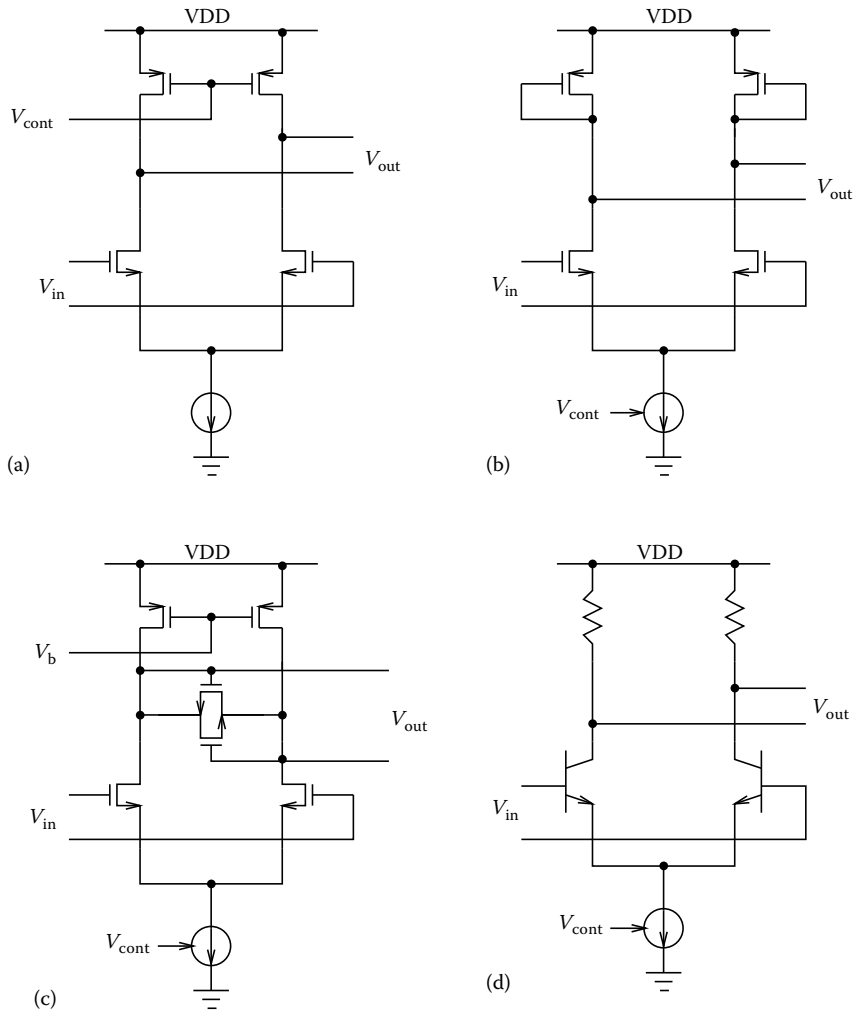

FIGURE 5.7 The gain stages using of resistive tuning.

shift and DC gain per stage increases. Two-stage bipolar ring oscillator can be designed reliably [23], but CMOS implementations are not. Thus, CMOS ring oscillators utilize three or more stages typically.

5.3.2 Phase and Frequency Detectors

The PD type has the influence on the dynamic range of PLLs. Hold range, lock-in range, and pull-in range are analyzed in Section 5.2 based on the multiplier PD. Most of the other types of PD have a greater linear output span and a larger maximum output swing than a sinusoidal characteristic PD. A larger tracking range and a larger lock limit are available if the linear output range of PD increases. The three widely used PDs are XOR PD, edge-triggered JK-flipflop, and PFD. The characteristics of these PDs are plotted in Figure 5.8.

The XOR PD can maintain phase tracking when the phase error θ_e is confined in the range of

$$\frac{-\pi}{2} < \theta_e < \frac{\pi}{2}$$

as shown in Figure 5.8a. The zero phase error takes place when the input signal and the VCO output are quadrature in phase as shown in Figure 5.9a. As the phase difference deviates from $\frac{\pi}{2}$, the output duty cycle is no longer 50%, which provides a DC value proportional to the phase difference as shown in Figure 5.9b. But the XOR PD has a steady-state phase error if the input signal or the VCO output are asymmetric.

The JK-flipflop PD shown in Figure 5.10, also called a two-state PD, is barely influenced by the asymmetric waveform because it is edge-triggered. The zero phase error happens when the input signal and the VCO output are out-off phase as illustrated in Figure 5.10a. As shown in Figure 5.8b, the JK-flipflop PD can maintain phase tracking when the phase error is within the range of

$$-\pi < \theta_e < \pi$$

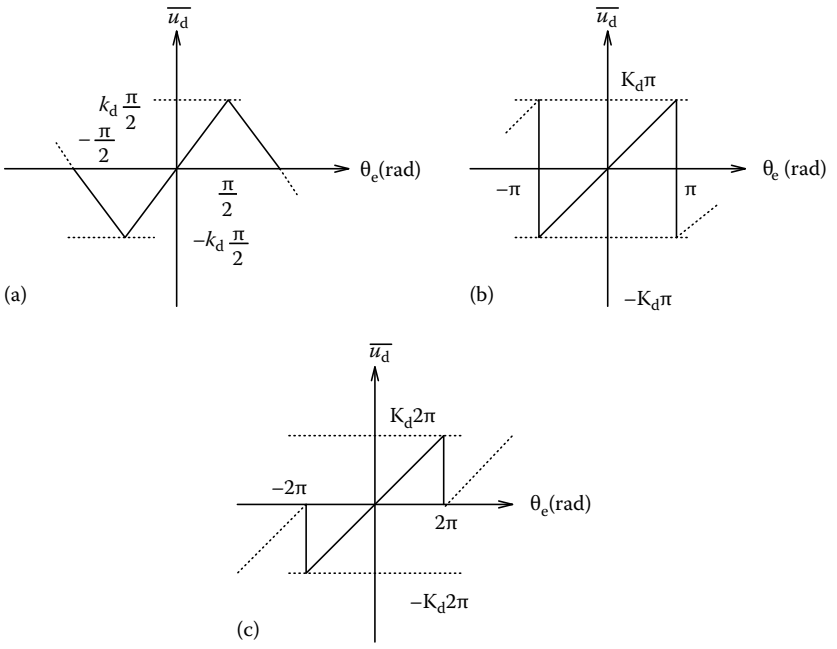

FIGURE 5.8 PD characteristics of (a) XOR, (b) JK-flipflop, and (c) PFD.

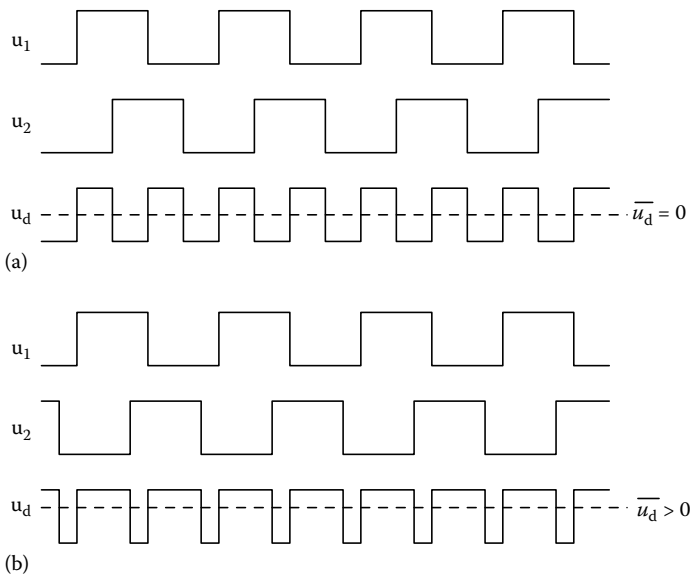

FIGURE 5.9 Waveforms of the signals for the XOR PD: (a) waveforms at zero phase error and (b) waveforms at positive phase error.

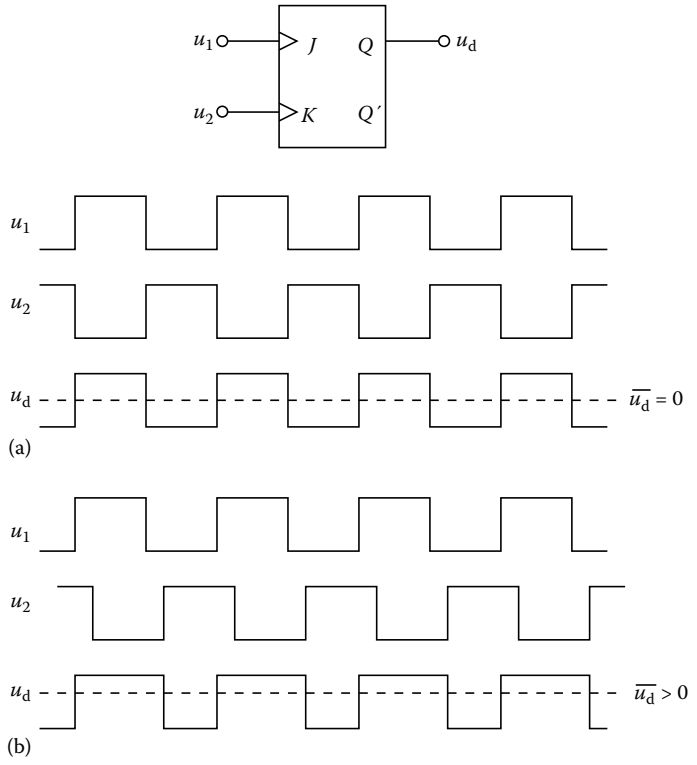

FIGURE 5.10 Waveforms of the signals for the JK-flipflop PD: (a) waveforms at zero phase error and (b) waveforms at positive phase error.

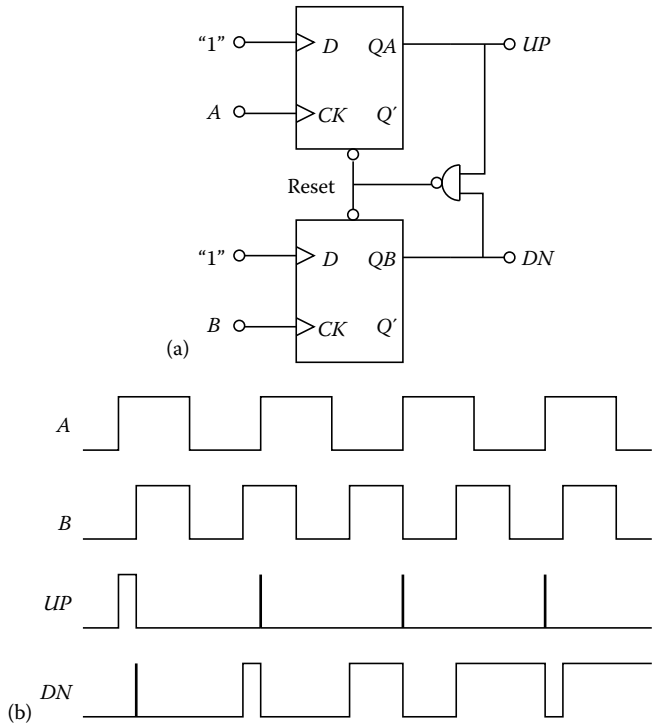

FIGURE 5.11 (a) PFD diagram and (b) inputs and outputs waveforms of PFD.

Here, a positive edge appearing at the J input triggers the flipflop into "high" state ($Q = 1$), and the rising edge of u_2 drives Q to zero. Figure 5.10b shows the output waveforms of the JK-flipflop PD for $\theta_e > 0$.

The PFD output depends not only on the phase error, but also on the frequency error. The characteristic is shown in Figure 5.8c. When the phase error is greater than 2π, the PFD works as a frequency detector. The operation of a typical PFD is as follows and the waveforms is shown in Figure 5.11. If the frequency of input A, ω_A, is less than the frequency of input B, ω_B, then the total width of positive pulses appearing at Q_A is shorter than at Q_B. Conversely, if $\omega_A > \omega_B$, the total width of positive pulses appears at Q_A is longer than at Q_B. If $\omega_A = \omega_B$, then the PFD generates pulses at either Q_A or Q_B with a width equal to the phase difference between the two inputs. The outputs Q_A and Q_B are usually called the "up" and "down" signals, respectively. If the input signal fails, which usually happens at the non-return-to-zero (NRZ) data recovery applications during missing or extra transmissions, the output of the PFD would stick on the high state (or low state). This condition may cause VCO to oscillate fast or slow abruptly, which results in noise jitter or even losing lock. This problem can be remedied by additional control logic circuits to make the PFD output to toggle back and forth between the two logic level with 50% duty cycle [19], the loop is interpreted as zero phase error. The "rotational FD" described by Messerschmitt can also solve this issue [9]. The output of a PFD can be converted to a DC control voltage by driving a three-state charge-pump which will be described in Section 5.3.4.

5.3.3 Loop Filters

For a PLL with given VCO and PD, LF is the critical component to determine the PLL characteristics, such as the damping factor that determines the relative stability, open-loop/closed-loop bandwidths that relate to the convergence speed in the initial state and the tracking capability in the steady state, and so on. Various types of LF will be introduced in this section.

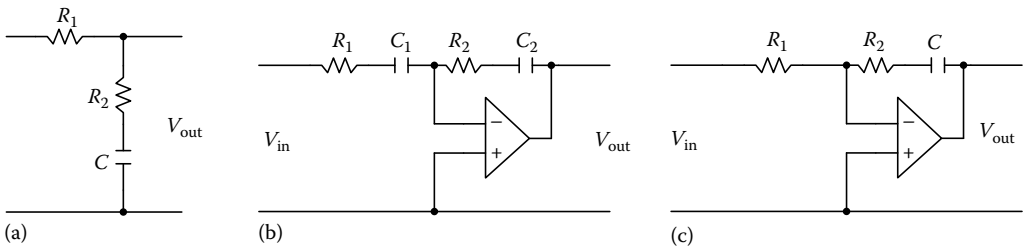

FIGURE 5.12 (a) Passive lead-lag filter, (b) active lead-lag filter, and (c) active PI filter.

5.3.3.1 Continuous-Time LFs

Figure 5.12 shows three types of LF that are widely used. Figure 5.12a is a passive lead-lag filter with transfer function $F(s)$ given by

$$F(s) = \frac{1 + s\tau_2}{1 + s(\tau_1 + \tau_2)} \tag{5.31}$$

where

$\tau_1 = R_1 C$
$\tau_2 = R_2 C$

Figure 5.12b shows an active lead-lag filter, whose transfer function is repeated here for convenience

$$F(s) = k_a \frac{1 + s\tau_2}{1 + s\tau_1} \tag{5.32}$$

where

$\tau_1 = R_1 C_1$
$\tau_2 = R_2 C_2$
$k_a = -\frac{C_1}{C_2}$

A "PI" filter is shown in Figure 5.12c. The transfer function is given by

$$F(s) = \frac{1 + s\tau_2}{s\tau_1} \tag{5.33}$$

where

$\tau_1 = R_1 C$
$\tau_2 = R_2 C$

Their Bode plots are shown in Figure 5.13a through c, respectively. High order filters could be used in some applications, but additional filter poles introduce a phase shift. In general, it is not trivial to maintain the stability of high order systems.

The transfer functions of the LFs shown in Figure 5.12 are substituted for $F(s)$ in Equation 5.2 in order to analyze the phase transfer function. We obtain the phase transfer functions as follows: for the passive lead-lag filter

$$H(s) = \frac{k_d k_o (1 + s\tau_2/\tau_1 + \tau_2)}{s^2 + s(1 + k_d k_o \tau_2/\tau_1 + \tau_2) + (k_d k_o/\tau_1 + \tau_2)} = \frac{\omega_n(2\zeta - (\omega_n/k_d k_o))s + \omega_n^2}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{5.34}$$

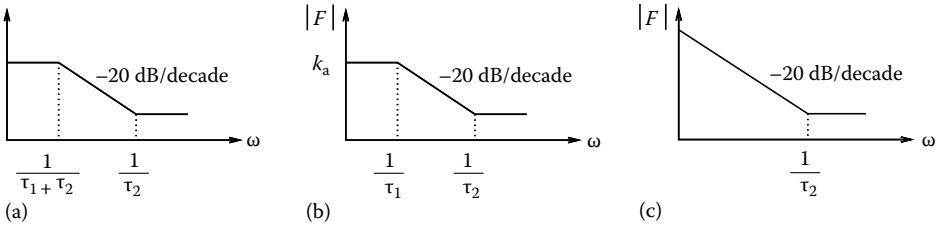

FIGURE 5.13 Bode plots of (a) passive lead-lag filter, (b) active lead-lag filter, and (c) active PI filter.

for the active lead-lag filter

$$H(s) = \frac{k_d k_a k_o (1 + s\tau_2/\tau_1)}{s^2 + s(1 + k_d k_a k_o \tau_2/\tau_1) + (k_d k_a k_o/\tau_1)} = \frac{\omega_n(2\zeta - (\omega_n/k_d k_a k_o))s + \omega_n^2}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{5.35}$$

and for the active PI filter

$$H(s) = \frac{k_d k_o (1 + s\tau_2/\tau_1)}{s^2 + s(k_d k_o \tau_2/\tau_1) + (k_d k_o/\tau_1 + \tau_2)} = \frac{2\zeta\omega_n s + \omega_n^2}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{5.36}$$

If the condition $k_d k_o \gg \omega_n$ or $k_d k_o k_a \gg \omega_n$ is true, this PLL system is called a "high gain loop." If the reverse is true, the system is a "low gain loop." Most practical PLLs are a high gain loop for good tracking performance. For a high gain loop, Equations 5.34 through 5.36 become approximately

$$H(s) \approx \frac{2\zeta\omega_n s + \omega_n^2}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{5.37}$$

Similarly, assuming a high gain loop, the approximate expression of the phase-error transfer function $H_e(s)$ for all three LF types becomes

$$H_e(s) \approx \frac{s^2}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{5.38}$$

The magnitude frequency responses of $H(s)$ for a high gain loop with several values of damping factor are plotted in Figure 5.14. It exhibits that the loop performs an LPF on the input phase signal. That is, the second-order PLL is able to track both phase and frequency modulations of the input signal as long as the modulation frequency remains within the frequency band roughly between zero and ω_n.

The transfer function $H(s)$ has a −3 dB frequency, $\omega_{-3\text{ dB}}$, that stands for the close loop bandwidth of the PLL. The relationship between $\omega_{-3\text{ dB}}$ and ω_n is presented here to provide a comparison with a familiar concept of bandwidth.

In a high gain loop case, by setting $|H(j\omega)| = \frac{1}{\sqrt{2}}$ and solving for ω, we can find

$$\omega_{-3\text{ dB}} = \omega_n\left[2\zeta^2 + 1 + \sqrt{(2\zeta^2 + 1)^2}\right]^{\frac{1}{2}} \tag{5.39}$$

The relationship between $\omega_{-3\text{ dB}}$ and ω_n for different damping factors is plotted in Figure 5.15 [4].

The magnitude frequency responses of $H_e(s)$ are plotted in Figure 5.16. A high pass characteristic is observed. It indicates that the second-order PLL tracks the low frequency phase error but cannot track high frequency phase error.

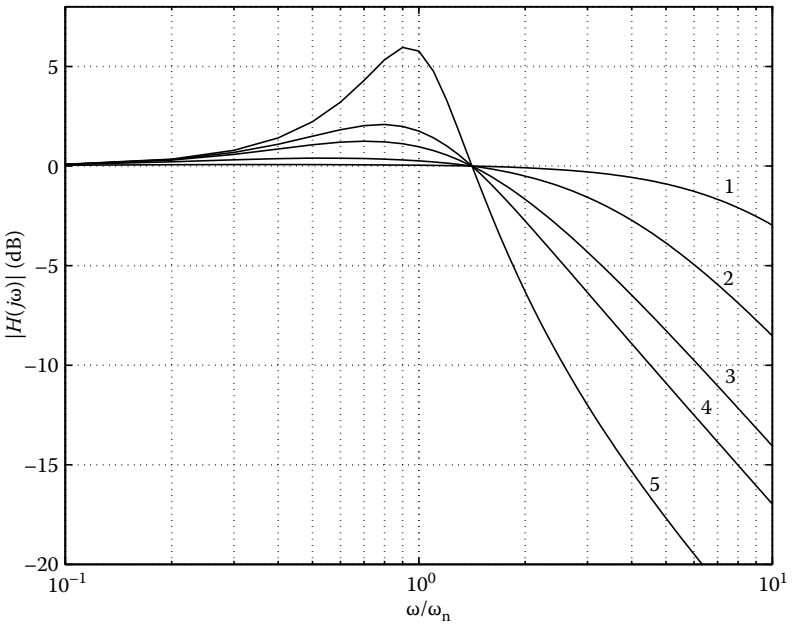

FIGURE 5.14 Frequency responses of the phase transfer function $H(j\omega)$ for different damping factors. Trace1: $\zeta = 5$, Trace2: $\zeta = 2$, Trace3: $\zeta = 1$, Trace4: $\zeta = 0.707$, Trace5: $\zeta = 0.3$.

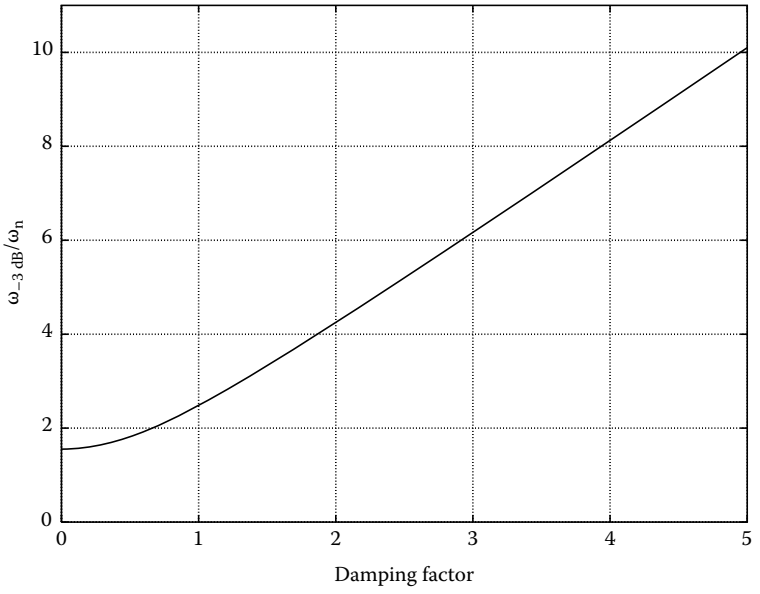

FIGURE 5.15 $\omega_{-3\ dB}$ bandwidth of a second-order loop versus different damping factors.

5.3.3.2 Transformations from *s*-Domain to *z*-Domain

As mentioned in the Section 5.1.3, the function blocks of the ADPLL is implemented by purely digital circuits, and the signals within the loop are digital too. In addition, the SPLL implemented by a microcontroller, microcomputer, or DSP is another type of PLL in discrete-domain (*z*-domain).

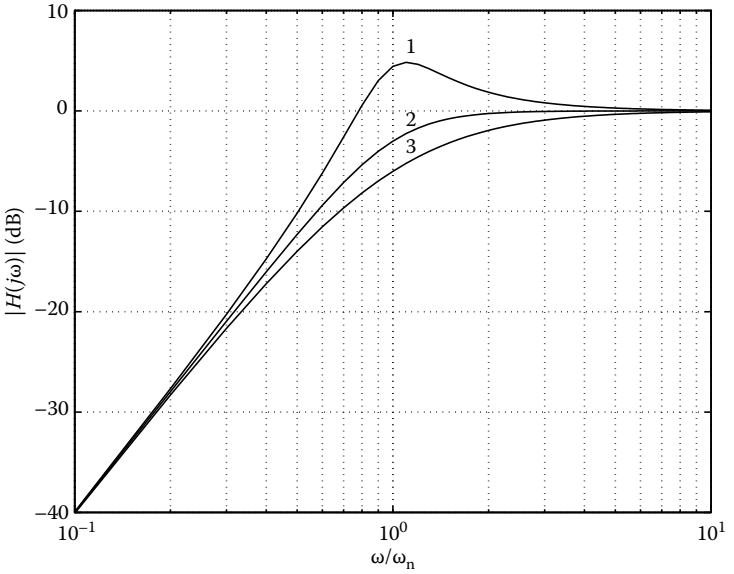

FIGURE 5.16 Frequency responses of the phase-error transfer function $H_e(j\omega)$ for different damping factors. Trace1: $\zeta = 0.3$, Trace2: $\zeta = 0.707$, Trace3: $\zeta = 1$.

Therefore, the analysis and design of a PLL had better be in discrete-domain. The basic types of LF and their features have been described in Section 5.3.3.1. Here, the corresponding discrete-time version of the three basic types of LF will be described after the introduction of transformations from continuous-domain (*s*-domain) to discrete-domain. There are two popular methods to transform a filter from continuous-domain to discrete-domain: backward difference method and bilinear transformation method. Figure 5.17 shows the principle of the backward difference method that we approximate the area under each segment of continuous curve by a rectangular area. Referring to Figure 5.17, the backward difference method means to approximate the integration areas of $\int_{(k-1)}^{kT} y(t)\mathrm{d}t$ by $y(kT)T$. Based on the backward difference method, the *z*-domain equivalent transfer function $H(z)$ of an *s*-domain transfer function $H(s)$ is simple and obtained by the substitution

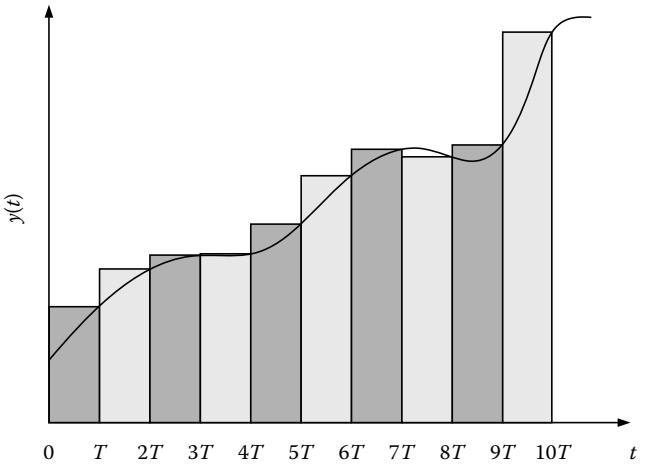

FIGURE 5.17 Backward difference method using a rectangular area approximation.

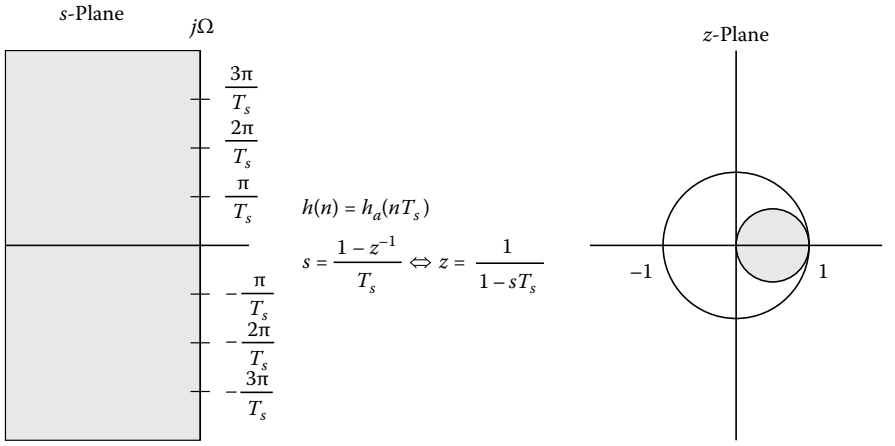

FIGURE 5.18 Mapping of the left half of the s-plane into the z-plane by the backward difference method.

$$H(z) = H(s)\big|_{s=\frac{1-z^{-1}}{T_s}} \tag{5.40}$$

One of the advantages of the backward difference method is that it will produce a stable discrete-time filter for a stable continuous-time filter. Figure 5.18 shows the mapping of the left half of the s-plane into the z-plane by the backward difference method. However, there is considerable distortion in the transient and frequency response characteristics of the discrete-time filter obtained in this method since the stable region is mapped into only a circle within the unit circle of z-plane.

From calculus and Figure 5.17, a good approximation is obtained only if the continuous-time signal changes very slowly over the sampling interval T_s. In other words, the signal bandwidth has to be much smaller than the sampling rate since the mapping from s-domain to z-domain should become distorted while the sampling period is too long. To reduce the distortion, it is desired to use a faster sampling frequency, that is, a smaller sampling period.

Figure 5.19 shows the principle of the bilinear transformation method that we approximate the area under each segment of continuous curve by a trapezoidal area. Therefore, the bilinear transformation method is also called the trapezoidal integration method to approximate the integration areas $\int_{(k-1)}^{kT} y(t)\mathrm{d}t$

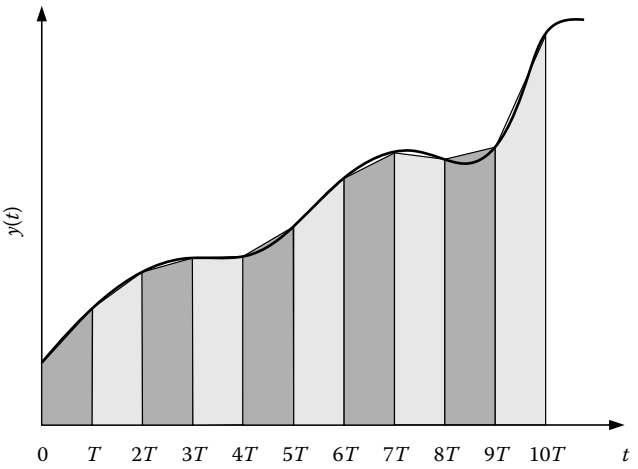

FIGURE 5.19 Bilinear transformation method using trapezoidal area approximation.

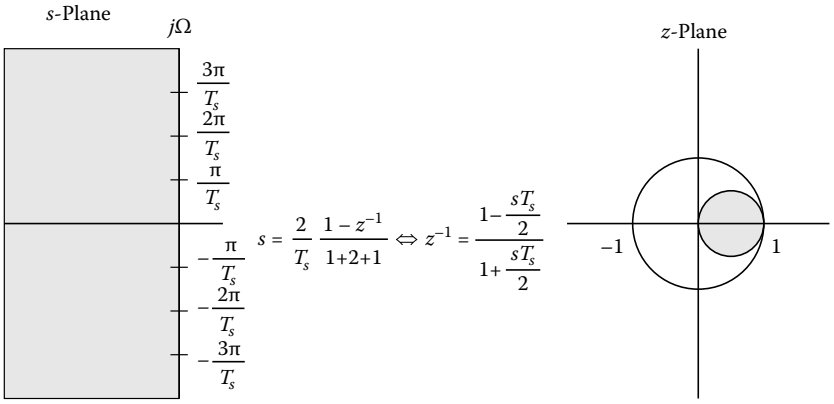

FIGURE 5.20 Mapping of the left half of the *s*-plane into the *z*-plane by the bilinear transformation method.

by $\frac{1}{2}[y(kT) + y((k-1)T)]T$. Thus, the *z*-domain equivalent transfer function $H(z)$ of a continuous-time filter $H(s)$ is obtained by

$$H(z) = H(s)\big|_{s=\frac{2}{T_s}\frac{1-z^{-1}}{1+z^{-1}}} \tag{5.41}$$

By means of bilinear transformation method, the entire left half of the *s*-plane is mapped into the unit circle with center at the origin of the *z*-plane as shown in Figure 5.20. Hence, the bilinear transformation method produces a stable discrete-time filter for a stable continuous-time filter. Furthermore, there is no frequency folding by means of the bilinear transformation method since it maps the entire *jw* axis of the *s*-plane into one complete revolution of the unit circle in the *z*-plane.

5.3.3.3 Discrete-Time LFs

As mentioned in the Section 5.3.3.1, there are three typical LFs for a phase-locked filter. Using backward difference transformation, the discrete-time transfer functions of passive lead-lag filter, active lead-lag filter, and active PI filter can be obtained as follows:

Passive lead-lag filter:

$$F_{\text{back,PLL}}(z) = \frac{T_s + \tau_2 - \tau_2 z^{-1}}{T_s + \tau_1 + \tau_2 - (\tau_1 + \tau_2)z^{-1}} \tag{5.42}$$

Active lead-lag filter:

$$F_{\text{back,ALL}}(z) = k_a \frac{T_s + \tau_2 - \tau_2 z^{-1}}{T_s + \tau_1 - \tau_1 z^{-1}} \tag{5.43}$$

Active PI filter:

$$F_{\text{back,PI}}(z) = \frac{T_s + \tau_2 - \tau_2 z^{-1}}{\tau_1(1 - z^{-1})} \tag{5.44}$$

On the other hand, the discrete-time transfer functions of passive lead-lag filter, active lead-lag filter, and active PI filter can be written, using the bilinear transformation, as follows:

Passive lead-lag filter:

$$F_{\text{bilinear,PLL}}(z) = \frac{T_s + 2\tau_2 + (T_s - 2\tau_2)z^{-1}}{T_s + 2\tau_1 + 2\tau_2 + (T_s - 2\tau_1 - 2\tau_2)z^{-1}} \tag{5.45}$$

Active lead-lag filter:

$$F_{\text{bilinear,ALL}}(z) = k_a \frac{T_s + 2\tau_2 + (T_s - 2\tau_2)z^{-1}}{T_s + 2\tau_1 + (T_s - 2\tau_1)z^{-1}} \tag{5.46}$$

Active PI filter:

$$F_{\text{bilinear}}(z) = \frac{T_s + 2\tau_2 + (T_s - 2\tau_2)z^{-1}}{2\tau_1(1 - z^{-1})} \tag{5.47}$$

From the viewpoint of implementation, all the discrete-time LFs have the transfer function format of a first-order infinite impulse response filter:

$$F_{\text{LF}}(z) = \frac{b_0 + b_1 z^{-1}}{1 - a_1 z^{-1}} \tag{5.48}$$

The differences in hardware requirements are small, but the system characteristics and performance are dramatic. Using an approach similar to the Weiner filter theory, Jaffe and Rechtin [30] investigated the optimal LFs for PLLs with different inputs. For a frequency step input, the form of active PI filter is shown to be optimal.

5.3.4 Charge-Pump PLL

A charge-pump PLL usually consists of four major blocks as shown in Figure 5.21. The PD is a purely PFD. The charge-pump circuit converts the digital signals UP, DN, and null (neither up nor down) generated by the PD into a corresponding charge-pump current I_p, $-I_p$, and zero. The LF is usually a passive RC circuit converting the charge-pump current into an analog voltage to control VCO. The purpose of the "charge-pump" is to convert the logic state of the phase-frequency detector output into an analog signal suitable for controlling the VCO. The schematic of the charge-pump circuit and the LF is shown in Figure 5.22. The linear model shown in Figure 5.3 can be employed to describe a charge-pump PLL. k_d is the equivalent gain of a charge-pump circuit. If the loop bandwidth is much smaller than the input frequency, the detailed behavior within a single cycle can be ignored. Then the state of a PLL can be assumed to be only changed by a small amount during each input cycle. Actually the "average" behavior over many cycles is what we are interested in. The average current charging the capacitor is given by

$$\begin{aligned} I_{\text{avg}} &= \frac{Q}{T} = \frac{I\Delta t}{T} \\ &= \frac{I\left(\frac{\phi_e}{2\pi}\right)T}{T} \\ &= \frac{I\phi_e}{2\pi} \end{aligned} \tag{5.49}$$

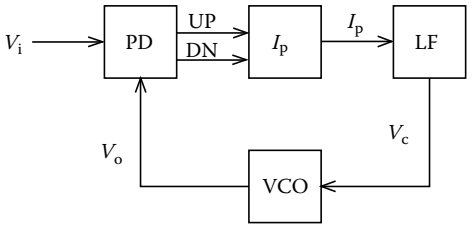

FIGURE 5.21 Charge-pump PLL diagram.

And the average k_d is

$$k_d \triangleq \frac{I_{\text{avg}}}{\phi_e} = \frac{I_{\text{avg}}}{2\pi} \tag{5.50}$$

The charge-pump current is transferred to the control voltage of the following VCO by the LF consisted of a resistor and a capacitor as shown in Figure 5.22. The impedance (transfer function) of the RC LF is given by

$$F(s) = R + \frac{1}{C_p s} = \frac{1 + RC_p s}{C_p s} = K_p + \frac{K_I}{s} \tag{5.51}$$

which has the format of an active PI filter. Therefore, the closed-loop transfer function can be obtained as

$$H(s) \triangleq \frac{\phi_{out}}{\phi_{in}} = \frac{k_d \cdot F(s) \cdot \frac{k_o}{s}}{1 + \frac{k_d k_o}{s}} = \frac{\frac{I_{avg}}{2\pi C_p}(RC_p s + 1)k_o}{s^2 + \frac{I_{avg}}{2\pi} k_o R s + \frac{I_{avg}}{2\pi C_p} k_o} \tag{5.52}$$

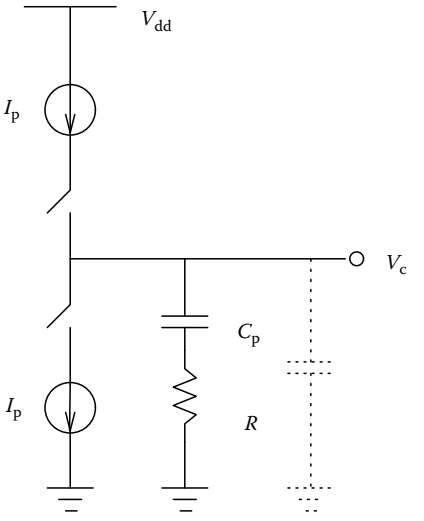

FIGURE 5.22 The schematic of LF.

Generally, a second-order system is characterized by the natural frequency $f_n = \frac{\omega n}{2\pi}$ and the damping factor ζ, and they can be expressed as follows:

$$\omega_n = \sqrt{\frac{I_{avg}}{2\pi C_p} k_o} \text{ rad/s}$$
$$\zeta = \frac{RC_p}{2}\omega_n \tag{5.53}$$

For the stability consideration, there is a limitation of a normalized natural frequency F_N [15],

$$F_N \triangleq \frac{f_n}{f_i} < \frac{\sqrt{1 + \zeta^2} - \zeta}{\pi} \tag{5.54}$$

In the single-ended charge pump, the resistor added in series with the capacitor shown in Figure 5.22 may introduce ''ripple'' in the control voltage V_c even when the loop is locked [16]. The ripple control voltage modulates the VCO frequency and results in phase noise. This effect is especially undesired in frequency synthesizers. In order to suppress the ripple, a second-order LF, as shown in Figure 5.22 with a shunt capacitor in dotted line, is used. This configuration introduces a third pole in the PLL. Stability issues must be taken care of furthermore. Gardner provides criteria for the stability of the third-order PLL [16].

An important property of any PLLs is the static phase error that arises from a frequency offset $\Delta\omega$ between the input signal and the free-running frequency of the VCO. According to the analysis in Ref. [16], the static phase error is

$$\theta_v = \frac{2\pi\Delta\omega}{k_o I_p F(0)} \text{ rad} \tag{5.55}$$

To eliminate the static phase error in conventional PLLs, an active LF with a high DC gain ($F(0)$ is large) is preferred. Nevertheless, the charge-pump PLL allows zero static phase error without the need of

a large DC gain of the LF. This effect arises from the input open circuit during the "null" state (charge-pump current is zero). Real circuits will impose some resistive loading R_s in parallel to the LF. Therefore, the static phase error, from Equation 5.55 will be

$$\theta_v = \frac{2\pi\Delta\omega}{k_o I_p R_s} \text{ rad} \tag{5.56}$$

The shunt resistive loading most likely comes from the input of a VCO control terminal. Compared with the static phase error of a conventional PLL as expressed in Equation 5.11, the same performance can be obtained from a charge-pump PLL without a high DC-gain LF [30].

5.3.5 PLL Design Considerations

5.3.5.1 Typical Procedures of PLL Design

A PLL design usually starts with specifying the key parameters such as natural frequency ω_n, lock-in range $\Delta\omega_L$, damping factor ζ, and the frequency control range which majorly depend on applications. Typical design procedures are described as follows:

Step 1. Specify the damping factor ζ. The damping factor determines the relative stability of a PLL. ζ should be considered as a critical parameter to achieve fast response, small overshoot, and minimum noise bandwidth B_L. If ζ is very small, large overshoot occurs and the overshoot causes phase jitter [19]. If ζ is too large, the response becomes sluggish.

Step 2. Specify the lock-in range $\Delta\omega_L$ or the noise bandwidth B_L. As shown in Equations 5.53 and 5.50, the natural frequency ω_n depends on $\Delta\omega_L$ and ζ (or B_L and ζ). If the noise is not the key issue of the PLL, we may ignore the noise bandwidth and specify the lock-in range. If the noise is concerned, we should specify B_L first, and keep the lock-in range of PLL.

Step 3. Calculate the ω_n according to step 2. If the lock-in range has been specified, Equation 5.53 indicates

$$\omega_n = \frac{\Delta\omega_L}{2\zeta} \tag{5.57}$$

If the noise bandwidth has been specified, Equation 5.50 indicates the natural frequency as

$$\omega_n = \frac{2B_L}{\zeta + \frac{1}{4\zeta}} \tag{5.58}$$

Step 4. Determine the VCO gain factor k_o and the PD gain k_d. k_o and k_d are both characterized by circuit architectures. They must achieve the requirement of the lock-in range specified in step 2. For example, if k_o or k_d is too small, the PLL will fail to achieve the desired lock-in range.

Step 5. Choose the LF. Different types of the LF are available as shown in Figure 5.12. According to Equation 5.9 through 5.11, ω_n and ζ specified above are used to derive the time constants of the LF.

5.3.5.2 PLL Bandwidth Control

As illustrated in previous sections, the PLL noise performance is contrary to the dynamic performances of a PLL such as lock-in range and acquisition speed, which are generally proportional to the PLL bandwidth or the nature frequency ω_n. For example, Equation 5.52 shows that it is desired to have large k_d or $F(\Delta\omega_L)$ to achieve wide lock-in range and fast acquisition. In contrast, Equations 5.59 and 5.60 show that it is desired to have a small nature frequency ω_n in order to reduce the output jitter. Besides, variations in process, voltage, and temperature can lead to uncertainties in loop parameters of a

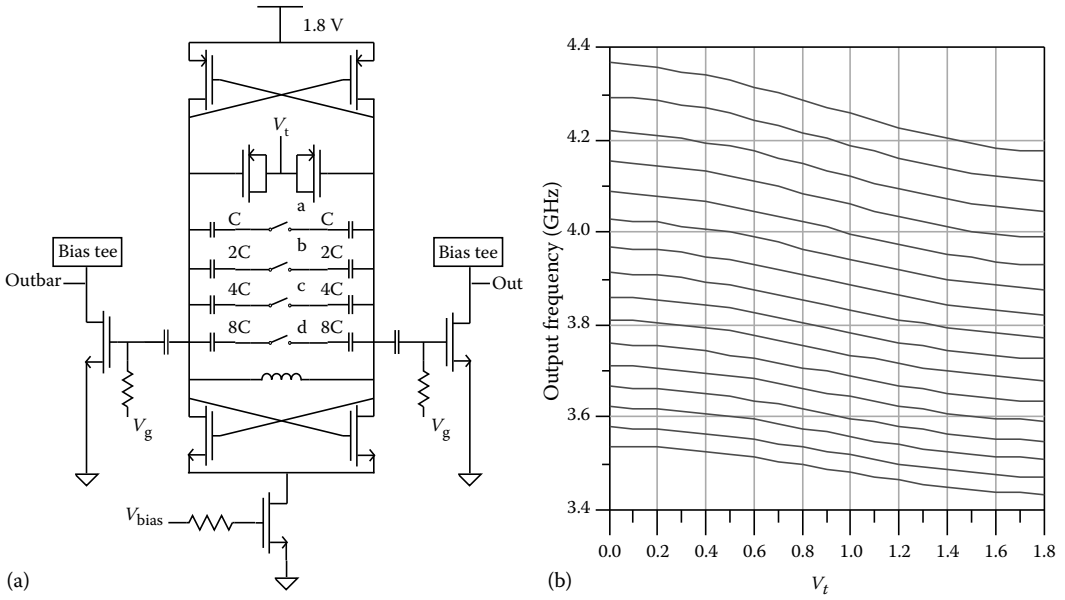

FIGURE 5.23 (a) Wide-range LC-tank VCO with capacitor array and (b) conversion gain k_o.

fixed-bandwidth PLL, such as the conversion gain k_o of VCO, the time-constant ratio τ_2/τ_1 of the LF, and the charge-pump current I_p. For example, variations in process, voltage, and temperature will cause the frequency of a ring oscillator to vary by a factor of 2–3 between its slowest and fastest conditions experientially. Figure 5.23 shows a wide-range LC-tank VCO with capacitor array to achieve low conversion gain k_o for superior phase noise performance. It can be seen that the VCO conversion gain k_o slightly varies from segment to segment of frequencies. Moreover, the curve of conversion gain k_o is nonlinear in any frequency segment. The design result shows a conversion gain range of 27–50 MHz/V. This means that the PLL bandwidth will vary by a factor of 2 due to the variation of VCO conversion gain k_o. Following the design procedures mentioned above, a conservative operating point is usually chosen to guarantee the stability for all conditions. Unfortunately, such a conservative design only achieves a suboptimal performance in most cases.

For achieving fast acquisition as well as a superior noise performance, many schemes of PLL bandwidth control are proposed in the literature [31–37]. Figure 5.24 shows the concept of PLL bandwidth control based on some monitoring techniques of the phase error. In Ref. [31], based on some modifications of the Kalman filtering formulation, an approach is developed to derive the optimal loop gain sequence of dual-loop DPLL, which is independent of measured noise statistics. In order to achieve low noise PLL as

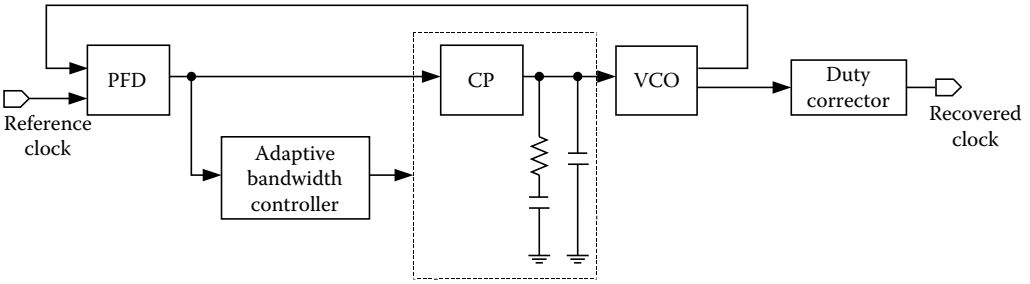

FIGURE 5.24 The concept of an adaptive-bandwidth PLL.

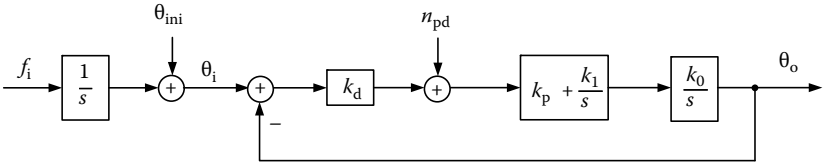

FIGURE 5.25 Linear model of a charge-pump PLL.

well as fast acquistion, Joonsuk Lee and Beomsup Kim [32] realize an analog bandwidth controller to adaptively control the current of charge-pump, that is the PLL bandwidth. Figure 5.25 shows the linear model of charge-pump PLL using a proportional–integral (PI) filter as shown in Figure 5.21. According to Equations 5.51 through 5.53, the damping factor ζ, that is, relative stability of such an adaptive-bandwidth PLL will vary during the lock-in process since the nature frequency ω_n is adaptively adjusted.

In order to develop a PLL and delay-locked loop (DLL) with adaptive-bandwidth to enable optimal performance over a wide frequency range and across process, voltage, and temperature variations, a discrete-time, open-loop dynamic model of the PLL/DLL is proposed to characterize the change in output variables in response to the sampled error, and to express the adaptive-bandwidth criteria in terms of the open-loop gains [37]. Furthermore, the scaling equations for the charge-pump current and the filter resistor are derived to achieve adaptive-bandwidth charge-pump PLL/DLLs with a constant damping factor ζ. It is regrettable that such scaling scheme is a challenge in the analog realization. In contrast, it is easier to maintain a constant damping factor ζ using a digital PI LF to achieve the adaptive bandwidth control. In Ref. [11], a modified structure of digital PI LF is proposed and shown in Figure 5.26. Based on such a modified structure, it is easy to derive the equivalent phase-transfer function in continuous-time domain that is represented in terms of the parameters of loop components as

$$\begin{aligned} H_\theta(s) &= \frac{\Theta_o(s)}{\Theta_i(s)} \\ &= \frac{k_d k_o K_P s + k_d k_o K_P K_I}{s^2 + k_d k_o K_P s + k_d k_o K_P K_I} \\ &= \frac{2\zeta\omega_n s + \omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \end{aligned} \tag{5.59}$$

where

$$\begin{aligned} \omega_n &= \sqrt{k_d k_o K_P K_I}, \\ \zeta &= 0.5\sqrt{k_d k_o K_P / K_I} \end{aligned} \tag{5.60}$$

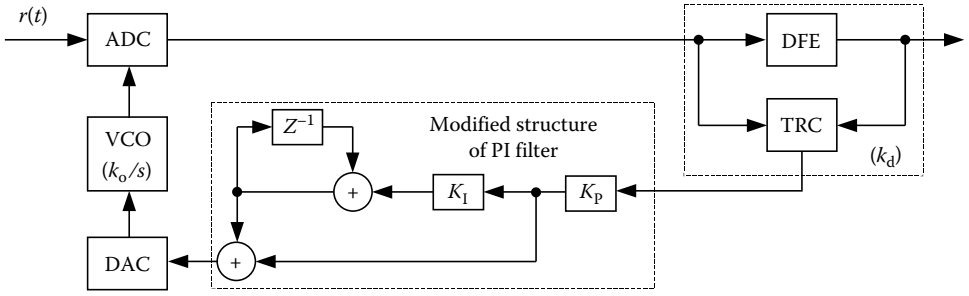

FIGURE 5.26 Timing recovery using a modified structure of digital PI LF.

denote the nature frequency and the damping factor, respectively. Referring to Equation 5.60, if a scaling factor of K_P and K_I is induced into the modified PI LF structure for adaptively adjusting the PLL bandwidth or the nature frequency ω_n, we can mantain a constant damping factor ζ while the PLL bandwidth is proportional to the scaling factor induced.

5.4 PLL Applications

5.4.1 Clock and Data Recovery

In data transmission systems such as optical communications, telecommunications, disk drive systems, and local networks, data are transmitted on baseband or passband. In most of these applications, only data signals are transmitted by transmitter, but clock signals are not transmitted in order to save hardware cost. Therefore, the receiver should have some schemes to extract the clock information from the received data stream and to regenerate transmitted data using the recovered clock. This scheme is called timing recovery or clock recovery.

To recover the data correctly, the receiver must generate a synchronous clock from the input data stream, the recovered clock must synchronize with the bit rate (the baud of data). The PLL can be used to recover the clock from the data stream, but there are some special design considerations. For example, because of the random nature of data, the choice of PFDs is restricted. In particular, three-state PD is not proper, because when there are no transitions in the data stream, the PD interprets that the VCO frequency is higher than the data frequency and remains its output in the ''down'' state, which makes the PLL lose lock as shown in Figure 5.27. Thus, the choice of PFD for random binary data requires a careful examination over whether data transitions are absent. One useful method is the rotational frequency detector described in Ref. [9]. The random data also causes the PLL to introduce undesired phase variation in the recovered clock, it is called timing jitter and this is an important issue of the clock recovery.

5.4.1.1 Data Format

Binary data are usually transmitted in an NRZ format as shown in Figure 5.28a because of the consideration of bandwidth efficiency. In NRZ format, each bit has a duration of T_B (bit period). The signal does not go to zero between adjacent pulses representing 1's. It can be shown in Ref. [24] that the corresponding spectrum has no line component at $f_B = \frac{1}{T_B}$, most of the spectrum of this signal lines below $\frac{f_B}{2}$. The term ''NRZ'' distinguishes itself from another data type called ''return-to-zero'' (RZ) as shown in Figure 5.28b, where the signal goes to zero between consecutive bits. Therefore, the spectrum of RZ data have a frequency component at f_B. For a given bit rate, RZ data need wider transmitting bandwidth; therefore, NRZ data are preferable when channel or circuit bandwidth is a concern.

Due to the lack of a spectral component at the bit rate of NRZ format, a clock recovery circuit may lock to spurious signals or fail to lock at all. Thus, a nonlinear process for the NRZ data is essential to create a frequency component at the baud rate.

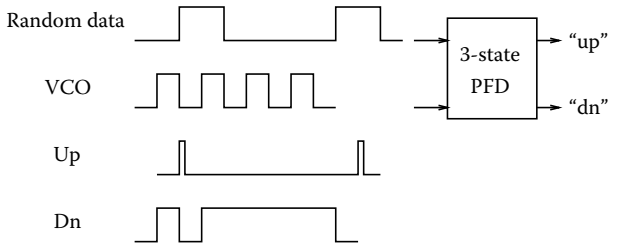

FIGURE 5.27 Response of a three-state PD to random data.

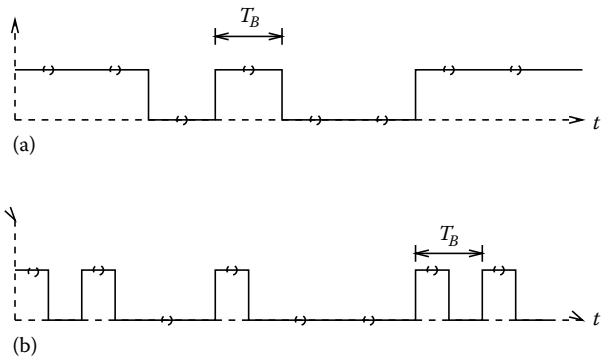

FIGURE 5.28 (a) NRZ data and (b) RZ data.

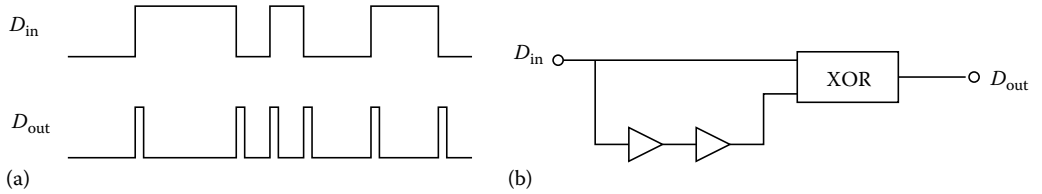

FIGURE 5.29 Edge detection of NRZ data.

5.4.1.2 Data Conversion

One way to recover the clock signal from the NRZ data is to convert it to an RZ-like data that have a frequency component at the bit rate, and then recover clock from data using a PLL. Transition detection is one of the methods to convert NRZ data to RZ-like data. As illustrated in Figure 5.29a, the edge detection requires a mechanism to sense both positive and negative data transitions. In Figure 5.29b, NRZ data are delayed and compared with itself by an exclusive-OR gate; therefore, the transition edges are detected. In Figure 5.30, the NRZ data V_i is first differentiated to generate pulses corresponding to each transition. These pulses are made to be all positive by squaring the differentiated signal v_i. The result is that the signal V_i' looks just like RZ data, where pulses are spaced at an interval of T_B.

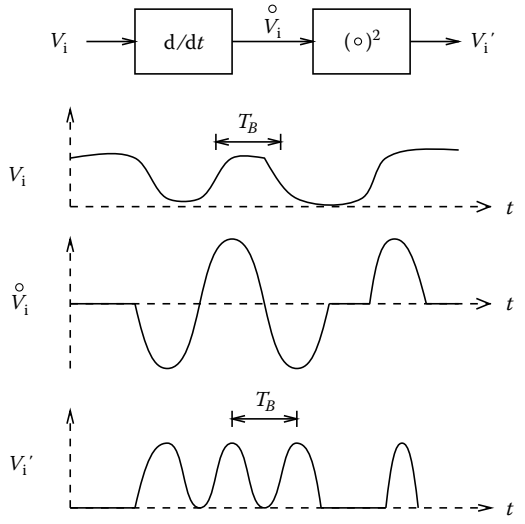

FIGURE 5.30 Converting NRZ to RZ-like signal.

5.4.1.3 Clock Recovery Architecture

Based on different PLL topologies, there are several clock recovery approaches. Here, the early–late and the edge-detector-based methods will be described.

Figure 5.31 shows the block diagram of the early–late method. The waveforms for the case in which the input lags the VCO output are shown in Figure 5.32, where the early integrator integrates the input signal for the early-half period of the clock signal, and holds it for the remainder of the clock signal. On the other

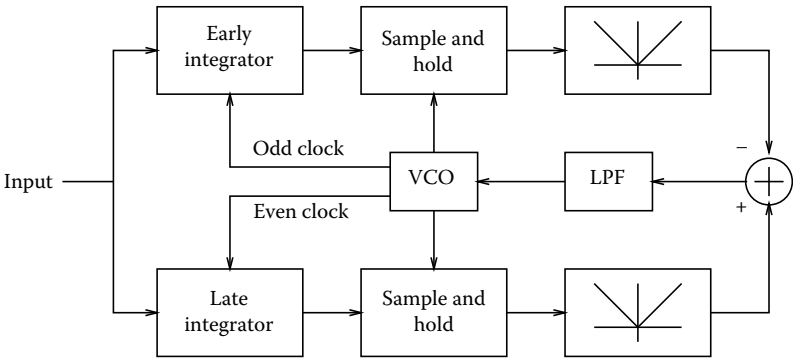

FIGURE 5.31 Early–late block diagram.

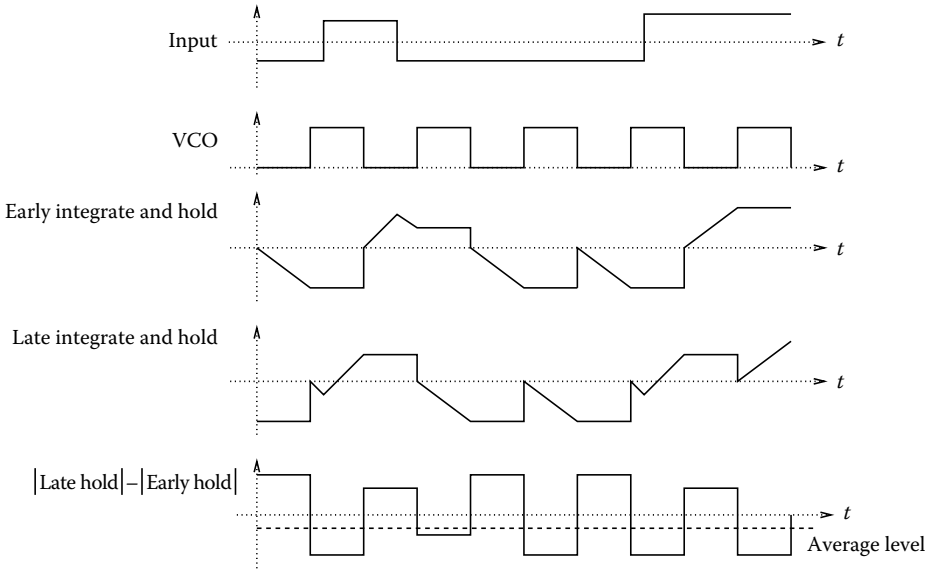

FIGURE 5.32 Clock waveforms for early–late architecture.

hand, the late integrator integrates the input signal for the late-half period of the clock signal and holds it for the next early-half period. The average difference between the absolute values of the late hold and the early hold voltage generated from an LPF gives the control signal to adjust the frequency of the VCO. As mentioned above, this method is popular for rectangular pulses. However, there are some drawbacks in this method. As this method relies on the shape of pulses, a static phase error can be introduced if the pulse shape is not symmetric. In high-speed applications, this approach requires a fast settling integrator that limits the operating speed of the clock recovery circuit and the acquisition time cannot be easily controlled.

The most widely used technique for clock recovery in high performance, wide-band data transmission applications is the edge-detection-based method. The edge-detection method is used to convert data format such that the PLL can lock the correct baud frequency. More details have been described in Section 5.4.1.2. There are many variations of this method depending on the exact implementation of each PLL loop component. The ''quadricorrelator'' introduced by Richman [7] and modified

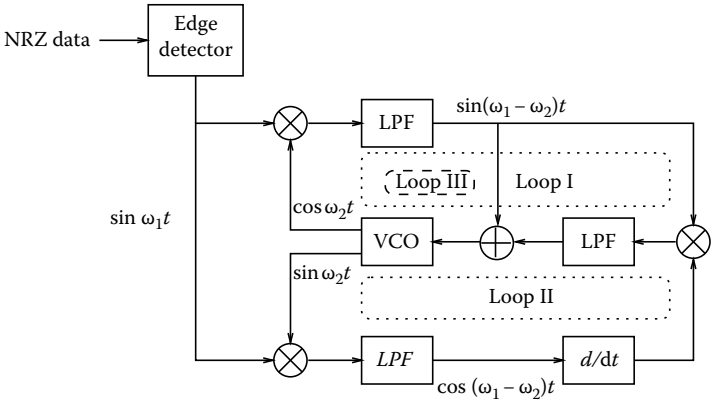

FIGURE 5.33 Quadricorrelator.

by Bellisio [25] is a frequency-difference discriminator and has been implemented in a clock recovery architecture. Figure 5.33 [26] is a phase-frequency locked loop using edge-detection method and quadricorrelator to recover timing information from NRZ data. As shown in Figure 5.33, the quadricorrelator follows the edge-detector with a combination of three loops sharing the same VCO. Loops I and II form a frequency-locked loop that contains the quadricorrelator for frequency detection. Loop III is a typical PLL for phase alignment. Since the phase- and frequency-locked loops share the same VCO, the interaction between two loops is a very important issue. As described in Ref. [26], when $\omega_1 \approx \omega_2$, the DC feedback signal produced by loops I and II approaches zero and loop III dominates the loop performance. A composite frequency- and PLL is a good method to achieve fast acquisition and a narrow PLL loop bandwidth to minimize the VCO drift. Nevertheless, because the wide band frequency-locked loop can response to noise and spurious components, it is essential to disable frequency-locked loop when the frequency error gets into the lock-in range of the PLL to minimize the interaction. More clock recovery architectures are described in Refs. [19,21,23,27–29].

5.4.2 Delay-Locked Loop

Two major elements for adjusting the timing are VCO and voltage-controlled delay line (VCDL). Figure 5.34 shows a typical DLL [12,13] that replaces the VCO of a PLL with a VCDL. The input signal is delayed by an integer multiple of the signal period because the phase error is zero when the phase difference between V_{in} and V_o approaches multiple of the signal periods. The VCDL usually consists a number of cascaded gain stages with variable delay. Delay lines, unlike ring oscillators, cannot generate a signal; therefore, it is difficult to make frequency multiplication in a DLL.

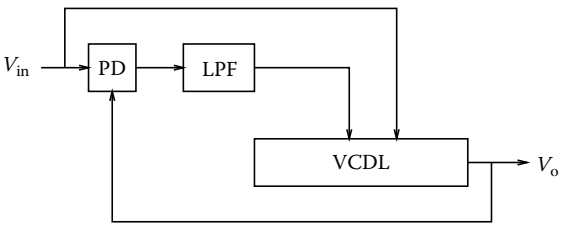

FIGURE 5.34 DLL block diagram.

In a VCO, the output "frequency" is proportional to the input control voltage. The phase transfer function contains a pole, which is $H(s) = \frac{k_o}{s}$ (k_o is the VCO gain). In a VCDL, the output "phase" is proportional to the control voltage, and the phase transfer function is $H(s) = k_{VCDL}$. So the DLL can be easily stabilized with a simple first-order LF. Consequently, DLLs have much more relaxed trade-offs among gain, bandwidth, and stability. This is one of the two important

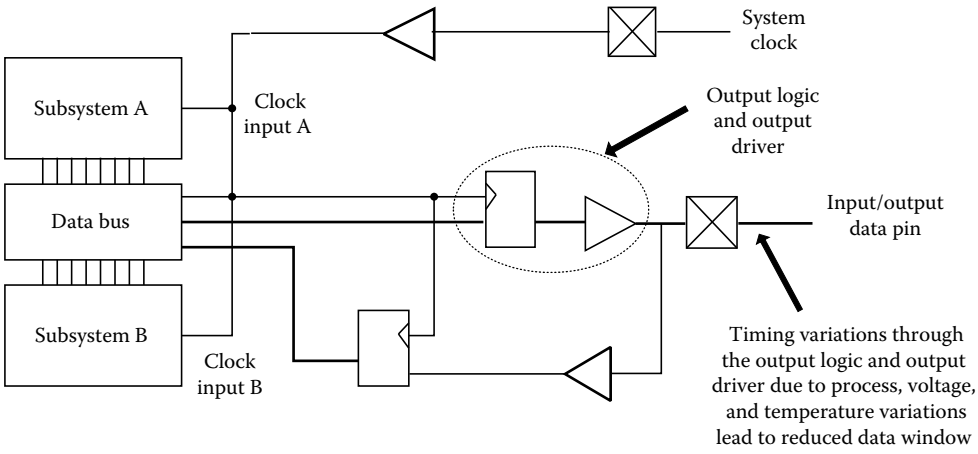

FIGURE 5.35 Modern digital systems use synchronous communication to achieve high-speed signaling to and from the bus between the subsystems.

advantages over PLLs. Another advantage is that delay lines typically introduce much less jitter than VCO [14]. Because a delay chain is not configured as a ring-oscillator, there is no jitter accumulation since the noise does not contribute to the starting point of the next clock cycle.

A typical application of DLL is to synchronize the clock edges of subsystems within a digital system to access the bus between subsystems. Figure 5.35 shows modern digital systems that use synchronous communication to achieve high-speed signaling to and from the bus between the subsystems. Subsystems that communicate synchronously use a clock signal as a timing reference so that data can be transmitted and received with a known relationship to this reference. A difficulty in maintaining this relationship is that process, voltage, and temperature variations can alter the timing relationship between the clock and data signals of subsystems, resulting in reduced timing margins. Figure 5.36 shows that on the left side the data valid window (the time over which data can be sampled reliably by the receiver) can be large at low signaling speeds [38]. Even in the presence of a substantial shift in the data valid window across operational extremes, the resulting data valid window can still be large enough to transmit and receive the data reliably. Unfortunately, the variations in process, voltage, and temperature can result in the loss of

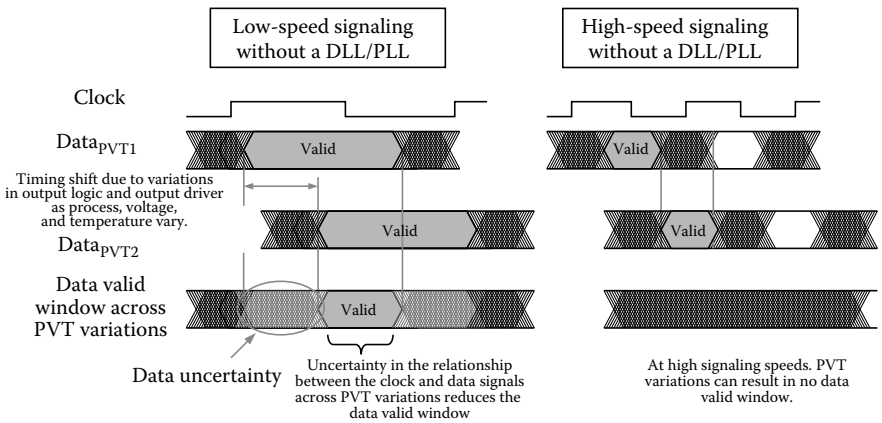

FIGURE 5.36 The timing relationships between the clock and data signals of subsystems in a conventional digital system.

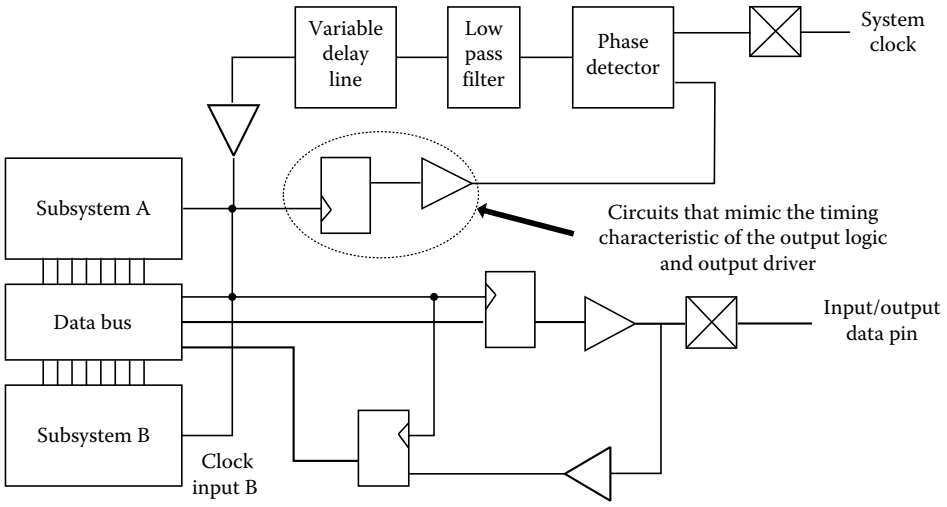

FIGURE 5.37 DLL-on-chip to maintain the timing relationship between a clock signal and an output data signal.

the data valid window when the signal speed is increased as also shown on the right-hand side of Figure 5.36. This problem gets worse as signaling speeds increase, limiting the ability of subsystems to communicate data at higher speeds.

The function of DLLs and PLLs to synchronize a signal with a reference or an input signal in frequency as well as in phase can be used to maintain such a fixed timing relationship between signals of subsystems. Figure 5.37 shows how a DLL is used to maintain the timing relationship between a clock signal and an output data signal. The PD detects phase differences between the clock and output data and sends control information through an LPF to a variable delay line that adjusts the timing of the internal clock to maintain the desired timing relationship. The PD must account for the timing characteristics of the output logic and output driver. This is important since it estimates the phase differences between the clock and the data driven by the output driver, where the timing relationships of subsystems are changed over time due to the process, voltage, and temperature variations. Maintaining the timing relationships between the clock and output data with DLLs and PLLs results in improved timing margins as shown in Figure 5.38. Then, the important limitation to increasing signaling speeds is addressed.

5.4.3 Frequency Synthesizer

A frequency synthesizer generates any of a number of frequencies by locking a VCO to an accurate frequency source such as a crystal oscillator. For example, RF systems usually require a high-frequency local oscillator whose frequency can be changed in small and precise steps. The ability of multiplying a reference frequency makes PLLs attractive for synthesizing frequencies.

The basic configuration used for frequency synthesis is shown in Figure 5.39a. The system is capable of generating the frequency at an integer multiple of the reference frequency. A quartz crystal is usually used as the reference clock source because of its low jitter characteristic. Due to the limited speed of CMOS device, it is difficult to generate frequency directly in the range of GHz or more. To generate higher frequencies, prescalers are used, which are implemented with other IC technologies such as ECL. Figure 5.39b shows a synthesizer structure using a prescaler V, where the output frequency becomes

$$f_{\text{out}} = \frac{NVf_{\text{i}}}{M} \tag{5.61}$$

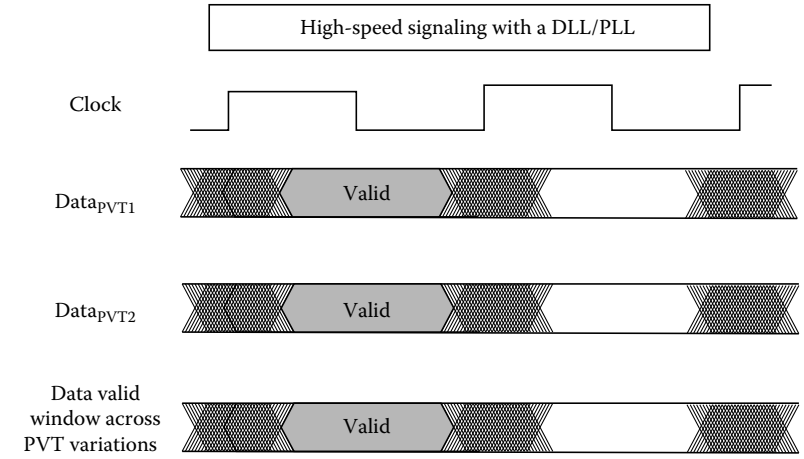

FIGURE 5.38 Timing relationships between subsystems when a DLL is employed for synchronizing the bus access.

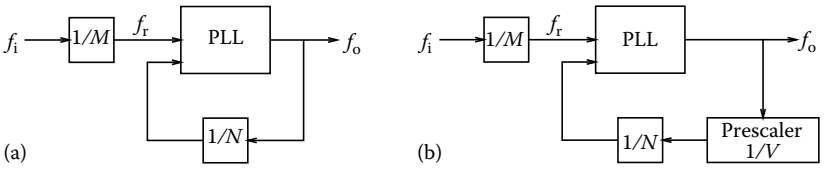

FIGURE 5.39 Frequency-synthesizer block diagrams: (a) basic frequency-synthesizer system and (b) system extends the upper frequency range by using an additional high-speed prescaler.

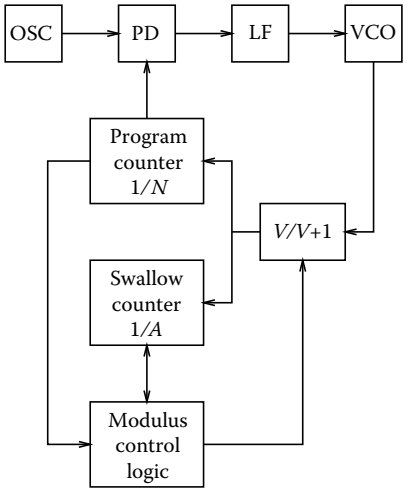

FIGURE 5.40 The block diagram of dual-modulus frequency synthesizer.

Because the scaling factor V is obviously much greater than one, it is no longer possible to generate any desired integer multiple of the reference frequency. This drawback can be circumvented by using a so-called dual-modulus prescaler as shown in Figure 5.40. A dual-modulus prescaler is a divider whose division can be switched from one value to the other by a control signal. The following shows that the dual-modulus prescaler makes it possible to generate a number of output frequencies that are spaced only by one reference frequency. The VCO output is divided by $V/V+1$ dual-modulus prescaler. The output of the prescaler is fed into a "program counter" $1/N$ and a "swallow counter" $1/A$. The dual-modulus prescaler is set to divide by $V+1$ initially. After "A" pulses out of the prescaler, the swallow counter is full and changes the prescaler modulus to V. After additional "N–A" pulses out of the prescaler, the program counter changes the prescaler modulus back to $V+1$ and restarts the swallow counter. Then the cycle

is repeated. In this way, the VCO frequency is equal to $(V+1)A + V(N-A) = VN + A$ times of the reference frequency. Note that N must be larger than A. If this is not the case, the program counter would be full earlier than the $1/A$ and both counters would be reset. Therefore, the dual-modulus prescaler would never be switched from $V+1$ to V. For example, if $V=64$, then A must be in the range of 0–63 such that $N_{\min}=64$. The smallest realizable division ratio is

$$(N_{\text{tot}})_{\min} = N_{\min} V = 4096 \tag{5.62}$$

The synthesizer of Figure 5.40 is able to generate all integer multiple of the reference frequency starting from $N_{\text{tot}}=4096$. For extending the upper frequency range of frequency synthesizers but still allowing the synthesis of lower frequency, the four-modulus prescaler is a solution [1].

Based on the above discussions, the synthesized frequency is an integer multiple of a reference frequency. In RF applications, the reference frequency is usually larger than the channel spacing for loop dynamic performance considerations, in which the wider loop bandwidth for a given channel spacing allows faster settling time and reduces the phase jitter requirements to be imposed on the VCO. Therefore a ''fractional'' scaling factor is needed. Fractional division ratios of any complexity can be realized. For example, a ratio 3.7 is obtained if a counter is forced to divide by 4 in seven cycles of each group of 10 cycles and by 3 in the remaining three cycles. On the average, this counter divides the input frequency by 3.7 effectively.

6.1 Introduction

Linear lumped reactance parameter networks loaded by resistors can be used to form pulses of different shapes [1,2]. The most known applications [2] require the networks that form pulses of the so-called quasi-rectangular shape. The network excitation is usually a step voltage, and it is required that the network output response (in this case it is the step response) is a pulse of finite duration. In a realizable network, the fronts of this pulse should have ''rounded'' corners, and the slopes of the fronts should also be finite. Below this is done using a semi-period of $\sin^2 t$ function.

These pulse-forming networks will be considered first, and it will be shown that the required result may be obtained using different input excitations and using, of course, different networks. The pulse of the same shape can be obtained when the excitation is a step, an impulse or even a sinusoidal function. The last result looks surprising for linear networks, yet the reader should understand that the output pulse is shaped during the transient period, when the sinusoidal voltage is turning on. When the transient is over, the steady-state response of the network is zero.

This reconsideration of the old problem establishes a certain difference between synthesis in time domain and frequency domain. The output signal time-domain approximation, in case of pulse-forming

networks, should also result in a realizable transfer function. But this synthesis results in many solutions not only because of many possible realizations of the same transfer function. In addition, one may change input excitation (even though in practice the choice of input excitations is limited), then find modified transfer function, and then synthesize new networks. This modification of input signal is not used in the frequency-domain synthesis where it is assumed that the input excitation is the sinusoidal signal.

The method of approximation proposed here gives new and useful results even for the case of the step voltage input excitation and quasi-rectangular shape of the output response. It is shown that if the output pulse is delayed with respect to the input step, then it is possible to shape the output pulse so that its amplitude will be higher than the amplitude of the applied input step voltage. The increase of amplitude is usually connected with the idea of using a transformer, yet the pulse-shaping circuit may provide transformerless change of amplitude.

The approximation developed here for pulse forming may also be applied to the synthesis of wideband amplifier transfer functions. Unfortunately, an initial attempt of using $\sin^2 t$ for this purpose [3] did not bring any general results, and the required transfer functions were found numerically [4]. But even this attempt was forgotten, and the transfer functions of the wideband amplifiers were found indirectly. They were obtained starting from the frequency domain and investigating the time-domain response of the filter transfer functions. It was found that the step responses of the Bessel filters do not have overshoot. It happened that exactly this transient response is required in realization of the wideband amplifiers. Yet, as shown here, using $\sin^2 t$ in the approximation of the impulse response allows one to find the realizable transfer functions directly, on the basis of requirements formulated in the time domain to the step response.

Finally, the considered approximation method allows one to find realizable transfer functions for the networks with the step or impulse response representing the sinusoidal pulse of finite duration, and with the pulse envelope that can be of an arbitrary shape. As an example, we consider the case when this envelope is also of sinusoidal shape. The pulses of these shapes find applications in ultra-wideband transmission networks and wavelet signal analysis. These pulse-shaping networks are usually realized by active networks. Yet, the fact that at least one physically realizable network is available is important for using of algorithms, which are able to improve an approximation and find a transfer function that is better suitable for the chosen realization method.

Many of the results given here can be found in [5]. Considering that this source of information is not easily accessible, a sincere effort is done to summarize all available material.

6.2 Networks Forming Quasi-Rectangular Output Pulses

In this section, we consider all procedures required in the synthesis of pulse-forming networks [5,6]. They start by approximation of the output pulse in the time domain and finding the Laplace transform of this pulse. Then, we review the requirements imposed on the realizable transfer function. After that we consider the second round of approximation, when the Laplace transform is approximated by an algebraic ratio obtained from the spectral representation of the Laplace transform. Finally, we give examples of realization. Some of these procedures will be omitted in parts dedicated to the wideband amplifier transfer functions and forming of the sinusoidal pulses.

6.2.1 Quasi-Rectangular Output Pulse and Its Laplace Transform

Assume that it is required to find reactance networks forming a quasi-rectangular pulse for three cases of input excitation, $v_i(t)$, namely, the unit impulse, the unit step, and the sinusoid with unit amplitude. The ratio of two polynomials approximating the Laplace transform of the output response will be the same for all three cases. In case of impulse excitation, $v_i(t) = \delta(t)$, this ratio is directly equal to the transfer function of the pulse-forming network. In case of $v_i(t) = u(t)$, a unit step voltage, the required transfer function is obtained by multiplication of the approximating ratio by s, and in case of $v_i(t) = \sin \Omega t$ this ratio is multiplied by $(s^2 + \Omega^2)$.

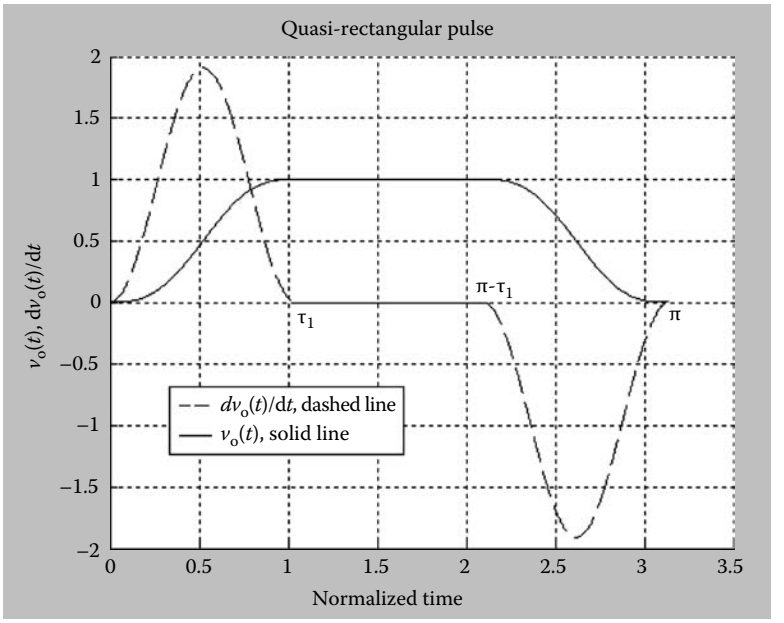

FIGURE 6.1 Quasi-rectangular pulse.

The required output response, $v_o(t)$, is a symmetric pulse (Figure 6.1) of the normalized duration $\tau = \pi$ for all considered cases of excitation. Assume that the derivative, dv_o/dt, of this response is approximated by one semi-period of $\sin^2(\pi t/\tau_1)$ function for the initial front of the pulse, and one delayed negative semi-period of $\sin^2(\pi t/\tau_1)$ for the rear front. The duration of each front is equal to τ_1. Then dv_o/dt is described by the following system of equations:

$$\frac{dv_o}{dt} = \begin{cases} A\sin^2(\pi t/\tau_1) & 0 < t < \tau_1 \\ 0 & \tau_1 < t < (\tau - \tau_1) \\ -A\sin^2[\pi(t - \tau + \tau_1)/\tau_1] & (\tau - \tau_1) < t < \tau \\ 0 & t > \tau = \pi \end{cases}. \tag{6.1}$$

The amplitude, A, will be obtained from the normalization condition

$$A\int_0^{\tau_1} \sin^2(\pi t/\tau_1)dt = 1. \tag{6.2}$$

This gives $A = 2/\tau_1$. This value of A is also equal to the maximal slew rate of the fronts, so that the approximate rise and fall times can be evaluated as

$$\tau_r = \tau_f = 1/A = \tau_1/2. \tag{6.3}$$

These rise and fall times are close to ones defined by 0.1 and 0.9 levels of the output pulse.

The Laplace transform of $(2/\tau_1)\sin^2(\pi t/\tau_1)$ function is equal to [7]

$$F_0(s) = \frac{1}{\tau_1}\frac{4(\pi/\tau_1)^2}{s\left[s^2 + 4(\pi/\tau_1)^2\right]}. \tag{6.4}$$

Using the shift theorem [8], one finds that the Laplace transform of the sine-squared pulse will be

$$F_1(s) = \frac{1}{\tau_1} \frac{4(\pi/\tau_1)^2}{s\left[s^2 + 4(\pi/\tau_1)^2\right]} (1 - e^{-s\tau_1}). \tag{6.5}$$

The derivative dv_0/dt includes two (one positive, another negative) sine-squared pulses shifted with respect to each other by $\tau - \tau_1$. Using the shift theorem again, and considering that

$$\mathbf{L}[dv_0/dt] = sV_o(s), \tag{6.6}$$

where $V_o(s)$ is the Laplace transform of $v_o(t)$, one obtains that

$$V_o(s) = \frac{1}{\tau_1} \frac{4(\pi/\tau_1)^2}{s^2\left[s^2 + 4(\pi/\tau_1)^2\right]} (1 - e^{-s\tau_1}) \left[1 - e^{-s(\pi-\tau_1)}\right]. \tag{6.7}$$

This $V_o(s)$ may be considered as an impulse response of a nonrealizable (using lumped parameters) transfer function. But if, following [5], its real, $\mathrm{Re}V_o(j\omega)$, and imaginary, $\mathrm{Im}V_o(j\omega)$, parts are expanded in infinite products, then the finite number of terms in these products may be used for approximation of $\mathrm{Re}V_o(j\omega)$ and $\mathrm{Im}V_o(j\omega)$. This further approximation allows one to obtain a realizable transfer function $H_0(s)$ of the pulse-forming network excited by the input unit impulse. As one will see below, the obtained transfer function includes zeros on the $j\omega$-axis only, and the denominator order may be controlled.

Then, if $v_i(t)$ is a step function, the required transfer function is equal to $H_1(s) = sH_0(s)$. If $v_i(t)$ is sin Ωt, the required transfer function is $H_2(s) = (s^2 + \Omega^2)H_0(s)$.

6.2.2 Realization Requirements

We remind here the requirements that should be imposed on the algebraic ratio if it represents the transfer function of a reactance network loaded by resistor [9,10].

Let $F(s)$ be the Laplace transform of network impulse response, and $F(j\omega) = P(\omega) + jQ(\omega)$. One can find a realizable network if $F(s)$ allows the approximation

$$H_a(s) = \frac{N(s)}{D(s)} = \frac{A_1 s^\mu N_1(s)}{D_2(s) + A_2 s D_1(s)}. \tag{6.8}$$

Here $H_a(s)$ is the ratio of two polynomials, and deg $N(s) \le$ deg $D(s)$, $N_1(s)$, $D_1(s)$, and $D_2(s)$ are even polynomials with zeros on the $j\omega$-axis only, that is, $N_1(s) = \prod_{l=1}^{\nu} \left(s^2 + c_l^2\right)$, $D_2(s) = \prod_{k=1}^{n} \left(s^2 + a_k^2\right)$, $sD_1(s) = s\prod_{k=1}^{n-1} \left(s^2 + b_k^2\right)$, and a_k and b_k are alternating (for odd denominator polynomials both product superscripts in $D_1(s)$ and $D_2(s)$ should be equal). A_1 and A_2 are the positive real constants. Indeed, the function (Equation 6.8) allows then realization as a transfer function of a reactance network loaded by resistor [9,10].

The conditions that should be imposed on real and imaginary parts of realizable $H_a(s)$ are obtained the following way. To avoid separate discussions for even and odd μ let us consider the function

$$H_{a1}(s) = s^{-\mu} H_a(s) = \frac{A_1 N_1(s)}{D_2(s) + A_2 s D_2(s)}. \tag{6.9}$$

Then one can write that

$$\mathrm{Re}\, H_{a1}(j\omega) = \frac{A_1 \prod_{l=1}^{\nu} \left(c_l^2 - \omega^2\right) \prod_{k=1}^{n} \left(a_k^2 - \omega^2\right)}{D_2^2(-\omega^2) + A_2^2 \omega^2 D_1(-\omega^2)} \tag{6.10}$$

and

$$\operatorname{Im} H_{a1}(j\omega) = -\frac{A_1 A_2 \omega \prod_{l=1}^{\nu}\left(c_l^2 - \omega^2\right)\prod_{k=1}^{n-1}\left(b_k^2 - \omega^2\right)}{D_2^2(-\omega^2) + A_2^2\omega^2 D_1(-\omega^2)}. \tag{6.11}$$

Hence, if $F(s) = s^{\mu_1}F_1(s)$ and $F_1(j\omega) = P_1(\omega) + jQ_1(\omega)$, then (1) both $\mathrm{Re}F_1(j\omega)$ and $\mathrm{Im}F_1(j\omega)$ should be approximated by the ratios so that each of them includes 2ν simple zeros located at $\omega = \pm\gamma_k$, (2) the approximating ratio for $\mathrm{Re}F_1(j\omega)$ includes, in addition, $2n$ simple zeros located at $\omega = \pm\alpha_k$, (3) the approximating ratio for $\mathrm{Im}F_1(j\omega)$ includes, in addition, $2(n-1)$ simple zeros located at $\omega = \pm\beta_k$, and (4) α_k and β_k should alternate. Then the approximating ratio

$$H_a(s) = \frac{A_1 s^{\mu_1}\prod_{l=1}^{\nu}\left(s^2 + \gamma_l^2\right)}{\prod_{k=1}^{n}\left(s^2 + \alpha_k^2\right) + A_2 s\prod_{k=1}^{n-1}\left(s^2 + \beta_k^2\right)}, \tag{6.12}$$

where $\mu_1 = \mu$, and $a_k = \alpha_k$, $b_k = \beta_k$, and $c_l = \gamma_l$, may be used as a transfer function for the network realization. The constants A_1 and A_2 can be calculated equating $F(s)$ and $H_a(s)$ at two points of the s-plane (the most convenient points are usually $s = 0$ and $s = j$, the final choice may be decided by computer calculations).

One can see that if $\deg N(s) \le \deg D(s) - 2$, the multiplication of the numerator in Equation 6.12 by s or by $(s^2 + \Omega^2)$ does not violate the realization condition.

Representing thus obtained $H_a(s)$, for example, as

$$H_a(s) = \frac{[A_1 s^{\mu} N_1(s)]/D_2(s)}{\{[A_2 s D_1(s)]/D_2(s)\} + 1} = -\frac{y_{21}(s)}{y_{22}(s) + 1}, \tag{6.13}$$

one finds $y_{21}(s) = -A_1 s^{\mu} N_1(s)/D_2(s)$ and $y_{22}(s) = A_2 s N_1(s)/D_2(s)$. These two parameters are sufficient to realize the network [9,10] within a constant multiplier for $y_{21}(s)$.

6.2.3 Second Approximation Step: Approximation for Realization

Now we find the approximation to the output response Laplace transform (Equation 6.7). This step is leading to realizable transfer functions. We rewrite $V_o(s)$ as

$$V_o(s) = \frac{16(\pi/\tau_1)^2}{\tau_1 s^2\left[s^2 + 4(\pi/\tau_1)^2\right]} \cdot e^{-\frac{s\pi}{2}} \cdot \sinh\left(\frac{s\tau_1}{2}\right) \cdot \sinh\left[\frac{s(\pi - \tau_1)}{2}\right]. \tag{6.14}$$

Substituting $s = j\omega$ one can find that

$$\mathrm{Re}V_o(j\omega) = \frac{16(\pi/\tau_1)^2}{\tau_1\omega^2\left[4(\pi/\tau_1)^2 - \omega^2\right]} \cdot \cos\left(\frac{\omega\pi}{2}\right) \cdot \sin\left(\frac{\omega\tau_1}{2}\right) \cdot \sin\left[\frac{\omega(\pi - \tau_1)}{2}\right] \tag{6.15}$$

and

$$\mathrm{Im}V_a(j\omega) = -\frac{16(\pi/\tau_1)^2}{\tau_1\omega^2\left[4(\pi/\tau_1)^2 - \omega^2\right]} \cdot \sin\left(\frac{\omega\pi}{2}\right) \cdot \sin\left(\frac{\omega\tau_1}{2}\right) \cdot \sin\left[\frac{\omega(\pi - \tau_1)}{2}\right]. \tag{6.16}$$

Taking into consideration that [11]

$$\sin x = x\prod_{k=1}^{\infty}\left(1-\frac{x^2}{k^2\pi^2}\right) \tag{6.17}$$

and

$$\cos x = \prod_{k=0}^{\infty}\left(1-\frac{x^2}{(2k+1)^2\pi^2}\right), \tag{6.18}$$

one can see that $\mathrm{Re}V_o(j\omega)$ has real zeros at $\alpha_k = \pm(2k+1)$, where $k = 0, 1, 2, \ldots$, and $\mathrm{Im}V_a(j\omega)$ has zeros at $\beta_k = \pm 2k$, where $k = 0, 1, 2, \ldots$ as well. These zeros are alternating on ω-axis. In addition, both $\mathrm{Re}V_o(j\omega)$ and $\mathrm{Im}V_o(j\omega)$ have common zeros located at $\gamma_k = \pm 2\pi\ k$, where $k = 2, 3, 4, \ldots$ (the zeros for $k = 0, 1$ are canceling the poles), and $\gamma_k = \pm 2\pi k/(\pi - \tau_1)$, where $k = 1, 2, 3 \ldots$ (the zero for $k = 0$ is canceling the pole). Then, in accordance with the previous part, to approximate $V_a(s)$ one may use the algebraic ratio

$$H_a(s) = \frac{N(s)}{D(s)} = \frac{A_1\prod_{k=2}^{\nu_1}\left[s^2+(2\pi k/\tau_1)^2\right]\prod_{k=1}^{\nu_2}\left[s^2+(2\pi k/(\pi-\tau_1))^2\right]}{\prod_{k=0}^{n_1}\left[s^2+((2k+1)^2\right]+A_2 s\prod_{k=1}^{n}(s^2+4k^2)} \tag{6.19}$$

To have the approximation with sufficient number of terms in the products, it is rational to find the spectral function

$$|V_o(j\omega)| = \left|\frac{16(\pi/\tau_1)^2\sin(\omega\tau_1/2)\sin[\omega(\pi-\tau_1)/2]}{\tau_1\omega^2\left[4(\pi/\tau_1)^2-\omega^2\right]}\right| \tag{6.20}$$

and evaluate the spectrum bandwidth ω_m. The zeros included in the approximating products should be located in the spectrum bandwidth, and they will determine the subscripts in the products of Equation 6.21. The following two possibilities should be considered for n_1 and n. When $n_1 = n - 1$, then the denominator degree is odd, when $n_1 = n$ then this degree is even. If ω_m is chosen, then, in case of the odd degree $2n \approx \omega_m$ (i.e., $n \approx \omega_m/2$), and in case of the even degree $2n_1 + 1 \approx \omega_m$ (i.e., $n_1 \approx \omega_m - 0.5$). Hence, the odd degree allows one to obtain the approximating transfer function with more "dense" location of real and imaginary part zeros in the spectrum bandwidth, which usually results in a better approximation in the time domain as well.

From the other side, to obtain the simplest transfer function one has to choose $\nu_1 = 1$. Then, the first product in the numerator is equal to unit and will not include any multipliers. Considering that $(2\pi/\tau_1)$ represents now the upper approximation frequency, one can find the other superscripts in the approximating products from the approximate equalities

$$\begin{cases}\dfrac{2\pi}{\tau_1}\approx\dfrac{2\pi\nu_2}{\pi-\tau_1}\\[2ex]\dfrac{2\pi}{\tau_1}\approx 2n \text{ or } (2n_1+1)\end{cases} \tag{6.21}$$

that give $\nu_2 \approx (\pi - \tau_1)/\tau_1$ and $n \approx \dfrac{\pi}{\tau_1}$; $n_1 \approx \dfrac{\pi}{\tau_1} - \dfrac{1}{2}$. This results in

$$H_a(s) = \frac{A_1\prod_{k=1}^{\nu_2}\left[s^2+\left(\frac{2\pi k}{\pi-\tau_1}\right)^2\right]}{\prod_{k=0}^{n_1}\left[s^2+(2k+1)^2\right]+A_2 s\prod_{k=1}^{n}(s^2+4k^2)}. \tag{6.22}$$

The constants A_1 and A_2 can be found equating $V_o(s)$ given by Equation 6.7 and this $H_a(s)$ at two points of the s-plane. Using Equation 6.13 one can then find the realizable $y_{22}(s)$ and $y_{21}(s)$ required for the network synthesis.

6.2.4 Pulse-Forming Networks with Non-Delayed Output Pulses

As examples, we synthesize the pulse-forming networks that should have the output response, which is the quasi-rectangular pulse with duration of fronts equal to $\tau_1 = \pi/3$, so that the rise and fall times are $\pi/6$ each. To obtain the simplest network, one has to put $\nu_2 = 2$, $n = 3$, and $n_1 = 2$. Then $V_o(s)$ for the case of $v_i = \delta(t)$ will be approximated by the ratio

$$H_a(s) = \frac{A_1(s^2+9)(s^2+36)}{[(s^2+1)(s^2+9)(s^2+25) + A_2 s(s^2+4)(s^2+16)(s^2+36)]}. \tag{6.23}$$

Equating Equations 6.7 and 6.23 at $s = 0$ and $s = j$ one can find that $A_1 = 1.453$ and $A_2 = 0.152$. Hence, the network transfer function for this case is equal to

$$H_0(s) = \frac{1.453(s^2+9)(s^2+36)}{[(s^2+1)(s^2+9)(s^2+25) + 0.152s(s^2+4)(s^2+16)(s^2+36)]}. \tag{6.24}$$

The impulse response, $h_o(t)$, of this transfer function is shown in Figure 6.2 (the initial output pulse, $v_o(t)$, is also shown for comparison).

If $v_i = u(t)$ then the network transfer function for this case of excitation is equal to

$$H_1(s) = \frac{1.453s(s^2+9)(s^2+36)}{[(s^2+1)(s^2+9)(s^2+25) + 0.152s(s^2+4)(s^2+16)(s^2+36)]}. \tag{6.25}$$

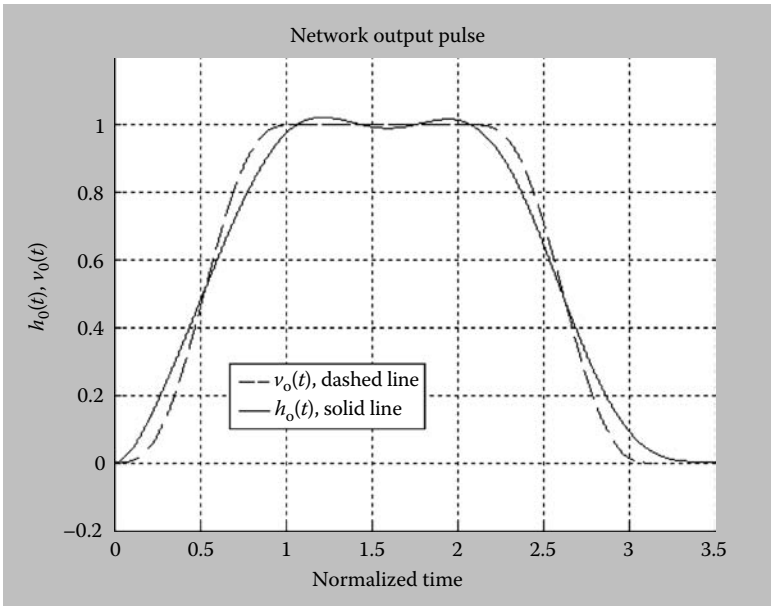

FIGURE 6.2 Pulse-forming network output response.

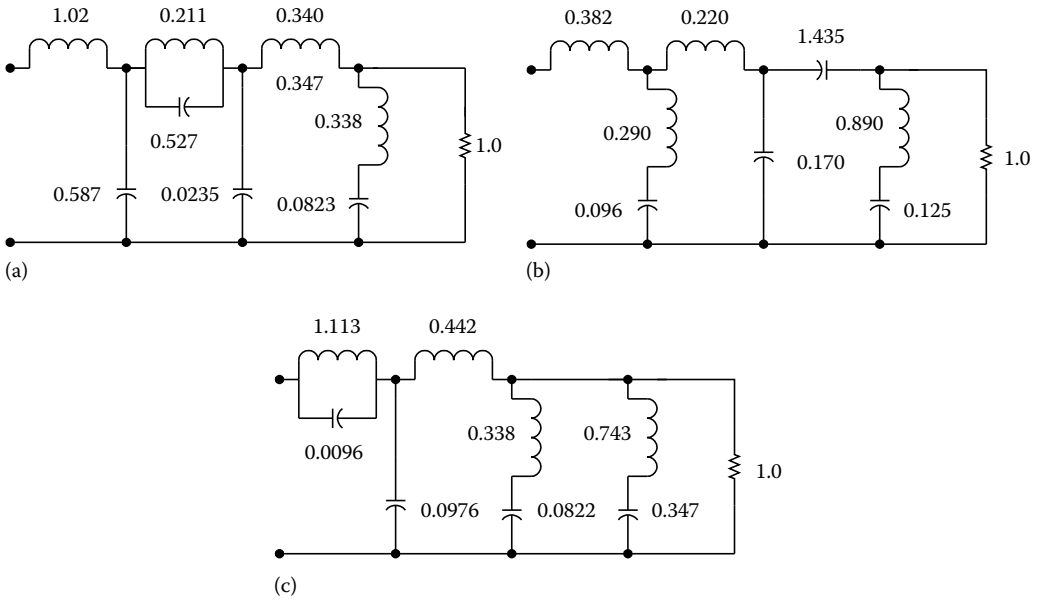

FIGURE 6.3 Pulse-forming networks: (a) $v_i = \delta(t)$, (b) $v_i = u(t)$, and (c) $v_i = \sin \Omega t$.

Finally, assume that $v_i = \sin 4t$. Then the zeros that are due to the input signal will coincide with one pair of zeros in the denominator odd part. This will simplify the realization. The transfer function for this case of excitation is equal to

$$H_2(s) = \frac{1.453(s^2+9)(s^2+16)(s^2+36)}{[(s^2+1)(s^2+9)(s^2+25) + 0.152s(s^2+4)(s^2+16)(s^2+36)]}. \tag{6.26}$$

The realizations of the functions (Equations 6.24 through 6.26) were obtained dividing their numerators and denominators by $(s^2+1)(s^2+9)(s^2+25)$. This gives

$$y_{22}(s) = \frac{0.152s(s^2+4)(s^2+16)(s^2+36)}{(s^2+1)(s^2+9)(s^2+25)}, \tag{6.27}$$

common for all three networks. Then this parameter was realized by standard procedures [9,10] taking into consideration the location of $y_{12}(s)$ zeros for each network. The results of these realizations are shown in Figure 6.3.

One can also verify that for the network of Figure 6.3b, the voltage source efficiency coefficient representing the ratio of the output pulse amplitude to input step amplitude is equal to 0.743, that is, nearly 1.5 times higher than with the usual approach [1,2].

If the required duration of pulse is τ_0 s, and the load resistor is R ohms, then each value of inductance should be multiplied by $\tau_0 R/\pi$ and the value of each capacitor by $\tau_0/(R\pi)$.

6.2.5 Pulse-Forming Networks with Delayed Output Pulse

The above-mentioned voltage source efficiency coefficient increases when the output pulse is delayed [12]. Yet, this delay should be used judiciously. The increase of source efficiency results in a more complicated circuit. In addition, the rise and fall times increase, that is, slew rate of the fronts

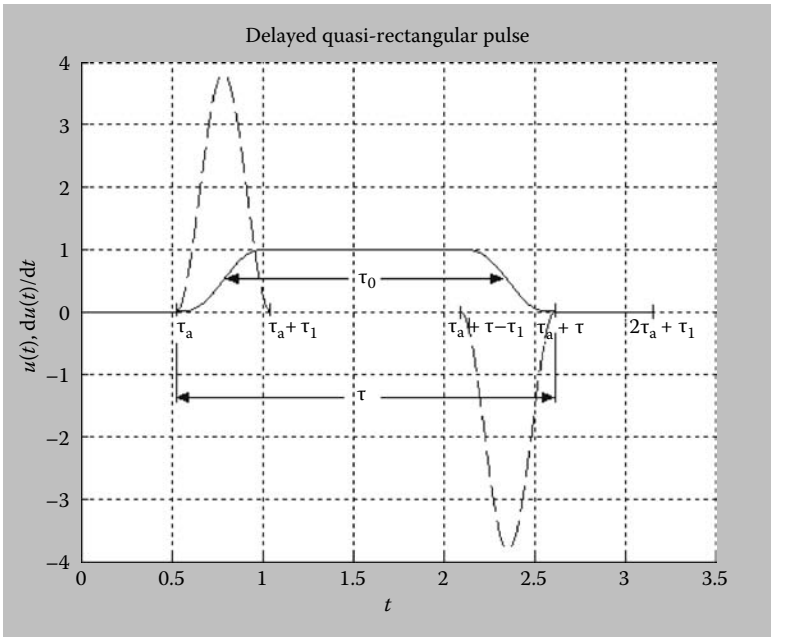

FIGURE 6.4 Delayed quasi-rectangular pulse.

deteriorates. It is possible to prepare a table that helps to visualize a possible trade-off between the delay, the circuit complexity, and the voltage source efficiency coefficient. The calculations given below follow the above-developed pattern.

Let the required output response be a delayed symmetric pulse $u(t)$ (Figure 6.4). Assume that the derivative, $\mathrm{d}u/\mathrm{d}t$, of this response is described by delayed positive and delayed negative semi-periods of sine-squared function. These semi-periods determine the duration of fronts that is equal to τ_1. Then $\mathrm{d}u/\mathrm{d}t$ can be described by the following equations:

$$\frac{\mathrm{d}u}{\mathrm{d}t} = \begin{cases} 0 & 0 \le t < \tau_a \\ A\sin^2\left[\frac{\pi}{\tau_1}(t-\tau_a)\right] & \tau_a \le t < \tau_a + \tau_1 \\ 0 & \tau_a + \tau_1 \le t < \tau_a + \tau - \tau_1 \\ -A\sin^2\left[\frac{\pi}{\tau_1}(t+\tau_1-\tau-\tau_a)\right] & \tau_a + \tau - \tau_1 \le t < \tau_a + \tau \\ 0 & t > \tau_a + \tau \end{cases} \tag{6.28}$$

The normalized time is defined by the condition

$$2\tau_a + \tau = \pi. \tag{6.29}$$

To obtain the normalized magnitude of unity for the output pulse amplitude, one has to choose the value of A from the equation

$$A\int_{\tau_a}^{\tau_a+\tau_1} \sin^2\left[\frac{\pi}{\tau_1}(t-\tau_a)\right]\mathrm{d}t = 1. \tag{6.30}$$

This gives

$$A = 2/\tau_1. \tag{6.31}$$

This value is again equal to the maximal slew rate of the fronts, and the approximate rise and fall times can be evaluated as

$$\tau_r = \tau_f = 1/A = \tau_1/2. \tag{6.32}$$

The value of $\tau_0 = \tau - \tau_1$ will be considered as the pulse duration at the level of 0.5.

We repeat here, for convenience, the Laplace transform of $(2/\tau_1)\sin^2(\pi t/\tau_1)$ [7] that is equal to

$$F_0(s) = \frac{1}{\tau_1}\frac{4(\pi/\tau_1)^2}{s\left[s^2 + 4(\pi/\tau_1)^2\right]}. \tag{6.33}$$

The derivative du/dt includes two (one positive, another negative) delayed sine-squared pulses shifted with respect to each other by $\tau_0 = \tau - \tau_1$. Using the shift theorem [8], and, considering that $\mathbf{L}[du/dt] = sU(s)$, where $U(s)$ is the Laplace transform of $u(t)$, one obtains that

$$U(s) = \frac{4(\pi/\tau_1)^2}{\tau_1}\frac{e^{-s\tau_a}(1 - e^{-s\tau_1})\left[1 - e^{-s(\tau-\tau_1)}\right]}{s^2\left[s^2 + 4(\pi/\tau_1)^2\right]}. \tag{6.34}$$

This result can be rewritten as

$$U(s) = \frac{16(\pi/\tau_1)^2}{\tau_1}\frac{e^{-s\left(\tau_a+\frac{\tau}{2}\right)}\sinh\left(\frac{s\tau_1}{2}\right)\sinh\left[\frac{s(\tau-\tau_1)}{2}\right]}{s^2\left[s^2 + 4(\pi/\tau_1)^2\right]}. \tag{6.35}$$

For the normalized time defined by Equation 6.29, one can rewrite this result as

$$U(s) = \frac{16(\pi/\tau_1)^2}{\tau_1}\frac{e^{-s\frac{\pi}{2}}\sinh\left(\frac{s\tau_1}{2}\right)\sinh\left[\frac{\xi\pi s}{2}\right]}{s^2\left[s^2 + 4(\pi/\tau_1)^2\right]}, \tag{6.36}$$

where $\xi = \frac{1}{1+(2\tau_a+\tau)/\tau_0} < 1$. Using the expansion [11] of

$$\sinh(x) = x\prod_{k=1}^{\infty}\left(1 + \frac{x^2}{4k^2\pi^2}\right) \tag{6.37}$$

and approximating

$$\sinh\left(s\frac{\tau_1}{2}\right) \approx \frac{s\tau_1}{2}\left(1 + \frac{s^2\tau_1^2}{4\pi^2}\right) \tag{6.38}$$

and

$$\sinh\left(\frac{\xi\pi s}{2}\right) \approx \frac{\xi\pi s}{2}\prod_{l=1}^{\nu}\left[1 + \frac{s^2}{(2l/\xi)^2}\right] \tag{6.39}$$

(the choice of ν is discussed below), one can write

$$U(s) \approx Ce^{-s\frac{\pi}{2}} \prod_{l=1}^{\nu} \left[s^2 + \left(\frac{2l}{\xi} \right)^2 \right], \tag{6.40}$$

where $C = (\xi\pi)^{2\nu+1} / \left(4^{\nu} \prod_{l=1}^{\nu} l^2 \right)$. The approximation (Equation 6.38) defines the maximum frequency, ω_m, where Equation 6.40 is valid on the $j\omega$-axis, namely,

$$(2\pi)/\tau_1 \leq \omega_m < (4\pi)/\tau_1 \tag{6.41}$$

(the calculations show that using $(3\pi)/\tau_1$ for the right-hand side is usually sufficient).

In this problem, the output pulse $u(t)$ is usually the result of application of a step voltage to the network input. Then, if the Laplace transform of this input voltage is written as

$$U_1(s) = 1/(Ks), \tag{6.42}$$

then the realized value of K (it will be defined below) gives us the voltage source efficiency coefficient.

The ratio $U(s)/U_1(s)$ is a nonrealizable transfer function. Yet, using the previously developed approach, it is possible to find further approximation to Equation 6.40 so that the resulting ratio will be realizable.

We calculate $\mathrm{Re}U(j\omega)$ and $\mathrm{Im}U(j\omega)$ for the approximation (Equation 6.40). Substituting $s = j\omega$ one finds that

$$\mathrm{Re}U(j\omega) \approx C \cos\left(\omega \frac{\pi}{2} \right) \prod_{l=1}^{\nu} \left[\left(\frac{2l}{\xi} \right)^2 - \omega^2 \right] \tag{6.43}$$

and

$$\mathrm{Im}U(j\omega) \approx -C \sin\left(\omega \frac{\pi}{2} \right) \prod_{l=1}^{\nu} \left[\left(\frac{2l}{\xi} \right)^2 - \omega^2 \right]. \tag{6.44}$$

Taking into consideration Equations 6.18 and 6.19, one can see that $\mathrm{Re}U(j\omega)$ has real zeros at $\alpha_k = \pm(2k+1)$ with $k = 0, 1, 2, \ldots$ and $\mathrm{Im}U(j\omega)$ has zeros at $\beta_k = \pm 2k$ with $k = 0, 1, 2, \ldots$ as well. These zeros are alternating (or interlacing). In addition, both $\mathrm{Re}U(j\omega)$ and $\mathrm{Im}U(j\omega)$ have common zeros located at $\gamma_l = \pm 2l/\xi$ with $l = 1, 2, \ldots, \nu$. Then, in accordance with the previous part, to approximate $U(s)$ in the bandwidth defined by Equation 6.41, one can use the algebraic ratio

$$U_a(s) = \frac{A_1 \prod_{l=1}^{\nu} [s^2 + (2l/\xi)^2}{\prod_{k=0}^{n_1} \left[s^2 + (2k+1)^2 \right] + A_2 s \prod_{k=1}^{n} (s^2 + 4k^2)}. \tag{6.45}$$

The coefficients A_1 and A_2 may be found equating $U_a(s)$ given by Equation 6.45 to $U(s)$ given by Equation 6.36 at two points of the s-plane.

The Equation 6.41 defines the maximum approximation bandwidth ω_m for Equation 6.45 as well. To obtain simpler networks, it is better to be closer to the left-hand side of this inequality. Then, one can find ν from the approximate condition

$$2\nu/\xi \approx 2\pi/\tau_1. \tag{6.46}$$

Then, n_1 may have two values, namely $n_1 = n$ for even-order denominators and $n_1 = n - 1$ for odd-order ones. This gives two approximate equations $2\pi/\tau_1 \approx 2n$ and $2\pi/\tau_1 \approx 2n_1 + 1$ for the even- and odd-part superscripts of the denominator.

Finally, to obtain the transfer function for the input step voltage, one has to multiply the approximating ratio $U_a(s)$ by Ks. This finally gives

$$H(s) = \frac{KA_1 s \prod_{l=1}^{\nu} \left[s^2 + (2l/\xi)^2\right]}{\prod_{k=0}^{n_1} \left[s^2 + (2k+1)^2\right] + A_2 s \prod_{k=1}^{n} (s^2 + 4k^2)}. \tag{6.47}$$

Representing this $H(s) = N(s)/[D_2(s) + A_2 s D_1(s)]$ as in Equation 6.13, one obtains $y_{21}(s) = -N(s)/D_2(s)$ and $y_{22}(s) = A_2 s D_1(s)/D_2(s)$, two parameters that are sufficient to realize the network within a constant multiplier for y_{21}.

The maximum value of K is defined by the Fialkov condition [9], which specifies that for the unbalanced two ports, the transfer function numerator coefficients should be less or equal to the denominator coefficients for the corresponding degrees of s. The finalized voltage source efficiency coefficient depends on the realized value of A_1.

As an example, we consider the network with the step response that approximates the delayed quasi-rectangular pulse with the following parameters: the delay time $\tau_a = \pi/6$, the duration of each front is $\tau_1 = \pi/6$, the pulse duration calculated at the level of 0.5 of the output amplitude is $\tau_0 = \pi/2$, and the total pulse duration is $\tau = (2\pi)/3$. The reader may notice that this pulse was used in Figure 6.4 to illustrate the problem. The dashed line shows the pulse shape corresponding to the initial assumptions described by Equation 6.28.

Using the pulse parameters one can find that $\xi = (\tau - \tau_1)/\pi = 0.5$. Then, using Equations 6.41 and 6.46, one can find that $\nu = 3$, $n = 6$, and $n_1 = 6$. This allows one to find the ratio that approximates the Laplace transform (Equation 6.36) as

$$U_a(s) = \frac{A_1(s^2 + 16)(s^2 + 64)(s^2 + 144)}{\prod_{k=0}^{6} \left[s^2 + (2k+1)^2\right] + A_2 s \prod_{k=1}^{6} (s^2 + 4k^2)}. \tag{6.48}$$

Equating Equations 6.36 and 6.48 at $s = 0$ and $s = j$, one can find $A_1 = 1.945 \times 10^5$ and $A_2 = 1.329$. The original, $u_a(t)$, corresponding to this transform is shown in Figure 6.5. The network transfer function, thus, is given by the ratio

$$H(s) = \frac{K \times 1.945 \times 10^5 s(s^2 + 16)(s^2 + 64)(s^2 + 144)}{\prod_{k=0}^{6} \left[s^2 + (2k+1)^2\right] + 1.329 s \prod_{k=1}^{6} (s^2 + 4k^2)}. \tag{6.49}$$

Finally, one divides the numerator and denominator of $H(s)$ by $\prod_{k=0}^{6} \left[s^2 + (2k+1)^2\right]$ and obtains

$$y_{22} = \frac{1.329 s \prod_{k=1}^{6} (s^2 + 4k^2)}{\prod_{k=0}^{6} \left[s^2 + (2k+1)^2\right]} \tag{6.50}$$

and

$$y_{21} = \frac{K \times 1.945 \times 10^5 s(s^2 + 16)(s^2 + 64)(s^2 + 144)}{\prod_{k=0}^{6} \left[s^2 + (2k+1)^2\right]}. \tag{6.51}$$

Using the Fialkov condition, one can find that the maximal achievable voltage source efficiency coefficient is $K = 0.984$.

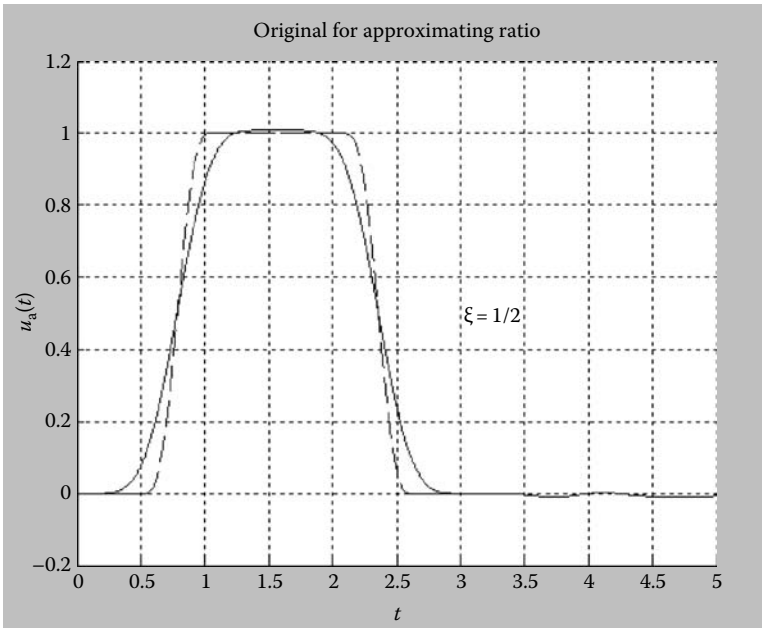

FIGURE 6.5 Step response of the pulse-shaping network.

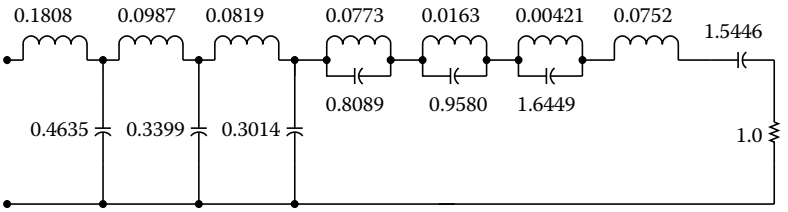

FIGURE 6.6 Realization of the pulse-shaping network.

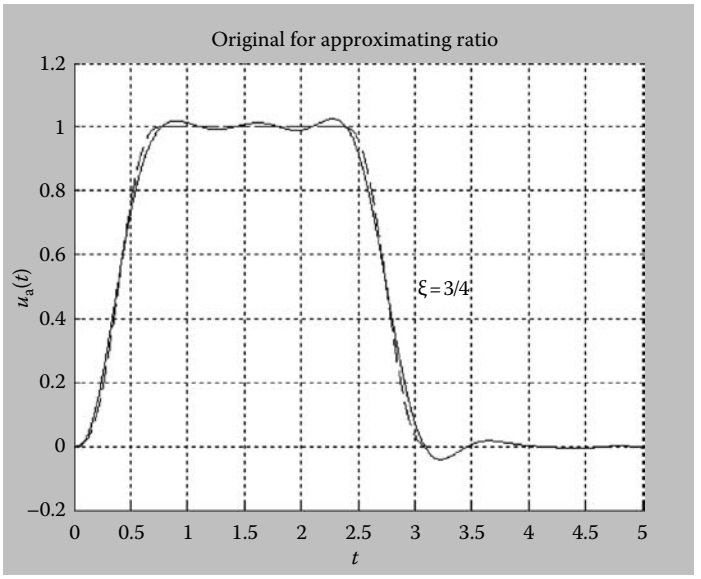
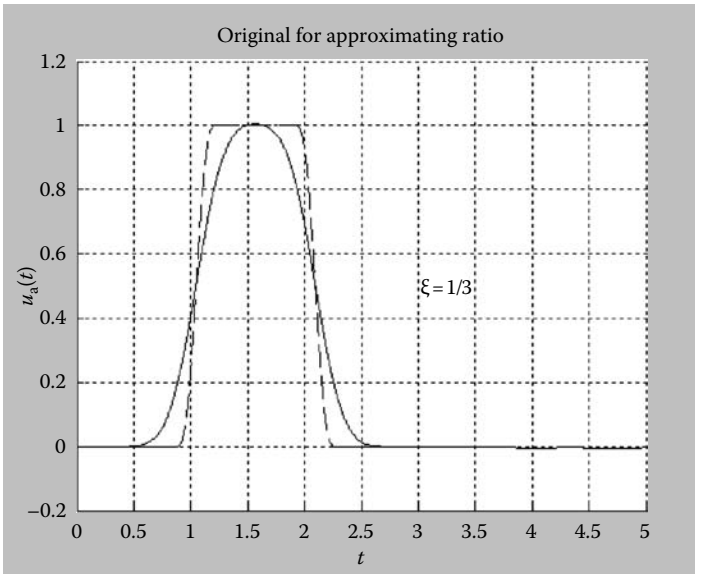
A realization of this transfer function is shown in Figure 6.6. It starts by realization of common zeros of y_{22} and y_{21} (i.e., by realization of poles of y_{22}^{-1} at $s=0$, $s\to\infty$, $s=\pm j4$, $s=\pm j8$, and $s=\pm j12$) and finishes by the Cauer form to realize other zeros of y_{21} located at $s\to\infty$.

One can verify that the realized value of A_1 is equal to 1.911×10^5. Hence, the realized value of K will be less than the maximum achievable one and equal to 0.967.



The normalized duration of pulse was $\pi/2$, the normalized value of the load was unit. If the required duration of pulse is τ_r s and the load resistor is R ohms, then each value of inductance in the network of Figure 6.6 should be multiplied by $2\tau_r R/\pi$ and the value of each capacitor by $2\tau_r/(R\pi)$.

Table 6.1 shows that with increase of delay, the maximum voltage source efficiency coefficient increases as well so that the output pulse amplitude can be larger than the amplitude of the input step voltage. The table was calculated for the pulses with the same ratio $\tau_1/\tau_0=1/3$ when the shape of pulse in absolute time is preserved, and in all cases $\nu=3$. We also indicated the required transfer function parameters as well.



To better visualize the deflection of the realized shapes of the output pulses from the initially assumed shapes, Figure 6.7a and b shows the output pulses for the first and the third lines, respectively, of the

TABLE 6.1 Delay Influence on Voltage Source Efficiency

(b)

FIGURE 6.7 Deterioration of output pulse with increasing delay: (a) $\xi = 3/4$ (no delay) and (b) $\xi = 1/3$, $\tau_a/\pi = 5/18$.

Table 6.1 as well. One can see that with increasing delay, the slew rate of the fronts deteriorates and differs from that initially assumed. The duration of the pulse at the level of 0.5 is preserved.

If the zeros of y_{12} coincide with the zeros of y_{22}, the realization is simplified. This was the case in the considered example (it is easy to verify that it is also valid for the transfer function obtained from the third line of Table 6.1). Usually, it can be easily done for one zero only.

6.3 Transfer Functions of Wideband Amplifiers

Wideband amplifiers with a monotonic step response are frequently used for amplification of pulse signals. Their investigation was started by Elmore [13], and the basic results of this work are still used in the design [14–16]. Elmore's approach allowed one to obtain the relationships between the delay time, rise time, and the number of stages for such amplifiers. Yet, this approach introduces a strong limitation: it requires that the poles of transfer functions should be located on the negative real axis of the *s*-plane [13]. The synthesis of the filters with maximally flat delay (Bessel filters) [17] and the Gaussian-response filters [18] removed this restriction. But the transfer functions of these filters were found indirectly, from the requirements in the frequency domain. There is no immediate relationship between the delay-to-rise-time ratio (which is the main parameter in the design of the amplifiers with monotonic step response) and the filter order. One has to simulate their step responses using the available tables of transfer function poles [19], evaluate the delay-to-rise-time ratio, and then decide upon the required order of the transfer function.

It was shown in [4] how to find the transfer function numerically with a monotonic step response starting from the requirements to the delay-to-rise-time ratio. Later on, this problem was solved in [20], yet the results of this work are not easy to apply for design of wideband amplifier transfer functions. Finally, follow the approach proposed in [5], it was shown in [21,22] how to find the transfer functions with monotonic step response and optimized delay-to-rise-time ratio.

Here, we consider a particular case of the solution given in [21]. The amplifier transfer functions tabulated below are obtained when the amplifier impulse response is approximated by the period of $\sin^2(\pi\, t/\tau)$ function (here $\tau \le \pi$). This period is symmetrically located within the interval $0 \le t \le \pi$ of the normalized time t. Then, one repeats the above outlined approximation steps. One finds the Laplace transform of the output response. Approximating further this Laplace transform by a suitable transfer function, one can find an all-pole realizable transfer function of ''maximal for chosen τ order.''

The results of this synthesis procedure are represented by the table of step-response parameters for the transfer functions from the fourth to tenth order. The parameters are also compared with Bessel and Gaussian filter transfer functions of the corresponding order. The table of corresponding transfer functions poles is also given. We do not give the realization of the tabulated transfer functions by LC two-port networks loaded by resistor. The transfer functions of wideband amplifiers are usually realized by active networks, and their realization can be found elsewhere [23]. The proposed method is easily extended on the synthesis of delay networks [24].

6.3.1 Parameters of the Step Response and Its Laplace Transform

Here, the amplifier impulse response, $h(t)$, is approximated by the period of the $\sin^2(\pi\, t/\tau)$ function (here $\tau \le \pi$) symmetrically located within the interval $0 \le t \le \pi$ of the normalized time t, i.e.,

$$h(t) = \begin{cases} 0 & 0 \le t \le (\pi - \tau)/2 \\ A \sin^2 \frac{\pi}{\tau}\left(t - \frac{\pi}{2} + \frac{\tau}{2}\right) & \frac{\pi-\tau}{2} \le t \le \frac{\pi+\tau}{2} \\ 0 & (\pi + \tau)/2 \le t \le \pi \end{cases}. \tag{6.52}$$

The amplitude, A, of the impulse response will be chosen from the normalization condition of the step response, $u(t)$, so that

$$\int_{(\pi-\tau)/2}^{(\pi+\tau)/2} h(t)\mathrm{d}t = 1. \tag{6.53}$$

One finds that $A = 2/\tau$. Then, the delay time $\tau_d = \pi/2$, the rise time $\tau_r = 1/A$, and the delay-to-rise-time ratio, ρ, is equal to

$$\rho = \tau_d/\tau_r = \pi/\tau. \tag{6.54}$$

Using the tables [7] and the delay theorem [8], one finds the Laplace transform of Equation 6.52 as

$$F(s) = \frac{4(\pi/\tau)^2(1-\mathrm{e}^{-\tau s})}{\tau\, s\left[s^2+(2\pi/\tau)^2\right]}\mathrm{e}^{-\left(\frac{\pi-\tau}{2}\right)s}. \tag{6.55}$$

In the following, we will also need the numerical values of this transform at $s = 0$ and $s = j$. One can find that $F(0) = 1$ and $F(j) = -j\frac{8(\pi/\tau)^2\sin(\tau/2)}{\tau\left[(2\pi/\tau)^2-1\right]}$.

6.3.2 Transfer Function Approximation

The Laplace transform (Equation 6.55) can be rewritten as

$$F(s) = \frac{8(\pi/\tau)^2\sinh(\tau s/2)}{\tau s\left[s^2+(2\pi/\tau)^2\right]}\mathrm{e}^{-s\frac{\pi}{2}}. \tag{6.56}$$

Using the expansion (Equation 6.37) for the function of sinh x, and approximating the infinite product with two terms, as

$$\sinh(s\tau/2) \approx \frac{s\tau}{2}\left(1+\frac{s^2\tau^2}{4\pi^2}\right), \tag{6.57}$$

one finds that $F(s)$ can be approximated as

$$F(s) \approx \mathrm{e}^{-s\frac{\pi}{2}}. \tag{6.58}$$

The validity region of this approximation is determined by the first term in the discarded part of the approximation (Equation 6.57). On the $j\omega$-axis, the border for the maximal frequency, ω_m, where the approximation (Equation 6.58) is still valid, is thus, determined by the inequalities

$$(2\pi)/\tau < \omega_m < (4\pi)/\tau. \tag{6.59}$$

On the $j\omega$-axis, the function (Equation 6.58) becomes

$$F_a(j\omega) = \cos(\omega\pi/2) - j\sin(\omega\pi/2). \tag{6.60}$$

The functions $\cos(\omega\pi/2)$ and $\sin(\omega\pi/2)$ can also be represented as infinite products as in Equations 6.17 and 6.18, one can write that

$$F_a(j\omega) = \prod_{i=0}^{\infty}\left(1 - \frac{\omega^2}{(2i+1)^2}\right) - j\frac{\omega\pi}{2}\prod_{i=1}^{\infty}\left(1 - \frac{\omega^2}{4i^2}\right). \tag{6.61}$$

Using the finite number of terms in the products, one can approximate $F(j\omega)$ as

$$F_a(j\omega) \approx \prod_{i=0}^{n_1}\left(1 - \frac{\omega^2}{(2i+1)^2}\right) - j\frac{\omega\pi}{2}\prod_{i=1}^{n}\left(1 - \frac{\omega^2}{4i^2}\right). \tag{6.62}$$

This result allows one to find a realizable transfer function

$$H_a(s) = \frac{A_1}{\prod_{i=0}^{n_1}\left[s^2 + (2i+1)^2\right] + A_2 s\prod_{i=1}^{n}(s^2 + 4i^2)} \tag{6.63}$$

that approximates $F(s)$ given by Equation 6.56.

The following two possibilities should be considered for n_1 and n. If $n_1 = n$, then the denominator degree is even, if $n_1 = n - 1$ then the denominator degree is odd. Indeed, if these conditions are satisfied, and A_1 and A_2 are positive, then the denominator of $H_a(s)$ is a Hurwitz polynomial [9]. The denominator roots will be located in the left half of the s-plane, and this $H_a(s)$ can be realized as a cascade connection of first- and second-order low-pass stages.

The approximation will be the best if one takes the maximum possible value of n_1 or n in Equation 6.63. Substituting $s = j\omega$ in Equation 6.63, one can find that

$$H_a(j\omega) = \frac{A_1\prod_{i=0}^{n_1}\left[(-\omega^2 + (2i+1)^2\right] - jA_2\omega\prod_{i=1}^{n}(-\omega^2 + 4i^2)}{\left(\prod_{i=0}^{n_1}\left[\left(-\omega^2 + (2i+1)^2\right)\right]^2 + A_2^2\omega^2\left(\prod_{i=1}^{n}(-\omega^2 + 4i^2)\right)^2\right)} \tag{6.64}$$

Comparing Equations 6.64 and 6.62, one can see that to have the maximal order of the transfer function one has to take the maximal value of n_1 or n in Equation 6.62 as well. But the choice of n_1 and n is defined, as it follows from Equation 6.59, by the following inequalities

$$\begin{cases} (2\pi)/\tau < 2n_1 + 1 < (4\pi)/\tau \\ (2\pi)/\tau < 2n < (4\pi)/\tau \end{cases}. \tag{6.65}$$

One has to choose the largest value satisfying one of these inequalities. If this largest value is $n_1 = m$, then one takes $n = m$ as well and obtains the transfer function of even order. If this largest value is $n = m$, then one takes $n_1 = m - 1$, and obtains the transfer function of odd order.

Finally, to find A_1, one equates $H_a(s)$ and $F(s)$ at $s = 0$. This gives $A_1 = \prod_{i=1}^{n_1}(2i+1)^2$. Equating $H_a(s)$ and $F(s)$ at $s = j$ one finds

$$A_2 = \frac{\tau[(2\pi/\tau) - 1]A_1}{8(\pi/\tau)^2\sin(\tau/2)\prod_{i=1}^{n}\left[(2i)^2 - 1\right]}.$$

6.3.3 Example of Transfer Function Design

Assume that we design an amplifier transfer function with $\rho = 1.6$. This requires that $\tau = 5\pi/8$. Substituting this value in Equation 6.65, one obtains the inequalities

$$\begin{cases} 3\frac{1}{5} < 2n_1 + 1 < 6\frac{2}{5} \\ 3\frac{1}{5} < 2n < 6\frac{2}{5} \end{cases}. \tag{6.66}$$

From these inequalities, one finds that $n = 3$ and $n_1 = 2$. Hence, the realizable transfer function

$$H_a(s) = \frac{A_1}{\prod_{i=0}^{i=2}\left[s^2 + (2i+1)^2\right] + A_2\prod_{i=1}^{i=3}\left[s^2 + (2i)^2\right]} \tag{6.67}$$

of the seventh-order approximating $F_a(s)$ (and, hence $F(s)$ given by Equation 6.56) is found. It has the maximal possible order for the required τ. The constants A_1 and A_2 can be calculated equating $F(s)$ given by Equation 6.56 and $H_a(s)$ given by Equation 6.67 at the points $s = 0$ and $s = j$. One finds that $A_1 = 225$ and $A_2 = 0.1522$. Hence, the realizable transfer function

$$H_a(s) = \frac{225}{(s^2+1)(s^2+9)(s^2+25) + 0.1522s(s^2+4)(s^2+16)(s^2+36)} \tag{6.68}$$

is approximating $F(s)$ for $\tau = 5\pi/8$.

The impulse and step responses for this transfer function are shown in Figure 6.8. One can see that the impulse response of Equation 6.68 is close to the response (Equation 6.52) for $t = 5\pi/8$, and the step

response is practically monotonic (the overshoot is 1.3% and the undershoot is 0.9%). The realized delay-to-rise-time ratio obtained in simulation is $\rho_s = 1.5$.

6.3.4 Tabulated Results

The results of our derivation are summarized in two tables. Table 6.2 gives the step-response parameters of the derived transfer functions. In Table 6.2, D is the degree of the transfer function denominator, ρ is the estimate of delay-to-rise-time ratio obtained from Equation 6.54, ρ_s is the delay-to-rise-time ratio obtained in simulations of approximating transfer functions, Ov is the step-response overshoot obtained in simulations, and Un is the undershoot also obtained in simulations.

These overshoot and undershoot columns deserve some discussion. Let us return to the example, the step response of the transfer function with $D = 7$ (Figure 6.8). As one can see, the step response $u(t)$ does not have the overshoot as it usually appears in ''normal'' transfer functions, that is, during application of the pulse signal. Here one has a small postpulse wave located in the interval $\pi < t < 2\pi$. One can verify that this is valid for all proposed transfer functions. Finally, Table 6.2 gives the comparison of the proposed transfer functions with the transfer functions of the Bessel (ρ_b, Ov_b) and Gaussian (ρ_g, no overshoot) filter transfer functions. Table 6.3 gives the poles of the transfer functions.

6.4 Forming a Sinusoidal Pulse

Recently, most of the industrial emphasis in ultra-wideband technology (UWB) has focused on the short range, high-data-rate applications. However, due to its low power properties, impulse UWB is also suitable for low-power, low-data-rate applications [25]. One of the challenges in such low-power systems is how to efficiently generate the pulses. Several common pulse waveforms were studied, with the relation between their spectral characteristics and waveform parameters pointed out [26,27]. The approximation method described here allows one to synthesize the pulse-forming reactance networks loaded by resistors, and these networks may represent, in applications to UWB systems, model of transmitting antennas.

Comparing the complexities of the network forming pulses of different shapes gives additional information for UWB system design. The developed synthesis approach is suitable for many pulse forms used in UWB systems, but for the reasons of space limitations, we consider only an example of synthesis of the network forming sinusoidal pulse with sinusoidal envelope [28]. In [29], one can find information on the pulse-forming network for monocycle pulse.

6.4.1 Required Transfer Function

Let the required output pulse $u(t)$ be a sinusoidal oscillation of a radian frequency ν with a sinusoidal envelope, $\sin \Omega t$ that has the finite duration of $\Omega t_d = \pi$ in the normalized time (Figure 6.9), that is,

$$u(t) = \begin{cases} g(t) \sin \nu t = \sin \Omega t \sin \nu t & 0 \le \Omega t \le \pi \\ 0 & \Omega t > \pi \end{cases}. \tag{6.69}$$

It is assumed here that Equation 6.69 is the impulse or a step response. Then using the shift theorem [8], one can find that the Laplace transform of the envelope $g(t)$ is

$$G(s) = \frac{\Omega(1 + e^{-\pi s})}{s^2 + \Omega^2} \tag{6.70}$$

Considering that $\sin \nu t = (e^{j\nu} - e^{-j\nu})/(2j)$ and using the theorem of complex translation [8], one writes that the Laplace transform of $u(t)$ is equal to

$$F(s) = \frac{\Omega}{2j}\left[\frac{1 + e^{-\pi(s-j\nu)}}{(s - j\nu)^2 + \Omega^2} - \frac{1 + e^{-\pi(s+j\nu)}}{(s - j\nu)^2 + \Omega^2}\right]. \tag{6.71}$$

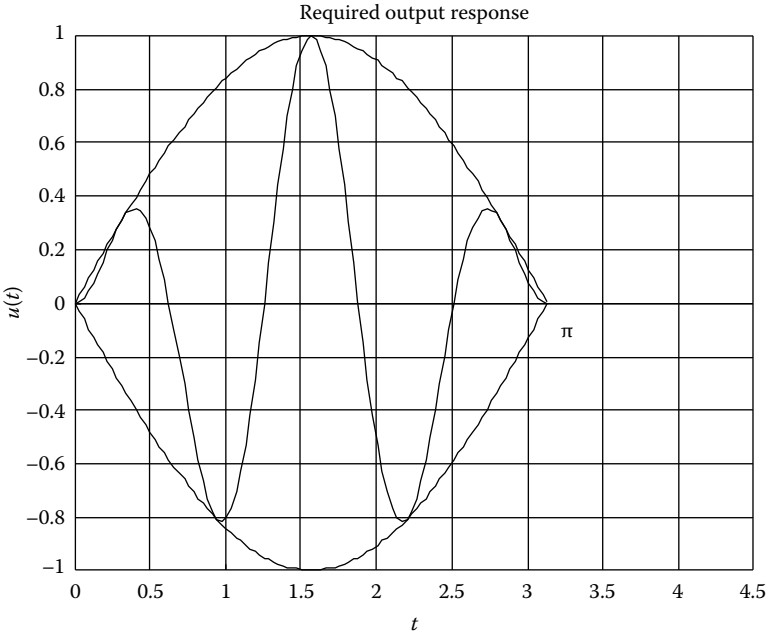

FIGURE 6.9 Required output response with sinusoidal envelope.

After some simple algebra, one obtains that

$$F(s) = \frac{2\nu\Omega s\left[1-(-1)^{\nu+1}e^{-\pi s}\right]}{\left[s^2+(\nu+\Omega)^2\right]\left[s^2+(\nu-\Omega)^2\right]}. \tag{6.72}$$

Considering that $\Omega = 1$ and assuming that ν is an integer, one can rewrite that

$$F(s) = \frac{2\nu s\left[1-(-1)^{\nu+1}e^{-\pi s}\right]}{\left[s^2+(\nu+1)^2\right]\left[s^2+(\nu-1)^2\right]}. \tag{6.73}$$

It is possible to consider two cases. If $\nu+1$ is even, then Equation 6.73 becomes

$$F_{ev}(s) = \frac{4\nu s e^{-\frac{\pi}{2}s}\sinh\left(\frac{\pi}{2}s\right)}{\left[s^2+(\nu+1)^2\right]\left[s^2+(\nu-1)^2\right]}. \tag{6.74}$$

If $\nu+1$ is odd, then Equation 6.73 becomes

$$F_{odd}(s) = \frac{4\nu s e^{-\frac{\pi}{2}s}\cosh\left(\frac{\pi}{2}s\right)}{\left[s^2+(\nu+1)^2\right]\left[s^2+(\nu-1)^2\right]}. \tag{6.75}$$

Then, Equations 6.74 and 6.75 do not belong to a class of realizable transfer functions if they are the transforms of impulse responses. Their multiplication by s (for the case if they are transforms of the step responses) does not give realizable functions either. One has again to truncate the decompositions into products for transcendental functions, and to find the required final approximation.

6.4.2 Approximation for Realization

Now, we find the approximations to the Laplace transforms (Equations 6.74 and 6.75) resulting in the realizable transfer functions. Let us restrict ourselves by the last case ($\nu+1$ is odd) only. The other case can be considered in a similar way. Substituting $s = j\omega$, one can find that

$$\mathrm{Re}F_{odd}(j\omega) = \frac{2\nu\omega\sin\left(\frac{\pi}{2}\omega\right)\cos\left(\frac{\pi}{2}\omega\right)}{\left[-\omega^2+(\nu+1)^2\right]\left[-\omega^2+(\nu-1)^2\right]} \tag{6.76}$$

and

$$\mathrm{Im}F_{odd}(j\omega) = \frac{2\nu\omega\cos^2\left(\frac{\pi}{2}\omega\right)}{\left[-\omega^2+(\nu+1)^2\right]\left[-\omega^2+(\nu-1)^2\right]}. \tag{6.77}$$

Taking Equations 6.17 and 6.18 into consideration, one can see that $\mathrm{Re}F_{odd}(j\omega)$ and $\mathrm{Im}F_{odd}(j\omega)$ have common zeros at $\omega = 0$; and $\omega = \pm1$; ±3; ±5; … (due to the common multiplier $\cos(\pi\omega/2)$), yet the zeros $\omega = \pm(\nu-1)$ and $\omega = \pm(\nu+1)$ of this multiplier are not common zeros (they are canceled by the poles). Then, the $\mathrm{Re}F_{odd}(j\omega)$ has the zeros at $\omega = 0$; ±2; ±4; ±6; … (due to the multiplier $\sin(\pi\omega/2)$), and the $\mathrm{Im}F_{odd}(j\omega)$ has the zeros at $\omega = \pm1$; ±3; ±5; … (due to the second multiplier of $\cos(\pi\omega/2)$). Hence in the last two groups, the zeros are alternating. One can see that the ratio $H_{odd}(s)$ for approximation of $F(s)$ should have the form

$$H_{\text{odd}}(s) = \frac{A_1 s \prod_{k=0,\, k\neq\nu-1,\, k\neq\nu+1}^{k=\rho} \left[s^2 + (2k+1)^2\right]}{\prod_{k=0}^{n} \left[s^2 + (2k+1)^2\right] + A_2 s \prod_{k=1}^{n_1} (s^2 + 4k^2)}. \tag{6.78}$$

Indeed, if one calculates $\text{Re}H_{\text{odd}}(j\omega)$ and $\text{Im}H_{\text{odd}}(j\omega)$ and compare them with $\text{Re}F_{\text{odd}}(j\omega)$ and $\text{Im}F_{\text{odd}}(j\omega)$, one finds that the zeros of $\text{Re}H_{\text{odd}}(j\omega)$ and $\text{Im}H_{\text{odd}}(j\omega)$ have the same properties: there are common zeros (due to the numerator) and alternating zeros (due to even and odd polynomials in the denominator). The number of zeros is, of course, finite, and is defined by the order of $H_{\text{odd}}(s)$. In practice it is sufficient to choose $\rho = \nu + 2$. Then one chooses $n = n_1$ for even and $n = n_1 - 1$ for odd polynomials in the denominator. The maximal of these two numbers $\max(n, n_1) \geq \rho$. The approximation becomes better when the order of $H_{\text{odd}}(s)$ increases. The constants A_1 and A_2 can be found equating $F_{\text{odd}}(s)$ and $H_{\text{odd}}(s)$ at two points of the s-plane. The case of $F_{\text{ev}}(s)$ is treated in a similar way.

6.4.3 Example

As an example, we consider the network that should have the impulse response

$$u(t) = \begin{cases} \sin t \sin 5t & 0 \leq t \leq \pi \\ 0 & t > \pi \end{cases}. \tag{6.79}$$

(It is this pulse that was shown in Figure 6.9.) We have $\nu + 1 = 6$, that is, the even case. It is easy to find that the Laplace transform of Equation 6.79 is equal to

$$F_{\text{ev}}(s) = \frac{20 s e^{-\frac{\pi}{2}s} \sinh\left(\frac{\pi}{2}s\right)}{(s^2 + 4^2)(s^2 + 6^2)}. \tag{6.80}$$

The real and imaginary parts of this function are

$$\text{Re}F_{\text{ev}}(j\omega) = -\frac{20\omega \cos\left(\frac{\pi}{2}\omega\right) \sin\left(\frac{\pi}{2}\omega\right)}{(-\omega^2 + 16)(-\omega^2 + 36)} \tag{6.81}$$

and

$$\text{Im}F_{\text{ev}}(j\omega) = \frac{20\omega \sin^2\left(\frac{\pi}{2}\omega\right)}{(-\omega^2 + 16)(-\omega^2 + 36)}. \tag{6.82}$$

In the interval $0 \leq \omega \leq 8$, the functions $\text{Re}F_{\text{ev}}(j\omega)$ and $\text{Im}F_{\text{ev}}(j\omega)$ have double common zero at $\omega = 0$, and simple common zeros at $\omega = \pm 2$ and $\omega = \pm 8$. The zeros at $\omega = \pm 4$ and $\omega = \pm 6$ are not common zeros, after cancelation of poles at $\omega = \pm 4$ and $\omega = \pm 6$ they disappear from $\text{Re}F_{\text{ev}}(j\omega)$ and left in $\text{Im}F_{\text{ev}}(j\omega)$ only. The function $\text{Re}F_{\text{ev}}(j\omega)$ has zeros at $\omega = \pm 1; \pm 3; \pm 5; \pm 7$. These zeros are alternating with the zeros $\omega = 0\ \pm 2; \pm 4; \pm 6; \pm 8$ that occur in $\text{Im}F_{\text{ev}}(j\omega)$ due to the second $\sin(\pi\omega/2)$ multiplier in the numerator of Equation 6.82. As a result, one can use the ratio

$$H_{\text{ev}}(s) = \frac{A_1 s^2 (s^2 + 4)(s^2 + 64)}{[(s^2 + 1)(s^2 + 9)(s^2 + 25)(s^2 + 49) + A_2 s (s^2 + 4)(s^2 + 16)(s^2 + 36)(s^2 + 64)]}. \tag{6.83}$$

The coefficients A_1 and A_2 can be found, for example, equating Equations 6.81 and 6.84 at $s = j4$ and $s = j5$. One finds that $A_1 = 2.65762$ and $A_2 = 0.13288$.

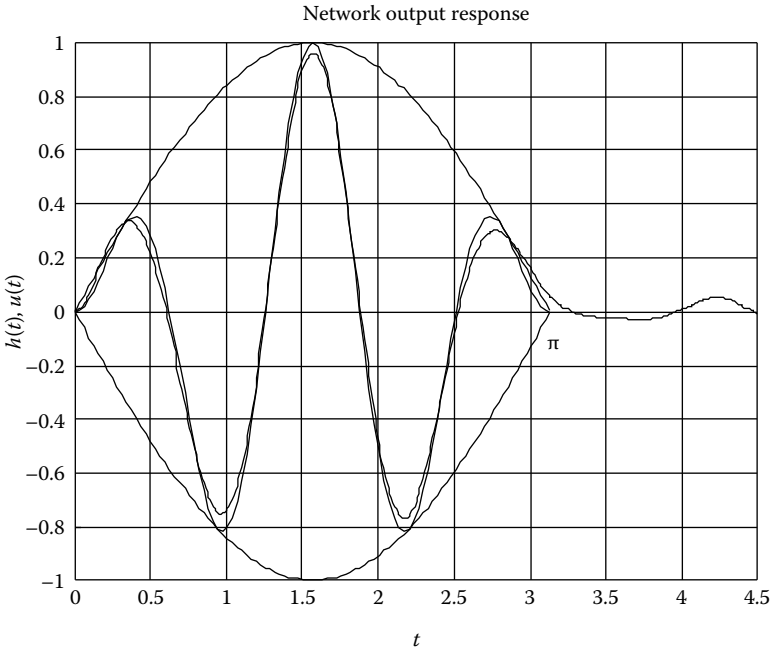

FIGURE 6.10 Network output response.

Because Equation 6.80 is the impulse response, one takes directly

$$H(s) = H_{ev}(s). \tag{6.84}$$

Figure 6.10 shows the inverse Laplace transform $h(t) = \mathbf{L}^{-1}(H(s))$ of this transfer function that is compared with $u(t)$ given by Equation 6.79.

Dividing the numerator and denominator of $H(s) = H_{ev}(s)$ by the odd part of the denominator one writes that

$$y_{21} = -\frac{A_1 s}{A_2(s^2+16)(s^2+36)} \tag{6.85}$$

and

$$y_{22} = \frac{(s^2+1)(s^2+9)(s^2+25)(s^2+49)}{A_2 s(s^2+4)(s^2+16)(s^2+36)(s^2+64)}. \tag{6.86}$$

The LC-realization using these two parameters is shown in Figure 6.11. The realization is done within a constant multiplier for y_{21}. It starts by realization of the private poles of y_{22} at $s = 0$, $s = \pm 2$, and $s = \pm j8$. The residual admittance

$$y'_{22} = \frac{2.850s(s^2+24.936)}{(s^2+16)(s^2+36)} \tag{6.87}$$

is realized, first, by subtraction of the poles of $1/(y'_{22})$ at $s = 0$ and $s = \infty$. This provides the zeros at $s = 0$ and $s = \infty$ common for y_{21} and y'_{22}. Then, after subtraction of the series elements corresponding to these

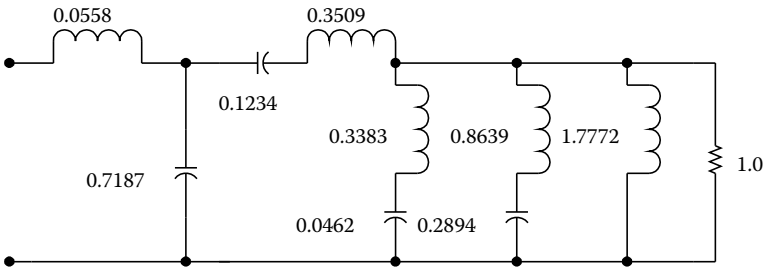

FIGURE 6.11 Realization of the pulse-shaping network.

poles of $1/(y'_{22})$, the final residual conductance is realized to provide two additional zeros of y_{21} at $s = \infty$. One can find that this realization provides the level of y_{21} that is 3.553 times higher than that given by Equation 6.85.

One can see that multiplication of Equation 6.83 by s gives the realizable function as well. The realization of the network providing Equation 6.79 as the step response is not given here for the reason of space limitation.

6.5 Summary

The synthesis of a pulse-forming network with output response that is close to a rectangular shape pulse requires two step approximation procedure. The derivative of this output response is described by positive and delayed negative semi-periods of the sine-squared function. This is the first step of approximation procedure. The real and imaginary parts of Laplace transform of thus approximated output pulse are expanded in infinite products. Then, using a finite number of terms in these products, one obtains an algebraic ratio that approximates this Laplace transform. This is the second step of approximation procedure.

If the input excitation is the unit impulse function, the obtained ratio is directly the required transfer function realizable by a reactance network loaded by resistor. Two closely connected realizable transfer functions (providing the same output) are obtained by simple multiplication of the previously obtained transfer function by s (if the input excitation is the unit step function) or by $(s^2 + \Omega^2)$ (if the input excitation is the sinusoid of unit amplitude and of frequency Ω).

The synthesis of a linear network shaping a nonperiodic (in the considered case quasi-rectangular) pulse from the sinusoidal voltage is using the short period of time after turning on this input voltage. The zeros of transfer function are used to reject the periodic solution and create zero solution during the network steady-state operation. The efficiency of this pulse-shaping circuit may be insufficient; yet, conceptually the synthesis procedure is not very much different from the synthesis of pulse-shaping networks using for this purpose the discharge of a capacitor.

The two-step approximation resulting in the realizable reactance networks may be extended on the wide variety of output pulses including wideband amplifier transient responses and sinusoidal pulses of finite duration and with wide variety of envelop shape.

The method is simple, and the output response is approximated with a small error. The network complexity to obtain better approximations can be easily controlled. The approximation precision as well as the network complexity can be improved using computer methods [30].

The proposed procedure for synthesis of pulse-forming networks is based on approximation of the meaningful part of the output signal spectrum. The zeros of real and imaginary parts of approximated and approximating functions coincide in the meaningful part of the spectrum, and their amplitude values are close to each other. This closeness of spectrums provides good approximation in the time domain.

7.1 Introduction

Real-time and off-line processing of continuous-time signals by digital means (digital signal processing [DSP]) has become a viable processing mode over analog means for several reasons, some of which are digital signal processors, microcontrollers, and microprocessors. These are inexpensive, programmable, reproducible, consume low power, have computing speeds suitable for signals with bandwidths beyond base band video, and can operate in extreme environments. Some broad application areas of DSP are automotive industry, consumer electronics, communication systems, and medical systems.

Since real-world signals are continuous in time, the technologist must properly interpret results of processing signals by digital means. This requires an understanding of the origin of and relationship among the basic tools used for DSP. We shall first consider the Fourier series (FS) concept for continuous-time periodic signals. Everything that follows will be based on this concept.

This chapter is intended for those who have some experience with the material generally covered in a first course on continuous-time signals and systems, and would like a brief introduction to the fundamentals of DSP.

7.1.1 Fourier Series for Continuous-Time Periodic Signals

Given is a real and periodic signal $x(t)$, which satisfies

$$x(t) = x(t + T_0)$$

for some period T_0 and all t. One period of $x(t)$ is $x_p(t) = x(t)$, for $t_0 \le t < t_0 + T_0$ and $x_p(t) = 0$ for $t < t_0$ and $t \ge t_0 + T_0$, where t_0 is arbitrary. The periodic signal $x(t)$ can be written as the periodic extension of $x_p(t)$, which is

$$x(t) = \sum_{r=-\infty}^{+\infty} x_p(t - rT_0)$$

Let us approximate $x(t)$ by a sum of sinusoidal functions given by

$$\hat{x}(t) = \hat{a}_0 + \sum_{k=1}^{\infty} \hat{a}_k \cos(k\omega_0 t) + \sum_{k=1}^{\infty} \hat{b}_k \sin(k\omega_0 t)$$

where ω_0, called the fundamental frequency, is found with $\omega_0 = 2\pi/T_0$ rad/s and $f_0 = 1/T_0$ Hz. The frequency ω of each sinusoidal function is $\omega = k\omega_0$. Therefore, the approximation $\hat{x}(t)$ is also periodic with period T_0. The approximation error is

$$e(t) = x(t) - \hat{x}(t)$$

We choose the coefficients $\hat{a}_0$, $\hat{a}_k$, and $\hat{b}_k$ to minimize the mean square error given by

$$\varepsilon^2\left(\hat{a}_0, \hat{a}_k, \hat{b}_k\right) = \frac{1}{T_0} \int_0^{T_0} e^2(t)\mathrm{d}t$$

which is a quadratic function of $\hat{a}_0$, $\hat{a}_k$, and $\hat{b}_k$. Denote the $\hat{a}_0$, $\hat{a}_k$, and $\hat{b}_k$ that minimize ε^2 by a_0, a_k, and b_k, respectively. Setting the partial derivatives of ε^2 with respect to $\hat{a}_0$, $\hat{a}_k$, and $\hat{b}_k$ to zero gives

$$a_0 = \frac{1}{T_0} \int_0^{T_0} x(t)\mathrm{d}t$$

which is the average value of $x(t)$, and

$$a_k = \frac{2}{T_0} \int_0^{T_0} x(t) \cos(k\omega_0 t)\mathrm{d}t$$

$$b_k = \frac{2}{T_0} \int_0^{T_0} x(t) \sin(k\omega_0 t)\mathrm{d}t$$

If $x(t)$ satisfies the Dirichlet conditions, which are that $x(t)$ must

1. Have a finite number of extrema in any given time interval
2. Have a finite number of discontinuities in any given time interval
3. Be absolutely integrable over a period

then setting $\hat{a}_0 = a_0$, $\hat{a}_k = a_k$, and $\hat{b}_k = b_k$ gives $\varepsilon^2(a_0, a_k, b_k) = 0$, and we write

$$x(t) = a_0 + \sum_{k=1}^{\infty} a_k \cos(k\omega_0 t) + \sum_{k=1}^{\infty} b_k \sin(k\omega_0 t) \tag{7.1}$$

which is called the FS representation of $x(t)$, and the a_0, a_k, and b_k are the trigonometric FS coefficients of $x(t)$. If $x(t)$ is discontinuous at $t = t_d$, then for $t = t_d$, the FS converges to the average value of $x(t)$ about $t = t_d$, which is

$$\frac{x(t_d^-) + x(t_d^+)}{2} \tag{7.2}$$

Furthermore, if $x(t)$ is everywhere finite and continuous, then we have the stronger result that $e(t) = 0$.

For further development, it is more convenient to apply Euler's identity, which is

$$e^{j\alpha} = \cos(\alpha) + j\sin(\alpha) \tag{7.3}$$

for any real number α, and then $x(t)$ becomes

$$x(t) = a_0 + \sum_{k=1}^{\infty} a_k \frac{e^{jk\omega_0 t} + e^{-jk\omega_0 t}}{2} + \sum_{k=1}^{\infty} b_k \frac{e^{jk\omega_0 t} - e^{-jk\omega_0 t}}{j2}$$

Let

$$X_k = \frac{a_k}{2} - j\frac{b_k}{2}$$

Since $a_k = a_{-k}$ and $b_k = -b_{-k}$, we have $X_{-k} = X_k^*$, and therefore, we can write

$$x(t) = \sum_{k=-\infty}^{+\infty} X_k e^{jk\omega_0 t} \tag{7.4}$$

where $X_0 = a_0$ and

$$X_k = \frac{1}{T_0} \int_{t_0}^{t_0+T_0} x(t) e^{-jk\omega_0 t} dt \tag{7.5}$$

for any t_0. This representation for $x(t)$ is called the complex FS, and the X_k are called the complex FS coefficients. We say that $x(t)$ and X_k are a FS pair, which is denoted by $x(t) \leftrightarrow X_k$. In general, the FS coefficients X_k are complex. However, if $x(t)$ is an even time function, then X_k is real, which means that $x(t)$ can be represented with only cosine terms, and if $x(t)$ is an odd time function, then X_k is imaginary, which means that $x(t)$ can be represented with only sine terms.

Let us write X_k in polar form to get

$$X_k = \left\| X_k \right\| e^{j\angle X_k}$$

where

$||X_k||$ is the magnitude of X_k

$\angle X_k$ is the angle of X_k

then Equation 7.4 becomes

$$x(t) = X_0 + 2\sum_{k=1}^{\infty} \left\| X_k \right\| \cos(k\omega_0 t + \angle X_k) \tag{7.6}$$

Notice that $||X_k|| = ||X_{-k}||$, an even function of k, and $\angle X_k = -\angle X_{-k}$, an odd function of k. Here we see that $||X_k||$ gives information about the amplitude and $\angle X_k$ gives information about the phase angle of the sinusoidal contribution to $x(t)$ at the frequency $\omega = k\omega_0$. Thus, $||X_k||$ versus k is called the magnitude spectrum of $x(t)$, and $\angle X_k$ versus k is called the phase spectrum of $x(t)$.

As we study cyclical phenomena, we are interested to know the strengths and time displacements of sinusoidal components in $x(t)$ at the frequencies $f = kf_0$ Hz.

7.1.2 Example and Discussion

To be practical, we must truncate the series in Equation 7.4 to use a finite number of terms, giving

$$x(t) \cong \sum_{k=-K}^{+K} X_k e^{jk\omega_0 t} \tag{7.7}$$

To see what happens for different values of K, let us apply Equation 7.7 to the periodic signal shown in Figure 7.1.

The complex FS coefficients for this signal are given by

$$X_k = \frac{1}{3}\int_0^3 x(t)e^{-jk\frac{2\pi}{3}t}\,dt = \frac{1}{3}\int_{0.5}^{2.0} 4e^{-jk\frac{2\pi}{3}t}\,dt = \frac{4}{k\pi}e^{-jk\frac{5\pi}{6}}\,\sin\left(k\frac{\pi}{2}\right), \quad k \neq 0$$

and $X_0 = 2$. Figure 7.2 shows the magnitude spectrum of $x(t)$, which shows the amplitudes of the sinusoidal components of $x(t)$ at the frequencies $f = kf_0$ Hz.

Figure 7.3 shows the application of Equation 7.7 for increasing values of K. Notice the oscillation, called Gibbs oscillation, about points of discontinuity in $x(t)$. Even as K is increased, the oscillation remains with

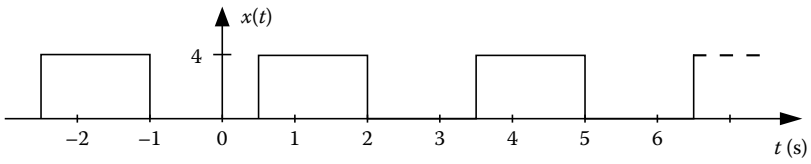

FIGURE 7.1 A periodic signal with discontinuities.

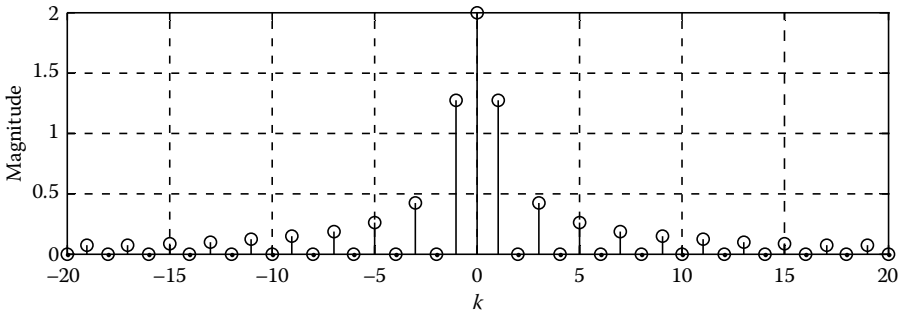

FIGURE 7.2 Magnitude spectrum for $-20 \leq k \leq +20$.

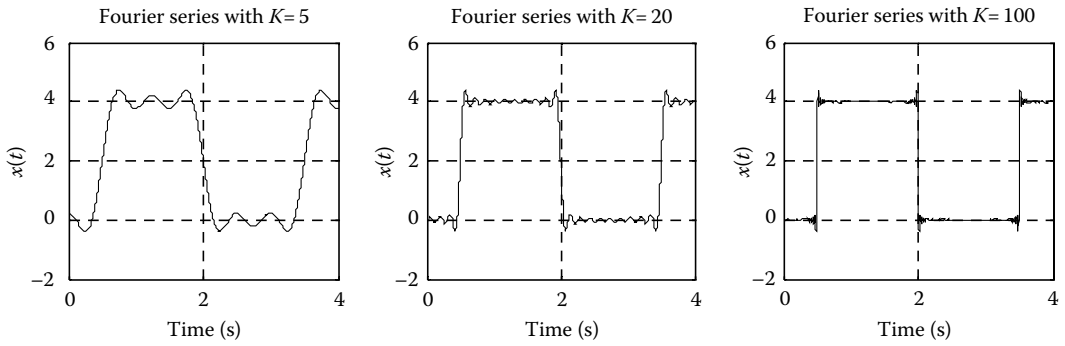

FIGURE 7.3 FS representation with $K = 5$, $K = 20$, and $K = 100$.

an amplitude exceeding $x(t)$ by about 7% of the change in $x(t)$ from one side of the discontinuity to the other side. Also notice that Gibbs oscillation becomes more and more concentrated about the discontinuities as K is increased.

7.1.3 Discrete-Time Signals

We obtain a discrete-time signal by uniformly sampling a continuous-time signal at some sampling rate f_s samples/s (Hz), which is expressed by

$$x(nT) = x(t)|_{t=nT}$$

where n, an integer, is called the discrete-time index and $T = 1/f_s$ is the sample time increment. If T is known and fixed, we may write the discrete-time signal as $x(n)$ instead of $x(nT)$.

Some discrete-time signals are a matter of definition. A few standard signals are

1. Unit step function,
   $u(n - n_0) = \begin{cases} 1, & n - n_0 \geq 0 \\ 0, & n - n_0 < 0 \end{cases}$
2. Unit pulse function (also called the Kronecker delta function),
   $\delta(n - n_0) = \begin{cases} 1, & n - n_0 = 0 \\ 0, & n - n_0 \neq 0 \end{cases}$
3. Exponential function,
   γ^n, for some real or complex constant γ
4. Sinusoidal function,
   $\cos(\theta n + \varphi)$

In terms of a continuous timescale, these discrete-time signals are only defined at the discrete time points given by $t = nT$.

The unit step function is commonly used to start (or stop) a given signal. For example, a sinusoidal pulse can be expressed as $\cos((\pi/4)n)(u(n) - u(n - 8))$, which is one cycle of the sinusoid. The unit pulse function is used to position a value at a time point. For example, $x(n) = -5\delta(n - 2)$ positions the value -5 of x to occur at the time $n = 2$, while for all other n, x has zero value. Through Euler's identity (Equation 7.3), a sinusoidal function can be expressed as the sum of two complex conjugate exponential functions.

We can write any discrete-time signal $x(n)$ as a linear combination of unit pulse functions given by

$$x(n) = \sum_{i=-\infty}^{+\infty} x(i)\delta(n - i) \tag{7.8}$$

7.1.4 Discrete Fourier Transform

For practical signals a function expression for $x(t)$ is usually not available, and therefore we cannot implement Equation 7.5 to find the spectrum X_k of $x(t)$. However, $x(t)$ can be sampled to obtain

$$x(nT) = x(t)|_{t=nT}$$

where T is determined with

$$T = \frac{T_0}{N} \tag{7.9}$$

for some integer N, which makes $x(n)$ a periodic discrete-time signal. We now develop an algorithm to find information about X_k, given $x(n)$.

To process $x(n)$, which can have values in a continuous range, by digital means, we must input each sample $x(n)$ into an analog-to-digital converter to obtain $x_{\mathrm{d}}(n)$, a digital signal, where each sample can have only one of a finite number of possible values. We approximate $x(n)$ with $x_{\mathrm{d}}(n)$, and

$$x(n) = x_{\mathrm{d}}(n) + e_{\mathrm{q}}(n)$$

where $e_{\mathrm{q}}(n)$ is the quantization error. In the following work $x(n)$ will be used for DSP. This may be acceptable if quantization error is negligible.

With the choice for T in Equation 7.9, $x(n)$ is periodic with period N, and with Equation 7.4, $x(n)$ becomes

$$x(n) = \sum_{k=-\infty}^{\infty} X_k \mathrm{e}^{jk\omega_0 nT}$$

Since $\omega_0 = \frac{2\pi}{T_0} = \frac{2\pi}{NT}$, we get for $x(n)$

$$x(n) = \sum_{k=-\infty}^{\infty} X_k \mathrm{e}^{jk\frac{2\pi}{NT}nT} = \sum_{k=-\infty}^{\infty} X_k \mathrm{e}^{j\frac{2\pi}{N}kn}$$

Let us write $k = m + rN$, where $m = 0, 1, \ldots, N-1$ and $r = \ldots, -2, -1, 0, 1, 2, \ldots$ are integers, and then $x(n)$ can be written as

$$x(n) = \sum_{r=-\infty}^{\infty} \sum_{m=0}^{N-1} X_{m+rN} \mathrm{e}^{j\frac{2\pi}{N}(m+rN)n} = \sum_{m=0}^{N-1} \sum_{r=-\infty}^{\infty} X_{m+rN} \mathrm{e}^{j\frac{2\pi}{N}mn}$$

where $\mathrm{e}^{j(2\pi/N)rNn} = 1$. Let $\hat{X}\ (k)$ be determined with

$$\hat{X}(k) = \sum_{r=-\infty}^{\infty} X_{k+rN}$$

and then $x(n)$ becomes

$$x(n) = \sum_{k=0}^{N-1} \hat{X}(k) \mathrm{e}^{j\frac{2\pi}{N}kn} \tag{7.10}$$

Notice that $\hat{X}(k)$ and X_k are related because $\hat{X}(k)$ is the periodic extension of X_k, and therefore $\hat{X}(k)$ is periodic, so that $\hat{X}(k) = \hat{X}(k + iN)$ for any integer i and all k. Knowing X_k, we can find $\hat{X}(k)$, $k = 0, 1, \ldots, N-1$. Since $\hat{X}(k)$ is periodic, we have $\hat{X}(k) = \hat{X}(k-N)$, and since the FS coefficients satisfy $X_k^* = X_{-k}$, we have $\hat{X}^*(k) = \hat{X}(N-k)$, and therefore

$$\hat{X}(k) = \hat{X}^*(N-k), \quad k = 0, 1, \ldots, N-1$$

This means, for example, that $\hat{X}^*(-1) = \hat{X}(1) = \hat{X}^*(N-1)$.

It would be very useful if we could obtain $\hat{X}(k)$ directly from $x(n)$. To do this, multiply both sides of Equation 7.10 by a particular exponential function, giving

$$x(n)e^{-j\frac{2\pi}{N}nm} = e^{-j\frac{2\pi}{N}nm}\sum_{k=0}^{N-1}\hat{X}(k)e^{j\frac{2\pi}{N}kn} = \sum_{k=0}^{N-1}\hat{X}(k)e^{j\frac{2\pi}{N}(k-m)n}$$

where m is any integer in the range $0, 1, \ldots, N-1$. Summing the left-hand and right-hand sides of this equation for $n = 0, 1, \ldots, N-1$ gives

$$\sum_{n=0}^{N-1}x(n)e^{-j\frac{2\pi}{N}nm} = \sum_{n=0}^{N-1}\sum_{k=0}^{N-1}\hat{X}(k)e^{j\frac{2\pi}{N}(k-m)n} = \sum_{k=0}^{N-1}\hat{X}(k)\sum_{n=0}^{N-1}e^{j\frac{2\pi}{N}(k-m)n}$$

Applying the formula for the sum of a geometric series gives

$$\sum_{n=0}^{N-1}e^{j\frac{2\pi}{N}(k-m)n} = \begin{cases} N, & k = m \\ \dfrac{1 - e^{j\frac{2\pi}{N}(k-m)N}}{1 - e^{j\frac{2\pi}{N}(k-m)}} = 0, & k \neq m \end{cases}$$

and therefore

$$\sum_{n=0}^{N-1}x(n)e^{-j\frac{2\pi}{N}nm} = N\hat{X}(m)$$

This results in the discrete Fourier transform (DFT) $X(k)$ of $x(n)$, $n = 0, 1, \ldots, N-1$, which is given by

$$X(k) = \sum_{n=0}^{N-1}x(n)e^{-j\frac{2\pi}{N}nk}, \quad k = 0, 1, \ldots, N-1 \tag{7.11}$$

and therefore

$$X(k) = N\hat{X}(k) = N\sum_{r=-\infty}^{\infty}X_{k+rN} \tag{7.12}$$

Equation 7.10 becomes

$$x(n) = \frac{1}{N}\sum_{k=0}^{N-1}X(k)e^{j\frac{2\pi}{N}kn} \tag{7.13}$$

which is called the inverse DFT (IDFT). Like $\hat{X}(k)$, $X(k)$ is periodic with period N and $X(k) = X^*(N-k)$. We write that $X(k) = \text{DFT}\{x(n)\}$ and $x(n) = \text{IDFT}\{X(k)\}$.

Equations 7.11 and 7.13 are very similar. If $x(n)$ is real, then conjugating Equation 7.13 gives

$$x(n) = \frac{1}{N}\sum_{k=0}^{N-1} X^*(k)e^{-j\frac{2\pi}{N}kn} = \frac{1}{N}\text{DFT}\{X^*(k)\}$$

Therefore, if we have an algorithm to compute Equation 7.11, the DFT, then that same algorithm, instead of Equation 7.13, can be used to compute the IDFT.

While our interest is to investigate the spectral properties of a continuous-time periodic signal with Equations 7.11 and 7.12, Equation 7.13 is a discrete-time FS representation for a discrete-time periodic signal, and Equation 7.11 is used to find the discrete-time FS coefficients. We say that $x(n)$ and $X(k)$ are a discrete Fourier series (DFS) pair, which is denoted by $x(n) \leftrightarrow X(k)$. Notice that for a discrete-time periodic signal, the FS uses a finite number of discrete-time sinusoids, while for a continuous-time periodic signal, the FS in Equation 7.4 uses a countable infinite number of sinusoids. Furthermore, $X(k)$ is a periodic function in the frequency domain with period N.

7.1.5 Examples and Discussion

Given $x(n)$, the result of sampling a continuous-time periodic signal $x(t)$, we apply Equation 7.11 to obtain $X(k) = \text{DFT}\{x(n)\}$, because, in view of Equation 7.12, over one period of $X(k)$ we expect to obtain a function that potentially behaves like X_k, the spectrum of the continuous-time periodic signal. An important property of $x(t)$ that strongly influences the relationship between X_k and $X(k)$ is whether or not $x(t)$ is bandlimited. If $x(t)$ is bandlimited, then there is some positive integer M such that $X_k = 0$ for $|k| > M$. We say that the bandwidth of $x(t)$ is $\text{BW} = Mf_0$ Hz. Denote the BW by f_c.

To see the effect of selecting an appropriate sampling frequency f_s, let us work with the bandlimited signal given by

$$x(t) = 6\cos\left(10\pi t + \frac{\pi}{4}\right) + 4\sin\left(30\pi t - \frac{\pi}{3}\right) \tag{7.14}$$

Here, $f_0 = 5$ Hz, and $f_c = 15$ Hz, with $M = 3$. Figure 7.4 shows the magnitude spectrum of $x(t)$. The spectral points occur at the frequencies given by $f = k(1/T_0) = kf_0$ Hz, $k = -M, \ldots, 0, 1, 2, M$.

Now, let us sample this $x(t)$ over one period to obtain $N = 10$ time domain samples $x(n)$, $n = 0, 1, \ldots, N-1$. The magnitude of the DFT of $x(n)$ is shown in Figure 7.5. Here we see two periods of the magnitude of $X(k)$ obtained from $||X_k||$ and its first translation $||X_{k-N}||$. Depending on N, the translations of X_k to all integer multiples of N may overlap. In Figure 7.5, N is large enough to prevent the overlap of the translations of X_k, and therefore one period of $X(k)/N$ gives X_k without error. Notice that for $k = 0, 1, \ldots, M$ we have $||X_k||$ for positive frequencies, and for $k = N-1, N-2, \ldots, N-M$ we have $||X_k||$ for negative frequencies.

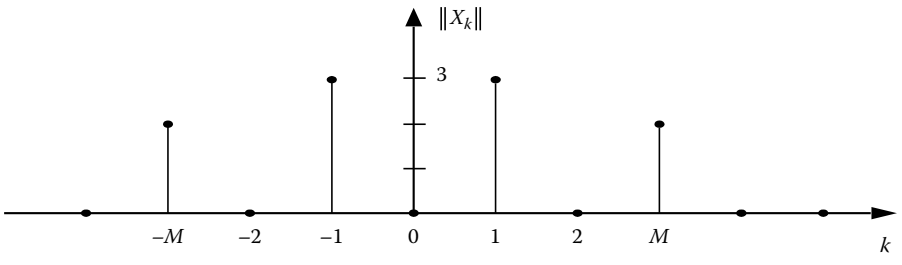

FIGURE 7.4 Magnitude spectrum of a bandlimited signal.

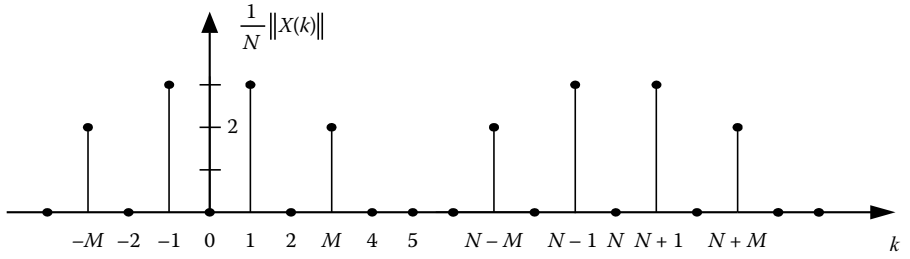

FIGURE 7.5 Two periods of the magnitude of $X(k)$.

In general, if $x(t)$ is bandlimited and $N - M > M$, then the translations of X_k to integer multiples of N cannot overlap. This condition can be written as

$$\frac{N-M}{T_0} > \frac{M}{T_0} \rightarrow \frac{N}{NT} - Mf_0 > Mf_0$$

Therefore, if $x(t)$ is bandlimited to f_c and the sampling frequency f_s satisfies

$$f_s > 2f_c \tag{7.15}$$

such that T_0/T is an integer, which means that f_s must be an integer multiple of f_0, then the DFT of $\{x(n)\}$ gives the spectrum of $x(t)$ without error. This is called the sampling theorem.

In Figure 7.5, the sampling frequency is given by $f_s = \frac{1}{T} = \frac{N}{T_0} = 50$ Hz, and therefore Equation 7.15 is satisfied. Moreover, $x(t)$ can have sinusoidal components with frequencies in the range $0 \leq f < f_s/2$, and the DFT gives X_k without error.

Now, let us try an f_s that does not satisfy Equation 7.15, and such that the frequency points again occur at integer multiples of $f_0 = 5$ Hz. For example, let $f_s = 25$ Hz, giving $N = 5$. Figure 7.6 shows the magnitude of $X(k)$. Like in Figure 7.5, we use the DFT to give the spectrum of $x(t)$ in the frequency range $0 \leq f < f_s/2$, and here $f_s/2 = 12.5$ Hz, which corresponds to $k = 0, 1, 2$. From Figure 7.6, we conclude that $x(t)$ has sinusoidal components at the frequencies 5 and 10 Hz. However, only the spectral point at 5 Hz is correct. The spectral point at 10 Hz, which does not occur in $x(t)$, is called aliasing error, and we cannot even determine that $x(t)$ has a sinusoidal component at 15 Hz. If the original $x(t)$ did consist of sinusoids only at the frequencies 5 and 10 Hz, then Figure 7.6 would be correct.

To obtain correct results with the DFT, we must know the bandwidth and period of a given periodic signal $x(t)$. However, it may not be realistic to assume that we can know this information about a given

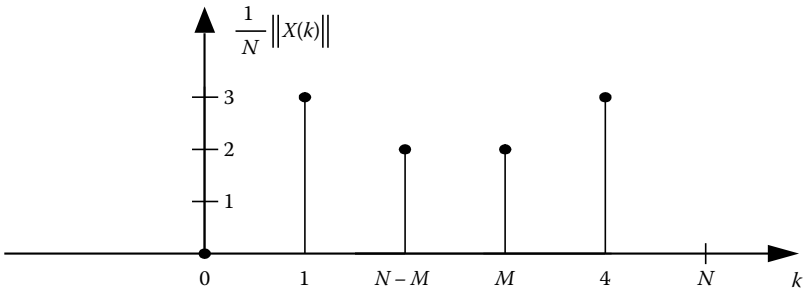

FIGURE 7.6 Magnitude of $X(k)$ for $k = 0, 1, 2, \ldots, N-1$, $N = 5$, and $f_s = 25$ Hz.

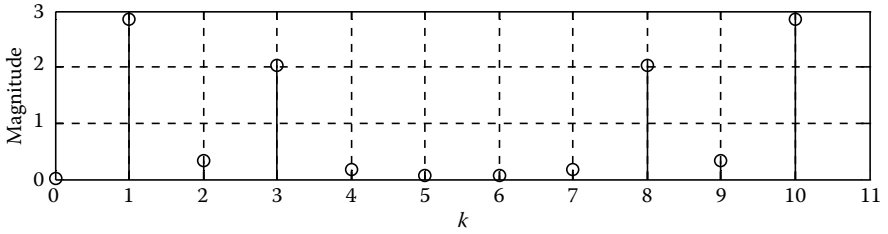

FIGURE 7.7 Magnitude spectrum for $k = 0, 1, \ldots, N-1$, $N = 11$, and $f_s = 53$ Hz.

signal. Furthermore, $x(t)$ may not even be bandlimited (e.g., see Figure 7.2.), in which case translations of X_k to form $X(k)$ will overlap and aliasing error cannot be avoided.

In comparison to the results shown in Figure 7.5, let us try an f_s that does satisfy the sampling theorem of Equation 7.15 for the signal given by Equation 7.14. For example, let $f_s = 53$ Hz. For this sampling frequency, $T_0/T = 10.6$ is not an integer. Therefore, let us set N to $N = 11$, which means that effectively we consider one period $x_p(t)$ to be defined for $0 \leq t < T_0$, where $T_0 = NT = 0.210325$ s. Therefore, the DFT will obtain spectral points at integer multiples of $f_0 = 1/T_0 = 4.7545$ Hz, instead of 5 Hz, as in Figure 7.5. While the signal given by Equation 7.14 is bandlimited, a periodic extension of $x_p(t)$ is a periodic signal with discontinuities at period boundaries, and therefore we have a signal that is not bandlimited. Figure 7.7 shows the magnitude of $X(k)$, and we see that, while it is similar to the magnitude spectrum given in Figure 7.5, this result is an approximation of the spectrum of the signal given by Equation 7.14.

The spectral points in Figure 7.5 at 5 and 15 Hz have spread out about these frequencies in Figure 7.7. This is called leakage error. Leakage error occurs when we use a sample time range other than an integer multiple of the period of the given periodic signal.

If it is practically possible, it is useful to sample the continuous-time signal over a longer time range. For example, with the sampling frequency used to produce the result shown in Figure 7.7, let us obtain $N = 50$ samples of $x(t)$. In this case, $x_p(t)$ becomes the segment of $x(t)$ for $0 \leq t < T_0$, where $T_0 = NT = 0.9434$ s. It is likely that we will still have discontinuities at the period boundaries of the periodic extension of $x_p(t)$, which means that the resulting periodic signal is not bandlimited, and aliasing error cannot be avoided. Since T_0 is not an integer multiple of the period of the given $x(t)$, we will incur leakage error. However, we now have a higher frequency resolution determined by $f_0 = 1/T_0 = 1.06$ Hz.

Figure 7.8 shows the magnitude of the DFT of $x(n)$, $n = 0, 1, \ldots, 49$. Notice that the spectral point at $k = 0$ is not zero, which means that the average value of the periodic signal is not zero, even though the

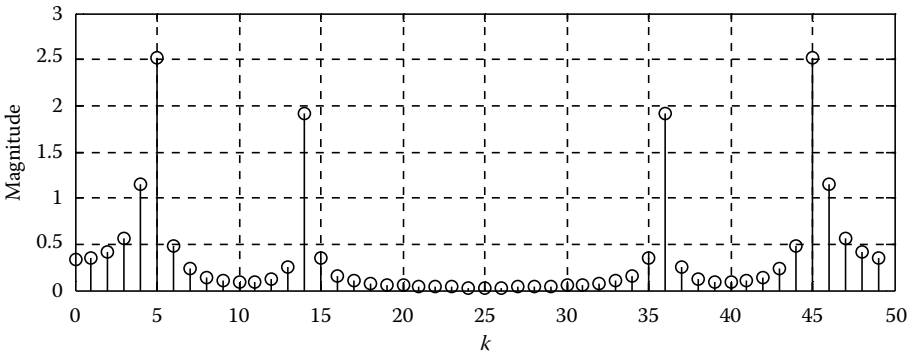

FIGURE 7.8 Magnitude spectrum for $k = 0, 1, \ldots, N-1$, $N = 50$, and $f_s = 53$ Hz.

given $x(t)$ has a zero average value. Also, there is leakage error, as expected, and there is significant aliasing error at higher frequencies, i.e., as $k \rightarrow 25$. Nevertheless, like in Figure 7.7, this magnitude spectrum is an approximation of the magnitude spectrum shown in Figure 7.5.

We can reduce the aliasing error shown in Figure 7.8 by reducing the discontinuities that occur at the period boundaries of the periodic extension of $x_p(t)$. Let us view $x_p(t)$ to be given by

$$x_p(t) = x(t)w(t) \tag{7.16}$$

where $w(t)$, which is called a window function, is given by $w(t) = w_R(t)$, the rectangular window, and

$$w_R(t) = \begin{cases} 1, & 0 \leq t < T_0 \\ 0, & \text{otherwise} \end{cases}$$

We can write $w_R(t) = u(t) - u(t - T_0)$, where $u(t)$ is the unit step function.

To eliminate the discontinuities at period boundaries, let the window function be given by $w(t) = w_H(t)$, where

$$w_H(t) = \frac{1}{2}\left(1 - \cos\left(\frac{2\pi t}{T_0}\right)\right) w_R(t)$$

which is called the Hann window. Notice that $w_H(t = 0) = w_H(t = T_0) = 0$. Using the Hann window in Equation 7.16 gives the magnitude spectrum shown in Figure 7.9. Notice the reduced magnitudes about the frequencies of sinusoids in the given $x(t)$. There are numerous other widow functions that could also have been used.

7.1.6 DFT Applications

The DFT has many properties that account for its wide application. Here, we examine how the DFT can be involved to compute the linear convolution of two discrete-time signals. Let $x_1(n)$ and $x_2(n)$ be two periodic discrete-time signals, each having period N. The circular convolution of $x_1(n)$ and $x_2(n)$, which is denoted by $x_1(n) \otimes x_2(n)$, is another periodic signal $x_3(n)$ with period N given by

$$x_3(n) = x_1(n) \otimes x_2(n) = \sum_{i=0}^{N-1} x_1(i)x_2(n-i) = \sum_{i=0}^{N-1} x_1(n-i)x_2(i) \tag{7.17}$$

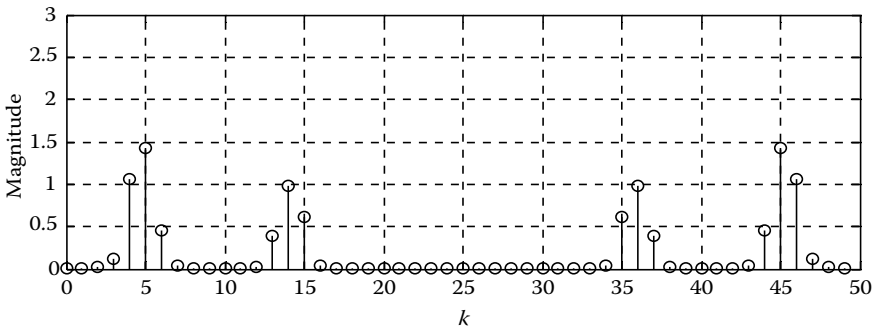

FIGURE 7.9 Magnitude spectrum for $N = 50$, $f_s = 53$ Hz, and $w(t) = w_H(t)$.

It is not difficult to show that $X_3(k) = \text{DFT}\{x_3(n)\}$ is given by

$$X_3(k) = X_1(k)X_2(k) \tag{7.18}$$

which is called the circular convolution theorem. In other words, circular convolution in the time domain can be transformed to multiplication in the frequency domain. Therefore, instead of using Equation 7.17 to find the circular convolution of $x_1(n)$ and $x_2(n)$, we find $x_3(n)$ with the IDFT of $X_3(k)$ found with Equation 7.18. This is the indirect convolution method.

Now consider the linear convolution of $y_1(n)$ and $y_2(n)$, which are not periodic, to obtain $y_3(n)$ given by

$$y_3(n) = \sum_{i=-\infty}^{+\infty} y_1(n-i)y_2(i) = \sum_{i=-\infty}^{+\infty} y_1(i)y_2(n-i) = y_1(n)^* y_2(n) \tag{7.19}$$

Let us assume that $y_1(n)$ and $y_2(n)$ have finite durations, and $y_1(n)$ is given for $n = 0, \ldots, N_1 - 1$ and $y_2(n)$ is given for $n = 0, \ldots, N_2 - 1$. The duration N_3 of $y_3(n)$ will be $N_3 = N_1 + N_2 - 1$.

To employ the DFT, let N be any integer such that $N > N_3$, and define periodic signals $x_1(n)$ and $x_2(n)$ with periods given by

$$x_1(n) = \begin{cases} y_1(n), & n = 0, \ldots, N_1 - 1 \\ 0, & n = N_1, \ldots, N - 1 \end{cases} \quad \text{and} \quad x_2(n) = \begin{cases} y_2(n), & n = 0, \ldots, N_2 - 1 \\ 0, & n = N_2, \ldots, N - 1 \end{cases}$$

We now find the circular convolution $x_3(n)$ of $x_1(n)$ and $x_2(n)$ with the indirect convolution method, and then over one period of $x_3(n)$ we get $y_3(n) = x_3(n)$ for $n = 0, \ldots, N_3 - 1$. At this point, we may expect that the indirect convolution method will require more computation than the direct convolution method using Equation 7.17. However, we will develop a computationally efficient algorithm, called the fast Fourier transform (FFT) to compute the DFT that will make the indirect convolution method more computationally efficient than the direct convolution method.

An operation similar to linear convolution is the linear correlation operation given by

$$r_{12}(l) = \sum_{n=-\infty}^{+\infty} y_1(n)y_2(n-l) \tag{7.20}$$

where l, $l = 0, 1, \ldots$, is called the lag index. However, the correlation $r_{12}(l)$, which is useful to investigate the similarity of two signals, can be obtained with

$$r_{12}(l) = y_1(l)^* y_2(-l) \tag{7.21}$$

Again, we assume that $y_1(n)$ and $y_2(n)$ have finite durations of N_1 and N_2, respectively, and the duration of $r_{12}(l)$ will be $N_3 = N_1 + N_2 - 1$.

To employ the DFT, we define $x_1(n)$ and $x_2(n)$ as before, and by indirect convolution compute

$$x_3(l) = x_1(l) \otimes x_2(-l)$$

to get $r_{12}(l) = x_3(l)$ for $l = 0, \ldots, N_3 - 1$. The DFT of $x_2(-n)$ is given by $X_2^*(k)$, where $X_2(k)$ is the DFT of $x_2(n)$.

7.1.7 Fast Fourier Transform

The FFT is a collection of algorithms that can compute the DFT, $X(k)$, $k = 0, \ldots, N-1$, of a discrete-time signal, $x(n)$, $n = 0, \ldots, N-1$, much more efficiently than with Equation 7.11. The efficiency of the FFT occurs when N can be expressed as a product of many small integers, $N = N_1\, N_2 \ldots N_I$. An ideal case occurs when N is a power of 2, $N = 2^L$, for some integer L, and then the FFT algorithm is called the radix-2 FFT algorithm. Other possibilities are, for example, $N = 3^K$, resulting in a radix-3 FFT, or N is a product of many different small integers, resulting in a mixed-radix FFT. Here, we will outline the development of the radix-2 FFT, and even more specifically, the decimation in time radix-2 FFT.

Before we start the FFT development, let us assess the computational requirements of Equation 7.11, the DFT operation. It is generally assumed that sinusoidal values are found by table lookup, which requires time that is negligible compared to multiplication time. If the DFT input is a set of N complex numbers, then the DFT will require a total of N^2 complex multiplications to obtain the set of N outputs, and we will use this for assessment of DFT computational requirements. We will see how the radix-2 FFT works to require only $NL/2$ complex multiplications.

We start by assuming that the number of points is $N = 2^L$, for some integer L. If for a given discrete-time signal $x(n)$ the number of points N is not a power of two, then we can augment the given $x(n)$ with a sufficient number of zero points for a total number of points that is a power of 2.

Since N is even, we can split the DFT summation in Equation 7.11 into two parts having an equal number of summation terms. Let the first part come from the even indexed terms in Equation 7.11, and let the second part come from the odd indexed terms, and we get

$$X(k) = \sum_{n=0}^{N-1} x(n) \mathrm{e}^{-j\frac{2\pi}{N}nk} = \sum_{n,\text{even}} x(n) \mathrm{e}^{-j\frac{2\pi}{N}nk} + \sum_{n,\text{odd}} x(n) \mathrm{e}^{-j\frac{2\pi}{N}nk}$$

Even n can be written as $n = 2i$, and odd n can be written as $n = 2i + 1$, for $i = 0, 1, \ldots, N_1 - 1$, where $N_1 = N/2$, which is an even integer. Now we have

$$X(k) = \sum_{i=0}^{N_1-1} x(2i) \mathrm{e}^{-j\frac{2\pi}{N}(2i)k} + \sum_{i=0}^{N_1-1} x(2i+1) \mathrm{e}^{-j\frac{2\pi}{N}(2i+1)k}$$

Let $x_0(n)$ and $x_1(n)$ be the N_1 point number sequences defined by

$$\begin{aligned} x_0(n) &= x(2n) \\ x_1(n) &= x(2n+1), \quad n = 0, 1, \ldots, N_1 - 1 \end{aligned}$$

and therefore we get

$$X(k) = \sum_{n=0}^{N_1-1} x_0(n) \mathrm{e}^{-j\frac{2\pi}{N_1}nk} + \mathrm{e}^{-j\frac{2\pi}{N}k} \sum_{n=0}^{N_1-1} x_1(n) \mathrm{e}^{-j\frac{2\pi}{N_1}nk}$$

Now let

$$X_0(k) = \sum_{n=0}^{N_1-1} x_0(n) \mathrm{e}^{-j\frac{2\pi}{N_1}nk} \tag{7.22}$$

$$X_1(k) = \sum_{n=0}^{N_1-1} x_1(n) \mathrm{e}^{-j\frac{2\pi}{N_1}nk}, \quad k = 0, 1, \ldots, N_1 - 1 \tag{7.23}$$

and therefore we get

$$X(k) = X_0(k) + e^{-j\frac{2\pi}{N}k}X_1(k), \quad k = 0, 1, \ldots, N-1 \tag{7.24}$$

An N-point DFT, $X(k)$, is periodic with period N. We see that Equations 7.22 and 7.23 are each N_1-point DFTs, and therefore $X_0(k)$ and $X_1(k)$ are periodic with period N_1. An N_1-point DFT requires N_1^2 complex multiplications. To find $X(k)$, let us use Equation 7.24 only for $k = 0, 1, \ldots, N_1$. However, for $k = N_1, N_1 + 1, \ldots, N-1$, let $m = k - N_1$, so that m varies from $m = 0$ to $m = N_1 - 1$, and Equation 7.24 becomes

$$X(N_1 + m) = X_0(N_1 + m) + e^{-j\frac{2\pi}{N}(N_1+m)}X_1(N_1 + m)$$

Or, since $X_0(k)$ and $X_1(k)$ are periodic with period N_1, we have

$$X(N_1 + k) = X_0(k) - e^{-j\frac{2\pi}{N}k}X_1(k), \quad k = 0, 1, \ldots, N_1 - 1 \tag{7.25}$$

The only difference between Equations 7.24 and 7.25 is addition of two terms in Equation 7.24 and subtraction of the same two terms in Equation 7.25.

Figure 7.10 combines Equations 7.24 and 7.25 for $k = 0, 1, \ldots, N_1 - 1$. This structure is called a butterfly operation. To find $X(k)$ for $k = 0, 1, \ldots, N-1$ given $X_0(k)$ and $X_1(k)$ for $k = 0, 1, \ldots, N_1 - 1$ requires $N/2$ complex multiplications, one complex multiplication for each butterfly operation. The $N/2$ butterfly operations are the first stage of reducing the computational requirements of the DFT operation.

The sequence of steps toward the first stage started with splitting the summation of Equation 7.11 by decimating $x(n)$ and finished with Equations 7.24 and 7.25, which is illustrated by Figure 7.10. We continue to obtain the second stage by decimating $x_0(n)$ into $x_{00}(n)$ and $x_{10}(n)$ from the even and odd, respectively, indexed points in $x_0(n)$ and by decimating $x_1(n)$ into $x_{01}(n)$ and $x_{11}(n)$ from the even and odd, respectively, indexed points in $x_1(n)$ to reduce the computational requirements for $X_0(k)$ and $X_1(k)$. This second stage requires $N_1/2 + N_1/2 = N/2$ complex multiplications. We continue through L stages, where in the last stage, each of the $N/2$ DFT operations is a 2-point DFT consisting of a single butterfly operation. Therefore, the last stage also requires $N/2$ complex multiplications. The overall algorithm is called the decimation in time radix-2 FFT, and it requires $NL/2$ complex multiplications to compute the DFT, compared to a direct DFT computation, which requires N^2 complex multiplications.

Suppose a signal $x(t)$ with BW = 3.6 kHz is sampled at the rate $f_s = 8$ kHz to obtain $N = 2^{13}$ points (about a 1 s time interval). A direct DFT requires approximately 67,000,000 complex multiplications, while an FFT requires approximately 53,000 complex multiplications, a reduction in time by a factor of 1264. The efficiency of the FFT improves as N is increased. With the FFT, indirect convolution can be demonstrated to be much more efficient than direct convolution.

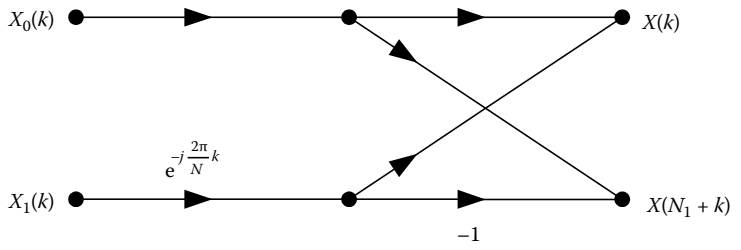

FIGURE 7.10 Butterfly operations of the first stage.

7.1.8 Continuous-Time Fourier Transform

By sampling a periodic continuous-time signal we developed the DFT operation and found a relationship between the result of a DFT operation $X(k)$ and the spectrum X_k of the continuous-time periodic signal. We also came to understand how $X(k)$ can be different from X_k, the FS coefficients. However, real-world continuous-time signals are not necessarily periodic. Here, we extend the concept of a FS approximation of a periodic continuous-time signal to an aperiodic continuous-time signal.

Consider the arbitrary aperiodic signal shown in Figure 7.11, where T_0 is large enough to contain the signal within the time range $-T_0/2 < t < T_0/2$. Over this time range the given signal can be represented with the FS of Equation 7.4, which is repeated here for convenience

$$x(t) = \sum_{k=-\infty}^{+\infty} X_k e^{jk\omega_0 t} \tag{7.26}$$

where

$$X_k = \frac{1}{T_0} \int_{-T_0/2}^{+T_0/2} x(t) e^{-jk\omega_0 t} dt \tag{7.27}$$

If in Figure 7.11 we let T_0 go to infinity, then the FS in Equation 7.26 represents the given signal for all t. Let us see what happens as T_0 is increased. If the integral in Equation 7.27 remains finite, then the X_k will go to zero. Since the spectral points occur at the frequencies given by $\omega = k\omega_0$, where $\omega_0 = 2\pi/T_0$, the spectrum tends toward a continuous function of frequency. Therefore, in view of Equation 7.27, let us work with

$$X(j\omega) = \lim_{T_0 \to \infty} X_k T_0 \tag{7.28}$$

which gives

$$X(j\omega) = \int_{-\infty}^{+\infty} x(t) e^{-j\omega t} dt \tag{7.29}$$

where $k\omega_0$ has become the continuous frequency ω. And then, Equation 7.26 becomes

$$x(t) = \frac{1}{2\pi} \lim_{T_0 \to \infty} \sum_{k=-\infty}^{+\infty} X_k T_0 e^{jk\omega_0 t} \frac{2\pi}{T_0}$$

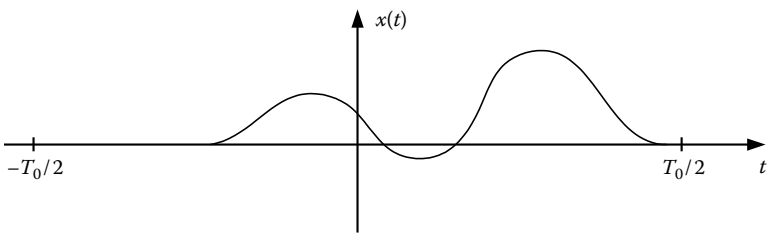

FIGURE 7.11 An arbitrary aperiodic signal.

TABLE 7.1 FT Properties

Linearity	$c_1x_1(t) + c_2x_2(t) \leftrightarrow c_1X_1(j\omega) + c_2X_2(j\omega)$
Time shift	$x(t - t_0) \leftrightarrow X(j\omega)e^{-j\omega t_0}$
Modulation	$x(t)e^{j\omega_0 t} \leftrightarrow X(j(\omega - \omega_0))$
Linear convolution	$x_1(t)^*x_2(t) = \int_{-\infty}^{+\infty} x_1(t-\tau)x_2(\tau)d\tau \leftrightarrow X_1(j\omega)X_2(j\omega)$
Derivative	$\frac{d}{dt}x(t) \leftrightarrow j\omega X(j\omega)$
Multiplication	$x_1(t)x_2(t) \leftrightarrow \frac{1}{2\pi}X_1(j\omega)^*X_2(j\omega)$
Energy (Parseval's theorem)	$\int_{-\infty}^{+\infty} \lvert x(t)\rvert^2 dt = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \lVert X(j\omega)\rVert^2 d\omega$

which gives

$$x(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} X(j\omega)e^{j\omega t}d\omega \tag{7.30}$$

We should view Equation 7.30 similar to Equation 7.26, which is that Equation 7.30 expresses an aperiodic continuous-time signal in terms of a linear combination of an uncountable infinite number of sinusoids. Equation 7.29 gives the Fourier transform (FT) $X(j\omega)$, which is a complex function of the continuous real frequency variable ω, of the continuous-time function $x(t)$, and it describes how the strengths of sinusoidal components of $x(t)$ are distributed over frequency. In view of Equation 7.28, $X(j\omega)$ is the spectral density of $x(t)$. Equation 7.30 gives the inverse FT of $X(j\omega)$, and we say that $x(t)$ and $X(j\omega)$ are a FT pair, denoted by $x(t) \leftrightarrow X(j\omega)$.

The FT has many properties that are widely applied in continuous-time signal and system analysis and design. Assume that we have the FT pair $x(t) \leftrightarrow X(j\omega)$. Table 7.1 gives a few important properties.

7.1.9 Examples and Discussion

The FT of a signal may not exist. For example, for $x(t) = u(t)$, the unit step function, we must utilize an impulse function to express its FT. In view of Equation 7.28, the FT of a sinusoidal signal also requires using impulse functions. A sufficient condition for the existence of the FT is that

$$\lVert X(j\omega)\rVert \le \int_{-\infty}^{+\infty} \left\lVert x(t)e^{-j\omega t}\right\rVert dt = \int_{-\infty}^{+\infty} \lVert x(t)\rVert dt < \infty$$

which means that the signal $x(t)$ must be absolutely integrable.

Consider the signal $x(t)$ given by $x(t) = \sin(\omega_0 t)w_R(t)$, where $w_R(t)$ is a rectangular window extending from $-\tau/2$ to $+\tau/2$, and $x(t)$ is a sinusoidal pulse. To understand the reasons for the features of $X(j\omega)$, the FT of $x(t)$, let us first consider $w_R(t)$. The FT of $w_R(t)$ is given by

$$W_R(j\omega) = \int_{-\tau/2}^{+\tau/2} e^{-j\omega t}dt = \frac{1}{-j\omega}(e^{-j\omega\tau/2} - e^{+j\omega\tau/2}) = \tau\frac{\sin(\omega\tau/2)}{\omega\tau/2}$$

which is a real function of ω, since $w_R(t)$ is an even function, and its magnitude is shown in Figure 7.12. The first zeros of $W_R(j\omega)$ occur at $\omega = \pm 2\pi/\tau$, and within this frequency range we have a feature called the main lobe of $W_R(j\omega)$. Outside this frequency range are the side lobes of $W_R(j\omega)$. We see that as

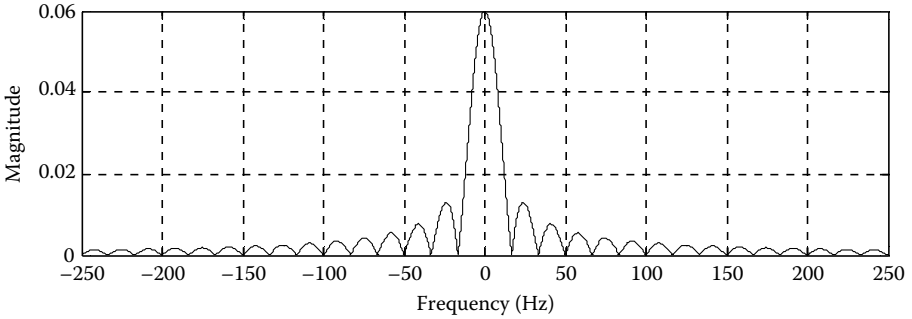

FIGURE 7.12 Spectral density magnitude, $\tau = 0.06$ s.

τ is increased, which makes $w_R(t)$ occur over a longer time range, the main lobe narrows and more energy of $w_R(t)$ is concentrated about $\omega = 0$ and within a smaller frequency range. Conversely, as τ is decreased, which makes $w_R(t)$ occur over a shorter time range, the main lobe broadens and the energy of $w_R(t)$ is spread out over a wider frequency range.

In $x(t)$, let $\omega_0 = 100\pi$ rad/s. The spectral density $X(j\omega)$ of $x(t)$ can be found with the modulation property, which translates $W_R(j\omega)$ up to $\omega = +\omega_0$ and down to $\omega = -\omega_0$. This is shown in Figure 7.13, where we see the main lobes positioned about $\omega = \pm\omega_0$.

In view of the properties given in Table 7.1, the FT is very well suited to investigate the spectral nature of a signal. It is also useful to study the frequency selective behavior of a linear and time invariant (LTI) continuous-time system. Let $h(t)$ denote the impulse response of an LTI system. If the system is initially at rest, then the response $y(t)$ to an input $x(t)$ is given by

$$y(t) = h(t)^* x(t) = \int_{-\infty}^{+\infty} h(t-\tau)x(\tau)\mathrm{d}\tau \tag{7.31}$$

and if the FT $H(j\omega)$ of the impulse response $h(t)$ exists, then by the convolution property we have

$$Y(j\omega) = H(j\omega)X(j\omega)$$

where $H(j\omega)$ is called the system transfer function. Therefore, with $H(j\omega)$ we can find how the system modifies the spectral density of the input to obtain the spectral density of the output. Furthermore, if the input is a sinusoid given by

$$x(t) = A\cos(\omega t + \phi)u(t)$$

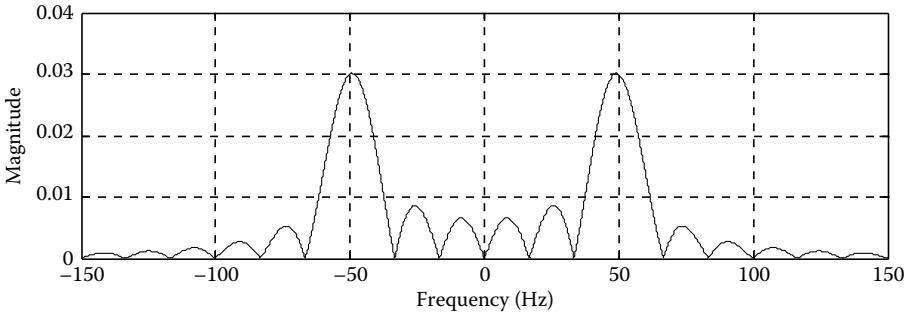

FIGURE 7.13 Spectral density of a sinusoidal pulse.

then the steady-state response of the system will be

$$y(t) = A\|H(j\omega)\| \cos(\omega t + \phi + \angle H(j\omega))$$

which shows the frequency-selective behavior of the system. We plot $||H(j\omega)||$ and $\angle H(j\omega)$ versus ω to see the frequency response of the system.

7.1.10 Discrete-Time Fourier Transform

As for continuous-time periodic signals, we want to study continuous-time aperiodic signals and continuous-time LTI systems by digital means. We start by sampling $x(t)$, the inverse FT of $X(j\omega)$, at the sampling rate $f_s = 1/T$ Hz, and Equation 7.30 becomes

$$x(nT) = \int_{-\infty}^{+\infty} X(j2\pi f) e^{j2\pi f nT} \mathrm{d}f$$

Breaking the frequency range into intervals of length f_s results in

$$x(nT) = \sum_{r=-\infty}^{+\infty} \int_{(2r-1)\frac{f_s}{2}}^{(2r+1)\frac{f_s}{2}} X(j2\pi f) e^{j2\pi f nT} \mathrm{d}f$$

Let us change the integration variable from f to $\lambda = f - rf_s$, and then we have

$$x(nT) = \sum_{r=-\infty}^{+\infty} \int_{-\frac{f_s}{2}}^{+\frac{f_s}{2}} X(j2\pi(\lambda + rf_s)) e^{j2\pi(\lambda + rf_s)nT} \mathrm{d}\lambda$$

Interchanging summation and integration and simplifying the exponential term results in

$$x(nT) = \int_{-\frac{f_s}{2}}^{+\frac{f_s}{2}} \sum_{r=-\infty}^{+\infty} X(j2\pi(\lambda + rf_s)) e^{j2\pi\lambda nT} \mathrm{d}\lambda$$

Reverting to f for the frequency variable gives

$$x(nT) = \int_{-\frac{f_s}{2}}^{+\frac{f_s}{2}} \sum_{r=-\infty}^{+\infty} X(j2\pi(f - rf_s)) e^{j2\pi f nT} \mathrm{d}f \tag{7.32}$$

Let $\hat{X}(j2\pi f)$ be determined with

$$\hat{X}(j2\pi f) = \sum_{r=-\infty}^{+\infty} X(j2\pi(f - rf_s)) \tag{7.33}$$

which is the periodic extension of $X(j2\pi f)$, and therefore $\hat{X}(j2\pi f)$ is a periodic function of frequency with period f_s. And, Equation 7.32 becomes

$$x(nT) = \int_{-\frac{f_s}{2}}^{+\frac{f_s}{2}} \hat{X}(j2\pi f) e^{j2\pi f nT} df \tag{7.34}$$

If we know $X(j2\pi f)$, the FT of the real-time function $x(t)$, then we can find $\hat{X}(j2\pi f)$ with Equation 7.33. It would be useful if we could obtain $\hat{X}(j2\pi f)$ directly from the samples $x(nT)$ of $x(t)$. Since $\hat{X}(j2\pi f)$ is a periodic function, having an even magnitude and odd phase, we can write it as a FS, which is

$$\hat{X}(j2\pi f) = \sum_{n=-\infty}^{+\infty} \hat{x}_n e^{-jn\frac{2\pi}{f_s}f} \tag{7.35}$$

where the $\hat{x}_n$ are the FS coefficients given by

$$\hat{x}_n = \frac{1}{f_s} \int_{-\frac{f_s}{2}}^{+\frac{f_s}{2}} \hat{X}(j2\pi f) e^{jn\frac{2\pi}{f_s}f} df \tag{7.36}$$

In view of Equation 7.34, we have $\hat{x}_n = Tx(nT)$. Based on Equation 7.35, let

$$X(e^{j\omega T}) = \sum_{n=-\infty}^{+\infty} x(nT) e^{-j\omega nT} \tag{7.37}$$

which is called the discrete-time Fourier transform (DTFT) of $x(nT)$. Then, $\hat{X}(j\omega) = TX(e^{j\omega T})$, and Equation 7.34 becomes

$$x(nT) = \frac{1}{\omega_s} \int_{-\frac{\omega_s}{2}}^{+\frac{\omega_s}{2}} X(e^{j\omega T}) e^{j\omega nT} d\omega \tag{7.38}$$

which is called the IDTFT. A sufficient condition for the existence of the DTFT is

$$\left\| X(e^{j\omega T}) \right\| = \left\| \sum_{n=-\infty}^{+\infty} x(nT) e^{-j\omega nT} \right\| \leq \sum_{n=-\infty}^{+\infty} \|x(nT)\| < \infty$$

which means that $x(nT)$ must be absolutely summable. We say that $x(nT)$ and $X(e^{j\omega T})$ are a DTFT pair, denoted by $x(nT) \leftrightarrow X(e^{j\omega T})$.

With Equation 7.33, we have

$$X(e^{j\omega T}) = \frac{1}{T} \sum_{r=-\infty}^{+\infty} X(j(\omega - r\omega_s)) \tag{7.39}$$

With Equation 7.39 we can find information about the spectral density of $x(t)$ from the DTFT of $x(nT)$.

7.1.11 DTFT Model

The DTFT is often defined based on the block diagram shown in Figure 7.14, where the impulse sampler is an impulse train $\delta_T(t)$ given by

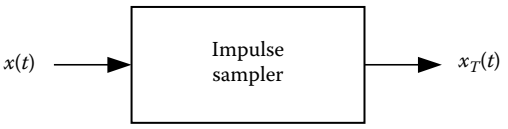

FIGURE 7.14 Model of the sampling process.

$$\delta_T(t) = \sum_{n=-\infty}^{+\infty} \delta(t - nT)$$

and $\delta(t)$ is the Dirac impulse function. The impulse sampler output is

$$x_T(t) = x(t)\delta_T(t) = \sum_{n=-\infty}^{+\infty} x(nT)\delta(t - nT) \tag{7.40}$$

and the FT of $x_T(t)$ gives Equation 7.37, which is the DTFT of $x(nT)$.

7.1.12 Sampling Theorem

Suppose a signal $x(t)$ is bandlimited. Then, there is some ω_c such that $X(j\omega) = 0$ for $|\omega| > \omega_c$. Let us use the spectral density shown in Figure 7.15 to illustrate what happens when we apply the DTFT.

If we sample $x(t)$, then according to Equation 7.39 the DTFT of $x(nT)$ is the periodic extension of $X(j\omega)$, as shown in Figure 7.16. Here, the sampling frequency is high enough to prevent translations of $X(j\omega)$ from overlapping, which means that the spectral density $X(j\omega)$ is contained entirely within the frequency range $(-\omega_s/2, +\omega_s/2)$ of the DTFT of $x(nT)$. Therefore, if

$$\omega_s > 2\omega_c \tag{7.41}$$

then $X(j\omega)$ can be recovered from one period of $X(e^{j\omega T})$ without error.

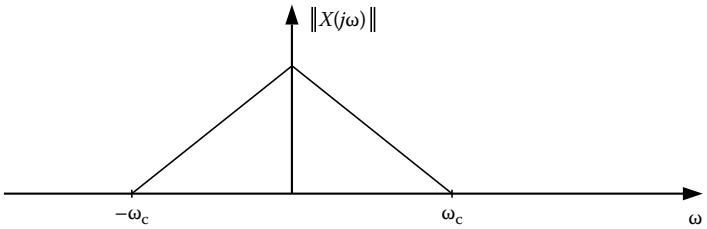

FIGURE 7.15 Spectral density magnitude of a bandlimited signal.

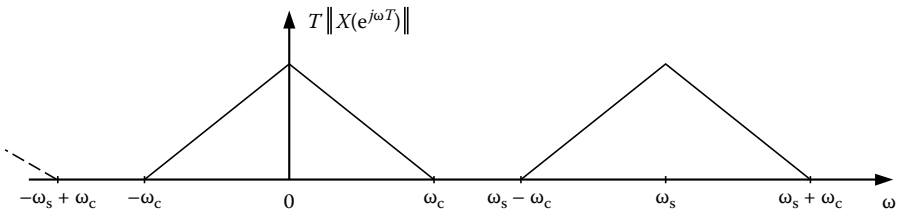

FIGURE 7.16 Magnitude of the DTFT.

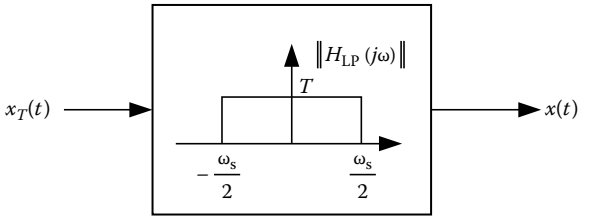

FIGURE 7.17 Ideal low-pass filter magnitude frequency response.

Since, for example, Figure 7.16 also shows the magnitude of the FT of $x_T(t)$, according to Equation 7.40, we can obtain the signal $x(t)$, which has the spectral density shown in Figure 7.15, if we process $x_T(t)$ with an analog low-pass filter as shown in Figure 7.17.

We will find $x(t)$ by convolving the input with the impulse response of the ideal low-pass filter. The impulse response $h_{LP}(t)$ is given by

$$h_{LP}(t) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} H_{LP}(j\omega)e^{j\omega t}d\omega = \frac{1}{2\pi}\int_{-\omega_s/2}^{+\omega_s/2} Te^{j\omega t}d\omega = \frac{\sin\left(\frac{\omega_s}{2}t\right)}{\frac{\omega_s}{2}t}$$

and then we get

$$x(t) = h_{LP}(t)^* x_T(t) = \sum_{n=-\infty}^{+\infty} x(nT)\frac{\sin\left(\frac{\omega_s}{2}(t-nT)\right)}{\frac{\omega_s}{2}(t-nT)} \tag{7.42}$$

which is called the data reconstruction formula, to obtain $x(t)$, for all t, from the samples $x(nT)$. Together, Equations 7.41 and 7.42 are called the time sampling theorem.

If the sampling frequency ω_s does not satisfy Equation 7.41, then the DTFT produces results like those shown in Figure 7.18. Here we see translations of $X(j\omega)$ overlap. In the frequency range $\omega_s - \omega_c$ to $\omega_s/2$, where $\omega_c > \omega_s/2$, the DTFT of $x(nT)$ is not the same as $X(j\omega)$. This difference is called aliasing error. If we reproduce an analog signal with Equation 7.42, then this analog signal will have energy in the frequency range $\omega_s - \omega_c$ to $\omega_s/2$ that is not the same as that of the given signal $x(t)$. In this situation, if the sampling frequency ω_s cannot be increased to avoid aliasing error, then the given signal should be processed by a low-pass filter, called an antialiasing filter, with bandwidth equal to $\omega_s/2$, which becomes the effective bandwidth of the signal that will be sampled. If the resulting samples are used to reconstruct an analog signal, then the resulting analog signal will not have the very high frequency spectral content of the given signal $x(t)$ in the frequency range $\omega_s/2$ to ω_c.

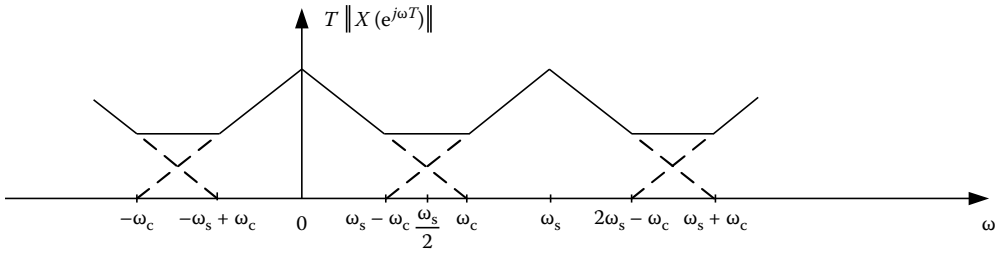

FIGURE 7.18 Magnitude of the DTFT, $\omega_s < 2\omega_c$.

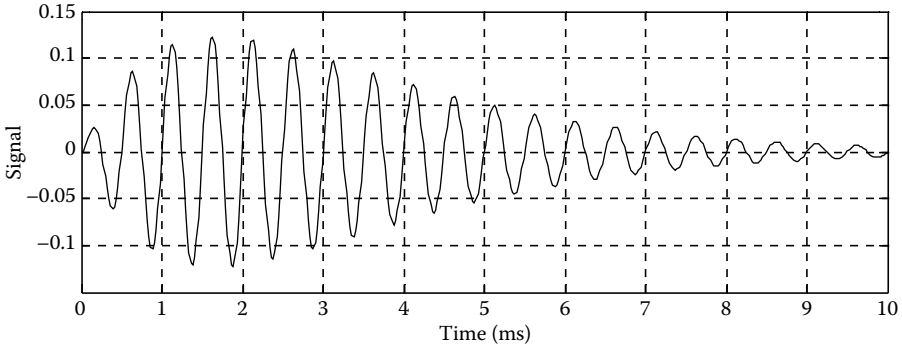

FIGURE 7.19 An exponentially weighted sinusoidal pulse.

If an analog signal $x(t)$ is not bandlimited, then aliasing error cannot be avoided. An antialiasing filter could be used at the cost of eliminating the high frequency sinusoidal components of the signal. Let us use the signal $x(t) = (e^{-at} - e^{-bt})\sin(2\pi f_0 t)u(t)$, where $a = 500$, $b = 700$, and $f_0 = 2000$ Hz, to illustrate what happens. This signal is shown in Figure 7.19. We see that $x(t)$ is a tone that gains strength and then loses strength. The FT of $e^{-at}u(t)$ is $1/(j\omega + a)$, and then the modulation property can be used to find the FT of $x(t)$.

The DTFT of $e^{-anT}u(n)e^{-j\omega_0 nT} = (e^{-aT}e^{-j\omega_0 T})^n u(n)$ is given by

$$\sum_{n=0}^{+\infty} e^{-(aT+j\omega_0 T)n}e^{-j\omega nT} = \lim_{N\to\infty}\sum_{n=0}^{N-1}(e^{-(a+j\omega_0+j\omega)T})^n = \lim_{N\to\infty}\frac{1-(e^{-(a+j\omega_0+j\omega)T})^N}{1-e^{-(a+j\omega_0+j\omega)T}}$$
$$= \frac{1}{1-e^{-aT}e^{-j(\omega+\omega_0)T}} \tag{7.43}$$

The magnitudes of $X(j\omega)$ and $X(e^{j\omega T})$ are shown in Figure 7.20, where they are shown normalized to show them on the same scale. Within the frequency range 0 to $f_s/2$ we see aliasing error that increases as the frequency increases toward $f_s/2$. If we increase the sampling frequency, then the aliasing error will decrease.

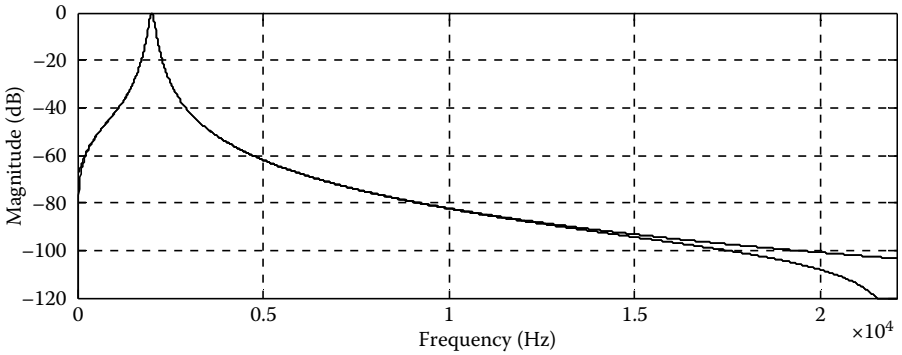

FIGURE 7.20 Magnitude of the FT and the DTFT, for $f_s = 44.1$ kHz.

Multiplication	$x_1(nT)x_2(nT) \leftrightarrow \frac{1}{2\pi}X_1(e^{j\omega T}) \otimes X_2(e^{j\omega T})$
Energy (Parseval's theorem)	$\sum_{n=-\infty}^{+\infty} \lvert x(nT)\rvert^2 = \frac{1}{2\pi}\int_0^{\omega_s} \lVert X(e^{j\omega T})\rVert^2 d\omega$

7.1.13 DTFT Properties

The DTFT has properties, most of which are analogous to properties of the FT. In Table 7.2 are given a few important properties of the DTFT.

7.1.14 Example and Discussion

For practical signals we only have a finite number of samples of $x(nT)$, say N samples, and therefore we must truncate the summation in Equation 7.37, and compute $X(e^{j\omega T})$ by digital means. This means that we can find the DTFT for only a finite number of frequencies. Let us evaluate the truncated DTFT at the frequencies given by

$$\omega = k\frac{\omega_s}{N}, \quad k = 0, 1, \ldots, N-1$$

and then the DTFT becomes

$$X(e^{j\omega T})\big|_{\omega=k\frac{\omega_s}{N}} = \sum_{n=0}^{N-1} x(nT)e^{-jk\frac{\omega_s}{N}nT} = \sum_{n=0}^{N-1} x(nT)e^{-j\frac{2\pi}{N}kn} = X(k) \tag{7.44}$$

which is the DFT of $x(nT)$, $n=0, 1, \ldots, N-1$.

Let us window the signal shown in Figure 7.19. Regardless of how wide the window is, the windowed signal $x_p(t)$ is one period of a periodic signal to which we are applying the DFT. Therefore, we should consider using a window such as $w_H(t)$ over the time range $0 \le t < T_0$. From Figure 7.19 we see that using $T_0 = 5.0$ ms does not incur discontinuities at period boundaries of the periodic extension of $x_p(t)$. Let us obtain $N = 226$ samples of $x(t)$ at the same rate $f_s = 44.1$ kHz. Then the duration of $x_p(t)$ becomes $T_0 = 5.1247$ ms. Figure 7.21 shows the magnitude of the FT of $x(t)$ and its approximation that was found with the DFT. While the DFT produces a peak near f_0, there is aliasing error above and below this frequency. This can be improved if $N(T_0)$ is increased.

7.1.15 Linear and Time Invariant Discrete-Time Systems

The discrete-time system (DTS) that we shall study is described by the block diagram shown in Figure 7.22, where $x(n)$ is the input to the system and $y(n)$ is the response or output of the system. We assume that the output and input are related by the difference equation given by

$$y(n)+a_1y(n-1)+\cdots+a_Ny(n-N)=b_0x(n)+b_1x(n-1)+\cdots+b_Mx(n-M) \tag{7.45}$$

where the a_i, $i=1,\ldots,N$ and b_i, $i=0,1,\ldots,M$ are real constants.

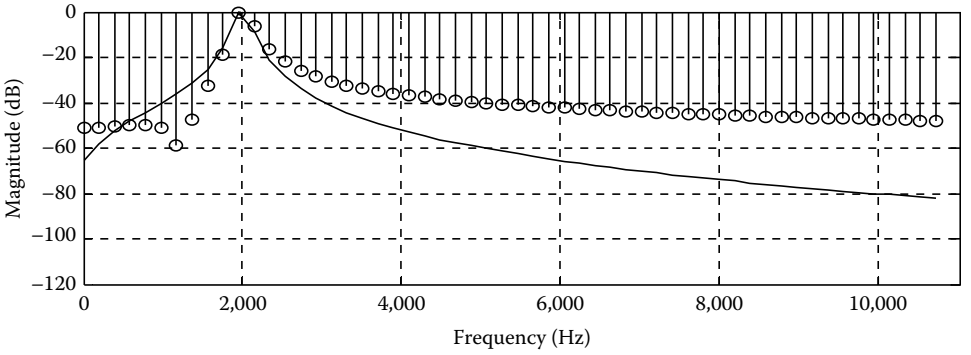

FIGURE 7.21 DFT approximation of the FT of $x(t)$.

To operate the DTS, reorganize Equation 7.45 to express the present output in terms of past outputs and present and past inputs, and we get

$$y(n) = \sum_{i=0}^{M} b_i x(n-i) - \sum_{i=1}^{N} a_i y(n-i) \qquad (7.46)$$

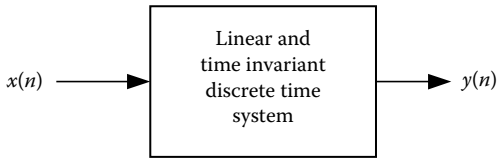

FIGURE 7.22 Block diagram of a DTS.

Suppose an input is applied starting at some time, say $n=0$. Then, to compute $y(n=0)$ given the first input $x(n=0)$, we must know

$$y(-1), y(-2), \ldots, y(-N)$$

which are the outputs prior to applying the input. These outputs are called the initial conditions of the DTS. Having computed $y(0)$, we can then compute $y(n=1)$, once we receive $x(n=1)$, and this can be continued for as long as we want to operate the DTS.

If in Equation 7.45 the right-hand side includes terms such as $b_{-1}x(n+1), b_{-2}x(n+2), \ldots$, then to compute a present output $y(n)$, knowledge of future inputs is required, and DTS cannot be operated in real time. Such a system is said to be noncausal. A system is said to be causal if a present output does not depend on a future value of the input. To operate a system in real time, it must be a causal system. However, when an entire history of an input is known, then at any time within this history, future values of the input are known, and a noncausal system can be operated. Both a causal and a noncausal system can be operated this way, which is referred to as off-line processing.

The DTS described by Equation 7.45 is a LTI system. Suppose all initial conditions are zero; we say the system is initially at rest. Let $y(n)=y_1(n)$ denote the response when the input is $x(n)=x_1(n)$, and similarly for $y_2(n)$ and $x_2(n)$. Then the DTS is a linear system if when the input is $x(n)=c_1x_1(n)+c_2x_2(n)$, then the response is given by $y(n)=c_1y_1(n)+c_2y_2(n)$ for any constants c_1 and c_2. The DTS is a time invariant system if when $y(n)=y_1(n)$ is the reponse to $x(n)=x_1(n)$, then $y(n)=y_2(n)=y_1(n-i)$ is the response to $x(n)=x_2(n)=x_1(n-i)$, for any time shift i.

A very useful function to know about an LTI DTS is its unit pulse response. This is the solution of Equation 7.45, which is denoted by $h(n)$, when $x(n)=\delta(n)$ and all initial conditions are zero. If the system is causal, then for $n<0$, we must have $h(n)=0$. To find $h(n)$, we first solve the simpler problem given by

$$v(n) + a_1 v(n-1) + \cdots + a_N v(n-N) = x(n) \qquad (7.47)$$

where initial conditions are zero and $x(n) = \delta(n)$. Therefore, we already have $v(0) = 1$. If we can determine the solution $v(n)$ of Equation 7.47, then, since the DTS is LTI and in view of the right-hand side of Equation 7.45, $h(n)$ is given by

$$h(n) = b_0 v(n) + b_1 v(n-1) + \cdots + b_M v(n-M) \tag{7.48}$$

For $n > 0$, Equation 7.47 becomes

$$v(n) + a_1 v(n-1) + \cdots + a_N v(n-N) = 0 \tag{7.49}$$

which is a homogeneous equation. Therefore, we can instead solve Equation 7.49 for initial conditions given by $v(0) = 1$, $v(-1) = 0, \ldots, v(N-1) = 0$. We want to find a function that can satisfy Equation 7.49. Let us try $v(n) = K\gamma^n$, for some nonzero constants K and γ. Substituting this $v(n)$ into Equation 7.49 gives

$$K\gamma^n + a_1 K\gamma^{n-1} + a_2 K\gamma^{n-2} + \cdots + a_N K\gamma^{n-N} = 0$$

and after multiplying by K^{-1} and γ^{-n} we get

$$Q(\gamma^{-1}) = 1 + a_1\gamma^{-1} + a_2\gamma^{-2} + \cdots + a_{N-1}\gamma^{-(N-1)} + a_N\gamma^{-N} = 0 \tag{7.50}$$

which is called the characteristic equation of the DTS, and $Q(\gamma^{-1})$ is called the characteristic polynomial. The characteristic equation has N roots, γ_i, $i = 1, 2, \ldots, N$, which can be real or complex, and Equation 7.50 can be factored to become

$$Q(\gamma^{-1}) = \prod_{i=1}^{N} (1 - \gamma_i\gamma^{-1}) = 0$$

Notice that these roots are not determined by the input. They are a characteristic of the system. Let us assume that they are distinct. Since each function γ_i^n can satisfy Equation 7.49, the solution is a linear combination of these exponential functions, and we have

$$v(n) = \sum_{i=1}^{N} K_i\gamma_i^n$$

The N constants K_i can be found by setting up N equations in N unknowns by applying the initial conditions of Equation 7.49. With $v(n)$ and Equation 7.48 we can then obtain the unit pulse response $h(n)$.

It is important to note that the unit pulse response is a linear combination of exponential functions with behavior that is determined by the roots of the characteristic equation. These roots can be real or they can occur in complex conjugate pairs. For example, if a root γ is real, then $h(n)$ will contain the term $K\gamma^n$ that may decrease exponentially to zero if $||\gamma|| < 1$, remain at unity if $\gamma = 1$, or increase exponentially if $||\gamma|| > 1$. Or, if a complex conjugate pair of roots occurs, then $h(n)$ will contain the sum of terms $K\gamma^n + K^*(\gamma^*)^n = 2||K||\ ||\gamma||^n \cos(n\angle\gamma + \angle K)$ that will oscillate and increase or decrease exponentially. If we require that $\lim_{n\to\infty} h(n) = 0$, then all roots of the characteristic equation must satisfy $||\gamma_i|| < 1$, $i = 1, 2, \ldots, N$.

A DTS can be categorized into two very different classes. Suppose that in Equation 7.45, $a_i = 0$ and $i = 1, 2, \ldots, N$. Then, Equation 7.46 becomes

$$y(n) = \sum_{i=0}^{M} b_i x(n-i) \tag{7.51}$$

and the present output depends on present and past inputs. If the input has a finite duration, then the response will have a finite duration. In fact, if $x(n) = \delta(n)$, then the unit pulse response is given by

$$h(n) = \sum_{i=0}^{M} b_i \delta(n-i)$$

which has a finite duration. Therefore, the DTS described by Equation 7.51 is called an FIR (finite impulse response) system, because the unit pulse response has a finite duration. However, if at least one a_i in Equation 7.45 is not zero, then in Equation 7.46 the present output will depend on the past outputs, which means there is feedback in the system. In this case the response to $x(n) = \delta(n)$ can never become and remain zero indefinitely. Such a DTS is called an IIR (infinite impulse response) system, because the response to a finite duration input will have an infinite duration.

7.1.16 Convolution

We can find the response of LTI DTS initially at rest to any input by writing the input as in Equation 7.8. Since the DTS is LTI, the response to $x(i)\delta(n-i)$ is $x(i)h(n-i)$, and the response to $x(n)$ is given by

$$y(n) = \sum_{i=-\infty}^{+\infty} h(n-i)x(i) = h(n)^* x(n) = \sum_{i=-\infty}^{+\infty} h(i)x(n-i) \tag{7.52}$$

which is called the linear convolution operation. Since the DTS is time invariant, the response to $x(n-n_0)$ is

$$y(n-n_0) = h(n)^* x(n-n_0)$$

7.1.17 Stability

A DTS is said to be bounded-input-bounded-output (BIBO) stable if for a bounded input the output is bounded. If the input is bounded, then for some real and positive number $x_{\max}$, we have $||x(n)|| \leq x_{\max}$ for all n. For a bounded output, Equation 7.52 becomes

$$\|y(n)\| = \left\| \sum_{i=-\infty}^{+\infty} h(i)x(n-i) \right\| \leq \sum_{i=-\infty}^{+\infty} \|h(i)x(n-i)\| \leq \sum_{i=-\infty}^{+\infty} \|h(i)\| x_{\max} = x_{\max} \sum_{i=-\infty}^{+\infty} \|h(i)\| < \infty$$

A sufficient condition for BIBO stability of an LTI DTS is that the unit pulse response must be absolutely summable.

Recall that the nature of the unit pulse response is determined by the roots of the characteristic equation (Equation 7.50). If all roots satisfy the condition $||\gamma_i|| < 1$, then we can show that $h(n)$ is absolutely summable. Moreover, we then have $\lim_{n\to\infty} h(n) = 0$. This means that if we apply a finite duration input to an initially at rest system, then eventually, the system will approach the rest state. An important distinction between FIR and IIR systems is that an FIR system is unconditionally stable, while an IIR system can be stable or unstable, depending on the roots of the characteristic equation.

7.1.18 Frequency Response

A major concern is the steady-state response of the DTS described by Equation 7.46 when the input is a sinusoid given by

$$x(n) = A\cos(\omega nT + \phi)$$

If the DTS is stable, then, in steady state, the response will be a sinusoid. It will be easier to determine the steady-state response if we work with an input $v(n)$ defined by

$$v(n) = e^{j\omega nT}$$

and let $w(n)$ denote the response to $v(n)$. Since

$$x(n) = \frac{A}{2}e^{j\phi}v(n) + \frac{A}{2}e^{-j\phi}v^{*}(n)$$

and since the DTS is a linear system, then the response $y(n)$ to $x(n)$ must be

$$y(n) = \frac{A}{2}e^{j\phi}w(n) + \frac{A}{2}e^{-j\phi}w^{*}(n)$$

With Equation 7.52, $w(n)$ is given by

$$\begin{aligned} w(n) &= \sum_{i=-\infty}^{+\infty} h(i)v(n-i) = \sum_{i=-\infty}^{+\infty} h(i)e^{j\omega(n-i)T} = e^{j\omega nT}\sum_{i=-\infty}^{+\infty} h(i)e^{-j\omega iT} \\ &= H(e^{j\omega T})e^{j\omega nT} \end{aligned}$$

where $H(e^{j\omega T})$ is the DTFT of the unit pulse response $h(n)$, and therefore $y(n)$ becomes

$$y(n) = \frac{A}{2}e^{j\phi}H(e^{j\omega T})e^{j\omega nT} + \frac{A}{2}e^{-j\phi}H^{*}(e^{j\omega T})e^{-j\omega nT}$$

Expressing $H(e^{j\omega T})$ in polar form, then with Euler's identity we get

$$y(n) = A\left|H(e^{j\omega T})\right|\cos\left(\omega nT + \phi + \angle H(e^{j\omega T})\right) \tag{7.53}$$

Let us consider another approach to find $y(n)$. First, let us substitute $v(n)$ into Equation 7.45 to get

$$\begin{aligned} w(n) + a_1 w(n-1) + \cdots + a_N w(n-N) &= b_0 e^{j\omega nT} + b_1 e^{j\omega(n-1)T} + \cdots + b_M e^{j\omega(n-M)T} \\ &= (b_0 + b_1 e^{-j\omega T} + \cdots + b_M e^{-j\omega MT})e^{j\omega nT} \end{aligned}$$

Since the right-hand side of this equation is an exponential function, then the left-hand side must also be an exponential function. Let us try $w(n) = We^{j\omega nT}$, for some unknown constant W, and then we get

$$W(1 + a_1 e^{-j\omega T} + \cdots + a_N e^{-j\omega NT})e^{j\omega nT} = (b_0 + b_1 e^{-j\omega T} + \cdots + b_M e^{-j\omega MT})e^{j\omega nT}$$

Therefore, we can solve for W, and $w(n)$ is

$$w(n) = \frac{(b_0 + b_1 e^{-j\omega T} + \cdots + b_M e^{-j\omega MT})}{(1 + a_1 e^{-j\omega T} + \cdots + a_N e^{-j\omega NT})}e^{j\omega nT}$$

Then, $H(e^{j\omega T})$ is given by

$$H(e^{j\omega T}) = \frac{(b_0 + b_1 e^{-j\omega T} + \cdots + b_M e^{-j\omega MT})}{(1 + a_1 e^{-j\omega T} + \cdots + a_N e^{-j\omega NT})} \tag{7.54}$$

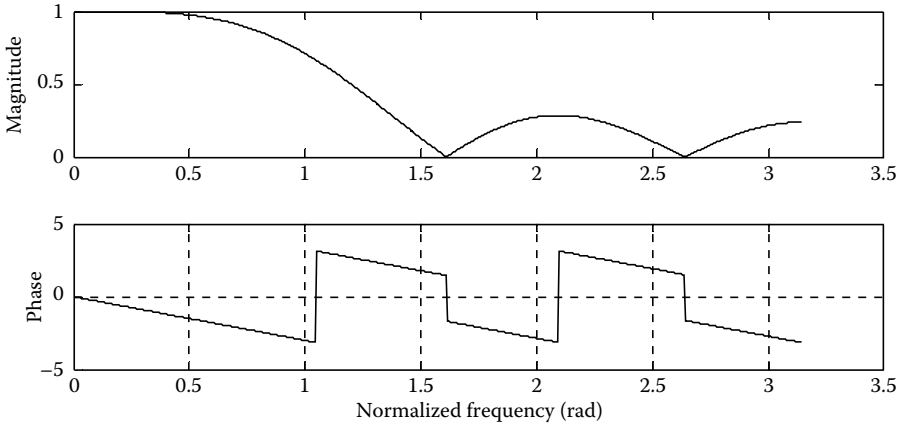

FIGURE 7.23 Magnitude and phase frequency response of an FIR filter.

which we can find by inspection of the given difference equation. In view of Equation 7.53 we have that $H(e^{j\omega T})$ gives the frequency response of the DTS. Notice that $H^*(e^{j\omega T}) = H(e^{-j\omega T})$, and therefore $||H(e^{j\omega T})||$ is an even periodic function of ω and $\angle H(e^{j\omega T})$ is an odd periodic function of ω.

7.1.19 Examples and Discussion

With Equation 7.54 we can assess the frequency selective behavior of an LTI DTS. Consider the FIR DTS given by

$$y(n) = 1/21[-2x(n) + 3x(n-1) + 6x(n-2) + 7x(n-3) + 6x(n-4) + 3x(n-5) - 2x(n-6)]$$

The frequency response is

$$H(\mathrm{e}^{j\omega T}) = 1/21[-2 + 3\mathrm{e}^{-j\omega T} + 6\mathrm{e}^{-j2\omega T} + 7\mathrm{e}^{-j3\omega T} + 6\mathrm{e}^{-j4\omega T} + 3\mathrm{e}^{-j5\omega T} - 2\mathrm{e}^{-j6\omega T}]$$

To see the frequency selective behavior of this DTS we could plot the magnitude of the frequency response for $0 \leq \omega \leq \omega_s/2$. Instead, let us plot the magnitude versus $\theta = \omega T$, where $0 \leq \theta \leq \pi$. Figure 7.23 shows the magnitude and phase frequency response, and we see that this DTS is a low-pass filter. Furthermore, this FIR filter has a phaseshift characteristic that varies linearly with frequency. The step changes in phase are due to wraparound when the phase changes from, for example, $-\pi$ to $+\pi$.

As a comparison, let us assess the frequency selective behavior of the IIR LTI DTS described by

$$y(n) = 0.09780\ x(n) + 0.19560\ x(n-1) + 0.09780\ x(n-2) + 0.94175\ y(n-1) - 0.33296\ y(n-2)$$

with $H(\mathrm{e}^{j\omega T})$ given by

$$H(\mathrm{e}^{j\omega T}) = \frac{0.09780 + 0.19560\mathrm{e}^{-j\omega T} + 0.09780\mathrm{e}^{-j2\omega T}}{1 - 0.94175\mathrm{e}^{-j\omega T} + 0.33296\mathrm{e}^{-j2\omega T}}$$

Figure 7.24 shows magnitude and phase frequency response of this IIR DTS. This is a low-pass filter, and the transition from the passband to the stopband is not very sharp. The phaseshift does not vary linearly with frequency.

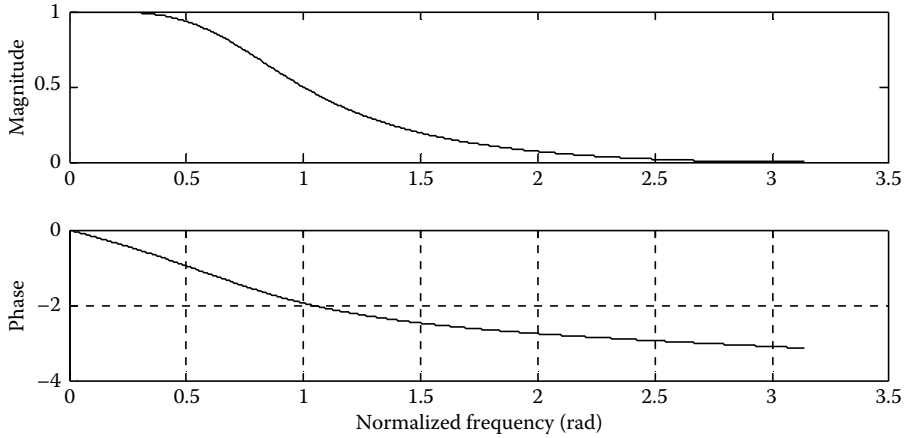

FIGURE 7.24 Magnitude and phase frequency response of an IIR filter.

These two filters have similar performance. Each has advantages and disadvantages compared to the other filter. For example, the FIR filter is unconditionally stable and it has a linear phase characteristic, and the IIR filter has a sharper magnitude frequency response with less computation than required by the FIR filter.

7.1.20 Ideal Digital Filters

We can design the coefficients of the digital filter described by Equation 7.45 to achieve filter performance that comes arbitrarily close to an ideal filter performance. Figure 7.25 shows the ideal performance of several standard filter types. The frequency response for each filter is specified over the frequency range, $-\omega_s/2 \leq \omega \leq \omega_s/2$, which is the frequency range of the filter input. Then, this frequency response is extended periodically to integer multiples of ω_s.

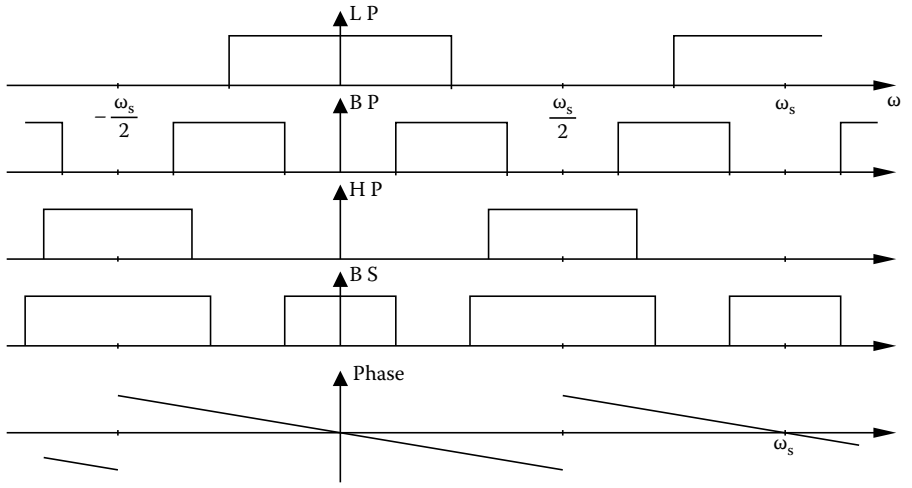

FIGURE 7.25 Ideal frequency response of a low-pass (LP), band-pass (BP), high-pass (HP), and band-stop (BS) digital filter.

To justify an ideal linear phase characteristic, let us consider an input $x(t) = A_1 \cos(\omega_1 t + \phi_1) + A_2 \cos(\omega_2 t + \phi_2)$ of an analog filter, where ω_1 and ω_2 are within the passband of the analog filter. To preserve the input wave shape, the output $y(t)$ can be a delayed version of the input. Now we have

$$\begin{aligned} y(t) = x(t - t_0) &= A_1 \cos(\omega_1(t - t_0) + \phi_1) + A_2 \cos(\omega_2(t - t_0) + \phi_2) \\ &= A_1 \cos(\omega_1 t + \phi_1 - t_0\omega_1) + A_2 \cos(\omega_2 t + \phi_2 - t_0\omega_2) \end{aligned}$$

and to preserve the input wave shape, the input to output phase change must be proportional to frequency.

7.1.21 *z*-Transform

While the DTFT is useful for spectral analysis, its wider application to system analysis is limited, because, for example, not even the DTFT of a discrete-time sinusoidal signal exists. Given a discrete-time signal $x(nT)$, let us consider instead the DTFT given by

$$Y(\sigma, e^{j\omega T}) = \text{DTFT}\{e^{-\sigma nT} x(nT)\} = \sum_{n=-\infty}^{+\infty} e^{-\sigma nT} x(nT) e^{-j\omega nT} \tag{7.55}$$

for some real number σ. Assuming that $Y(\sigma, e^{j\omega T})$ exists, taking its IDTFT gives

$$e^{-\sigma nT} x(nT) = \frac{1}{\omega_s} \int_{-\frac{\omega_s}{2}}^{+\frac{\omega_s}{2}} Y(\sigma, e^{j\omega T}) e^{j\omega nT} d\omega$$

and after multiplying both sides of this equation by $e^{\sigma nT}$ we get

$$x(nT) = \frac{1}{\omega_s} \int_{-\frac{\omega_s}{2}}^{+\frac{\omega_s}{2}} e^{\sigma nT} Y(\sigma, e^{j\omega T}) e^{j\omega nT} d\omega \tag{7.56}$$

For convenience, let

$$z = e^{\sigma T} e^{j\omega T} = e^{(\sigma + j\omega)T} = \|z\| e^{j\angle z} \tag{7.57}$$

and let $X(z)$ denote $Y(\sigma, e^{j\omega T})$, and therefore, Equation 7.55 becomes

$$X(z) = \sum_{n=-\infty}^{+\infty} x(n) z^{-n} \tag{7.58}$$

which is called the bilateral z-transform (BZT) of $x(n)$. We write $X(z) = Z\{x(n)\}$. In Equation 7.56, let us change the integration variable from the real variable ω to the complex variable z. When $\omega = -\omega_s/2$, $z = e^{\sigma T} e^{-j\pi}$, and when $\omega = +\omega_s/2$, $z = e^{\sigma T} e^{j\pi}$, and therefore z follows a circle of radius $||z|| = e^{\sigma T}$. We also have

$$\frac{dz}{d\omega} = jT e^{\sigma T} e^{j\omega T} = jTz$$

and therefore Equation 7.56 becomes

$$x(nT) = \frac{1}{\omega_s} \oint X(z) z^n \frac{dz}{jTz} = \frac{1}{j2\pi} \oint X(z) z^{n-1} dz \tag{7.59}$$

which is called the inverse z-transform, denoted by $x(n) = Z^{-1}\{X(z)\}$. Notice that the integration path is a circle with a radius determined by σ.

7.1.22 Bilateral z-Transform Properties

The BZT has many useful properties. For our development we will use the properties given in Table 7.3.

7.1.23 z-Plane

To see the utility of introducing the factor $e^{-\sigma nT}$ in Equation 7.55, let us obtain the BZT of $x(n) = \gamma^n u(n)$ for any real or complex number γ. With Equation 7.58 we have

$$X(z) = \sum_{n=-\infty}^{+\infty} \gamma^n u(n) z^{-n} = \sum_{n=0}^{+\infty} \left(\frac{\gamma}{z}\right)^n = \lim_{N\to\infty} \sum_{n=0}^{N-1} \left(\frac{\gamma}{z}\right)^n = \lim_{N\to\infty} \frac{1 - \left(\frac{\gamma}{z}\right)^N}{1 - \left(\frac{\gamma}{z}\right)} = \frac{1}{1 - \gamma z^{-1}}, \quad \left\|\frac{\gamma}{z}\right\| < 1$$

If $||\gamma|| > 1$, then $x(n)$ increases exponentially, and it does not have a DTFT. However, $x(n)$ does have a BZT, because we restrict z with σ to satisfy the convergence condition, $||z|| = e^{\sigma T} > ||\gamma||$, which requires $\sigma > \frac{1}{T} \ln\|\gamma\|$. If σ satisfies this condition, then the product $e^{-n\sigma T}\ \gamma^n$ decreases exponentially. The function $e^{-n\sigma T}$ is called the convergence factor.

We say that $x(n)$ and $X(z)$ are a BZT pair, denoted by

$$\gamma^n u(n) \leftrightarrow 1/(1 - \gamma z^{-1}), \quad \|z\| > \|\gamma\| \tag{7.60}$$

This transform pair includes signals such as

$$x(n) = u(n), \quad \gamma = 1$$
$$x(n) = \cos(\theta n) u(n) = \frac{1}{2} e^{j\theta n} u(n) + \frac{1}{2} e^{-j\theta n} u(n), \quad \gamma = e^{j\theta} \quad \text{and} \quad \gamma = e^{-j\theta}$$

and many other signals by applying BZT properties. For example, notice that Equation 7.60 can be obtained with $Z\{u(n)\}$ and the modulation property.

If $||\gamma|| < 1$, then $x(n)$ decreases exponentially, and it has a DTFT. It also has the BZT given in Equation 7.60. With $||\gamma|| < 1$, the condition $\sigma > \frac{1}{T} \ln\|\gamma\|$ allows σ to be negative, and with a negative σ the convergence factor increases exponentially, while the product $e^{-n\sigma T}\gamma^n$ still decreases exponentially. We can even set σ to $\sigma = 0$, which with Equation 7.57 converts the BZT to the DTFT.

TABLE 7.3 BZT Properties

Linearity	$c_1 x_1(n) + c_2 x_2(n) \leftrightarrow c_1 X_1(z) + c_2 X_2(z)$
Time shift	$x(n - n_0) \leftrightarrow X(z) z^{-n_0}$
Modulation	$x(n)\alpha^n \leftrightarrow X(z\alpha^{-1})$
Linear convolution	$x_1(n) * x_2(n) = \sum_{i=-\infty}^{+\infty} x_1(n-i) x_2(i) \leftrightarrow X_1(z) X_2(z)$

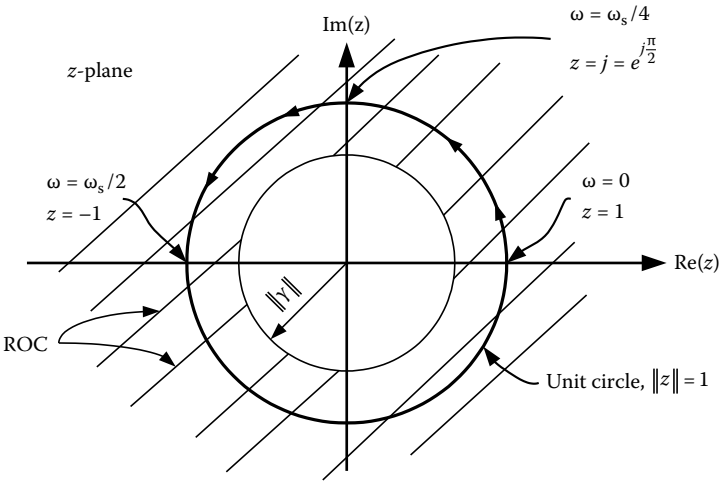

FIGURE 7.26 The z-plane, showing the unit circle and an ROC.

These different situations can be nicely pulled together by describing them with respect to the unit circle in the z-plane, as shown in Figure 7.26. The convergence condition, $||z|| > ||\gamma||$, does not impose any restriction on the angle of z. Therefore, the BZT of $x(n) = \gamma^n u(n)$ converges for all z outside a circle in the z-plane having a radius equal to $||\gamma||$, and this region of the z-plane is called the region of convergence (ROC). If $||\gamma|| < 1$, which means that $x(n)$ has a DTFT, then the ROC is outside a circle that is inside the unit circle in the z-plane (see Figure 7.26). However, if $||\gamma|| > 1$, which means that the DTFT of $x(n)$ does not exist, then the ROC is outside a circle that is outside the unit circle. This means that if the ROC of the BZT includes the unit circle, then $X(z)$ can be evaluated for $z = e^{j\omega T}$ ($||z|| = 1$), and a BZT can be converted to a DTFT by setting z to $z = e^{j\omega T}$.

The ROC is an important information about the BZT of a signal, because there can be an ambiguity between $X(z)$ and its inverse z-transform. To see why this is true, let us find the BZT of $x(n) = -\gamma^n u(-n-1)$, which is zero for $n \geq 0$. Applying Equation 7.58 gives

$$X(z) = \sum_{n=-\infty}^{+\infty} -\gamma^n u(-n-1) z^{-n} = -\sum_{n=-\infty}^{-1} \gamma^n z^{-n} = -\sum_{n=1}^{+\infty} (\gamma^{-1} z)^n = -\sum_{n=0}^{+\infty} (\gamma^{-1} z)^n + 1$$
$$= 1 - \frac{1}{1-\gamma^{-1} z} = \frac{1}{1-\gamma z^{-1}}, \left\|\gamma^{-1} z\right\| < 1 \rightarrow \|z\| < \|\gamma\| \tag{7.61}$$

Here the ROC is the interior of a circle in the z-plane. If $||\gamma|| > 1$, then the ROC includes the unit circle and $x(n)$ decreases exponentially as $n \rightarrow -\infty$, which means that the DTFT of $x(n)$ exists. However, if $||\gamma|| < 1$, then the ROC does not include the unit circle and $x(n)$ increases exponentially as $n \rightarrow -\infty$, which means that the DTFT of $x(n)$ does not exist.

If the BZT of Equation 7.60 or 7.61 is given, we cannot know the inverse z-transform unless we also know the convergence condition. In Equation 7.60, $x(n)$ is said to be a right-handed signal, and its ROC is a region in the z-plane outside a circle, and in Equation 7.61, $x(n)$ is said to be a left-handed signal, and its ROC is a region in the z-plane inside a circle. Consider how the ROC must change if we time reverse a signal. For either kind of signal, right-handed or left-handed, if the ROC includes the unit circle, then it has a DTFT. We will work with right-handed signals unless explicitly stated otherwise, in which case the ROC is the type given in Equation 7.60 and illustrated in Figure 7.26.

7.1.24 Transfer Function

Given an input $x(n)$ of an LTI DTS, the convolution Equation 7.52 of the input with the unit pulse response $h(n)$ gives the response of the DTS under zero initial conditions. Applying the convolution property in Table 7.3 to Equation 7.52 gives

$$Y(z) = H(z)X(z) \tag{7.62}$$

where $H(z) = Z\{h(n)\}$, which is called the transfer function of the system. We assume that the DTS is causal, and therefore $h(n)$ is a right-handed signal. If $x(n) = \delta(n)$, then $X(z) = 1$, and, as expected, $y(n) = h(n)$.

Let us apply the linearity and time-shift properties of the BZT, and take the BZT term-by-term of Equation 7.45 to get

$$Y(z) + a_1 Y(z)z^{-1} + \cdots + a_N Y(z)z^{-N} = b_0 X(z) + b_1 X(z)z^{-1} + \cdots + b_M X(z)z^{-M}$$

Having converted the difference equation to an algebraic equation permits us to find

$$Y(z) = \frac{b_0 + b_1 z^{-1} + \cdots + b_M z^{-M}}{1 + a_1 z^{-1} + \cdots + a_N z^{-N}} X(z) \tag{7.63}$$

and therefore, $H(z)$ in Equation 7.62 is given by

$$H(z) = \frac{b_0 + b_1 z^{-1} + \cdots + b_M z^{-M}}{1 + a_1 z^{-1} + \cdots + a_N z^{-N}} = \frac{P(z^{-1})}{Q(z^{-1})} = \frac{b_0 \prod_{i=1}^{M} (1 - z_i z^{-1})}{\prod_{i=1}^{N} (1 - p_i z^{-1})} \tag{7.64}$$

The z_i, $i = 1, \ldots, M$ are called the zeros of $H(z)$, and the p_i, $i = 1, \ldots, N$ are called the poles of $H(z)$.

Comparing Equations 7.64 and 7.50, we see that the denominator of $H(z)$ is the characteristic polynomial, and therefore the poles of $H(z)$ are the roots of the characteristic equation, which determine the behavior of the unit pulse response. Therefore, $h(n)$ is a linear combination of the exponential functions, p_i^n, $i = 1, 2, \ldots, N$. This means that the DTS is stable if all the poles of $H(z)$ are inside the unit circle in the z-plane. Furthermore, the ROC of $H(z) = Z\{h(n)\}$ is outside a circle with a radius equal to the magnitude of the pole having the largest magnitude among all the poles of $H(z)$. Therefore, if the DTS is stable, $H(z)$ can be converted to the DTFT with $z = e^{j\omega T}$.

Comparing Equations 7.64 and 7.54, we see that the frequency response of the DTS can be found by evaluating $H(z)$ on the unit circle, where $z = e^{j\omega T}$. This is depicted in Figure 7.26, where for $\omega = 0$, $z = 1$. As ω is increased from $\omega = 0$ to $\omega = \omega_s/2$, the angle of z, $\angle z = \omega T$, changes from $\angle z = 0$, where $z = 1$, to $\angle z = \pi$, where $z = -1$.

7.1.25 Unilateral z-Transform

Consider a signal $x(n)$, which is defined over $-\infty < n < +\infty$. Generally, $x(n)$ is not a right-handed or a left-handed signal. Let us express $x(n)$ as

$$x(n) = x_l(n) + x_r(n) = x(n)u(-(n+1)) + x(n)u(n)$$

where $x_l(n) = 0$, $n \geq 0$ and $x_r(n) = 0$, $n < 0$, so as to have $x_l(n)$ account for the left-handed part of $x(n)$, while $x_r(n)$ accounts for the right-handed part of $x(n)$. The BZT of $x(n)$ is

$$X(z) = \sum_{n=-\infty}^{-1} x(n)z^{-n} + \sum_{n=0}^{+\infty} x(n)z^{-n} = Z\{x_l(n)\} + Z\{x_r(n)\} = X_l(z) + X_r(z) \tag{7.65}$$

Suppose we are only interested to observe a signal $x(n)$ for $n \geq 0$, even if it is not strictly a right-handed signal. Then, with

$$Z^{-1}\{X(z)\} = x(n)$$

we can find $x(n)$ for $n \geq 0$, and we also get $x(n)$ for $n < 0$. However, we can also find $x(n)$ for $n \geq 0$ with

$$Z^{-1}\{X_r(z)\} = x_r(n)$$

Therefore, we will now only work with

$$X(z) = \sum_{n=0}^{+\infty} x(n)z^{-n} \tag{7.66}$$

which is called the unilateral z-transform, or just z-transform (ZT). This does not imply that $x(n)$ for $n < 0$ must be zero. Instead, we prefer to avoid involving $X_l(z)$.

The bilateral and unilateral z-transforms have many properties in common, while for some properties the difference is very useful. Consider the ZT of $y(n) = x(n-1)$. Notice that $y(0) = x(-1)$, and therefore

$$Z\{y(n) = x(n-1)\} = \sum_{n=0}^{+\infty} y(n)z^{-n} = \sum_{n=0}^{+\infty} x(n-1)z^{-n} = x(-1) + z^{-1}\sum_{n=0}^{+\infty} x(n)z^{-n}$$

Generally, we have

$$Z\{x(n-i)\} = x(-i) + z^{-1}Z\{x(n-(i-1))\}, \quad i \geq 1 \tag{7.67}$$

which is not the same as the time-shift property given in Table 7.3 for the BZT.

Unlike BZT, ZT can be used to find the complete response of an LTI DTS as described by Equation 7.45. We assume that the input $x(n)$ is zero for $n < 0$. Taking the term-by-term ZT of Equation 7.45 gives

$$\begin{aligned} Y(z) + a_1\big(y(-1) + z^{-1}Y(z)\big) + \cdots + a_N\big(y(-N) + z^{-1}Z\{y(n-(N-1))\}\big) \\ = b_0X(z) + b_1z^{-1}X(z) + \cdots + b_Mz^{-M}X(z) \end{aligned}$$

which can be rearranged to become

$$(1 + a_1z^{-1} + a_2z^{-2} + \cdots + a_Nz^{-N})Y(z) - Y_{IC}(z^{-1}) = (b_0 + b_1z^{-1} + b_2z^{-2} + \cdots + b_Mz^{-M})X(z)$$

where $Y_{IC}(z^{-1})$ accounts for all initial condition terms. If all initial conditions are zero, then $Y_{IC}(z^{-1}) = 0$. Solving for $Y(z)$ results in

$$Y(z) = \frac{Y_{\mathrm{IC}}(z^{-1})}{Q(z^{-1})} + H(z)X(z) \tag{7.68}$$

We can factor the denominator of $X(z)$, and write

$$X(z) = \frac{P_x(z^{-1})}{\prod_{i=1}^{N_x}(1 - p_{x,i}z^{-1})}$$

where the $p_{x,i}$, $i = 1, \ldots, N_x$, are the N_x poles of $X(z)$. Therefore, Equation 7.68 becomes

$$Y(z) = \frac{Y_{\mathrm{IC}}(z^{-1})}{\prod_{i=1}^{N}(1 - p_i z^{-1})} + \frac{P(z^{-1})}{\prod_{i=1}^{N}(1 - p_i z^{-1})} \frac{P_x(z^{-1})}{\prod_{i=1}^{N_x}(1 - p_x z^{-1})}$$

Let us assume that the poles of $H(z)$ and the poles $X(z)$ are distinct, and then a partial fraction expansion of the right-hand side of this equation has the form

$$Y(z) = \sum_{i=1}^{N} \frac{K_{\mathrm{IC},i}}{1 - p_i z^{-1}} + \sum_{i=1}^{N} \frac{K_i}{1 - p_i z^{-1}} + \sum_{i=1}^{N_x} \frac{K_{x,i}}{1 - p_{x,i} z^{-1}}$$

The complete solution $y(n)$ of Equation 7.45 is given by

$$y(n) = \sum_{i=1}^{N} K_{\mathrm{IC},i}(p_i)^n u(n) + \sum_{i=1}^{N} K_i(p_i)^n u(n) + \sum_{i=1}^{N_x} K_{x,i}(p_{x,i})^n u(n) \tag{7.69}$$

If the input $x(n)$ is zero, then $y(n)$ in Equation 7.69 consists of only the first sum term, which is called the zero-input response. If all initial conditions are zero, then $y(n)$ in Equation 7.69 consists of the second and third sum terms, which together are called the zero-state response. Furthermore, the first and second sum terms are due to the poles of $H(z)$, and together they are called the transient response. There can be a transient response even if all initial conditions are zero.

The third sum term in Equation 7.69 is a discrete-time function like the input, and it is called the steady-state response. In digital filtering a signal, this is the part of the complete response that is of main concern. We prefer that the transient response quickly decays to negligible levels. If the input is, for example, a single sinusoid, then $N_x = 2$, and the third sum term in Equation 7.69 will consist of the sum of two complex conjugate exponential functions that combine via Euler's identity to become a sinusoid, as given in Equation 7.53.

7.1.26 Conclusion

The concept of a FS was developed as the minimum mean square error solution for the problem of approximating a continuous-time periodic signal with a linear combination of sinusoidal functions. If the continuous-time periodic signal is everywhere continuous, then the approximation error is zero. By sampling FS, DFT was obtained, and its relationship to the spectral nature of the continuous-time signal was found. Depending on the bandwidth of the continuous-time signal, the sampling rate and the sampling duration, we came to understand the kinds of errors that can occur when the DFT is used to study the spectral nature of a signal. The DFT is a widely applied method of signal and system analysis, because the DFT can be efficiently computed with the FFT, which was demonstrated by the development of the decimation in time radix-2 FFT.

The FS concept was extended to aperiodic continuous-time signals, resulting in the FT. By sampling the inverse FT, the DTFT was obtained, and its relationship to the spectral nature of the continuous-time signal was found. The sampling theorem came by studying this relationship. The DTFT was applied to signal and system analysis, and for practical reasons, the DFT again played an important role.

To broaden the class of signals to which the DTFT can be applied, a convergence factor was introduced, resulting in the BZT. The relationship between the DTFT and BZT was thoroughly investigated to understand the role of the BZT in spectral analysis. The BZT was modified to work with right-handed signals resulting in the unilateral z-transform, or just ZT. The ZT was applied to find the complete response of a DTS, a main advantage of the ZT.

The next step for the reader may be to investigate methods for the design of digital filters, as can be found in the references and elsewhere, where the DFT, DTFT and ZT, which are all based on the concept of a FS, play major roles.

8.1 MOS Logic Circuits

John P. Uyemura

8.1.1 Introduction

MOS-based technology has become the default standard for high-density logic designs for several reasons. The most obvious is that MOSFETs can be made with side dimensions of <0.1 μm (10^{-7} m), allowing for complex logic functions to be constructed in small areas. The section is an investigation of the basics of designing and characterizing logic gates in an MOS technology.

8.1.2 MOSFET Models for Digital Circuits

The properties of digital logic gates are derived from a large-signal analysis of the circuits. Because transistor characteristics are intrinsically nonlinear, accurate analytic modeling becomes quite complicated, and closed-form solutions can be difficult to come by. To overcome this problem, simplified MOSFET models are used to estimate the circuit operation in first-cut designs. Once the basic operation is established, computer simulations are used to obtain more accurate information.

Square-law models are useful for understanding the operation of MOS logic circuits. Consider first an *n*-channel, enhancement-mode MOSFET that has a threshold voltage $V_{Tn} > 0$. As shown in Figure 8.1, the primary device voltages are V_{DS}, V_{GS}, and V_{SB}. The value gate–source voltage V_{GS} relative to the threshold voltage V_{Tn} determines if drain current I_D flows. If $V_{GS}, < V_{Tn}$ then $I_D \approx 0$, establishing the condition of ''cutoff.'' Elevating the gate–source voltage to a value $V_{GS}, > V_{Tn}$ places the MOSFET into the ''active region'' where I_D will be nonzero if a drain–source voltage V_{DS} is applied; the value of I_D depends on the values of the device voltages.

To describe active operation, we introduce the drain–source saturation voltage $V_{DS,sat}$ defined by

$$V_{DS,sat} = V_{GS} - V_{Tn} \tag{8.1}$$

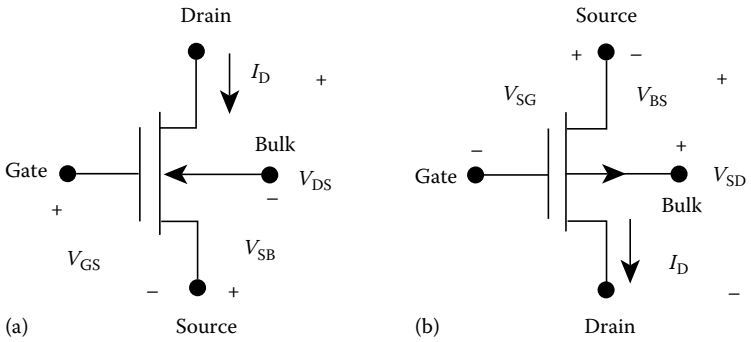

FIGURE 8.1 MOSFET symbols. (a) *n*-channel MOSFET; (b) *p*-channel MOSFET.

The threshold voltage is affected by the affected by the source–bulk (body) voltage V_{SB} by

$$V_{Tn} = V_{T0n} + \gamma\left(\sqrt{2|\phi_F| + V_{SB}} - \sqrt{2|\phi_F|}\right) \tag{8.2}$$

where

V_{T0n} is the nFET zero-body-bias threshold voltage
γ is the body bias (or, body effect) coefficient
ϕ_F is the bulk Fermi potential

When $V_{DS} \cdot V_{DS,sat}$, the MOSFET is nonsaturated with

$$I_D \approx \left(\frac{\beta_n}{2}\right)\left[2(V_{GS} - V_{Tn})V_{DS} - V_{DS}^2\right] \tag{8.3}$$

In this equation β_n is the device transconductance given by $\beta_n = k'_n(W/L)$, with k'_n the process transconductance in units of [A/V^2], W the channel width, and L the channel length; the width-to-length (W/L) is called the "aspect ratio" of the transistor. The process transconductance is given by $k'_n = \mu_n C_{ox}$ where μ_n is the electron surface mobility and C_{ox} the oxide capacitance per unit area. For an oxide layer with thickness t_{ox}, the MOS capacitance per unit area is calculated from

$$C_{ox} = \frac{\varepsilon_{ox}}{t_{ox}} \tag{8.4}$$

where ε_{ox} is the oxide permittivity. In the current technologies t_{ox} is smaller than about 60 Å. If $V_{DS} \geq V_{DS,sat}$, the MOSFET is saturated with

$$I_D \approx \left(\frac{\beta_n}{2}\right)(V_{GS} - V_{Tn})^2 \tag{8.5}$$

This ignores several effects, most notably that of "channel-length modulation," but is still a reasonable approximation for estimating basic performance parameters.

The structure of the MOSFET gives rise to several parasitic capacitances that tend to dominate the circuit performance. Two types of capacitors are contained in the basic model shown in Figure 8.2. The contributions C_{GS} and C_{GD} are due to the MOS layering of the gate–oxide semiconductor, which is the origin of the field effect. The total gate capacitance G_G is calculated from

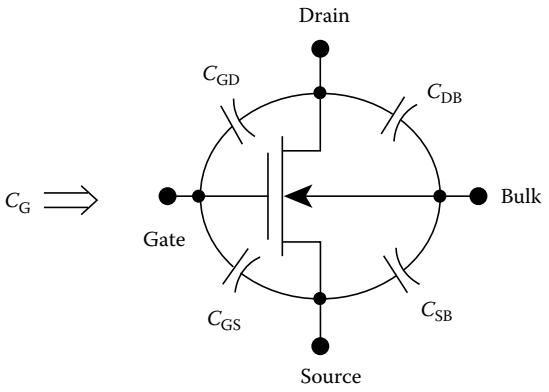

FIGURE 8.2 MOSFET capacitances.

$$C_G = C_{ox} WL \tag{8.6}$$

and the gate–source and gate–drain contributions can be approximated to first order by

$$C_{GD} \approx \frac{C_G}{2} \approx C_{GS} \tag{8.7}$$

Capacitors C_{DB} and C_{SB} are depletion contributions from the reverse-biased *pn* junction at the drain and source. These are nonlinear, voltage-dependent elements that decrease with increasing reverse voltage.

A *p*-channel MOSFET (pMOS or pFET) is the electrical complement of an *n*-channel device. An enhancement-mode pFET is defined to have a negative threshold voltage, i.e., $V_{Tp} < 0$. It is common to use device voltage of V_{SG}, V_{SD}, and V_{BS}, as shown in Figure 8.1 to describe the operation. Cutoff occurs if $V_{SG} < |V_{Tp}|$, while the device is active if $V_{SG} \geq |V_{Tp}|$. The saturation voltage of the pFET is defined by

$$V_{SD,sat} = V_{SG} - |V_{Tp}| \tag{8.8}$$

With $V_{SG} \geq |V_{Tp}|$ and $V_{SG} < V_{SD,sat}$, the transistor is nonsaturated with

$$I_D \approx \left(\frac{\beta_p}{2}\right)\left[2\left(V_{SG} - |V_{Tp}|\right)V_{SD} - V_{SD}^2\right] \tag{8.9}$$

For the pFET, β_p is the device transconductance $\beta_p = k'_p$ (W/L); where $k'_p = \mu_p C_{ox}$ is the process transconductance, and (W/L) is the aspect ratio of the device. In complementary metal–oxide–semiconductor (CMOS) inverters nFETs and pFETs are used in the same circuit, and it is important to note that $k'_n > k'_p$ due to the fact that the electron mobility is larger than the hole mobility, typically by a factor of 2 to 8.

It is often convenient to use the simplified MOSFET symbols shown in Figure 8.3. The polarity of the transistor (nMOS or pMOS) is made explicit by the absence or presence of the gate inversion "bubble," as shown. These symbols do not show the bulk electrode explicitly, but it is important to remember that all nFETs have their bulks connected to the lowest voltage in the circuit (usually ground), while all pFET bulks are connected to the highest voltage (usually the power supply V_{DD}).

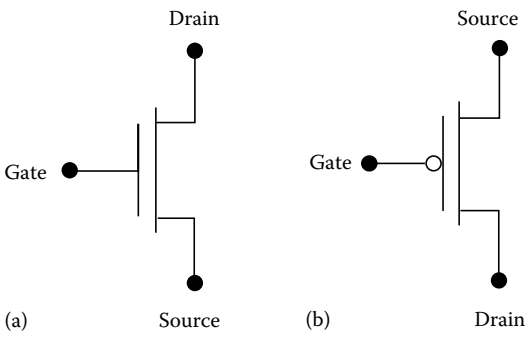

FIGURE 8.3 Simplified MOSFET symbols. (a) nMOSFET; (b) pMOSFET.

In digital circuit design, it is useful to model MOSFETs as voltage-controlled switches, as shown in Figure 8.4. The MOSFET switches are controlled by a gate input signal *G*, which is taken to be a Boolean variable. Employing a positive logic convention, $G = 0$ corresponds to a low voltage (below V_{Tn}), while $G = 1$ is a high voltage. The operation of the FET switches is straightforward. An input of $G = 0$ places the nFET into cutoff, corresponding to an OPEN switch; $G = 1$ implies active operation, and the switch is CLOSED. The pFET has a complementary behavior, with $G = 0$ giving a CLOSED switch, and $G = 1$ giving an OPEN switch.

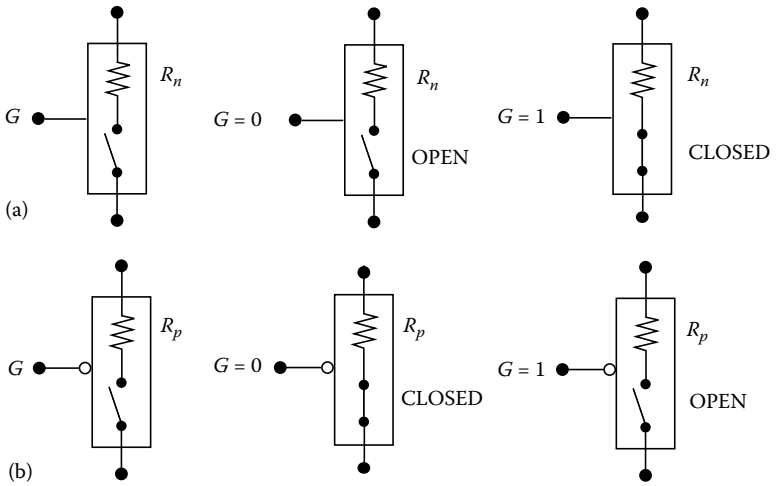

FIGURE 8.4 MOSFET switching models. (a) nFET switch model; (b) pFET switch model.

The switch models include parasitic drain-to-source resistance R_n and R_p, which are usually estimated using

$$R_n = \frac{1}{k'_n(\mathrm{W/L})_n(V_{\mathrm{DD}} - V_{\mathrm{T}n})}$$
$$R_p = \frac{1}{k'_p(\mathrm{W/L})_p(V_{\mathrm{DD}} - V_{\mathrm{T}p})} \tag{8.10}$$

These equations illustrate the general dependence that the drain–source resistance R is inversely proportional to the aspect ratio (W/L). However, the MOSFET is at best a nonlinear resistor, so that these are only rough estimates. It is important to note the MOSFET parasitic capacitances C_{GS}, C_{GD}, C_{SB}, and C_{DB} must be included in the switching models when performing transient analysis.

8.1.3 The Digital Inverter

An ideal digital inverter is shown in Figure 8.5. In terms of the Boolean variable A, the inverter accepts A and produces the complement $\overline{A}$. Electronic implementation of the inverter requires assigning voltage ranges for V_{in} and V_{out} to represent logic 0 and logic 1 states. These are chosen according to the DC

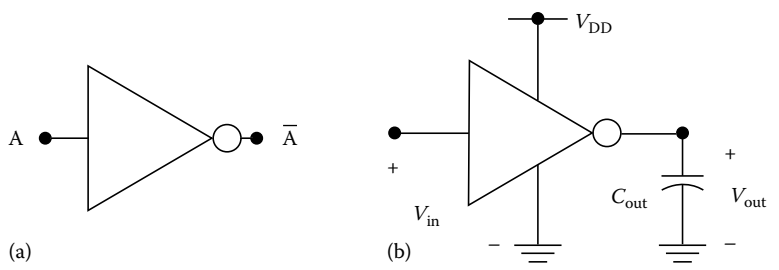

FIGURE 8.5 Basic inverter. (a) Ideal inverter symbol. (b) Electronic parameters.

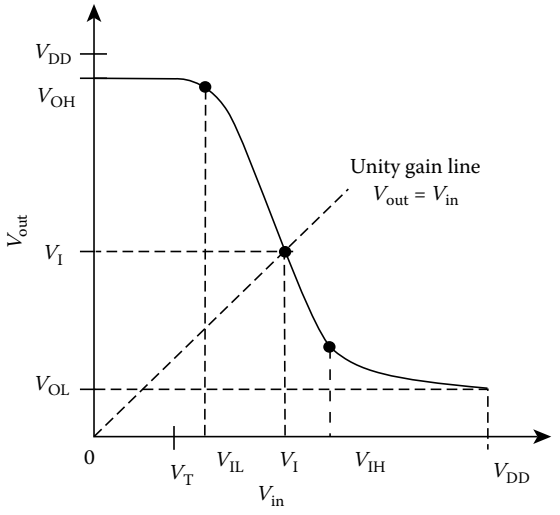

FIGURE 8.6 Inverter VTC.

voltage transfer characteristics (VTC) of the electronic circuit. A VTC is simply a plot of the output voltage V_{out} as a function of V_{in}; a general VTC is shown in Figure 8.6.

Consider first the output voltage V_{out}. The maximum value of V_{out} is denoted by V_{OH}, and is called the output high voltage. This is used to represent an ideal logic 1 output voltage. Conversely, the smallest value of V_{out} is denoted as V_{OL}, and is called the output low voltage. V_{OL} is the output logic 0 voltage. The logic swing of the inverter is then defined by $(V_{OH} - V_{OL})$. The range of input voltage V_{in} used to represent logic 0 and logic 1 input states is usually determined by points on the VTC at which the slope has a value of $(dV_{out}/dV_{in}) = -1$. Logic 0 voltages are those with values between 0 V and V_{IL}, the input low voltage. Similarly, voltages in the range from the input voltage V_{IH} to V_{OH} represent logic 1 input levels. The intersection of the VTC with the unity gain line defined by $V_{out} = V_{in}$ gives the inverter threshold voltage V_I; this represents the switching point of the circuit. The numerical value of V_{OH}, V_{OL} V_{IL}, V_{IHt}, and V_I are determined by the circuit and topology and the characteristics of the devices used in the circuit.

The transient characteristics of the gate are defined by two basic transition times. Figure 8.7 shows V_{in} and V_{out}, and the most important output switching intervals. The input voltage has been taken as an ideal step-like pulse. In a more realistic situation the input voltage is better approximated by a ramp or an exponential. The idealized pulse is used here because it allows a comparison among various circuits.

The most important switching properties of the inverter are the low-to-high time t_{LH}, and the high-to-low time t_{HL} as shown in Figure 8.7. These represent the minimum response times of the inverter.

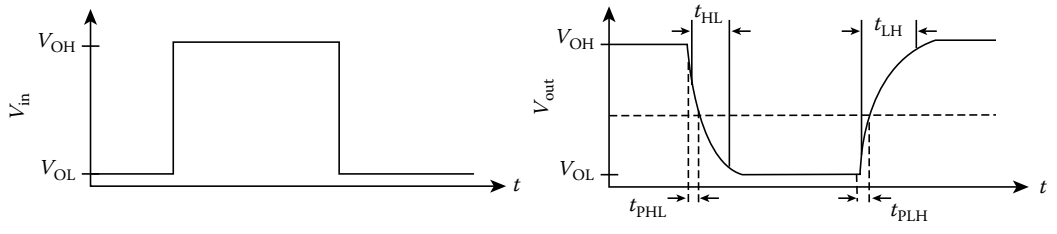

FIGURE 8.7 Inverter switching times.

Note that these time intervals are usually defined between the 10% and 90% voltages instead of the full logic swing. The maximum switching frequency is computed from

$$f_{\max} = \frac{1}{t_{\mathrm{LH}} + t_{\mathrm{HL}}} \tag{8.11}$$

The propagation delay t_{P} for the gate is the average time required for a change in the input to be seen at the output. It is computed using the time intervals t_{PHL} and t_{PLH} shown in the diagram from

$$t_{\mathrm{P}} = \left(\frac{1}{2}\right)(t_{\mathrm{PHL}} + t_{\mathrm{PLH}}) \tag{8.12}$$

Note that the transition times for this parameter are measured to the 50% voltage.

8.1.4 nMOS Logic Gates

Early generations of MOS logic circuits were based on a single type of MOSFET. The Intel 4004, for example, used only pMOS transistors, while subsequent microprocessor chips such as the Intel 8088, the Zilog Z80, and the Motorola 6800 used only *n*-channel MOSFETs. Although all current MOS-based designs are implemented in CMOS, which employs both nMOS and pMOS devices, it is worthwhile to examine nMOS-only logic circuits. This provides an introduction to the basic characteristics of MOS logic circuits, many of which are used in even the most advanced CMOS techniques.

Several types of inverter circuits can be constructed using *n*-channel MOSFETs. Three configurations are shown in Figure 8.8. Each circuit uses a switching transistor MD, known as the "driver," which is controlled by the input voltage V_{in}. The VTC is determined by the load device that connects the drain of MD to the power supply V_{DD}. The MD can be viewed as the switched "pull-down" device, while the load serves as the "pull-up" device. In Figure 8.8a, a simple linear resistor with a value R_{L} is used as the load. The circuits in Figure 8.8b use an enhancement-mode (defined with $V_{\mathrm{T}n} > 0$) nMOSFET biased into saturation, while Figure 8.8c has a depletion-mode nMOSFET (where $V_{\mathrm{T}n} < 0$) as an active load. Active loads provide better switching characteristics due to the nonlinearity of the device. In addition, MOSFETs are much smaller than resistors and process variations are not as critical because the circuit characteristics depend on the ratio of driver-to-load dimensions.

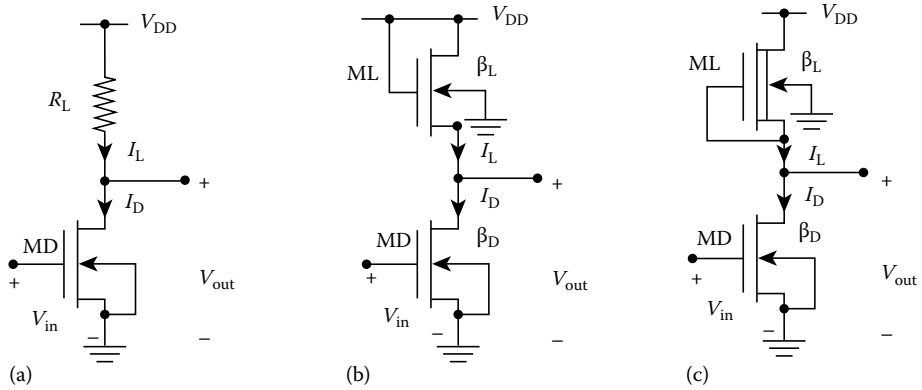

FIGURE 8.8 nMOS inverter circuits: (a) resistor load; (b) saturated enhancement model MOSFET load; and (c) depletion mode MOSFET load.

Although the three nMOS inverter circuits are similar in structure, they have distinct switching properties. Consider the output voltage swing. Figure 8.8a and c both have $V_{OH} \approx V_{DD}$, but the active load in Figure 8.8b gives

$$V_{OH} = V_{DD} - V_{TL} \tag{8.13}$$

with the threshold voltage computed from

$$V_{TL} = V_{T0n} + \gamma\left(\sqrt{2|\phi_F| + V_{OH}} - \sqrt{2|\phi_F|}\right) \tag{8.14}$$

This is referred to as a ''threshold voltage loss,'' and is due to the fact that the load must have a minimum gate–source voltage of $V_{GSL} = V_{TL}$ to be biased into the active mode. Obviously, $V_{OH} < V_{DD}$ for this circuit.

The value of $V_{OL} > 0$ is determined by a ratio of driver parameters to load parameters. In Figure 8.8a, this ratio is given by $R_L\beta_D$, which is inversely proportional to V_{OL}. This means a small V_{OL} requires that both the load resistance and the driver dimensions are large. In Figure 8.8b and c, V_{OL} is set by the driver-to-load ratio $\beta_R = (\beta_D/\beta_L) = (W/L)_D/(W/L)_L$; increasing β_R decreases V_{OL}. For the depletion MOSFET load circuit in Figure 8.8c, the design equation is given by

$$\beta_R = \frac{|V_{TL}|^2}{2(V_{DD} - V_{TD})V_{OL} - V_{OL}^2} \tag{8.15}$$

A condition of $\beta_R > 1$ is generally required to achieve a functional inverter, implying that the driver MOSFET is always larger than the load device. Also, note that is not possible to achieve $V_{OL} = 0$ because this requires an infinite driver-to-load ratio.

The transient switching characteristics are obtained by including the output capacitance C_{out} as shown in Figure 8.5 at the output. C_{out} consists of the input gate capacitance seen looking in the MOSFET of the next stage, and also has parasitic contributions from the MOSFETs and interconnects. By using a switch model for the driver, it is seen that the transient characteristics are determined by the time required to charge and discharge C_{out}. The high-to-low time t_{HL} represents the time it takes to discharge the capacitor through the driver MOSFET with a device transconductance value of β_D. A rough estimate is obtained using the RC time constant such that $t_{HL} \approx 2R_D\ C_{out}$, with R_D the equivalent resistance. Similarly, the low-to-high time t_{LH} is the time interval needed to charge C_{out} through the load device. With respect to Figure 8.8c has the best transient response such that $t_{LH} \approx 2R_L\ C_{out}$, where R_L represents the equivalent resistance of the load MOSFET. nMOS circuits in the mid-1980s had inverter transition times on the order of a few nanoseconds. Because the DC design requires that $\beta_R = (\beta_D/\beta_L) > 1$, and the drain–source resistance of a MOSFET is inversely proportional to β, these circuits exhibit nonsymmetrical switching times with $t_{LH} > t_{HL}$. The propagation delay times can be estimated using $t_{PHL} \approx R_D\ C_{out}$ and $t_{PLH} \approx R_L\ C_{out}$ because these are measured relative to the 50% voltage levels.

MOS-based logic design allows one to easily construct other logic functions using the inverter circuit as a guide. For example, adding another driver MOSFET in parallel gives the NOR operation, while adding a series connected driver yields the NAND operation; these are shown in Figure 8.9.

Complex logic gates for AOI (AND-OR-INVERT) and OAI (OR-AND-INVERT) canonical logic functions can be constructed using the simple rules

- nMOSFETs (or groups) in parallel provide the NOR operation
- nMOSFETs (or groups) in series provide the NAND operation

Examples are provided in Figure 8.10. It should be noted that this type of circuit structuring is possible because the drain and source are interchangeable. The main problem that arises in design complex

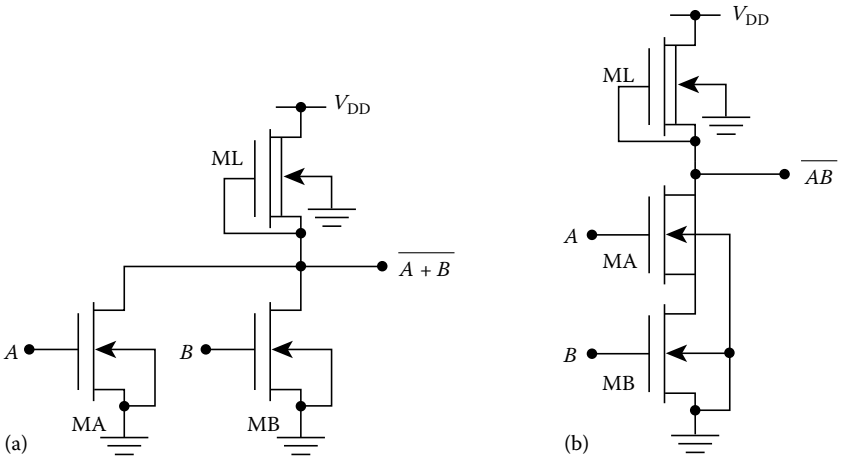

FIGURE 8.9 nMOS NOR and NAND gates: (a) two-input NOR gate and (b) two-input NAND gate.

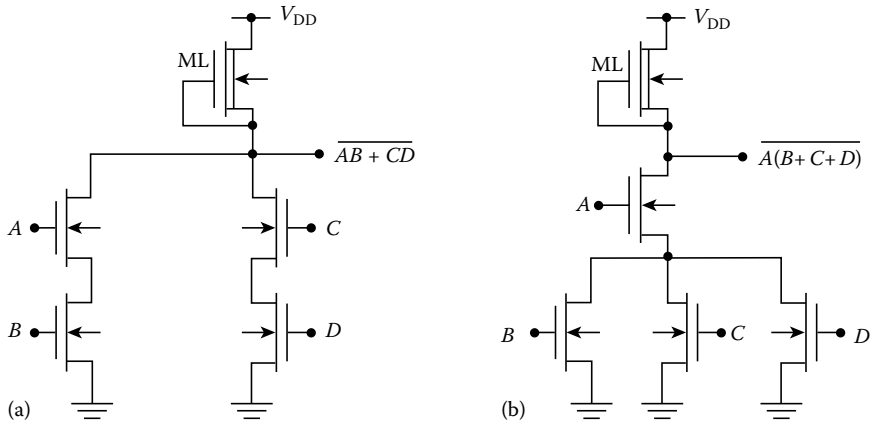

FIGURE 8.10 nMOS AOI logic gates.

nMOS logic gates is that the circuit requires large driver-to-load ratios to achieve small V_{OL} values. The switching FET arrays collectively act like a driver network that must be designed to have a large overall effective β value. Although parallel-connected MOSFETs are not a problem, the pull-down resistance of series-connected MOSFETs can be large unless the individual aspect ratios are increased. Satisfying this condition requires additional chip area, decreasing the logic density.

8.1.5 CMOS Inverter

A CMOS inverter is shown in Figure 8.11. This circuit uses a pair of transistors, one nMOS and one pMOS, connected with their gates together. When $V_{in} < V_{Tn}$, the pFET is active and the nFET is in cutoff. Conversely, when $V_{in} > (V_{DD} - V_{Tn})$, the nFET is active while the pFET is in cutoff. The two MOSFETs are said to form a complementary pair.

The complementary arrangement of the MOSFETs gives the circuit a full rail-to-rail output range, i.e., $V_{OL} = 0$ V and $V_{OH} = V_{DD}$. The devices are connected in such a way that terminal voltages satisfy

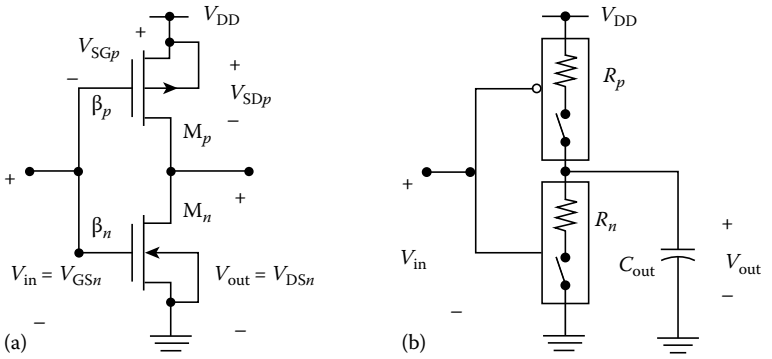

FIGURE 8.11 CMOS inverter: (a) circuit and (b) switch model.

$$\begin{aligned} V_{GSn} + V_{SGp} &= V_{DD} \\ V_{DSn} + V_{SDp} &= V_{DD} \end{aligned} \tag{8.16}$$

Note in particular the relationship between the gate–source voltages. Increasing the voltage on one transistor automatically decreases the voltage applied to the other. This provides the VTC with a very sharp transition, as shown in Figure 8.12. Moreover, the shape of the VTC is almost insensitive to the power supply value V_{DD}, which allows CMOS circuits based on this construction to be used with a range of values. The minimum value of V_{DD} is set by the device the device threshold voltages, and is usually estimated as being about 3 V_T. This is based on the input switching voltage V_{in}, and allows one V_T to switch the nFET, one V_T to switch the pFET, and one V_T for separation. Currently, V_T values equal ~0.5 V, so that the minimum V_{DD} is about 1.5 V. Because V_T is set in the fabrication, the minimum power supply used in low-voltage designs depends upon the process specifications. The maximum value of the power supply voltage is limited by the reverse breakdown voltages of the drain–bulk junctions. This is typically around 14–17 V.

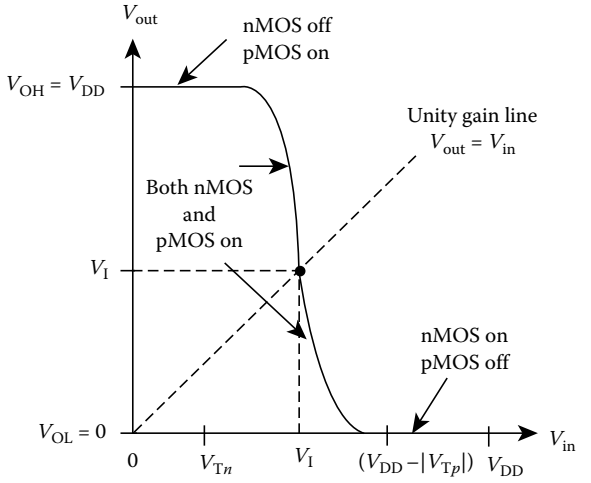

FIGURE 8.12 CMOS VTC.

Because the structure of the CMOS circuit automatically gives a full-rail output logic swing, the DC design of the gate centers around setting the inverter threshold voltage V_I. At this point, both FETs are saturated, and equating currents gives the expression

$$V_I = \frac{\sqrt{\beta_n/\beta_p}V_{Tn} + (V_{DD} - |V_{Tp}|)}{1 + \sqrt{\beta_n/\beta_p}} \tag{8.17}$$

This equation shows that V_I can be set by adjusting the ratio β_n/β_p. If $\beta_n = \beta_p$, and $V_{Tn} \approx |V_{Tp}|$, then $V_I \approx (V_{DD}/2)$. Increasing this ratio decrease the inverter switching voltage. If the nFET and pFET are of equal size, then $\beta_n > \beta_p$ (as $k'_n > k'_p$), and $V_I < (V_{DD}/2)$.

The transient characteristics are obtained by analyzing the charge and discharge current flow paths through the transistors. By using the switch model in Figure 8.11b, the primary time constants are

$$\begin{aligned} \tau_n &= R_n C_{out} = \frac{C_{out}}{\beta_n(V_{DD} - V_{Tn})} \\ \tau_p &= R_p C_{out} = \frac{C_{out}}{\beta_p(V_{DD} - |V_{Tp}|)} \end{aligned} \tag{8.18}$$

Analyzing the transitions with a step input voltage yields

$$\begin{aligned} t_{HL} &= \tau_n \left[\frac{2(V_{Tn} - V_0)}{(V_{DD} - V_{Tn})} + \ln\left(\frac{2(V_{DD} - V_{Tn})}{V_0} - 1 \right) \right] \\ t_{LH} &= \tau_p \left[\frac{2(|V_{Tp}| - V_0)}{(V_{DD} - |V_{Tp}|)} + \ln\left(\frac{2(V_{DD} - |V_{Tp}|)}{V_0} - 1 \right) \right] \end{aligned} \tag{8.19}$$

where $V_0 = 0.1\ V_{DD}$ is the 10% voltage. Noting once again that $k'_n > k'_p$, equal size transistors will give $t_{LH} > t_{HL}$. To obtain symmetrical switching, the pMOSFET must have an aspect ratio of $(W/L)_p = (k'_n > k'_p)\ (W/L)_n$. This illustrates that while the ratio of β-values sets the DC switching voltage V_I, the individual choices for β_n and β_p determine the transient switching times. In general, fast switching requires large transistors, illustrating the speed vs. area trade-off in CMOS design. The propagation delay time exhibits the same dependence.

Another interesting characteristic of the CMOS inverter is the power dissipation. Consider an inverter with stable logic 0 or logic 1 inputs. Because one MOSFET is in cutoff, the DC power supply current I_{DD} is very small, being restricted to leakage levels. The standby DC power dissipation is $P_{DC} = I_{DD}V_{DD} \approx 0$, so that static logic circuits do not dissipate much power under static conditions. Appreciable I_{DD} from the power supply to ground flows only during a transition. Dynamic power dissipation, on the other hand, occurs due to the charging and discharging of the output capacitance C_{out}. The dynamic power dissipation can be estimated by

$$P_{Dynamic} = C_{out}V_{DD}^2 f \tag{8.20}$$

where f is the switching frequency of the signal. Qualitatively, this is understood by noting that this is just twice the average stored energy multiplied by the frequency. This illustrates the important result that the power dissipation of a CMOS circuit increases with the switching frequency.

8.1.6 Static CMOS Logic Gates

Static logic gates are based on the inverter. The term ''static'' means that the output voltages (logic levels) are well defined as long as the inputs are stable. The nFET rules discussed for nMOS logic gates still apply

to CMOS. However, static logic gates provide an nFET and a pFET for every input. Proper operation requires that rules be developed for the pMOSFET array as follows:

- pMOSFETs (or groups) in parallel provide the NAND operation
- pMOSFETs (or groups) in series provide the NOR operation

When these rules are compared to the nMOS rules, it is seen that the nFET and pFET arrays are logical duals of one another (i.e., OR goes to AND, and vice versa).

An N-input static CMOS logic gate requires 2 N transistors. NAND and NOR gates are shown in Figure 8.13 using the rules; this type of logic is termed series-parallel, for obvious reasons. Examples of complex logic gates are shown in Figure 8.14. Note in particular the circuit in Figure 8.14b. This implements the XOR function by means of

$$A \oplus B = \overline{AB + \overline{A}\,\overline{B}} = A\overline{B} + \overline{A}B \tag{8.21}$$

Reductions of this type are often performed to work the AOI or OAI equation into a more familiar form.

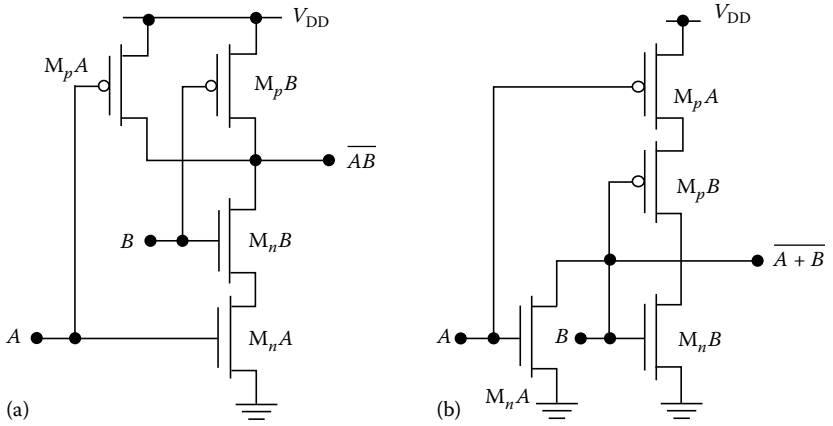

FIGURE 8.13 CMOS: (a) NAND and (b) NOR gates.

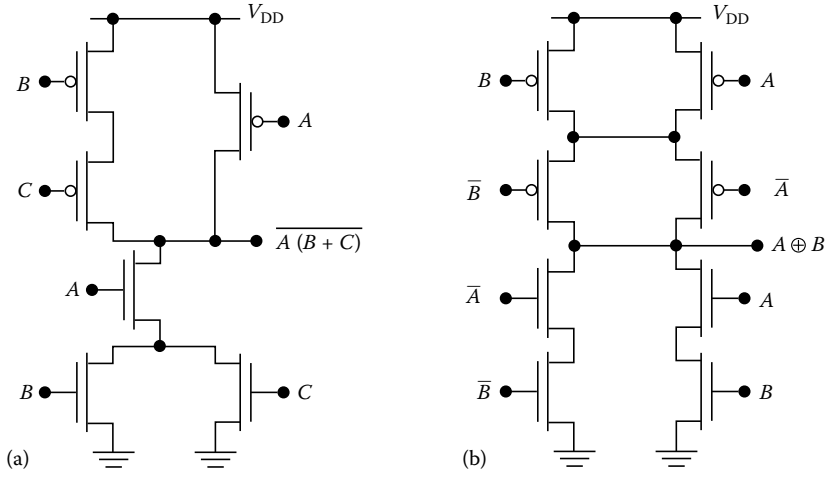

FIGURE 8.14 CMOS AOI logic examples: (a) AOI gate and (b) XOR circuit.

As seen from these examples, the logic function is determined by the placement of the nFETs and pFETs in their respective arrays. Electrically, the design problem centers around choosing the aspect ratios to achieve acceptable switching times. Because a MOSFET has a parasitic drain–source resistance that varies as $(1/\beta)$, series-connected transistor chains exhibit larger time constants than parallel-connected arrangements. Recalling that $R_n < R_p$ shows that for equal size devices, series chains of nFETs are preferable to the same number of series-connected pFETs. Consequently, NAND gates are used more frequently than NOR gates, and AOI logic functions with a small number of OR operations are better. It is also possible to expand to transistor arrays that are not of the series-parallel type, such as a delta configuration, but it is difficult to devise general design guidelines for these circuits.

Canonical CMOS static logic design is based on using pairs of nMOS and pMOS transistors. In modern very large scale integration (VLSI) design, the design complexity is limited by the interconnect (as opposed to the number of transistors), so that the need to connect every input to two transistors may result in problems in the chip layout. Pseudo-nMOS circuits provide an alternative to standard CMOS circuits. These logic gates implement logic using nFET arrays; however, the pMOS array is replaced by a single *p*-channel MOSFET that acts as a load device. Figure 8.15 shows an inverter and an AOI circuit implement based on pseudo-nMOS structuring. In both circuits, the load pMOSFET is biased active with $V_{SGp} = V_{DD}$ by grounding the gate. Although the circuits are simplified, two main problems arise with this type of circuit. First, the output low voltage V_{OL} is determined by the driver-to-load ratio $(\beta_n/\beta_p) > 1$, so that large driver nFETs are required. Second, if the input voltage is high, then the circuit dissipates DC power. Despite these drawbacks, pseudo-nMOS circuits may be useful in certain situations.

Transmission gates (TGs) provide another approach to implementing logic functions in CMOS. The properties of TGs are discussed in more detail in Section 8.2. However, because they are useful for certain types of logic gates, a short discussion has been included here. A basic TG consists of an nMOSFET and a pMOSFET in parallel, as shown in Figure 8.16a; the symbol in Figure 8.16b represents the composite structure. TGs act like voltage-controlled switches: logically, a condition of $C = 0$ gives an open switch, while $C = 1$ gives a closed switch. TGs can pass the full range of voltages (from 0 V to V_{DD}) in either direction; this is not possible with a single device, due to the threshold voltage characteristic discussed earlier in this section.

Figure 8.17 illustrates a simple 2:1 multiplexer (MUX) with two input lines, D_0 and D_1, and a control bit *S*. When $S = 0$, the upper TG is closed, and the output is $F = D_0$. Conversely, $S = 1$ closes the bottom TG, so $F = D_1$. The operation of this circuit is expressed by

$$F = \overline{S}D_0 + SD_1 \tag{8.22}$$

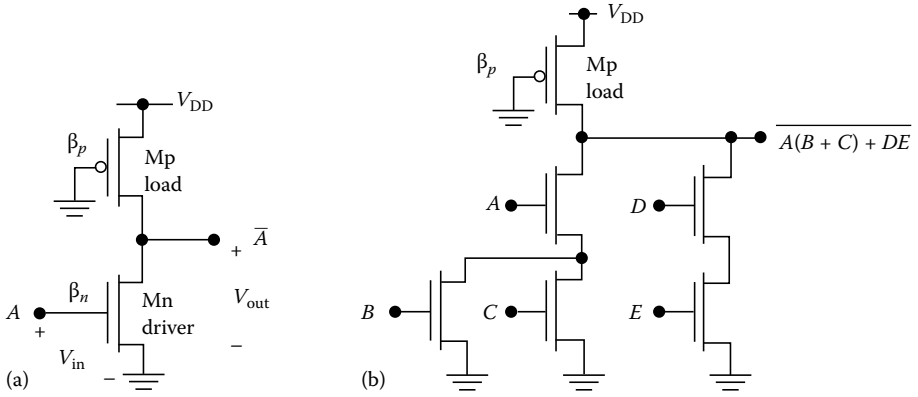

FIGURE 8.15 Pseudo-nMOS logic circuits: (a) Inverter and (b) AOI logic gate.

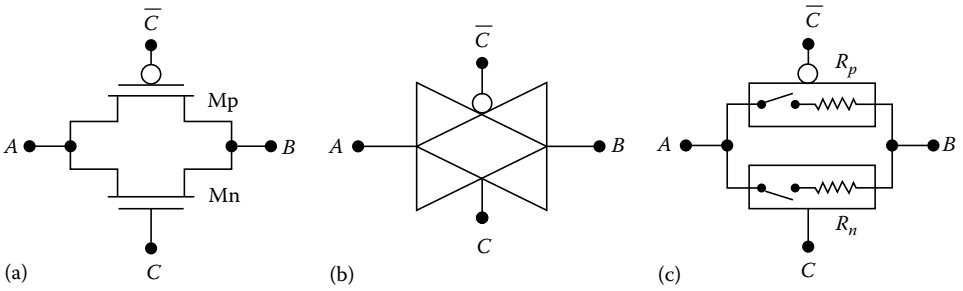

FIGURE 8.16 Transmission gate: (a) circuit; (b) symbol; and (c) switching model.

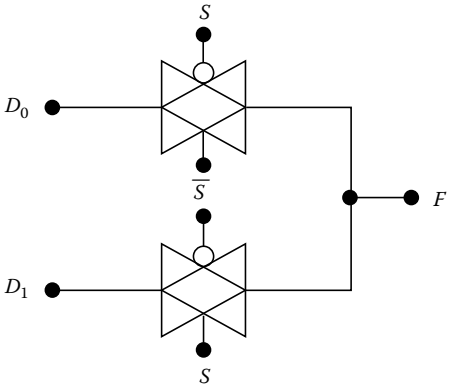

FIGURE 8.17 TG-based 2:1 multiplexer.

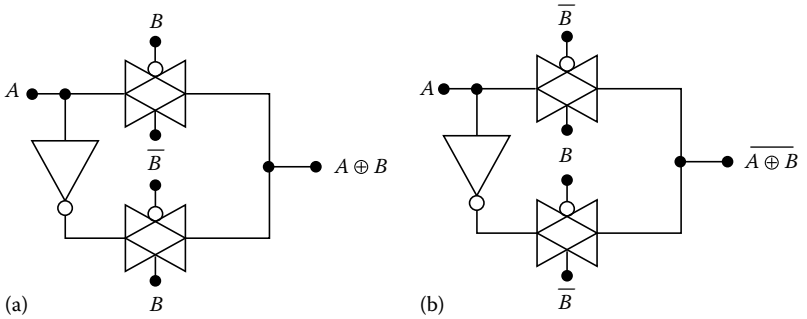

FIGURE 8.18 TG-based (a) XOR and (b) XNOR logic gates.

The circuit can be expanded easily to create larger multiplexers. For example, an 8:1 requires three select bits, and each of the eight lines will be a switching network using three TGs. Several other TG-based logic functions are popular in CMOS design. Figure 8.18 shows the exclusive-OR (XOR) and exclusive-NOR (XNOR) circuits. The primary drawbacks of TG-based logic circuits are that (1) the TG does not have a connection to the power supply, and acts as a parasitic RC element to the stage that drives it, and (2) the chip layout may become large, complicated, or both. In particular, (1) implies that TG circuits may be slower than equivalent functions designed using basic static CMOS techniques.

8.1.7 Dynamic CMOS Logic Gates

Dynamic CMOS logic gates are characterized as having outputs that are valid only for a limited time interval. Although this property inherently makes the circuit design more challenging, dynamic logic circuits can potentially achieve fast switching speeds. In general, dynamic circuits use parasitic capacitors in the MOS circuit to store charge Q. Because $Q = CV$, the presence or absence of charge corresponds to a logic 1 or logic 0 level, respectively, MOSFETs are used as voltage-controlled switches to "steer" the charge on and off the logic nodes. Several dynamic logic families have appeared in the literature, each having distinct characteristics. We now merely touch on some characteristics of a basic circuit which illustrates the important points.

Consider the dynamic logic circuit in Figure 8.19 for a three-input NAND gate. The transistors labeled MP and MN are controlled by the clock $\phi(t)$, and provide synchronization of the data flow. Note the presence of capacitors C_{out}, C_1, C_2, and C_3. These represent parasitic capacitances due to the transistors and interconnect, and are crucial to the operation.

The circuit is controlled by the timing provided by $\phi(t)$. When $\phi = 0$, MP is ON and MN is OFF. During this time, C_{out} is charged to a voltage $V_{out} = V_{DD}$, which is called a "precharge event." When ϕ changes to a level $\phi = 1$, MP is driven into cutoff, but MN is biased ON; the operation of the circuit during this time is termed a "conditional discharge event." If the inputs are set to $(A, B, C) = (1, 1, 1)$, then all three logic transistors, MA, MB, and MC, are ON, and C_{out} can discharge through these transistors and MN to a final voltage of $V_{out} = 0$ V. If at least one input is a logic 0, then C_{out} does not have a direct discharge path to ground. Ideally, V_{out} would stay at V_{DD}. However, charge leakage occurs across the reverse-biased drain–bulk *pn* junctions in the MOSFETs, eventually leading to a value of $V_{out} = 0$ V. Typically, the output voltage can be held only for a few milliseconds, thus leading to the name "dynamic circuit."

Another problem that arises in dynamic logic circuits is that of charge sharing. Consider the three-input NAND gate with inputs of $(A, B, C) = (0, X, X)$ during the precharge, where X is a do not care condition. The total charge transferred to the circuit from the power supply is

$$Q_T = C_{out} V_{DD} \tag{8.23}$$

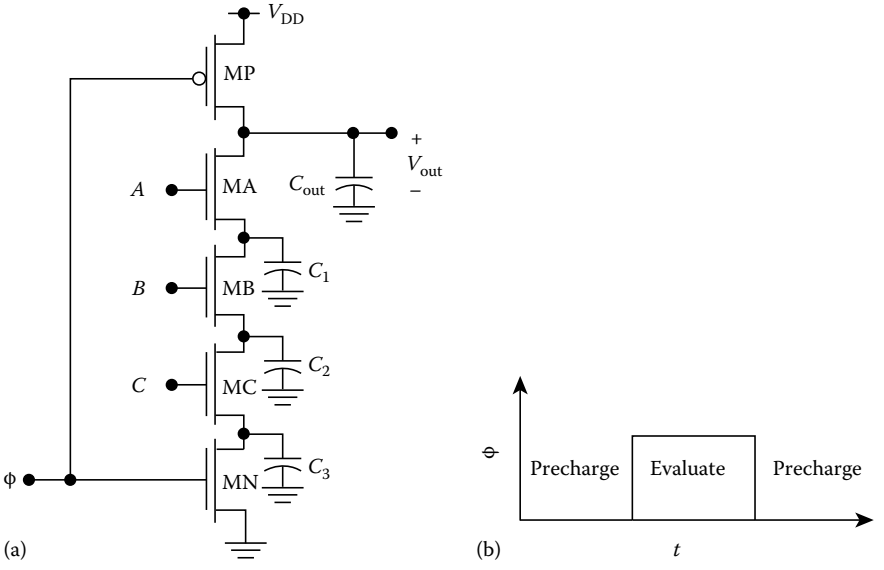

FIGURE 8.19 Dynamic CMOS logic gate: (a) three-input NAND gate and (b) timing intervals.

Now suppose that the inputs are switched to $(A, B, C) = (1, 1, 0)$ during the evaluation phase. MOSFETs MA and MB are ON, but MC is OFF, blocking the discharge path. Charge sharing occurs because the charge originally stored on C_{out} is now shared with C_1 and C_2. After the transients have decayed, the three capacitors are in parallel, Ignoring any threshold drop, they will share the same final voltage V_f such that

$$Q_T = (C_{out} + C_1 + C_2)V_f \tag{8.24}$$

Equating the two expressions for charge gives

$$V_f = \frac{C_{out}}{C_{out} + C_1 + C_2} V_{DD} < V_{DD} \tag{8.25}$$

To ensure that the output voltage remains at a logic 1 high voltage, the capacitors must satisfy the relation

$$C_{out} \gg C_1 + C_2 \tag{8.26}$$

The capacitance values are proportional to the sizes of the contributing regions, so that the performance is closely tied to the layout of the chip.

8.2 Transmission Gates

Robert C. Chang and Bing J. Sheu

A signal propagates through a transmission gate (TG) in a unique manner. In conventional logic gates, the input signal is applied to the gate terminal of an MOS transistor and the output signal is produced at the drain or the source terminal. In a TG, the input signal propagates between the source and the drain terminals through the transistor channel, while the gate voltage is held at a constant value. The TG is turned off if the voltage applied to the gate terminal is below the threshold voltage. The TG approach can be used in digital data processing to implement special switching functions with high performance as well as a small transistor count [1]. It also can be used in analog signal processing to act as a compact voltage-controlled resistor.

8.2.1 Digital Processing

8.2.1.1 Single Transistor Version

A TG can be constructed by a single nMOS or pMOS transistor, as shown in Figure 8.20. For an nMOS TG to pass a signal V_{in} to the output terminal, the selection signal S is set to the logic 1 value, i.e., the gate

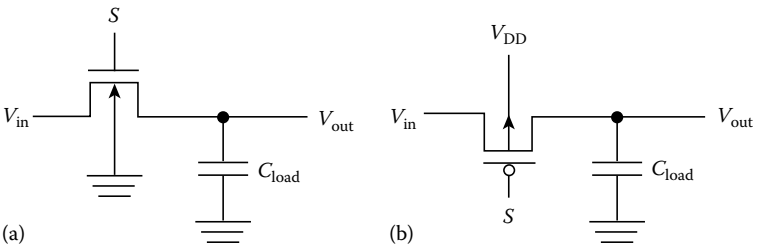

FIGURE 8.20 (a) nMOS TG and (b) pMOS TG.

voltage V_G is set to a high voltage value V_{DD}. If the input signal is also the V_{DD} value, the output voltage V_{out} is determined by [2],

$$V_{out}(t) = (V_{DD} - V_{thn})\left[\frac{t/\tau_{nc}}{1 + (t/\tau_{nc})}\right] \tag{8.27}$$

where

V_{thn} is the threshold voltage of the nMOS transistor with the body effect
τ_{nc} is the charging time constant which can be expressed as

$$\tau_{nc} = \frac{2C_{out}}{\mu_n C_{OX}(W/L)(V_{DD} - V_{thn})} \tag{8.28}$$

where

μ_n is the carrier mobility
C_{OX} is the per-unit-area capacitance value
W/L is the transistor aspect ratio

If time t goes to ∞, then V_{out} will approach $V_{DD} - V_{thn}$, which indicates that a threshold voltage loss occurs in the signal from the input node to the output node. This is due to the fact that V_{GS} must be greater than the threshold voltage to turn on the nMOS transistor. Owing to this voltage reduction, an nMOS TG can only transmit a "weak" logic 1 value. However, a logic 0 can be transmitted by an nMOS TG without penalty. In order to analyze this case, we set $V_{in} = 0$ and $V_{out}(t = 0) = V_{DD} - V_{thn}$. The output voltage V_{out} is determined by

$$V_{out}(t) = (V_{DD} - V_{thn})\left[\frac{2e^{-(t/\tau_{nd})}}{1 + e^{-(t/\tau_{nd})}}\right] \tag{8.29}$$

where the discharge time constant can be expressed as

$$\tau_{nd} = \frac{C_{out}}{\mu_n C_{OX}(W/L)(V_{DD} - V_{thn})} \tag{8.30}$$

Notice that V_{out} will approach zero as time goes to infinity. Input–output (I–O) characteristics of an nMOS TG are shown in Figure 8.21.

The schematic diagram of a pMOS TG is shown in Figure 8.20b. For a pMOS TG to pass a signal V_{in} to the output terminal, the selection signal S is set to the logic 0 value. To transmit a logic 0 value with the initial V_{out} value being V_{DD}, the expression for V_{out} is given as

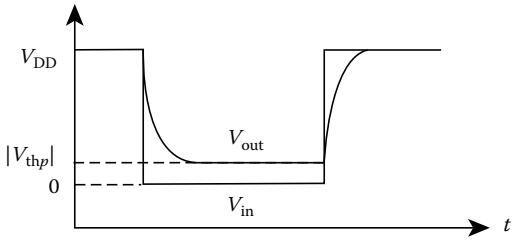

FIGURE 8.21 Characteristics of nMOS TG.

$$V_{out}(t) = |V_{thp}| + \frac{V_{DD} - |V_{thp}|}{1 + (V_{DD} - |V_{thp}|)(t/2\tau_{pd})} \tag{8.31}$$

where τ_{pd} is the discharging time constant for the pMOS TG. As time goes to infinity, V_{out} will approach $|V_{thp}|$, so that the pMOS TG can only transmit a "weak" logic 0 value. On the other hand, the pMOS TG can perfectly transmit a logic 1 value. To analyze this case, we set $V_{in} = V_{DD}$ and assume the initial V_{out} value as $|V_{thp}|$. The expression for V_{out} is given as

$$V_{out}(t) = V_{DD} - (V_{DD} - |V_{thp}|)\left(\frac{2e^{-(t/\tau_{pc})}}{1 + e^{-(t/\tau_{pc})}}\right) \tag{8.32}$$

where τ_{pc} is the charging time constant for the pMOS TG. The output voltage will approach V_{DD} as time goes to ∞. The transfer characteristics of the pMOS TG is shown in Figure 8.22.

8.2.1.2 Complementary Transistor Version

Figure 8.23 is the schematic diagram of a complementary transistor version of the TG which can be constructed by combining the characteristics of nMOS and pMOS TGs. The CMOS TG can transmit both the logic 0 and logic 1 values without any degradation. The voltage transmission properties of the single transistor and CMOS TGs are summarized in Table 8.1. The overall behavior of the CMOS TG can

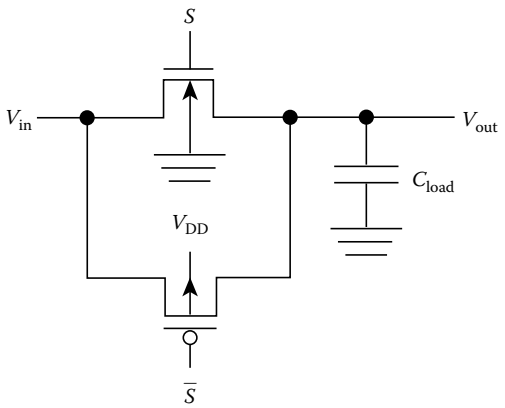

FIGURE 8.22 Characteristics of pMOS TG.

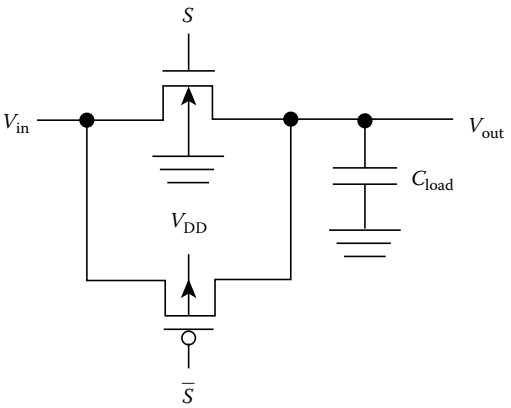

FIGURE 8.23 CMOS TG.

TABLE 8.1 Transmission Gate Characteristics

V_{out} V_{in} Type	$V_{in} = 0$ (Logic 0)	$V_{in} = V_{DD}$ (Logic 1)
nMOS	0	$V_{DD} - V_{thn}$
pMOS	$\|V_{thp}\|$	V_{DD}
CMOS	0	V_{DD}

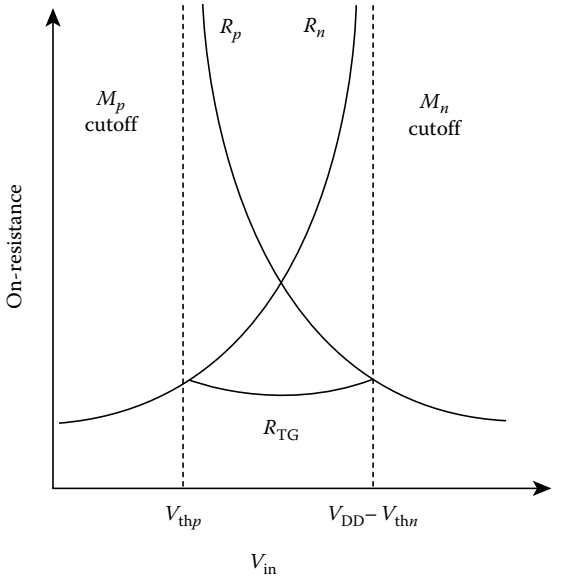

FIGURE 8.24 TG resistances.

be described as follows. When the selection signal S is low, both the nMOS and pMOS transistors are cut off. The output voltage V_{out} will remain at a high impedance state. When the selection signal S is high, both the nMOS and pMOS transistors are turned on and the output voltage will be equal to the input voltage.

Three regions of operation exist for a CMOS TG. In region 1 $V_{in} < |V_{thp}|$, then nMOS transistor is in the triode region and the pMOS transistor is in the cutoff region. Because the pMOS transistor is turned off, the total current, I_{tot}, is supplied by the nMOS transistor and I_{tot} decreases as V_{in} increases. In region 2 $|V_{thp}| < V_{in} < V_{DD} - V_{thn}$ both the nMOS and pMOS transistors are in the triode region. In this region, the nMOS transistor current decreases and the pMOS transistor current increases as V_{in} increases. Thus, I_{tot} is approximately a constant value. In region 3, $V_{in} > V_{DD} - V_{thn}$ the nMOS transistor is turned off and the pMOS transistor is in the triode region. The plot of the TG on-resistance is shown in Figure 8.24.

8.2.1.3 Pass-Transistor Logic

Pass-transistor logic is a family of logic which is composed of TG. Methods for deriving pass-transistor logic using nMOS TGs have been reported [3]. Figure 8.25 shows the schematic diagram of the pass-transistor logic in which a set of pass signals, P_is, are applied to the sources of the nMOS transistors and another set of control signals, C_is, are applied to the gates of the nMOS transistors.

The desired logic function F can be expressed as $F = C_1 \cdot P_1 + C_2 \cdot P_2 + \cdots + C_n \cdot P_n$. When C_is are high, P_is are transmitted to the output node. P_is can be logic 0, logic 1, true, or complement of the ith input variable X_i, or the high-impedance state Z. Constructing a Karnaugh map can help one to design the pass-transistor circuit. The pass function rather than the desired output values is put to the corresponding locations in the Karnaugh map. Then any variables that may act as a control variable or a pass variable are grouped.

For example, consider the design of a two-input XOR function. The truth table and the modified Karnaugh map of the XOR function are given in Tables 8.2 and 8.3, respectively. By grouping the A column when B is 0, and the $\overline{A}$ column when B is 1, the function can be expressed as

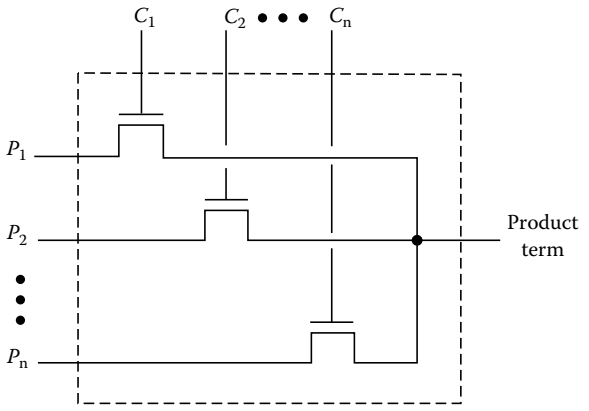

FIGURE 8.25 Model for pass transistor logic.

TABLE 8.2 Truth Table of XOR Function

A	B	A_B	Pass Function
0	0	0	$A+B$
0	1	1	$\overline{A}+B$
1	0	1	$A+\overline{B}$
1	1	0	$\overline{A}+\overline{B}$

TABLE 8.3 Modified Karnaugh Map for XOF Function

		B			
		0		1	
A	0	A		$\overline{A}$	
			B		B
	1	A		$\overline{A}$	
			$\overline{B}$		$\overline{B}$

$$F = \overline{B} \cdot A + B \cdot \overline{A} \tag{8.33}$$

where

B is a control variable

A is a pass variable

Figure 8.26a and b shows the schematic diagrams of nMOS and CMOS implementations of the XOR function. When the control variable B is with a logic 0 value, the pass variable A is transmitted to the output. When the control variable B is with a logic 1 value, the pass variable $\overline{A}$ is transmitted to the output. Another implementation of the XOR function is shown in Figure 8.26c.

It is not permitted to have groupings that transmit both true and false values of the input variable to the output simultaneously. The final expression must contain all the cells in the Karnaugh map. Note that

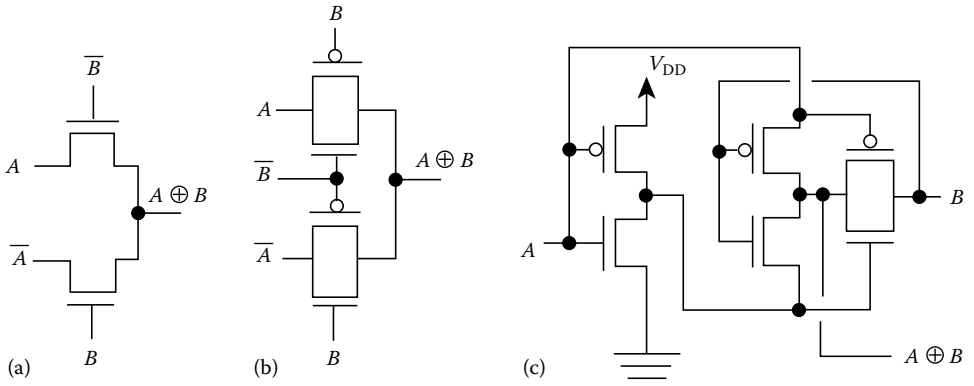

FIGURE 8.26 XOR gates: (a) nMOS version; (b) complementary version I; and (c) complementary version II.

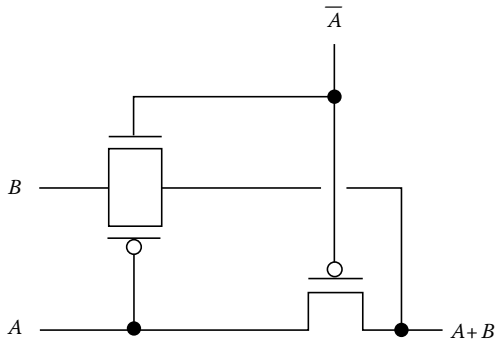

FIGURE 8.27 OR gates.

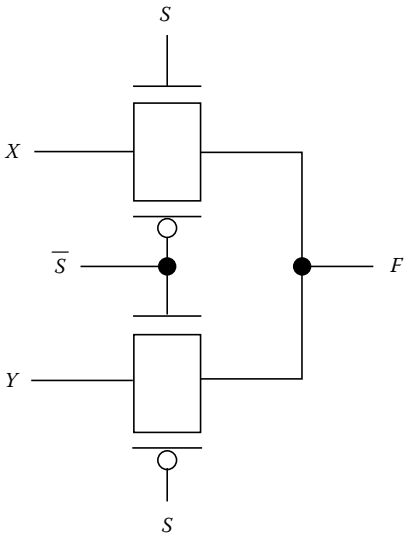

FIGURE 8.28 A two-input multiplexer.

the *p*-transistor circuit is the dual of the *n*-transistor circuit. Thus, the *p*-pass function must be constructed when a complementary version is required. In addition, the pass variable with logic 0 value is transmitted by the nMOS network in a complementary implementation while the pass variable with logic 1 value is transmitted by the pMOS network.

The OR function can be constructed by one pMOS transistor and one CMOS TG, as shown in Figure 8.27. When the input signal *A* is with the logic 0 value, the CMOS TG is turned on and the input signal *B* is passed to the output node. On the other hand, if the input signal *A* is with the logic 1 value, the pMOS TG is turned on and the logic 1 value of input signal *A* is transmitted to the output node. Because the pMOS TG can propagate a "strong" logic 1 value it is not necessary to use another CMOS TG.

TGs can be used to construct a multiplexer which selects and transmits one of the inputs to the output. Figure 8.28 is the circuit schematic diagram of a two-input multiplexer, which is composed of CMOS TGs. The output function of the two-input multiplexer is

$$F = X \cdot S + Y \cdot \overline{S} \tag{8.34}$$

If the selection signal *S* is at a logic 1 value, the input signal *X* is transmitted to the output. On the other hand, if the selection signal *S* is at a logic 0 value, the input signal *Y* is transmitted to the output. Multiplexers are important components in CMOS data manipulation structures and memory elements.

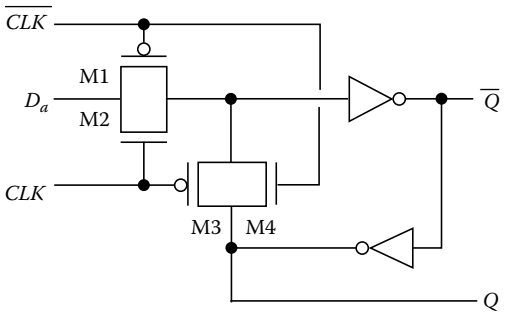

FIGURE 8.29 A CMOS *D* latch.

A basic *D* latch can be constructed by two TGs and two invertes, as shown in Figure 8.29. When the *CLK* signal is at a logic 0 value, pass transistors M1 and M2 are turned off so that the input signal D_a cannot be transmitted to the outputs Q and $\overline{Q}$. In addition, pass transistors M3 and M4 are turned on so that a feedback path around the inverter pair is established and the current state of Q is stored. When the *CLK* signal is at a logic 1 value, M1 and M2 are turned on and M3 and M4 are turned off. Thus, the output signal Q is set to the input signal D_a and $\overline{Q}$ is set to $\overline{D}_a$. Because the output signal Q will follow the change of input signal D_a when the *CLK* signal is high, this circuit is a positive level-sensitive *D* latch. A positive edge-trigger register or so-called *D* flip-flop can be designed by combining one positive level-sensitive *D* latch and one negative level-sensitive *D* latch. By cascading *D* flip-flops, a shift register can be constructed.

TGs can be used in the design of memory circuits. A typical random access memory (RAM) architecture consists of one row/word decoder, one column/bit decoder, and memory cells. The memory cells used in RAMs can be categorized into static cells and dynamic cells. Memory data/charges are stored on the latches in static cells, while on the capacitors in dynamic cells. The static random access memories (SRAMs) are not forced to include the refresh circuitry and are faster than the dynamic random access memories (DRAMs). However, the size of SRAM cells is much larger than that of DRAM cells. The most commonly used circuit in the design of SRAM cells is the six-transistor circuit shown in Figure 8.30. Four transistors are used to form two cross-coupled inverters. The other two transistors, M1 and M2, are TGs to control the read/write operation of the memory cell. If the word line is not selected, the data stored on the latch will not change as long as the leakage current is small. If the word line is selected, the transistors M1 and M2 are turned on. Through the *bit* and $\overline{bit}$ lines, data can be written into the latch or the stored data can be read out by the sense amplifier. TGs can also be found in the four-transistor DRAM cell circuit, as shown in Figure 8.30b. When the *Read* line is selected, pass transistor M1 is turned on and the data stored on the capacitor C_1 are read out. When the *Write* line is selected, pass transistor M2 is turned on and the data from *data_W* line are written into the cell.

Figure 8.31 is the circuit schematic diagram of a TG adder, which consists of four TGs, four inverters, and two XOR gates [4]. The *SUM* output, which represents $A \oplus B \oplus C$, is constructed by a multiplexer controlled by $A \oplus B$ and its complement. Notice that when $A \oplus B$ is false, the *CARRY* output equals *A* or *B*. Otherwise, *CARRY* output takes the value of input signal *C*. Although the TG adder has the same

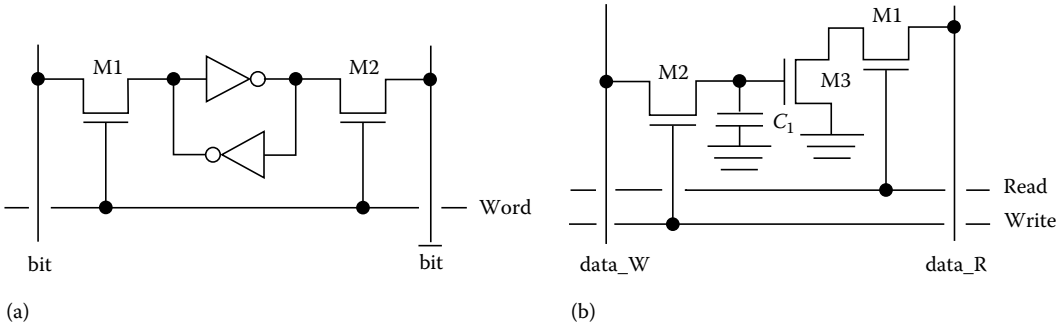

FIGURE 8.30 (a) SRAM cell and (b) DRAM cell.

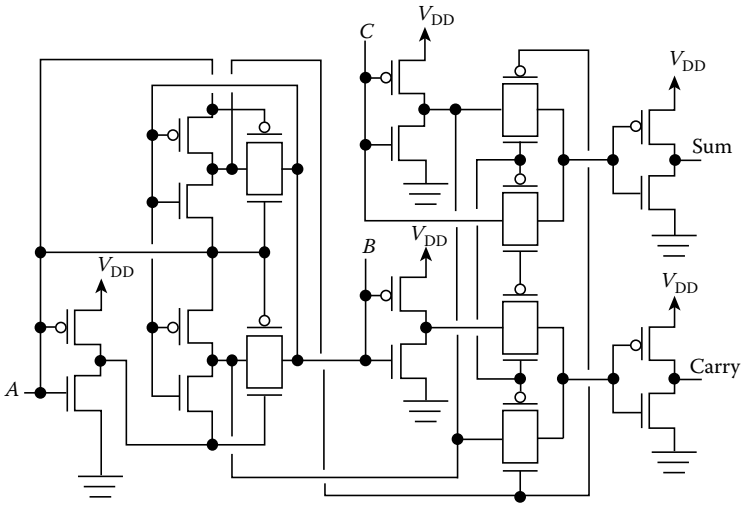

FIGURE 8.31 TG adder.

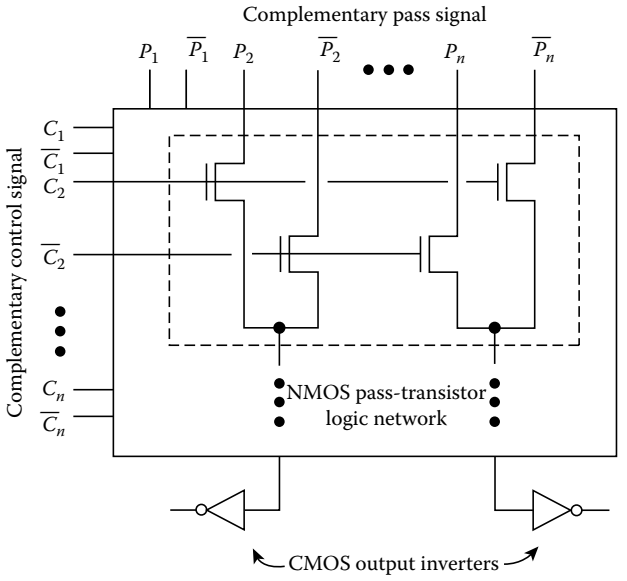

FIGURE 8.32 Schematic structure of the basic CPL circuit.

number of transistors as the combinational adder, it has the advantage of having noninverted *SUM* and *CARRY* output signals and an equal delay time for the *SUM* and *CARRY* output signals.

Another form of differential CMOS logic, complementary pass-transistor logic (CPL), has been developed and utilized on the critical path to achieve very high speed operation [5]. Figure 8.32 is the circuit schematic diagram of the basic CPL structure using an nMOS pass-transistor logic organization. The CPL is constructed by an nMOS pass-transistor logic network, complementary inputs and outputs, and CMOS output inverters. As the nMOS pass transistor will transmit a logic 1 signal with one threshold voltage reduction, the output signals must be amplified by the CMOS inverters which can shift the logic threshold voltage and drive a large capacitive load. One attractive feature of the CPL design

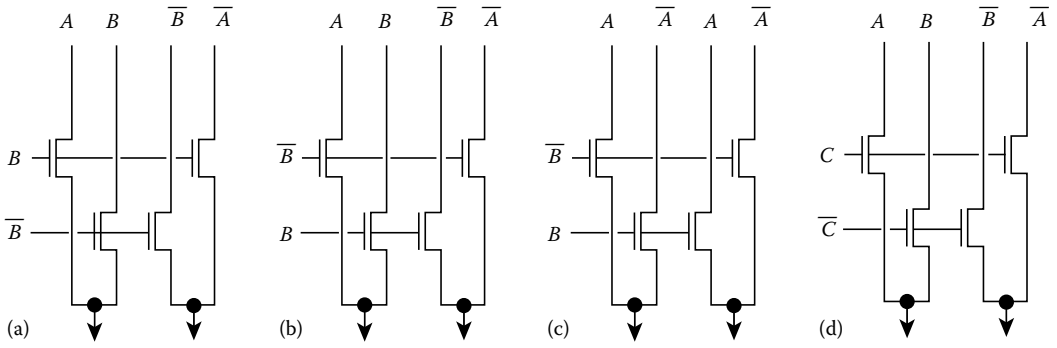

FIGURE 8.33 CPL circuit modules: (a) AND/NAND; (b) OR/NOR; (c) XOR/XNOR; and (d) Wire-AND/NAND.

is that complementary outputs are generated by the simple four-transistor circuits. Because inverters are not required in CPL circuits, the number of critical-path gate stages can be reduced.

Figure 8.33 shows the schematic diagrams of four basic CPL circuit modules: an AND/NAND module, an OR/NOR module, an XOR/XNOR module, and a wired-AND/NAND module [5]. By combining these four circuit modules, arbitrary Boolean functions can be constructed. These modules have an identical circuit schematic and are distinguished by different arrangements of input signals. This property of CPL is quite suitable for master-slice design.

The schematic diagram of a CPL full adder is shown in Figure 8.34. Both the circuitry to produce the *SUM* output signal and the circuitry to produce the *CARRY* output signal are constructed from basic CPL modules. The *SUM* circuitry consists of two XOR/XNOR modules, while the *CARRY* circuitry consists of three wired-AND/NAND modules. The CMOS output inverters are fixed ''overhead'' because they are required whether the circuit has one, two, or many inputs. Thus, designing with a complex Boolean function in a CPL gate is preferred to minimize the delay time and overall device count.

Figure 8.35 is the block diagram of a 16×16 bit multiplier, which is constructed by using a parallel multiplication architecture. A carry-look-ahead (CLA) adder and a Wallace-tree adder array are used to minimize the critical-path gate stages. The number of transistors in the CPL multiplier is less than that in a full CMOS counterpart [6].

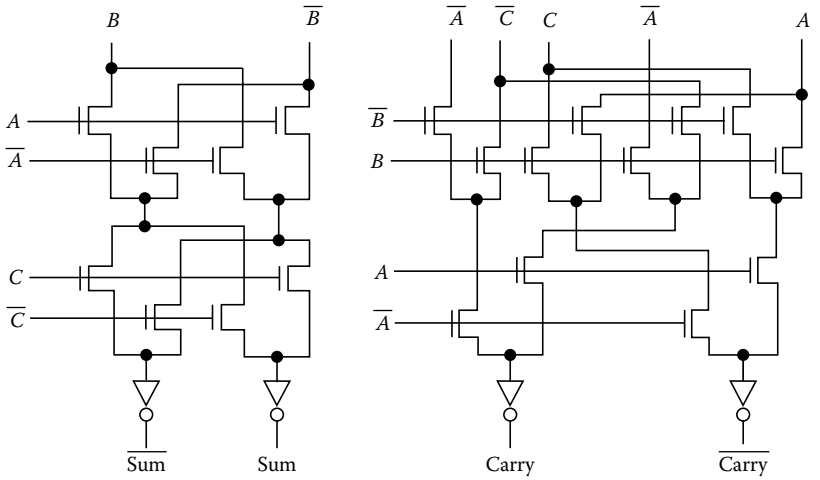

FIGURE 8.34 CPL full adder circuit.

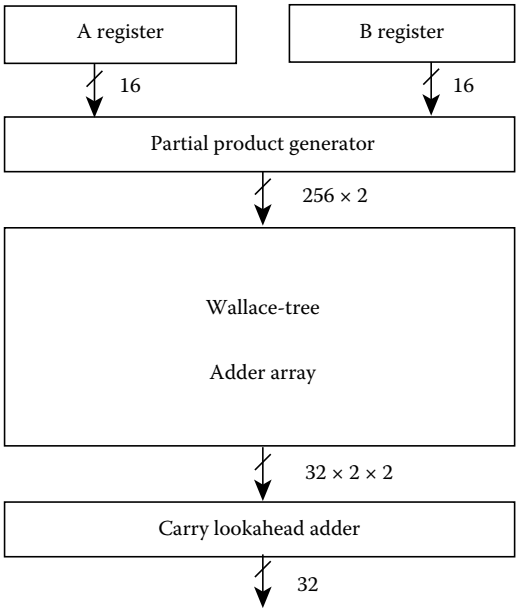

FIGURE 8.35 Block diagram of the 16 × 16 bit multiplier.

Due to the continued device miniaturization and the recent drive of portable systems, VLSI systems have been pushing toward low-voltage, low-power operation. Various techniques from system level to device level were developed to reduce the operating voltage and the power consumption of the VLSI circuits [7,8]. The low-power design can be addressed at four levels: algorithm, architecture, logic style, and integration. At the logic design level, capacitive loads are to be reduced and the number of charging/discharging operations are to be minimized. A CPL is one of the most attractive logic families that can achieve very low power consumption. The input capacitance in CPL is about half that of the CMOS configuration because pMOS can be eliminated in logic organization. Therefore, CPL can achieve a higher speed and dissipate less power. Experimental results [5] show that for the same delay time of the CMOS full adder operating at 5 V, the CPL adder requires only a 2 V supply. As the supply voltage decreases, the delay time will increase, but the power-delay product will decrease. Hence, it is desirable to operate at the slowest allowable speed to reduce power dissipation. Experimental results indicate that performance of CPL logic style is better than the conventional CMOS logic style from the viewpoint of power consumption.

8.2.2 Analog Processing

8.2.2.1 MOS Operational Amplifier Compensation

The frequency stabilization of a basic two-stage CMOS amplifier can be achieved by using a pole-splitting capacitor C_C [9]. The pole p_1 due to the capacitive loading of the first stage is pushed down to a very low frequency, and the pole p_2 due to the capacitance at the output node of the second stage is pushed to a very high frequency. However, a right-half-plane zero is introduced by the feedthrough effect of the compensation capacitor C_C. It will degrade the stability of the op-amp and make the second stage behavior like a short-circuited configuration at high frequencies. In order to remove the effects of the zero, a source follower can be inserted in the path from the output back through the compensation capacitor. Another approach is to insert a nulling resistance, R_Z, in series with the compensation capacitor. If R_Z is set to $1/g_{M2}$, where g_{M2} is the transconductance of the second stage, the zero

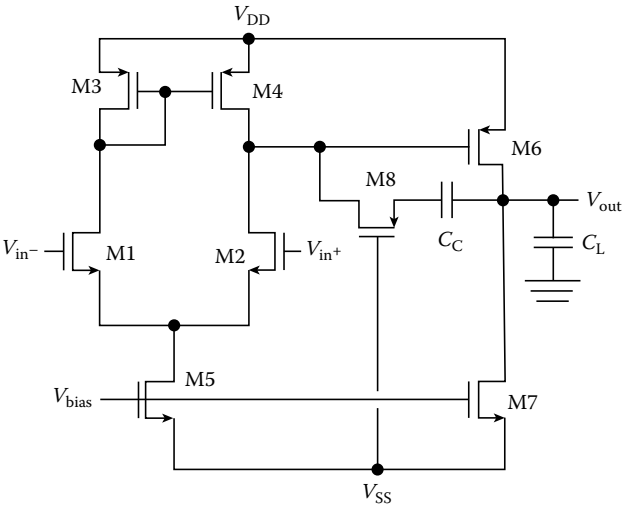

FIGURE 8.36 CMOS op-amp.

vanishes and the feedthrough effect is cancelled out. A single transistor or complementary version of the TG can be used to implement R_Z. Figure 8.36 is the schematic diagram of a basic two-stage op-amp supplemented by a feedback branch (M8, C_C) for compensation [10]. Capacitance C_L is the load capacitance to be driven by the amplifier. The pMOS TG M8 is biased in the triode region and provides the equivalent resistance.

TGs can be used to construct the cascode configuration of an op-amp. A fully differential folded-cascode op-amp is shown in Figure 8.37 [10]. The output cascode stage consists of TGs M5 to M10.

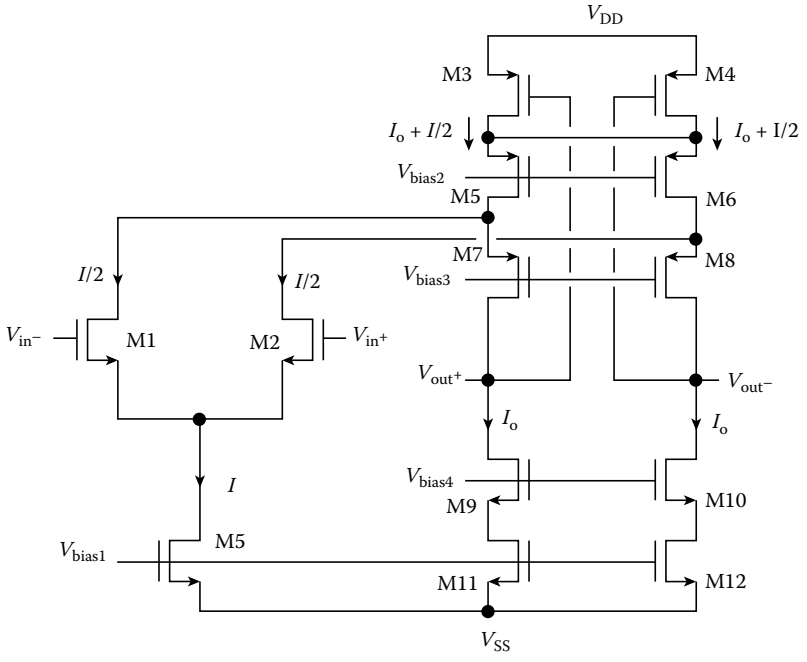

FIGURE 8.37 A fully differential CMOS op-amp with stabilized DC output level.

A high output impedance can be achieved by using the split-load arrangement. The bias voltage V_{bias1} establishes the bias current I of the input stage, and a bias current I_{o} in the output transistors M7 to M12. Thus, each transistor of M3 to M6 has a stabilized current $I_{\text{o}} + I/2$. The source voltages of M5 and M6 are stabilized because they conduct stabilized currents and their gate voltages are fixed at V_{bias2}. This fixes $|v_{\text{DS}\,3}|$ and $|v_{\text{DS}\,4}|$. Let transistors M3 and M4 have the same W/L ratio and bias them in the triode region by choosing a suitable value for V_{bias2}. If the output common-mode voltage $v_{\text{o,c}}$ drops, the resistance of M3 and M4 reduces, which increases $|v_{\text{GS}\,5}|$ and $|v_{\text{GS}\,6}|$. Because the current in M5 and M6 remains unchanged, $|v_{\text{DS}\,5}|$ and $|v_{\text{DS}\,6}|$ are forced to decrease. Then, the drain voltages of M5 and M6 increase, which increases $|v_{\text{GS}\,7}|$ and $|v_{\text{GS}\,8}|$. Therefore, $|v_{\text{DS}\,7}|$ and $|v_{\text{DS}\,8}|$ reduce which forces v_{o}^{+} and v_{o}^{-} to rise. The common-mode voltage $v_{\text{o,c}}$ is thus increased. This approach can increase the common-mode rejection ratio (CMRR) of the op-amp. The negative feedback scheme tends to keep $v_{\text{o,c}}$ at a constant value. It means that the small-signal common-mode output is zero or a very small value. Thus, a high CMRR is achieved.

8.2.2.2 Transimpedance Compensation

The optical receiver is an important component of the optical fiber communication system. One of the basic modules in a high performance optical receiver is the low-noise preamplifier. Several approaches are available to design the preamplifier. One approach is to use the transimpedance design which can avoid the equalization and limited dynamic range problems by using negative feedback. TGs can be used to provide the feedback resistance for a transimpedance amplifier.

A complete preamplifier circuit schematic is given in Figure 8.38 [11]. This circuit consists of three gain stages and two TGs. Each gain stage is composed of a pMOS current source achieving a common-source amplification with a folded nMOS load. One TG transistor, M10, functions as a feedback resistor and the other, M11, functions to implement the automatic gain control function. The gate voltage of M10 is derived from another circuit which minimizes the temperature and power supply dependence of the feedback resistance [11]. Transistor M11 is controlled by the automatic gain control voltage [12] and is normally off. If the input current to the preamplifier forces the output voltage out of its linear range, M11

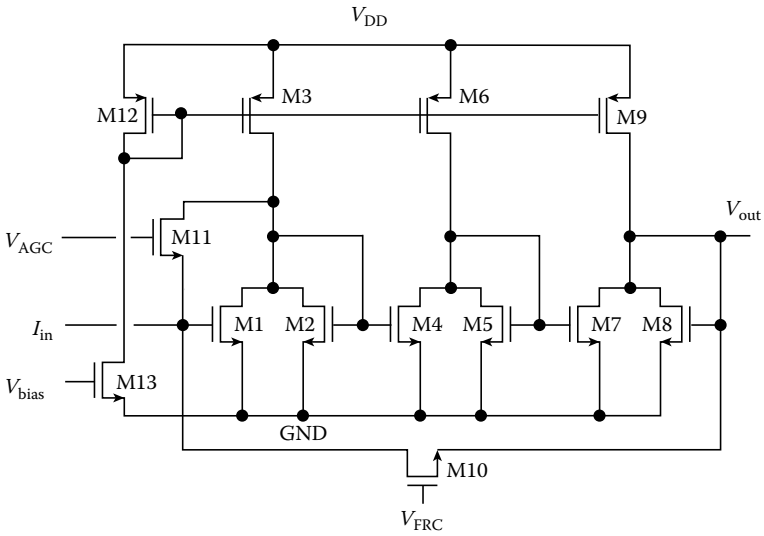

FIGURE 8.38 Circuit schematic of a preamplifier.

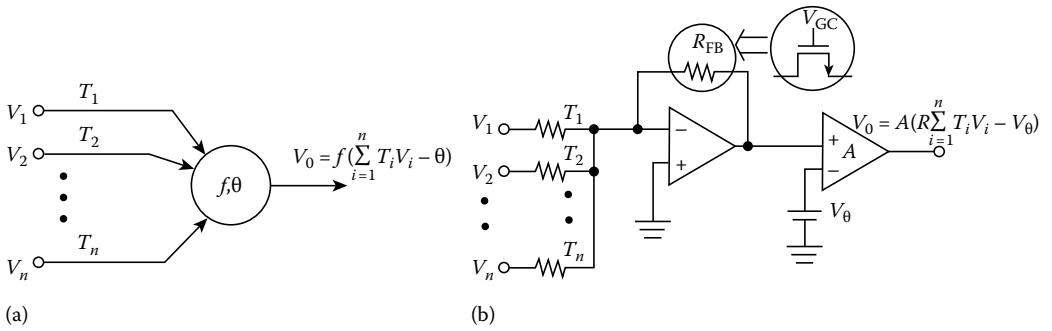

FIGURE 8.39 Neuron and synapse operation: (a) mathematical model and (b) analog circuit model with adjustable gain.

is turned on and begins to shunt current away from the feedback resistor and into the first stage output node.

With recent progress in intelligent information processing, artificial neural networks can be used to perform several complex functions in scientific and engineering applications, including classification, pattern recognition, noise removal, optimization, and adaptive control [13]. Design and implementation of VLSI neural networks have become a very important engineering task. The basic structure of an artificial neural network consists of a matrix of synapse cells interconnecting an array of input neurons with an array of output neurons. The inputs, V_i, are multiplied by weight values, T_i, of the synapses. The results of the multiplication are summed and compared to the threshold value θ_i in the output neurons. Schematic diagrams of a mathematical model of a neuron and its electronic counterpart are shown in Figure 8.39. The circuit in Figure 8.39b uses a gain-controllable amplifier in which the voltage gain is controlled by changing the feedback resistance. The feedback resistor R_{FB} can be constructed by the TG structure so that feedback resistance can be adjusted by the gain-control voltage V_{GC} [14].

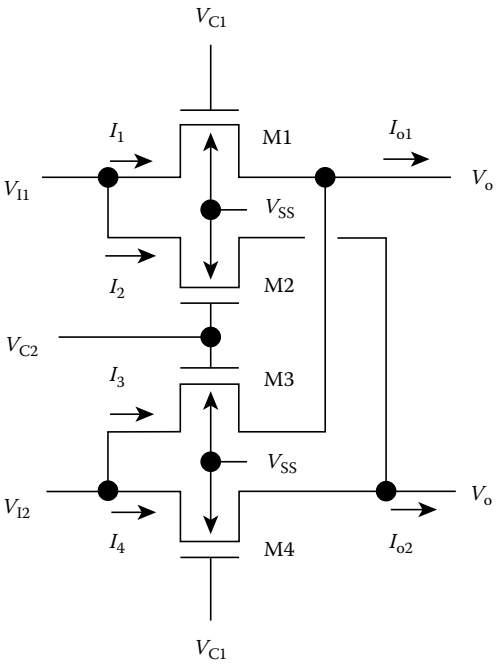

FIGURE 8.40 Double-MOS implementation of a differential AC resistor.

8.2.2.3 Continuous-Time Filters

Resistors are important components in the construction of continuous time filters [15]. However, the implementation of resistors by integrator circuit (IC) fabrication technologies was found to be lacking in several areas of performance. The TG can be used to realize active resistance. For example, a double-MOS differential configuration, shown in Figure 8.40, is used to implement a differential AC resistor [16].

This circuit consists of four nMOS TGs. Not only can it linearize the AC resistor, but it can also eliminate the effects of the bulk-source voltage [17]. To determine the AC resistance, assume that all the transistors are matched and are biased in the triode region.

The current I_{o1} and I_{o2} can be expressed as

$$\begin{aligned} I_{o1} &= I_1 + I_3 \\ &= \mu_n C_{OX}(W/L)\left[(V_{C1} - V_0 - V_{thn})(V_{I1} - V_0) - (1/2)(V_{I1} - V_0)^2\right] \\ &\quad + \mu_n C_{OX}(W/L)\left[(V_{C2} - V_0 - V_{thn})(V_{I2} - V_0) - (1/2)(V_{I2} - V_0)^2\right] \end{aligned} \tag{8.35}$$

$$\begin{aligned} I_{o2} &= I_2 + I_4 \\ &= \mu_n C_{OX}(W/L)\left[(V_{C2} - V_0 - V_{thn})(V_{I1} - V_0) - (1/2)(V_{I1} - V_0)^2\right] \\ &\quad + \mu_n C_{OX}(W/L)\left[(V_{C1} - V_0 - V_{thn})(V_{I2} - V_0) - (1/2)(V_{I2} - V_0)^2\right] \end{aligned} \tag{8.36}$$

Equations 8.35 and 8.36 can be combined to determine the differential current

$$I_{o1} - I_{o2} = \mu_n C_{OX}(W/L)[(V_{C1} - V_{C2})(V_{I1} - V_{I2})] \tag{8.37}$$

Thus, r_{ac} is given by

$$r_{ac} = \frac{V_{I1} - V_{I2}}{I_{o1} - I_{o2}} = \frac{1}{\mu_n C_{OX}(W/L)(V_{C1} - V_{C2})} \tag{8.38}$$

Because all transistors are required to be biased in the triode region, Equation 8.38 holds when

$$V_{I1}, V_{I2} \leq \min\left[V_{C1} - V_{thn}, V_{C2} - V_{thn}\right] \tag{8.39}$$

The double-MOSFET differential resistor is really a transresistance, thus, it can be applied only to differential-in, differential-out op-amps.

8.2.2.4 Switched-Capacitor Circuits

Switched-capacitor circuits make use of TGs in processing the analog signals [10,16]. This approach uses switches and capacitors and is in discrete time. If the clock rate is much higher than the signal frequency, an AC resistor can be implemented by combining switches and capacitors. The equivalent resistance is dependent only on the clock rate and the capacitor. The circuit schematic diagram of the direct digital integrator (DDI) is shown in Figure 8.41. The resistance is realized by two MOS switches and one capacitor. The difference equation can be expressed as

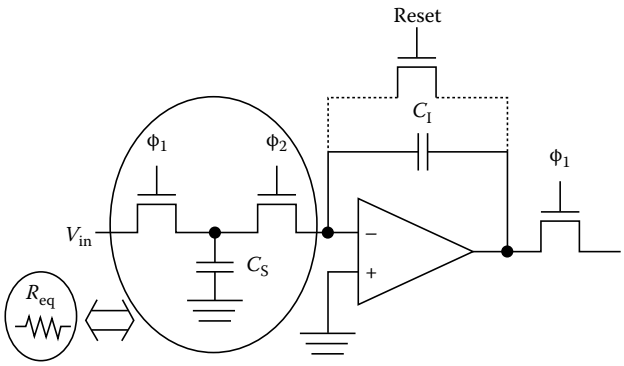

FIGURE 8.41 Direct digital integrator.

$$v_{0,n+1} = v_{0,n} - \frac{C_S}{C_I} v_{in} \tag{8.40}$$

After taking the z-transform, the new expression becomes

$$z \cdot V_0(z) = V_0(z) - \frac{C_S}{C_I} V_{in}(z) \tag{8.41}$$

By rearranging the various terms, the transfer function of the DDI can be expressed as

$$\frac{V_0(z)}{V_{in}(z)} = -\frac{C_S}{C_I} \cdot \frac{z^{-1}}{1 - z^{-1}} \tag{8.42}$$

By setting $z = e^{j\omega T}$, the frequency response can be determined:

$$\frac{V_0}{V_{in}}(j\omega) = -\frac{C_S}{C_I} \frac{1}{j\omega T} \cdot \frac{\omega T/2}{\sin(\omega T/2)} \cdot e^{-j\omega T/2} \tag{8.43}$$

where T is the period of the clock. In Equation 8.43, the first term corresponds to an ideal integrator, the second term contributes to the magnitude error, and the third term is the phase error. Because the frequency response of the ideal integrator is $-[j\omega R_{eq} C_I]^{-1}$, the equivalent resistance value is determined by

$$R_{eq} = \frac{T}{C_S} \tag{8.44}$$

A ladder network can be constructed by cascading the DDI integrators. In the ladder network all cascaded stages sample the input signal at clock Φ_1 and transform the signal at clock Φ_2, where Φ_1 and Φ_2 are nonoverlapping clock signals. This clocking scheme induces the extra half-cycle phase delay. This phase error can cause extra peaking in frequency response and generate cyclic response. In order to remove the excess phase, other integrators, such as lossless digital integrators (LDI) or bilinear integrators, can be used. In an LDI ladder network, the odd-number stages sample the input signal at clock Φ_1 and transform the signal at clock Φ_2, while the even-number stages sample the input signal at clock Φ_2 and transform the signal at clock Φ_1. Thus, the frequency response of an LDI integrator can be expressed by

$$\frac{V_0}{V_{in}}(j\omega) = -\frac{C_S}{C_I} \frac{1}{j\omega T} \cdot \frac{\omega T/2}{\sin(\omega T/2)} \tag{8.45}$$

Figure 8.42 is the circuit schematic diagram of the bottom-plate differential-input LDI. Output of an LDI integrator is more insensitive to parasitic components.

Figure 8.43 is the circuit schematic diagram of a differential bilinear integrator. The transfer function of the bilinear integrator is

$$\frac{V_0^+ - V_0^-}{V_{in}^+ - V_{in}^-} = \frac{C_S}{C_I} \cdot \frac{1 + z^{-1}}{1 - z^{-1}} \tag{8.46}$$

As the output of the bilinear integrator does not change during clock Φ_1, it can be used to feed another identical integrator.

TGs can be used to initialize the switched-capacitor circuits. For example, capacitor C_I in Figure 8.41 is to perform the integration function and to be reset or discharged before operation. An nMOS TG can be

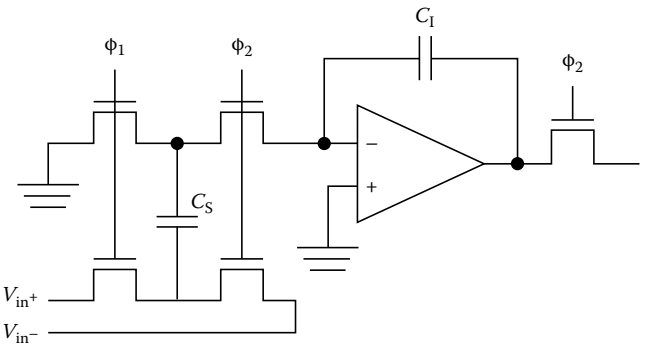

FIGURE 8.42 Bottom-plate differential-input lossless digital integrator.

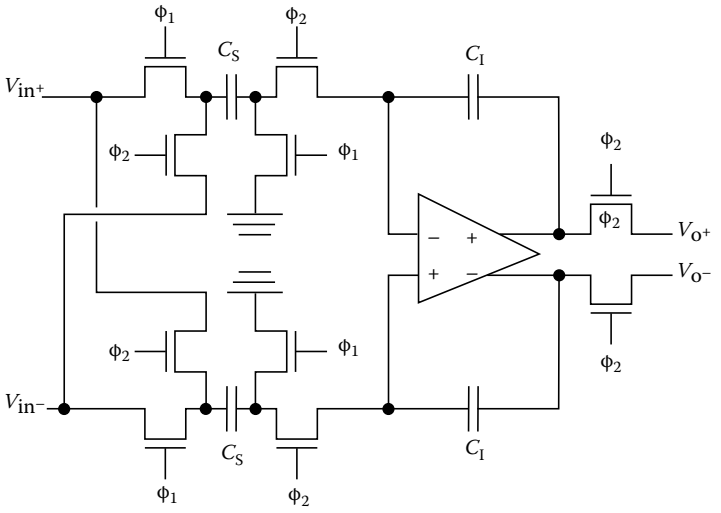

FIGURE 8.43 Differential bilinear integrator.

put in parallel with the capacitor C_I. Before normal operation, the TG is turned on and the capacitor C_I is discharged so that the initial capacitor voltage value is reset to zero.

The accuracy of switched-capacitor circuits is disturbed by charge injection when the controlling switch turns off. The turn-off of an MOS switch consists of two phases. The gate voltage is higher than the transistor threshold voltage V_{th} during the first phase. A conduction channel extends from the source to the drain of the transistor. As the gate voltage decreases, mobile carriers exit through both the drain and the source terminals and the channel conduction decreases. During the second phase, the gate voltage is smaller than V_{th} and the conduction channel no longer exists. The coupling between the gate and the data-holding node is only through the gate-to-diffusion overlap capacitance. The following analysis is focused on the switch charge injection due to the first phase of the switch turn-off.

Figure 8.44 is the circuit schematic corresponding to the general case of switch charge injection. Capacitance C_L is the lumped capacitance at the data-holding node. Capacitance C_S could be the lumped capacitance associated with the amplifier output node, while resistance R_S could be the output resistance of an op-amp. Let C_G represent the total gate capacitance of the switch, including both the channel

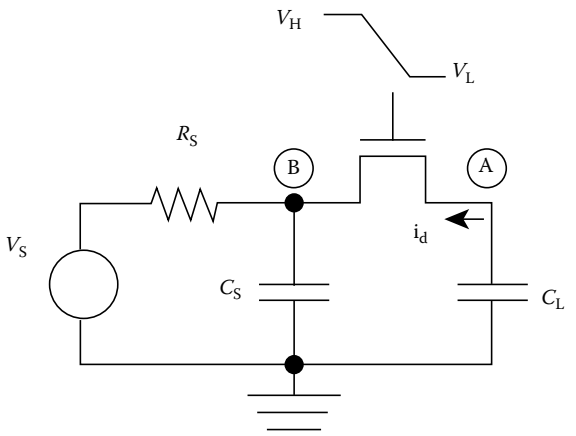

FIGURE 8.44 Circuit for analysis of switch charge injection.

capacitance and gate-to-drain/gate-to-source overlap capacitances. Kirchhoff's current law at node *A* and node *B* requires

$$C_L \frac{dv_L}{dt} = -i_d + \frac{C_G}{2} \frac{d(V_G - v_L)}{dt} \tag{8.47}$$

and

$$\frac{v_S}{R_S} + C_S \frac{dv_S}{dt} = i_d + \frac{C_G}{2} \frac{d(V_G - v_S)}{dt} \tag{8.48}$$

where v_L and v_S are the error voltages at the data-holding node and the signal-source node, respectively. Gate voltage is assumed to decrease linearly with time from the turn-on value V_H:

$$V_G = V_H - \alpha t \tag{8.49}$$

where α is the falling rate. When the transistor is biased in the strong inversion region,

$$i_d = \beta(V_{HT} - \alpha \cdot t)(v_L - v_S) \tag{8.50}$$

where

$$\beta = \mu C_{OX} \frac{W}{L} \tag{8.51}$$

and

$$V_{HT} = V_H - V_S - V_{thn} \tag{8.52}$$

Here, V_{thn} is the transistor effective threshold voltage, including the body effect. For small-geometry transistors, narrow- and short-channel effects should be considered in determining the V_{thn} value. Under the condition $|dV_G/dt| \gg |dV_L/dt|$ and $|dV_S/dt|$, and Equations 8.47 and 8.48 can be simplified to

$$C_L \frac{dv_L}{dt} = -\beta(V_{HT} - \alpha t)(v_L - v_S) - \frac{C_G}{2}\alpha \tag{8.53}$$

and

$$\frac{v_S}{R_S} + C_S \frac{dv_S}{dt} = \beta(V_{HT} - \alpha t)(v_L - v_S) + \frac{C_G}{2}\alpha \tag{8.54}$$

No closed-form solution to this set of equations can be found. Numerical integration can be employed to find final results. Analytical solutions to special cases are given next.

Figure 8.45a is the circuit schematic diagram of the case, with only a voltage sourced at the signal-source node. Because $C_S \gg C_L$, v_S can be approximated as zero and the governing equation reduces to

$$C_L \frac{dv_L}{dt} = -\beta(V_{HT} - \alpha t)v_L - \frac{C_G}{2}\alpha \tag{8.55}$$

When the gate voltage reaches the threshold condition, the error voltage at the data-holding node is

$$v_L = -\sqrt{\frac{\pi\alpha C_L}{2\beta}}\left(\frac{C_G}{2C_L}\right)\text{erf}\left(\sqrt{\frac{\beta}{2\alpha C_L}}V_{HT}\right) \tag{8.56}$$

Notice that the value of the error function erf(·) can be found from mathematical tables.

Another special case is when the source capacitance is negligibly small, as is shown in Figure 8.45b. The governing equations reduce to

$$C_L \frac{dv_L}{dt} = -\beta(V_{HT} - \alpha t)(v_L - v_S) - \frac{C_G}{2}\alpha \tag{8.57}$$

and

$$\frac{v_S}{R_S} = \beta(V_{HT} - \alpha t)(v_L - v_S) + \frac{C_G}{2}\alpha \tag{8.58}$$

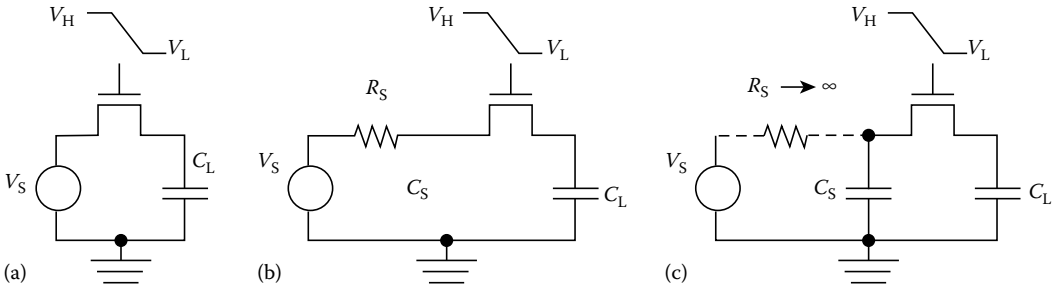

FIGURE 8.45 Special cases of switch charge injection: (a) no source resistance and capacitance; (b) no source capacitance; and (c) infinitely large source resistance.

When the gate voltage reaches the threshold condition, the error voltage at the data-holding node is

$$v_L = -\frac{\alpha C_G}{2C_L}\exp\left(-\frac{V_{HT}}{\alpha C_L R_S}\right)\cdot\int_0^{V_{HT}/\alpha}[\beta R_S(V_{HT}-\alpha\theta)+1]^{1/C_L\beta R_S^2\alpha}$$
$$\cdot\exp\left(\frac{\theta}{C_L R_S}\right)\left(2-\frac{1}{1+\beta R_S(V_{HT}-\alpha\theta)}\right)d\theta \tag{8.59}$$

If a time constant $R_S C_S$ is much larger than the switch turn-off time, then the channel charge will be shared between C_S and C_L, as shown in Figure 8.45c. For the case of a symmetrical transistor and $C_S = C_L$, half of the channel charge will be deposited to each capacitor. Otherwise the following equations can be used to find the results:

$$C_L\frac{dv_L}{dt} = -\beta(V_{HT}-\alpha t)(v_L - v_S) - \frac{C_G}{2}\alpha \tag{8.60}$$

and

$$C_S\frac{dv_S}{dt} = \beta(V_{HT}-\alpha t)(v_L - v_S) + \frac{C_G}{2}\alpha \tag{8.61}$$

We can multiply Equation 8.61 by the ratio C_L/C_S and then subtract the result from Equation 8.60 to obtain

$$C_L\frac{d(v_L - v_S)}{dt} = -\beta(V_{HT}-\alpha t)\left(1+\frac{C_L}{C_S}\right)(v_L - v_S) - \frac{\alpha C_G}{2}\left(1-\frac{C_L}{C_S}\right) \tag{8.62}$$

When the gate voltage reaches the threshold condition, the amount of voltage difference between the data-holding node and the signal-source node becomes

$$v_L - v_S = -\sqrt{\frac{\pi\alpha C_L}{2\beta(1+C_L/C_S)}}\left(\frac{C_G(1-C_L/C_S)}{2C_L}\right)$$
$$\cdot\,\mathrm{erf}\left(\sqrt{\frac{\beta(1+C_L/C_S)}{2\alpha C_L}}V_{HT}\right) \tag{8.63}$$

9.1 Programmable Logic Devices

Festus Gail Gray

Traditional programmable logic devices (PLDs) and field programmable gate arrays (FPGAs) allow circuit designers to implement logic circuits with fewer chips relative to standard gate level designs based on primitive gates and flip-flops. As a result, layout and unit production costs are generally reduced. In this chapter, we use the term ''programmable device'' to refer to the class of moderately complex single-chip devices, in which the user in the field can program the function of the device. We include

TABLE 9.1 Complexity Ladder of Devices

Device	Complexity of a Single Chip	Range of Realizable Functions	Initial Design and Cost of Design Change	Unit Product Cost (High Volume)	Time to Market
SSI discrete gate chip	Lowest	All functions	High	High	High
MSI chip		Narrow	High	High	High
PLD[a]		Moderate	Low	Moderate	Low
LSI (PROM)[a]		All combinational functions with n inputs	Very low	Moderate	Low
FPGA		Wide	Low	Moderate	Low
MPGA		Wide	High	Low	High
Standard cell		Wide	High	Low	High
Custom chip	Highest	All functions	Very high	Very low	Very high

[a] Field programmable.

such devices as the programmable logic array (PLA), programmable array logic (PAL), programmable read-only memory (PROM), and the FPGA. Since most commercial vendors provide software design aids for mapping designs to their specific chips, initial design costs and time to market are low. Another important advantage of programmable device designs is ''flexibility.'' Design changes do not require physical changes to the printed circuit board as long as the revised functions still fit onto the same programmable chip. The low cost of design revisions makes programmable chips very attractive for prototype design and low volume production. Designers often move up the design ladder once proven designs move into high volume production.

Table 9.1 shows the position of PLDs, PROMs, and FPGAs on the complexity ladder of device types. In the ''range of realizable functions'' column, we compare the range of realizations for various device types. Discrete gates can implement any function if enough gates are available. MSI chips implement very specialized functions such as shift registers, multiplexers (MUXs), decoders, etc. Table 9.1 compares programmable devices (PLDs, FPGAs, and PROMs) relative to the range of functions that can be implemented on a single chip. A PROM chip with n address inputs can implement any combinational function of n variables. A PLD chip with n inputs can implement only a subset of the combinational functions of n variables. Gate arrays can implement a wide range of both combinational and sequential functions. The programmable devices are characterized by low time to market, low design cost, low cost of modifications, and moderate production costs. Nonfield programmable devices such as mask programmable gate arrays (MPGAs), standard cell devices, and full custom devices are characterized by high initial design costs and longer time to market, but have lower volume production costs. Custom chips are preferred for large volume production because of the very low unit production costs. However, initial design costs and the cost of design changes are very high for custom chip design. Also, the design of custom chips requires highly trained personnel and a large investment in equipment. The low design cost, low cost of design changes, and low time to market make PLDs and FPGAs good choices for lower volume production and for prototype development.

The primary difference between PLDs and FPGAs arise because of a difference in the ratio of the number of combinational logic (CL) gates to the number of flip-flops. PLD devices are better for applications that require complex CL functions that drive a relatively small number of flip-flops, such as finite-state machine (FSM) controllers or purely CL functions. FPGAs are better for devices that require arithmetic operations (adders, multipliers, and arithmetic logic units [ALUs]), or that require a large number of registers and less complex CL functions, such as digital filters.

9.1.1 PLD Device Technologies

Companies produce PLD devices in different technologies to meet varying design and market demands. There are two categories of technologies. ''Process technology'' refers to the underlying semiconductor

structure, which affects device speed, power consumption, device density, and cost. ''Programming technology'' refers to the physics of chip programming and affects ease of programming and the ability to reprogram or to reconfigure chips.

9.1.1.1 Process Technologies

The dominant technologies in PLD devices are bipolar and CMOS. Bipolar devices are faster and less expensive to manufacture, but consume more power than CMOS devices. The higher power requirements of bipolar devices limit the gate density. Typical CMOS devices, therefore, achieve much higher gate densities than bipolar devices. The power consumption of CMOS devices depends on the application because a CMOS device only consumes power when it is switching states. The amount of power consumed increases with the speed of switching. Therefore, the total amount of power consumed depends on the frequency and speed of state changes in the device. Some devices have programmable power standby activation that puts the device in a lower power consumption configuration if no input signal changes for a predefined amount of time. The device then responds to the next input change much slower than normal but switches back to the faster speed configuration and maintains the faster speed as long as input changes continue to occur frequently. When programmed in the ''standby power mode,'' power consumption is reduced on the average at the expense of response time of the device. When programmed to operate in the ''turbo'' mode, the device stays in the faster configuration at all times. The result is higher power consumption, but faster response time. The mode of operation is selected by the user to match the requirements of an application.

To take advantage of the higher densities of CMOS devices and still be compatible with bipolar devices, many CMOS PLAs have special driver circuits at the input and output pins to allow pin compatibility with popular bipolar devices such as the commonly used TTL devices.

ECL is a very high-speed technology used in some PLD devices. Although ECL has the highest speed of the popular technologies, the power consumption is very high which severely limits the gate density.

Security is another issue that is related to process technology. Many PLDs have a programmable option that prevents reading the program. Since the software provided by most manufacturers allows the user to read the program in the chip in order to verify correct programming, it is extremely easy to copy designs. To prevent illegal copying of patented designs, one simply blows the ''security fuse,'' which permanently prevents anyone from reading the program by normal means. However, the program in most bipolar circuits can easily be read by removing the case and examining the programmed fuses under a microscope. CMOS PLDs are much more secure because it is virtually impossible to determine the program by examining the circuit.

9.1.1.2 Programming Technologies

The programming technologies used in PLDs are virtually the same as the programming technologies available for read-only memories (ROMs). Programming technologies are divided into two broad categories: mask programmable devices and field programmable devices.

In mask programmable technologies, identical base chips are produced in mass. The final metallization step is simply omitted. A mask programmable PLD chip is programmed by performing a final metal deposition step that selects the programming options. Clearly, this step must be performed at the manufacturer's plant. The user makes entries on order forms that specify how the chip is to be programmed and sends it to the manufacturer. The manufacturer must then prepare one or more production masks prior to making the chip. Mask programmable devices incur a high setup cost to make the first device, but unit production costs are typically less than half of that for field programmable technologies. The usual practice is to use field programmable devices for prototype work and implement only proven designs in mask programmable technologies when a large production volume is required. Many PLD devices are available in both mask programmable and field programmable versions, which make the conversion easy and reliable.

The user can program field programmable technologies directly. Specialized equipment is needed. Modern programming devices can actually program both ROM and PLD devices. The programmer is typically controlled by a small computer (PC) and uses files prepared in standard format (JEDEC) by software provided by the manufacturer or written by software vendors. Such software can include elegant features such as a programming language (ABEL, VHDL, Verilog, etc.), truth table input, equation input, or state machine input. Selection of a chip vendor should include careful evaluation of the support software for programming the chip.

Field programmable PLD technologies can be classified into three broad categories: fusible link PLDs, ultraviolet erasable PLDs (EPLDs), and electrically erasable PLDs (EEPLDs). Field programmable ROMS come in analogous forms: fusible link ROMs (PROMs), ultraviolet erasable ROMS (EPROMs), and electrically erasable ROMS (EEPROMs).

Fusible link PLDs typically utilize bipolar process technology. The programmer blows selected fuses in the device. Because higher than normal voltages and currents are required to blow the fuses, programming fusible link PLDs can be quite stressful for the device. Overheating is a common problem. However, this technology is quite well developed and the design of programming devices is sufficiently mature so that reliable results can be expected as long as directions are carefully followed. Fusible link technologies provide the convenience of on-site programming, which reduces the time required to develop designs and the time required to make design changes. The trade-off involves at least a twofold increase in per unit cost and a significant reduction in device density relative to mask programmable devices because the fuses take up considerable chip space. A fusible link PLD can be programmed only once because the blown fuses cannot be restored.

''Ultraviolet EPLDs'' have a window on the top of the chip. Programming the chip involves storing charges at internal points in the circuit that control switch settings. Shining ultraviolet light through the window on the chip can dissipate the charges. Therefore, EPLDs provide the convenience of reprogramming as a design evolves. On the downside, EPLDs cost at least three times as much per chip as mask programmable PLDs and operate at much slower speeds. Since EPLDs typically utilize CMOS technology, they are slower than fusible link PLDs, but require less power. Therefore, EPLDs are often used in development work with the final design being implemented in either fusible link technology (for faster speed) or mask programmable technology (for faster speed and lower density). In spite of the fact that EPLDs cost more than fusible link PLDs, the reprogramming feature eventually results in a lower cost for development than using fusible link PLDs. This technology requires an additional piece of hardware to erase the chips.

EEPLDs provide the convenience of reprogramming without the need to erase the previous program because the chip is programmed by setting the states of flip-flops inside the device. It is, therefore, not necessary to purchase an erasing device. The reprogramming also requires less time to accomplish. Of course, EEPLD chips cost more and have a lower gate density than EPLD chips.

9.1.2 PLD Notation

PLDs typically have many logic gates with a large number of inputs. Also, there are often many gates that have the same set of inputs. For example, the PAL22V10 has 132 AND gates, each with the same 44 gate inputs. Obviously, the diagram for such a complex circuit using standard AND gate symbols would be extremely complex and difficult to read.

Figure 9.1 is the conventional diagram for an eight-input AND gate. Clearly, a similar diagram for a 44-input AND gate would be very cumbersome. Figure 9.2 is the same eight-input AND gate in PLD notation. The eight parallel

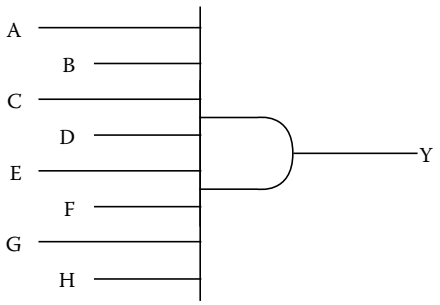

FIGURE 9.1 Conventional diagram for an eight-input AND gate.

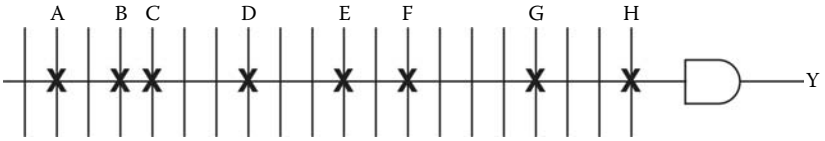

FIGURE 9.2 PLD notation for an eight-input AND gate.

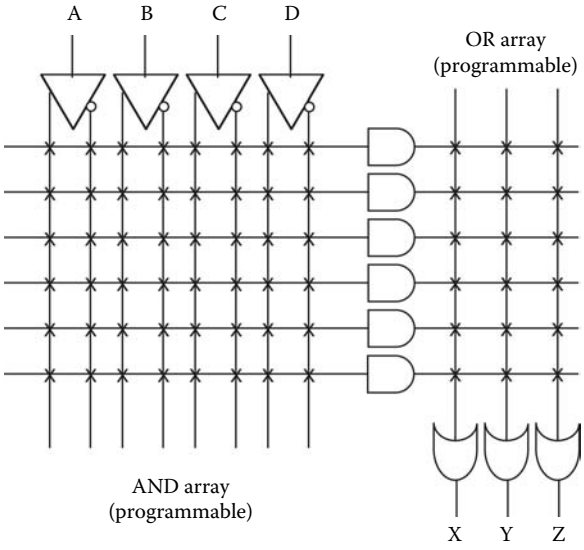
wires that actually occur as inputs to the AND gate are represented by a single horizontal line in PLD notation. The actual inputs to the AND gate are drawn perpendicular to the single line. There are usually more signal lines than just the eight needed for this gate. An *X* is placed at the intersection of the single line with each of the perpendicular lines that provide actual inputs to the AND gate. Keep in mind that the single horizontal line actually represents eight parallel wires that are not physically connected to each other.

By comparing the internal structures of PLAs, PALs, and PROMs, we will describe the capabilities and limitations of each type of PLD. Since the PAL is currently the most popular PLD device, we will describe design methodology for both combinational and sequential PAL devices. By emphasizing the difference between designing with PALs and designing with standard logic gates, we provide practical insights about PLD design.

9.1.3 Programmable Logic Array

Figure 9.3 shows that the basic PLA consists of a programmable AND array followed by a programmable OR array. Vertical lines in the AND array represent the input variables (A, B, C, D). Since each input drives many AND gates, an internal buffer provides high current drive signals in both true and complemented format for each input variable. Initially, there is a connection from each input variable and its complement to each AND gate. In this example circuit, each AND gate initially has eight inputs ($A, \overline{A}, B, \overline{B}, C, \overline{C}, D, \overline{D}$). Each AND gate input line contains a fuse or electronic switch. We program the chip by blowing the fuses in lines that we do not need, or by programming the electronic switches. After



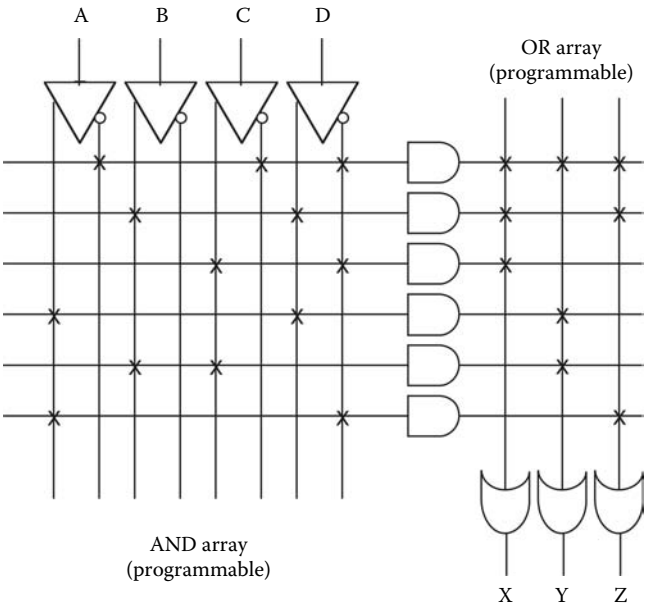


FIGURE 9.3 Basic architecture for a PLA.

$X = \overline{A} \cdot \overline{C} \cdot \overline{D} + B \cdot D + C \cdot \overline{D}$
$Y = \overline{A} \cdot \overline{C} \cdot \overline{D} + A \cdot D + B \cdot C$
$Z = \overline{A} \cdot \overline{C} \cdot \overline{D} + B \cdot D + A \cdot \overline{D}$

FIGURE 9.4 An example of a programmed PLA.

programming, we remove the X's from the lines that are disconnected. For example, in the programmed chip of Figure 9.4, the upper AND gate implements product term $(\overline{A} \cdot \overline{C} \cdot \overline{D})$.

In the OR array of Figure 9.3, there is an initial connection from each AND gate output to every input on each OR gate. Again, the single vertical line connected on the input side of each OR gate represents all six wires. Each of the input lines to the OR gates also contains a fuse or programmable switch. Figure 9.4 shows that, after programming, output X connects to product terms $\overline{A} \cdot \overline{C} \cdot \overline{D}$, $B \cdot D$, and $C \cdot \overline{D}$.

The number of product lines on a chip limits the range of functions that fit onto the chip. The PLA chip in Figure 9.3 can implement any three functions (X, Y, Z) of the same four variables (A, B, C, D) as long as the total number of required product terms is less than or equal to six. However, there are 100 different product terms involving four variables. So, practical chips have many more product lines than this contrived example.

In order to fit functions onto the chip, designers must be able to simplify multiple output functions using gate sharing whenever possible. Finding a minimal gate implementation of multiple output functions with gate sharing is a very complex task. The goal is to minimize the total number of gates used. The size of gates does not matter. For example, whether an AND gate has four inputs or two inputs is not important. All that changes are the number of fuses that are blown. This differs dramatically from the minimization goals when discrete gates are used. For discrete gate minimization, a four-input gate costs more than a two-input gate. Therefore, the classical minimization programs need to be modified to reflect the different goals for PLA development.

Three parameters determine the capacity of a PLA chip. Let n be the number of inputs, p the number of product term lines, and m the number of outputs. Then, the PLA chip can implement any m functions of the same n variables that require a total of p or fewer product terms. The device complexity is proportional to $(m + n)p$.

9.1.4 Programmable Read Only Memory

The PROM is the most general of the CL PLD devices described in this section. However, from a structural viewpoint, the PROM is a special case of the PLA in which the AND array is fixed and the OR array is programmable. Figure 9.5 is a conceptual diagram of a PROM. The filled circles in the AND array represent permanent connections. The X's in the OR array indicate that it is programmable. The number of product lines in a PROM is 2^n; whereas the number of product lines in a typical PLA is much smaller. A PROM has a product line for each combination of input variables. Since any logic function of n variables can be expressed in a canonical sum of minterms form in which each product term is a product of exactly n literals, the PROM can implement any function of its n input variables.

To demonstrate the generality of the PROM, Figure 9.6 shows how the PROM of Figure 9.5 must be programmed so as to implement the same set of logic functions that are programmed into the PLA of Figure 9.4. The PROM program follows directly from the truth table for a logic function. The truth table for the logic functions X, Y, and Z appears in Table 9.2. The correspondence between the truth table and the program in the PROM of Figure 9.6 is straightforward. A logic 1 in the truth table corresponds to an X in the figure and a logic 0 in the table corresponds to the absence of an X.

A PROM with n address lines (serving as n input variable lines) and m data lines (serving as m output variable lines) can implement any m functions of the same n variables. Unlike a PLA, a PROM has no restrictions due to a limited number of product lines. The PROM contains an n input, 2^n output decoder that generates 2^n internal address lines that serve as product lines. Since the decoder grows exponentially in size with n, the cost of a PROM also increases rapidly with n. The justification for a PLA is to reduce the cost of the PROM decoder by providing fewer product terms since many practical functions require significantly fewer than 2^n product terms. As a result, some n variable functions will not fit onto a PLA chip with n input variables, whereas any n variable function will fit onto a PROM with n address lines.

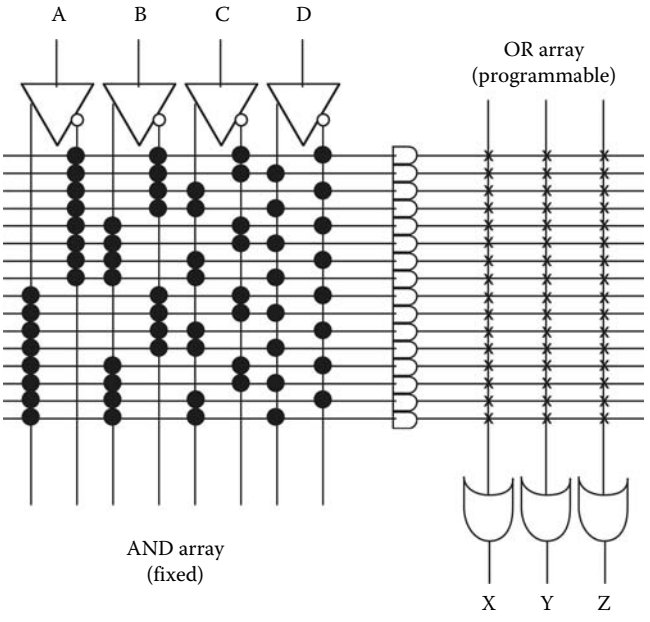

FIGURE 9.5 Conceptual diagram of a PROM.

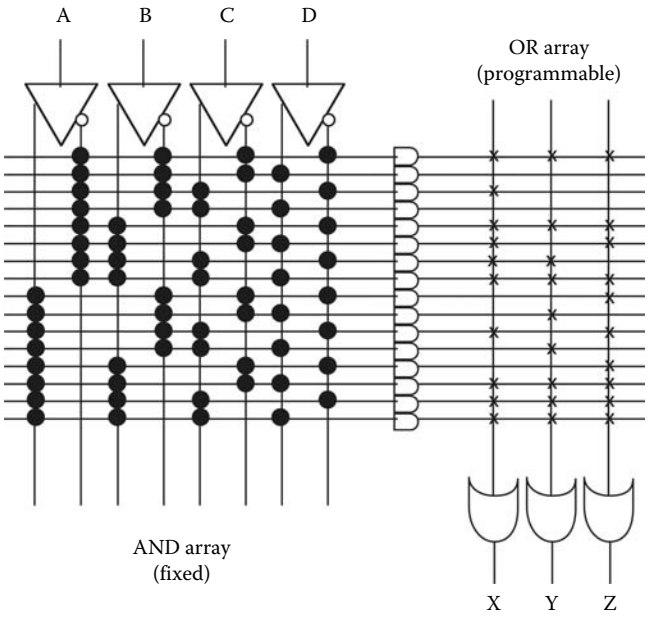

FIGURE 9.6 An example of a programmed PROM.

0111	111	1111	111

9.1.5 Programmable Array Logic

PAL is the most popular form of PLD today. Lower price, higher gate densities, and ease of programming all tend to make PAL more popular than PLA. On the negative side, the range of functions that can fit onto a chip with the same number of inputs, outputs, and product lines is less for a PAL than for a PLA.

Figure 9.7 is the basic architecture of a PAL. The PAL architecture is a special case of the PLA architecture in which the OR array is fixed. The filled circles in the OR array indicate permanent connections. Only the AND array is programmable. Compare this PAL architecture with the PLA architecture in Figure 9.3. Since the OR array is not programmable, it is immediately evident that fewer functions will fit onto the PAL. In the PLA, the product terms can be divided among the three

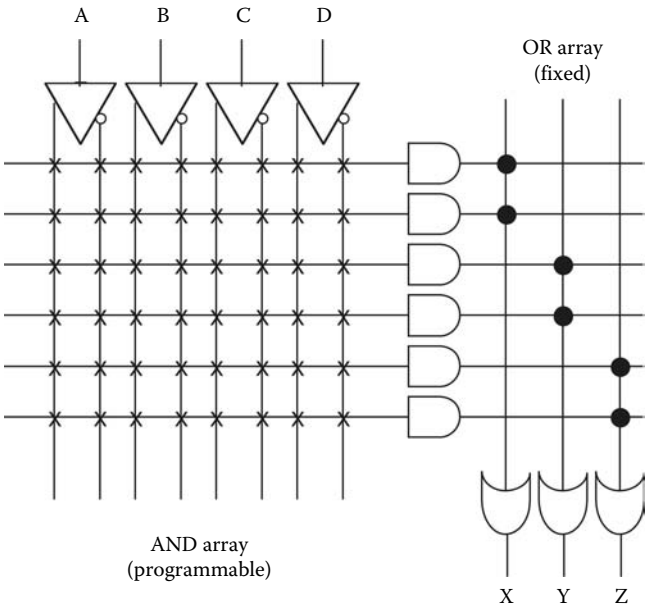

FIGURE 9.7 Basic architecture of a PAL.

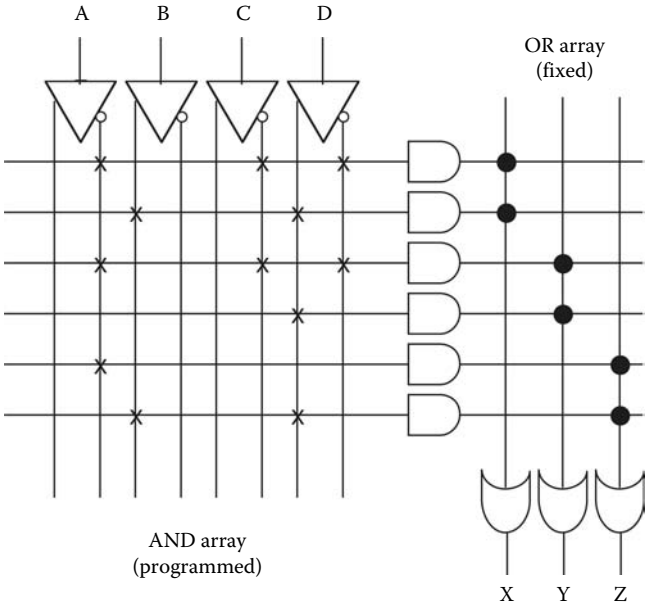

outputs in any way desired and product terms that are used in more than one output can share the same product line. In the PAL, each output is limited to a fixed number of product terms. In Figure 9.7, all outputs are limited to two product terms. In addition, if two output functions both require the same product term in a PAL, two different product lines must be used.

Consider the three functions implemented on the PLA in Figure 9.4. Since the three functions require a total of nine product terms, they will not fit onto the PAL of Figure 9.7. However, any function that would fit onto this PAL would obviously fit onto the PLA since the OR array in the PLA can be programmed to be identical to the OR array of the PAL. Figure 9.8 is an example of three functions that fit onto this PAL. Note that we must use two different product lines to provide the same product term ($\overline{A} \cdot \overline{C} \cdot \overline{D}$) to outputs X and Y.

In order to describe the range of applications for a PAL, we must know the number of inputs, n, the number of outputs, m, and the number of product lines that are permanently connected to each output OR gate. The PAL of Figure 9.7 has four inputs, $n = 4$, three outputs, $m = 3$, and has two product lines connected to each OR gate. This PAL is described as a 2-2-2 PAL with four-input variables. Many PALs have the same number of product terms permanently connected to each output. In this case, the three parameters n, m, and p completely describe the size of the PAL. For PALs, the parameter p usually represents the number of product terms per output instead of the total number of product terms, as was the case for PLAs.

The minimization algorithm for multiple output PALs is significantly less complex than the minimization algorithm for a PLA because gate sharing is eliminated as a possibility by the fact that the OR array is not programmable. This means that each output function can be minimized independently. Minimizing a single output function is much less complex than minimizing a set of output functions where gate sharing must be considered.

Overall, the higher density, less complex minimization algorithms, and lower cost of PALs tend to offset the additional functional capabilities of PLAs.

$X = \overline{A} \cdot \overline{C} \cdot \overline{D} + B \cdot D$

$Y = \overline{A} \cdot \overline{C} \cdot \overline{D} + D$

$Z = \overline{A} + B \cdot D$

FIGURE 9.8 An example of a programmed PAL.

9.1.6 Classification of Combinational Logic PLD Devices

The programmability of the AND and OR array provide a convenient means to classify CL PLD types. The classification of Table 9.3 illustrates comparative features of CL PLD devices. Even though PLAs have the most general structure (i.e., both the AND and OR arrays are programmable), the number of functions that fit onto the chips is limited by the number of product terms per output. ROMs and PROMs have fixed AND arrays, but all possible product terms are provided. Therefore, PROMs and ROMs are the most general devices from a functional viewpoint. Applications are only limited by the size and cost of available devices. PALs are the most restricted devices from both the structural and functional viewpoints. Nevertheless, the lower cost relative to PROMS and PLAs, higher gate densities relative to PLAs, and wider variety of available chip types have contributed to a rapid rise in popularity of PAL devices. For this reason, we will concentrate on PAL devices in the rest of this section.

TABLE 9.3 Classification of Combinational PLD Devices

AND Array	OR Array	Device	Typical Number of Product Terms per Output Gate
Fixed	Mask programmable	ROM	2^n
Fixed	Field programmable	PROM, EPROM, EEPROM	2^n
Field programmable	Fixed	PAL	16
Field programmable	Field programmable	PLA	50–150

9.1.7 Designing with Combinational Logic PAL Devices

Determining if a function will fit onto a PAL device is a complex procedure. To demonstrate the difficulty, we will examine the types of functions that can fit onto a PAL16L8 chip. Figure 9.9 shows that the PAL16L8 chip has eight-output pins and 16 pairs of vertical input lines to the AND array. The "L" in the chip name indicates that the eight outputs are all active low CL outputs. The most important information not provided by the device name is the number of product terms per output, which is seven for this device. An additional product term provides an output enable for each output pin, so there are eight product lines per output pin (a total of 64 product lines). There are 10 primary input pins (pin numbers 1–9 and 11). In terms of our definitions, it would seem that $n = 10$, $m = 8$, and $p = 7$. As we will demonstrate, this simplistic analysis significantly understates the capacity of this chip.

A simplistic analysis would say that the PAL16L8 chip could implement any eight functions of the 10 input variables as long as each function requires no more than seven product terms. As far as it goes, this statement is correct. However, it significantly understates the capacity of the chip because it does not take into account the fact that six of the output pins are internally connected as inputs to the AND array (pins 13–18). This is the source of the additional six inputs to the AND array. These internal feedback connections significantly expand the capacity of the chip.

Consider the following logic function.

$$X = A\overline{B}C + B\overline{C}D + \overline{A}E + D\overline{E}F + \overline{A}C + \overline{D} + \overline{F}GH + F\overline{G}I + BE\overline{H} + \overline{C}H + \overline{I}J + \overline{B}E\overline{J} + \overline{D}H$$

It appears that this logic function will not fit onto the PAL16L8 chip because it requires 13 product terms and each output has only seven product lines. However, if not all chip outputs are needed for the application, we can use one of the feedback lines to fit this function onto the chip.

We first partition the function X as follows:

$$X = A\overline{B}C + B\overline{C}D + \overline{A}E + D\overline{E}F + \overline{A}C + \overline{D} + Y$$
$$Y = \overline{F}GH + F\overline{G}I + BE\overline{H} + \overline{C}H + \overline{I}J + \overline{B}E\overline{J} + \overline{D}H$$

Since Y has only seven product terms, we will map function Y to the macrocell connected to pin 18 and use the feedback line from pin 18 to connect Y to a pair of vertical lines in the AND array. Function Y is now available to all other cells as an input variable. Since function X also has seven product terms, we will map X to the macrocell connected to pin 17. One of the product terms in X is the single variable Y. Figure 9.10 shows the final implementation. To obtain the needed product terms for output X, we used two macrocells in the array. As a result, pin 18 is no longer available as an output.

Two practical matters need to be considered. First, some signals must now pass through the AND array twice as they proceed from an input to an output due to the feedback path. Therefore, the delay of the chip is now twice what it was when the feedback path was not utilized. Second, the buffer inverts the outputs; therefore, we actually obtain X on pin 17. If X is specified to be active low, then the output on pin 17 is exactly what we need. If the output X is specified to be active high, then an inverter is required. Since PALs are available with both active low and active high outputs, a designer should select an appropriate PAL to eliminate the need for inverters.

Another feature that adds to the flexibility of the chip is that pins 13–18 can be used either as inputs or as outputs. For example, the enable for the output buffer at pin 15 can be permanently disabled. Since pin 15 is connected directly into the AND array, it is no different from any other input, say pin 2. Of course, by permanently disabling the buffer at pin 15, the OR array connected to the buffer is also disconnected. In order to use pin 15 as an input, we must give up the use of the macrocell connected to pin 15. However, dual use pins and feedback lines dramatically extend the range of applications for the chip. For example, suppose we need only one output and select pin 19 for that use. Then, pins 13–18 are available either as inputs or as feedback lines. We can therefore fit a wide range of functions onto the chip with varying numbers of inputs and product terms.

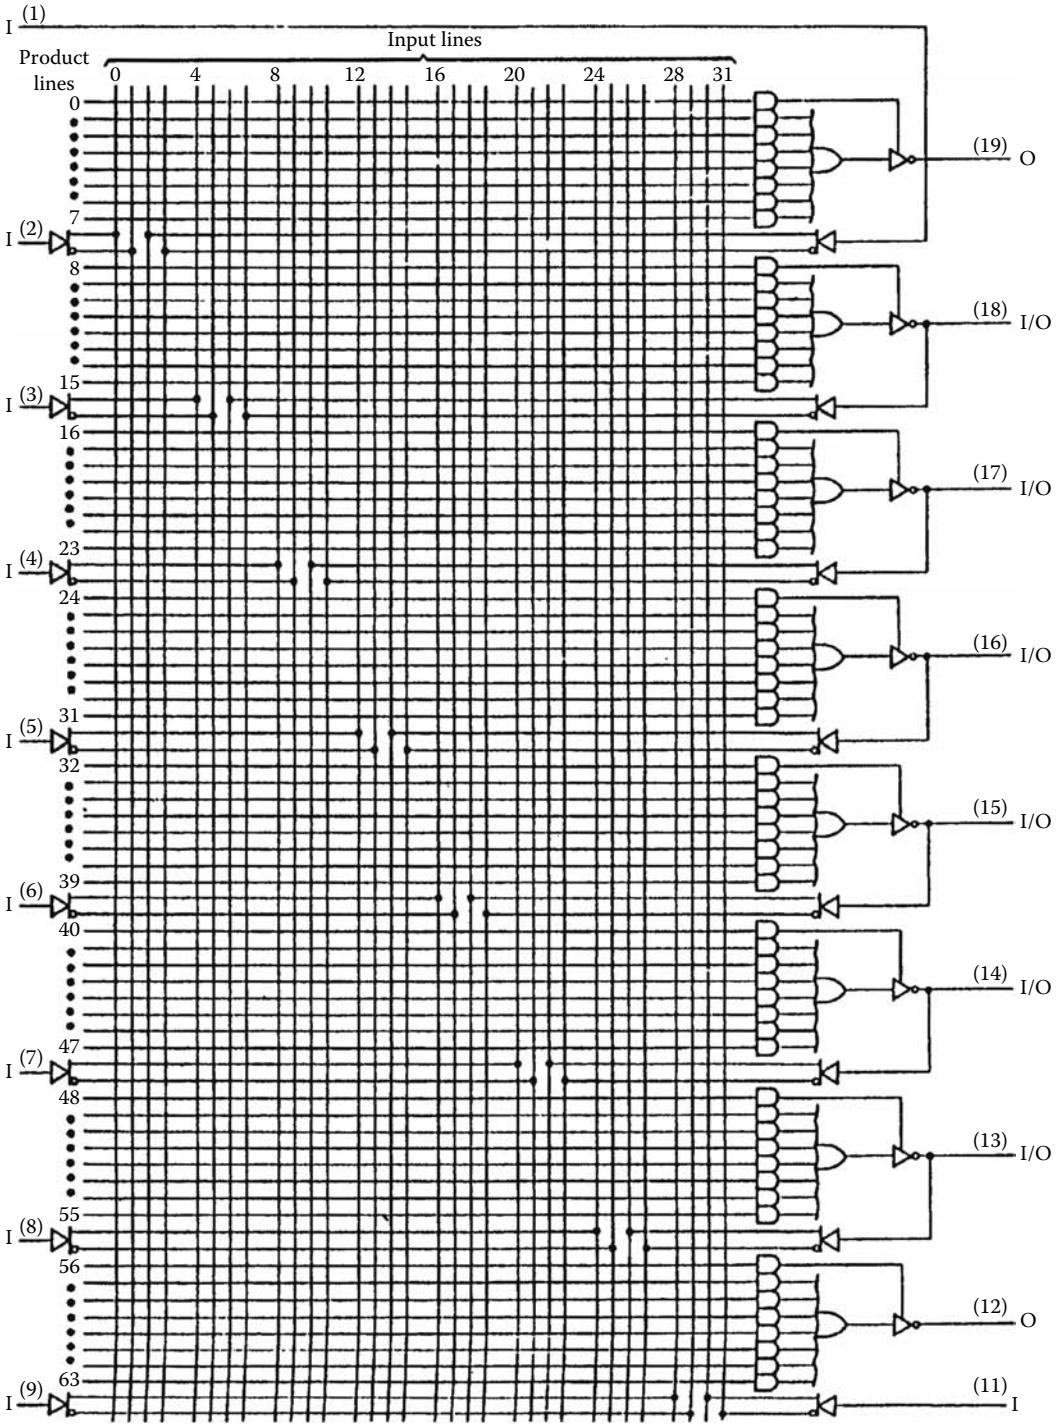

FIGURE 9.9 Logic diagram of PAL 16L8 chip. (Courtesy of Texas Instruments, Dallas.)

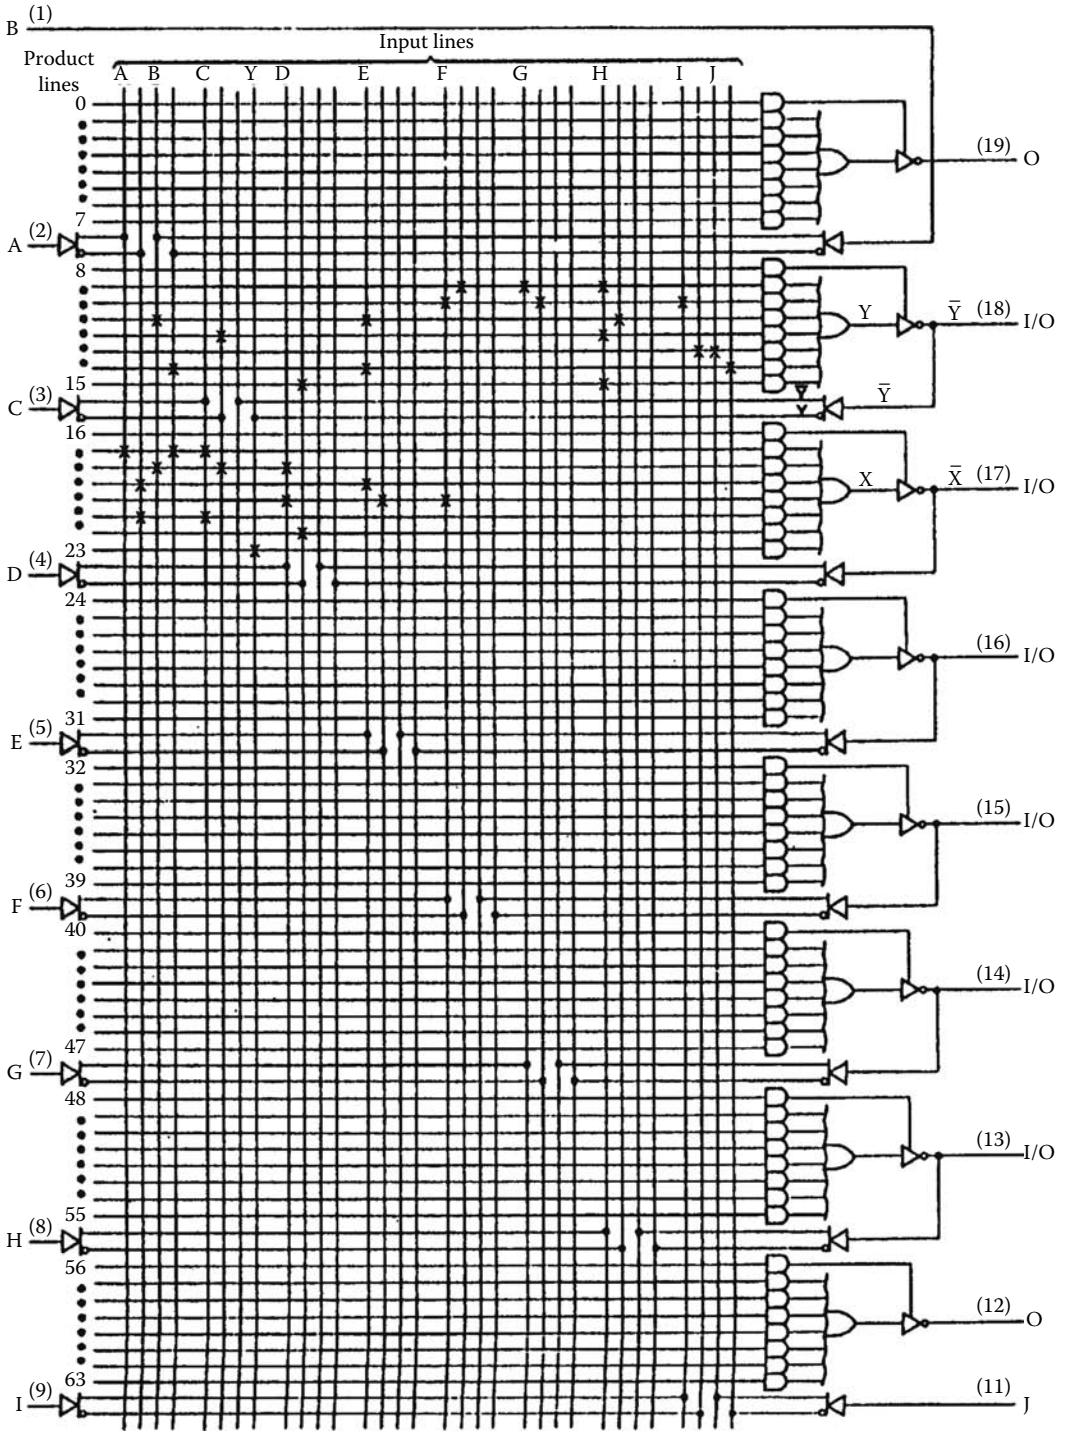

FIGURE 9.10 Implementation of function with 13 product terms on PAL16L8 chip.

Assuming that we need only the one output on pin 19, then we could have up to 16 inputs (pins 19, 11, 13–18). We could, of course, use only the seven product lines in the macrocell connected to pin 19 to implement our function. We, therefore, conclude that the PAL16L8 chip can implement any single function of 16 variables that requires no more than seven product terms.

If we need more product terms but not as many input variables, then we can connect pin 11 to pin 12. This connects the output on pin 12 back into the AND array the same as any other input variable. The output on pin 19 can pick up the seven product terms on pin 12 as an input. This takes up one of the product lines for pin 19, but six product lines remain. Therefore, the single output on pin 19 can now have up to 13 product terms. However, pin 11 is no longer available as an input. Therefore, we must conclude that the PAL16L8 can implement any single function of 15 variables that requires no more than 13 product terms.

If we want to maximize the number of product terms for a single output at pin 19, then we can use pins 13–18 and pin 11 as feedback lines. Each feedback line contributes seven product terms. The AND array for pin 19 can pick up all 49 product terms by using one product line to pick up each feedback variable. All product lines are now busy. The OR gate at pin 19 then sums all 49 product terms. The only pins that are now available for inputs are 1–9. We therefore conclude that the PAL16L8 can implement any single function of nine variables that requires 49 or fewer product terms.

Clearly, there are many combinations of implementations with a variety of values for the number of inputs, the number of outputs, and the number of product terms per output. Table 9.4 shows the full range of possible implementations. For example, from the tables we note that the PAL16L8 can implement any three functions of 10 variables in which the product terms are distributed among the three outputs in any of the following ways: 7–7–37, 7–13–31, 7–19–25, 13–13–25, or 13–19–19. The notation 7–7–37 means that two of the outputs require at most seven product terms and that the third output requires at most 37 product terms. To accomplish these results, five of the output pins must be devoted to feedback lines.

Any implementation that uses a feedback line will have a time delay equal to twice that of a single macrocell. In the delay column of Table 9.4, symbol T_A represents the delay that a signal experiences while passing through the AND–OR array one time. In implementations that do not use feedback lines, signals experience a maximum delay of T_A. For implementations that use one or more feedback lines, the delay is $2T_A$ because some input signals propagate through the AND–OR array twice before reaching an output pin. However, none of the implementations in the table requires more than twice the normal time delay for a single macrocell.

Although the tables cover broad generalizations for classes of functions that will fit onto the PAL16L8 chip, there are certain special types of more complex functions that will fit. For example, suppose that input variables A, B, C, D, E, F, G, H, and I occupy pins 1–9. Further suppose that we implemented functions S, T, V, W, X, Y, and Z using the macrocells connected to pins 12, 13, 14, 15, 16, 17, and 18, respectively. Further suppose that we connect pin 12 to pin 11 so that all of these functions are connected to a pair of vertical input lines in the AND array. Thus, all of these functions are now available to the single output P at pin 19. This approach allows many very complex logic functions to fit onto the chip.

Example 9.1

Let each of the functions S, T, V, W, X, Y, and Z be a sum of products expression involving the nine input variables with at most seven product terms. For example, S might be

$$S = A\bar{B}CD\bar{E}F\bar{G}HI + \bar{A}B\bar{C}DE\bar{F}GH\bar{I} + \bar{B}CD\bar{E}F\bar{G}HI + \bar{F}GH\bar{I} + \bar{A}H\bar{I} + \bar{D}EF\bar{G}HI + ABCDEFGHI$$

Variables T, V, W, X, Y, and Z could be of similar complexity.

TABLE 9.4 Range of Implementations of PAL16L8 Chip

m	*n*	Number of Product Terms per Output	Delay
1	16	7	T_A
1	15	13	$2T_A$
1	14	19	$2T_A$

4	14	7–7–7–7	T_A
4	13	7–7–7–13	$2T_A$
4	12	7–7–7–19, 7–7–13–13	$2T_A$
4	11	7–7–7–25, 7–7–13–19, 7–13–13–13	$2T_A$
4	10	7–7–7–31, 7–7–13–25, 7–7–19–19, 7–13–13–19, 13–13–13–13	$2T_A$
5	13	7–7–7–7–7	T_A
5	12	7–7–7–7–13	$2T_A$
5	11	7–7–7–7–19, 7–7–7–13–13	$2T_A$
6	12	7–7–7–7–7–7	T_A
6	11	7–7–7–7–7–13	$2T_A$
6	10	7–7–7–7–7–19, 7–7–7–7–13–13	$2T_A$
7	11	7–7–7–7–7–7–7	T_A
7	10	7–7–7–7–7–7–13	$2T_A$
8	10	7–7–7–7–7–7–7–7	T_A

Then, output P might be

$$P = A\overline{B}CD\overline{E}FG\overline{H}IS\overline{T}VW\overline{X}Y\overline{Z} + B\overline{C}DEF\overline{G}\overline{S}T\overline{V}WXY\overline{Z} + \cdots$$

where P has at most seven such product terms.

The delay of this implementation is still twice the delay of one basic macrocell.

Example 9.2

This example illustrates embedded factors. Each equation has at most seven product terms involving the listed variables.

$$S = f(A - I) = \overline{A}BC\overline{D}E\overline{F}GH\overline{I} + A\overline{B}\overline{C}DEF\overline{G}HI + \cdots$$

$$T = f(S, A - I) = AB\overline{C}D\overline{E}FG\overline{H}IS + \overline{A}BCD\overline{E}\overline{F}GHI\overline{S} + \cdots$$

$$V = f(S, T, A - I) = \overline{C}DE\overline{F}GH\overline{I}\overline{S}T + BC\overline{D}HIS\overline{T} + \cdots$$

$$W = f(S, T, V, A - I) = \overline{A}BCD\overline{E}F\overline{G}HI\overline{S}T\overline{V} + \overline{D}E\overline{F}HIS\overline{T}V + \cdots$$

$$X = f(S, T, V, W, A - I) = \overline{A}\overline{B}CDE\overline{F}GH\overline{I}ST\overline{V}\overline{W} + \overline{E}T\overline{V}W + \cdots$$

$$Y = f(S, T, V, W, X, A - I) = ABC\overline{D}EFG\overline{H}IS\overline{T}VW\overline{X} + \overline{D}H\overline{I}S\overline{T}V\overline{W}X + \cdots$$

$$Z = f(S, V, T, W, X, Y, A - I) = A\overline{B}CD\overline{E}FGH\overline{I}S\overline{T}V\overline{W}X\overline{Y} + \overline{F}H\overline{I}WXY + \cdots$$

$$P = f(S, V, T, W, X, Y, Z, A - I) = A\overline{B}CD\overline{E}FG\overline{H}IS\overline{T}VW\overline{X}Y\overline{Z} + B\overline{C}DEF\overline{G}ST\overline{V}WXY\overline{Z} + \cdots$$

The delay of this implementation is eight times the delay of a single macrocell because an input signal change might have to propagate serially through all of the macrocells on its way to the output at pin 19.

These examples demonstrate that very complex functions can fit onto the chip. Determining the optimum way to factor the equations is a very complex issue. Chip manufacturers and third-party vendors provide software packages that aid in the fitting process.

9.1.8 Designing with Sequential PAL Devices

The concept of registered outputs extends the range of PAL devices to include sequential circuits. Figure 9.11 is the logic diagram for the PAL16R4 chip. Again, this chip has 16 pairs of inputs to the AND array. The R4 part of the designation means that the chip has four outputs connected directly to D type flip-flops, i.e., the outputs are registered. Let us add another parameter, k, to designate the number of flip-flops on the chip. An examination of Figure 9.11 indicates that the PAL16R4 also has four combinational outputs with feedback connections to the AND array. These pins are I/O pins because they can also be used as inputs if the OR output to the pins is permanently disabled. All outputs are active low. The chip has eight-input pins. Using our parameter system, the PAL16R4 apparently has $n = 8$, $m = 4$, $k = 4$, $p = 7$ for combinational pin outputs and $p = 8$ for registered pin outputs. However, as for the PAL16L8, these numbers significantly understate the capabilities of this chip.

Since the four registered outputs are also connected back into the AND array, this chip can implement a sequential circuit with the registered outputs serving as state variables. Therefore, this chip can implement any eight-input, four-output, sequential circuit that needs no more than four-state variables (16 states) and no more than seven product terms for each output or eight product terms for each state variable. Separate pins provide an enable for the state variables (pin 11) and a clock for the flip-flops (pin 1). Thus, the state variables are also available at output pins.

By an analysis similar to that used in the previous section, we can utilize the feedback lines to significantly expand the types of circuits that will fit onto the PAL16R4 chip. Table 9.5 shows the range of basic possibilities.

For example, the table indicates that the PAL16R4 chip can implement any single output, eight-input, sequential circuit that requires no more than four-state variables (16 states) and in which the available product terms may be divided among the outputs and state variables in seven different distributions. The notation (7)-(8–8–8–26) means that the single output can have up to seven product terms, that one state variable can have up to 26 product terms, and that the other three state variables can have up to eight product terms each.

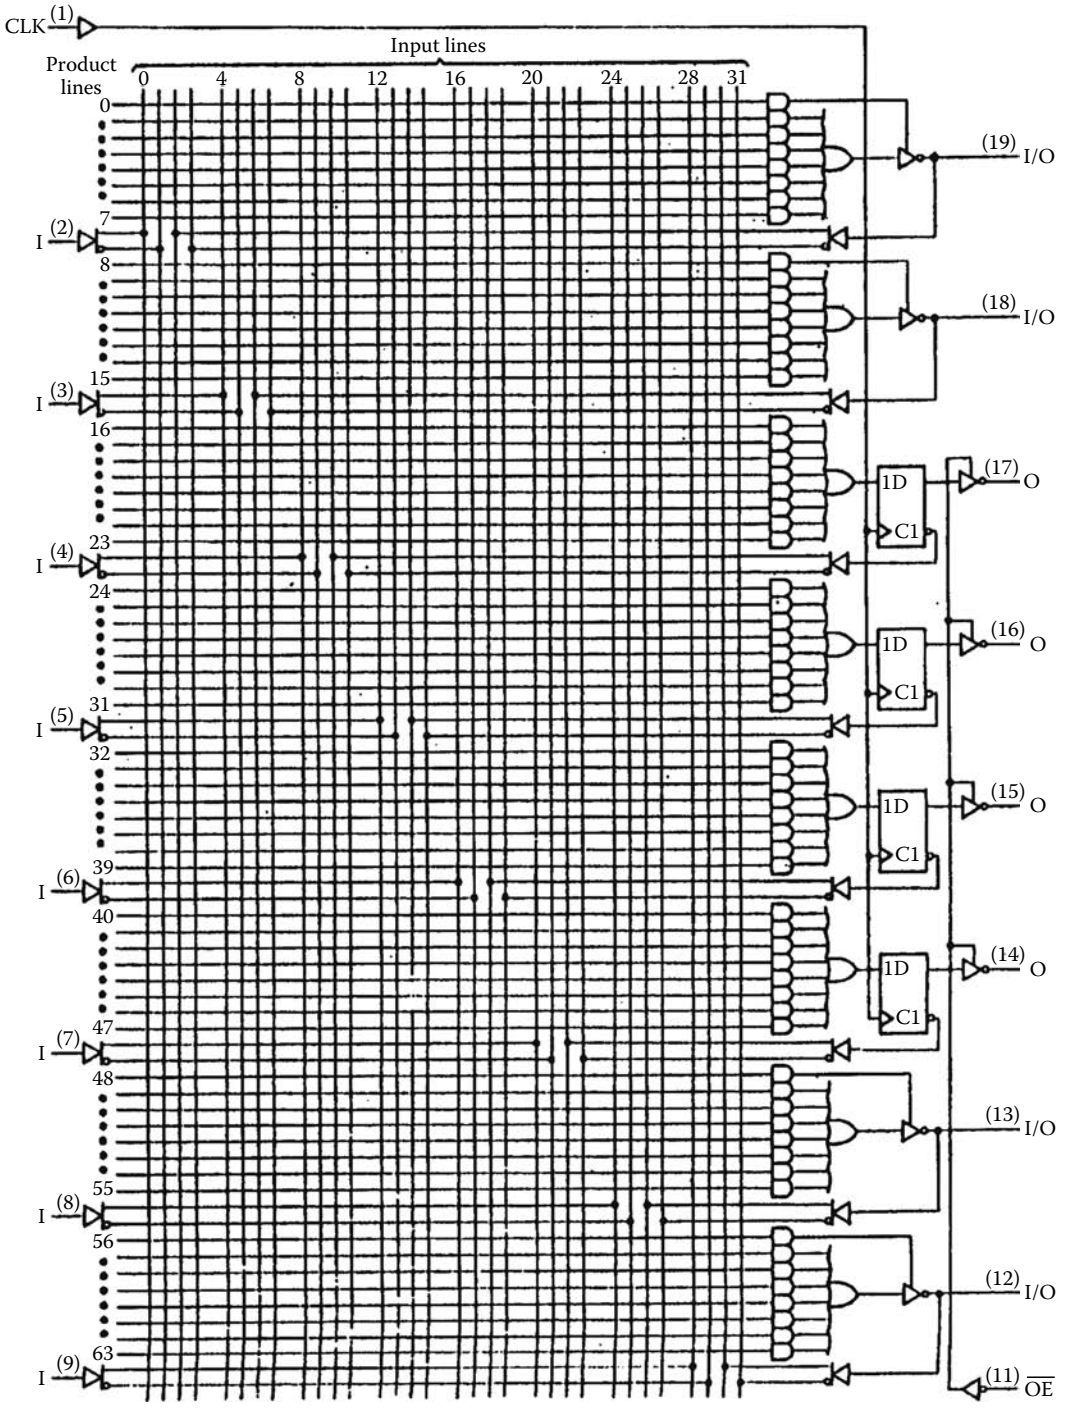

FIGURE 9.11 Logic diagram of PAL16R4 chip.

TABLE 9.5 Range of Basic Implementations of PAL16R4 Chip

M	n	K	Number of Product Terms per (Combinational Output)–(State Variable)	Delay
1	11	4	(7)−(8–8–8–8)	T_A
1	10	4	(7)−(8–8–8–14), (13)−(8–8–8–8)	$2T_A$

4	8	4	(7–7–7–7)−(8–8–8–8)	T_A

9.1.9 Designing with PALs Having Programmable Macrocell Outputs

The PAL16R4 chip has limited application potential because the outputs from pins 14–17 ''must'' be registered. Most new chips allow a user to decide whether to have registered or combinational outputs at each pin and also allow the user to select either active high or active low outputs.

The PAL22V10 chip (see architecture in Figure 9.12) demonstrates this additional flexibility. Each of 10 macrocells contains a normal PAL AND array and an I/O architecture control block. Each PAL AND array provides a differing number of product terms permanently connected as inputs to an OR gate and an additional product term that enables an output buffer. The number of product terms per output is printed near the OR gate symbol (8, 10, 12, 14, 16, 16, 14, 12, 10, 8). Figure 9.13 shows that this chip is similar in form to the PAL chips described earlier in this chapter. There are 22 vertical pairs of input lines to the AND array. Of these pairs, 11 are connected directly to input pins labeled $I_1 - I_{11}$ (pins 2–11, 13). Ten pairs are feedback lines from the architecture control blocks of the 10 macrocells. Each macrocell is associated with a bidirectional pin (pins 14–23) that can be used either as an input pin, an output pin, or a bidirectional bus pin. If used as a bidirectional bus pin, the designer must control the O/E using a

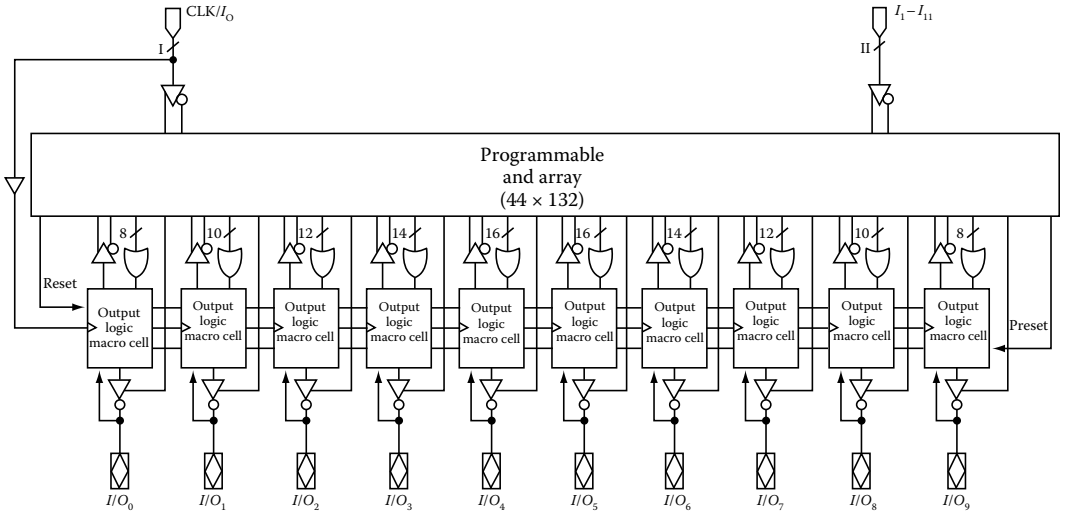

FIGURE 9.12 Architecture of the PAL22V10 chip. (Courtsey of Advanced Micro Devices, Inc., Sunnyvale.)

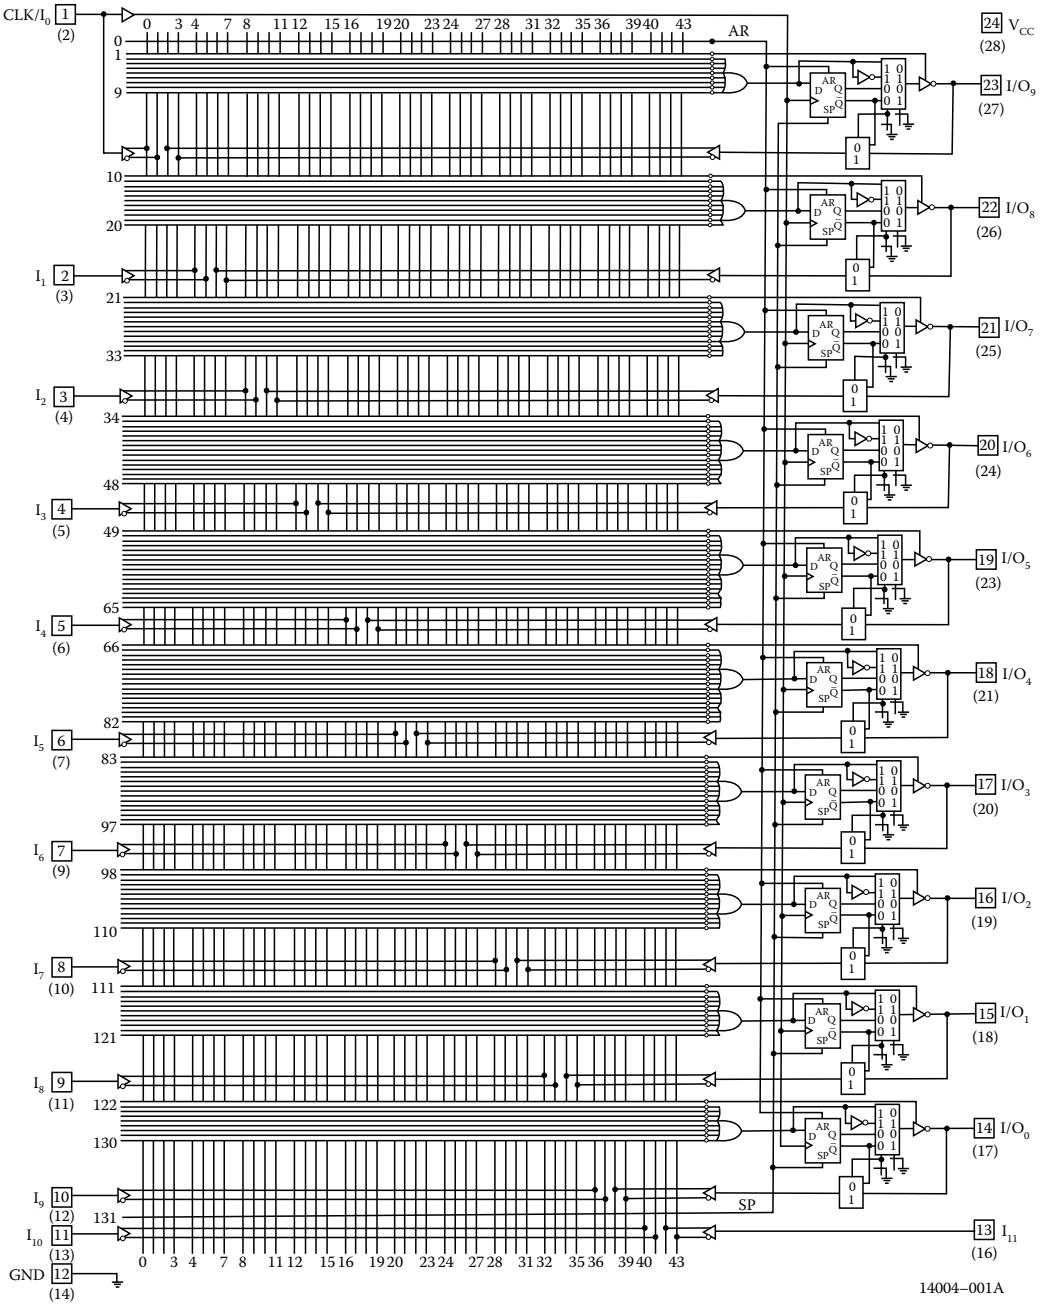

FIGURE 9.13 Complete circuit diagram for the PAL22V10 chip. (Courtesy of Advanced Micro Devices, Inc., Sunnyvale.)

product term from the AND array. The 22nd pair, labeled CLK/I_0, is connected to pin 1. If the chip is being used to implement a purely combinational circuit, pin 1 can be used as an additional input variable. If a sequential circuit is being implemented, pin 1 must be used as the clock signal for the flip-flops.

The architecture control block in each macrocell provides designer control over the signal that is connected to the bidirectional pin and feedback line associated with that macrocell. Figure 9.14 shows

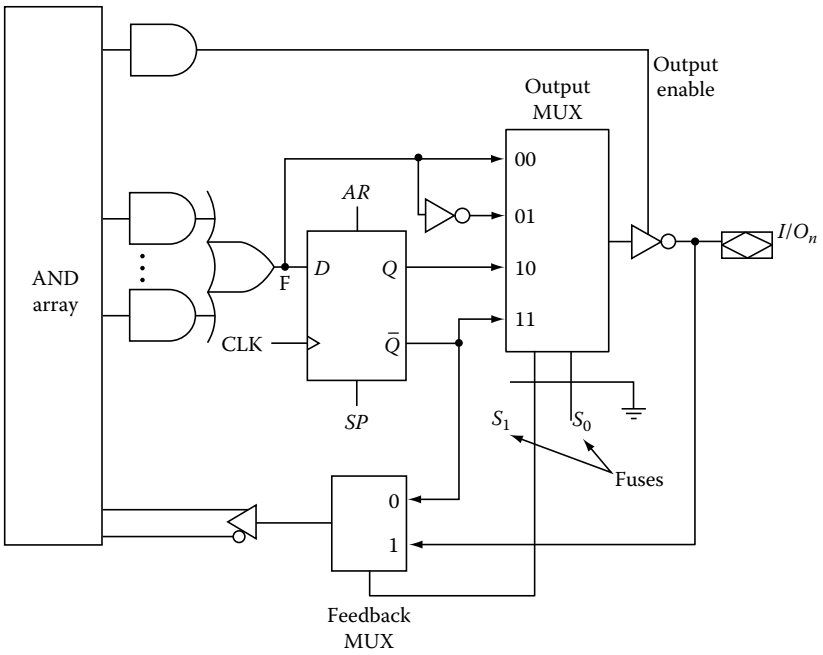

FIGURE 9.14 Macrocell architecture of PAL22V210 chip. (Courtesy of Advanced Micro Devices, Inc., Sunnyvale.)

that the architecture control block contains a D-flip-flop, an inverter, two MUXs with programmable select lines, and an output buffer with an enable. The Output MUX selects either the direct output of the combinational AND array (either active high or active low) or the data value stored in the D-flip-flop (either active high or active low). If the O/E is active, the buffer steers the signal selected by the Output MUX to the pin. An inactive enable causes the buffer to enter the high impedance state, which effectively disconnects the buffer from the pin. The pin can then be an input or can be connected to an external bus.

The feedback signal selected by the Feedback MUX is either the pin signal or the data value stored in the flip-flop (low active). Therefore, the feedback line can be used to expand the number of product terms, to provide a state variable for a sequential circuit, to provide an additional input for the chip, or to implement a bidirectional pin.

Figures 9.13 and 9.14 show that the common clock input to all flip-flops comes directly from pin 1, that a single product (SP) term provides a common synchronous preset for all flip-flops, and that another single product line (AR) provides a common asynchronous reset for all flip-flops. The asynchronous reset occurs when the product line is active independent of clock state. The synchronous preset occurs only on the active edge of the clock when the preset product line is active.

The two programmable MUXs in the architecture control block significantly increase the flexibility of the chip compared to either the PAL16L8 or the PAL16R4. Table 9.6 shows several combinations of switch settings along with typical applications for each setting.

The PAL22V10 is much more versatile than either the PAL16L8 or the PAL16R4. Since pins 14–23 can be used as inputs, combinational outputs, or registered outputs, the following inequalities describe the possibilities.

If the chip is used to implement a CL function, the constraints are

$$n \leq 22, \quad m \leq 10$$

$$(n + m) \leq 22$$

TABLE 9.6 Applications for Combinations of Switch Settings for the PAL22V10 Chip

Name	Output Connection	Feedback Connection	Application
INP	None	Pin	Use pin as input only
COCF	Combinational	Combinational	Combinational output and/or combinational feedback
COIF	Combinational	Pin (input)	Bidirectional pin implementing a combinational output
RORF	Register	Register	Typical state machine controller
ROIF	Register	Pin (input)	Bidirectional pin with registered output. Bus applications

For sequential circuits, the constraints are

$$n \leq 21, \quad m \leq 10, \quad k \leq 10$$

$$(m + k) \leq 10, \quad (n + m + k) \leq 21$$

because the clock signal for the flip-flops uses one of the input pins (pin 1).

Table 9.7 shows representative sizes for circuits that will fit onto the PAL22V10 chip.

9.1.10 FPGA Technologies

Due to the relatively high complexity of FPGAs, almost all FPGAs use CMOS process technology because of its high density and low power characteristics. Currently, there are two popular FPGA programming technologies, static RAM (SRAM), and anti-fuse.

The anti-fuse device gets its name from the fact that its electrical properties are the dual of the electrical properties of a fuse. The anti-fuse is a pair of conducting plates separated by a dielectric insulator, similar to a small capacitor. By contrast, the fuse is a pair of terminals separated by a thin conducting wire. A fuse is programmed by passing a high current through the thin wire causing the wire to heat up and melt, producing an open circuit where a short circuit previously existed. Fusible link technology is used in many PLA and EPROM devices. By contrast, the anti-fuse is programmed by applying a high voltage across the dielectric insulator that permanently breaks down the dielectric insulator, producing a short circuit where an open-circuit previously existed. Both fusible-link and anti-fuse devices are nonvolatile which makes them particularly well-suited for use in extreme environments, such as space and other high radiation environments. Anti-fuse technology also provides higher speed operation than other technologies.

SRAM chips are volatile (i.e., they lose their program when power is removed) and have lower density and slower speed than anti-fuse chips. On the positive side, SRAM chips are lower cost, re-programmable and, therefore, dynamically reconfigurable. In the current marketplace, SRAM chips have captured most of the popular commercial market.

9.1.11 FPGA Architectures

Figure 9.15 shows a high-level layout of an FPGA chip. Each chip contains a two-dimensional array of identical configurable logic blocks (CLBs). The FPGA in Figure 9.15 has 64 CLBs arranged in an 8×8 array. The user can program the CLBs to implement specific combinational or sequential logic functions. A programmable interconnect structure is permanently placed in the space between CLBs. The user programs switches that make desired connections between his programmed CLBs either by setting SRAM bits or by permanently closing the anti-fuses. Programmable I/O blocks are located around the perimeter of the chip that allows the user to connect signals to pins on the chip.

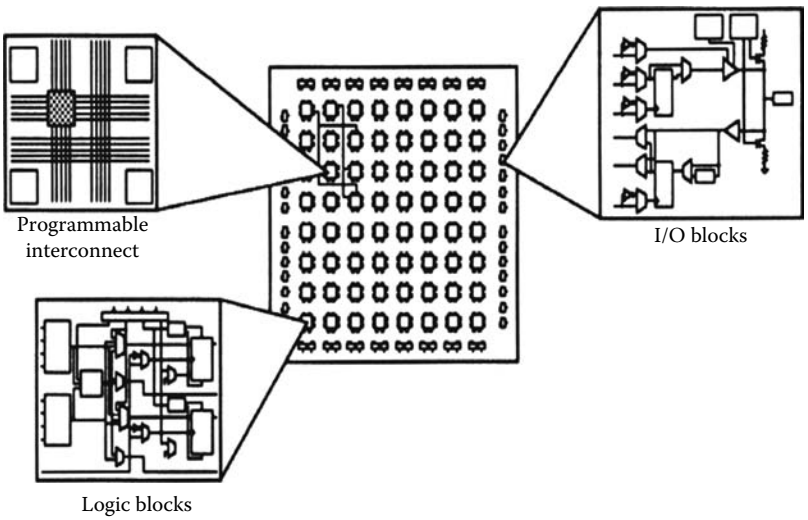

FIGURE 9.15 FPGA architecture. (Courtesy of Xilinx, San Jose.)

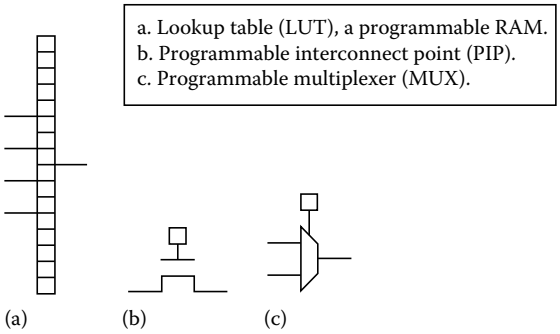

FIGURE 9.16 Programmable FPGA elements. (Courtesy of Xilinx, San Jose.)

For convenience, in this paragraph we describe FPGA elements using SRAM terminology. Anti-fuse devices have similar components. FPGAs have three basic programmable elements, illustrated in Figure 9.16. The lookup table (LUT) is a programmable RAM. The LUT shown in Figure 9.16a is a 16×1 RAM. It has four address inputs and one data output. It is programmed by storing either a logic 1 or a logic 0 in each RAM location. The value at a specific location is read out (looked up) by applying the address at the RAM inputs. A programmable interconnect point (PIP) is simply a CMOS pass transistor with a programmable SRAM bit controlling the gate signal. If a connection between the two transistor terminals for the PIP in Figure 9.16b is desired, a logic 1 is stored in the SRAM control bit. If no connection is desired, a logic 0 is stored in the SRAM control bit. SRAM bits also control the address lines of programmable MUXs. The MUX in Figure 9.16c has two input lines and therefore can be controlled by one SRAM bit. Programming the SRAM control bit to be logic 0 connects the upper MUX input to the MUX output. Programming the SRAM control bit to be logic 1 connects the lower MUX input to the MUX output.

To illustrate the principles, consider the minimal CLB shown in Figure 9.17. This CLB has three input signals (A, B, and C) and one output signal (X). The CLB has one 8×1 LUT and one D flip-flop with a reset input (R). It has three 2×1 programmable MUXs with SRAM control bits labeled M1, M2, and M3, respectively. The MUX controlled by M3 connects either the LUT output (F) or the bit stored in the flip-flop (Q) to the CLB output (X). If $M3 = 0$, the D flip-flop is bypassed and the CLB will implement the CL function stored in the LUT. If $M3 = 1$, the CLB will implement a sequential function. The MUX controlled by SRAM bit M2 selects either the LUT output (F) or the input signal (C) as the reset signal for the flip-flop. The MUX controlled by SRAM bit M1 selects either input signal C or the bit stored in the flip-flop (Q) as the third address input (E) to the LUT. Inputs *A* and *B* are permanently connected to two of the LUT address lines.

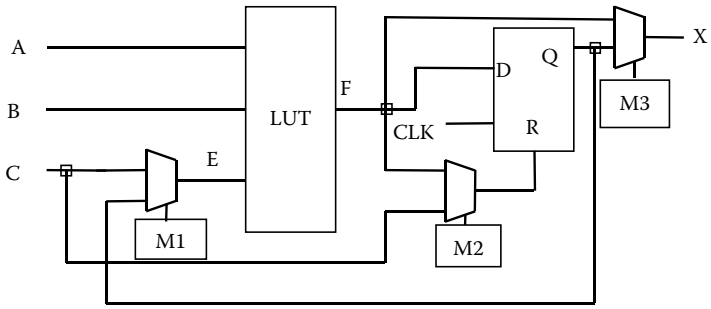

FIGURE 9.17 A minimal CLB.

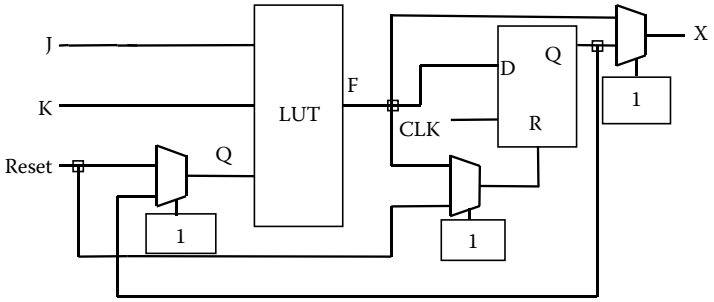

FIGURE 9.18 Minimal CLB programmed to be a JK flip-flop.

TABLE 9.8 Contents of LUT for Programmed CLB

J	K	Q	F
0	0	0	0
0	0	1	1
0	1	0	0
0	1	1	0
1	0	0	1
1	0	1	1
1	1	0	1
1	1	1	0

To illustrate how the minimal CLB in Figure 9.17 could be programmed, we will show how to program it to implement a JK flip-flop. M3 will be 1 to select the flip-flop output as the CLB output. M2 will be 1 to select input C as the flip-flop reset signal. M1 will be 1 to select the flip-flop output (Q) as the E input to the LUT. Input A will be designated as the J input and input B will be designated as the K input for the flip-flop. Figure 9.18 shows the programmed CLB with all signal names related to their use in the JK flip-flop. Table 9.8 shows how the LUT must be programmed to implement the function of a JK flip-flop.

Figure 9.19 shows an actual CLB in the XC4010XL chip, a small FPGA chip manufactured by Xilinx. This CLB uses the same small set of elements that we used in the minimal CLB. This CLB contains 2 D-flip-flops, 3 LUTs, and 16 programmable MUXs.

If the user had to directly program each CLB and each PIP in the interconnect structure, the task would be formidable. However, most chip manufacturers provide software packages that allow the user to specify the device function using a variety of high-level abstractions. In the next section, we will discuss this process in more detail.

9.1.12 Design Process

From the previous discussion, it is clear that fitting designs to PLD chips is a complex process. PLD manufacturers and third-party vendors market software packages that help engineers map designs onto chips. Selecting a package appropriate for a particular design environment is a critical decision that will significantly affect the productivity of the design group.

There are basically three types of development system packages: user designed packages, vendor designed packages, and universal packages. Since these programs are very complex and require many

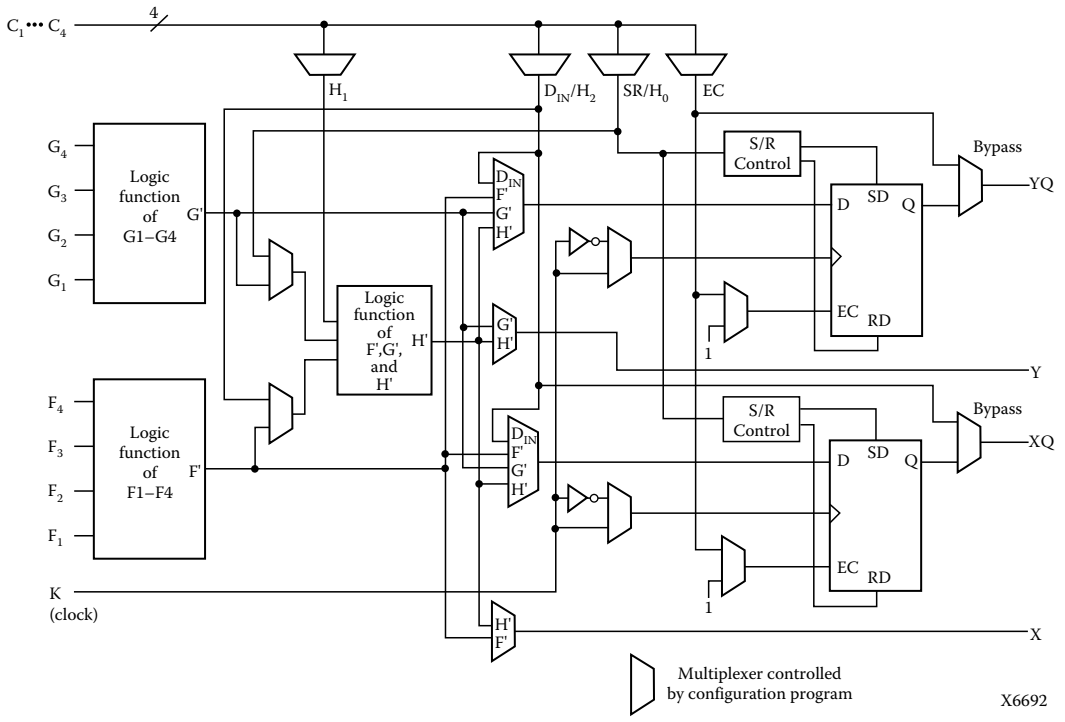

FIGURE 9.19 Actual CLB for the XC4010XL chip. (Courtesy of Xilinx, San Jose.)

years of effort to develop, most design groups will lack the time and resources to develop their own. Many vendors provide design aids that are specific to a particular product line. There is a great danger in becoming dependent upon one vendor's products because new products in this field appear frequently. Clearly, a universal design package that supports a wide variety of product lines is most desirable. A variety of development systems with different features, capabilities, and price is available.

Figure 9.20 shows a flow diagram for the process typically used to design PLAs and FPGAs. ''Design entry'' refers to the use of an editor to create a source file that specifies the functional behavior of the device. High-level simulation verifies correct functional behavior of the device. ''Logic synthesis'' refers to the process of implementing the design using the primitive elements present on a specific chip, such as gates, flip-flops, registers, etc. Most development systems support prelayout simulation at this level to verify that the design still functions correctly. ''System partitioning'' and ''mapping'' refers to the process of grouping blocks of primitive elements into sets that map directly into major chip structures, such as CLBs in FPGAs or AND–OR arrays in PLDs. ''Place and route'' refers to mapping the structures into specific locations on the chip and making connections between them. The software package then performs a timing analysis on the final design to verify that design timing specifications are met. Finally, the chip is configured by generating an output file that can be read by the chip programmer.

9.1.12.1 Design Entry

It is essential for a universal development system to have a variety of design entry modes. Many vendors market the more complex design entry modes as optional features. This section describes some of the more common design entry modes and their value to PLD and FPGA designers.

"Boolean equations" are an important method of design entry. A PLD design system must support Boolean equation entry because the AND–OR arrays on PLD chips directly implement Boolean equations. Almost all PLD designers will use Boolean equation entry extensively. Boolean equation entry is also useful for FPGA designs.

"Truth table" entry allows specification of a CL function by defining the output for each of the 2^n input combinations. This form is particularly valuable if "don't care" entries exist. Truth table entry is most commonly used for functions with a small number of input variables that are not easily described by Boolean equations. Code converters, decoders, and LUTs are examples. A good design tool will support truth table entry.

"Symbolic state machine" entry is crucial for PLD and FPGA designers because both PLDs and FPGAs are often used to implement state machine controllers. Current tools have features described as state machine entry that vary dramatically in form and usefulness. Before selecting a tool, the specifics of the state machine entry format should be carefully investigated. The most useful formats allow symbolic representation of states and specification of state transitions using some form of conditional statement such as "if_then_else," or "case." Relational operators are also useful in this context. The tool should perform automated state assignment and should fit the state variable equations to the target chip.

"State diagrams" using graphics are useful, but not essential. This feature is mainly a convenience, provided that symbolic state machine entry is available.

"Schematic" entry is a widely accepted way to describe logic systems. To be useful, it must be combined with a powerful partitioning and mapping tool that can fit the circuit onto chips. Schematic entry is useful to convert existing gate level designs into PLD or FPGA implementations.

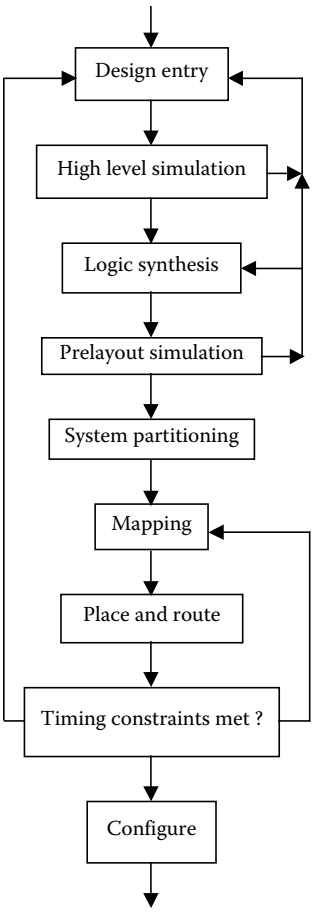

FIGURE 9.20 Design process.

"Hardware description language (HDL)" entry is potentially the most useful of all methods. Popular HDL languages are VHDL, Verilog, and System C. Using these languages, a designer can specify an executable specification of his device. Mature simulators exist for all of these languages that allow functional verification of the high level HDL design.

9.1.12.2 Logic Synthesis

Logic synthesis is the process of transforming a given description of a device produced by one of the design entry methods described in the previous section into an equivalent netlist using primitive components. For example, the process of transforming a symbolic state machine description or an HDL description into a netlist is an example of logic synthesis. The power of the synthesis algorithms in a development system is perhaps the most important feature of the system.

HDL synthesis tools are beginning to be mature enough for use in both PLD and FPGA designs. Very good synthesis tools exist for subsets of the popular HDL languages. Full synthesis tools for all language constructs are still in the research phase. In the next section, we will illustrate how to synthesize FPGA designs using the VHDL language.

"Logic minimization" is obviously an essential process in a PLD development system because the number of product terms per output gate on PAL chips is limited. Recall that the goal of logic minimization for PLD designs is to reduce the number of product terms, not the size of the product terms. Classical logic minimization algorithms use cost functions that reward reduction of the number of gate inputs. This is important for TTL gate implementations, for example, because an eight-input gate costs

about four times as much as a four-input gate. In PLD designs, the number of gate inputs does not matter. Each product term consumes one product line in the chip. A one-literal product term, such as X, costs exactly the same as a ten-literal product term, such as ABCDEFGHIJ. Therefore, traditional logic minimization programs, such as Espresso, need to be modified for PLD development. If product terms can be shared among different outputs, then multiple output minimization is necessary. However, for most PAL devices, the product terms cannot be shared; therefore, single output minimization algorithms are sufficient. Single output minimization algorithms are much less complex and take much less time to execute than multiple output minimization algorithms. Therefore, systems that do single output minimization result in higher productivity. Therefore, be careful of systems that advertise well-known traditional logic minimization algorithms to market their products, especially if multiple output minimization is stressed.

''Equation factoring,'' which is sometimes called ''multiple level minimization,'' is essential in order to fit large functions onto PLD chips using multiple cells combined with feedback lines inside the chips. This feature is missing from most vendor PLD development systems. However, in order to provide effective automated PLD synthesis, this operation is absolutely necessary. In most current PLD development systems, the designer must interact with the synthesis program to implement multiple level minimization. Such interaction requires extensive skill from the user of the software package.

9.1.12.3 Simulation of Designs

All good development systems include some form of simulation capability. The simulators vary widely in scope, user interface, and general usefulness.

Behavioral simulation allows high-level design descriptions to be simulated independent of implementation. Behavioral simulators verify the input–output behavior of the device. Correct behavioral simulation verifies the correctness of the algorithms prior to mapping the design to specific hardware components.

Device simulators verify the function of the design after mapping the design to a specific chip but before actually programming the chip. This is the most common type of simulator in current PLD development systems. A device simulator will construct a software model of the target PLD architecture, map the design to that architecture, and then simulate the behavior of the specific PLD. The better simulators will provide timing information as well as functional information.

9.1.12.4 Mapping Designs to Chips

System partitioning, mapping, place and route, and configure functions are usually performed by vendor-specific development software. These software packages usually accept a netlist as input and produce an output file that can be read by the programming tool.

```
SynchronousRegProcess: process (CLK)
 begin
  -- No other statements here
  if (CLK'event and CLK='1') then
   if RESET ='0' then
    AREG <='0';
   else
    AREG <= A;
   end if;
  end if;
  -- No other statements here
 end process;
```

FIGURE 9.21 VHDL code for register with synchronous reset.

9.1.13 VHDL Synthesis Style for FPGAs

Since HDL synthesis is one of the most popular ways to design FPGAs, we will show representative synthesis techniques for VHDL, one of the common HDL languages. The user may use these examples as templates to write code that will synthesize successfully.

9.1.13.1 Registers and Flip-Flops

Figure 9.21 shows a VHDL template for a register, AREG, with synchronous reset signal (RESET) and data input, A. In VHDL, entities are called processes. This code defines a process named

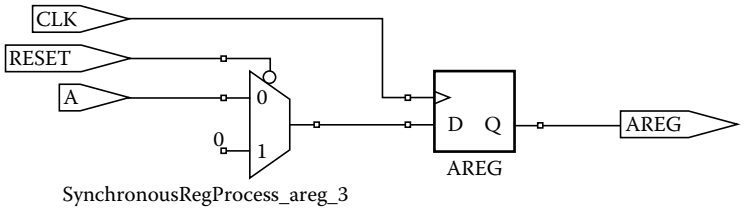

FIGURE 9.22 Synthesis of VHDL code in Figure 9.21.

SynchronousRegProcess. The list of signal names in the parentheses following the word process is called the sensitivity list for the process. The sensitivity list for a register process must contain the clock signal for the process. The notation, CLK'event, is a Boolean expression that is TRUE when signal CLK changes value. This change may either be a rising edge or a falling edge. Combining CLK'event with CLK = '1' specifies a rising edge triggered clock. The notation *AREG <= A* specifies that the current value of input signal A is assigned to register AREG on the rising edge of signal CLK. Similarly, the notation, AREG <= '0', implies that signal AREG is reset to 0 on the rising edge of CLK when RESET = '0'. Current synthesis semantics dictate the following constraints on the VHDL code.

1. The "if" statement that identifies the clock signal must be the only top level statement in the process. No other statements may come before or after this "if" statement, as indicated by comments in the VHDL code.
2. The condition that identifies the clock signal for the register (CLK'event and CLK = '1'), must contain no other conditions. For example, we could not implement the synchronous reset by writing (if CLK'event and CLK = '1' and RESET = '0' then...).
3. Only one clock edge may occur in each process. That is, it is unacceptable to have both CLK1'event ad CLK2'event in the same process.

Figure 9.22 shows how a synthesis tool will synthesize this VHDL code into a clocked register. Note that the RESET signal is low active (a logic 0 causes a reset).

Figure 9.23 shows a VHDL template for a register, AREG, with an asynchronous reset. The same restrictions that were listed for the synchronous register also apply here. Notice that the primary differences are that, in the asynchronous register, signal RESET must be in the sensitivity list and the RESET test occurs before the test for the clock edge, whereas the test for RESET in the synchronous register occurs after the test for the clock edge. Figure 9.24 shows how a synthesis tool synthesizes the VHDL code in Figure 9.23 into a register with an asynchronous reset signal.

```
Asynchronous_Reset: process (CLK, RESET)
 begin
  if RESET = '0' then
   AREG <= '0';
  elsif (CLK'event and CLK = '1') then
   AREG <= A;
  end if;
 end process;
```

FIGURE 9.23 VHDL code for a register with asynchronous reset.

FIGURE 9.25 VHDL code for combinational logic.

9.1.13.2 Combinational Logic

Consider the ones counter truth table of Table 9.9. The input is a 3-bit vector, A, and the output is a 2-bit vector, C. The output reflects the number of ones in the input vector. For example, if A = 111, then C = 11 indicating that A has 3 ones.

There are many ways to represent CL using VHDL. The most direct way is to use a case statement, as shown in Figure 9.25. This type of code is directly related to the truth table format. It simply specifies the output for each combination of the inputs. Figure 9.26 shows how a synthesis tool synthesizes the code in Figure 9.25. Note that it takes the unusual approach of using a MUX as part of the circuit. The reason for this is that the target FPGA chip has many MUXs in its CLBs (see Figure 9.19).

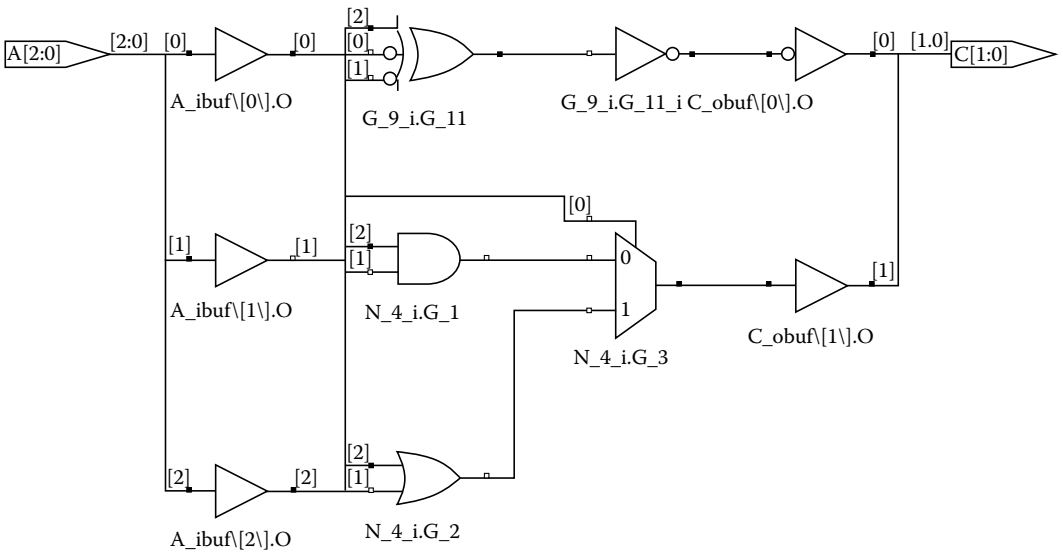

FIGURE 9.26 Synthesis of VHDL code Figure 9.25.

9.1.13.3 Latches

Figure 9.28 shows that the VHDL code in Figure 9.27 synthesizes as a latch with output signal name Q. Note that the process sensitivity list must include both the latch input data signal name, DATA, and the latch enable signal name, ENABLE. Also, the code for a latch may not contain an expression referring to an edge, such as ENABLE'event. The reason that the synthesis tool produces a latch is that a new value is not assigned to signal Q during every call to the process. A new value is only assigned when ENABLE = '1'. Otherwise, the signal Q must not change, i.e., it must retain its old value when ENABLE = '0'. This action requires a latch.

Figure 9.30 shows that the VHDL code in Figure 9.29 synthesizes as CL and does not produce a latch. In this VHDL code, signal Q is assigned a new value every time the process is called. Therefore, the synthesized circuit is CL instead of a latch.

9.1.14 Synthesis of State Machines

Figure 9.31 shows a VHDL template for a state machine. First, the code includes a declaration of a data type called STATE_TYPE. This data type is simply a list of the names of the states. The names should be chosen to reflect the purpose of the state, such as INITIAL, IDLE, TRANSMIT, RECEIVE, etc. Next, a signal, STATE, is declared to be of type STATE_TYPE. Signal STATE keeps track of the current state of

```

FIGURE 9.31 VHDL template for a state machine.

the state machine. The architecture consists of two processes. Process STATE_PROCESS updates the current state on each positive transition of clock signal CLK. Process OUTPUT_PROCESS updates the state machine outputs whenever there is a change in state. As written, these processes implement a Moore state machine. To design a Mealy state machine, simply add the machine input signals to the OUTPUT_PROCESS sensitivity list. The state machine has a low-active asynchronous RESET signal that initializes the state machine to state S0. A case statement performs data transfer statements and computes the next state based on the current state. For other approaches to using high-level languages to design digital systems, see Ref. [8].

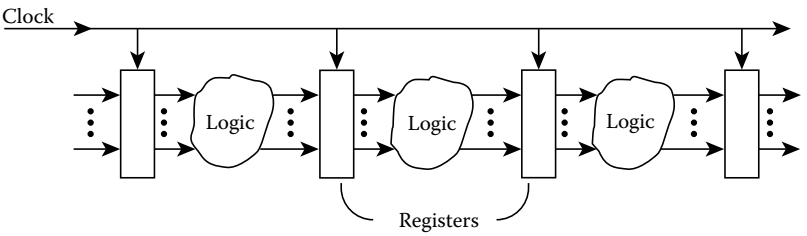
9.2 Clocking Schemes

Wayne D. Grover

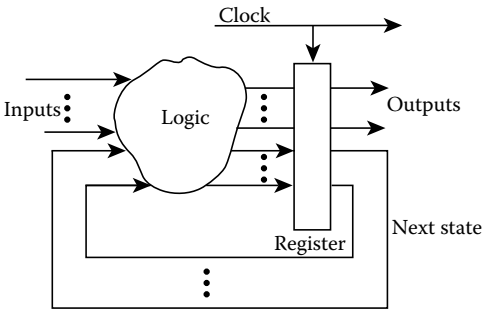
9.2.1 Introduction

Advances in very large-scale integrated (VLSI) processing technology, particularly CMOS, have resulted in nanometer-scale processes with applications at clock speeds of several gigahertz. For example, at the time of this revision the state of the art is fairly well represented by the Intel Core2 Duo processor chip, which is implemented in 65 nm CMOS, consists of 376 million transistors, and clocks at 2.66 GHz. New design challenges must be mastered to realize systems at an ever-increasing clocking rates and circuit sizes. In particular, clocking-related issues of skew, delay, power dissipation, and switching noise can be design-limiting factors. In large synchronous designs, the clock net is typically the largest contributor to on-chip power dissipation and electrical noise generation, particularly ''ground bounce,'' which reduces noise margin. Ground bounce is a rise in ground potential due to surges of current returning through a nonzero (typically inductive) ground path impedance. At the board and shelf level, clock distribution networks can also be a source of electromagnetic emissions, and may require considerable delay tuning for optimization of the clock distribution network.



In the past, multiphase clocking schemes and dynamic logic structures helped minimize transistor count, but this is now less important than achieving low skew, enhancing routability, controlling clock-related switching noise, and providing effective CAD tools for clock net synthesis and documentation. For these reasons, a shift has occurred toward single-phase clocking and fully static logic in all but the largest custom designs today. In addition, phase-feedback control schemes using phase-locked loops (PLLs) are becoming common, as are algorithmic clock-tree synthesis methods.

This section focuses on the issues and alternatives for on-chip and multichip clocking, with the primary emphasis on CMOS technology. We first review the fundamental nature and sources of skew and the requirements for the clocking of storage elements. We then outline and compare a number of ''open-loop'' clock distribution approaches, such as the single-buffer, clock trunk, clock ring, H-tree, and balanced clock tree approaches. PLL synchronization methods and PLL-based clock generation are then outlined. In closing, we look at future technologies and developments for high-speed clocking. The concepts and methods of this section apply to many circuit technologies on- and off-chip. However, we emphasize CMOS because CMOS processes (including bi-CMOS) presently represent the vast majority of digital VLSI designs and are expected to continue to do so.



Asynchronous, self-timed, and wavefront array systems are outside the scope of this chapter. These approaches aim to minimize the need for low-skew synchronous clocking. However, truly asynchronous modules tend to require a large overhead in logic for interaction with each other, so that speed, size, and power often suffer relative to synchronous design. Nonetheless, self-timing can be an effective approach for random-access memory (RAM and ROM) cells, to which considerable optimization effort can be invested for reuse in many designs. Self-timed methods should be considered the alternative to fully synchronous design in large, highly modularized systems, particularly where well-defined autonomous modules have relatively infrequent interactions. The main issues in self-timed systems are the possibly high delay required to avoid metastability problems between self-timed modules, and the circuit costs of the synchronization protocol for intermodule communication.

9.2.2 Clocking Principles

Most of us accept the clocked nature of digital systems without question, but what, fundamentally, is the reason for clocking? Any digital system can be viewed either as a pipeline or as an FSM architecture, as outlined in Figure 9.32. In the pipelined architecture clocked sections are cascaded, each section comprising an asynchronous CL block followed by a latch or storage element that samples and holds the logic state at the clock instant. In the FSM, the only difference is that the next state input and the system outputs are determined by the asynchronous logic block, and the sampled next state value (S) are fed back into the CL. The FSM can therefore be conceptually unfolded and also represented in a pipeline fashion. The fundamental reason for clocking digital systems is seen in this pipelined abstraction of a digital system: it is to bring together and retain coordination among asynchronously evolved intermediate results. With physical delays that are temperature, process, and input dependent in CL, we need to create ''agreed-upon time instants'' at which all analog voltages in a system are valid when interpreted as Boolean logic states. Clocking deals with delay uncertainty in logic circuit paths by holding

(a) Pipelined architecture

(b) Finite-state machine atchitecture

FIGURE 9.32 Architecture of digital systems.

up the fast signals and waiting for the slower signals so that both are valid before they are again combined or interact with each other. Without this coordination purely asynchronous logic would develop severe propagation path differences, and be slow in repetitive operations. Ultimately, a valid state would evolve, but all inputs would have to be stable for the entire time required for this evolution. On the other hand, when the overall CL function is appropriately partitioned between clocked storage latches, system speed can approach the limit given by the delay of a single gate because each logic subblock is reused in each clock period.

From this, we obtain several insights: (1) only the storage elements of a digital system need become loads on the clock net (assuming state logic gates); (2) the system cannot be clocked faster than the rate set by the slowest combinational signal path delay between clocked storage elements; (3) any uncertainty in clock timing (skew) is indistinguishable from uncertainty in the settling time of the intervening CL; and (4) for a logic family to work, its storage elements must: (a) at no time be transparent (i.e., simultaneously connect input to output), (b) have a setup time less than $(T - t_{clk-Q})$ where T is the clock period and t_{clk-Q} is the clock-to-Q output delay of the same type of flop, and (c) have a hold time less than their clock-to-output delay. The last points may be better appreciated by considering that the CL block may be null, i.e., a zero-delay wire, such as in a shift-register.

An implication of [4(a)] is that two-phase nonoverlapping clocks, or an equivalent sequencing process, are fundamentals for the storage elements of a digital system. This may sound unusual to readers who have already designed entire systems with SSI and MSI parts, or in gate-array design systems, without having seen anything but single-phase edge-triggered flip-flops, latches, counters, etc. However, at least two clock phases (or clock-enabling phases) are internally required in any clocked storage device. An analogy is of a ship descending in elevation through a lock [27]. During the first clock phase, sluice gates ''charge'' the lock up to the incoming water level and open the input gate to bring a ship in. Throughout this phase, it is essential that the output gate is closed, or water will race destructively right though the lock. Only when the ship is entirely in the lock and the input gate is closed (isolating the input) can the output sluice gates be opened to equalize the water level to that on the outgoing side, allowing the ship to leave (producing a new output). Similarly, in a flip-flop or latch, the currently stored value, which appears at the output, must be isolated from the input while the input evolves to its next value.

9.2.2.1 Skew and Delay

Clock ''skew'' is defined, most generally, as the difference in time between the actual and the desired instant of active clock edge at a given clocked storage element. In the majority of designs in which the desired instant of clocking is the same at all storage elements, skew is the maximum difference in clock waveform timing at different latches. Clock skew is of concern because it ultimately leads to the violation of setup or hold times within latches, or to clock race problems in multiphase clocking. Furthermore, from a design viewpoint, uncertainty in clock timings must be treated as equivalent to actual clock skew. Skew or timing uncertainty are therefore equivalent to an increase in critical path logic delay. In either case, the clock period must be extended to ensure valid logic levels and proper setup/hold requirements relative to the clock time.

To illustrate the equivalence of skew (either actual of design timing uncertainty) to a loss of system speed, consider a 200 MHz process used in a design which has 25% skew (i.e., actual clock edge dispersion or, equivalently, uncertainty in clock timing is 1.25 ns). If a competitor uses the same process at 200 MHz and achieves 5% skew (0.25 ns), then the latter design has 20% more of each 5 ns clock cycle for settling CL paths. Alternatively, for the same logic functions, the low-skew system could be clocked at 250 MHz with the same timing margins as the high-skew system. Skew, therefore, represents a loss of performance relative to basic process capabilities developed at the great expense. However, skew reduction costs relatively little, and is in the logic designer's control, not the process developer's and yet it is directly equivalent to a basic enhancement in process speed.

Skew is usually of primary concern on-chip or within any module that is designed on the presumption of a uniform clock phase throughout the module. Clock ''delay,'' on the other hand, is the difference

between the nominal clock edge time at an internal flip-flop and the system clock, or timing reference, external to the chip. While skew is typically managed internal to the die, delay is of concern at the system level to ensure external setup and hold time requirements. Skew and delay may be independent in any given clock distribution scheme. For example, an on-chip clocking tree that yields essentially zero skew may, nonetheless, impart a high clock delay, which will be of importance at the system level. The ''early clock'' technique and some PLL methods (presented later) can be used to address on-chip clock delay problems.

9.2.2.2 Isochronic or Equipotential Regions

The clock distribution problem arises at all scales of system design, from on-chip clock distribution in VLSI and wafer-scale integration (WSI) to the synchronization of circuit packs tens of meters apart. These applications are unified as a generic problem: synchronous clocking of ''electrically large'' systems, i.e., systems in which propagation time across the system is significant relative to the clock period. In such systems:

$$D/v > k/f_{\text{app}} \tag{9.1}$$

where

D is the characteristic scale or distance of the system
v is the propagation velocity
f_{app} is the application clock frequency
k is the skew requirement as a fraction of the clock period

For all locations around a clock entry point at which Equation 9.1 is false, we can consider events to be essentially simultaneous (or, equivalently, the region is a single electrical node), and the clock can be distributed within such regions without delay equalization. The region over which clock can be distributed without any significant skew is also known as an equipotential [27] region, or an isochronic region [1]. In this section, we are concerned only with cases in which Equation 9.1 is true, but it is implicit that the clocked end nodes may be either clocked loads directly or a buffer that feeds a local isochronic region.

The diameter (and shape) of an isochronic region on-chips depends on the wire type employed for interconnection. To control skew on chip, we need to consider delay differences due both to wire lengths and to the lumped capacitive efforts of the driven loads. Where the RC time constant of the wiring interconnect τ_w is much less than the RC combination of the driving source resistance and the lumped capacitance of N clocked loads on the net ($\tau_{\text{net}} = R_s C_{\text{gate}} N = N\tau_g$), we can consider all points on a net to be isochronic, meaning that the net acts like one electrical node characterized by the total lumped capacitance of gates on the net. Wires on a chip are often modeled as distributed R_0C_0 sections, where R_0 and C_0 are the resistance and capacitance per unit length, respectively (see Figure 9.33). In such cases, the propagation delay for a wire of length l follows the diffusion equation [31].

$$\tau_w = R_0 C_0 l^2/2 \tag{9.2}$$

Therefore, if we consider a net of length l with N standard loads, we can consider the net to be isochronic if $\tau_w \ll N\tau_g$. From Equation 9.2, this implies

$$l \ll \sqrt{\frac{2NR_sC_{\text{gate}}}{R_0C_0}} \tag{9.3}$$

This relationship provides a guideline for the maximum length over which wire delays may be neglected relative to gate-charging delays. Based on typical values for a 1 μm process, $\tau_g < 500$ ps, isochronic regions for lightly loaded lines ($N = 1$) are up to 10,000λ for lines in third layer metal, 5,000 and 8,000λ

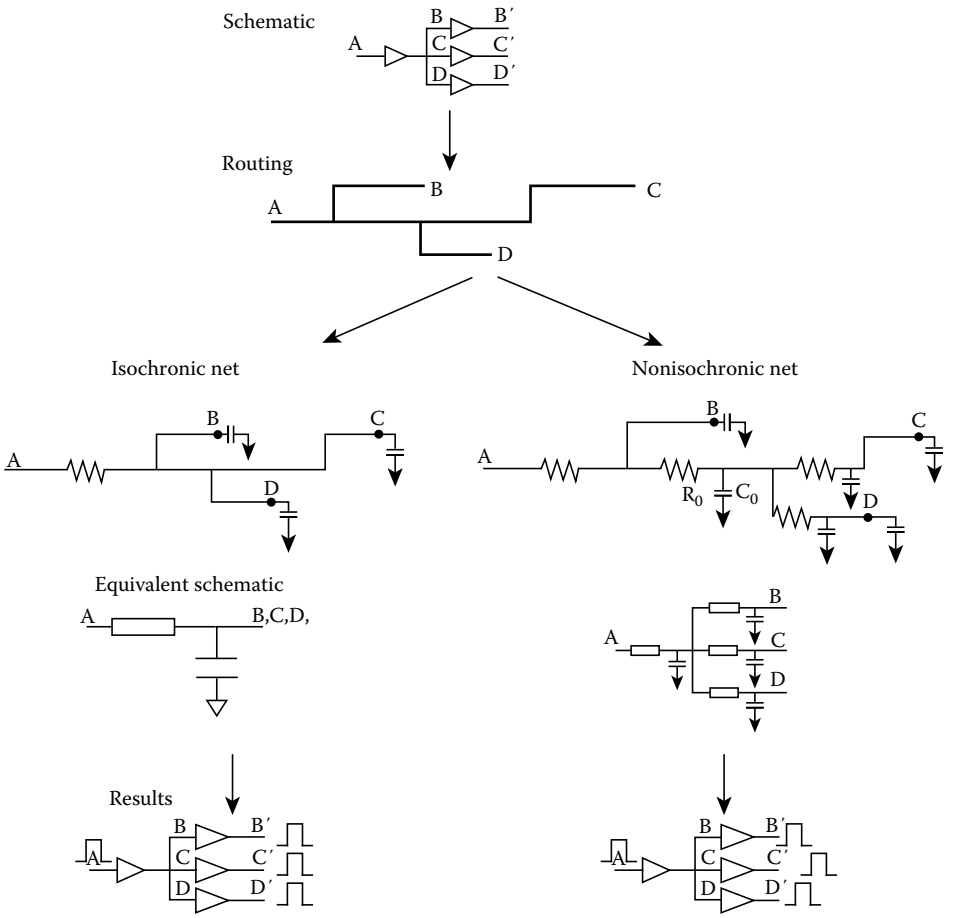


FIGURE 9.33 Isochronic and nonisochronic passive wiring nets.

for first and second layer metal, respectively, and 200λ for polysilicon wires, where λ is the minimum feature size of the process [31]. This illustrates the importance of distributing clock within metal layers to the greatest extent possible. Even a few short polysilicon links may introduce sufficient series resistance to drastically reduce the isochronic region for the given clock line. This also illustrates that if clock is distributed in metal layers, and is always buffered before exceeding the isochronic distance, it will be primarily differences in lumped capacitive loads and not wire length that determine clock signal delays, and hence relative clock skews.

9.2.2.3 Nature of Skew On-Chip

The concept of isochronic regions helps us understand the nature of clock skews in VLSI and helps explain why on-chip skews may be greater than those between off-chip points that are physically many more times distant. A key realization is that signals do not propagate at the "speed of light." If they did, absolute delays across even the largest chips (2 cm edges) would be subnanosecond and the isochronic diameter would easily encompass an entire die at clock speeds up to 200 MHz. Rather, on-chip propagation delay depends much more on the time needed for output drivers to charge the total lumped capacitance associated with all the gate inputs of the driven net. In other words, fanout and driver current

abilities have more to do with delay than path lengths. This is especially true when clock distribution is exclusively via metal layers, as is the norm in a modern design. On the other hand, off-chip, we route signals via impedance-controlled coaxial or microstrip lines, or via optical fiber, and these media typically do exhibit propagation velocities of 0.6–0.8 c. Therefore, off-chip, differences in physical propagation distances are the dominant source of skew, while on-chip, it is imbalances in driver loads that are the most common source of skew.

In on-chip cases in which wire diffusion delays and lumped capacitive effects are both significant, a difference in line length can also result in skew due to a different total wiring capacitance. In addition, equal length lines that go through different metallization layers or through polysilicon links will have different delays due to different levels of capacitive coupling to V_{ss} and different series resistances, especially in the case of polysilicon links. Accordingly, an important principal to simplify clock net design is to aim for buffering levels and fanouts that yield isochronic conditions for the passive wiring nets between buffered points on the clock net. This simplifies skew control in clock net design because attention then only need be paid to balancing loads on each buffer and to matching the number of buffers in each clock path. The alternative, in which passive wiring nets are not isochronic, requires detailed delay modeling of each wire path, taking into account the actual routing, the R_0C_0 of the wire type, the temperature, and the exact position of each lumped load on the wiring path. The important concept, however, is that by the choice of metal layers, line widths, and/or loadings, one can establish formally defined isochronic conditions on some or all portions of a complete clock net, which, in its entirety, is far too large to be isochronic. When fully isochronic subregions (such as a wide clock trunk) can be established, or even when a defined region is not isochronic but has delay that is simply and reliably predicted from position (such as on a clock ring), the remaining clock net layout and skew control problem is simplified, design risk is lowered, and pre- and postlayout simulations are more consistent because final routing of clock paths from these reference regions is shortened and overall uncertainty reduced. We shall see and use this principle in analyzing the popular clock distribution schemes that follow.

The skew that intrinsically arises from differences in RC time constants of either lines or gate loads is aggravated by threshold variations in buffers and clocked loads due to minute differences in electronic parameters and lithographic variation in line widths and lengths at different devices. Time-constant and threshold effects interact to give a worst-case skew, which is the difference between the time at which the voltage response of line with the slowest time constant, τ_{max}, crosses the threshold of the logic element with the highest threshold, V_{Tmax}, until switching of the device with the lowest threshold driven by the line with fastest RC time constant. Taking the difference of the earliest and latest switching times we have [32]

$$\delta = \tau_{min}\ \ln\left(1 - \frac{V_{Tmin}}{V_{DD}}\right) - \tau_{max}\ \ln\left(1 - \frac{V_{Tmin}}{V_{DD}}\right) \tag{9.4}$$

Equation 9.4 implies that a clock system design in which buffered electrical segments of the clock net have 10% variation in τ about τ_{nom}, and 10% variation of V_T about $V_{DD}/2$, will have an estimated skew of at least 17% of τ_{nom}.

9.2.2.4 Single-Phase Clocking

Clocks ultimately always drive a storage register or latch of some type. The form of clock signal(s) required in a system therefore depends on the type of latch or flip-flop element used and on properties of the CL circuits used. True single-phase clocking is the most complex clocking principles with which to design systems, and has traditionally not been used, although recent work has assessed some truly single phase logic families [2]. The reason for caution with single-phase clocking is that invalid states may be passed to the output in two ways, as shown in Figure 9.34a if the CL delay is less than T_h (i.e., too fast) or (Figure 9.34b) the CL delay is

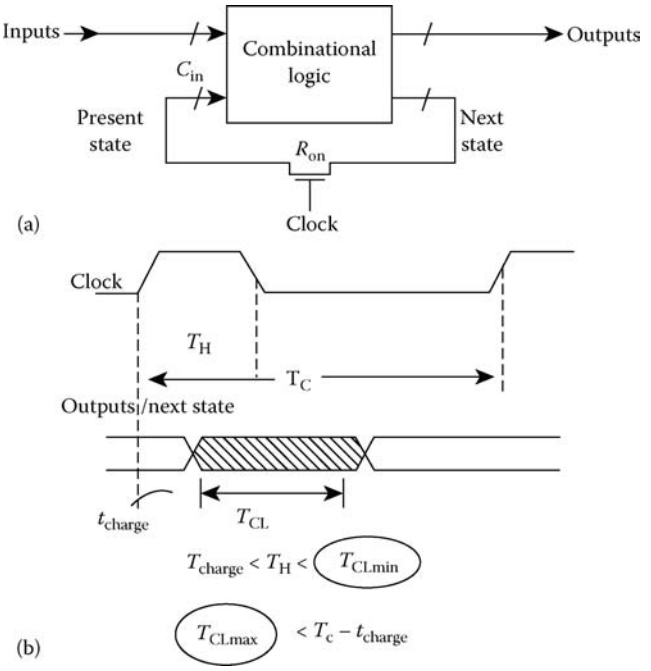

FIGURE 9.34 In single-phase clocking the CL path must be neither too slow nor too fast.

greater than $T_C - t_{charge}$ (i.e., too slow). In other words, a two-sided (min and max) constraint on logic path delay exists for single-phase clocking [27]. This means that although attractive to minimize total interconnect, buffer counts, and interphase skew is avoided, truly single-phase clocking involves a greater design risk and timing analysis complexity. Because of this, the most common overall clocking scheme is single-phase clock distribution with local generation of a two-phase clock.

9.2.2.5 Two-Phase Clocking

With two nonoverlapping clock phases, we can eliminate one of the risks of single-phase clocking, that of a logic path being too fast. On the first phase the input is made transparent and allowed to affect the CL, charging the inputs through R_{on} C_{in} in time t_{charge}. During this time, the CL outputs are isolated from the input latch. On the second phase, the new CL output values are stored by the second phase latch while the input latch is opaque, isolating inputs from the new values until the next phase one clock time. A nonoverlapping period between phases ensures that at no time does direct transparency occur from input to output. With two-phase nonoverlapping clocks, as shown in Figure 9.35a, we need to ensure only that the maximum delay in the CL is less than $T_C - t_{charge} - T_3 - t_{preset}$. It is essential that the nonoverlapping interval, T_2, be greater than zero, but T_3 can be arbitrarily short. When present, however, T_3 acts as an extra timing margin against skew.

It is obviously desirable to make T_2 as small as possible, but we can do so only when distributing two-phase clock directly if the interphase skew is less than T_2. In the worst case, the interphase skew may be twice the skew of each of the two clock phase nets individually. Skew, therefore, necessitates at least a 1:1 derating in speed for two-phase clocking in addition to the basic loss of clock cycle time for logic settling, to ensure correct operation of storage devices. If skews in the two clock phase nets are uncorrelated, however, the extra penalty could be as high as 2:1. Every nanosecond of skew in the clock net for each phase then not only reduces the basic critical path logic timing margin by 1 ns, but also adds 2 ns to the T_2 requirement.

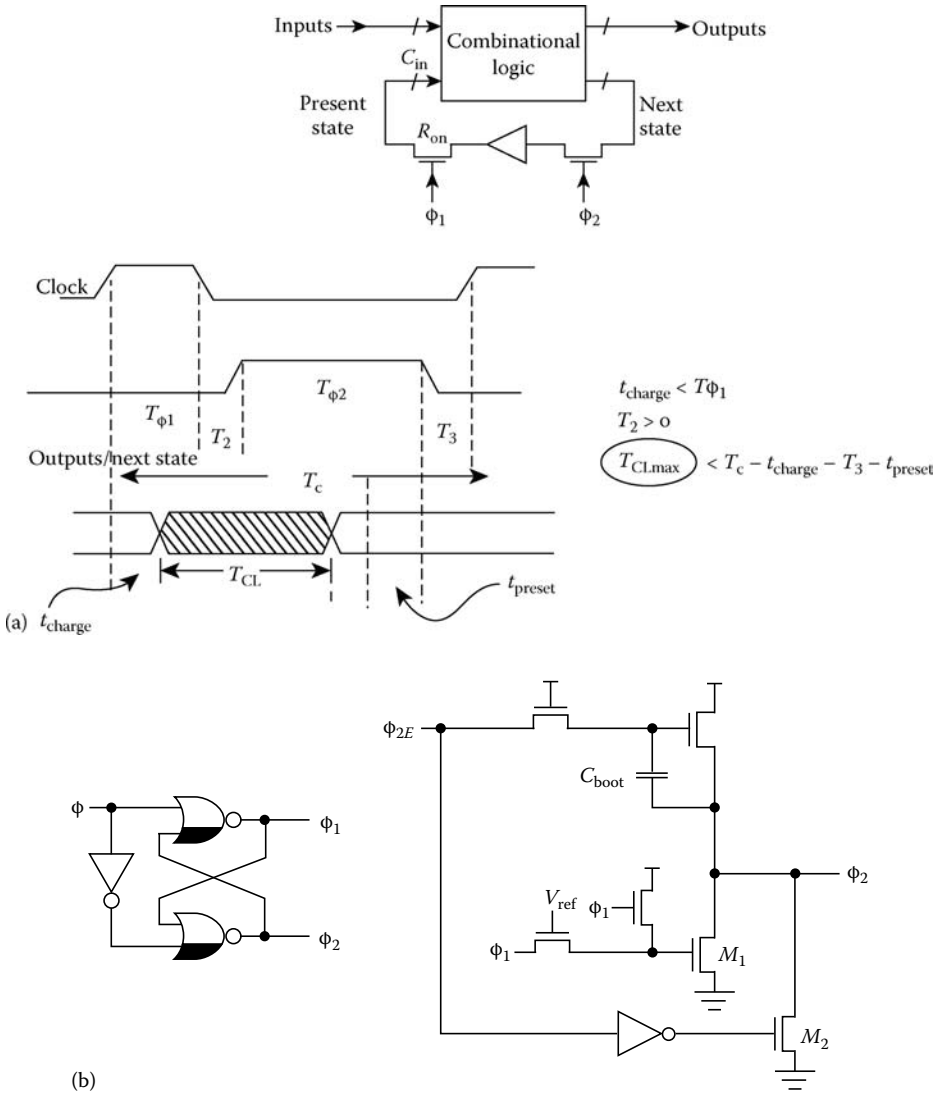

FIGURE 9.35 (a) With nonoverlapping two-phase clocks, no lower limit exists on the CL delay; and (b) generator for two-phase nonoverlapping clock and buffer circuit to ensure nonoverlap period. (From Glasser, L.A. and Dobberpuhl, D.W., *The Design and Analysis of VLSI Circuits*, Addison-Wesley, Reading, MA, 1985, 349.)

Therefore, in high-performance systems we have quite an incentive to distribute a single clock phase throughout the design and accept the extra logic required to generate two-phase clocks locally at each device (or small group of similar devices) that requires them.

9.2.2.6 Two-Phase Clock Generator Circuit

The canonical form of circuit to generate the local two-phase nonoverlapping clocks from a single phase clock is shown in Figure 9.35b. The feedback of ϕ_2 into NOR1 ensures that ϕ_2 must be low before ϕ_1 can go high after the single-phase ϕ_{in} input has gone low, and vice versa. A special clock buffer circuit is shown in Figure 9.35b, which helps ensure that a period of nonoverlap exists in the presence of the threshold variations in the driven loads [12]. It does this by using transistor M_1 to clamp the ϕ_2 output

low until far into the fall of ϕ_1. ϕ_2 is held low until ϕ_1 has fallen below ($V_{ref} - V_{thresh}$) to finally cut off M_1. V_{ref} might be set at 2 V in a 5 V process, thereby ensuring that ϕ_1 is well below the logic threshold of all clocked loads before ϕ_2 begins to rise, while at the same time minimizing but guaranteeing the existence of a nonoverlap period, which is lost processing time.

9.2.2.7 Multiple-Phase Overlapping Clocks

Generating and/or distributing nonoverlapping clocks with a minimal T_2 can be quite difficult in large systems. An alternative is to define three or more primary functional logic steps and use a similar number of overlapping clock phases. In this case, the multiple stages of clocking removes the need for the guaranteed nonoverlap period in two-phase clocking. Let us consider three-phase overlapping clocking. The principles generalize to any higher number of phases.

In three-phase clocking, the middle phase can be thought of as providing the nonoverlap time, which ensures time isolation between I/O activation for the module enabled on each clock phase. In fact, each phase plays a similar isolating role with respect to operations performed on its adjacent phases. Figure 9.36 illustrates the concept. The number of phases and the role for each phase typically reflects some natural cycle or step sequence of the basic system being designed; for example: bus input, add to accumulator, bus output.

In WSI systems, in which uncertainty in clock delays, circuit speeds, and interconnect impedances may be high [10], overlapping clock logic can give high tolerance to clock skew, and is compatible with self-timing in selected subcircuits. Three-phase overlapping clocking has a distinct advantage: no hazard exists unless all three clock phases overlap in time. In the presence of severe clock skew, this can be a major advantage. Although called overlapping clocks, the circuits still function if successive phases do not actually overlap, although speed is sacrificed if overlap is lost.

9.2.2.8 Overlapping Clock Phase Generator

Figure 9.37 illustrates a circuit for generating three-phase overlapping clocks. Phase overlap is ensured because it is the onset of each phase that kills its predecessor. A Johnston counter comprised of three static *D*-flip-flops generates the phase-enabling signals which sequence the actual generator stage, which is comprised of the three cross-coupled NOR gates. A deliberately limited positive-going drive ability of the enable input ensures that the Johnston counter exercises underlying rate and sequence control, while the output waveforms are determined by the interactions between the actual clock phase signals. While the enable inputs to each NOR are logically sufficient to drive the output high when the other input is low, they are arranged not to be able to drive the NOR output low on their own when the enable signal returns high. The output of phase *i* therefore stays high after its own enable signal has

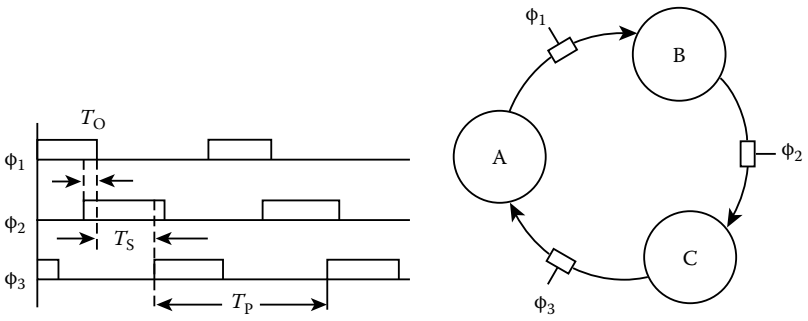

FIGURE 9.36 Principle of multiphase clocking. Outputs are isolated from inputs by other stages of nonactive logic even though any two active clock waveforms may overlap. (From Glasser, L.A. and Dobberpuhl, D.W., *The Design and Analysis of VLSI Circuits*, Addison-Wesley, Reading, MA, 1985, 352.)

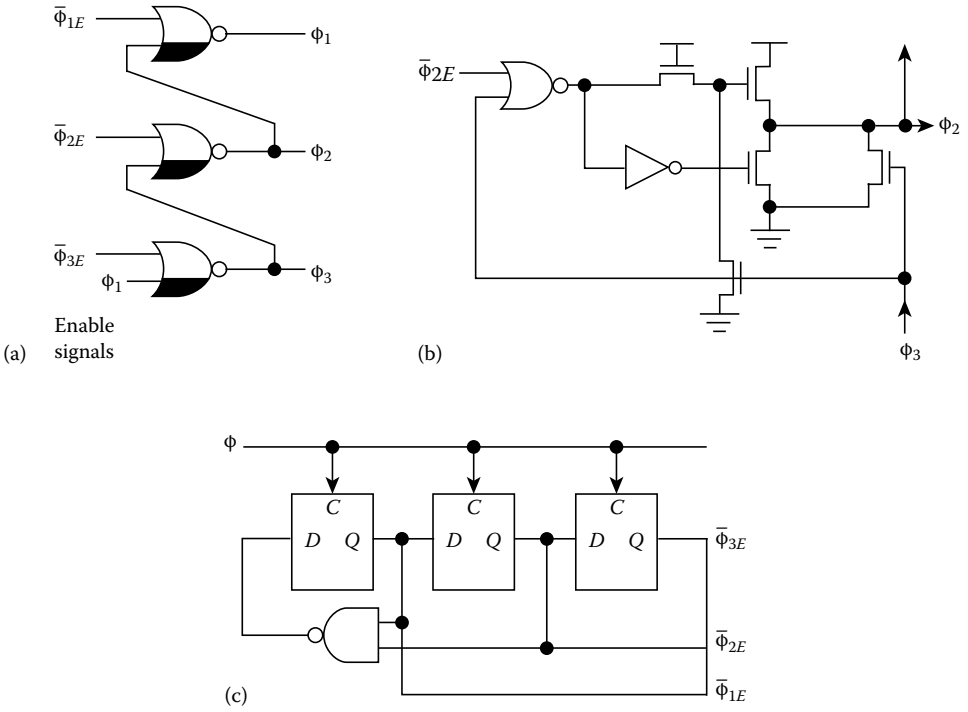

FIGURE 9.37 Three-phase clock generator logic and buffer design to ensure overlap. (From Glasser, L.A. and Dobberpuhl, D.W., *The Design and Analysis of VLSI Circuits*, Addison-Wesley, Reading, MA, 1985, pp. 348 and 354.)

disappeared (gone high) until the phase $i+1$ output is also high in response to the low-going phase $i+1$ enable. Figure 9.37 shows this logic and a NORing clock buffer circuit in which the phase $i+1$ signal is necessary to assist in returning the phase i output to zero.

9.2.2.9 Clocking Latches

A latch is a storage element which is level sensitive to the clock waveform. The latch output conforms to the input that is present while the clock waveform is at its active level for that latch, and then continues to hold that value when the clock level falls below the active level. Latches have setup and hold time requirements analogous to those in the flip-flops that follow. Circuit designs for high and low active latches are given in [31]. By combining latches of opposite active polarity, with logic between the stages, there can be two logic operations per clock period. In this type of operation, however, skew adds to the needed clock period as usual, but in addition any imbalance in the clock duty cycle requires a further margin because the minimum duty cycle half-width must remain greater than the worst-case logic delay. The clock edges also must be kept sharp enough that transparency never occurs between two successive latches working on opposite clock phases simultaneously, or that some minimum logic delay always exists between latches that exceeds the possible overlap time. The DEC ALPHA microprocessor was an example of a two-phase latch machine in which both phases drive latches that are active in the respective phases permitting logic evaluation twice per cycle. This is one case in which to control the very high transistor count, two-phase clock is distributed globally rather than generated at each module. The entire clock net on each phase is driven from a single large buffer placed at the center of the die where a PLL is also fabricated to advance the on-chip clocking phase relative to external bus timing, thereby compensating for buffer delay.

Two principles for maintaining 50% clock duty cycle in a latch machine are (1) whenever generating or phase-locking to a system clock, do so at twice the rate needed, then (frequency) divide by two. This results in 50/50 clock waveform, regardless of the original clock source waveform. (2) When repeatedly buffering clock in a chain, or when distributing clock through a hierarchy of clock buffers, use inverting clock buffers at each stage. Inverting the clock at every buffering stage inherently counteracts the effects of different rise and fall times in buffers. Otherwise, these can accumulate to extend or shorten the ON period of the clock waveform. For example, if a noninverting buffer has greater fall time than rise time, a clock path transiting several of these buffers will develop a broadened ON period. This effect is self-compensating in a chain of inverting buffers.

9.2.2.10 Clocking Flip-Flops

Flip-flops are more complex storage circuits than latches, but have no dependency on clock duty cycle because they are sensitive only during an active edge of the clock waveform. A rising edge *D*-flip-flop (for instance) updates its output to match its *D* input on the rising edge of the clock waveform. The *Q* output retains the updated value thereafter, regardless of further changes in the input or clock waveform (with the exception of another rising clock transition). A latch is a more fundamental circuit element than the *D*-flip-flop in that edge-triggered behavior is attained only by implementing two latches and generating a pair of two-phase nonoverlapping clock pulses internally, in response to the active clock transition at the edge-triggered input.

For instance, Figure 9.38 shows a typical *D*-flip-flop in which inverters I_1 and I_2 generate the internal two-phase clock signals for level-sensitive latches L_1 and L_2. In specialized applications, it may be advantageous to design a custom module within which multiphase clocks are distributed directly, without incurring greatly increased skew problems. For example, an error-correcting codec ASIC prototype for 45 Mb/s digital communications includes a 2613 stage tapped delay line comprised of seven-gate single-phase *D*-flip-flop modules. The use of single-phase clock flip-flops in this context is relatively expensive, but appropriate for fast validation of the system design. For cost- and power-reduced production in volume, a more detailed latch-based design using directly distributed two-phase nonoverlapping clocks may be worthwhile. In general, while it is most common to conduct system design based on the single-phase clocking model, two-phase or multiphase clocking may be advantageous within specialized substructures.

Although edge triggered, a minimum clock pulse width is still typically required to deliver enough switching energy on the clock line. For correct operation (specifically, to avoid uncertain outputs due to metastability) of an edge-triggered flip-flop, data must be stable at the input(s) for a minimum setup time before the clock edge, and the data must remain stable at the input for the hold time, after the clock edge. The time until the *D*-flip-flop output is valid after the clock edge occurs is the clock-to-*Q* delay. For hazard-free transfer of data from one stage to another with *D*-flip-flops, without assuming a minimum logic delay constraint between stages, the clock-to-*Q* delay must exceed the hold time. Typical values for a range of *D*-flip-flop types in a 1.5 μm CMOS process are $t_{\text{setup}} = 0.8$–1.5 ns, $t_{\text{hold}} = 0.2$–0.4 ns, and $t_{\text{clk}-Q} = 1.3$–3.5 ns for *Q* output fanouts of 1–16, respectively. With the extra input logic delays in a JK flip-flop, many JK flip-flop cell implementations exhibit $t_{\text{hold}} = 0.0$ ns. By comparing magnitudes of typical setup and hold time requirements, it is apparent that skew is more likely to cause a setup time violation on critical delay logic paths than it is to result in a hold time violation.

9.2.2.11 Role of Clocks in Dynamic Logic

Clock signals are also used to implement a variety of logic gate functions in a dynamic circuit style, i.e., based on short-term charge storage, not static logic. This typically involves precharging on one phase and logic evaluation steered by the inputs on the second phase. The ''Domino'' logic approach combines a dynamic NMOS gate with a static CMOS buffer [8]. In ''NORA'' (no-race), logic dynamic logic blocks are combined with clocked CMOS latch stages. A variety of other dynamic logic circuits, using up to four clock signals to structure the precharge and to evaluate timing, are covered by [12,31]. In all of these gate

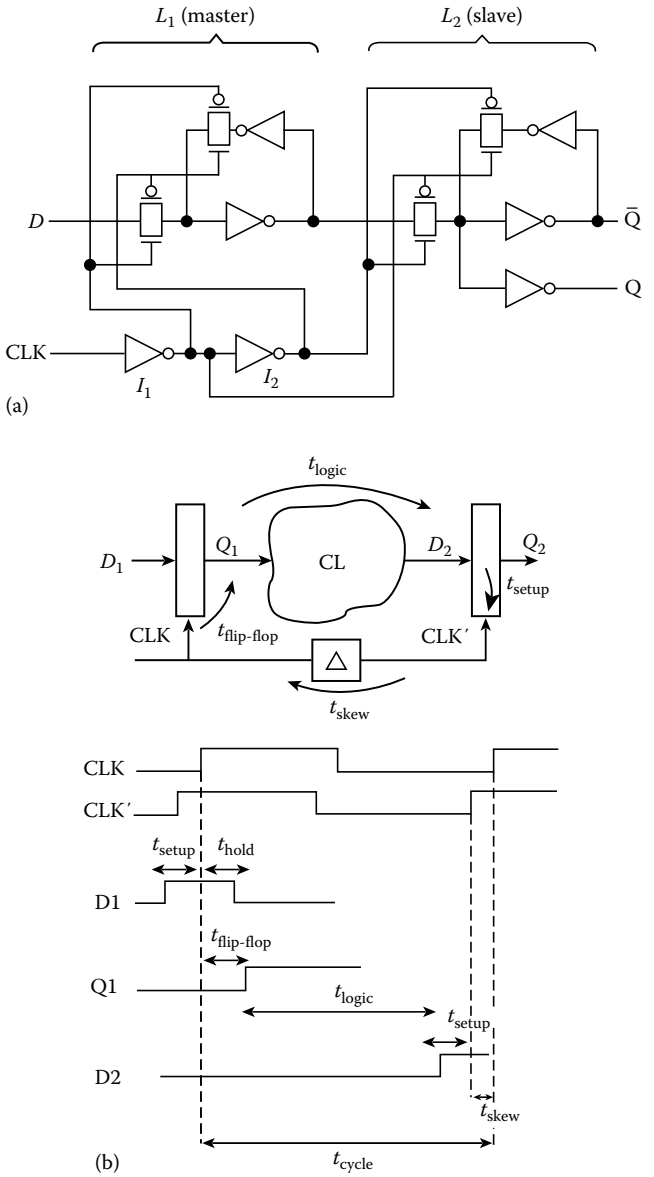

FIGURE 9.38 (a) Two-phase latch structure of a typical CMOS positive edge-triggered *D*-flip-flop; and (b) setup, hold, and delay times for a *D*-flip showing how skew is equivalent to a shorter clock period and threatens setup time margin. (From Bakoglu, H.B., *Circuits, Interconnections and Packaging for VLSI*, Addison-Wesley, Reading, MA, 1990, 345.)

level circuit implementations, the clocking-related issues are ultimately manifestations of the basic principles already seen for two-phase clocking; i.e., of never simultaneously enabling a direct path from input (or precharge source) to output. These logic styles were developed to reduce transistor counts. However, modern designers will most often be faced with a greater challenge in managing system-level problems of skew in a single clock phase distributed to static register than the challenge of reducing transistor count.

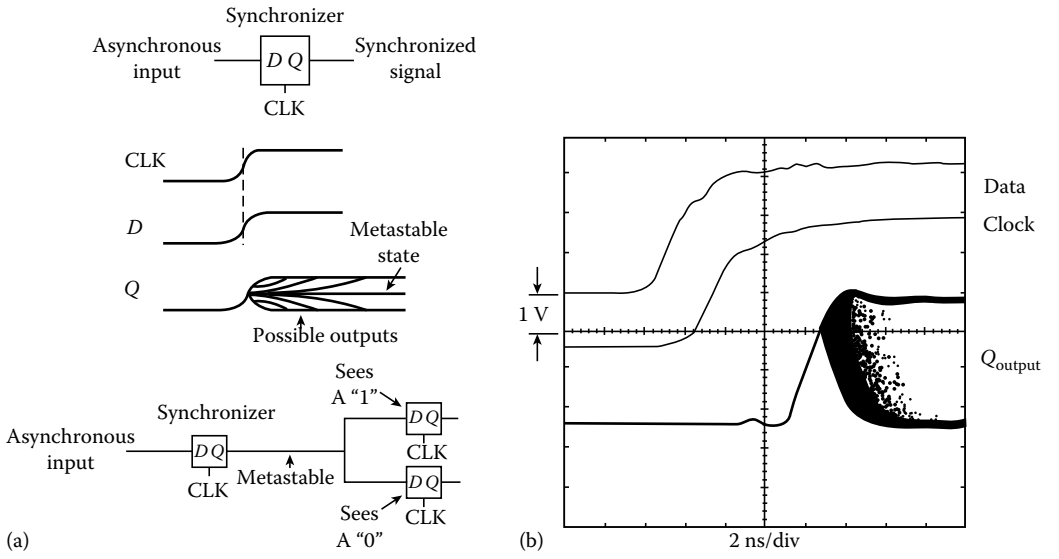

FIGURE 9.39 (a) Metastability in a synchronizer circuit. (From Bakoglu, H.B., *Circuits, Interconnections and Packaging for VLSI*, Addison-Wesley, Reading, MA, 1990, 357.) (b) Experimental illustration of metastability in 74F/74 (TTL) *D*-flip-flop showing output rise before indeterminate final response (10 s point accumulation). (From Johnson, M.W. and Graham, M., *High-Speed Digital Design: A Handbook of Black Magic*, Prentice Hall, Englewood Cliffs, NJ, 1993, 130.)

9.2.2.12 Synchronizers and Metastability

Many systems need to sample external inputs which may be timed independently of the synchronous system clock, such as switch-based control inputs, keyboard states, or external process states in a real-time controller. The external state needs to be synchronized with the system time base for processing. Metastability leading to synchronizer failure is a fundamental possibility that can never be entirely eliminated.

Figure 9.39 is a basic synchronizer circuit. Our concern is that it is possible for the synchronizer output to take an arbitrarily long time to settle to one or the other valid logic states if the input signal voltage is sampled in the intermediate voltage range, i.e., $V_{iL} < V_{in}(t) < V_{iH}$. In this range, it is possible to find the input voltage at a value that leaves the cross-coupled latches internal to a flip-flop in an intermediate state, with insufficient positive feedback to snap the output to either high or low valid states. System noise or quantum fluctuation will ultimately perturb such a precarious balance point and the output runs to one direction or the other, but it can take an arbitrarily long time for the synchronizer to reach a valid output state. As shown in Figure 9.39b, some flip-flop outputs may also tend to rise at least halfway toward the positive output level before deciding the input was really a zero. This glitch may trigger edge-sensitive circuits following the synchronizer.

Fortunately, the probability of an indeterminate latch output falls exponentially with the time T after sampling the possibility indeterminate input

$$P(t > T) = f_{clk} f_{in} \Delta e^{-T/\tau_{sw}} \tag{9.5}$$

where

f_{clk} is the synchronous sampling frequency
f_{in} is the frequency of external transitions to be synchronized
Δ is the time taken for the input voltage in transition to cross from V_{iL} to V_{iH} (or vice versa)
τ_{sw} is the time constant characterizing the bandwidth of the latch device

Having recognized the strict possibility of a metastable logic state resulting from synchronizer input, the designer can address the issue in several practical ways:

1. Use a high gain fast comparator to minimize Δ by minimizing the voltage range V_{iL} to V_{iH}.
2. Ensure or specify fast transition in external sensors or other devices to be sampled, if design control extends to them.
3. If there is no real-time penalty from an additional clock period of input response delay, the synchronizing latch should be followed by one or two more identical synchronizer latch stages, thereby increasing T in Equation 9.5 to reduce the chance of a metastable state being presented to internal circuitry to an acceptably low probability.

The effect of input metastability on the system also should be analyzed for its impact. If it is extremely crucial to avoid a metastability hazard, then phase-locking the external system to the system clock may be considered, or if the system and external timebases are free running but well characterized (e.g., in terms of a static frequency offset or known phase modulation), then the anticipated times of synchronization hazard may be calculated and avoided or otherwise resolved.

As a practical matter, the way in which design software handles metastability should be considered. Potentially metastable conditions should be flagged as a warning to the user, but not necessarily treated as a violation prohibited by the design environment. Some applications, particularly in VLSI for telecommunications, need design support for plesiochronous (near-synchronous), phase-modulated, or jittered signal environments. This implies test vector support to represent clocks interacting through logic at slightly different long-term or instantaneous free-running frequencies with design and simulation rules that permit the metastable conditions inherent as such clocks walk relative to one another. Circuit simulations must be allowed to continue with a random value resulting from the simulated ''synchronizer failure'' to be useful in such applications.

9.2.2.13 Controlled Introduction of Skew

Skew is not necessarily all bad. In fact, from the viewpoint of the system power supply, and power and grounded-related noise current surges, it is undesirable to have all logic transitions occurring exactly simultaneously. In a CMOS IC with 20 K register stages at 0.1 pF load each and a 1 ns clock rise time, 10 A of peak current can be drawn by the clock net. This can present a serious $L\,dI/dt$ problem through power and ground pins and can even lead to electromigration problems for the metallic clock lines. Chip clocking strategies should take this into account early in the design by seeking ways to deliberately stagger or slightly disperse the timing of some modules with respect to others. Also, the system clock waveform may not necessarily need the fastest possible rise time. Consistent with avoiding slow-clock problems, and controlling threshold-related skew in buffers, the clock edge should not be made faster than this as an end in itself. Excessively fast clock edges clock edges only aggravate power and ground noise problems as well as ringing and potentially causing electromagnetic radiation problems in the chip-to-chip interconnect. These principles motivate the widely used 10 K ECL logic family, which is based on the much-faster 100 K series with explicit measures to slow down the rise and fall times of the basic 100 K logic gates.

When considering random skew, it may or may not be beneficial to pursue skew reduction below a certain level in the design. In the case of a microprocessor or a design in which the fastest possible IC speed is always useful skew reduction does mean a performance improvement. In some other applications, however, the clock speed is set by the application. For instance, a VLSI circuit for a telecommunications MUX may be required to operate at a standard line rate of 45 MHz. In this case there may be no premium for a design that can perform the same functions at a higher speed. A working design with skew of 5–7 ns (out of a 22 ns clock period) may then be more desirable than a functionally equivalent design with 0.5 ns skew because dI/dT effects are eased by distributing the total switching current over time in the former. This principle may be important in practice as automated clock synthesis tools become more widely used and effective at achieving low skew, possibly creating unnecessary system-level noise and

EMI emission problems. Future clock-related CAD tools should possibly aim to disperse clock timing at various loads while satisfying a target worst-case skew, rather than absolutely minimizing skew.

Strictly speaking, skew can also be beneficial when allowed to build up in a controlled way in certain regular logic structures. For instance, by propagating clock in the opposite direction to data in a shift register, one enhances the effective setup time of the data transfer from register to register. In general, however, it is not feasible or advisable to try to design every clock path with a desired (nonsimultaneous) clocking time at each register, taking into account the individual logic paths of signals leading each clocked latch input. Especially when designing larger systems mediated by CAD tools for placement, routing, and delay estimation, the most practical and low-risk approach is to consider any deviations from a common nominal clock time as undesired skew. Indeed, for any one latch, timing margin may be enhanced by the actual skew that arises, but with thousands of logic paths, it is impossible to analyze the relative data and clock timing for each latch. Only one instance in which the skew works against the assumed timing margin is enough to fail a design. Therefore, the ''customized skew'' approach is recommended only for small and very high speed specialized circuit design.

9.2.2.14 Clock Signal Manipulation

As a matter of design discipline, some commercial ASIC and cell-based layout systems may prohibit a designer from directly gating or manipulating a clock signal. Any needed clock qualification is done through defined enable or reset inputs on register structures. As in software development, in which structured design disciplines have been developed, gating the clock may be riskier than its apparent efficiency warrants. In addition, clock gating within random logic designs can interfere with test pattern generation. The risk also exists of creating clock glitches or even logical lockups when clocked logic functions decode conditions that gap its own clock. On the other hand, in high performance and in large system-level designs, clock gating for power down and ''clock tuning'' may be unavoidable.

Wagner [30] discusses clock pulse-width manipulation, defining four canonical subcircuits that can be used to ''chop,'' ''shrink,'' or ''stretch'' the clock waveform for either delay tuning or duty cycle maintenance. The effect of these circuits on the positive pulse portion of a clock waveform is shown in Figure 9.40, where AND gates have delay d_a, OR gates have delay d_0, inverters have delay d_i and the delay elements have delay D. Aside from a single gate delay, the chopper and stretchers leave the rising edge unaltered and tune the trailing edge. These can be used to maintain a balanced clock duty cycle or to tune the nonoverlap period in two-phase clocking. The shrinker delays the rising edge of the clock as might be helpful to specifically delay clocking a latch or a flip-flop that is known to follow a particularly long logic path delay. This is not generally a preferred design approach, especially when manufacturing repeatability and temperature dependence of delay elements are considered.

By ''clock gating,'' we mean selectively removing or masking active phases or edges from the clock signal at one or more latches. One valid reason to gate the clock in CMOS is to reduce power consumption. Many circuit designs possess large modules or subsystems which it makes sense to stop cycling in certain application states. Gating the clock off is therefore the simplest form of power management, because CMOS has negligible power dissipation in a static state. However, even for this simple use of clock gating, the main issue is avoiding glitches when gating the clock.

Before gating any clock, the designer should see if gating can be avoided with an alternate design style. For example, if it is desired to hold the data on one register for a number of cycles while other registers on the same clock proceed, a preferred approach is to use a 2:1 MUX at the register input. Rather than gate the clock, the MUX is steered to select the register's own output for those cycles in which gating would have occurred. Ultimately, if it is appropriate to gate out one or more clock pulses, a recommended way of doing so in rising edge active logic is to OR out the undesired clock edges, decoding the clock gapping conditions on the same clock polarity as the one being qualified (see Figure 9.41). A natural tendency seems to be to AND out the gapped clock edge and/or to decode the gapping condition on CLK, but these approaches are more apt to generate clock line glitch than the OR-based approach. In the AND approach

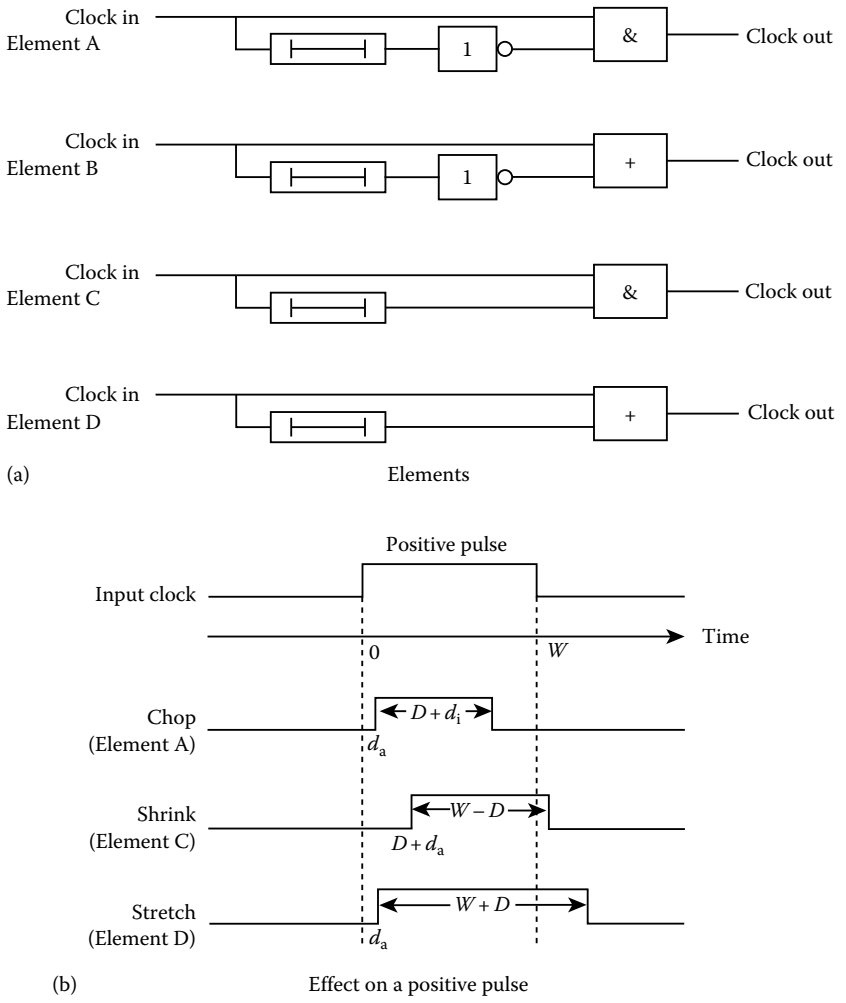

FIGURE 9.40 Standard circuits for chopping, stretching, and shrinking a clock waveform to adjust duty cycle or timing margins. (Adapted from Wagner, K.D., *A Survey of Clock Distribution Techniques in High Speed Computer Systems*, Report CRC 86-20, Stanford University Center for Reliable Computing, Stanford, CA, December, 1986, 15.)

the gating line returns high at the same time as the falling edge after the last-gapped active edge. In the case of minimum delay through the gapping logic the risk is that both AND inputs are momentarily above threshold.

9.2.2.15 Minimizing Delay Relative to an External Clock

In a large system, skew can build up between clock and data at the system level, even if the clock is skew-free everywhere within the ICs because data paths through ICs can build up delay relative to the system clock. For instance, if an ECL or TTL system clock line is distributed to a large CMOS IC, then the system clock must be level shifted and a large clock buffer may be required in each IC to drive its internal clock net. The delay through the on-chip clock interface and buffer can mean that even if the chip timing is internally skew-free, the on-chip clock is significantly delayed relative to the external system timing. Short of using the phase-lock methods described later, a simple technique to minimize this form of system-level skew is either to retime chip outputs with a separate copy of the system clock that has not

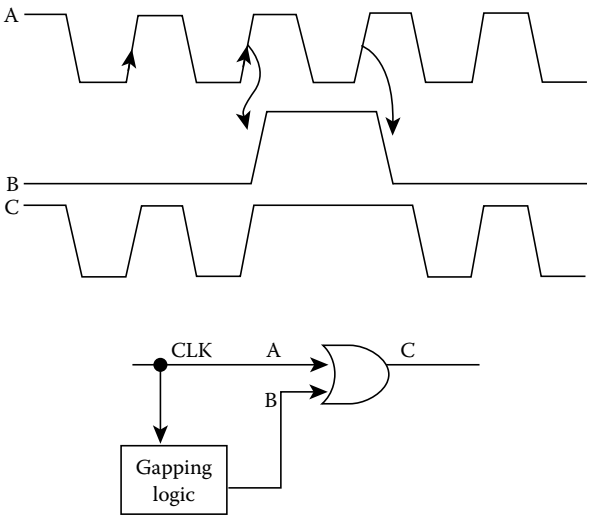

FIGURE 9.41 OR-ing out a clock edge when clock gating is essential.

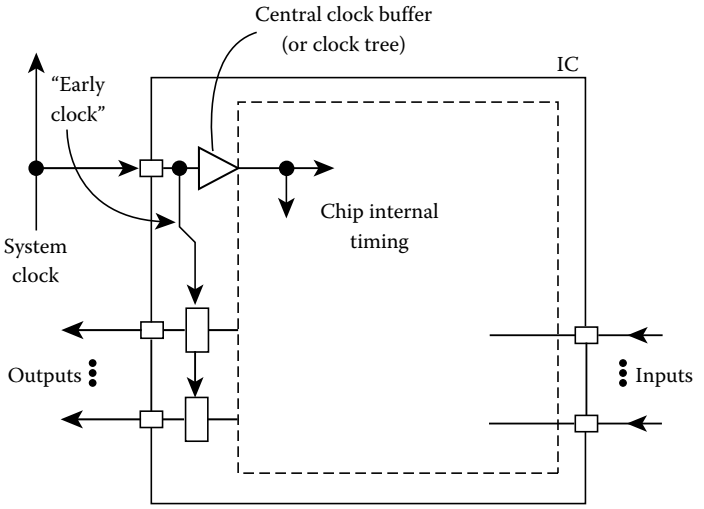

FIGURE 9.42 The "early clock" technique for reducing chip delay relative to external system timing.

gone through the internal clock buffer, or, if electrically compatible, to use the external system clock to directly retime the output signals from each IC (Figure 9.42). This is called the "early clock" concept. Note that this assumes an adequate timing margin exists in the final stage of internal logic to permit the relatively early sampling of logic states.

9.2.3 Clock Distribution Schemes

9.2.3.1 Single-Driver Configurations

Often a single on-chip clock buffer is the simplest and best approach to clock distribution. A single adequately sized clock buffer is typically located at the perimeter to drive the entire clock net of the chip,

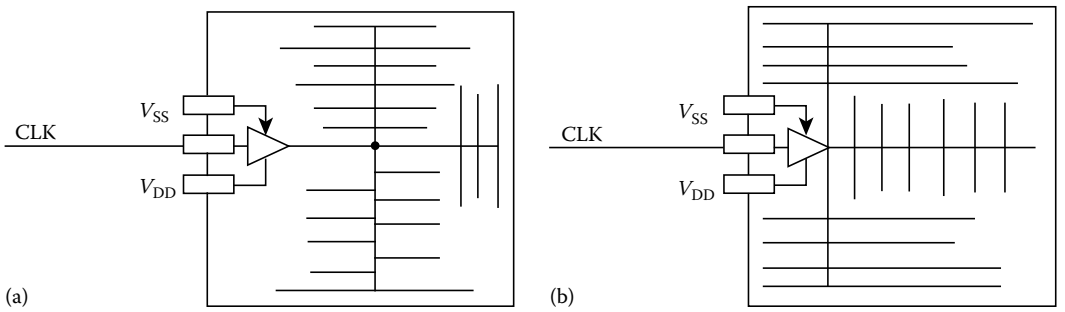

FIGURE 9.43 Single clock buffer placed in the I/O perimeter with dedicated power, ground pins (a) branching from a medial point on die (current density on line to medial point may be high) and (b) branching immediately (skew may be high).

as shown in Figure 9.43. This approach can also perform well in large systems if the clock is distributed in a low R_0C_0 routing layer, such as third-layer metal. The main advantage regarding skew is that no matter how the single-clock driver delays or otherwise responds to the external clock input, the output waveform is electrically common to all loads. No intervening buffers and no separate passive net segments develop skew. Moreover, if the global clock net comprises an electrically isochronic region ($NC_{gate} \gg l^2\,RC_{wire}$) in which clock loads are reasonably uniformly distributed, the clock net voltage rises virtually simultaneously at all points on the charging clock net, resulting in extremely low skew. Often this leads to lower skew than in a buffered clock fanout tree. There is also only one global clock wiring net, simplifying documentation.

On the other hand, skew can be larger and more routing dependent with a single buffer (than with some following schemes) when clock routing lengths vary significantly and wiring capacitance and resistance are significant. In such cases an isochronic net is not an accurate model, and performance depends on the way clocked loads are distributed on arms branching from the medial clock node. It is possible for neighboring flip-flops to be connected to the central driver via quite different path lengths, making prelayout simulation relatively uncertain and requiring considerable postlayout tuning. Another caution is that even if no actual skew is present because a single waveform is common to all loads, the rise time of the clock waveform may show considerable loading effects, so that threshold-dependent skew arises in the clocked loads. Finally, the potential for conducted switching noise problems is high with the single-buffer configuration because the entire clock net capacitance is charged in typically under 1 ns. Power supply decoupling and ground bound problems and even current density (electromigration limits) considerations may need to be given special attention if using this configuration. It is usually recommended that the single clock buffer be physically adjacent to the clock input pin, and the clock pin should be flanked by dedicated power and ground pins that feed only the clock driver. This principle, which applies in general to clock input buffers in all clocking schemes, keeps the clock switching noise out of the core power and ground bus lines. Also, the delay through a large clock buffer may be considerable, so a lightly loaded ''early clock'' can be picked off from the buffer input and used to retime chip output registers, or a PLL may advance the phase to the internal clock buffer to align internal and external timing regardless of the buffer delay.

An interesting central clock buffer design, which also has attributes of the clock trunk scheme which follows is reported in [9]. Here, the area for central clock driver fabrication is a strip across the center along one axis of the die. External clock is fed from one pin on the same axis as the buffer, and internal clock lines radiate systematically away from the central linear distributed buffer. Data flow is also highly structured and arranged to progress away from the central driver strip, further minimizing clock-to-data skew.

9.2.3.2 Four-Quadrant Clocking Approaches

In the quadrant-oriented approach, we may use up to four clock pads and four smaller clock drivers placed at the centers of the die edge, preferably also with dedicated power and ground from flanking pins. There may be one, two, or four external clock pins. Figure 9.44a shows a quadrant scheme tested in [24]. In Figure 9.44b, a single-pin quadrant-oriented scheme in 1 μm, two-layer metal CMOS achieved 0.6 ns skew among 400 registers. A four-pin quadrant approach was successfully used in [29] to develop a 90 MHz CMOS CPU. If more than one pin is used for clocking, pin count goes up but absolute delay through the clock buffers can be reduced. The maximum wiring RC delay on the internal clock net and the peak current and $L\,dI/dt$ effects through any one pin and bonding wire inductance may all be reduced in this case. Total loads on each of the four internal clock nets should be well balanced and/or the drivers sized for the actual number of loads in each quadrant. In many cases, reduction of each clocked area to one fourth of the die area can result in isochronic regions for which no further design attention other than total load balancing is required for clock routing within each region. The quadrant approach can also reduce the clock routing problem when the clock shares only two metallization layers available for all signal routing. Two other considerations apply to the quadrant schemes: (1) external tracking to multiple clock pins should be laid out with delay balancing in mind; (2) skew should be particularly considered on data paths which must cross from quadrant to quadrant, bridging timing across clock subnetworks.

9.2.3.3 Symmetric and Generalized Clock Buffer Trees

A symmetric or regular clock buffer tree (Figure 9.45a) has equal fanouts from buffers at the same level, equivalent (or isochronic) passive interconnect paths at each stage, identical buffer types at each level, and equal groups of loads at each leaf of the tree. This ideal can be approximated if loads are regularly distributed and layout and routing can be controlled to ensure equal interconnect delays from each buffer to its subtending buffers. The remaining skew will primarily be due to threshold variation in buffers and terminal loads.

A more general view of the clock buffer tree that arises with irregular layouts and routing is that the buffer tree has unequal interconnect delays and differing numbers of loads at each buffer. Figure 9.45b illustrates the electrical model of such a clock tree. (R and C values are all different.) The basic approach to skew control in such a generalized buffer tree is to size each buffer specifically for the individual loads it drives and the delay of the interconnect path to its input from the preceding level buffer. In practice, this means that generalized clock buffer trees may be the most handcrafted (and/or custom-tuned) of all designs, especially in a large system-level clock tree that extends down from a master clock source through multiple shelves, backplanes, connectors, circuit packs, and individual ICs. The system-level hierarchical clock tree design for the VAX 8800 is a good example described by Samaras [25]. Here, a two-phase clock was distributed to 20 large circuit packs over a 21 in. backplane with a global skew of 7.5 ns, for operation at about 50 MHz (37% skew).

Some basic methods and principles are, however, identifiable for designing generalized buffer trees so that it is not all just careful tuning and handcrafting:

1. Inverting buffers at each level will preserve clock duty cycle better than a tree of noninverting buffers.
2. Total delay (root to leaves) of the clock net is theoretically minimized when driving primarily capacitive loads, by a fanout ratio $e = 2.718\ldots$ at each level of the tree [23]. In practice, this implies a fanout ratio of about $n = 3$, with appropriately sized buffers, if delay is to be minimized. However, $n = 3$ can lead to relatively deep trees of many buffers in which skew can build up from threshold and time-constant variations as in Equation 9.4.
3. If identical buffers are used within each level, then the design aim is to make sure that the load of further buffers and/or interconnect RC load is delay-equivalent for each buffer. Dummy loads may be required to balance out portions of the clock tree whose total fanout is not needed. At the end-nodes of the tree equal numbers of standard loads should be grouped together on each leaf node, within a locally isochronic region.

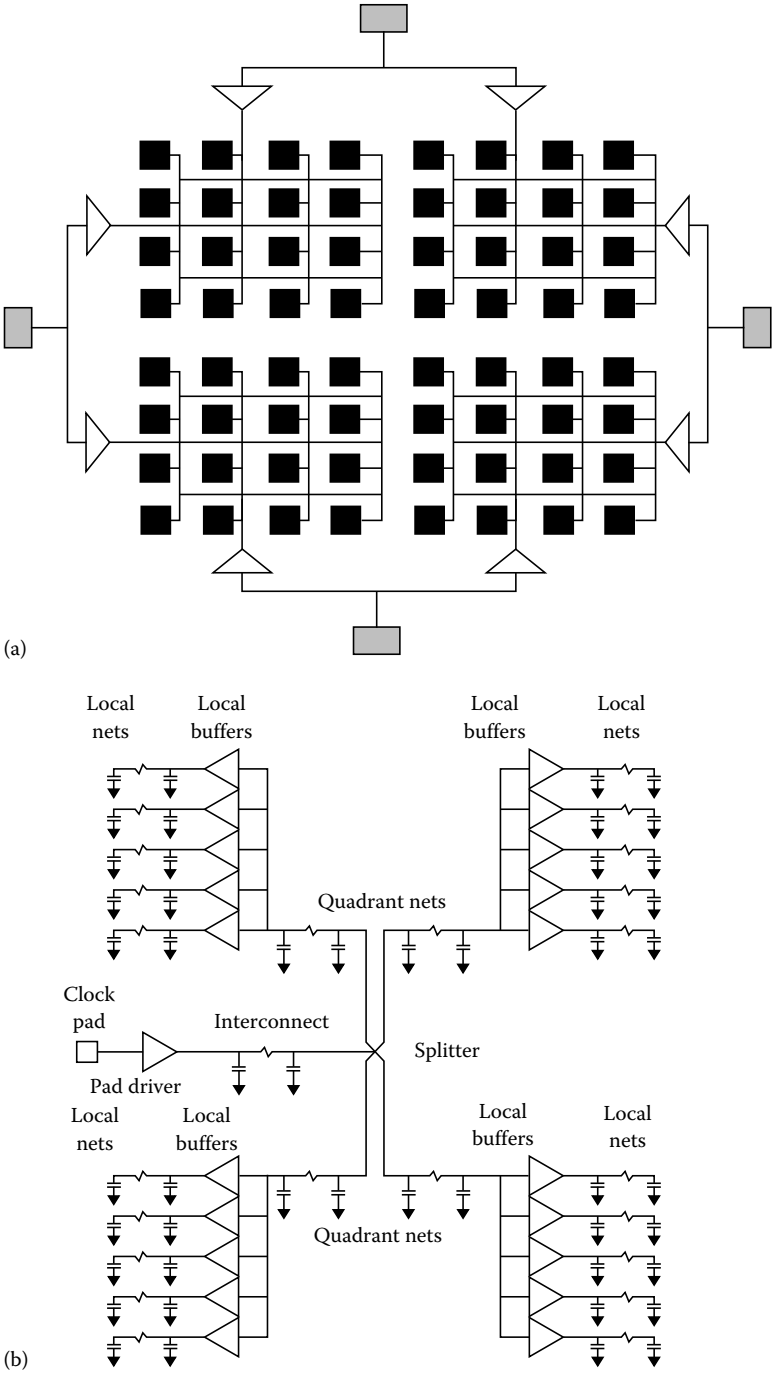

FIGURE 9.44 Quadrant-oriented clock distribution schemes: (a) 4 pins, 2 parallel buffers per quadrant. (From Nigam, N. and Keezer, D.C., A comparative study of clock distribution approaches for WSI, *Proc. IEEE 1993 Int. Conf. WSI*, 243–251, 1993.) (b) Single-pin quadrant scheme with 2 buffer levels. (From Boon, S., Butler, S., Byrne, R., Setering, B., Casalanda, M., and Scherf, A., High performance clock distribution for CMOS ASICS, *Proc. IEEE 1989 Custom Integrated Circuits Conf.*, 1989, 15.4.1–15.4.5.)

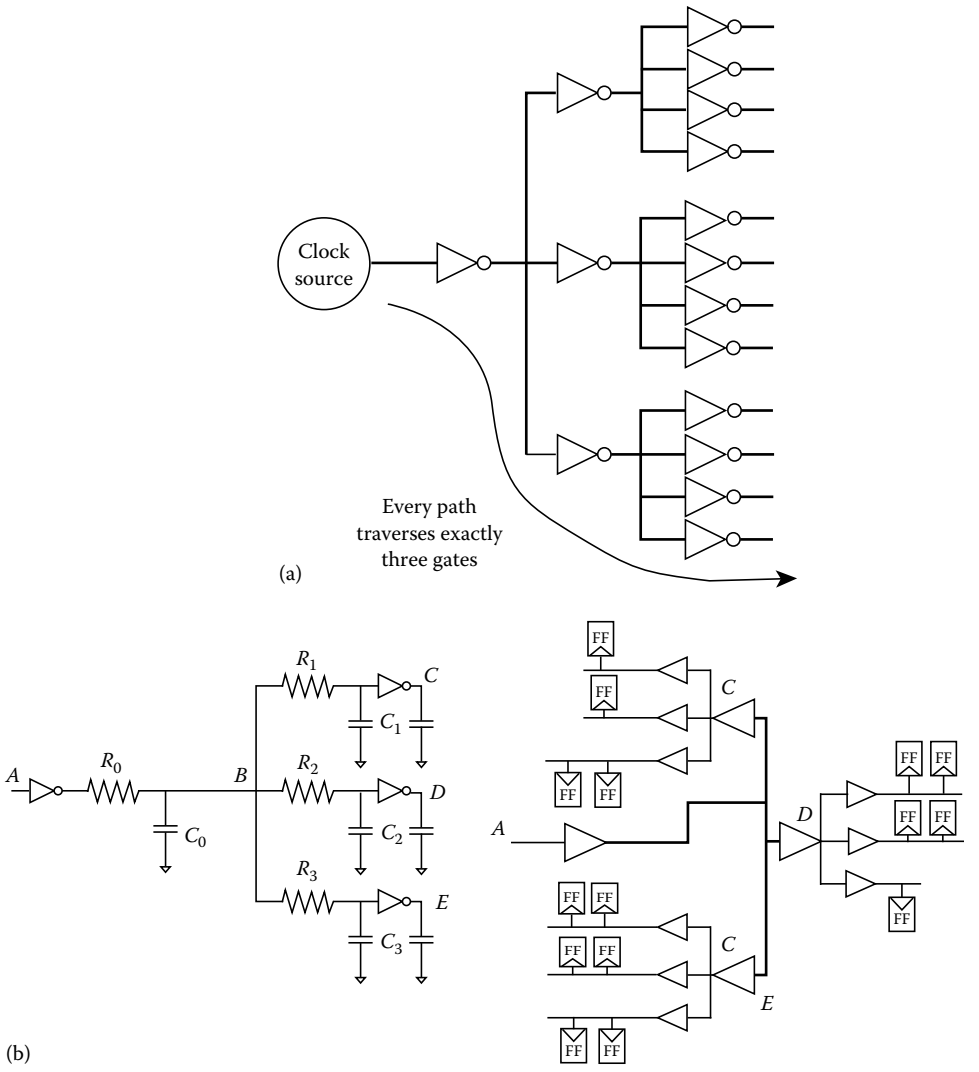

FIGURE 9.45 (a) Idealized symmetric buffer clock tree. (From Johnson, M.W. and Graham, M., *High-Speed Digital Design: A Handbook of Black Magic*, Prentice Hall, Englewood Cliffs, NJ, 1993, 348.) (b) Generalized clock buffer tree where interconnects and loads are not identical.

4. If the tree is deep, the skew among members of one local clock group at the bottom of the tree may be considerably smaller than the skew than the skew between groups of clocked loads at different end-nodes of the tree. If the inter- and intragroup skews are separately characterized, however, logic path delays can be designed to take advantage of the low intragroup skew and to allow greater timing margin on intergroup paths [25].
5. The choice of clock buffer type for use in any clock tree should take into account the effects of power supply sensitivity. For example, the "bootstrapped clock buffer" of Figure 9.46a can provide a very sharp rise time, although with relatively high delay through the buffer. Sharp rise times minimize skew due to switching threshold variations in the following buffers or clocked loads. The output switching time of the bootstrapped clock buffer is, however, relatively sensitive to supply

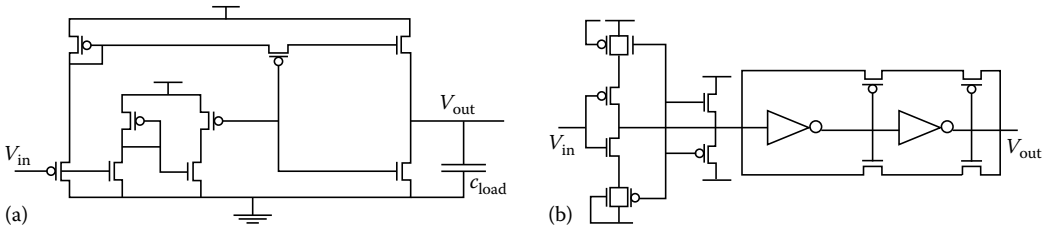

FIGURE 9.46 (a) Bootstrapped clock buffer for use in first level of a clock tree; and (b) phase-correcting clock buffer for use deeper in clock tree. (From Fried, J., *Proceeding of the IFIP Workshop on Wafer Scale Integration*, G. Saucier and J. Trilhe, Eds., North-Holland, Amsterdam, 1986, 127–141.)

voltage. On the other hand, the ''phase-correcting buffer'' of Figure 9.46b is very tolerant to supply variations, but is not as fast in its output rise time. This leads to a mixed buffer strategy in which the bootstrapped buffer is used in the relatively small population of buffers in the first few stages of a clock tree. Here, special attention can be paid to ensuring well-equalized power voltages. The phase-correcting buffer is more appropriate in later stages, nearer the more numerous individual loads, among which on-chip or wafer supply levels may exhibit more IR voltage drop variation.

Algorithms for the generalized clock tree design problem are also emerging. The algorithm in [28] can generate a buffer design based on custom transistor sizing to drive each heterogeneous load, all with the same nominal delay. A still more general optimization approach is under development by Cirit [5]. The sizes of all buffers in the tree are jointly optimized with respect to unequal interconnect RC totals and unequal loads that each drives, as in Figure 9.45b. Thus, the minimum ''total'' tree delay is found for which all paths from root to leaf of the tree also have ''equal'' delay. The procedure is intended to be iterated along with placement and routing alternatives until a set of feasible buffer sizes and acceptable total delay is found.

9.2.3.4 Clock Trunk Schemes

The clock trunk concept is gaining popularity and is now supported within several CAD systems for CMOS processes with two or more metallization layers. Three variants of clock trunk structures are shown in Figure 9.47. An input clock signal is buffered (its input pad is at the center of one side of the chip edge) and is routed either to the midpoint, or one or both ends of the internal clock ''trunk.'' The trunk itself is a metal line specially widened for low resistance, thereby making delay and the $R_0[C_{load} + C_0]$ rise time particularly small on the trunk portion of the overall clock net. As long as the lumped capacitive loads (C_{load}) dominate the trunk's C_0, the time constant of the trunk drops as it is widened. C_0 can be kept particularly low by forming the trunk in third-layer metal. The idea is to size and drive the clock trunk so that an isochronic region is created down the middle of the die, reducing all remaining clock path distances to not more than half the die diameter and setting up a situation in which the final distribution of clock from the isochronic trunk to the loads is in line with one routing axis. This means that branch routing from the trunk to loads can be exclusively contained within one metal layer and travel in a shortest direct line from trunk to load. This is highly desirable for processes in which all horizontal and vertical routing are dedicated to one metal layer or the other. Overall layout and routing is simplified and clock paths are predictable and uniform in routing and wiring type. If, however, the total fanout is very small, the wide metal trunk may add more to trunk capacitance than it decreases R_0 in the $R_0[C_{load} + C_0]$ product for the trunk. This is undesirable because for an isochronic trunk, we want C on the trunk to be dominated by its loads, not by the distributed capacitance of the trunk. In practice, therefore, the trunk scheme is typically recommended for fanouts of over 50. Below this, a single buffer scheme is recommended.

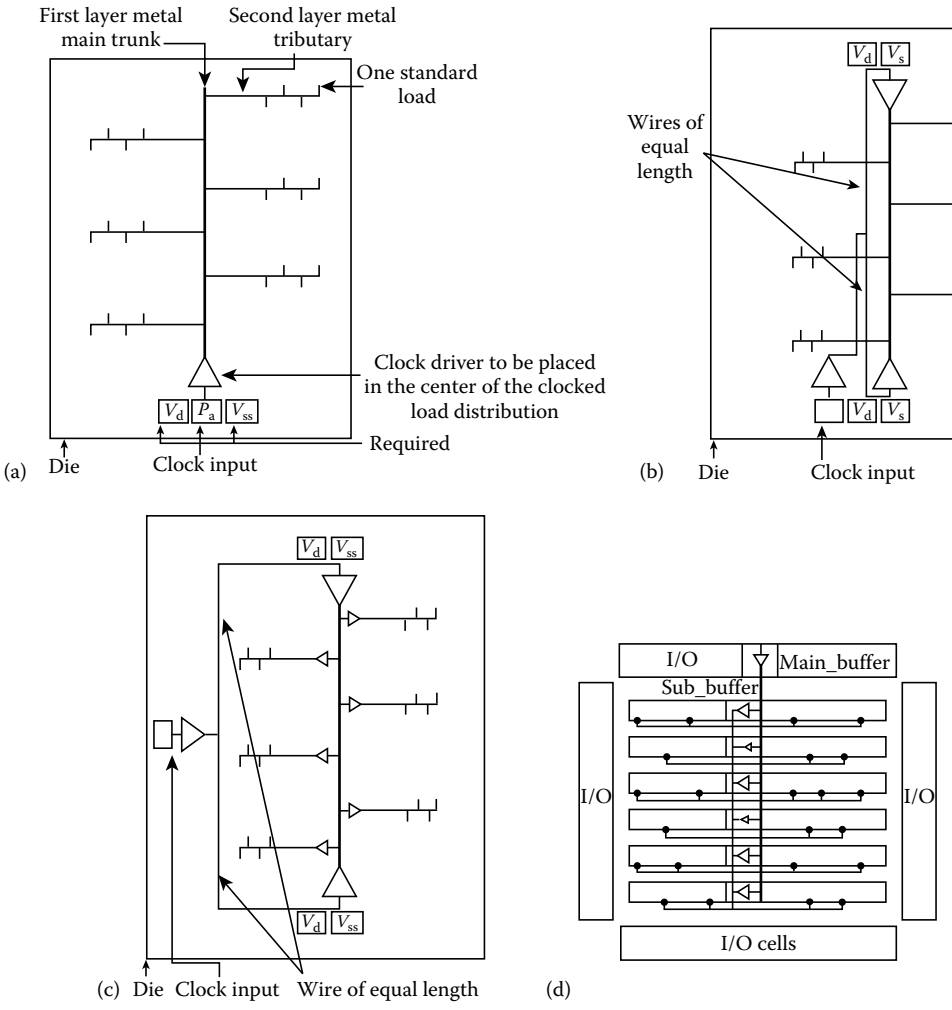

FIGURE 9.47 The clock trunk concept: (a) single-ended unbuffered clock trunk, (b) double-ended unbuffered, (c) buffered clock trunk, (From LSI Logic Corp., *Clock Scheme for One Micron Technologies*, Rev. 1.1, LSI Logic Application Note, Aug. 1992.) and (d) clock trunk with shorted branch buffer outputs. (From Saigo, T., Watanabe, S., Ichikawa, Y., Takayama, S., Umetsu, T., Mima, K., Yamamoto, T., Santos, J., and Buurma, J., *Proc. IEEE 1990 Custom Integrated Circuits Conf.*, 1990, 16.4.1–16.4.4.)

By designing with the following principles for single-ended, double-ended, and buffered clock trunks, clock nets of up to 2000 fanouts can achieve <1.5 ns skew in 1.0 or 0.7 μm CMOS gate array technology [21]. When the clock fanout is between 50 and 500 unit loads, a single-ended trunk scheme, as shown in Figure 9.47a provides a good trade-off among skew, area, and delay. A single clock driver input buffer is used to drive the trunk line, which is typically realized by six first-layer metal lines in parallel with metal filled in. Clock trunk sizing for a given fanout must set a minimum width to take current density limits into account, given that all of the clock net current flows through the trunk if the tributaries are not buffered. Tributaries of nominally constant fanout branch out in second-layer metal. To the extent possible, macrocells and hard-coded megacells should be laid out with the clock trunk in mind, ideally permitting the clock trunk to be located in the middle of the logic to which it fans out.

The tributary branches may or may not be buffered with their own clock drivers, depending on the total number of loads to be driven. Buffering primarily has the effect of reducing overall delay, rise time, and total current density in the trunk, by allowing a smaller trunk driver. Form a purely skew-oriented view, however, it is better not to have the secondary drivers as long as the trunk is isochronic and the size and delay of the main driver is acceptable. When using local buffering, it is important that the branch loads on all tributaries be balanced, more so than when using an unbuffered trunk. Local buffering is, therefore, primarily a way of distributing the total buffering load so that no one buffer needs to be extremely large.

For layout software simplicity, the main trunk may be constrained to use vertical (or horizontal) routing channels only. The main trunk (or each of possibly several main trunks) should be placed as close as possible to the centroid of area of all the loads which it drives. Layout or floorplanning software for commercial ASIC design can typically assist the designer in clock trunk placement by visualizing the spatial distribution of clock loads.

When a design has between 500 and 2000 clock fanouts, a double-ended clock trunk, as in Figure 9.47b or c is recommended. The double-ended clock drivers are internal buffers which use the I/O slots of two pins that will not be used externally thereafter. Both single-ended and double-ended clock trunk schemes use only one external clock input pin, with adjacent pins providing an AC ground and switching noise isolation by powering the drivers with dedicated V_{ss} and V_{DD} pins for the clock buffers. In general, clock input pins should always be surrounded by nondriven pins to minimize the possibility of cross talk coupling into the clock waveform. Clock pins also should be chosen so that minimal internal routing is required between the predriver associated with the input pad and the clock trunk drivers. As a clock trunk design is laid out, the spike current draw from V_{ss} due to simultaneous switching of large fanouts on the clock net should be assessed and considered in determining how many V_{ss} pins are needed in a particular design.

In the double-ended trunk scheme, some care must be taken to ensure that an equal-length path can be routed from the midpoint of the trunk, where the clock input branches to the trunk drivers at both ends of the clock trunk, and that a direct routing from the side of the die to the branch point at the center of the die is feasible. Particularly when preconfigured macrocell function have been placed, the metallization layer needed to bring the clock predriver into the middle of the die may be blocked. This leads to the recommendation that the clock input pin be placed on the side of the die that is in line with the clock trunk (see Figure. 9.47c). The line to the branch point and the two branch lines can then use the same metallization layer as the clock trunk and can be automatically provided for as part of the routing channel width reserved by the clock trunk layout software.

The two double-ended arrangements will have a basic skew given by the (nontrunk) R_0C_0 delay across one half of the chip's dimension (typically under 300 ps), plus skew due to any imbalance in buffer loads and thresholds. An advantage of the buffered clock trunk is that the capacitive load of the clock tree is distributed somewhat in both time and position across multiple buffer stages, reducing the current spikes occurring during a clock edge and their impact on ground bounce and injected power supply noise. On the other hand, a total of three or four buffer stages associated with this structure (for low skew in large applications) may cause high delay between the clock edge used to latch incoming and outgoing data on chip and the external system clock. Clock net fanouts achievable using the clock trunk scheme in commercial gate arrays are summarized in Table 9.10.

In even larger dies with famous of over 3 K flip-flops, multiple symmetrically driven double-ended clock trunks can be established to control the maximum distance of any point from a clock trunk. For example, with two trunks placed one fourth of the die width in from the sides, no load is over one fourth the die diameter from a trunk, and the loading of branch buffers is half that required with one trunk. Branch lines from different trunks should not be connected together where they meet in the middle of the die. These points are far enough away in terms of delay from their common driving points that joining them could cause power-wasting buffer output fights. In a further variant on the buffered clock trunk, buffers have their outputs ganged (i.e., shorted) by an additional vertical metal line parallel to the trunk,

TABLE 9.10 Fanouts of Clock Trunk Schemes in 1 μm CMOS Gate

Clock Frequency (MHz)	Single-Ended Trunk	Double-Ended Trunk	Double-Ended Trunk with Local Buffering
50	500	2000	>2000
60	450	1500	>1500
70	400	1200	>1200

Note: Arrays (maximum number of clock loads driven with <1.5 ns skew).

close to the buffer outputs. The effect of shorting the branch buffers is to equalize the propagation delay through the trunk and distribute the capacitance per buffer more uniformly. This has been found to reduce skew considerably if the branch buffers were not equally loaded and also reduced skew (although less so) in the balanced buffer case [26].

9.2.3.5 Clock Ring Configuration

The clock ring approach shown in Figure 9.48 combines aspects of the clock trunk, quadrant, and the single large buffer approaches to achieve a combination of moderately low skew, and moderately low delay without the possibly high routing-dependent skew of the pure single-buffer scheme. The ring approach also simplifies overall clock and signal routing conflicts in a two-layer metal process. The external clock is buffered at entry with a moderate- to large-scale buffer, which drives a clock ring that follows the die perimeter. The ring is not a widened trunk because typically less than 50 other buffers are driven off the ring, not the entire clock net. Therefore, with relatively low C_{load} on the ring, it is not widened. The extra capacitance of a widened ring would be relatively high (on a square die, the total ring length will be four times the length of a corresponding central trunk) and only increase skew and delay. The ring drives secondary buffers sized to drive balanced groups of flip-flops in the core of the chip. The aim of the ring on a large die is not to create a wholly isochronic perimeter, although this could be approached by driving the ring at multiple symmetric locations. Rather, the ring establishes a relatively low-skew reference perimeter from which any interior clock load can be reached either by a purely

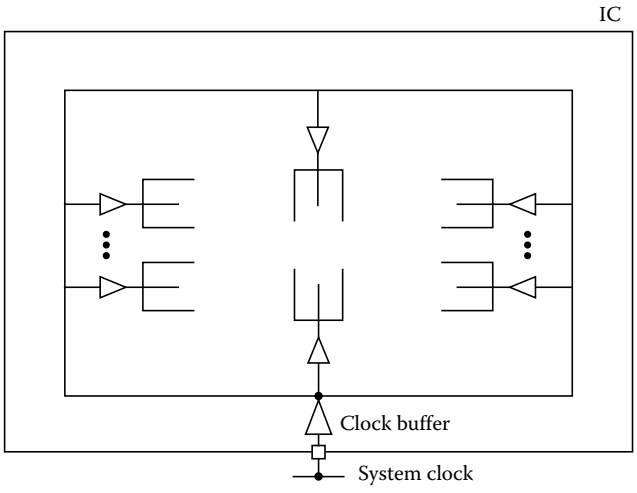

FIGURE 9.48 The clock ring concept.

vertical path or purely horizontal path (i.e., in a direct line of a single metal layer) no longer than one half the die size. The worst-case routing distance from the ring is the same as in the clock trunk scheme, but two thirds of all locations are within half that distance in the ring, whereas only one-half of all uniformly distributed loads are within half of the maximum distance of a central trunk. In practice, with good load balance on the secondary drivers, clock skew of 0.8–1.0 ns has been obtained in a designs of up to 30 K gates. If the secondary drivers are well balanced, skew in this architecture will depend primarily on the R_0C_0 delay from the ring driving point to its far side, around the periphery, typically 0.8 ns for a die of 350–400 mil. Relatively low chip delay is obtained by using the clock signal on the ring as an ''early clock'' with which to time I/O latches. The ring is electrically closed as this helps distribute the subbuffer capacitance and equalize delays, especially if driven at two opposing points.

9.2.3.6 H-Trees

The H-Tree is an area-efficient regular structure most suited to clock distribution in systems in which the synchronized modules are identical in size and placed in regular array. Figure 9.49 illustrates a 256 module H-tree tested on a 4 in. wafer by Keezer and Jain [17]. The scheme balances the R_0C_0 delay through the clock network by geometric symmetry so that the delay is nominally constant from the root to any leaf node. Loads are clocked only at leaf nodes of the tree. The minimum feature size of the process can be assumed to set the line width of the H-tree at its leaf nodes and each preceding level has progressively wider lines to maintain constant current density and to minimize impedance mismatch effects (at wafer scale and above) when no branching buffers exist. The H-tree is driven by a buffer at its root and may or may not have additional buffers at branching points. ASIC manufacturers have been able to achieve skew below 500 ps at fanouts of >5000 with experimental H-tree layouts in third-layer metal [22].

The H-tree approach is most practical only if an entire layer in a multilayer PCB or a third or fourth metallization layer in CMOS can be dedicated for H-tree clock distribution. Otherwise, the H-tree may encounter (or cause) a large number of routing blockages or require poly links which will disrupt

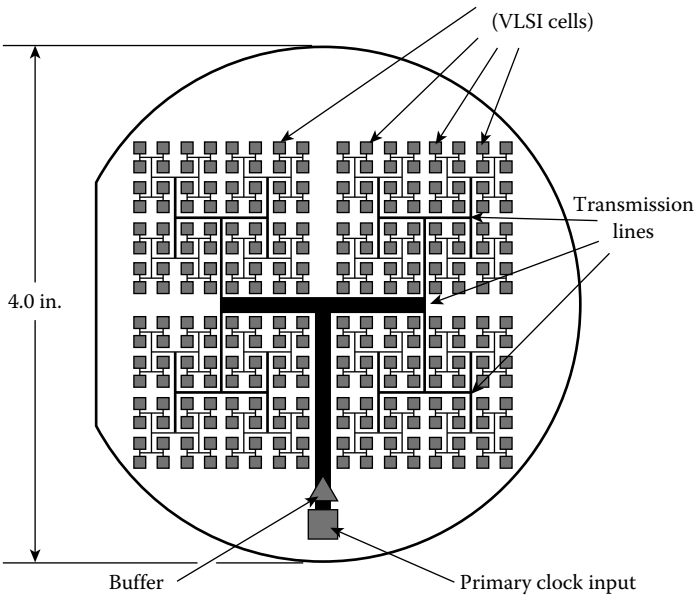

FIGURE 9.49 The H-tree concept illustrated in the form of a 256-cell passive H-tree for wafer-scale integration. (From Keezer, D.C. and Jain, V.K., *IEEE Int. Conf. WSI*, 1992, 168–175.)

the H-tree performance. In addition, many VLSI designs include memory cells or other hardcoded cells that are incompatible with the ideal symmetry of the H-tree. However, if a suitable layer is available for H-tree layout, it may be applied to random-logic designs by considering each leaf of the node as a clock supply point for all clocked loads within an isochronic region around each leaf node. The whole die is then tiled with overlapping isochronic regions, each fed from out of the plane by a leaf of the overlying H-tree. Each leaf of the H-tree might also use a variably sized buffer to drive the particular number of clocked loads of the random logic layout that fall in its particular leaf node zone.

Kung and Gal-Ezer [18] have given an expression for the time constant of an H-tree, which characterizes the total delay from root node to leaf:

$$\tau_H = 1.43\ N^3\left(3 - \frac{2}{N}\right)R_0C_0 \tag{9.6}$$

where an $N \times N$ array of leaf nodes is drives. Absolute delay rises as N^3 for large N. This in itself does not limit the clocking speed because, at least theoretically, more than one clock pulse could be propagating toward the leaf nodes within the H-tree. As a practical matter, however, the delay of the H-tree expressed in Equation 9.6 is essentially a rise time effect on the clock waveform. A slow rising edge out of the H-tree can lead to significant skew due to threshold variations in the leaf node buffers. These considerations apply to the on-chip context in which the H-tree clock network is dominated by RC diffusion delay effects. Equation 9.6 also describes an unbuffered H-tree. By placing buffers at selected levels of the overall tree, total propagation delay through the tree will increase, but the bandwidth of the tree may be preserved by effectively reducing N to the portions of the overall tree between buffers, in Equation 9.6. In contrast to the rapid bandwidth fall-off on-chip, at the multi-chip module level of system integration an H-tree may be designed from an impedance-controlled transmission line standpoint to obtain very high clock bandwidth. In experiments of this type, Bakoglu [3] has achieved 30 ps of skew at 2 GHz with a 16 leaf H-tree covering a 15×15 cm wafer area.

In an H-tree the total clock path length doubles each time one moves up two levels from the leaf nodes toward the root. Based on this, Kugelmass and Steiglitz [19] have shown that given σ_b and σ_w as the standard deviation of buffer delay (if present) and wire delay, respectively, the total delay of an H-tree considering buffers and wires has variance:

$$\sigma^2 = \sigma_b^2 \log_2(N) = \sigma_w^2 2\left(\sqrt{N} - 1\right) \tag{9.7}$$

and that the average case skew between any two leaf nodes is bounded by

$$E[\text{skew}] = \sigma_w 4\sqrt{\sqrt{(N-1)}\ln(N)} \tag{9.8}$$

where N is large and wire length effects dominate. Average case (or expected) skew is the maximum difference between clock times, averaged over many design trials, not the average clock time difference in any one design. Kugelmass and Steiglitz [19] also give results for the probability that a sample value of the skew exceeds the mean skew by a given factor in either an H-tree or a binary tree, based on assumptions that all wire length and buffer delay variables are independent and identically distributed:

$$P(\text{skew} > E[\text{skew}] + a) \leq \left[1 + \left(\frac{a}{E[\text{skew}]}\right)^2 48\ (\ln N)^2/\pi^2\right]^{-1} \tag{9.9}$$

where a is the amount of time by which the mean skew is exceeded. These expressions may be used to estimate skew-limited production yield at a given target clock speed.

TABLE 9.11 Comparative Performance of Clock Distribution Networks (8 × 8 Array of Loads Clocked at 31 MHz and Constant Total Power, 650 mW)

Scheme	Delay (ns)	Skew (ns)	Rise/Fall Time (ns)
3-level symmetric buffer tree	7	3	12.5
Single buffer H-tree	15	∼0.0	38
Clock trunk with branch buffers	13	4	14.2
Clock trunk with ganged branch buffers	14.2	2	16
4-pin-quadrant scheme, 2 buffers per quadrant	4.3	1.3	9

9.2.3.7 Delay, Skew, and Rise Time Comparison

The five clock distribution schemes described thus far were studied in a unified, experimental way by Nigam and Keezer [24] using HSPICE simulations. They compared each scheme on a 5 in. wafer holding an 8 × 8 grid of modules to be clocked. Each module presented at a total load of 2 pF and the interconnect R and C values were taken for a typical 2 μm double-metal CMOS process. Clock distribution lines were 10 μm wide for the buffer tree and the H-tree, except for its trunk, which was 40 μm. The clock trunk schemes used a 20 μm trunk width. All interconnect was modeled as distributed RC, with transmission line delay effects included. The results are tabulated in Table 9.11 and give an excellent overview of the relative characteristics of each method. The H-tree has essentially no skew, but has the highest delay and slowest clock edge, which can translate into skew due to threshold variations in the loads. The clock trunk has good skew and moderate delay. The best overall performance is achieved by the four-quadrant scheme, essentially by virtue of reducing the clocking area to one fourth of the overall size of the other clock networks.

9.2.3.8 Balanced Binary Trees

A balanced binary tree (BBT) is an unbuffered clock distribution tree in which each branch node has exactly two subtending nodes, and the delay from the root to all leaf nodes is made constant by placing branch points at the "balance point" of the two subtending trees from any node. BBTs are not simply clock buffer trees with fanouts of two. The significance of the BBT is that constant delay is achieved through multiple levels, without any buffers, and the BBT can be constructed by a fairly simple algorithm. Passive BBTs also may be used in practice to implement delay-equalized fanout networks between the active buffer levels of a larger buffered clock tree. The BBT concept should not be confused with the buffered clock tree concept in general, however. The key is that the generalized buffer clock tree does not have path delay equivalence if its buffers are removed, whereas the BBT has this property.

The basic ideas and methods of generalized balanced tree synthesis are explained in [6]. The clock tree that results has two branches at every node. Clocked loads appear only at the leaves of the tree. The line lengths at each level can be different than those at other levels of the tree, and the two line segments that are children of any node also can be of unequal lengths. The key, however, is that at each branch the total distance from the branch point to any subtending leaf via one outgoing path is equal to that in the other outgoing direction.

Figure 9.50 illustrates the basic procedure for BBT synthesis. The process works from the bottom up, by considering all leaf node positions, i.e., clock entry points for modules or isochronic local regions. Leaf nodes are subjected to a generalized matching or pairing process in which each node is paired with the other node closest to it in the Manhattan street length sense within the available routing channels. A first-level branch point is then defined at the midpoint on each line joining the paired leaf nodes. A similar pairing of the first-level branch points then defines a new set of line segments, each of which has two leaf nodes symmetrically balanced at its ends. Second-level branch are then defined at the RC balance point

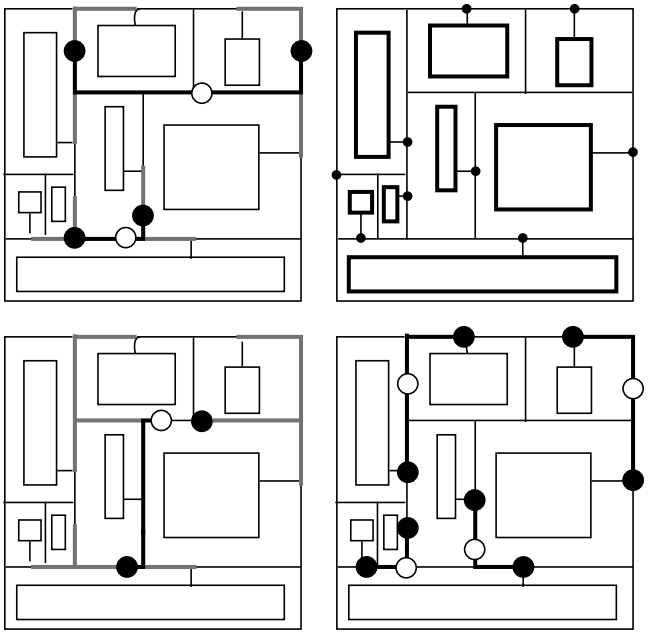

FIGURE 9.50 BBT synthesis in an eight-terminal net. Solid dots are roots of subtrees in the previous level; hollow dots are roots of new subtrees computed at the current level. (From Cong, J., Kahng, A., and Robins, G., *Proc. 4th IEEE Int. ASIC Conf.*, Sep. 1991, 14.5.1–14.5.4.)

on each line joining first-level branch points, and so on. Each iteration consists of finding the minimum path length matching of pairs of branch points from the previous iteration and defining the next set of branch points at the time-constant balance points on the line between just-matched, lower-level branch points. Assuming leaf nodes present equal loads, the first-level branch points are the midpoints of the pair-matching line segments. After that, the balance point for level i is the point on the line segment joining matched level $(i-1)$ branch points at which the total RC wiring time constants (simply total length if all wires and layers are identical) to the leaf nodes in the right and left directions are equal. This is repeated until only two branch points remain to be matched. A line is routed between them and driven by the clock signal at the final balance point, which defines the root of the BBT.

Clock trees developed in this way are in one sense highly structured and symmetric in that the total delay from root to any leaf is nominally constant, like the H-tree. Unlike the H-tree, however, the actual layout is irregular, allowing the BBT to accommodate the actual placement of cells and modules and to cope with the limited and irregular routing channels available in designs that do not use a completely regular layout.

Skew in BBTs has been considered theoretically and experimentally. Kugelmass and Steiglitz [19] showed that in a BBT with independent variations in the delay at each stage of the tree, with σ_0^2 variance, the expected skew is fairly tightly bounded by

$$E[\text{skew}] \leq \frac{4\sigma_0}{\sqrt{2\ln 2}} \ln N \tag{9.10}$$

where N is the number of leaf nodes of the tree.

Using the previous expressions we can compare the H-tree to a BBT. The comparison shows that when the regular structure of an H-tree is feasible, it is of relative merit for large fanouts because the expected skew grows more slowly ($O(N^{1/4}(\ln N)^{1/2})$) than the BBT tree in which expected skew grows as $O(\ln N)$.

For comparison, assuming 10,000 leaf nodes and the same σ_w per unit wiring length, the expected skew of the H-tree is about one half that expected of the BBT. This outcome is primarily because the BBT must be deeper (have more levels) than the H-tree for the same fanout.

Experimentally, Cong et al. [6] produced a large sample trials of 16- and 32-node BBT clock trees, synthesized on a 1000×1000 grid. It was shown that the BBT resulted in less than 2% of the skew from a corresponding minimum spanning tree (MST) for clock distribution to the same loads, even though the BBT had 24% to 77% more total routing length than the MST. The MST benchmark characterizes the skew that would typically result if the clock was routed as an ordinary signal net, with no special concern about skew.

An example of balanced clock tree synthesis supported by a gate array provider is [22], in combination with a three-level clock buffer tree hierarchy. Skew of $<$500 ps is achieved in 0.5 μm designs of up to 13,440 clocked loads. By using appropriately sized buffers and wire width at each level of the balanced tree, clock rise time is typically 0.8–0.9 ns at the terminal nodes. The clock tree compiler is invoked after floorplanning. The compiler takes into account the resistance and capacitance of different wire types, the length and width of wires, and the input capacitance of clock pins and buffers. Up to three active buffering levels can be used, with fanouts of up to 64, 14, and 15, respectively, from buffers at each level. The fanout subnet driven by each buffer is laid out as a (passive) BBT, so that the leaves of one balanced tree are the buffers that act as the roots of further passive binary balanced subtrees driven by the next buffering level. At the lowest level, local buffers each drive up to 15 loads via a final four-stage passive BBT.

9.2.3.9 Clocking Schemes Involving Phase-Locked Loops

A PLL is a negative-feedback control system in which the phase (and, implicitly, frequency) of a voltage-controlled oscillator (VCO) or phase shifter is brought into alignment, or to a predefined static phase offset, with respect to the phase of a periodic reference signal. The application of PLLs is most often to control skew and clock delay problems primarily at the multichip and interboard levels of system design.

Figure 9.51a shows how a PLL can be used to lock the on-chip clock phase at a selected point on-chip, to an external phase reference. Figure 9.51b shows the mid-trunk phase on a single-ended clock trunk being made to match the external phase reference. Here, the feedback line from the middle of the trunk to the PLL input is assumed to have negligible delay in itself because it is a metal line with only one standard load. Similarly, in the double-ended clock trunk scheme, the sense line can be connected one fourth of the way along the clock trunk. This will lock the internal system clock to the reference timing at two points on the clock trunk, as shown in Figure 9.51c, reducing overall skew to one fourth of that in the single-ended clock trunk scheme. The phase-sense line needs to be connected to the clock trunk at only one point because, by symmetry, the corresponding point from the other driver is similarly phase locked.

In general, when the phase-sense line has negligible delay, the clock phase at the sense point is driven into lock with the reference phase. Thus, in generating clock signals we can null out the delays of large buffers or drivers in the output circuits as well as their process and temperature-dependent variations, and, in general, coordinate clock and data phases at the inputs to another chip at any remote point by bringing the phase-sense line back from the actual point where the phase-controlled relationship is desired. In this way even the delay of an off-chip driver can be canceled out by including it within the PLL feedback loop. If delay in the phase-sensing feedback path is not negligible, then its effect is to advance the phase at the desired control point. The feedback delay can be compensated by a matching delay in the forward path from the VCO to the phase-sensing point, or at the PLL input. An inverter in the feedback signal path is also a convenient way to cause a 180° phase shift between referenced and VCO without requiring any loop delay.

With the addition of frequency divider (divide by N) in the feedback path, as in Figure 9.51d, the VCO operates at N times the frequency of the reference clock input. For $N = 2^n$ frequency multiplication, the feedback divider can be a simple ripple counter of n toggle flip-flop stages. For other multipliers, a synchronous counter is usually used. The delay-matching element at the PLL phase detector input compensates for delay from the feedback path divider. On-chip frequency multiplication can ease a

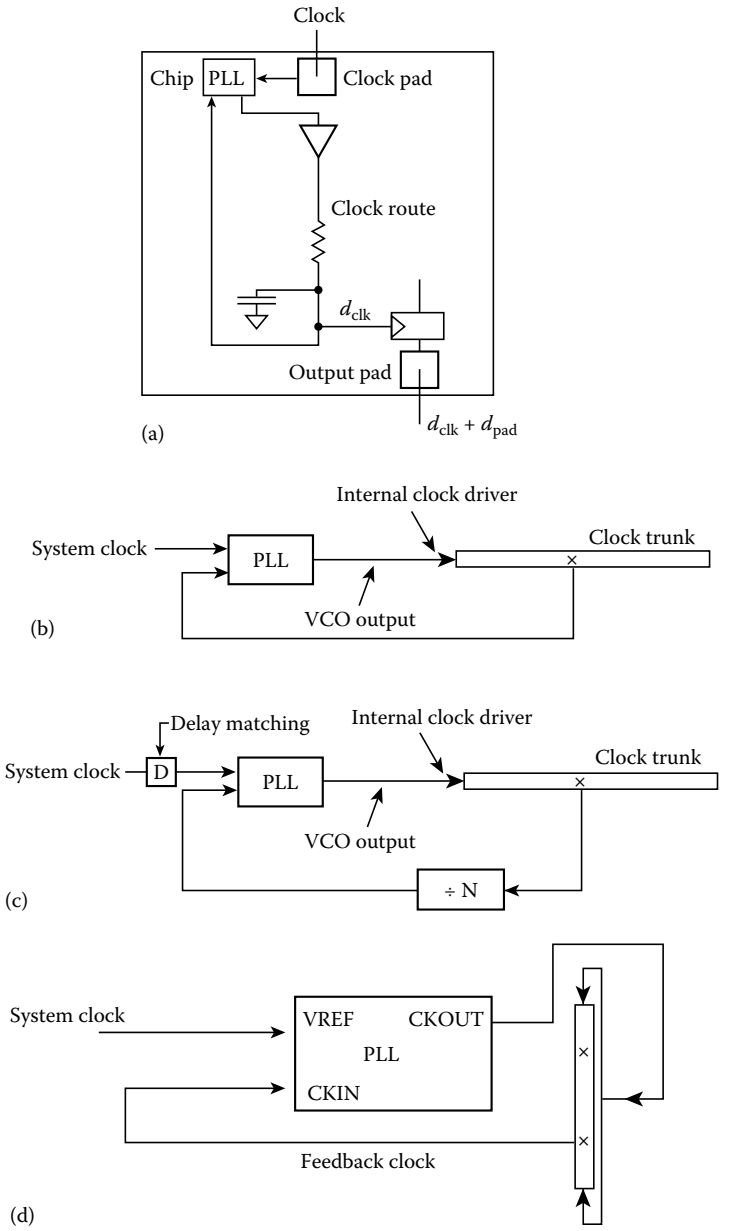

FIGURE 9.51 PLLs for skew and delay control: (a) canceling internal and clock net delay. (From Weste, N. and Eshraghian, K., *Principles of CMOS VLSI Design*, Addison-Wesley, Reading, MA, 1993, 335.) (b) Halving the skew in a single-ended clock trunk, (c) reducing double-ended clock trunk skew to one-fourth of the single-ended trunk, (d) one-chip frequency multiplication. (From LSI Logic Corp., *Phase-Locked Loop Application Note*, LSI Logic Application Note, Nov. 1991.)

number of system-level design problems. The overall system clock rate need not be equal to that of the fastest chip in the system. Transmission line effects across the relatively long distances of PCBs or backplanes can be reduced by operating at a lower clock frequency outside of the system ICs. The lower frequency of system reference distribution may also reduce power, and usually assists in meeting radiated

emission specifications for electronic equipment. Because a PLL regenerates the clock in each IC, a considerable amount of clock edge slew rate control can be used on the external system clock, further easing EMI and power supply switching noise problems. The difficulty of retaining clock waveform integrity getting on- and off-chip at high frequencies through inductive packaging and bonding leads is also eased for the same reason.

9.2.3.10 PLLs for CMOS

A block diagram of a PLL is shown in Figure 9.52a. The VCO exhibits a positive monotonic frequency of oscillation in response to a control voltage, characterized by the slope of its frequency vs. voltage curve. The loop filter, $H(f)$, is of a general low-pass characteristic, often of an all-poles design to avoid any jitter peaking (or AC gain) in the closed loop transfer function of the PLL. The loop filter must provide a DC coupled path between the phase detector and VCO. The phase (and/or frequency) detector compares the VCO output phase to the input reference phase and generates an output signal that is either of a DC nature or has a DC component that is proportional to the phase difference between the reference and feedback signal. The phase detector is characterized by the rate of change in the DC component of its output vs. phase input difference in V/rad.

A phase detector that is commonly used because of its all-digital nature and suitability for CMOS integration is Gardner's phase-frequency detector (PFD) [11] with charge pump outputs. The PFD produces an output that goes toward V_{DD} or V_{SS} in the presence of a negative or positive frequency offset, respectively, thereby slewing the VCO toward the lock frequency. Once in frequency lock, the PFD

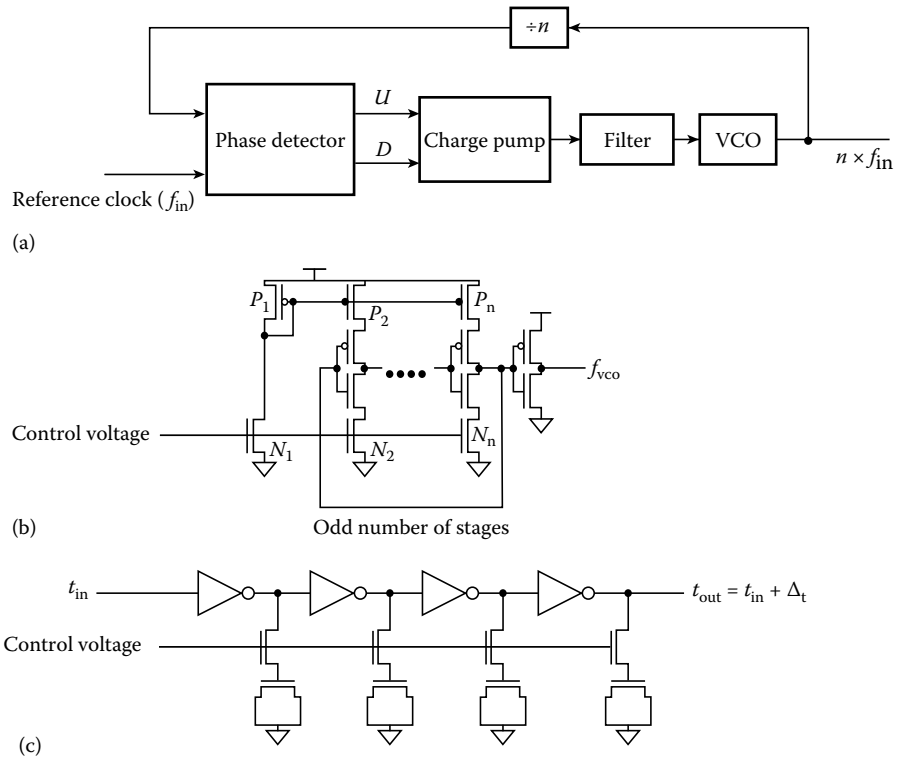

FIGURE 9.52 CMOS PLL circuits: (a) basic PLL block diagram, (b) CMOS VCO based on current-starved inverters, and (c) VCDL. (From Weste, N. and Eshraghian, K., *Principles of CMOS VLSI Design*, Addison-Wesley, Reading, MA, 1993, 336.)

produces pump up/pump down signals that vary in proportion to the time difference between reference and feedback clock edges at the PFD input. These pulse-width modulated signals drive a charge pump with a tristate buffer arrangement to either hold, bleed off, or supply charge to a capacitive storage element (i.e., the loop filter), thereby adjusting (and filtering) the voltage on the VCO control node to minimize the phase difference at the phase detector inputs.

For CMOS clocking system applications, the VCO is usually a form of a stable multivibrator in which the switching speed dependence of a CMOS inverter on its *n*-transistor pulldown current is exploited, as shown in Figure 9.52b. The VCO control voltage regulates the current flow in, and hence the speed of, each inverter stage through the extra *n*-transistor stage added to each inverter. Any odd number of such stages connected in a loop will oscillate, but now the relaxation period is voltage controlled. Weste and Eshragian [31] describe a 13-stage ''current-starved inverter'' VCO based on this approach. A related VCO design is based on varying the load capacitance seen by each inverter (in a chain of inverters) by applying the VCO control voltage to an *n*-MOSFET in series with the gate of another transistor configured as a capacitive load [16]. An on-chip RC loop filter can also be constructed from a CMOS transmission gate biased as a resistor and MOS gates used as capacitors (source and drain both connected to V_{SS}) [31].

If frequency multiplication is desired, a PLL with a true VCO is required. Otherwise, many PLL applications can use a voltage-controlled delay line (VCDL) in conjunction with a ''raw-clock'' input signal, as in Figure 9.52c. All the phase-lock feedback principles are the same, except we phase-shift the raw-clock input as required, rather than controlling the VCO oscillation phase. This eliminates the risk of the PLL ever failing to lock-in and may be simpler to fabricate. On the other hand, system design must take into account a more limited range of phase-shifting ability (a full half-cycle of phase control range may require a lot of delay stages) and to make sure initial delays are nominally centered within the positive-only delay control range of the VCDL. Another more subtle point is that while a VCO introduces a perfect integrator ($1/s$ term) in the PLL closed loop response, a VCDL does not. A VCDL, therefore, should not be simply substituted for a VCO without revisiting the closed loop response characteristics for noise bandwidth and possible jitter peaking.

Special power, grounding, and testing considerations apply when a PLL is used. A PLL is basically a linear circuit, so noise is especially important. Particularly when a frequency multiplying PLL is used, the VCO power supply should be well decoupled from system noise, and the input phase reference should be highly stable, as the PLL output clock will have N times the reference's phase noise. Noise voltages coupled into the analog PFD output and LPF signal path are similarly converted into phase noise that is N times worse than in a $\times 1$ PLL. Leadless on-chip decoupling capacitors are recommended as are dedicated power and ground pins for the PLL. The R and C components for the loop filter are often off-chip. In this case it is important that they are connected (depending on the $H(s)$ configuration) to the same analog ground reference as the VCO and PFD. The VCO output, or a divided down version of it, should be brought to an external pin for lock-in validation and as an aid in possible global system clock tuning. For testability, several other separate pins are typically required for independent access to I/O of the PFD, LPF, and VCO each. An on-chip PLL can require up to six or more pinouts.

9.2.3.11 Anceau's PLL Scheme

Anceau [1] developed a PLL-based approach for large systems in which modules are well-defined, relatively independent, and could be entirely self-timed if not for the need to avoid metastability in communication with other modules. Anceau recognized two natural system scales which are isochronic below different maximum frequencies. One is a global region encompassing the entire system, with a clock period determined by propagation distance delays, or, on-chip, by RC diffusion delays. The isochronic rate for this scale defines a slower clock rate for a system-wide communication bus. The second type of clocking region is smaller local regions which can run at full speed and are characterized by critical logic path delays and lumped capacitive loads within modules, not distance-dependent delays. Each smaller region will be free to operate in an almost self-timed mode.

The clocking style within each module (e.g., logic type and number of clock phases) can be as appropriate for the individual modules. Skew at the highest clock speeds in the system need be considered only within each module, except that timing must be controlled when reading the common data bus to avoid metastability. This is done by reference to the active edge of the slower-rate communications clock (comm_clk), formed by dividing down the master module clock frequency. The rising edge of comm_clk strobes the enabled driver data onto the bus. All other nondriving modules in the comm_clk cycle read the bus on an internal clock edge that is kept away in time form this transition in comm_clk, for metastability avoidance. Figure 9.53 illustrates the overall scheme. A PLL phase locks the module clock at a predefined angle relative to the comm_clk, thus keeping the raw module clock away from the transition times in the lower rate communication clock. The read timing is then safe because it is always preceded by the comm_clk transition on which new date were strobed to the bus. A monostable triggered by the comm_clk edge can be used inside each module as a delay generator to prohibit any bus read in the metastable region. This way, as long as modules write to the bus only on the comm_clk edge, other modules that read the bus will never do so at a moment when the bus data are still in transition.

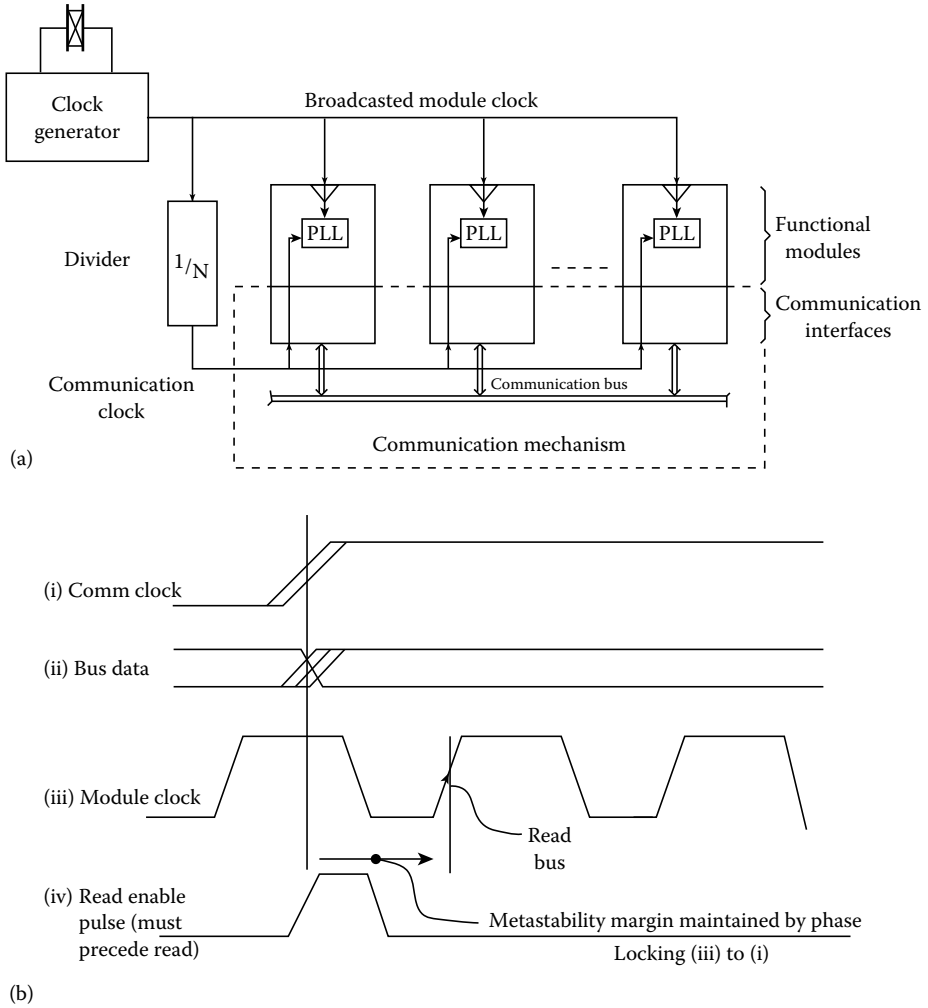

FIGURE 9.53 Anceau's scheme for metastability avoidance: (a) system architecture and (b) interface timing. (Adapted from Anceau, F., *IEEE J. Solid-State Circuits*, SC-17(1), 51, 1982.)

9.2.3.12 Grover's Interval-Halving PLL Scheme

A novel PLL-based approach to clock distribution in "electrically" large systems can synchronize all clocks in a large system on a single clock line [13,14]. In this scheme any number of nonisochronic points arbitrarily located on a single- or double-conductor reference line independently derive clock that is in absolute phase-lock to a common system-wide reference time. The central principle is that the time between appearances of an isolated pulse traveling down and back on a reference line is the same regardless of the point of observation, as shown in Figure 9.54a. This figure plots the trajectory in space-time of an isolated pulse that travels from a site at one end of a line and is returned at the end of the line to its origin (where it is electrically terminated). Figure 9.54a is drawn for the most general case of physically separate go and return conductors, looped at the right-hand end ($x = D$), but the space-time trajectory of the isolated pulse is identical if the line is a single conductor open-circuited at the end and driven by an impedance-matched source. Equivalently, a tristate buffer can terminate and regenerate the returning pulse at the end of the line for on-chip use. In either case, it is evident that the instant in time that is halfway between the outgoing and returning pulse edges is the same for all points of observation on the line, regardless of the propagation velocity of the line, i.e.,

$$\frac{t_1[x] + t_2[x]}{2} = t_1[D] = t_2[D] \equiv t_{\text{ref}} \tag{9.11}$$

where

$t_1[x]$, $t_2[x]$, are the times when the traveling pulse edge passes position x in Figure 9.54a
$t[D]$ is the time the reference pulse edge reaches (and departs) the reflection point

This time, called t_{ref}, is the midpoint between the two pluses as seen at every point of observation on the line.

This principle is adapted for single-line, skew-compensated clock distribution by periodic injection of a reference pulse onto a single conductor, reflection of this pulse at the end of the reference line, and generation of a local clock at all stations, such clock being phase-locked to the interval mid-time by a special interval halving PLL (IHPLL) circuit, as outlined in Figure 9.54b. The phase detector in the IHPLL is considerably simpler than the conventional PFD used in many CMOS PLL designs. This method can be adapted easily to a two-line operation, in which a full duty cycle waveform, rather than a narrow pulse, can be used to drive the looped reference line path. The reference line can be looped at one end and driven at the other, or split into two terminated lines, routed together as a pair, and driven together as shown in Figure 9.54c. In the latter case, all modules lock to the reference edge arrival at mid-path, rather than at its end.

In either of the two-conductor configurations, an edge-triggered, set–reset flip-flop function (Figure 9.54d) is the required phase detector. The two-conductor IHPLL approach avoids the need for an end-reflection or a tristate returning line driver, but requires layout of the reference line so that distances from the end are the same on both directions of the path at every tapping point. This is not hard to achieve on-chip, as the two halves of the looped path could be laid out identically. At the system level, however, the single-line variant has the advantage that uncontrolled cable and tracking lengths can be used without concern about delay equivalence in the return path, and an absolute minimum of cabling, connectors, and tracking is required for clock distribution. The interconnect is the same as that for a system in which clock is directly wired to all modules with a single line. However, this would normally be possible only if the whole system were one isochronic region.

Grover [13] reports experimental skew under 1 ns over 30 m on a coaxial cable which has an uncompensated delay of 147 ns. It was also shown that in the presence of the effects of the transmission line on the traveling reference pulse, the linear component of switching time error on the traveling reference pulse contributes no skew to the resultant clock phase. A phase-shifter variant of this scheme

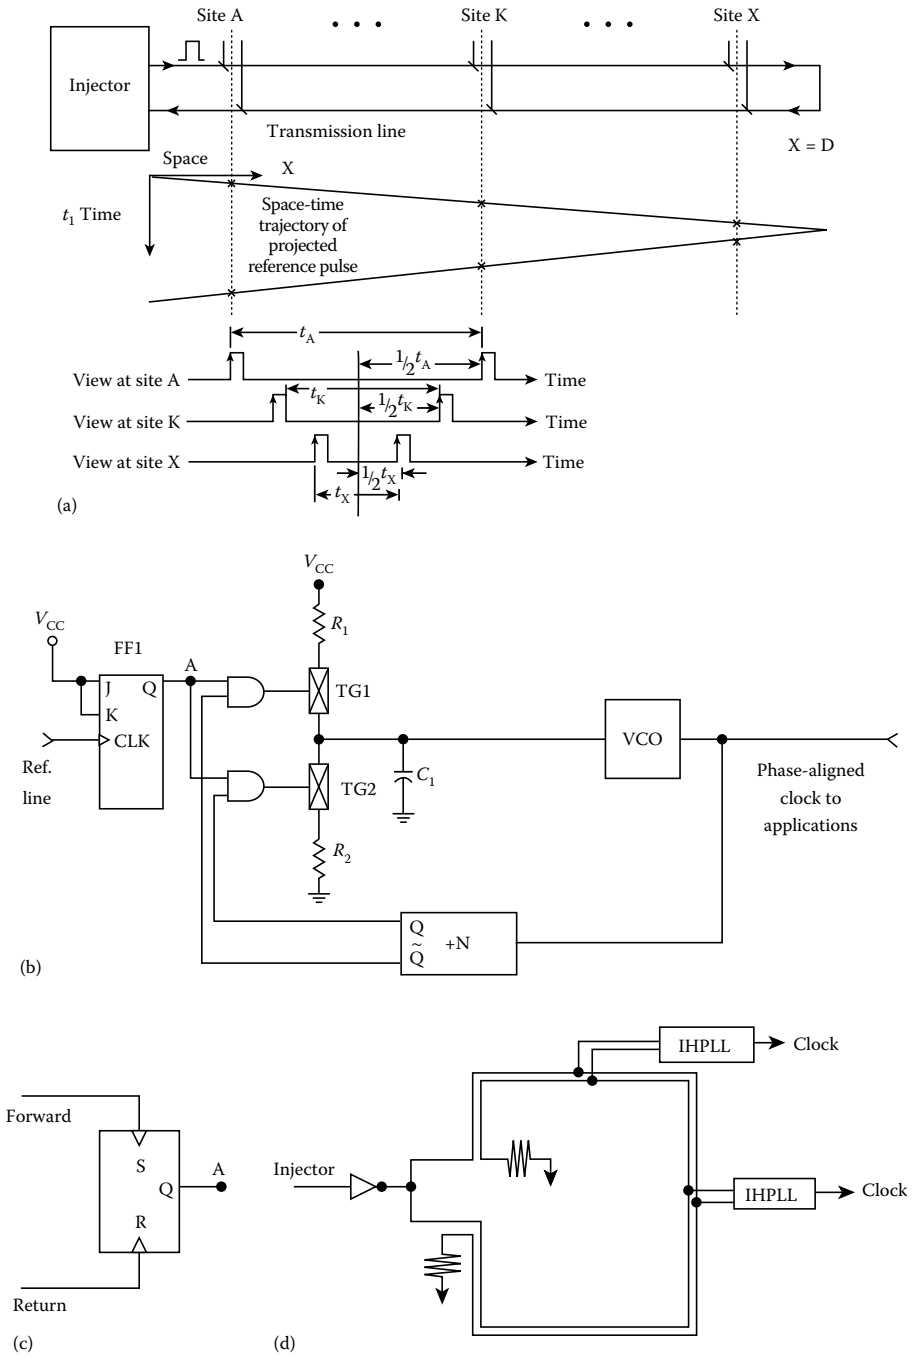

FIGURE 9.54 Grover's interval-halving clock distribution scheme: (a) interval-halving reference-time principle, (b) IHPLL circuit for single-line skew-compensated clock distribution, (From Grover, W.D., Method and apparatus for clock distribution and distributed clock synchronization, US Patent #5,361,277, Issued Nov. 1, 1994.) (c) phase detector for 2-line operation, and (d) driving two lines rather than one looped line.

uses a separate line to distribute raw-clock, which is then adaptively phase shifted at each point into the low-skew global phase by a voltage-controlled delay under the same feedback control sensing arrangement. Two-line operation, phase shifter, and other variations are described further in [14].

With this scheme, hierarchical clock distribution networks with delay-controlled cabling, delay-tuning, and numerous temperature- and load-dependent intermediate buffers may be replaced by one conductor with arbitrary routing. Both EMI and conducted noise are reduced by buffer driver elimination and because of the reduced average power of the reference pulse compared to the full clock signal. It may also be possible to add new clock-deriving taps in service, offering a growth path that is not limited by a predesigned clock–tree fanout limit. In many applications hybrids of reduced-depth clock trees, fanning out from skew-compensated roots on a single-line clock system of this type, may give the best combination of techniques.

Anceau's and Grover's schemes are similar in that a reference line is distributed to all modules and a PLL generates a local clock at each module. However, in the Anceau scheme modules do not run phase synchronously. Actual skew between modules remains arbitrarily high at the module clock frequency because the comm_clk line is set slow enough to be isochronic over the whole system. Actual delay in comm_clk, which is significant at the higher module rate, is not compensated at modules. Each module derives only enough information to coordinate its bus accesses with other modules, at the slower comm_clk frequency. In Grover's scheme, however, truly synchronous full-speed global clocking of all modules is achieved by returning the signal on the reference line (by reflection or looping) and exploiting the interval-halving time-reference principle and IH-PLL to cancel global skew. Gate-to-gate interaction on any clock cycle is feasible between modules in this case, as opposed to interaction only through the metastable-avoidance bus interface protocol.

9.2.3.13 Clock Tuning in Large Systems

In large systems, clock tuning at the chip, circuit pack, shelf, and rack levels of physical equipment may be required for the highest performance. Circuits to permit clock tuning can be a tapped delay-line circuit with a programmable selector, or (on a circuits card) a printed-in set of loops to be shunted out as needed by a suitcase jack, or a voltage-controlled varactor clock delay buffer. All of these are described in [15]. In general, to aid in the tuning process, one pin on each IC should be devoted to give external observability of the worst-case (if known) clock phase form inside the IC. This way the tuning process can compensate for the delays through I/O pads and clock buffers in large ICs.

Tuning begins by designing cable lengths, tracking, and connectors so that clock paths have nominally equivalent delays. The active tuning process then measures and adjusts relative delay starting from the master clock source to predefined levels of tuning points (TPs) electrically farther from the master clock source, denoted by TP_0. The delay measurement and adjustment repeats through lower level tuning points until the clock on in every IC is tuned. In going from the first to successive tuning points, it is preferable to refer delay measurements directly back to TP_0 each time. This may, however, be physically unmanageable, in which case delay tuning to level TP_n can be relative to TP_{n-1} although overall error relative to TP_0 will be higher in the relative tuning scheme. For systems that must grow in service, operational (i.e., in-service) signals should be the basis of the delay measurement, not requiring off-line signals or patterns.

One convenient way of indirectly measuring delay between points that are not easily accessed simultaneously for oscilloscope measurements is to make an oscillator out of the signal path to be measured. If the number of inversions in the path between TPs is odd, then an MUX can be switched to loop the tuning point signal at TP_n back to the TP_{n-1} driving point. A frequency counter can then measure the oscillation frequency, providing data to support automatic clock delay adjustments at the subordinate tuning point.

One mainframe computer used an automatic tuning scheme in which a clock phase-shifter chip produced multiple, slightly time-shifted copies of the clock on each system PCB. Individually selected delayed clock instances were then supplied to each IC on the board through a programmable crosspoint matrix IC. Each clock-receiving IC also provided several internal clock observation outputs to support

delay measurements down to the gate level. After automatically measuring the delays of the observable internal clocks in up to 30 ICs per board, the on-board clock selection matrix was programmed, giving each IC its best clock phase for overall system timing margins and minimal skew [30].

9.2.4 Future Directions

9.2.4.1 Current-Steered Logic

One way of reducing power supply noise injection from clocking is with current-steered logic. Experiments on differential current mode flip-flops in CMOS predict very short setup times (300–500 ps). Such devices would be very quiet electrically and much less susceptible to varying load effects on delay than on conventional CMOS. On the other hand, such devices might be about twice as large as conventional CMOS flip-flops and require more power. Using the bi-CMOS ability to integrate ECL type structures with CMOS may, however, be part of the solution for clocking very high speed medium-scale integrated devices.

9.2.4.2 Reduced Voltage Swing

Another potential method for reducing clocked load power consumption is to reduce voltage swings. Some experiments indicate a significant reduction in clock-related power and ground noise, but skew and delay objectives are more difficult to meet as the devices slow down in response to lower switching voltage swings.

9.2.4.3 Mixed Technology

Here, clock speed increases are envisaged by using current mode logic circuits selectively to implement critical timing paths in otherwise all-CMOS systems. New power reductions may also be obtained with ECL-based, high-speed, serial-multiplexed interfaces to replace wide buses which have many parallel CMOS drivers.

9.2.4.4 $\overline{Q}$ Elimination

Most logic families provide flip-flops with both Q and $\overline{Q}$ outputs as standard cells. An approach that could potentially have clock-related switching current and power is to eliminate the $\overline{Q}$ output buffer and develop corresponding logic synthesis tools to utilize inverted inputs and other logic means to assemble logic function without the $\overline{Q}$ outputs form flops. In one experiment of which the author is aware, $\overline{Q}$ buffers were removed, halving overall flip-flop power consumption, at the cost of only a 5% degradation in clock-to-Q delay.

9.2.4.5 Dedicated Layer for Clock Distribution

A number of workers are advocating or are already using dedicated third-layer metal for clock distribution. This affects process cost, but the advantages can be significant in high-performance applications. Third-layer metal is lower than other layers in resistance and capacitance. By moving the clock net, which is the largest single net in many designs, out of the other layers, routability of all other signals is improved and floorplanning simplified. Moreover, the clock tree can avoid uncertain delays due to unpredictable routing or due to polysilicon links in series when routing in fewer shared signal layers. In addition, noise due to clocking can be more easily isolated in the third-layer metal approach.

9.2.4.6 Optoelectronic Clock Distribution

Optical clock distribution takes advantage of the three-dimensional nature of imaging optics to remove all but the last-stage buffering levels of the clock distribution tree from the plane of the circuit, thereby eliminating multiple stages of buffering and metallization for clock routing. Figure 9.55 is an overview of the basic idea proposed by Clymer and Goodman [7]. The optical clock signal is generated off-chip and drives a laser diode at the top of the figure. The optical beam is expanded onto a transmission hologram,

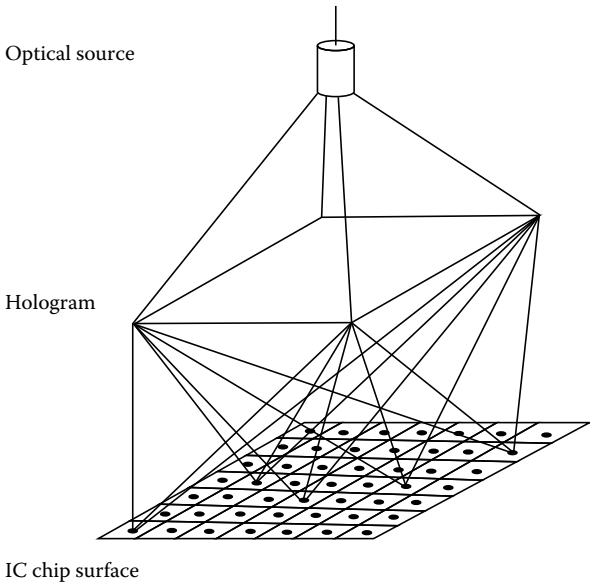

FIGURE 9.55 Clymer and Goodman's concept for wafer-scale optical clock distribution. (From Clymer, B.D. and Goodman, J.W., *Opt. Engin.*, 25(10), 1103, 1986.)

which focuses the light intensity onto predefined locations where optical detectors are fabricated into the wafer or die. The optical signal is detected, amplified, and used to drive a local clock generator-buffer which supplies a local isochronous regions. The optical path length differences are not equalized in this scheme because the optical path velocity is so high as to make the all optical path delays negligible as compared with the diffusion and lumped capacitive delays that determine the clock rare of the electronic system. When sources, detector, and packaging for this type of approach are developed, the potential exists for very low skew—high-speed clock distribution, with greater on-chip densities by eliminating most clock routing. One of the main challenges is in attaining uniform response times from the optical detector–amplifier combination (which tend to be sensitive to feature size variations) and the development of sources in the optical wavelength range for photodetectors that can be fabricated within the conventional CMOS circuit environment.

9.2.4.7 Reconfigurable Clock Nets

In WSI systems, where a single short in very large clock net may disable an entire wafer-level system, Fried [10] advocates methods of restructuring a clock net to enhance yield, primarily through the addition of a controllable tristate output stage to clock buffers within the clock distribution network. This way failed portions of the clock net can be isolated, or, with redundant interconnect and buffers, they may clocked by an alternate path. In particular, tristate buffers may be programmed on or off to select clock for each module from redundant connections to the central clock net, or to simply isolate failed clock net subregions from the drivers of unfailed portions.

9.3 MOS Storage Circuits

Josephine C. Chang and Bing J. Shev

In a large digital system, a sequence of operations must be performed for a particular function. The results of each operation depend on the results of previous operations. Therefore, the outputs of a logic circuit block typically depend not only on present input signals, but also on the history of the inputs. A CL circuit becomes more useful if it is combined with memory elements. To construct a sequential system, the most common and straightforward way is to employ a central clock to synchronize the sequence of operations.

Instead of using memory elements in a sequential system, we can use dynamic logic circuits to store temporary data. With the building blocks of inverters and transmission gates, the MOS transistors can be used as dynamic storage components to store data temporarily on the device capacitances. Dynamic storage is widely used in MOS technologies because of the simplicity of the required circuitry. Because a memory element such as a static circuit latch occupies a large area and consumes power, elimination of latches has a positive effect on circuit density and power consumption. However, the disadvantages of dynamic logic gates include high transient power disturbances and less noise margins in some applications [1].

Dynamic logic circuits design is based on the synchronized movement of charge through the MOS circuit. A typical capacitance value associated with a logic gate is on the order of a few femtofarads, with means the amount of charge $Q = CV$ dynamically stored on the capacitance is on the order of femtocoulombs. Therefore, perturbations from ideal behavior can become critical to the operation of a circuit.

9.3.1 Dynamic Charge Storage

The MOS technologies have two attractive features that lead to an efficient way to store data momentarily. These two features are the extremely high input impedance of MOS transistor and the ability of a MOS transistor to function as a nearly ideal electrical switch. In order to store the charge on a capacitive node, the node must be isolated from both the power supply and ground. Various types of storage nodes can be realized in CMOS technologies. For example, charge can be stored at a node between sources (or drains) of two MOS transistors such as nMOS–nMOS, pMOS–nMOS, and nMOS–pMOS [2]; or the source (or the drain) terminal of one MOS transistor connected to the gate terminal of a second MOS transistor. Because the stored charge will leak away over time, this circuit is termed ''dynamic storage circuit.''

Figure 9.56 shows the schematic diagrams of three combinations of source–drain connection. The distinction among the three connection types comes from the difference in voltage transmission levels for nMOS and pMOS gates.

Dynamic charge storage requires clocking the data at a sufficiently high rate so that the charge on the various nodes does not lead away significantly. Typically, this requires a minimum refresh rate of 500 Hz to 1 kHz, corresponding to a charge storage time of about to 2 ms.

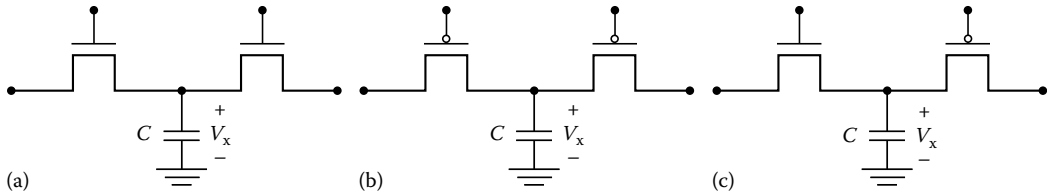

FIGURE 9.56 MOSFET source–drain connection storage nodes. (a) nMOS–nAMOS; (b) pMOS–pMOS; and (c) nMOS–pMOS.

9.3.1.1 nMOS–nMOS

An nMOS transistor is perfect for transmitting logic 0 signals, but imperfect for transmitting logic 1 signals due to the threshold voltage loss through the transistor. The voltage level of V_x which can be stored on the capacitor C is therefore limited by

$$0 \leq V_x \leq (V_{DD} - V_{th,n}) = V_{max} \tag{9.12}$$

where

$$V_{th,n} = V_{th\ 0,n} + \gamma_n\left(\sqrt{2\phi_{Fn} + V_{max}} - \sqrt{2\phi_{Fn}}\right) \tag{9.13}$$

Charge storage on an nMOS–nMOS node is affected by the leakage paths through the p-type bulk to the ground. This affects the long-term storage of a logic 1 value.

9.3.1.2 pMOS–pMOS

A pMOS–pMOS node is the complement storage component of an nMOS–nMOS node. The voltage level of V_x is limited by

$$V_{min} = \left|V_{th,p}\right| \leq V_x \leq V_{DD} \tag{9.14}$$

where

$$V_{th,p} = V_{th\ 0,p} + \left|\gamma_p\right|\left(\sqrt{\left|2\phi_{Fp}\right| + (V_{DD} - V_{min})} - \sqrt{2\left|\phi_{Fp}\right|}\right) \tag{9.15}$$

Because both p-channel MOS transistors have n-type bulks which are connected to V_{DD}, this type of storage node receives leakage current from the power supply. The logic 1 values can be held indefinitely, but the logic 0 values can only exist for a limited period of time.

9.3.1.3 nMOS–pMOS

A complementary nMOS–pMOS storage node can benefit from both nMOS and pMOS in transmitting logic 0 and logic 1, respectively. The voltage level which is stored on the capacitance is in the range of

$$0 \leq V_x \leq V_{DD} \tag{9.16}$$

If the maximum input value of V_{DD} is transmitted through the pMOS transistor and the minimum input value of 0 V is transmitted through the nMOS transistor. On the other hand, if the case is reversed, the

maximum input value is entered through the nMOS transistor and the minimum input value is entered through the pMOS transistor, then the voltage range is reduced to

$$\left|V_{\text{th,p}}\right| \leq V_{\text{x}} \leq V_{\text{DD}} - V_{\text{th,n}} \tag{9.17}$$

This type of operation should be avoided because it greatly reduces the noise margins. In a standard nMOS–pMOS storage node both leakage paths to the power supply and ground exist. The ability to retain logic 0 and logic 1 values depends on which leakage path dominates.

9.3.1.4 Source–Gate Connection

This type of storage node is the connecting point between the source terminal of a pass transistor and a gate terminal of another MOS transistor [3]. Electrical charge can be temporarily stored on or removed from the gate terminal of the second transistor. When the gate terminal of the pass transistor is at a logic low value, the pass transistor is turned off, and the charge on the gate terminal is isolated. This charge determines the stored logic value. If the stored charge is perfectly isolated, the logic value would be stored indefinitely. In a practical situation, the isolation is less than perfect, primarily because of leakage through the reverse-biased diode operation between the source diffusion region of the pass transistor and the substrate. In addition, leakage also can occur through the pass transistor. With the continuous advances in VLSI technologies, subthreshold leakage through the channel of the pass transistor becomes more important due to scale-down in device sizes. Leakage currents alter the node voltage, which may lead to a logic error.

Two major problems arise in maintaining the integrity of a stored logic state. First is the parasitic conduction paths in the transistors that lead to charge leakage. Leakage currents alter the node voltage, which may cause a logic error. The second problem is charge sharing, which occurs when two isolated storage nodes become connected by a switching event and must equalize their voltages by redistributing charge. Charge sharing may result in a logic error, or may block logic propagation entirely.

9.3.1.5 Charge Sharing

Beside charge leakage, a problem called charge sharing may also damage the integrity of a stored logic state. Charge sharing occurs when a dynamic charge-storage node is used to drive another isolated node in a switching network [4]. Typically, when two capacitors with different voltages are connected by a pass transistors, as shown on Figure 9.57, charge sharing may occur. When the pass transistor is turned on, the voltages on the capacitors equilibrate to some intermediate value. In Figure 9.57, capacitors C_1 and C_2 are in parallel when the transmission gate is conducting. This forces the voltages across C_1 and C_2 to be equal. If the two capacitors are charged to different initial voltages, charge sharing will occur when the

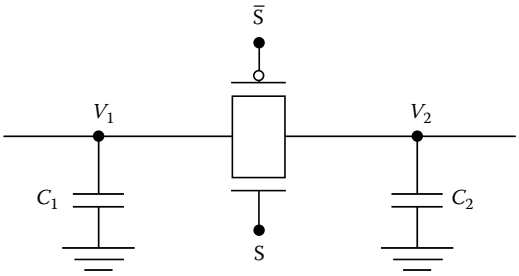

FIGURE 9.57 Charge-sharing-prone structure.

transmission gate turns on. Let the initial voltage charge on C_1 be V_1 and Q_1, and the initial voltage and charge on C_2 be V_2 and Q_2. The initial charge balance equation is

$$Q_1 + Q_2 = C_1V_1 + C_2V_2 \tag{9.18}$$

After the transmission gate turns on, the final charges on C_1 and C_2 become Q_1' and Q_2', respectively, and both capacitors are charged to the same value V'. The final charge balance equation is

$$Q_1' + Q_2' = (C_1 + C_2)V' \tag{9.19}$$

By applying the charge-conservation principle, we can obtain

$$V' = \frac{C_1V_1 + C_2V_2}{C_1 + C_2} \tag{9.20}$$

and

$$Q_1' = \frac{C_1}{C_1 + C_2}(C_1V_1 + C_2V_2) \tag{9.21}$$

A precharged circuit might work incorrectly due to charge-sharing errors, which could occur inside the pulldown network or at the output circuit. To control a precharged circuit, a gated clock can be present only at the input of the bottom transistor, while all other inputs to the gates of transistors in series in the pulldown chain must have a stable signal over the same clock phase to prevent charge-sharing problems. A ''sneak path'' is created when two pass transistors in series are both turned on at the same time and one is connected to V_{DD} while the other is connected to the ground. Charge can leak through this sneak path.

9.3.2 Shift Register

A frequent use of dynamic storage circuits is the shift register. Shift registers are most often used to provide temporary storage of digital signals. The shift register storage can be used as a simple way to delay the arrival of a signal for a specific number of clock cycles. Shift register storage is also frequently used as the temporary memory for a sequential logic circuit. In general, shift registers provide dense, limited access memory for many applications in digital integrated circuits.

9.3.2.1 Simple Shift Register

Figure 9.58 is the schematic diagram of a multistage MOS shift register, with each stage composed of a pass transistor and an inverter [5]. The nonoverlapping clock waveforms Φ_1 and Φ_2 are used. Assume that a logic signal is placed at the input of the first shift register stage while the Φ_1 clock is low and the transmission gate of the first stage is turned off. Next, when the Φ_1 clock goes high, if the signal at the input to the first stage is held constant, it will be propagated to the input of the inverter in the first stage. After a short delay, the output of the first inverter will provide the inverted logic signal to the input of the second shift register stage. At this time, the Φ_2 clock is low and the transmission gate in the second stage will not pass this signal. When the clock values change so that Φ_2 becomes high, the transmission gate of the second stage will propagate the output signal of the first stage to the second inverter, and then the output of the second stage is produced. This signal will be stopped by the transmission gate of the third stage because Φ_1 is low while Φ_2 is high. This sequence continues through the shift register chain as the clock signals alternate, causing the input signal to propagate through the shift register stages. The data are

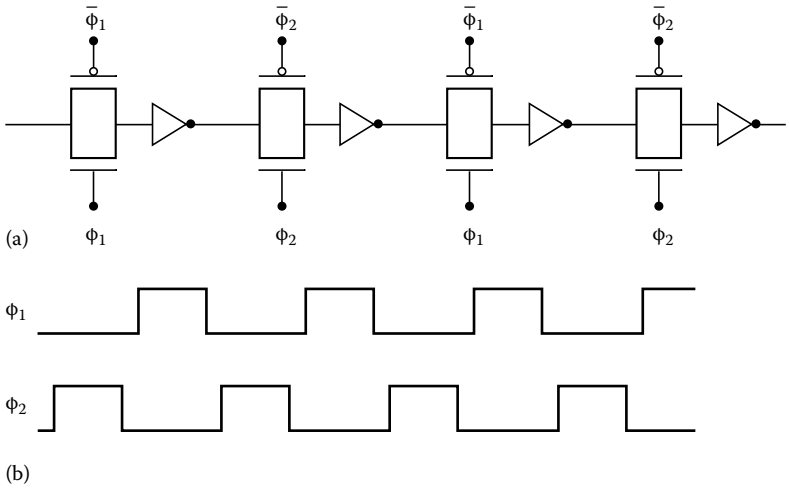

FIGURE 9.58 (a) A four-stage MOS register and (b) nonoverlapping waveforms of ϕ_1 and ϕ_2.

stored on the capacitances associated with the gate terminals of the inverter. The transmission gate acts as the switch that lets charge flow into and out of the capacitors when they are turned on. The charge is trapped at the capacitor when the transmission gate is turned off.

Each time the Φ_1 clock changes to a high value, the shift register input signal will propagate to the gate of the first inverter and the output signal of the first stage will be produced. A sequence of alternating Φ_1 and Φ_2 clock signals will cause an input signal to propagate through the whole structure at the rate of two stages of the shift register for each complete cycle of the clock signals. After N clock cycles, a logic input value will have shifted through $2N$ stages of the shift register chain. When a two-phase clock is used to control a shift register, it is important that the two clock phases do not overlap. If both phases of the clock were high simultaneously, a data value could propagate through multiple stages during the clock overlap time. This would cause erroneous operation of the shift register.

9.3.2.2 Parallel Shift Register

Several copies of the multistage shift registers can be combined in parallel with the same clock lines to form a parallel shift register to transmit a group of signals in lock-step fashion. Such a parallel shift of 8, 16, or 32 data bits is often used in microprocessor circuits. The basic structure of this set of shift registers demonstrates two principles which are important for the efficient geometrical layout of digital circuits. The data for the shift register flow from left to right while the control signals (Φ_1 and Φ_2 clocks) flow from top to bottom. Such an orthogonal structure of data paths and control signals within a circuit module is widely used to provide a regular organization of logic circuits within a VLSI chip. Physical layout of the shift register stages can be mirrored with respect to the ground and V_{DD} lines. This mirroring technique allows shared power and ground connections and reduces required circuit layout area. It is important to minimize the size of the basic shift register stage because this stage is repeated many times in a large shift register.

9.3.2.3 Clocked Barrel Shifter

A "barrel shifter" is a wraparound shifter that forms a very useful switch array [6]. The basic layout is shown in Figure 9.59. The inputs are labeled I_i; the shift controls $\Phi_2 \cdot \mathrm{SH}_i$, and the outputs O_i. The input lines run horizontally while the output lines run vertically. The operation of the first shift register

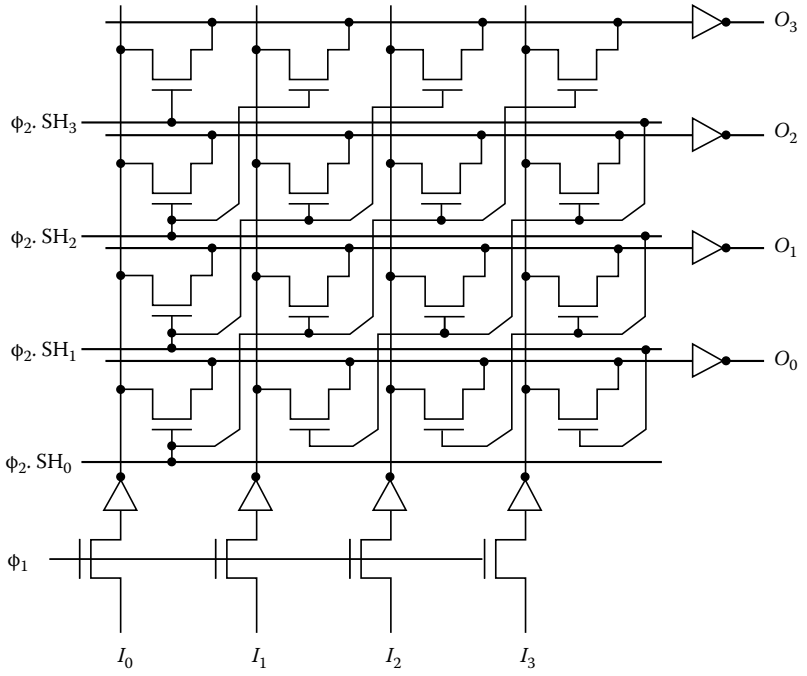

FIGURE 9.59 A four-bit clocked barrel shifter.

stage is the same as explained earlier. In the second stage for four output signals from the four inverters in the first stage can be shifted without changing the order or each signal can move up one, two, or three locations.

9.3.3 Dynamic CMOS Logic

The dynamic CMOS logic design consists of dynamic circuits based on precharging the output node to a particular level when the clock is at the logic 0 level. During the precharge phase, the inputs to the circuits change. When the clock is at the logic 1 value, the output of the logic gate may be pulled to a complementary value, depending on the input conditions.

The choice of using static or dynamic logic is dependent on many criteria. When low-power performance is desired, it appears that dynamic logic has some inherent advantages in a number of areas including reduced switching activity due to hazards, elimination of short-circuit dissipation, and reduced parasitic node capacitances. Static logic circuits have advantages on charge sharing and precharge operation.

Static circuits design can exhibit spurious transitions due to races. These spurious transitions dissipate extra power over that required to perform the computation. The number of these extra transitions is a function of input patterns, internal state assignment in the logic design, delay skew, and logic depth. Although it is possible with careful logic design to eliminate these transitions, dynamic logic intrinsically does not have this problem because any node can undergo at most one power-consuming transition per clock cycle [7].

Short-circuit currents are found in static CMOS circuits. However, by sizing transistors for equal rise and fall times, the short-circuit component of the total power dissipated can be kept to $<$20% of the dynamic switching component. Dynamic logic does not exhibit this problem, except for those cases in which static pullup devices are used to control charge sharing or when clock skew is significant. Dynamic

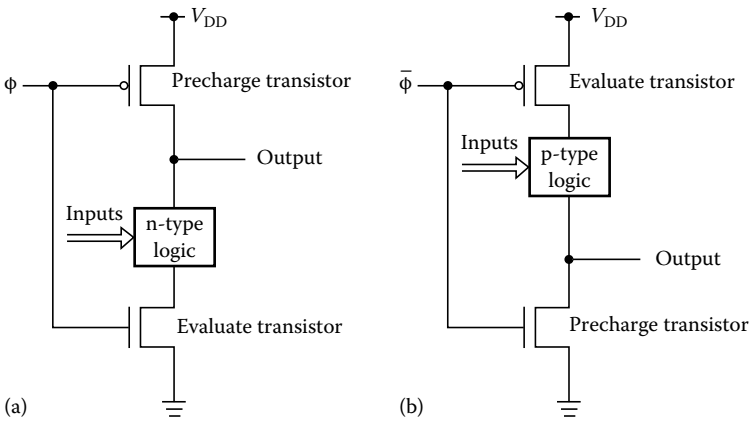

FIGURE 9.60 A precharge–evaluate logic gate.

logic typically used fewer transistors to implement a given logic function, which directly reduces the amount of capacitance being switched and thus has a direct impact in the power-delay product.

9.3.3.1 Precharge–Evaluate Logic

The schematic diagram of a basic precharge–evaluate logic is shown in Figure 9.60. It consists of an *n*MOS logic structure whose output node is precharged to V_{DD} by a pMOS precharge transistor; and conditionally discharged by the *n*-transistor network connected to the ground. Alternatively, an *n*-transistor precharge to the ground and a pMOS logic structure to conditionally discharge to V_{DD} may be used. A single-phase clock Φ is used for high-speed operation. For the former case, the precharge phase occurs when the clock Φ is low. The path to the ground is activated via the *n*-transistor network when the clock Φ is high. The input capacitance of this logic gate is the same as a pseudo-nMOS gate which has a single *p*-transistor, with the gate connected to the ground, as a load device. The pullup time is better than a pseudo-nMOS gate by virtue of the active switch but the pulldown time is increased due to the ground switch.

9.3.3.2 Clocked CMOS Logic

Clocked CMOS logic (C^2MOS) gates were originally used to build low-power dissipation logic gates. The reasons for the reduced dynamic power dissipation stem mainly from metal–gate CMOS layout considerations. The main use of such logic structures is to form clocked structures that incorporate latches or interface with other dynamic forms of logic structure. The gates have the same input capacitance as regular complementary gates, but larger rise and fall times due to the serially connected clocking transistors.

The schematic diagram of a clocked CMOS logic gate is shown in Figure 9.61. In this circuit, the clocked transistors are placed in series with the transistors in the *p*- and *n*-type logic blocks. The primary use of C^2MOS is in dynamic shift registers. In a C^2MOS dynamic shift register, the *p*-type logic black is a *p*-transistor network and the *n*-type logic is an *n*-transistor network. All transistors can normally be chosen as minimum-size devices because each stage is only required to drive the capacitance of an identical shift register stage.

Although the C^2MOS circuit requires the same number of transistors, external connections, and clock phases as the standard CMOS dynamic shift register, the layout is greatly simplified because the source/drain regions of the two *p*-channel transistors can be merged, and the corresponding regions of the two *n*-channel transistors can be merged. This feature helps to reduce circuit capacitance, number of contacts, and layout area.

Operation of the C^2MOS circuit is quite simple. The gates of the *p*MOS pullup transistor and the nMOS pulldown transistor of the inverter are both connected to the input signals. For a valid logic input,

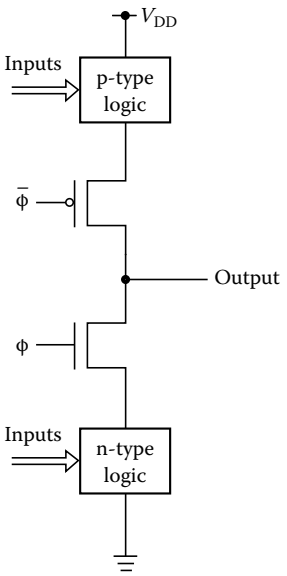

FIGURE 9.61 A clocked CMOS logic gate.

one of these transistors is turned off while the other is turned on. Clocked transistors placed in series with the pullup and pulldown transistors serve to connect these transistors to the output node when the clock Φ is high. If the input signals match the *n*-type logic portion, the output storage node will be discharged. Otherwise, the output storage node will be charged. When the clock Φ is low, the output node will remain in its present state. In contrast to other clocked logic circuits, the output of C^2MOS is available during the entire clock cycle, although it is actively driven only when the clock is high. A C^2MOS circuit is more susceptible to interference from the load circuit attached to the stage because the load capacitance is the storage node for the dynamic charge.

9.3.3.3 Domino CMOS Logic

The domino logic gate design can provide glitch-free cascades of nMOS logic structures. It is a modification to the clocked CMOS logic gate to allow a single clock to precharge and evaluate a cascaded set of dynamic logic blocks. A domino logic gate consists of two elements: a precharge–evaluate logic stage followed by a static inverter buffer at the output, as shown in Figure 9.62. The logic gate can be built in two forms: mostly *n*-transistors and mostly *p*-transistors. During the precharge phase when clock Φ is low, the output node of the dynamic gate is precharged high, and inverted by the static buffer to provide a logic 0 output for the domino CMOS gate. As subsequent logic stages are driven by this buffer, transistors in subsequent logic blocks will be turned off during the precharge phase. When the gate is evaluated, the node voltage of the logic stage is conditionally pulled down according to the input signal values. If the logic condition of the gate is satisfied, the node voltage is pulled down. It is inverted by the static buffer to provide a logic 1 output. Each gate in sequence can make at most one transition ($1 \rightarrow 0$). Hence, the buffer can only make a transition from ($0 \rightarrow 1$). In a cascaded set of logic blocks, each state evaluates and causes the next stage to evaluate in the same manner as a stack of dominos fall. Any number of logic stages may be cascaded, provided that the sequence can evaluate within the given clock phase. A single clock can be used to precharge and evaluate all logic gates within a block.

The structure has some limitations. First, only noninverting structures can be constructed. Second, each logic gate must be buffered. Finally, in common with a clocked CMOS gate, charge redistribution can be a problem. The effects of these problems can be minimized. For example, in complex logic circuits, such as ALUs, the necessary XOR gates may be implemented conventionally as complementary gates and driven by the last domino circuit. The buffer is often needed to drive large capacitive load and does not contribute to any extra cost.

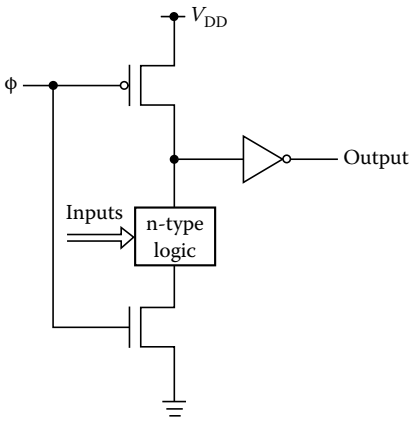

FIGURE 9.62 A domino CMOS logic gate.

Static storage of charge can be realized by a domino logic gate by including a weak *p*-transistor. A weak *p*-transistor is one that has low gain, which is realized with a small W/L ratio. It should have a small gain in order not to fight with the pulldown transistors, yet to balance the effects of leakage. This will allow low frequency or static operation when the clock is held high. In this case, the pullup speed could be an order of magnitude slower than the pulldown speed. Notice that the precharge transistor may be eliminated if the time between evaluation phases is long enough to allow the weak pullup to charge the output node.

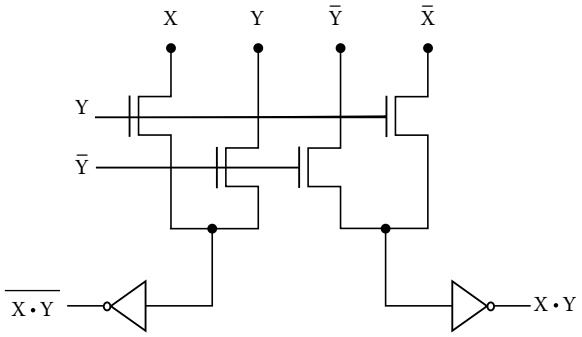

FIGURE 9.63 A CPL AND/NAND cell.

A domino logic gate has advantages over a simple precharge–evaluate logic structure. For example, the static buffer provides output-driving capability to either V_{DD} or the ground. In the precharge–evaluate logic gate the output can be favorably driven only to the ground in response to logical conditions, not to V_{DD}. When the logic condition of the precharge–evaluate gate is not satisfied, dynamic charge storage at the output must maintain the logic 1 value. The dynamic logic portion of a domino CMOS gate always has a fanout of 1, thereby simplifying device sizing within the gate structure.

9.3.3.4 Complementary Pass-Transistor Logic

The complementary pass-transistor logic (CPL) gate is constructed by using an nMOS pass-transistor network for logic function and eliminating the pMOS latch [8]. It consists of complementary inputs and outputs, nMOS pass transistor logic network, and CMOS output inverters. Figure 9.63 is the schematic diagram of a CPL AND/NAND cell. The pass-transistors function as pulldown and pullup devices. Thus, the pMOS latch can be eliminated, allowing the advantage of differential circuits to be fully utilized. One attractive feature of the CPL gate is that complementary outputs are produced by the simple four-transistor circuits. Because the logic 1 value level of the pass-transistor outputs is lower than the supply voltage V_{DD} by the threshold voltage of the pass-transistors, the signals must be amplified by the output inverters. In addition, the CMOS output inverters shift the logic threshold voltage and drive the capacitive load. The logic threshold shift is necessary because that of the output inverter is lower than half of the supply voltage, due to the lowering of the logic 1 value.

The CPL gate is attractive because fewer transistors are required to implement important functions. However, a CPL gate has two basis problems. First, the threshold drop across the single-channel pass-transistor results in reduced current drive and hence slower operation at a reduced supply voltage. This is important for low-power design because it is desirable to operate at the lowest possible voltage levels.

Second, because the logic 1 input value at the regenerative inverters is not V_{DD}, the pMOS device in the inverter is not fully turned off, and hence direct-path static power dissipation could be significant. To solve these problems, reduction of the threshold voltage has proven effective, although if taken too far it will incur a cost in dissipation due to subthreshold leakage and reduced noise margins.

9.3.3.5 Cascade Voltage Switch Logic

The cascade voltage switch logic (CVSL) gate is a differential style of logic circuit design requiring both true and complement signals to be routed to the gates [9]. Two complementary nMOS switch structures are constructed and then connected to a pair of cross-coupled p pullup transistors as shown in Figure 9.64a. When the inputs switch, node voltages Q and $\overline{Q}$ are either pulled up or down. Positive feedback applied to the p pullup transistors causes the gate to switch. The logic trees may be further minimized from the fully differential form using logic minimization algorithms. This version is slower than a

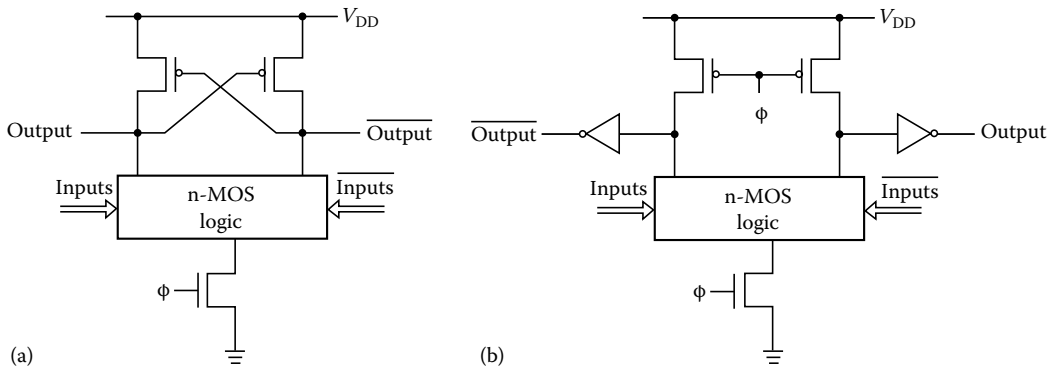

FIGURE 9.64 A CVSL gate: (a) static version and (b) dynamic version.

conventional complementary gate employing a *p*-tree and an *n*-tree because during the switching action, the *p* pullup transistors must compete with the *n* pulldown tree. The schematic diagram of a dynamic charge-storage version of the CVSL logic gate design is shown in Figure 9.64b. It consists of two domino logic gates with complementary input logic trees. The advantage of CVSL gate over a domino logic gate is the capability to generate a complete logic function rather than just the noninverting logic function. However, extra silicon area is needed.

9.3.3.6 NORA CMOS Dynamic Logic

NORA logic is capable of handling signal race problems in transmission pates [10]. It is based on dynamic CMOS logic, but uses latches instead of transmission gates to control signal flow. In a NORA logic dynamic nMOS and pMOS, logic circuits are cascaded into a C^2MOS latch. Figure 9.65 shows the schematic diagrams of both Φ stage and $\bar{\Phi}$ stage. Static inverters are provided at the outputs of dynamic circuits to realize logic inversion. This allows direct implementation of arbitrary functions without modification. In the Φ stage, the logic circuit used $\Phi = 0$ for precharge and $\bar{\Phi} = 1$ for evaluation. The latch accepts data when $\Phi = 1$ and holds the data when $\Phi = 0$. No new data can be accepted during the hold time. The operation in the $\bar{\Phi}$ stage is similar when reversing clock signals are used.

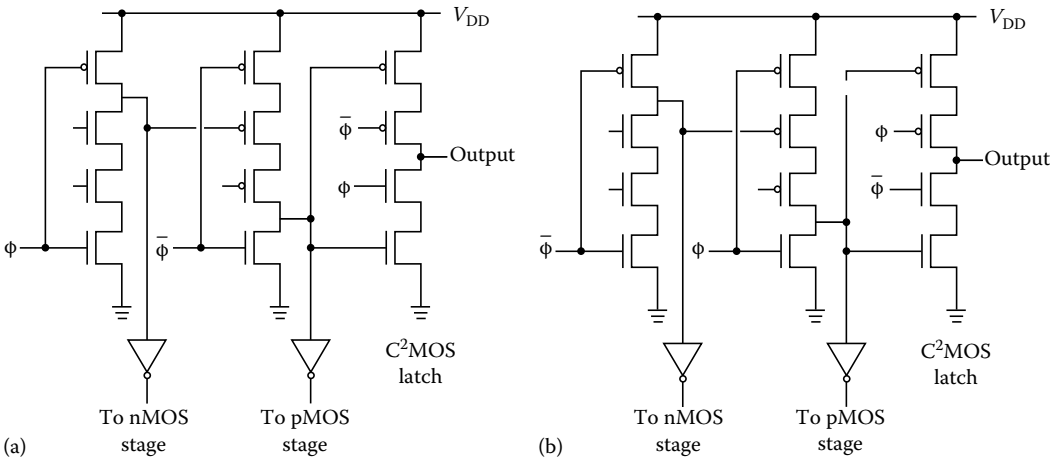

FIGURE 9.65 NORA clock stages: (a) Φ stage and (b) $\bar{\Phi}$ stage.

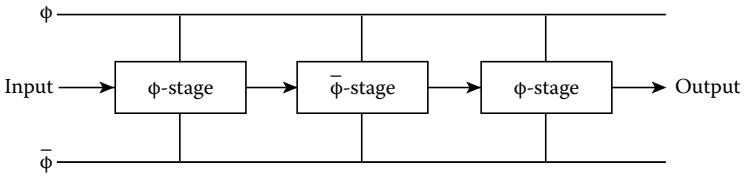

FIGURE 9.66 A NORA chain.

By alternating Φ and $\bar{\Phi}$ clock stages makes NORA chains well suited for pipelined logic. The schematic diagram of a generic structure of a NORA chain is shown in Figure 9.66 [2]. Logic flows through the chain at a rate set by the clock. The problem of logic races by using transmission gates as latches between logic circuits has been eliminated because of the dynamic C^2MOS latch circuit.

9.4 Microprocessor-Based Design

Roland Priemer

9.4.1 Introduction

During the past three decades, microprocessors have become components that are routinely and widely used in machines and systems that engineers design. This is due to their flexibility and ability to perform tasks at a low cost. Because they are programmable, microprocessors are used to achieve operations of devices and systems with complexity that we have come to take for granted. Engineers are embedding microprocessors into systems that are being employed in virtually all fields of human endeavor.

The competition among the numerous manufacturers of microprocessors has brought about a great variety of microprocessors to increase their suitability in ever-widening fields, more products, and new markets. Moreover, turnaround times have become short enough and costs have come down enough so that system and application engineers have the option to specify the design of a customized microprocessor to meet their application-specific performance requirements.

This section is intended to introduce the reader to design with a microprocessor. It is assumed that the reader is acquainted with the material that is generally covered in an introductory course on digital systems. The goal is to help the designer who is not experienced with the design of microprocessor-based systems to come to a basic understanding of what is involved. Two representative and significantly different microprocessors will be used to do this. These are the Zilog Z80, an enduring general-purpose microprocessor, and the Motorola M68HC11, also called a microcontroller. These and similar microprocessors have been used in many diverse kinds of dedicated applications.

The design and development of the hardware and the software are two broad aspects to utilizing a microprocessor. Here, the emphasis is on digital hardware design. To understand the role that a microprocessor plays in the design process we must understand the operation of several major building blocks. These are memory, architecture of a microprocessor (programmer model), the system bus and timing of bus signals, and supportive devices to interface these building blocks together. At the level of design to be considered here, hardware and software are and should remain inseparable. From both points of view, we gain a better understanding of the other. However, due to space limitations, no significant presentation of programming in assembly language is included in the sequel. Instead, software is only utilized to see how it influences hardware requirements and how it makes hardware work.

9.4.2 Features of a Microprocessor-Based System

Conceptually, Figure 9.67 depicts a microprocessor-based system. The inputs to the microprocessor are all binary (can only take on one of two values) or digital signals. However, the origins and meanings of these signals can be very diverse. Inputs can be due to manually activated switch closures from buttons or keypads or they can be due to switches that are embedded within sensors that detect, for example, presence or absence of an object, pressure that is over or under a certain level, temperature that is above or below a particular temperature, presence or absence of an ultrasound or light beam, voltage that is above or below a desired value, etc. An input can come from a real-time clock. Inputs can also be information about the status or readiness of devices that receive outputs from the microprocessor-based system.

A single digital signal is called a bit, and it can only take on one of two logic values, i.e., logic one or logic zero, which in the circuits that we will use correspond to 5 or 0 V, respectively. Typically, these circuits are designed to accept as logic one any voltage in the range 3.5–5, and accept as logic zero any

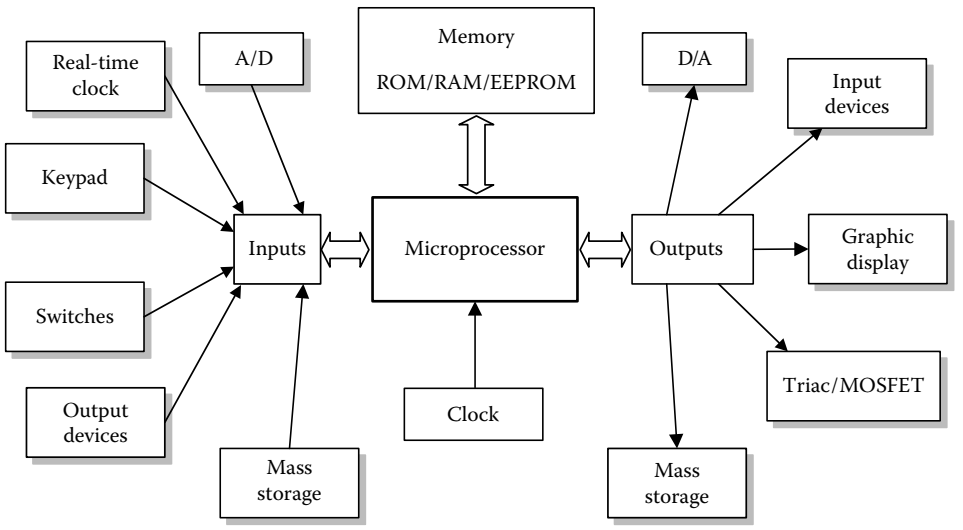

FIGURE 9.67 Conceptual diagram of a microprocessor-based system.

voltage in the range 0–1.5. Voltages in the range 1.5–3.5 will produce indeterminate results. Digital hardware using other voltage levels is also available. Of particular interest for portable applications are microprocessors using 3 V (or even 1.5 V) and 0 V. Unless explicitly noted, all signals are voltages as they vary with respect to a common reference.

Taken together, n-bits that are labeled, for example, with $d_{n-1}, d_{n-2}, \ldots, d_1, d_0$ can have any one of 2^n different binary combinations or binary assignments. A group of $n = 8$ bits is called a byte, which can take on any one of 256 different binary assignments. Another commonly used quantity is $2^{10} = 1024$, which is denoted by 1K. Thus, for example, we get $16\text{K} = 2^{14} = 16{,}384$.

Inputs can be analog in origin, and the microprocessor receives the result of sampling and analog-to-digital (A/D) conversion of an analog signal. Usually, analog signals are electrical signals generated by transducers that convert physical quantities of interest to voltages, such as, for example, speed of a motor, weight of an object, sound of someone speaking, stress of material under test, temperature in a building, electrocardiogram of a patient, acceleration of some structure, wind direction, oil pressure in an engine, etc. The analog signal can be the output of a receiver in a wireless communication application. The possibilities are endless. Thus, a microprocessor (the program it is executing) can receive information about time and the state of the world in which it is intended to operate.

The memory module of Figure 9.67 serves several purposes. First of all, it contains the binary instruction codes of the program that is executed by the microprocessor. The program instruction codes are another kind of input to the microprocessor. Memory may also be used for temporary storage and later retrieval of data produced by the program as it executes the algorithms that process the inputs. And, memory may contain various kinds of data tables that are referenced according to the instructions of the executing program. In contrast to the memory module, which must respond in time comparable to microprocessor speed of operation, slower mass storage devices also provide inputs that may be programs that will be transferred to memory for subsequent execution or that may be data that will be utilized by an executing program.

An important feature of using a microprocessor is that the functionality of an application is achieved mainly with software and the interaction through hardware between the software and the application environment. From a mass production viewpoint, this is almost a matter of trading hardware, a repeated expense, for software, a one-time expense, whenever possible. Thus, we are not concerned to design a general-purpose computer, but instead, we want to design the hardware that is sufficient to support the software that comprises the functionality of an application. Furthermore, using a microprocessor can achieve more than this, because with programmed hardware we can realize fundamental tasks such as conditional checking, storage, waiting, arithmetic, and timing, to mention a few, and higher level tasks such as complex algorithm calculations, decision making, control of machines, management of data, complex graphical interaction with the system user, and so on. When programmed properly, a microprocessor provides the ability to perform tasks that are difficult or impossible to achieve with any other kind of means or hardware.

The outputs from the microprocessor in Figure 9.67 are all digital signals. Like inputs, the meaning and destination of outputs can also be very diverse. Outputs can be one bit quantities that are intended to turn on and off, for example, light and sound indicators and devices such as, for example, TRIACs that can control AC power supply to equipment like AC motors, lights, heaters, and transformers, and, for example, power MOSFETs that can control DC power supply to equipment like solenoids, relays, DC motors, and lights. Outputs can be complex data structures that support graphical interaction between the user and the microprocessor-based system. As for inputs, here too the possibilities are endless. Outputs may be necessary to control the input devices or inform them of the readiness to receive inputs.

Outputs can also be 8, 16, or other multi-bit quantities that are, for example, printer control and text character codes, data to be placed in mass storage, a binary value to be transferred to a digital-to-analog (D/A) converter to synthesize an analog signal, data to be placed in memory, codes of characters to be displayed, data to be wirelessly communicated, protocols to establish communication links, and many other possibilities.

The clock module produces a voltage pulse train, called the system clock. Since microprocessor activity occurs due to level changes of the system clock, the speed at which the microprocessor executes instructions depends on the frequency of this pulse train. For example, if some particular microprocessor can fetch and execute an instruction in 5 clock cycles, and it can be clocked with a frequency of 250 MHz, then the microprocessor can execute the instruction in 20 ns. For most microprocessors, the number of clock cycles required to fetch and execute an instruction varies with the kind of instruction.

With all of the above modules interconnected to achieve a particular task, it will be the activity of the microprocessor, which is determined by the software that it executes, that controls the acquisition of inputs, processes the inputs, implements the intended functionality of the system, and generates and controls the placement of outputs.

Figure 9.68 shows a more functional structure than Figure 9.67 of a microprocessor-based system. An important feature of this structure is the use of a set of common communication paths, called the system bus, between all major modules. To identify any particular device, the microprocessor places a binary number, called an address, on the m-bit address bus. Actually, the electronic circuitry that comprises the microprocessor sets the voltages on the m address bus conductors to some combination of 0 and 5 V. There are 2^m different addresses that can be placed on the address bus. Every other module receives the address, and only the particular device that recognizes its own address, which is assigned and incorporated by the system designer, is supposed to respond. The data bus simultaneously transfers n-bits of data from the microprocessor to any device or from any device to the microprocessor. There are microprocessors with the number of address bits ranging from $m = 10$ to $m = 64$ and the number of data bits ranging from $n = 4$ to $n = 64$. We will work with microprocessors that produce an $m = 16$ bits wide address, which permits $2^{16} = 65{,}536 = 64\text{K}$ different addresses, and that use an $n = 8$ bits wide data bus. The control bus informs all modules about the kind of activity that is presently occurring or is about to take place on the system bus.

Usually, the different modules in the system have different time and electrical and operating characteristics. It is the purpose of the interfaces to make compatible the modalities of these different modules. Often, it is interface design that is the focus of an overall hardware design effort. Depending on the kind of control signals provided by a microprocessor and the kind of control signals that are preferred or required on the control bus, a microprocessor may also require an interface circuit to the system bus.

There are numerous different standard system bus definitions. For example, the public availability of the definition of the IBM PC bus has permitted the connection of innumerable different accessories, produced by many different manufacturers, to this bus. Such accessories and associated software were designed to be compatible with the definition of this bus standard. Over the past three decades, such standardization has contributed to the wide success of the PC in the home and in the workplace.

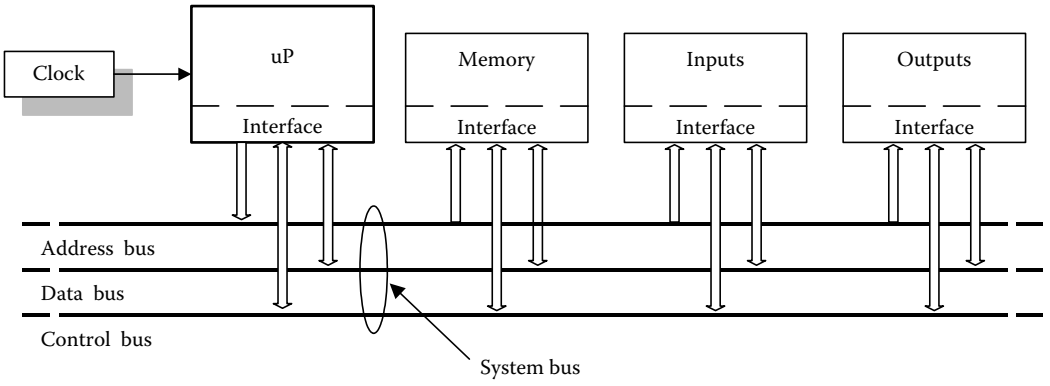

FIGURE 9.68 System block diagram.

However, in a dedicated application, adherence to a bus standard may not be necessary, particularly when there is no need to interconnect standardized modules. Here, we use the particular control signals of the microprocessor to form the system control bus as needed.

9.4.3 Memory

Almost all of the internal and external activity of a microprocessor depends on the ability to store, transfer, and retrieve data. A designer must understand how these operations take place. By way of presenting some memory devices, some terminology and supportive hardware are also introduced.

A circuit for a memory cell is shown in Figure 9.69. It is also called a binary cell (BC). Here, the activity of the flip-flop is determined by the logic signals at the points labeled *S*, for select, and R/$\overline{\text{W}}$, for read or write. The small circles attached to the OR gates and the buffers are called bubbles, and they mean logical complement. Thus, the buffer followed by a bubble is a NOT gate, and the flip-flop is made with two NOR gates. Another commonly used notation for logical complement is a small right triangle, as shown in the figure.

Note that we are using positive logic so that logic 1 means that a signal is high (5 V) and logic 0 means that a signal is low (0 V). When an operation or activity is enabled by taking a control signal high(low), then we say the control is active high(low). More briefly and without regard to the required level, an operation is enabled by asserting (or activating) its control signal(s).

The read and select control inputs of the BC are active high, while the write control input is active low, which is indicated by the bar over the *W*. To store a bit in the BC, the sequence of operations is (1) set the input, (2) set the R/$\overline{\text{W}}$ control signal low, and (3) momentarily select the cell. And, the write operation is complete.

A set of BCs that can be read or written in parallel is called a register, and the set of bits that a register can hold is called a word. A four words by 3 bits/word memory module is shown in Figure 9.70. The $m = 2$ bits input a_1a_0 is decoded with the 2×4 decoder, which has its own active low enable control. When enabled, the decoder output selects, according to its inputs, just one register (row of BCs) for a read or write operation. The binary assignment to a_1a_0 is called the address of the word to be referenced. For a read operation, the OR gates receive the bits of the selected word, while all other OR gate inputs are logic 0. For a write operation all BCs in a column receive the same input bit, while only the BC in the selected row accepts it. With additional columns, we can increase the register length to *n*-bits/word, and with an $m \times 2^m$ decoder we can have a memory size of 2^m registers, while only requiring *m* address bits to specify any particular memory register that is the object of a read or write operation (memory reference).

Figure 9.70 implies that the system data bus must consist of an *n*-bit unidirectional input bus to transfer data from memory to the microprocessor and an *n*-bit unidirectional output bus to transfer data from the microprocessor to memory. Practically, to reduce the number of communication paths, an *n*-bit bidirectional system data bus is preferred. This can be accommodated by connecting to each memory I/O bit pair, say the *i*th pair, an arrangement of tristate buffers as shown in Figure 9.71, where d_i

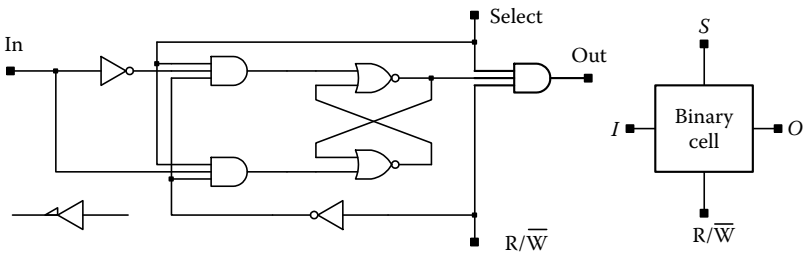

FIGURE 9.69 Circuit of a BC with select and R/$\overline{\text{W}}$ control.

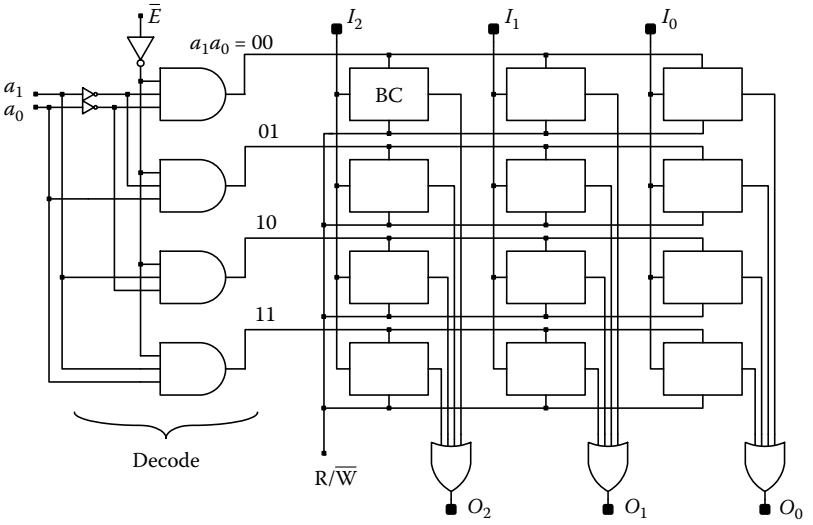

FIGURE 9.70 A multiword read/write memory circuit.

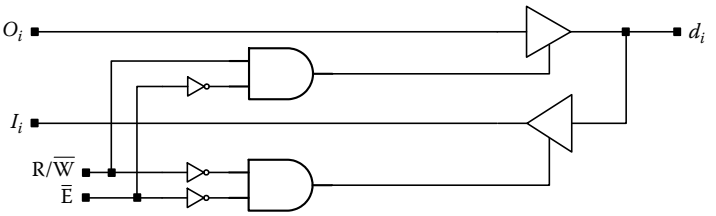

FIGURE 9.71 Unidirectional to bidirectional bus conversion.

is connected to the *i*th bit of the system data bus. When both buffers are in tristate (high impedance state), which occurs when $\overline{E}$ is high, then d_i is independent of O_i and I_i. Thus, the memory module can be electrically disconnected from the system bidirectional data bus. When $\overline{E}$ is asserted, then R/$\overline{W}$ controls the direction of data transfer. Figure 9.72 shows a more concise notation for the entire memory module. Here, the two address lines are grouped into one bus, and the three bidirectional data lines are grouped into another bus.

Since there is no particular required address sequence for reading or writing data to this memory, it is called random access memory (RAM). Since stored data remain intact as long as power is supplied to the circuit, this memory is called SRAM, contrary to another memory type, called dynamic RAM (DRAM),

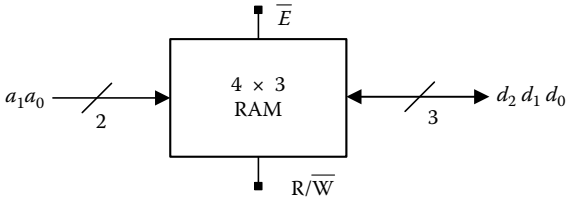

FIGURE 9.72 A memory module.

where the logic content of a BC is not based on the state of a bistable circuit, but is instead based on the presence or absence of charge on a cell capacitor. Since charge on capacitors dissipates, DRAM must be periodically refreshed, which requires additional control circuitry. However, DRAM can be fabricated to achieve much higher bit densities than of SRAM, resulting in the substantially lower cost of DRAM.

RAMs in various dimensions and package types are available. Commonly available SRAM chips range in size from 256×1 to $1024\text{K} \times 8$ (a 1 megabyte RAM), and the function and number of the control signals also vary a little. Commonly available DRAM chips range in size from $16\text{K} \times 1$ to $512\text{M} \times 1$ (a 512 megabit RAM). Important parameters for each memory type are the read and write cycle times, which must be less than the width of read and write time windows allowed by the devices that will reference this memory.

Larger RAM modules are constructed by the cascade and parallel connection of smaller RAMs. This is illustrated in Figure 9.73, which shows a $32\text{K} \times 8$ RAM made from $16\text{K} \times 4$ RAMs. If $\overline{E}$ is asserted, which takes the entire module out of tristate, then address bit a_{14} enables either RAMs 1 and 2 or RAMs 3 and 4 to access the data bus. The remaining address bits select a particular 4 bit register within each $16\text{K} \times 4$ RAM. Here, RAMs 1 and 3 hold the upper half of each data byte, while RAMs 2 and 4 hold the lower half of each data byte.

Whenever power is removed from the circuits of SRAM or DRAM, the data content is lost, and such memory devices are said to be volatile. To provide software for execution immediately after power is applied to a microprocessor, ROM is used. Figure 9.74 shows eight words by 2 bits/word ROM that has been, for example, programmed with the data given in the table. By opening, which is indicated with an *x*, the connections called links the ROM is programmed. These links remain open through power-down and power-up cycles, and thus, a ROM is said to be nonvolatile. The tristate buffers are controlled by the OE signal so that the ROM output can be electrically disconnected from a system data bus, which may then be used for transfer of data among other devices. An important parameter of a ROM is its read cycle time.

By providing a manufacturer a table of contents, a ROM can be programmed at the time of fabrication. Blank (unprogrammed) ROMs are available that can be one time programmed (OTP) in the field. These are called PROMs for PROM. There are also PROMs that can be erased by exposing the IC to a certain level of ultraviolet light for several minutes. Erasing is made possible by using an IC package with a clear

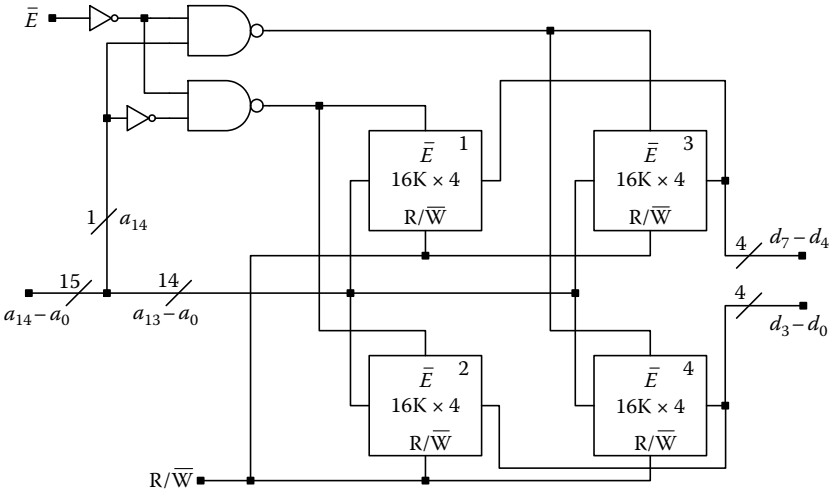

FIGURE 9.73 Cascade and parallel construction of a RAM module.

Address			Data	
a_2	a_1	a_0	O_1	O_0
0	0	0	0	1
0	0	1	1	1
0	1	0	0	0
0	1	1	0	1
1	0	0	1	0
1	0	1	1	1
1	1	0	1	1
1	1	1	0	0

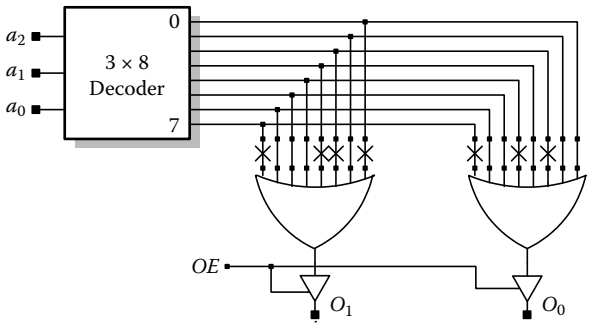

FIGURE 9.74 An eight words by 2 bits/word programmable ROM.

window just above the IC. These are called EPROMs for erasable PROM. After an EPROM has been erased, it can be programmed again.

Another EPROM type is the EEPROM that can be electrically erased by essentially overwriting previously stored data. However, the write cycle time is significantly longer than the write cycle time of conventional RAM. Commonly available PROMs and EPROMs range in size from 2K × 8 to 1024K × 8 (a 1 megabyte ROM). Commonly available EEPROMs are not as large as other ROMs, and they cost more than other ROM types. Like RAM modules, larger ROM modules can be made by combining smaller ROMs in a manner illustrated in Figure 9.73.

A recently developed memory type is the flash EEPROM, or flash memory. Its fabrication methodology is relatively inexpensive, and yields high-density memory modules having large data storage capacities. To rewrite to it, it must first be erased in bulk. These memories are used in, for example, digital cameras and portable flash mass storage devices.

Figure 9.75 shows an 8K × 8 EPROM and the package pin assignment. To place a byte into a particular ROM register, or program the ROM, the register address and intended content must first be supplied at

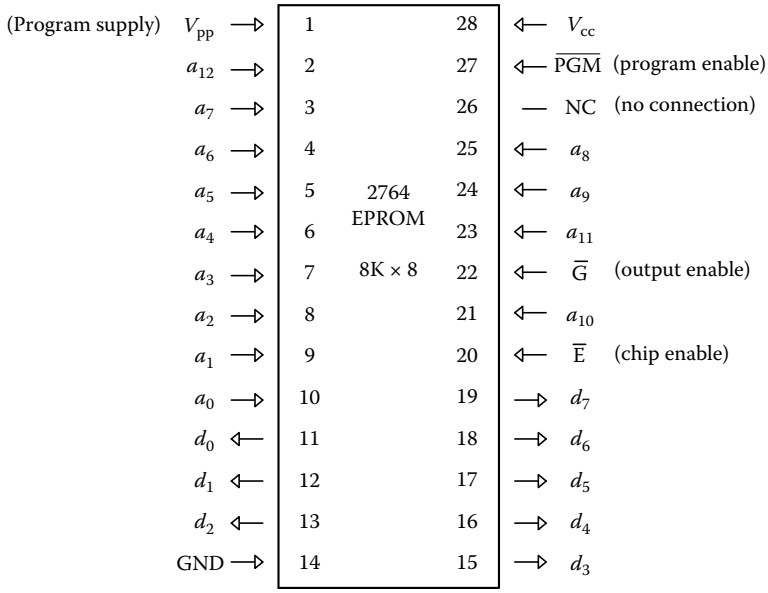

FIGURE 9.75 Pin assignment of a typical (the 2764) EPROM.

the address and data pins, respectively. Then, in addition to V_{CC}, the V_{PP} supply must be provided, the chip enable is asserted, and the $\overline{PGM}$ input is activated for a particular time duration. An instrument called a PROM programmer is used to do this. Some PROM programmers work by connection to a computer, and, in conjunction with software running on the computer, it can program a great variety of PROMs, which are selected from a menu of those PROMs supported by the software, with code in a file that it receives from the computer.

A programmed ROM can serve several purposes. Most computers have a ROM that contains program code that is always executed at power-up. Typically, this software, or firmware, is a utility (called a boot) that transfers software from a mass storage device to RAM. Then, after this transfer is complete, or perhaps after some additional ROM resident initializing code has executed, the software in RAM starts to execute. In a dedicated application, such as, for example, the microprocessor-based systems that control a car engine, it is more likely that ROM will contain all of the application software ready for use whenever the system is powered-up.

ROM is also used for other purposes. For example, by connecting three variables to the address inputs of the ROM given in Figure 9.74, this ROM can, through programming, be used to realize any two Boolean functions of three variables. ROMs are used to hold tables of data. For example, multiplication can be performed through table look-up. If the 4 bit binary codes of two digits that we want to multiply are used to form an 8 bit address of, for example, a 256×8 ROM, then the upper and lower halves of the retrieved data could each be the 4 bit binary codes of the product digits. The idea is that the address is formed with the input(s) of an operation (or argument of a function), and the precomputed and stored data are the output of the operation (or value of the function). EEPROMs are often used to hold tables of data that are generated during program execution, which must be available after a power-down and power-up cycle. A battery-backed RAM can also be used for such purposes.

Another way to use a ROM is for signal generation. By using a counter to supply an address sequence to a ROM, each bit of the data as it is clocked out of the ROM could be used as a control signal of some process. The frequency of the clock that drives the counter determines real time, and the variation between 0 and 1 of any particular data bit determines the resulting control signal shape. On the other hand, if the data word sequence coming from a ROM is inputted to a D/A converter, then a ROM can be used to generate an arbitrarily shaped analog signal that is repeated each time the counter repeats its count sequence.

The kind of memory that is used, its size, and the addresses to which any particular memory will be responsive must meet the requirements of an application. This information is often given in the form of a system memory map. The size of this map is the range of addresses that a microprocessor can specify.

With $m = 16$, an address in binary is denoted by $a_{15}a_{14}\ldots a_1a_0$. The most significant address bit a_{15} splits the entire 64K word memory space into two 32K word blocks, and 0xxxxxxxxxxxxxxx, where x means do not care, is any address in the lower 32K word block, while 1xxxxxxxxxxxxxxx is any address in the upper 32K word block. Similarly, address bits $a_{15}a_{14}$ together split the entire memory space into four 16K word blocks. If $a_0 = 0$, then the address is an even number, while if $a_0 = 1$, then it is an odd number.

Sometimes, it is more convenient to use hexadecimal notation. The symbol \$ will be placed in front of all numbers written with hexadecimal notation. Thus, \$XXXX is any 16 bit number in hexadecimal notation, while \$XX is any 8 bit number. As the most significant hexadecimal address digit changes by \$1, the address changes by 4K.

Suppose a design must include 8K bytes of EPROM starting at address \$0000, 1K bytes of EEPROM starting at address \$4000, and 32K bytes of RAM starting at address \$8000. The ROM, EEPROM, and RAM must be responsive to addresses in the ranges \$0000–\$1FFF, \$4000–\$43FF, and \$8000–\$FFFF, respectively.

Since the three most significant address bits split the memory space into eight 8K word blocks, the ROM should be enabled when these address bits are $a_{15}a_{14}a_{13} = 000$, and then the remaining address bits $a_{12}a_{11}\ldots a_1a_0$ covering an 8K word space are the address input to the ROM. Similarly, the EEPROM

should be enabled when $a_{15} \ldots a_{10} = 010000$, and the remaining address bits $a_9 \ldots a_1 a_0$ covering a 1K word space are the address input to the EEPROM. The RAM should be enabled when $a_{15} = 1$.

Thus, the size and desired position of a memory device determine how to place it in the memory space. The other important aspect of interfacing memory to the system bus and eventually to a microprocessor is that a memory module must be responsive to control signals issued by the microprocessor to present and accept data in certain particular time windows. This will be considered further when we look at the timing of microprocessor control signals. An alternative mode of operation would be for the microprocessor to automatically wait for a response signal from memory whenever it references memory before completing the memory reference cycle.

A memory map for this design is shown in Figure 9.76. Here we see the size, kind, and position in the memory space of the microprocessor of actual memory devices. When possible, it is also useful to describe the location and purpose of particular program code modules.

Assuming that the EPROM contains program code, some example instructions have been placed at the beginning of this memory. These are binary numbers that are machine instruction codes for the Z80 microprocessor. The Z80 microprocessor is a type of processor that after being reset, fetches instruction codes starting at address $0000. The first instruction, i.e., $ED $56, is the Z80 machine code that selects its method 1 for responding to interrupts. Another commonly used notation for hexadecimal is to attach the suffix H. The next instruction, i.e., 31H, is the machine code that loads the stack pointer (SP) register with an address given by the next 2 bytes, i.e., $F000. These instructions could be the part of a program that initializes the processor. To understand how an instruction is processed, it is useful to study the architecture of a microprocessor.

For programming convenience, programs are usually written using mnemonics of instruction codes that are indicative of instruction activity. The set of mnemonics and associated notational convention for all of the instruction codes that a particular microprocessor can execute form the assembly language of the microprocessor. Different microprocessors, with different instruction sets have different assembly languages. Furthermore, different manufacturers adopt different mnemonics

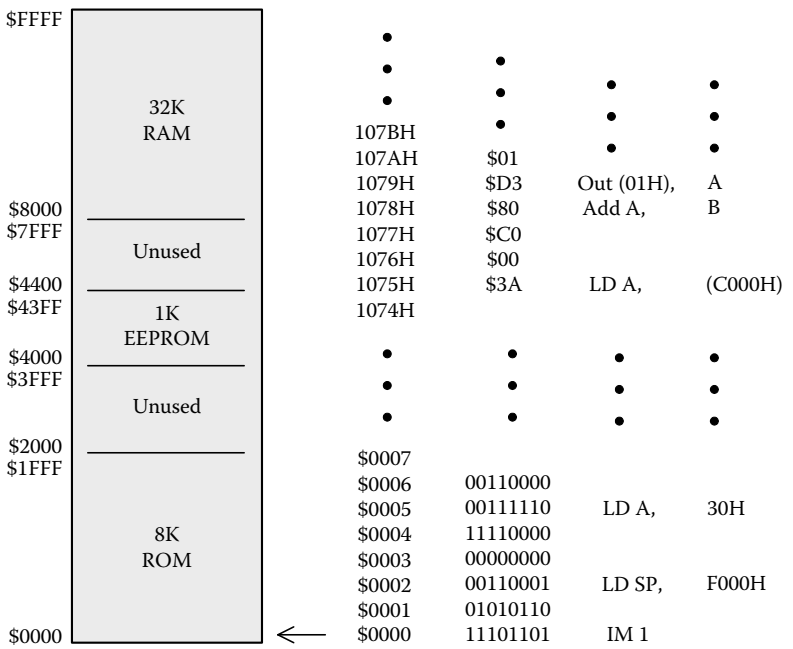

FIGURE 9.76 Memory map, sample ROM content, and assembly language source.

for their microprocessor instruction sets, causing another variation among assembly languages. However, in principle, there remain many common attributes from one assembly language to another. A program written in assembly language must be converted into machine code for storage and eventual execution. A program that performs this conversion is called an assembler. From the viewpoint of the assembler, an assembly language program is an input character string, and the machine code output is another character string.

9.4.4 Microprocessor Architecture

Employing a microprocessor in a dedicated application does not require detailed knowledge about its internal behavior. However, it is useful to have some insight about how instructions, i.e., their codes, are processed (executed) by the hardware. Understanding the relationship between software and hardware can affect the selection of a particular microprocessor, and the design process. Moreover, the hardware designer should also understand the programming model of a microprocessor.

From a programmer's viewpoint, a microprocessor is defined by its programming model and its instruction set, which together comprise the architecture of the microprocessor. The programming model consists of the set of internal registers that are involved in the execution of operations as specified by the instruction set. These registers do different specialized tasks. The purpose, capability, and number of these registers can vary greatly from one microprocessor to another.

Basically, within the programming model, microprocessors have four kinds of registers. There are address registers that are used to form and hold addresses to be used for referencing memory and other devices to obtain program instruction codes and their operands and to specify source and destination memory locations for data read and write operations. There are data registers that can be the source of data for an operation or the destination for the result of an operation. There are operational registers that have associated hardware to perform, for example, logical and arithmetic operations. And, there are status/control registers that configure the operation of the microprocessor and support different kinds of conditional instructions.

An operational register possessed by most microprocessors is the accumulator. It is commonly denoted by register A. Figure 9.77 illustrates how an A register functions within a microprocessor. Associated with reg. A are the ALU and the condition code register (CCR) or status register (SR). Inputs to the ALU can come from reg. A, reg. B, and the CCR, and its activity is determined by the function select word $f_{k-1} \ldots f_1 f_0$. Reg. A receives its input from the ALU, and reg. B receives its input from the n-bit internal data bus. The activity of this circuit is determined by the control signals that are applied at all of the points labeled with triangles. For example, by asserting the E, for enable, input of reg. A, the n-bit word coming from the ALU is latched (loaded) into reg. A. The content of reg. A can be placed on the internal data bus by asserting the control signal of the n tristate buffers connected to its output. The content of the internal n-bit data bus can be latched into reg. B by asserting its E control input.

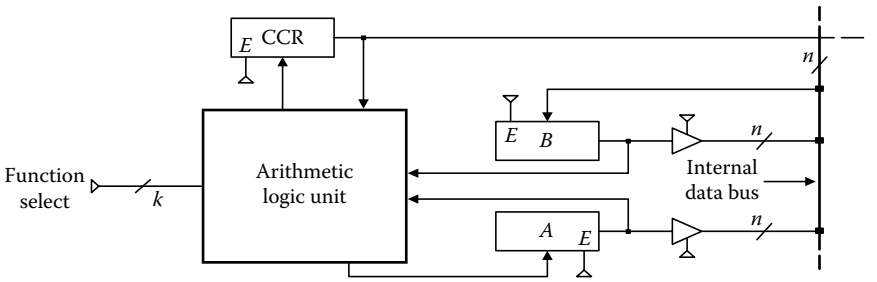

FIGURE 9.77 Register-to-register transfer activity of an accumulator.

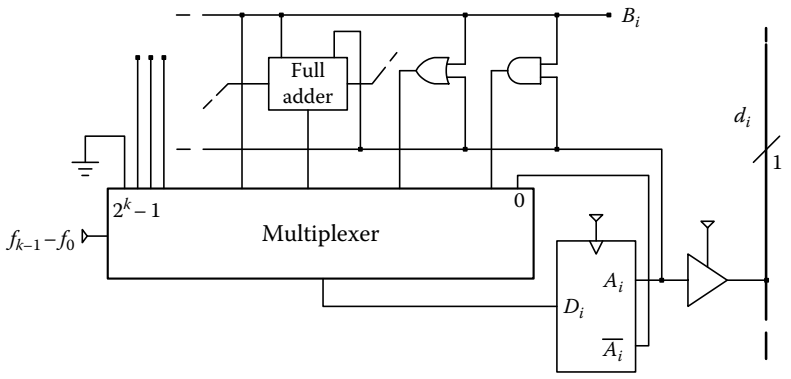

FIGURE 9.78 Bit level activity of an ALU.

Figure 9.78 illustrates how the ALU performs its task at the gate (bit) level. Notice how the function select lines determine, as they do for the MUXs of all the other bits, which MUX input is latched into the *i*th flip-flop of the accumulator when its *E* control input is asserted. For example, if $f_{k-1} \ldots f_0 = 0 \ldots 0$, then the accumulator will be complemented, as if the microprocessor has just read in the machine code for the complement accumulator instruction, which has the Z80 assembler mnemonic CPL. Thus, the machine codes of instructions such as ADD A, B; RLA; INC A; LD A, 80 H; etc., eventually determine the binary assignments of these function select lines to accomplish the instruction tasks. There can be as many as 2^k different operations involving the accumulator that can be achieved by this ALU structure.

All of the control bits required in Figures 9.77 and 9.78 come from memory called control ROM or microstore. Figure 9.79 illustrates the data paths of a microprogrammable microprocessor. Each word, consisting of perhaps 16–128 bits, in control ROM is called a microinstruction. The busing of microinstructions throughout the microprocessor is not shown in Figure 9.79. Instead, these interconnections are indicated by labeling with the small triangles.

Figure 9.79 also illustrates a level of design called the register transfer level. There is still another level of greater detail before we get to a level of IC design detail that shows the interconnection of transistors, resistors, diodes, and conductors. This is the logic gate level. However, at that level, the detail of design would probably be too much and detract from an understanding of microprocessor operation. Here the intent is to exemplify how hardware processes an instruction code.

Each microinstruction is partitioned into a set of fields, and one of these fields holds the accumulator function select line assignment. Other fields hold data that signify: (1) which registers are the source of data for the internal and external buses; (2) which registers are the destination of data on the internal and external buses; (3) register activity control such as clear, increment, decrement, load, and tristate; (4) a *j*-bit address of the next microinstruction; and (5) the external control word that informs external devices of the present microprocessor activity. Each microinstruction coming out of control ROM can cause many activities to take place at the same time within the microprocessor. The other registers in the diagram of Figure 9.79 perform the following tasks.

MAR—Memory Address Register. It holds the address that the microprocessor can place on the external address bus, and it is loaded from the internal address bus by asserting its enable input.

PC—Program Counter. This register holds the address of the next instruction or instruction operand. It can be cleared, loaded, and incremented by asserting appropriate enable inputs. To fetch program code (either an instruction code or instruction operand), its content is transferred to the MAR. Usually, after each time its content has been used to fetch a byte of program code, its content is incremented.

SP—Stack Pointer. It holds an address that points to RAM that can be used for temporary storage. It can be loaded, incremented, and decremented by asserting appropriate enable inputs. Certain

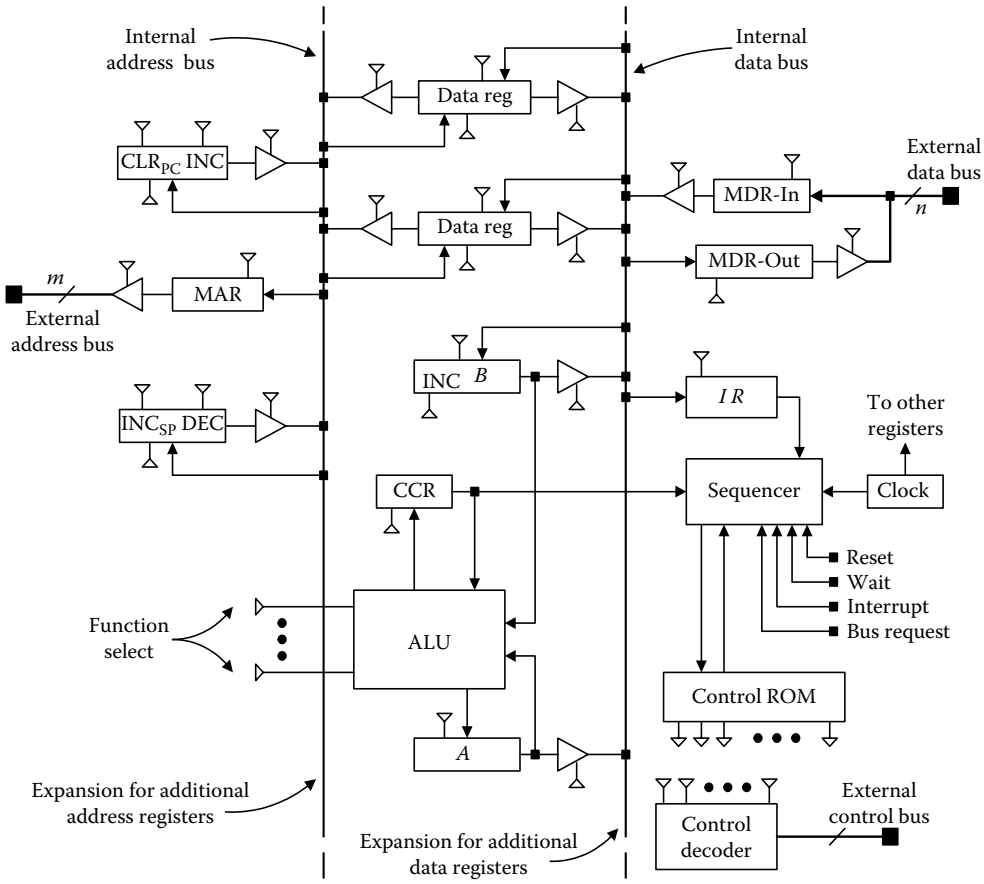

FIGURE 9.79 Data paths of a microprogrammable microprocessor.

instructions can cause its content to be transferred to the MAR for a memory read or write operation. The RAM that is referenced with the SP is called the stack. Typically, the SP is implicitly decremented before (after) writing to the stack, and it is implicitly incremented after (before) reading from the stack. Thereby, the stack is a last in and first out memory area that is used to support, among other things, subroutine calls.

MDR-IN—Memory Data Register IN. It receives its input from the external data bus, and it can drive the internal data bus.

MDR-OUT—Memory Data Register OUT. It receives its input from the internal data bus, and it drives the external data bus.

IR—Instruction Register. When the microprocessor is executing an instruction fetch from external memory, this register receives the content of the MDR-IN register, which is then assumed to be an instruction code.

CCR.—Each bit in this SR is indicative of the result of some previous microprocessor operation. The meanings of the flags (bits) in the CCR vary from one microprocessor to another. Typically, this register contains: (1) a carry flag that is set or reset depending on whether or not the previous add or subtract instruction produced a carry or required a borrow out of the most significant bit of the arithmetic operation, (2) a zero flag that is set if the previous instruction produced a zero result and reset if the instruction result is not zero, (3) an interrupt enable flag that can be set or reset by an instruction to

allow for software control over whether or not the microprocessor can respond to maskable interrupts, and (4) other flags. Usually, a microprocessor's instruction set includes program flow control instructions that are conditioned on these status flags such that if the flag is set (reset), then the instruction is executed, and if the flag is reset (set), then the instruction is not executed (skipped).

Sequencer. The sequencer consists mainly of a ROM and some sequential logic. It uses the instruction code and SR flags to form an address to its own ROM from which is obtained a *j*-bit microinstruction address that is applied to the control ROM. Furthermore, in response to asynchronous external control signals, such as reset, interrupt, bus request, wait, and others, it generates addresses of microinstructions that cause activity appropriate for these inputs.

Control Decoder. Depending on the input coming from control ROM, it generates external control signals that are intended to be used to inform external devices about the present activities of the microprocessor and to synchronize activities on the external address and data buses.

Data Register. This register is used for temporary storage of data. Usually, there are several registers like it. Some can also drive the lower byte of the internal address bus, while others can also drive the upper byte of the internal address bus. Still others can receive data from the upper or lower byte of the internal address bus. Some may have low-level arithmetic/logic capabilities.

The execution of each microprocessor instruction involves the execution of a set of microinstructions, called a microprogram. Thus, the functionality of a microprocessor's instruction set is determined by the microprograms stored in control ROM. After system reset or the completion of each instruction, unless an external asynchronous input is active, the microprogram that performs an instruction fetch is executed. It uses the content of the PC to point to the instruction, and it increments the PC so that the PC points to an instruction operand or the next instruction. Then, depending on the instruction code and SR content presented to the sequencer, a particular microprogram is executed to complete execution of an instruction. If an instruction code requires that operands be fetched, then the PC is further incremented so that, after an instruction has executed, the PC is pointing to the next instruction.

Microprograms for program flow control instructions such as JUMP or BRANCH elsewhere cause the PC to be loaded with the address operand of the instruction. Moreover, microprograms for instructions such as CALL or BRANCH subroutine first cause the SP to be used for storing in the stack the content of the PC before loading the PC with the address operand. Then, the microprogram for an instruction such as RETURN, which is used to terminate a subroutine, causes the SP to be used for retrieving from the stack the address of the instruction following the CALL subroutine instruction, which is then loaded into the PC.

This architecture can be expanded to include additional address registers and other special purpose address registers such as index registers, another PC and SP, additional accumulators and data registers, and so on. And, the widths of the address and data bus can be increased, contingent upon fabrication issues. Moreover, algorithmic instruction types can be supported since executing the desired activity of an instruction is a matter of writing a microprogram to accomplish all of the required register-to-register transfer activities.

9.4.5 Design with a General Purpose Microprocessor

The Z80 is a general purpose microprocessor, and it is available in a 40-pin dual in-line package (DIP). It is an 8 bit machine, i.e., its data bus is 8 bits wide. It has also evolved into a great variety of similar microprocessors. From a software development viewpoint, this machine has numerous features, as an examination of its extensive instruction set and programming model, which is given in Figure 9.80, will show. It has an accumulator (A), status or flag (F) register, six data registers (B, C, D, E, H, and L) that can be paired for use as address registers (BC, DE, and HL), an SP, a PC, two index registers (IX and IY), a register (I) that is used by its indirect vectored interrupt processing method, and a 7-bit counter register (R) that can be utilized for DRAM refresh. Furthermore, it can quickly change programming context by swapping with the alternate (primed) register set. Among its over 600 instructions, there are data transfer, arithmetic, logical and rotate, branch (or jump), stacking, I/O, program control, exchange,

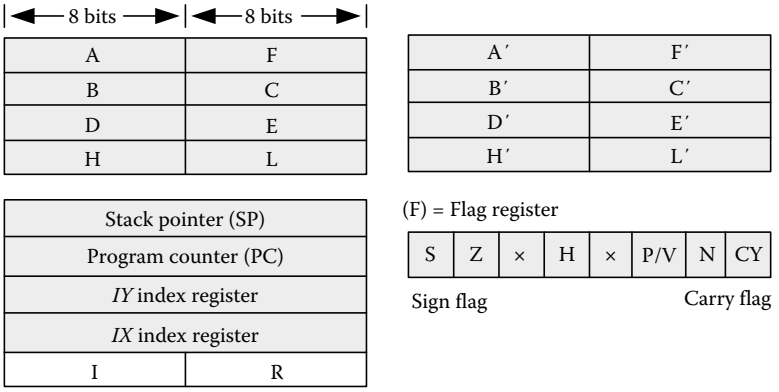

FIGURE 9.80 Z80 programming model.

block transfer, search, and bit manipulation instructions. Due to space limitations, the information given here is necessarily limited. Complete information can be found in textbooks or the data book from the manufacturer.

The pin assignment of the Z80 is shown in Figure 9.81. Power is supplied at pins 11 and 29, and a conventional crystal-controlled oscillator is used to provide the system clock ϕ at pin 6. If the load of each system address bus bit is only one or two TTL loads, then the outputs $a_{15}a_{14}\ldots a_1a_0$ can drive the system address bus. However, to accommodate a greater load, two unidirectional tristate octal buffers, as shown in Figure 9.81, can be used. These buffers also have hysteresis, which helps to produce sharper bus signals. Similarly, it is likely that the Z80 data signals $d_7d_6\ldots d_1d_0$ must be buffered to accommodate

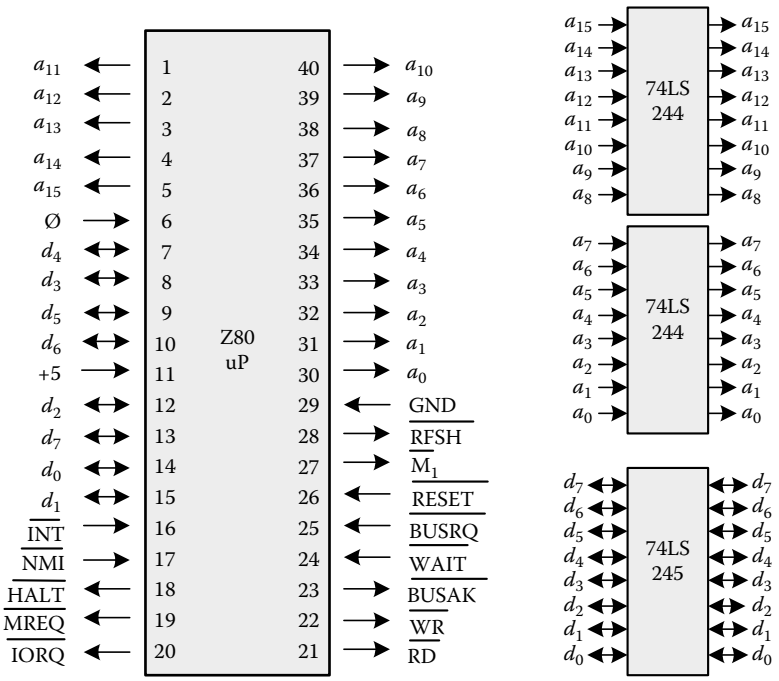

FIGURE 9.81 Pin assignment of the Z80 microprocessor.

system data bus loading. A bidirectional buffer, as shown in Figure 9.81, can be used for this. Z80 control signals must be used to control buffer direction. Also, define the system data bus by terminating it with pull-up resistors. The Z80 control signals perform the following tasks.

$\overline{\text{RESET}}$—This active low input resets the interrupt enable flag, clears registers I and R, causes all control signals to become inactive, sets the interrupt processing method to method 0, and clears the PC. When this input is released, the Z80 starts to fetch the first instruction code (op-code) from the memory register with address held by the PC.

$\overline{\text{MREQ}}$—This output becomes active whenever the Z80 is performing an operation, such as op-code fetch or instruction operand fetch that references an external device with a 16 bit address. It indicates that the address bus holds a valid address. The devices that respond are said to be positioned in the memory space.

$\overline{\text{IORQ}}$—This output becomes active whenever the Z80 is executing either an IN, for input, or an OUT, for output, instruction, both of which reference external devices with an 8 bit address that is placed on $a_7 \ldots a_0$. It also indicates that the address bus holds a valid 8 bit address. The devices that respond are said to be positioned in the I/O space, which is separate from the memory space.

$\overline{\text{RD}}$—This indicates that an external device must place valid data on the data bus, which the Z80 will soon accept.

$\overline{\text{WR}}$—This indicates that the Z80 is driving the data bus with valid data.

$\overline{\text{M}}_1$—This output is active while the Z80 is fetching an op-code. The only other time it becomes active is in response to a maskable interrupt.

$\overline{\text{HALT}}$—This output becomes active when the Z80 has stopped fetching additional instructions due to having executed a HALT instruction. The microprocessor can only continue instruction execution upon activation of an interrupt input.

$\overline{\text{WAIT}}$—This input, when active, causes the Z80 to hold constant its address and control signal outputs until this input is released (no longer active). When referenced, a slow memory or I/O device can cause the Z80 to wait by asserting the $\overline{\text{WAIT}}$ input until sufficient time has elapsed to allow the device to respond to the reference.

$\overline{\text{RFSH}}$—When active, this indicates that $a_6 \ldots a_0$ holds the content of counter register R, which, along with an active $\overline{\text{MREQ}}$ can be used to refresh dynamic memory.

$\overline{\text{NMI}}$—Whenever this nonmaskable interrupt input goes through an active low edge, an internal flip-flop is set, and other interrupts are disabled. The interrupt is said to be latched. At the completion of every instruction, this flip-flop is checked, and if it is set, then the Z80 first stacks the PC and then it loads the PC with \$0066, where the first op-code of an interrupt service routine must be located. This way of loading the PC in response to an interrupt is called a direct interrupt, and it is intended for an unconditional and fast response to, for example, battery low detected, temperature too high detected, or some other urgent situation, since it requires no further action from the interrupting device.

$\overline{\text{INT}}$—At the completion of every instruction the Z80 checks this maskable interrupt input. If it is active and interrupts have been enabled with the EI instruction, then interrupt processing commences according to the interrupt method stipulated by the IM i, $i = 0$, 1, or 2, instruction. If $i = 1$, for the direct method, the PC is first stacked, and then it is loaded with 0038H, the address used to obtain the first op-code of an interrupt service routine. If $i = 0$, for the vectored method, the Z80 acknowledges the interrupt by asserting the $\overline{\text{IORQ}}$ line while the $\overline{\text{M}}_1$ signal is active. This combined activity is then interpreted externally to be an interrupt acknowledge signal, denoted by $\overline{\text{INTA}}$. In response to the $\overline{\text{INTA}}$ signal, the interrupting device then has the opportunity to place the op-code for the one byte Z80 instruction RST, N on the data bus, where $N = 0, 1, \ldots, 7$. Then, the Z80 stacks the PC and loads it with an address given by 8 N. Thus, depending on N, a 3-bit code embedded within the RST instruction, the first op-code of

the interrupt service routine can be located in one of eight memory locations. If $i = 2$, for the indirect vectored method, the PC is first stacked, and then the Z80 acknowledges the interrupt by asserting the $\overline{\text{INTA}}$ signal. In response to the $\overline{\text{INTA}}$ signal, the interrupting device must then place a byte given by xxxxxxx0 on the data bus. The Z80 then uses this byte as the low address byte and the content of the I register as the high address byte to fetch two consecutive bytes from memory that are then loaded into the PC. Thus, the I register points to a 256 byte block of memory, where there can be 128 interrupt vectors one of which is selected by the byte provided by the interrupting device.

$\overline{\text{BUSRQ}}$ and $\overline{\text{BUSAK}}$—The first signal is an input that indicates to the Z80 that an external device wants to take control of the system bus. The Z80 completes execution of the present machine cycle, takes its address, data, and tristate control signals into tristate, and acknowledges the request with an active $\overline{\text{BUSAK}}$ signal.

Most of these signals are representative of the kinds of control signals that microprocessors have. Their usefulness becomes more apparent as we look at the timing of microprocessor activity and the impact this has on the design of hardware so that the microprocessor can accomplish read and write data transfers. Figure 9.82 shows the Z80 timing diagram for an op-code fetch, and Figure 9.83 shows timing diagrams for the other memory and I/O references. For the purpose of studying the timing of events, we do not have to know actual binary assignments on the address and data bus lines. Therefore, the

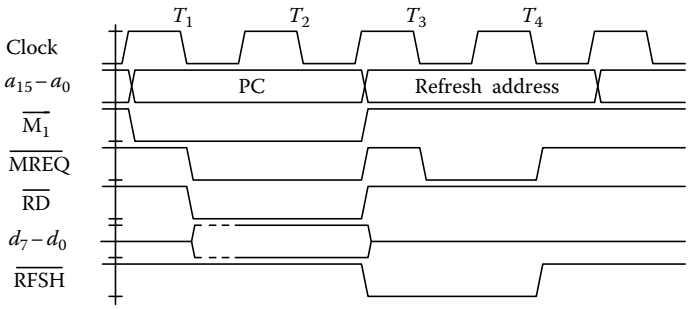

FIGURE 9.82 Z80 timing diagram for an op-code fetch.

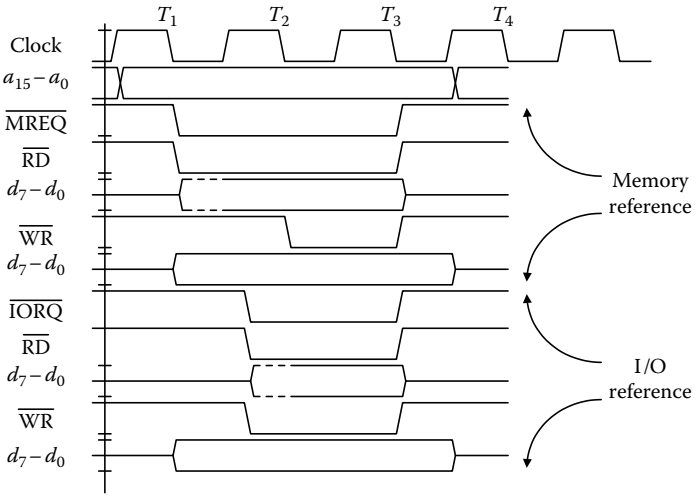

FIGURE 9.83 Z80 timing diagrams.

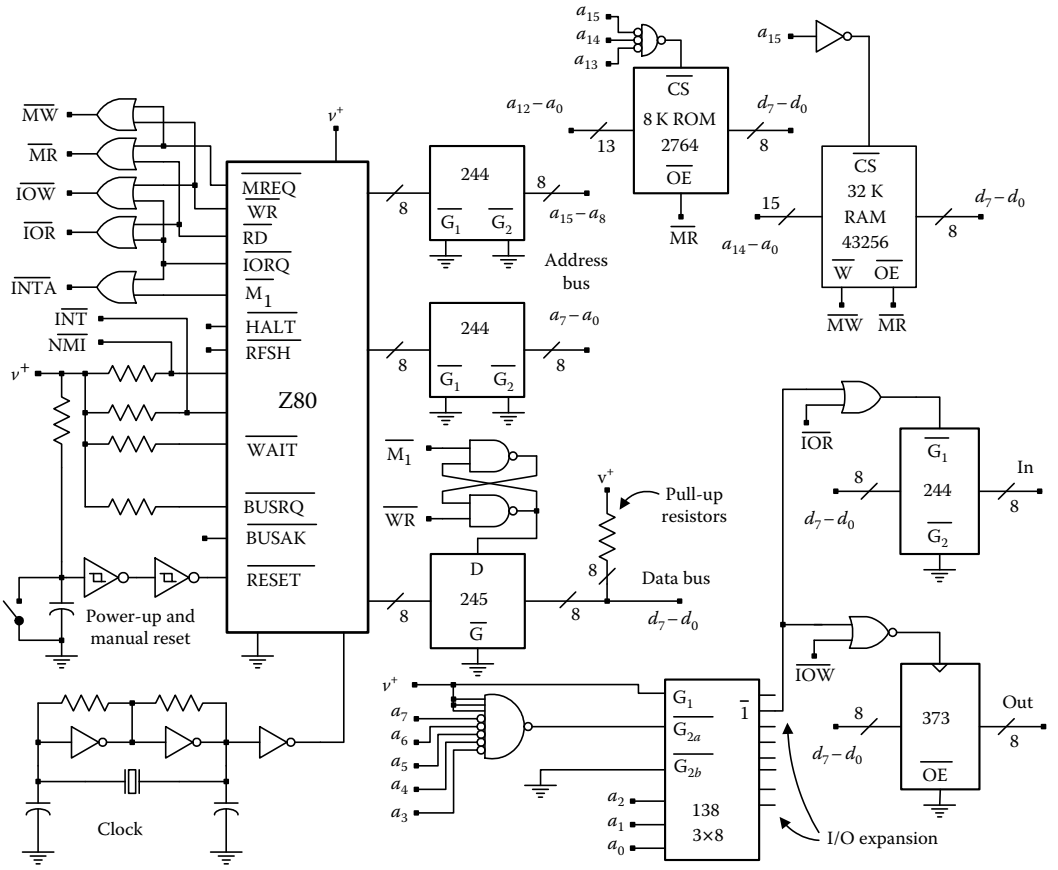

FIGURE 9.84 Z80-based microcomputer.

convention in these diagrams is intended to indicate when these signals either become relevant for the operation at hand or switch to the present binary assignment, whatever it may be, from some previous binary assignment.

As we look at the timing diagrams, it will also be useful to see how these signals are used. Figure 9.84 shows a schematic of a microcomputer designed according to the memory map of Figure 9.76. Whenever possible, labeling is used to indicate connections.

Depending on the instruction, the Z80 uses from 4 to 23 clock cycles to execute an instruction. A group of clock cycles within the execution time of an instruction that accomplishes a major activity is called a machine cycle. Each clock cycle within a machine cycle is labeled with T_i, $i = 1, 2, \ldots$, and all activities occur at either leading or trailing clock edges. To better understand such groupings, suppose that after executing many instructions that were retrieved from ROM, the Z80 is about to execute the next few instructions located in memory shown in Figure 9.76.

The PC is set to PC = 1075H, pointing to the op-code at memory location 1075H. This is the op-code for load accumulator with data using the two bytes that follow the op-code to form an address to point to the data, i.e., LD A (C000H). This is a 3 byte instruction, and, according to the Z80 manual, it requires 13 clock cycles, which are grouped into four machine cycles, to execute.

Referring to Figure 9.82, at the leading edge of the first clock cycle T_1 of the first machine cycle of this instruction the Z80 asserts the $\overline{M_1}$ signal, and it drives the external address bus with the address 1075H. At the trailing edge of clock cycle T_1, it asserts the $\overline{MREQ}$ signal and the $\overline{RD}$ signal. At the time that $\overline{RD}$

becomes active, the Z80's data bus input register is enabled to follow the content of the external data bus. At the leading edge of clock cycle T_3, the Z80's data bus input register is disabled from following the external data bus, and the content of this register is accepted as an op-code.

During the time interval from the trailing edge of T_1 until just before the leading edge of T_3, which is slightly less than 1.5 clock cycles, external hardware has the opportunity to place the addressed data, which will be processed as an instruction op-code, on the data bus. A designer must ensure that external hardware is fast enough to do this in a timely manner. If it is necessary to use an external device with an access time that is greater than this allotted time, then a counter, called a wait state generator, can be used. Once the slow external device detects (by address and control signal decode) that it is supposed to put valid data on the data bus, then it enables the wait state generator, which should be driven by the system clock, to activate the $\overline{\text{WAIT}}$ input of the microprocessor for a number of clock cycles that will give the device an opportunity to place data on the data bus. Each such clock cycle is called a wait state (labeled with T_w), and the number of wait states needed will depend on the access time of the device being referenced. If several external devices need to generate different numbers of wait states, then the outputs of the wait state generators of all such devices can be OR'd to present just one wait input to the microprocessor. Thereby, the machine can run as fast as each different external device will allow.

During the next 2 clock cycles, the received op-code is interpreted so that the Z80 becomes set to perform two more memory references, called machine cycles M_2 and M_3, to fetch each byte of the address operand. Machine cycle M_1 consists of 4 clock cycles, and while the Z80 is processing a retrieved op-code during clock cycles T_3 and T_4, the address bus is available for DRAM refresh. During machine cycle M_4, the address C000H, which was obtained during M_2 and M_3, is placed on the external address bus, and execution of this instruction is completed by transferring the content of memory location C000H to the accumulator. Machine cycles M_2 and M_3 each require 3 clock cycles, and machine cycle M_4 also requires 3 clock cycles. If whenever this RAM module is referenced, it issues wait states, then the actual number of clock cycles required to execute this instruction will be more than 13 clock cycles.

Notice that the op-code determines the kind and number of additional machine cycles that are necessary to complete execution of an instruction. It also determines how much the PC must be incremented. Thus, whenever execution of an instruction has been completed, the PC is pointing to an op-code of the next instruction. Furthermore, virtually all activity involves some kind of synchronized register-to-register transfer.

The op-code at location 1078H is the code for the 1 byte instruction, ADD A, B. Since this addition requires no additional memory reference, it requires 4 clock cycles (1 machine cycle) to execute. The next instruction, i.e., OUT (01H), A, is a 2 byte instruction, and it requires 3 machine cycles to execute. Since this is an OUT instruction, the Z80, during machine cycle M_3 does the following: (1) transfers the address 01 H, which it obtained during M_2, to the lower byte of the MAR to drive the lower byte of the system address bus, (2) transfers the content of the accumulator to the data bus out register at the trailing edge of T_1 to drive the external data bus, which, as shown in Figure 9.83, incurs a set-up delay, (3) activates the $\overline{\text{IORQ}}$ control signal at the leading edge of T_2, which incurs a set-up delay, and (4) activates the $\overline{\text{WR}}$ control signal, which also incurs a set-up delay, until the trailing edge of T_3. Thus, the I/O device that is supposed to receive the content of the accumulator has slightly less than 1.5 clock cycles during which it must capture the content of the system data bus. By decoding the address, which for an I/O device is called an I/O port address, and the control signals, an I/O interface can enable an external register to start to follow the data bus shortly after $\overline{\text{IORQ}}$ and $\overline{\text{WR}}$ have become active. Then, by the time that the $\overline{\text{WR}}$ signal becomes inactive, the external register should hold the content of the data bus.

9.4.6 Interfacing

The circuitry, or more broadly, the method that makes compatible the operations of devices so that these devices can exchange signals (data or codes) is loosely called an interface. The devices on opposite sides of an interface can be different in many ways. Interfacing two devices can encompass a variety of

requirements, such as, for example, (1) impedance matching, (2) voltage or current level conversion, (3) translation of control signal meanings, (4) protocol conversion, (5) signal timing alignment, (6) electrical isolation, (7) exchange of status information, (8) data format conversion, and (9) resolution of other incompatibility issues.

Figure 9.84 gives some examples of the goals of interface design. The unidirectional and bidirectional buffers make compatible the drive (current source) capability of the microprocessor and the drive requirements of the address and data bus. The particular control signals of the Z80 are interfaced to the system control bus with combinatorial logic to provide drive as well as more explicit control signals. The interfaces between the memory devices and the system bus utilize the address bus to position memory in the desired locations in the memory space. We must be certain that only one device can be a source to the data bus at a time. The interfaces also utilize control bus signals to produce the particular kinds of control signals required by the memory devices and to activate memory at times compatible with microprocessor timing.

Figure 9.84 also shows an input and an output port. The interface for this parallel I/O port also utilizes the address bus, and, instead of using control bus signals that go active due to memory reference instructions, it uses control bus signals that go active due to the IN and OUT instructions of the Z80. For output, it decodes the control bus and the lower half of the address bus to enable (clock) the octal latch to capture the content of the data bus at the right time and in response to the intended (its own) address $01. Thus, by executing an output instruction, like the one located at address $1079 in Figure 9.76, the octal latch receives the content of the accumulator. For input, the interface decodes the address and control bus to enable (take out of tristate) the octal buffer, which permits it to drive the data bus with its input at the right time and in response to the intended address. Thus, by executing an input instruction such as IN A, (01H), the accumulator will receive the byte at the buffer input. Depending on the address decode logic, the I/O port can be positioned anywhere in the I/O space of the microprocessor.

By using the $\overline{\text{MREQ}}$ control signal, instead of the $\overline{\text{IORQ}}$ control signal, and the entire address bus, I/O ports can also be positioned in the memory space of the microprocessor. The variety of conventional memory move instructions can then be used for I/O. Some microprocessors, like the M68HC11, do not have I/O space separate from memory space and instructions for I/O in addition to memory move instructions. Instead, no distinction is made between memory and I/O references. This eliminates the need for explicit control signals that interface hardware requires to distinguish memory and I/O references.

One or more parallel I/O ports can serve many different applications. With circuits like those given in Figure 9.85, a bit of an output port can turn on and off a light or sound indicator, or DC or AC power

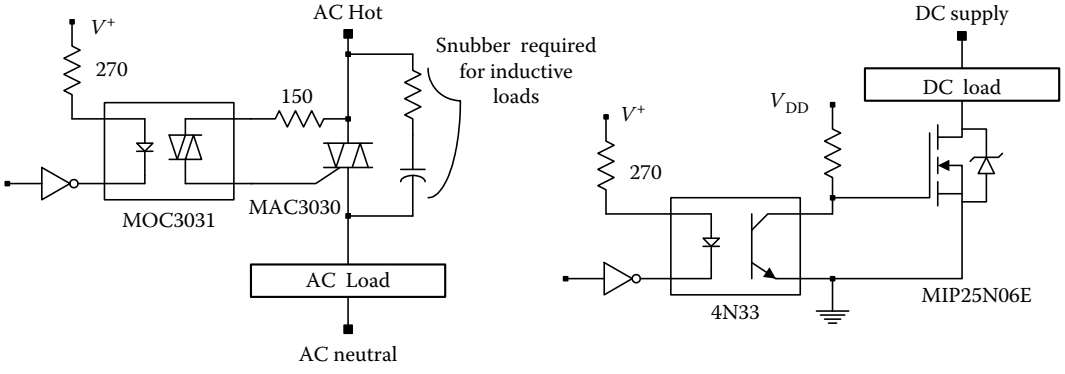

FIGURE 9.85 Circuits for opto-isolated power control.

supply to a load. With a set of bits, software can produce codes that control a device such as a printer. Since the octal latch in Figure 9.84 has a tristate output, O/E could be controlled by address and control signal decode from another microprocessor to place the octal latch output on another data bus. Thereby we accomplish data transfer between two machines. Or, software can produce binary time functions to control some process. An analog signal can be generated by outputting to a D/A converter, as shown in Figure 9.86.

Through a parallel input port a program can receive information. This may be the position of a set of switches, as shown in Figure 9.87, or the output of some kind of an encoder, such as a keypad encoder, rotating shaft position encoder, A/D converter, as shown in Figure 9.88, or even data from another microprocessor.

For data transfer from one system to another, the sender needs to know if the intended recipient is ready to receive data. And, if the data has been sent, then has it been received? To facilitate asynchronous

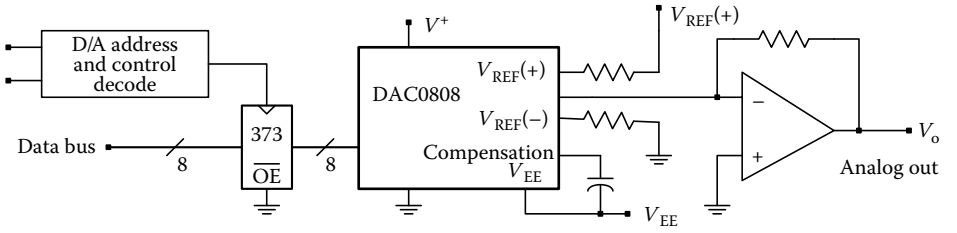

FIGURE 9.86 Output to a D/A converter.

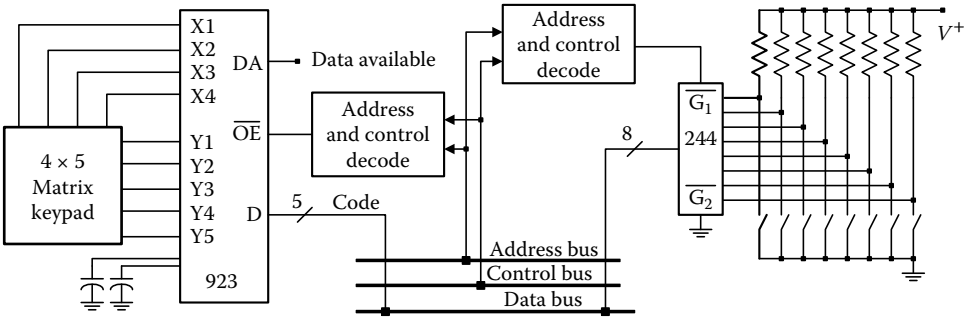

FIGURE 9.87 Circuits to input switch closures.

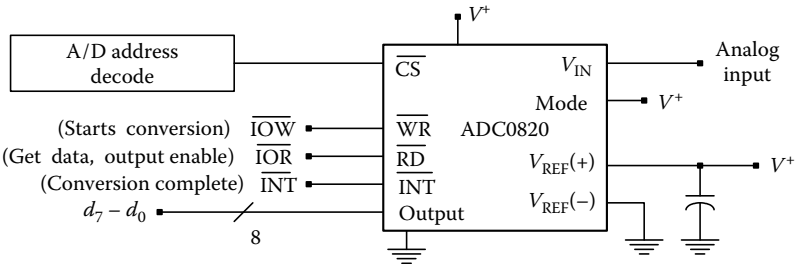

FIGURE 9.88 Write controlled A/D that includes sample and hold.

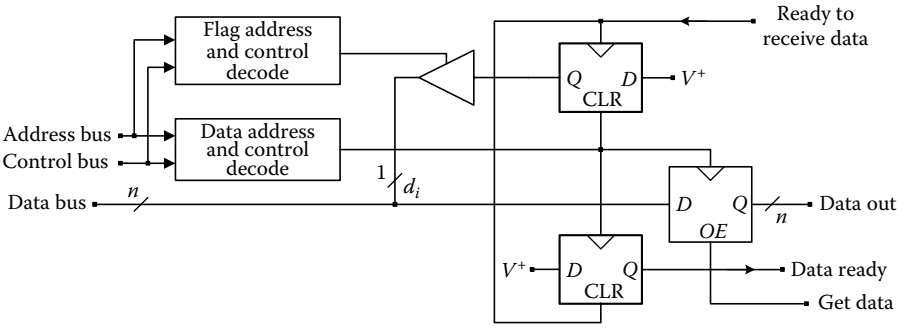

FIGURE 9.89 Output port with handshaking.

transfer of data, consider the output interface shown in Figure 9.89. This interface is the output port given in Figure 9.84 and additional circuitry to support ready to receive data and data ready flags. The sender can poll (obtain and check) the ready to receive data flag by inputting the data at the address assigned to flags. If data bit d_i is reset (logic 0), then continue polling the ready to receive data flag. If d_i is set (logic 1), then write data to the address assigned to be the data port, indivisibly reset the ready to receive data flag, and set the data ready flag. Thereby the sender cannot find that the ready to receive data flag is set until the recipient has found that the data ready flag is set, obtained the data, and set the ready to receive data flag, however little or much time this takes. Notice that setting the ready to receive data flag indivisibly resets the data ready flag. Thereby the recipient cannot find that data is available until it is new data, however little or much time this takes. There must be provision to reset the ready to receive data and data ready flags at system reset. The exchange of status information and the action among the flags is called handshaking. Figure 9.90 shows an input interface that includes handshaking. Here too, there must be provision to clear the data ready and ready to receive data flags at system reset.

To accomplish data transfer, the I/O methods of Figures 9.89 and 9.90 require that a program must continually poll the flags concerned with I/O. This works as long as the microprocessor is not required to do anything else. If the microprocessor must be used to do other tasks, then I/O can be serviced by either periodically polling I/O status flags or by using I/O status flags to interrupt the microprocessor while it is executing some program. Periodic polling of status flags may or may not be satisfactory. This depends on how much and how often I/O occurs.

Interrupt processing of the Z80, as well as the M68HC11, starts by asserting an interrupt input of the microprocessor. If more than one device must interrupt the microprocessor then using a microprocessor

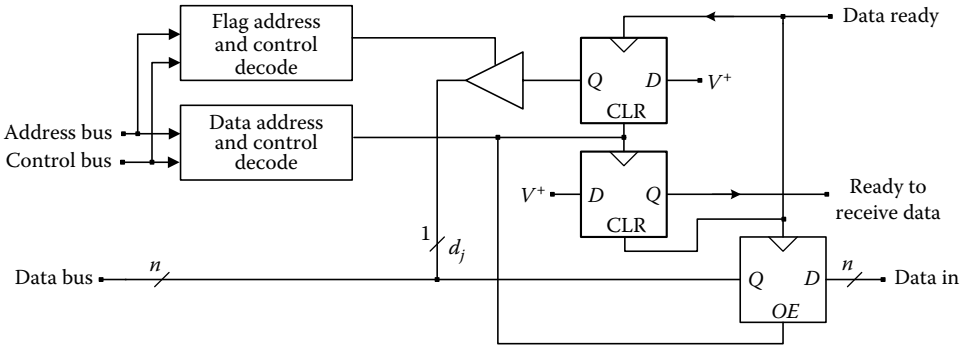

FIGURE 9.90 Input port with handshaking.

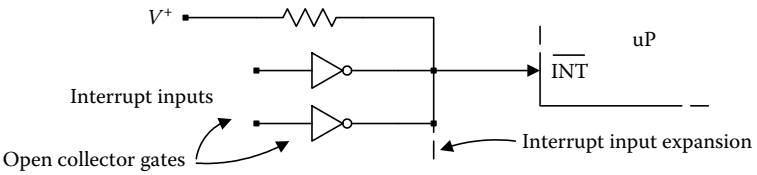

FIGURE 9.91 A wire OR'd circuit.

with many interrupt inputs might be useful. Or, all interrupt sources can be wire OR'd with open collector gates, as shown in Figure 9.91, to produce one interrupt signal. For example, the flip-flop output *Q* for the ready to receive flag in Figure 9.89 and the flip-flop output *Q* for the data ready flag in Figure 9.90 could each be connected to an inverter input in Figure 9.91. Either or both flags can then interrupt the processor. Any number of additional open collector gates could be added to include additional interrupt sources. By this method, the microprocessor discovers the occurrence of an interrupt, but must find out which device caused the interrupt.

If the Z80 is operating in direct interrupt mode, then the interrupt service routine, which starts at address 0038H, can input all of the status flags, check which flags are set, and respond with service priority determined by the software. Thus, any number of interrupts can be accommodated.

If the Z80 is operating in indirect vectored mode, then an interrupt causes it to respond with an active $\overline{\text{INTA}}$. The processor then accepts a byte from the data bus that must be provided by the interrupting device, and this byte, along with the content of the I register, is used as an address to get the interrupt service routine address from memory that is then loaded into the PC. Thus, the I register points to an interrupt vector table, and each interrupting device can point to the address of its own service routine.

If there is more than one interrupt source, then, since only one device is allowed to drive the data bus, a priority must be established, where the interrupting device with highest priority is serviced first. A daisy chain can be used so that hardware determines priority. This is shown in Figure 9.92. The device connected to the top of the chain has the highest priority. The $\overline{\text{INTA}}$ signal propagates down the chain until it is blocked by a set status flag. This condition is then used to place a response to $\overline{\text{INTA}}$ on the data bus.

In applications, such as control, it is often necessary that a program keep track of elapsed time. This can be accomplished with a circuit like the one shown in Figure 9.93. The 16 bit counter is clocked by the system clock or a clock derived from the system clock. The state of the counter is compared to the output of two registers, and a match, which clears the counter, is then used to interrupt the microprocessor. Thus, through I/O ports, software can set the time interval between interrupts, which can be disabled

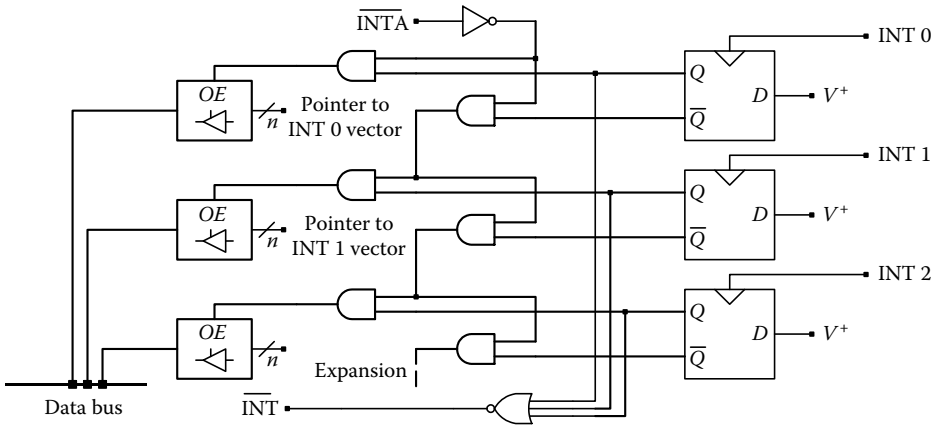

FIGURE 9.92 Priority with a daisy chain.

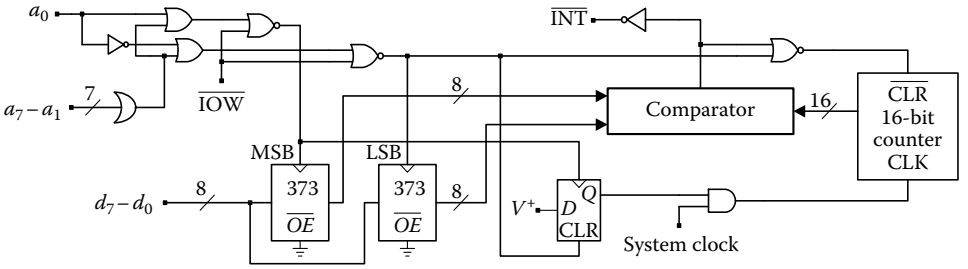

FIGURE 9.93 Timer-counter circuit.

(a write to the LSB) or enabled (a write to the MSB), and thereafter the microprocessor will be periodically interrupted to perform tasks in real time.

Solutions to interfacing problems are not unique. Variables such as the number of I/O devices, I/O device characteristics, amount of I/O, required response times, handshaking, software and hardware trade-offs, cost of parts and eventual manufacture, etc. all influence interface design. Also, there usually are numerous options to solving a particular problem. All of this requires an understanding of system (microprocessor) bus activity to properly time the occurrence of data transfer events. Then, there are issues of response to asynchronous events and status information about data transfer, polling and interrupt processing, and hardware and software trade-offs.

Solutions to common I/O problems such as parallel I/O, serial I/O, timer functions, etc. are often available within single IC packages. Typically, manufacturers of microprocessors provide a family of compatible ICs for each microprocessor. This can simplify the design task and reduce package count. Or, to reduce package count, consideration should also be given to combining gate level hardware into a single package of a PLD. Standardizing I/O can also reduce I/O coats. For example, the universal serial bus (USB) has been widely accepted to accommodate a great variety of I/O requirements.

9.4.7 Design with a Microcontroller

The M68HC11 is a microcomputer system within a single IC package. It is available in a 48 pin DIP and a 52 pin leaded chip carrier (LCC). In addition to the microprocessor, it can be configured for a variety of resources within the same package. These additional internal resources can be ROM (PROM or EPROM), RAM, parallel I/O ports, serial I/O ports, EEPROM, timer, and an A/D converter. Through a reserved bank of 64 status/control and I/O registers, software can select modes of operation of this additional hardware from a multitude of options. With these additional resources, especially the timer and A/D converter, the device is also called a microcontroller.

The programming model of the M68HC11 is shown in Figure 9.94. Registers A and B are both accumulators, and they can be used together as accumulator D for 16 bit add, subtract, multiply, and

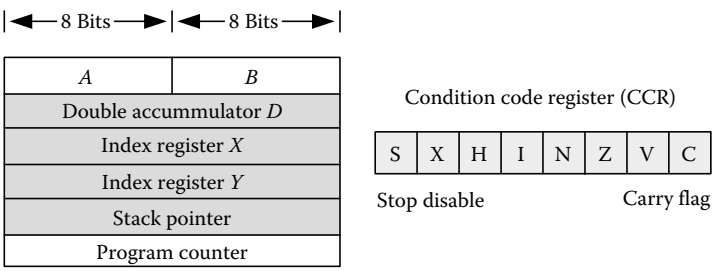

FIGURE 9.94 Programming model of the M68HC11.

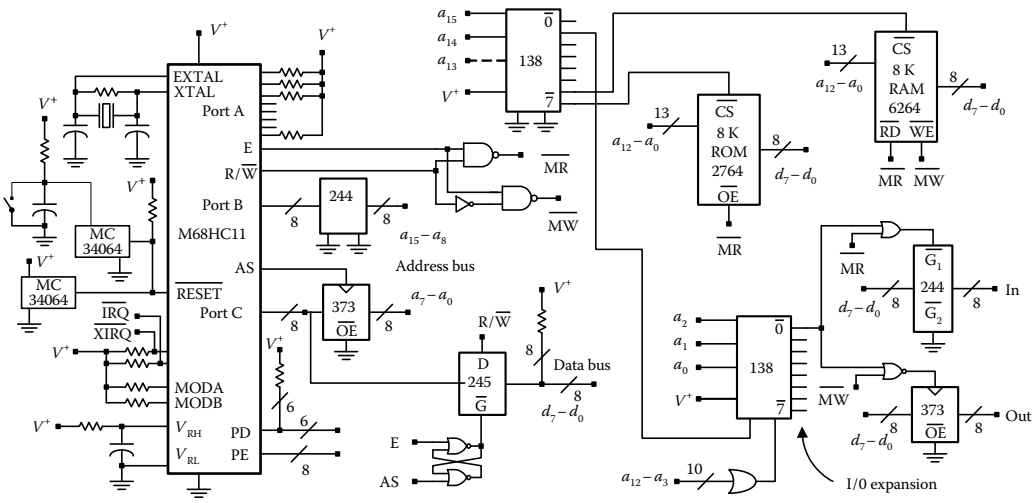

FIGURE 9.95 M68HC11A8-based microcomputer.

divide instructions. The machine language (op-codes), instruction set, and mnemonics are not the same as for the Z80, and so, the M68HC11 has its own assembly language.

The microcontroller also has different modes of operation. One of four modes is determined by the inputs at the two pins labeled MODA and MODB. These modes are MODB = 0, MODA = 0, special bootstrap, (01) special test, (10) normal single chip, and (11) normal expanded. We will consider the single chip and expanded modes of operation.

The M68HC11A8 is a version that has eight analog input channels, and in normal expanded mode of operation its pin functions are shown in Figure 9.95, which gives a diagram of a conventional microcomputer. Notice the selection of the normal expanded mode. For convenient reference, 38 of the 52 pins are grouped and labeled as follows: port A = pins 27–34, port B = pins 35–42, port C = pins 9–16, port D = pins 20–25, and port E = pins 43–50. The remaining pins are used for power supply (V_{SS} = pin 1 and V_{DD} = pin 26), the crystal for the internal clock circuit (pins 7 and 8), $\overline{\text{RESET}}$ (pin 17), nonmaskable interrupt ($\overline{\text{XIRQ}}$ = pin 18), maskable interrupt ($\overline{\text{IRQ}}$ = pin 19), control bus (AS = pin 4, E clock = pin 5, and R/$\overline{\text{W}}$ = pin 6), and analog input range (VRL = pin 51 to VRH = pin 52).

Port B provides the upper address byte. Port C is the data bus, and, to economize on the package pin count, the lower address byte is time-multiplexed with the data bus. The control signal AS, for address strobe, signifies when the data bus contains the lower address byte. The 74HC373 captures the lower address byte when AS is active. Thus, the external system address bus consists of port B and the output of the octal latch. The remainder of the control bus consists of the R/$\overline{\text{W}}$ signal and the E clock signal, which has a frequency equal to one-fourth the system clock frequency.

Since all I/O is memory mapped, the timing of system bus activity is especially straightforward. Figure 9.96 shows M68HC11 timing for all external memory references. After the lower address byte has been captured, the E clock goes high, the data bus is available for data transfer, and the R/$\overline{\text{W}}$ signal determines the direction. The E clock and the R/$\overline{\text{W}}$ signal together control read and write operations. During a read operation, the M68HC11 begins to follow the data bus at the leading edge of the E clock, and it accepts the content of the data bus at the trailing edge of the E clock. Thus, external hardware has slightly less than 2 clock cycles to provide valid data. During a write operation, the microprocessor begins to drive the data bus with valid data at the leading edge of the E clock. Thus, external hardware has slightly less than 2 clock cycles to follow the data bus, and at the trailing edge of the E clock it must accept the content of the data bus. All external memory references require one E clock cycle.

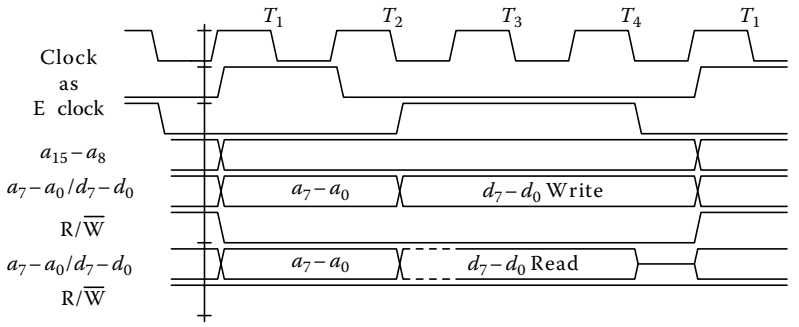

FIGURE 9.96 M68HC11 timing diagram for external memory references.

At power-up, an active low reset is accomplished with the MC34064 device in Figure 9.95. The output of this device switches low whenever its input supply is below a particular limit, and the output goes into tristate whenever its input exceeds a particular limit. Upon reset, the microprocessor initializes internal registers to default conditions, and then it reads memory locations $FFFE and $FFFF to obtain the reset vector that it loads into the PC. Thus, a designer can locate code that is to be executed at reset almost anywhere in the memory space.

Interrupt processing occurs in a similar way. Just prior to fetching each op-code the microprocessor checks the $\overline{\text{IRQ}}$ input. If it is active, and if the *I*-bit (interrupt mask) in the CCR is reset, then the microprocessor stacks 9 bytes (PC, D, IX, IY, and CCR) from the registers in its programming model, disables further interrupts by setting the *I*-bit, and then it reads memory locations $FFF2 and $FFF3 to obtain a vector that is loaded into the PC. The vector is the address of (points to) the first instruction of the $\overline{\text{IRQ}}$ interrupt service routine, which means that a designer can locate this service routine almost anywhere in the memory space.

The response to many interrupting sources can be handled in the same way as is illustrated by Figures 9.89 through 9.91, where the flags of interrupting devices are wire OR'd into one interrupt input to the microprocessor. Then, upon an interrupt, the service routine must first find out which device caused the interrupt. The control bus does not provide any special means to accomplish this. Moreover, as the service routine responds to each interrupt, there must be provision to clear each associated interrupting flag.

With the same vectored method, the M68HC11 is designed to accommodate numerous other external and internal sources of interrupts such as internal timer overflow, illegal op-code, software interrupt, nonmaskable interrupt, to name a few. Each interrupt is associated with two particular memory locations within the vector table, where its vector must be placed. This provides flexibility, and it does not require additional hardware for a reaction by an interrupting device to further control signals.

With the resources and method of interrupt processing of this microprocessor, the memory map of an M68HC11-based system is somewhat fixed. Figure 9.97 shows the memory map of the system given in Figure 9.95.

Through access to the system bus, additional memory and I/O ports can be added to this system. There are some restrictions. Internal address and control signal decoding positions the internal EEPROM block to start at memory location $B600. Because of its long write cycle time, we cannot store data into this memory with just a regular memory write instruction. There must be nonvolatile memory at the top end of the memory space to hold the vector table. The positions of the internal RAM and the control register block are programmable. The default locations are given in Figure 9.97. They can be positioned to start at any 4K boundary according to the data stored in the INIT register, which has address $103D after reset.

Many pins of the M68HC11 serve more than one purpose. For example, the mode select inputs are read during reset to determine the mode of operation. Thereafter, MODA is an active low output that

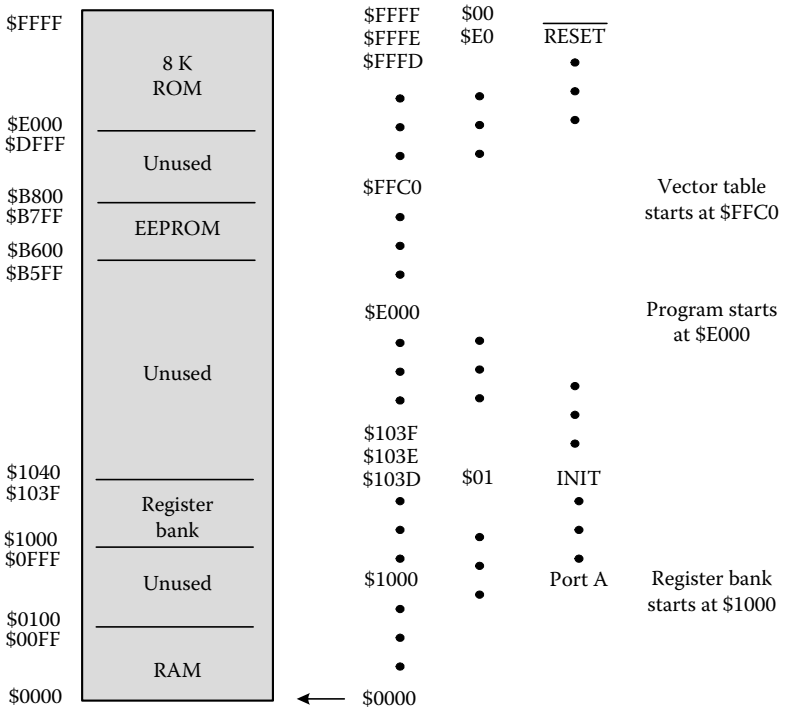

FIGURE 9.97 Memory map and sample ROM content.

becomes active during the first E cycle of each instruction. This is useful for debugging to know when the data bus must hold an op-code. The MODB pin can be used to provide standby power to maintain the content of the internal RAM when V_{DD} is not present.

Port A can serve as three input pins (PA0–PA2), four output pins (PA3–PA6), and one pin (PA7) that can be configured for input or output, depending on the data direction control bit labeled DDRA7 in the PACTL register at memory location $1026. From a programmer's viewpoint, port A is a memory register with address $1000, and the register that controls its I/O functionality is another memory register.

The M68HC11 has a free-running 16 bit counter that is clocked by the output of a programmable prescaler, which is clocked by the E clock. The 2 bytes of the counter can be read through buffers at locations $100E (high byte) and $100F (low byte). All M68HC11 timer functions are based on this counter. The 29 registers at locations $100B–$1027 are all concerned with using and configuring various kinds of timer functions. Thus, software can initiate a periodic real-time interrupt (RTI), which has an associated RTI vector located at $FFF0 and $FFF1.

Another purpose of port A is to provide access to some of these timer functions. For example, pins PA0–PA2 can be used to measure the edge-to-edge time durations of incoming pulses. The M68HC11 contains circuitry for edge detection, and for each input the edge polarity that is to be detected is programmable. Also, for each input there is a unique interrupt vector location associated with edge detection. Thus, to measure the period of a pulse train input at PA0, for example, the counter state must be captured upon an edge detection. For PA0, counter capture is controlled by the IC3F flag in register TFLG1 at location $1023. Registers at locations $101A and $101B receive the counter state. For PA0, edge detection interrupt is enabled with the IC3I flag in register TMSK1 at location $1022. The vector for this interrupt is located at $FFEA and $FFEB. If the *I*-bit in the CCR is reset, then an edge at PA0 will receive interrupt service, which should read the captured counter. Comparing counter states from successive edges of the same polarity can then be used to find the period.

Port D can serve as a general purpose 6-bit I/O port with address $1008. The direction of each bit is programmable through the DDRD register at location $1009. When serial communication is enabled, this port provides asynchronous serial input (RxD) at PD0 and serial output (TxD) at PD1. The baud rate is controlled by the contents of the BAUD register at location $102B. The five registers at locations $102B–$102F are all concerned with using and configuring asynchronous serial communication. From a programmer's viewpoint serial I/O are accomplished by a parallel read from and parallel write to memory location $102F, respectively. There are actually two responsive registers at this address that are distinguished by the R/$\overline{W}$ signal.

The other four pins of port D provide synchronous high speed serial communication. Pins PD3 and PD2 are used for transmitting and receiving serial data, respectively. Pin PD4 carries a clock signal to synchronize data transfer, and pin PD5 can be used to indicate the start of a data transfer. The three registers at locations $1028–$102A are all concerned with using and configuring synchronous serial communication. To reduce package size, pin count and communication paths, there are numerous devices that use serial I/O. Through port D, the M68HC11 can communicate with, for example, serial in LED/LCD display drivers, serial data out A/D converters, serial in/out EEPROMs, or even another microprocessor.

Port E can serve as an 8-bit digital input port with address $100A. These inputs are also each connected to a sample and hold circuit and then to an eight channel analog MUX, the output of which goes to a successive approximation A/D converter. The A/D converter produces an unsigned 8-bit number that is proportional to a DC voltage in the range VRL to VRH. An analog input equal to VRL (VRH) yields an A/D conversion result of $00 ($FF). Each A/D conversion requires 32 E clock cycles. Flags in register ADTCL at location $1030 control A/D conversion. Four consecutive conversions of a single channel, or one conversion of each of the lower four or the upper four channels can be obtained, depending flags in the ADCTL register. A/D conversion results are available from registers at locations $1031–$1034.

Needless to say, the M68HC11 is a complex machine with many options among its numerous features under software control. Features such as software security, failure detection and recovery, power-down/standby, and others have not been discussed.

In the single-chip mode as shown in Figure 9.98, ports B and C and the control signals serve other purposes. Here, port B is an 8-bit output port with address $1004. Pin 6, which is the R/$\overline{W}$ signal in the

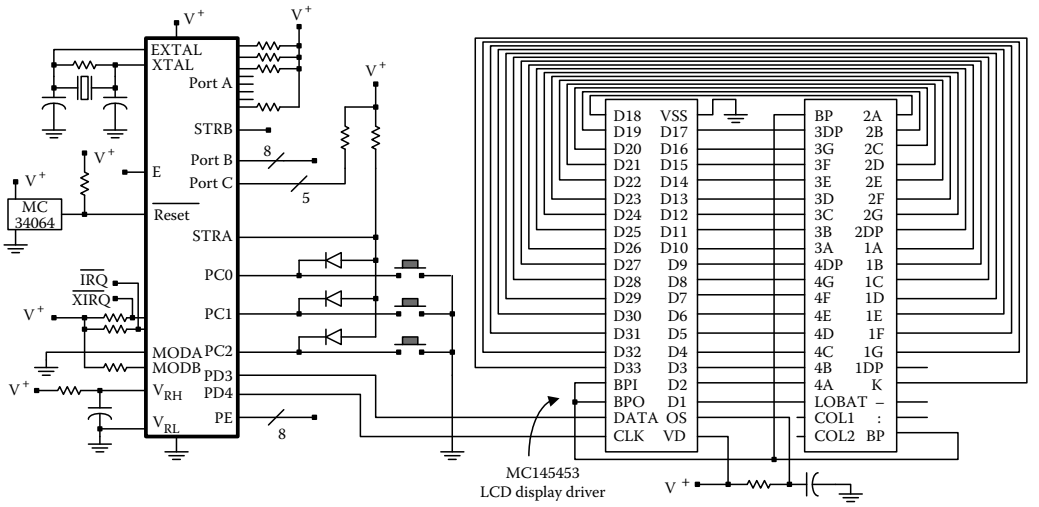

FIGURE 9.98 M68HC11 microcontroller used for a three button and four-digit LCD display device.

expanded mode, can now be configured as an output strobe (STRB) that produces a pulse whenever a write to $1004 (port B) occurs. Port C is a general purpose I/O port with address $1003, and its data direction is controlled by the DDRC register at location $1007. The eight pins of port C also go to a register with address $1005. Pin 4, which is the AS signal in the expanded mode, is now an input strobe (STRA). An edge, the polarity of which is programmable, at this input will cause the data at the port C pins to be latched into the register PORTCL with address $1005. Full handshaking is implemented, because when data are latched into the PORTCL register, the flag STAF in SR PIOC at location $1002 becomes set, and after both the flag and PORTCL have been read, the flag becomes reset.

In single-chip mode, there can be as many as 27(12) output bits and 11(26) input bits, depending on data direction control, or fewer I/O bits if some of these pins are used for A/D, serial communication, or timer functions. Moreover, software must reside in the internal 8K byte ROM of the M68HC11A8 or the internal 12K byte ROM of the M68HC11E9. Like external ROM, this ROM is positioned at the top end of the memory space. It must receive its content at the time of manufacture. With some restrictions, it can be enabled or disabled by the ROMON flag of the CONFIG register at location $103F. This is a special one byte EEPROM so that it will retain its content through power-down and power-up cycles. The M68HC711E9 is an EPROM version of the M68HC11E9. The EPROM can be programmed/erased in the field for development in the single-chip mode. There is also an OTP version of the E9. There are several other members of the M68HC11 family of microcontrollers with varying amounts of hardware resources.

Recently, the M68HC11 has evolved into the M68HC12. In addition to more of the resources available in the M68HC11, the M68HC12 has two expanded modes of operation using either an 8 bit data bus or a 16 bit data bus. Most noteworthy of this processor is its extensive and complex instruction set. In particular, there are instructions that make it convenient to implement fuzzy logic controllers, including fuzzification, inference engine, and defuzzification computing.

In contrast to the evolution of the M68HC11, the MSP430 microcontroller family from Texas Instruments has a very small instruction set, like an RISC machine, with instructions executing in single clock cycles. With its 14 bit A/D converter and fast multiply and accumulate instructions, it can be applied to do digital signal processing. Operating on 3 V, this processor is particularly well suited for low voltage, low power consumption, and portable applications.

The 8051-based family of microcontrollers from Intel has been widely utilized over the past three decades in embedded systems. It is manufactured by many companies. The Harvard architecture of its CPU is a distinctive feature of the processor.

The PIC microcontroller family from Microchip, Inc. is particularly easy to employ. Like most microcontrollers, it can be programmed in C, assembly language, and BASIC. Very low-cost development tools are available for it.

All of these microcontroller families are available with a variety of resources including ROM, RAM, EEPROM, parallel and serial I/O, A/D conversion, timers, LCD drivers, flash memory, and more within a package. When single package hardware resources can match application requirements, economical and compact hardware designs can be achieved.

9.4.8 Design Guidelines

Looking back at Figure 9.67, we see that its simplicity is deceptive. Nonetheless, in view of Figure 9.98 or even Figure 9.84, Figure 9.67 represents the typical embedded microprocessor application. To use a microprocessor requires an awareness of what may seem like an untold amount of information (facts). This should not and cannot be avoided. Time spent in the beginning to know the details will likely save time and expense that may have to be spent later to make revisions. Here, we have only raised a few issues to see the possibilities.

As we look at different processors we find that while the programming model, instruction set, and hardware resources change, hardware design is concerned with interfacing to achieve electrical, timing, and functional compatibility. There are some important principles that carry over from one

microprocessor to another. It is a component that is fundamentally intended to provide trade-offs between hardware and software. This is a matter of degree, and will vary from one application to another. Much care must be taken to suitably allocate the hardware/software trade-offs.

Software and hardware development tools such as software simulators, hardware in circuit emulators, logic analyzers, cross-assemblers and cross-compilers, real-time kernels, and others are necessary to be competitive in product development. Software will likely carry the greater burden to achieve products that function according to desired modes of operation, and it will also incur the greater development cost.

All of the manufacturers of microcontrollers mentioned above provide low-cost evaluation modules and software development tools. Once an application has been well defined, methods of implementation are sufficiently understood and required resources have been specified, it is worthwhile to exercise evaluation modules of several different microcontrollers to compare and find that microcontroller best suited for incorporation into the application.

9.5 Systolic Arrays

Kung Yao and Flavio Lorenzelli

9.5.1 Concurrency, Parallelism, Pipelining, and Systolic Array

9.5.1.1 Motivations and Definitions

Real-time high throughput rate processing constitutes one of the most demanding aspects of modern digital signal processing. In order to achieve the desired throughput rate, various forms of concurrent operations are needed. ''Concurrency'' denotes the ability of a processing system to perform more

than one operation at a given time. Concurrency can be achieved through either parallelism or pipelining, or both. ''Parallelism'' addresses concurrency by replicating some desired processing functions many times. High throughput rate is achieved by having simultaneous operations performed by these functions on different parts of the program. On the other hand, ''pipelining'' tackles concurrency by breaking some demanding part of the task into many smaller simpler pieces, with many corresponding processing elements (PEs), so that processing can be performed in a pipeline manner. This digital pipe is arranged so that it is capable of processing the instructions and data independent of the number of PEs in the pipe. Then, high throughput rate can be achieved by having fast PEs in the pipe. As we shall see, a ''systolic array'' can exploit both the parallelism and pipelining capability of some algorithms.

The term systolic array was coined by Kung and Leiserson [2] to denote one simple class of concurrent processors, in which processed data move in a regular and periodic manner similar to that of the systolic pumping action of the blood by the heart. The earlier definition of a systolic array by Kung [3] requires (1) only a small class of PEs is in the array, with each element in a class performing identical operation; (2) all operations are performed in a synchronous manner independent of the processed data—the only control data broadcast to the PEs is the synchronous clock signal; and (3) the PEs have only nearest-neighbor communications. These regular structure and local communication properties of a systolic array are consistent with efficient modern VLSI designs. Later, various extensions of these assumptions were made (1) some of the PEs can perform a limited number of different functions, depending on the presence of some control data; (2) wavefront array allows PEs to start/end/control their own processing tasks, depending on the data; and (3) PEs can have communications to few nearby neighbors; wraparound communications among PEs located at the edge of the array are allowed.

Systolic arrays can be designed as linear arrays or two-dimensional rectangular or triangular arrays. In Figure 9.99a, consider a uniprocessor system requiring μ time unit to complete a basic operation. If some task requires N such repeated identical operations, the effective throughput rate of this system is given by $r_a = 1/N\mu$. In Figure 9.99b, consider a linear array consisting of a single pipe with N such PEs. Then the rate of this linear systolic array is given by $r_b = 1/\mu$. This demonstrates the pipelining aspects of the array. In Figure 9.99c, consider a rectangular array consisting of M pipes, with each pipe having N PEs. The rate of this rectangular systolic array is given by $r_c = M/\mu$. This demonstrates both the pipelining and parallelism of the array. While the three models in Figure 9.99 are overly simple, nevertheless they demonstrate the fact that if a given task can be designed for systolic processing, different systolic arrays can yield significantly higher throughput rates as compared to a uniprocessor of a given capability. This is the most basic aspect of systolic processing in which a higher hardware complexity is traded for a higher throughput rate.

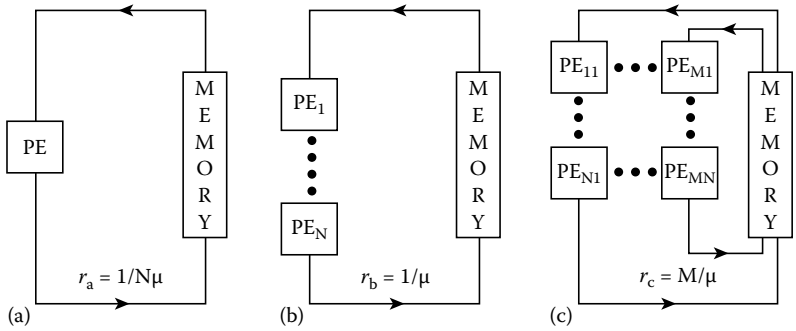

FIGURE 9.99 (a) A uniprocessor system, (b) a linear systolic array, and (c) a rectangular systolic array.

9.5.1.2 Systolic Arrays for Correlation

Consider the linear correlation of a data sequence $\{x_1, x_2, \ldots, x_M\}$ with a weight sequence $\{a_1, a_2, \ldots, a_N\}$ to yield an output sequence $\{y_1, y_2, \ldots, y_{M-N+1}\}$ given by $y_i = a_1 x_i + a_2 x_{i+1} + \cdots + a_N x_{i+N-1} = \Sigma_{J=1}^{N} a_j x_{i+j-1}$, $i = 1, 2, \ldots, M-N+1$. For the case of $N=3$ and $M > N$, we have

$$\begin{aligned} y_1 &= a_1 x_1 + a_2 x_2 + a_3 x_3 \\ y_2 &= a_1 x_2 + a_2 x_3 + a_3 x_4 \\ y_3 &= a_1 x_3 + a_2 x_4 + a_3 x_5 \\ &\vdots \end{aligned}$$

Here, we show two of many possible systolic arrays that can implement the above correlation operations. Design B1 in Figure 9.100a uses three identical PEs to perform the accumulation (multiply and add) operation. Here, the weights a_i are preloaded to the cells and stay throughout the computation. Partial results y_i move systolically from cell to cell. Starting at the third iteration, $y_1, y_2, \ldots$, are outputted from the rightmost cell at the rate of one output per iteration. For each iteration, an x_i is broadcast to all the cells, and a y_i, initialized to zero, enters the leftmost cell. The broadcasted data x_i is marked with an arrow $\downarrow$ in Table 9.12. Indeed, by comparison we see y_1, y_2, and y_3, outputted at iteration $T=3$, 4, and 5, agree with those given from the correlation equations.

In design B2, shown in Figure 9.100b, each input x_i is again broadcasted to each cell, each y_i stays at each cell to accumulate terms, while the weights a_i circulate around the cells in the array. A tag bit is associated with a_1 to reset the contents of the accumulator, while a tag bit is associated with a_3 to output the contents of the accumulator after the first two iterations. Data movements in design B2 are shown in

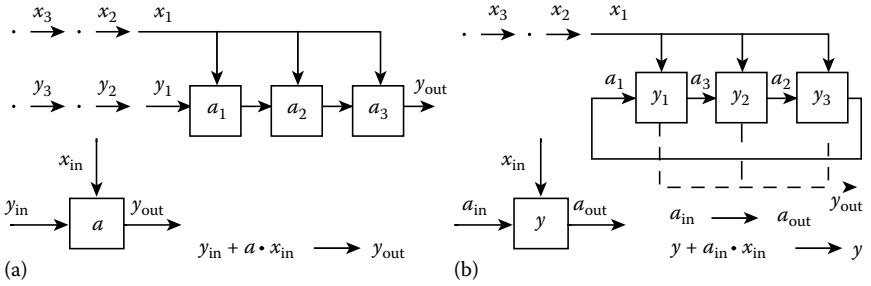

FIGURE 9.100 (a) Systolic array design B1 for correlation; and (b) systolic array B2 for correlation.

TABLE 9.12 Data Movement in Design B1

Iteration	Cell 1	Cell 2	Cell 3
$T=1$	$\downarrow x_1\ a_1$	$\downarrow x_1\ a_2$	$\downarrow x_1\ a_3$
$T=2$	$\downarrow x_2\ a_1$	$a_1 a_1 + \downarrow x_2\ a_2$	$x_1 a_2 + \downarrow x_2\ a_3$
$T=3$	$\downarrow x_3\ a_1$	$x_2 a_1 + \downarrow x_3\ a_2$	$x_1 a_1 + x_2 a_2 + \downarrow x_3\ a_3 \rightarrow y_1$
$T=4$	$\downarrow x_4\ a_1$	$x_3 a_1 + \downarrow x_4\ a_2$	$x_2 a_1 + x_3 a_2 + \downarrow x_4\ a_3 \rightarrow y_2$
$T=5$	$\downarrow x_5\ a_1$	$x_4 a_1 + \downarrow x_5\ a_2$	$x_3 a_1 + x_4 a_2 + \downarrow x_5\ a_3 \rightarrow y_3$

TABLE 9.13 Data Movement in Design B2

Iteration	Cell 1	Cell 2	Cell 3
$T=1$	$0 + a_1 \overset{\downarrow}{x_1}$	$a_3 \overset{\downarrow}{x_1}$	$a_2 \overset{\downarrow}{x_1}$
$T=2$	$a_1x_1 + a_2 \overset{\downarrow}{x_2}$	$0 + a_1 \overset{\downarrow}{x_2}$	$a_2x_1 + a_3 \overset{\downarrow}{x_2}$
$T=3$	$a_1x_1 + a_2x_2 + a_3 \overset{\downarrow}{x_3} \rightarrow y_1$	$a_1x_2 + a_2 \overset{\downarrow}{x_3}$	$0 + a_1 \overset{\downarrow}{x_3}$
$T=4$	$0 + a_1 \overset{\downarrow}{x_4}$	$a_1x_2 + a_2x_3 + a_3 \overset{\downarrow}{x_4} \rightarrow y_2$	$a_1x_3 + a_2 \overset{\downarrow}{x_4}$
$T=5$	$a_1x_4 + a_2 \overset{\downarrow}{x_5}$	$0 + a_1 \overset{\downarrow}{x_5}$	$a_1x_3 + a_2x_4 + a_3 \overset{\downarrow}{x_5} \rightarrow y_3$

Table 9.13. Note that resets occur at cell 1 at iteration 1, cell 2 at iteration 2, cell 3 at iteration 3, cell 4 at iteration 4, etc. Similarly, output y_1 occurs from cell 1 at iteration 3, y_2 from cell 2 at iteration 4, y_3 from cell 3 at iteration 5, etc.

9.5.1.3 Systolic Array Design Techniques

Systolic array designs, as shown above for the correlation case, can be obtained by ad hoc approaches. More formal procedures for the systematic design of systolic arrays have been proposed by Moldovan [7], Quinton [9], Kung [5], Rao [10], Darte and Delosme [1], and others. All those more formal procedures are collectively referred to as dependence graph mapping techniques for systolic array design.

In this approach, an algorithm must be formulated in the ''single assignment algorithm'' form. Each variable has a unique value during the evaluation of the algorithm. Those variables with multiple values can be converted to single values by vectorizing the variables through the introduction of new indices. As an example, consider the matrix multiplication of $C = AB$, where $A = [a_{ik}]$ is $N_1 \times N_3$, $B = [b_{kj}]$ is $N_3 \times N_2$, and $C = [c_{ij}]$ is $N_1 \times N_2$. A conventional formulation of this algorithm contains the expression, $c_{ij} = c_{ij} + a_{ik}\, b_{kj}$ for $i = 1$ to N_1, $j = 1$ to N_2, and $k = 1$ to N_3. We note, c_{ij} has multiple values for $k = 1, \ldots, N_3$. We can modify it to have single values by replacing it by the variable c_{ijk}. The previous equation for c_{ij} then becomes $c_{ijk} = c_{ij(k-1)} + a_{ik}\, b_{kj}$, $c_{ij0} = 0$, c_{ijN_3}, $i = 1, \ldots, N_1$, $j = 1, \ldots, N_2$, $k = 1, \ldots, N_3$.

All algorithm variables are assumed to be indexed variables with V variable names, denoted by the generic names of V_m, $1 \le m \le V$. In the above matrix–matrix multiplication problem $V = 3$, and we can take $X_1, = c$, $X_2 = a$, and $X_3 = b$. For each variable name, the domain of the index vectors is a subset in an S-dimensional space. This subset is called the algorithm's ''index space'' and S is its dimension. For most iterative signal processing problems, time is usually one of the index space coordinates. For the preceding matrix–multiplication problem, we need to propagate a_{ik} across the j variables as well as b_{kj} over the i variables in order to perform the basic multiplication operation. These and a_{ik} and b_{kj} are propagating variables because they involve no computations, but need to be made available at various stages of the computation. In the matrix–matrix problem, clearly $S = 3$ and the index space is $\mathbf{S}_0 = \{(i, j, k)\colon 1 \le i \le N_1, 1 \le j \le N_2, 1 \le k \le N_3,\}$. Furthermore, the initializations of the new variables are given by $a(i, 0, k) = a_{ik}$, $b(0, j, k) = b_{jk}$, $c(i, j, 0) = 0$, $c(i, j, N_3) = c_{ij}$, and the algorithm is finally given by $a(i, j, k) = a(i, j, -1, k)$, $b(i, j, k) = a(i - 1, j, k)$, $c(i, j, k) = c(i, j, k - 1) + a(i, j, j)b(i, j, k)$, for $(i, j, k) \in \mathbf{S}_0$.

In general, a point (or node) in the index space is called an ''index point.'' Thus, $X_m(I)$ is the variable X_m defined at the index point I. A dependence graph mapping is a representation of a single assignment algorithm, where the dependencies among the variables are represented by directed arcs among the nodes. A basic property of the class of algorithms of interest is that of ''shift-invariance.''

An algorithm is shift-invariant if the dependence graph is regular. That is, $X(I)$ depends on $Y(J)$, then $X(I + K)$ depends on $Y(J + K)$ for all I, J, and K in the index space. Three well-known shift-invariance algorithms include

1. Uniform recurrence equations (URE): $X_1(I) = F_1(X_1(I - D_1), \ldots, X_V(I - D_V))$, $X_i(I) = X_i(I - D_i)$, $2 \le i \le V$. Computation occurs only in $F_1(\cdot)$ and propagations in all the other variables, Clearly, the final form of the above matrix–matrix multiplication algorithm is a URE algorithm with

$V = 3$, $F_1(\cdot) = c(i, j, k)$, with $X_1(\cdot) = c(\cdot)$, $X_2(\cdot) = a(\cdot)$, $X_3(\cdot) = b(\cdot)$, $I = (i, \mathrm{i}, k)$, $D_1 = [0, 0, 1]^{\mathrm{T}}$, $D_2 = [0, 1, 0]^{\mathrm{T}}$, and $D_3 = [1, 0, 0]^{\mathrm{T}}$.

2. Generalized uniform recurrence equations (GURE): $X_m(I) = F_m(X_{m1}(I - D_{m1}), \ldots, X_{mk(m)}(I - D_{mk(m)}))$, $1 \leq m \leq V$, where $m_1, \ldots, m_{k(m)}$, belongs to $\{1, \ldots, m\}$. In GURE, we can have computations in all V functions of $F_m(\cdot)$. The number of independent variables $m_{k(m)}$ depends on each m. The shift index dependence, $I - D_{mi}$, is fixed for each X_{mi}.
3. Regular iterative algorithm (RIA): $X_m(I) = F_m(X_{m1}(I - D_{m1,m}), \ldots, X_{mk(m)}(I - D_{mk(m)m}))$, $1 \leq m \leq V$. Here, the shift index dependency, $I - D_{m_i m}$, is not fixed but is a function of m_i and m.

Each processor of the systolic array is assumed to have all the necessary computational modules to compute $F_m(\cdot)$. For URE, we need only one such module, but for GURE and RIA, we need V modules. The time required for the computation of $F_m(\cdot)$ is denoted by τ_m, and the minimum time between such computations is denoted by h_m. In most cases, we can set τ_m and h_m to unity. The design of a processor array to perform the algorithm requires spatial and temporal assignments. Each $X_m(I)$ must be assigned to a processor at each integral time slot. The processor "allocation function," $A(I)$ assigns all variables with the index I to the processors in the array. The "scheduling function," $S_m(I)$, assigns the start of the computation for the variable $X_m(I)$. The simplest form of scheduling and processor allocations are based on the projection of the high multidimensional dependence graph onto the lower dimensional processor array. Variables represented by nodes in the dependence graph are mapped to processors which perform the computations. The directed arcs of the dependence graphs are transformed to physical communication links in the processor array.

The essence of the allocation function $A(\cdot)$ is thus to return for every index value $I \in \mathbf{S}_0$ a vector which indicates the processor in charge of the computation represented by a point in a lower dimensional space. Analogously, the scheduling function $S_m(\cdot)$ provides the relative start of the execution for the computation indexed by I. These two functions cannot be chosen independently because two computations assigned to the same processor cannot be scheduled for the same time ("compatibility constraint"). Additional details on this constraint are given later. While in principle $A(\cdot)$ and $S_m(\cdot)$ can be any function, we shall consider only "affine functions," in the sense that $A(I) = A^{\mathrm{T}}I$, $S_m(I) = \lambda^{\mathrm{T}} i + \gamma_m$, where A is a suitable matrix, λ a vector, and γ_m an integral constant.

The dependence graph of an algorithm can be interpreted as a "lattice" embedded in a multidimensional integral space (i.e., a proper bounded subset of $\mathbf{Z}^s$, where $\mathbf{Z}$ is the set of relative integers), enclosed in a convex polyhedron. We assume the lattice to be "dense" in the sense that all the integral points in it correspond to actual computations. The whole procedure of mapping an algorithm onto a systolic-type processor consists of two conceptually different but interdependent operations of using a space transformation and a time transformation. The former actually "projects" the dependence graph onto a lower dimensional structure which then can be mapped one-to-one onto the physical array, while the latter gives the start of the execution of each computation.

For simplicity, consider the projection of the S-dimensional space onto an $(S-1)$ dimensional processor space. The more general problem of projecting the dependence graph onto an $(S-p)$-dimensional space ($p \geq 1$) can be expressed using a similar but more involved notation and is omitted here. Instead of considering allocation functions, we refer to the "projection vector u," which is orthogonal to the processor space onto which we project. Assume that we have chosen both the projection and the scheduling vectors (u and λ, respectively). For normalization purposes, they are chosen to be coprime vectors, such that the greatest common divisor of their components is 1, and their first nonzero element is positive.

Two sets of constraints must be satisfied by u and λ. Assume nodes I and J are located along a direction parallel to the projection vector u such that $J = I + \alpha u$, $\alpha \in \mathbf{Z}$. Then, the computations associated with the two nodes will be projected onto the same processor. Consequently, compatibility constraint requires that they be performed at different times. Analytically, this is equivalent to $|\lambda^{\mathrm{T}} u| \; \lambda \max_{m=1,\ldots,V} h_m$, which for $h_m = 1$ simplifies to $|\lambda^{\mathrm{T}} u| > 0$. Thus, for this case λ and u cannot be perpendicular. Furthermore, the

quantity $c = \Delta|\lambda^T u|$ represents the number of time slots between successive calculations scheduled on the same processor. $1/c$ is sometimes called the "efficiency" of the processors because the larger the c, the more time the processors can idle. One common approach is to select the projection vector and the scheduling vector to achieve the highest efficiency, with c being as close to 1 as possible.

Consider the case in which the variable $X_m(I)$ depends on $X_n(I - D_{nm})$. The "precedence constraint" implies the calculation of $X_n(I - D_{nm})$ must be scheduled to be completed before the start of the calculation of $X_m(I)$. Analytically, the precedence constraint is equivalent to $\lambda^T D_{nm} + \gamma_m - \gamma_n \geq \tau_n = 1$, for all $1 \leq m \leq v$ and for all dependences D_{nm}. If the γ constants are chosen to be all equal, the precedence constraint becomes $\lambda^T D_{nm} \geq 1 \; \forall \, m = 1, \ldots, V$.

Assume the precedence and compatibility constraints are satisfied and λ and u are coprime vectors. Then it is possible to extend both vectors to two unimodular matrices. A matrix with integral entries is called "unimodular" when its determinant is equal to ± 1. This implies that they admit integral inverses. The unimodular extension of coprime vectors is not unique. We will choose U and Λ to be the unimodular extended matrices that have u and λ, respectively, as their first columns. It is possible to show that the columns of any S-dimensional unimodular matrix can constitute a basis for the space Z^S. Moreover, if we denote $\sigma_1, \ldots, \sigma_s$ to be the columns of $\Sigma = U^{-T}$, then we have $\sigma_1^T u = 1$ and $\sigma_1^T u = 0$ for all $i = 2, \ldots, S$. Therefore, $\{\sigma_2, \ldots, \sigma_s\}$ will be a basis of the processor space of the resulting logic array. Similarly, the first column of T (the inverse of Λ^T) t_1, represents the direction in which time increases by one step; i.e., it is the vector defining the hyperplane of the points computed at the same time. The other columns of T (denoted by $t_2, \ldots, t_s$) are a basis of such a hyperplane.

If we denote by $\Sigma_+ = [\sigma_2, \ldots, \sigma_s]$ the matrix basis of the processor space, the allocation function and the scheduling function have the form $A(I) = \Sigma_+^T I, S_m(I) = \lambda^T I + \gamma_m$, $m = 1, \ldots, V$. With these elements we can have the complete description of the final array. The processors are labeled by $A(I) = \Sigma_+^T I$ as I ranges over the index space. The dependences D_{nm} are mapped onto communication links $\Sigma_+^T D_{nm}$ and the delay registers on such links must be in number equal to $\lambda^T D_{nm} + \gamma_m - \gamma_n - \tau_n = \lambda^T D_{nm} - 1$.

Reconsider the systolic correlation problem using the weights $\{a_1, \ldots, a_k\}$ and the data $\{x_1, \ldots, x_n\}$, as discussed earlier. Recall the correlation is given by $y_i = a_1 x_i + a_2 x_{i+1} + \cdots + a_k x_{i+k-1}$, $1 \leq i \leq n + 1 - k$. A recurrence equation formulation of this equation is given by $y(i,j) = y(i,j-1) + w(i,j)x(i,j), y(i,0) = 0, y_i = y(i,k)$; $w(i,j) = w(i-1,j)$, $w(1,j) = a_j$; and $x(i,j) = x(i+1,j-1)$, $x(i,0) = x_{i-1}$, all with $1 \leq i \leq n + 1 - k$, $1 \leq j \leq k$. A dependence graphical representation of these equations is shown in Figure 9.101a.

A URE reformulation of the recurrence equations yields $X_1(I) = y(i,j) = F_1(X_1(I - D_1), X_2(U - D_2), X_3(I - D_3))$, $X_2(I) = w(i,j) = X_2(I - D_2)$, $X_3(I) = x(i,j) = X_3(I - D_3)$, with the index point $I = [i,j]^T$ and

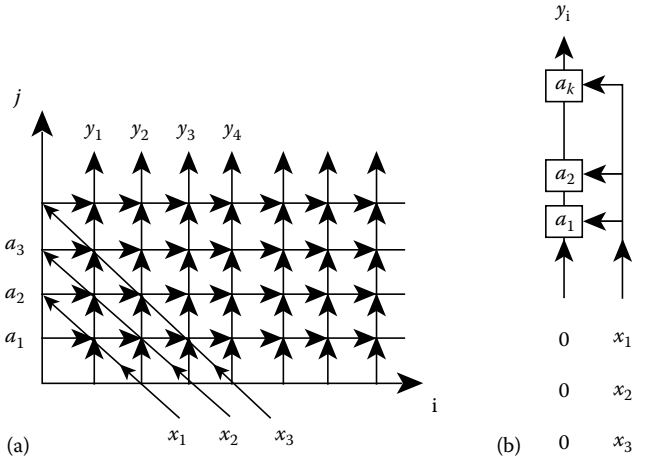

FIGURE 9.101 (a) Two-dimensional dependence graph and (b) one-dimensional dependence graph.

displacement vectors $D_1 = [0, 1]^T$, $D_2 = [1, 0]^T$, and $D_3 = [-1, 1]^T$. In particular, consider the URE representation of the B1 design based on the choice of $u = [1, 0]^T$, $\Sigma_+ = [0, 1]^T$, $\lambda = [1, 1]^T$, $\gamma_m = 0$, $m = 1$, 2, and 3, and $\tau_n = h_n = 1$, $n = 1$, 2, and 3. Then, the two-dimensional graph of Figure 9.101a is projected onto the one-dimensional graph of Figure 9.101b. Specifically, for any index $I = [i, j]^T$, the processor allocation function yields $A(I) = \Sigma_+^T I = j$, $i \le j \le k$, which is a valid projection from two-dimensions to one. On the other hand, the index point for each input data x_1 (with variable name of X_3) is given by $I = [i, l - i + 1]^T$, $l = 1, \ldots, n$. Then the scheduling function $S_3(I)$ is given by $S_3(I) = \lambda^T I = [1, 1]\ [i, 1 - i + 1]^T = i + l - i + 1 = l + 1$, $l = 1, \ldots, n$. This indicates each x_1 for the previously given I must be available at all the processors at time $l + 1$. Thus, there is no propagation and this means all the x_1 must be broadcasted to all the processors. However, the simplistic definition of a systolic design does not allow broadcasting. Indeed, the precedence constraint is *not* satisfied with D_3. That is, $\lambda^T D_3 = [1, 1]\ [-1, 1]^T = 0 \not\ge \tau_n = 1$. Of course, other choices of λ and u generate other forms of systolic array architecture for correlation. For more complicated signal processing tasks such as QR decomposition (QRD), recursive least-squares (LS) estimation, singular value decomposition (SVD), Kalman filtering (KF), etc., the design of efficient systolic array architectures are generally difficult. The dependence graph mapping technique provides a systematic approach to such designs by providing the proper selections of these λ and u vectors.

9.5.2 Digital Filters

The application of digital filtering has spread tremendously in recent years to numerous fields, such as signal processing, digital communications, image processing, and radar processing. It is well known that the sampling rate, which is closely related to the system clock, must be higher than the Nyquist frequency of the signals of interest. It follows that in order to perform real-time filtering operations when high frequency signals are involved, high-speed computing hardware is necessary.

Pipelining techniques have been widely used to increase the throughput of synchronous hardware implementations of a transfer function of a particular algorithm. Most algorithms can be described in a number of different ways, and each of these descriptions can be mapped onto a set of different concurrent architectures. Different descriptions may lead to realizations with entirely different properties, and can have a dramatic impact on the ultimate performance of the hardware implementation. Pipelining can also be used for other than throughput increase. For a fixed sample rate, a pipelined circuit is characterized by a lower power consumption. This is due to the fact that in a pipelined system capacitances can be charged and discharged with a lower power supply. Because the dissipated power depends quadratically on the voltage supply, the power consumption can be reduced accordingly.

An increase in the speed of the algorithm also can be achieved by using parallelism. By replicating a portion of the hardware architecture, similar or identical operations can be performed by two or more concurrent circuits, and an intelligent use of this hardware redundancy can result in a net throughput increase, at the expense of area. Note that VLSI technologies favor the design in which individual sections of the layout are replicated numerous times. A regular and modular design can be achieved at relatively low costs. For a fixed sample rate, parallelism can be exploited for a low power design due to the reduced speed requirements on each separate portion of the circuit.

Much work has been done in the field of systolic synthesis of finite and infinite impulse response (FIR/IIR) filters, as can be seen from the literature references. In the following subsection, we consider possible strategies that can be used to increase the throughput of the concurrent architectures of the FIR and IIR filters.

9.5.2.1 FIR Filters

FIR filters have been largely employed because of certain desirable properties. In particular, they are always stable, and causal FIR filters can posses linear phase. A large number of algorithms have been devised for the efficient implementation of FIR filters, which minimize the number of multipliers, the

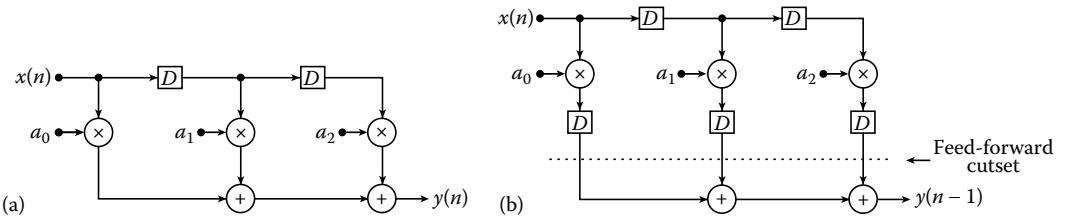

FIGURE 9.102 A three-tap FIR filter: (a) with no pipelining, the throughput is limited by the rate of one multiplication and two additions and (b) with pipelined circuit, the throughput is increased to the rate of one multiplication or two additions.

round-off noise, or the coefficient sensitivity. The generic expression that relates the output $y(n)$ at time n to the inputs $x(n-i)$ at times $(n-i)$ $i=0,1,\ldots,q$ is given by

$$y(n) = \sum_{i=0}^{q} a_i x(n-i)$$

where the $\{a_i\}_{i=0}^{q}$ are the FIR filter coefficients. Here, we consider only issues of pipelining and parallelism.

The pipeline rate, or throughput, of implemented nonrecursive algorithms such as FIR filters can be increased without changing the overall transfer function of the algorithms by means of a relatively simple modification of the internal structure of the algorithm. In particular, one set of latches and storage buffers can be inserted across any feed-forward cutset of the data flow graph. Figure 9.102b, illustrates the increase of throughout achieved by pipelining in a second-order three-tap FIR filter. The sample rate of the circuit of Figure 9.102a is limited by the throughput of one multiplication ''and'' two additions. After placing the latches at the locations shown in Figure 9.102b, the throughput can be increased to the rate of one multiplication ''or'' two additions. Pipelining can be used to increase the sample rate in all the cases in which no feedback loops are present. The drawbacks of pipelining are an increased latency and a larger number of latches and buffers.

Parallelism can be used to increase the speed of an FIR filter. Consider Figure 9.103, in which the three-tap FIR filter of Figure 9.102 was duplicated. Because at each time instant two input samples are processed and two samples are output, the effective throughput rate is exactly doubled.

As can be seen from Figure 9.103. parallelism leads to speed increase at a considerable hardware cost. For many practical implementations, parallelism and pipelining can be used concomitantly, when either method alone would be insufficient or limited by technology such as I–O, clock rate, etc.

9.5.2.2 IIR Filters

These are recursive filters in the sense that their output is function of current inputs as well as past outputs. The general I–O relationship is expressed by

$$y(n) = \sum_{j=1}^{p} a_i y(n-j) + \sum_{i=o}^{q} b_i x(n-i) \tag{9.22}$$

where the $\{a_j\}_{j=1}^{p}$ are the coefficients associated to the recursive part, and the $\{b_i\}_{i=0}^{q}$ are the coefficients associated to the nonrecursive portion of the filter. The associated transfer function is written as the following z-transform

$$H(z) = \frac{\sum_{i=0}^{q} b_i z^{-i}}{1 - \sum_{j=1}^{p} a_j z^{z-j}}$$

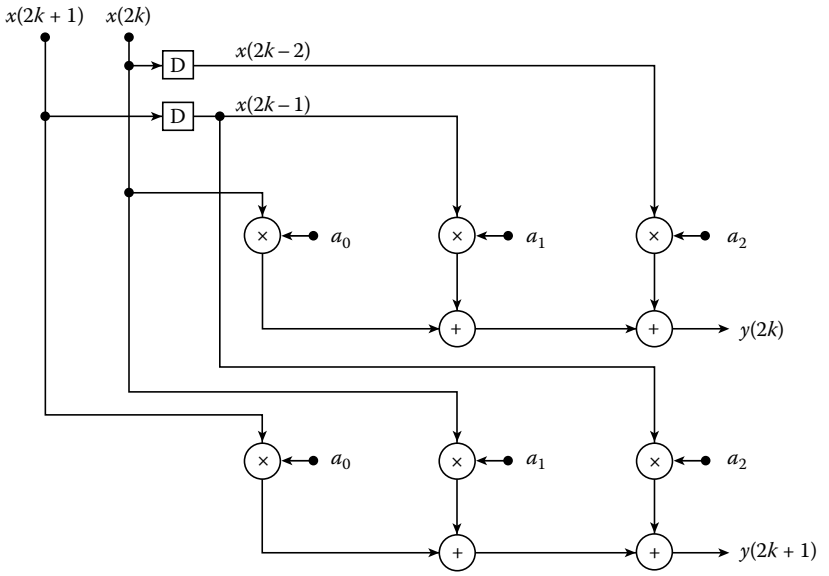

FIGURE 9.103 Three-tap FIR filter whose hardware has been duplicated to achieve double throughput rate.

For stability reasons, it is required that all the poles (i.e., the zeroes of the denominator of $H(z)$) be inside the unit circle in the z-plane.

Consider a circuit in which L loops are present each with latency τ_k, $k = 1, \ldots, L$. The number of latches present in each loop is equal to ν_k, $k = 1, \ldots, L$. Then the throughput period cannot be shorter than

$$T_{\max} \equiv \max_{k=l,\ldots,L} \left\lceil \frac{\tau_k}{\nu_k} \right\rceil$$

The pipeline can be increased by increasing the number of latches internal to the feedback loops. The computational latency associated with the internal feedback prevents one from introducing pipeline simply by inserting latches on feedforward cutsets. In fact, inserting latches in the loop would change the overall transfer function. This difficulty can be overcome by recasting the algorithm into an equivalent formulation from an I–O point of view. The transformations applied to the algorithm, prior to the mapping, have the purpose of creating additional concurrency, thereby increasing the achievable throughput rate. Without ever changing the algorithm's transfer function, additional delays are introduced inside the recursive loop. These delays are subsequently used for pipelining. In the sequel, we briefly describe two types of look-ahead techniques that generate the desired algorithmic transformations, namely the clustered and the scattered look-ahead techniques proposed by Loomis and Sinha [18] and Parhi and Messerschmitt [19], respectively. Look-ahead techniques are based on successive iterations of the basic recursion, in order to generate the desired level of concurrency. The implementation is then based on the iterated version of the algorithm.

Clustered look-ahead: In a pth order recursive system, the output at time n is a function of the past output samples $y(n-1)$, $y(n-2), \ldots, y(n-p)$. In the clustered look-ahead technique, the recursion is iterated m times so that the current output is a function of the cluster of p consecutive samples $y(n-m)$, $y(n-m-1), \ldots, y(n-m-p)$. The original order-$p$ recursive filter is emulated by a $(p+m)$th filter, where m canceling poles and zeroes have been added. In this way the m delays generated inside the feedback loop can be used to pipeline by m stages.

By iterating 9.22 m times, we can derive the following I–O relationship

$$y(n) = \sum_{j=1}^{p-1} \left[\sum_{k=j+1}^{p} a_k r_{j+m-k} \right] y(n-j-m) + \sum_{j=0}^{m-1} \sum_{k=0}^{q} b_k x(n-k-j)$$

where the coefficients $\{r_i\}$ can be precomputed off-line, and are such are such that $r_i = \Sigma_{k=1}^{p} a_k r_{i-k}$, $i > 0$, $r_0 = 1$, and $r_i = 0$, $i = -(p-1), \ldots, -1$. This implementation requires $(p+m)$ multiplications for the nonrecursive part, and p for the recursive part, for a total of $(2\,p+m)$, which grows linearly with m. The transfer function is equal to

$$H(z) = \frac{\sum_{j=0}^{m-1} \sum_{k=0}^{q} b_k z^{-k-j}}{1 - \sum_{j=1}^{p-1} \left[\sum_{k=j+1}^{p} a_k r_{j+m-k} \right] z^{-j-m}}$$

The clustered look-ahead technique does not guarantee that the resulting filter is stable because it may introduce poles outside the unit circle.

Consider the following simple example with a stable transfer function:

$$H(z) = \frac{1}{1 - 1.3z^{-1} + 0.35z^{-2}}$$

with poles at $z = 0.7$ and $z = 0.5$. The two-stage equivalent filter can be obtained by introducing the canceling pole-zero pair at $z = -1.3$, as follows:

$$H(z) = \frac{1 + 1.3z^{-1}}{(1 - 1.3z^{-1} + 0.35z^{-2})(1 + 1.3z^{-1})} = \frac{1 + 0.9z^{-1}}{1 - 1.34z^{-2} + 0.455z^{-3}}$$

Because a pole is found at $z = -1.3$, this transfer function is clearly unstable.

Scattered look-ahead: In the scattered look-ahead technique, the current output sample $y(n)$, is expressed in terms of the (scattered) p past outputs $y(n-m)$, $y(n-2m), \ldots, y(n-mp)$. The original order-p filter is now emulated by an order-mp filter. For each pole of the original filter, $(m-1)$ canceling pole-zero pairs are introduced at the same distance from the origin as the original pole. Thus, stability is always assured. The price we must pay is higher complexity, on the order of mp. To best describe the technique, it is convenient to write the transfer function $H(z)$ as a ratio of polynomials, i.e., $H(z) = N(z)/D(z)$. The transformation can be written as follows:

$$H(z) = \frac{N(z)}{D(z)} = \frac{N(z) \prod_{k=1}^{m-1} D\left(z e^{j(2\pi k/m)}\right)}{\prod_{k=0}^{m-1} D(z e^{j(2\pi k/m)})}$$

Note that the transformed denominator is now a function of z^{-m}.

Consider the example of the previous section. For the scattered look-ahead technique, it is necessary to introduce pole-zero pairs at $z = 0.7\ e^{\pm j(2\pi/3)}$ and $z = 0.5\ e^{\pm j(2\pi/3)}$. The transformed denominator equals $1 - 0.125z^{-3}$.

The complexity of the nonrecursive part of the transformed filter is $(pm+1)$ multiplications, while the recursive part requires p multiplications, for a total of $(pm+p+1)$ pipelined multiplications. Although the complexity is still linear in m, it is much higher than in the clustered look-ahead technique for a large value of p.

Parhi and Messerschmitt [19] presented a technique to reduce the complexity of the nonrecursive portion down to $O(p \log_2 m)$, applicable when m is a power of 2. This technique can be described as follows. Assume that the original recursive portion of the given IIR filter is given by

$$H(z) = \frac{1}{1 - \sum_{j=1}^{p} a_j^{(1)} z^{-j}}$$

An equivalent two-stage implementation of the same filter can be obtained by multiplying numerator and denominator by the polynomial $(1 - \Sigma_{j=1}^{p}(-1)^j a_j^{(1)} z^{-j})$, which is given by

$$H(z) = \frac{1 - \sum_{j=1}^{p} (-1)^j a_j^{(1)} z^{-j}}{1 - \sum_{j=1}^{p} a_j^{(2)} z^{-j}}$$

where the set of coefficient $\{a_j^{(2)}\}_{j=1}^{p}$ is obtained from the original set $\{a_j^{(1)}\}_{j=1}^{p}$ by algebraic manipulation. By repeating this process $\log_2 m$ times one can obtain an m-stage pipelined implementation, equivalent to the original filter. In this way the hardware complexity only grows logarithmically with the number of pipelining stages.

Bidirectional systolic arrays for IIR filtering: Lei and Yao [16] showed that many IIR filter structures can be considered as special cases of a general class of systolizable filters, as shown in Figure 9.104. These filters can be pipelined by rescaling the time so that $z' = z^{1/2}$, and by applying a cutset transformation. This time rescaling causes the hardware factorization to reduce to merely 50%, which is quite inefficient. Lei and Yao [17] later proposed two techniques to improve the efficiency of these bidirectional IIR filters.

In the first method (''overlapped subfilter scheme''), one makes use of the possibility to factor the numerator and the denominator of the given transfer function. For instance, if

$$H(z) = \frac{N(z)}{D(z)} = \underbrace{\frac{N_a(z)}{D_a(z)}}_{H_a(z)} \cdot \underbrace{\frac{N_b(z)}{D_b(z)}}_{H_b(z)}$$

where $a + b = p$, $a - b = 0$, 1, or 2, and p is the number of modules of the original transfer function. Then the two subfilters, $H_a(z)$ and $H_b(z)$, can be realized on the same systolic array of $a + 1$ modules, as in Figure 9.105. A multiplexer at the input of the array chooses the incoming data at even time instants, and the data from the output of the first module at odd time instants. The modules alternately perform operations associated to $H_a(z)$ and $H_b(z)$ in such away as to interleave the operations and have an overall 100% efficiency.

In the second technique (''systolic ring scheme'') the number of modules is about half of the order of the original transfer function. The modules of the new structure are arranged as a systolic ring, as in Figure 9.106. For example, a five-module ring can be used to implement a ten-module IIR filter: module i performs the operations associated to modules i and $(5 + i)$ of the original array, for $i = 1, \ldots, 5$. Note that in the original structure every other module is idle. The resulting ring is therefore 100% efficient.

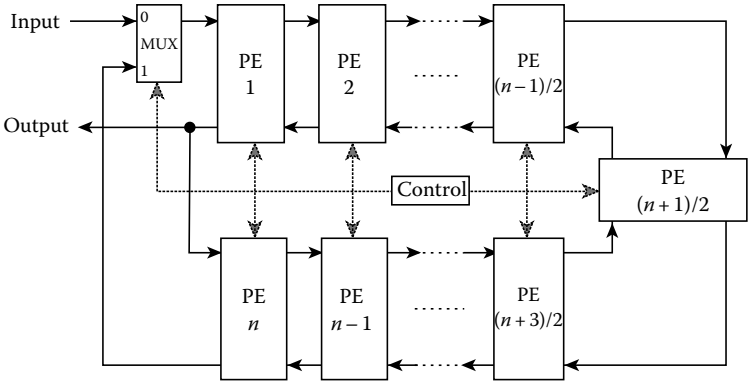

FIGURE 9.106 The systolic ring scheme for IIR filtering.

9.5.3 Systolic Word and Bit-Level Designs

Previous discussions on systolic array designs have taken place at the word level. This is to say that the smallest data or control item exchanged between pairs of processors is constituted by a ''word'' representable by B bits. Each processor in a word-level system has the capability of performing word-level operations. Some may be as complex as floating point multiplications or others as simple as square root operations, etc. The systolic array approach can be applied at various different levels beyond the word level, according to what is sometimes referred to as ''granularity'' of the algorithm description. Systolic arrays and associated dependence graphs can, in fact, be defined at high levels of description, in which each individual processor can, in principle, be a whole mainframe computer or even a separate parallel processor array. The communication between processors thus takes the form of complex protocols and entire data sequences. According to the same principle, the algorithm description can also be done at the lowest level of operation, namely, at the bit level, at which each processor is a simple latched logic gate, capable of performing a logic binary operation. The exchanged data and control also take the form of binary digits. The different approaches due to the different granularity of description have different merits and can be advantageously used in various circumstances or at different steps of the design.

These considerations bring to one possible design strategy, namely, the ''hierarchical systolic design.'' In this approach the complete systolic design is broken down to a sequence of hierarchical steps, each of which define the algorithm at different levels of granularity. At first, the higher level of description is adopted, the relative dependence graph is drawn, and, after suitable projection and scheduling, a high-level systolic architecture is defined. Subsequently, each high-level processor is described in terms of finer scale operations. Dependence graph and systolic architecture corresponding to these operations are produced and embedded in the higher level structure previously obtained. The process can continue down to the desired level of granularity. The simplest form of hierarchical design implies two steps. The first step involves the design of the word-level architecture. Second, the operations performed by each

work-level processor are described at bit level. The corresponding bit-level arrays are then nested into the word-level array, after ensuring that data flows at both levels are fully compatible.

The hierarchical approach has the merits of reducing the complexity of each step of the design. The dependence graphs involved usually have reduced dimensionality (thus, are more manageable), and the procedure is essentially recursive. The drawback of a hierarchical design is that it implicitly introduces somewhat arbitrary boundaries between operations, thereby reducing the set of resulting architectures. An approach that leaves all options open is to consider the algorithm at bit level from the outset. This approach has led to new insights and novel architectures. The price to pay is that the designer must deal with dependence graphs of higher dimensionality. As an example, the dependence graph of the inner product between two N-vectors, $c = \Sigma_{i=0}^{N-1} a_i b_i$ is two dimensional. If the same inner product is written at bit level, i.e., $c_k = \Sigma_{i=0}^{N-1} \Sigma_{j=0}^{B-1} a_{i,j} b_{i,k-j} +$ carries, $k = 0, \ldots, B-1$, then it produces a three-dimensional dependence graph.

Examples of the two design procedures applied to the convolution problem are considered below. First, consider the factors that can make bit-level design advantageous:

- *Regularity*. Most bit-level arrays are highly regular. Only relatively simple cells need to be designed and tested. The communication pattern is simple and regular. Neighbor-to-neighbor connections allow high packing density and low transmission delays.
- *High pipeline rate*. Because the individual cells have reduced computation time (on the order of the propagation delay through a few gates), the overall throughput can be made very high.
- *Inexpensive fault tolerance*. The use of bypass circuitry can be made without wasting too much of the silicon area.

It must be borne in mind that bit-level arrays realistically cannot be operated in wavefront array mode because the interprocessor hand-shaking protocols would be too expensive as compared to the data exchange. A good clock signal distribution is therefore needed to synchronize the array operations. In systolic arrays, unlike synchronous architectures of a different sort, only the incremental clock skew must be minimized by suitably designing the clock signal distribution lines. This problem may become particularly delicate in bit-level arrays, where the number of processors involved is very high.

9.5.3.1 Bit-Level Design of a Serial Convolver

Bit-level systolic design was first proposed by McCanny and McWhirter [29]. Subsequently, they and others have applied this technique to various algorithms. As a simple example, consider the bit-level design of a serial convolver. The word-level output of an N point convolver can be written as $y_k = \Sigma_{i=0}^{N-1} a_i x_{k-i}$, $k = 0, 1, \ldots$, where $\{a_i\}_{i=0}^{N-1}$ is a given set of coefficients and x_i, $i = 0, 1, \ldots$, is a sequence of input data. Coefficients and data values are assumed to be B-bit words. The word-level dependence graph is shown in Figure 9.107, together with one possible systolic realization. In this case, the coefficients are permanently stored in each individual cell. I/O values are propagated in opposite directions. In each PE, the corresponding coefficient is multiplied by the incoming data value. This product is added to the partial output value and the accumulated result is propagated forward. Each cell performs the simple multiply and add operation expressed by $y_{k,i+1} \leftarrow y_{k,i} + a_i x_{k-i}$, $y_k = y_{k,N}$.

According to the hierarchical approach, one must now proceed to determine the dependence graph corresponding to the bit-level description of the multiply-and-add operation. The complete dependence graph can be subsequently obtained by embedding the finer scale graph into the higher level graph. If both a_i and x_i are B-bit binary numbers, then the jth bit of y_{ki}, can be computed according to $y_{k,i,j} = y_{k,i,j} + s_{i,k,j}, s_{i,k,j} + \Sigma_{l=0}^{B-1} a_{i,l} x_{k-i,j-l} +$ carries, where $a_{i,l}$ and $x_{i,l}$, $l = 0, \ldots, B-1$, represent the lth bit of a_i and x_i. The dependence graph corresponding to this operation is given in Figure 9.108, where subscripts only indicate the bit position, and $B = 3$. Note that this graph is quite similar to the graph corresponding to a convolver, apart from the carry bits, which are taken care of by the insertion of an additional row of cells.

The combined dependence graph, obtained from the word dependence graph of Figure 9.107, in which each cell is replaced by the bit-level dependence graph of Figure 9.108, is given in Figure 9.109.

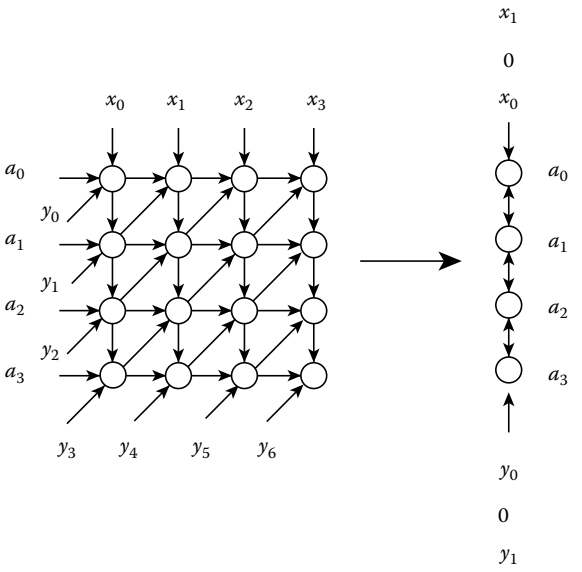

FIGURE 9.107 World-level dependence graph of an N point convolution operation with one possible systolic realization.

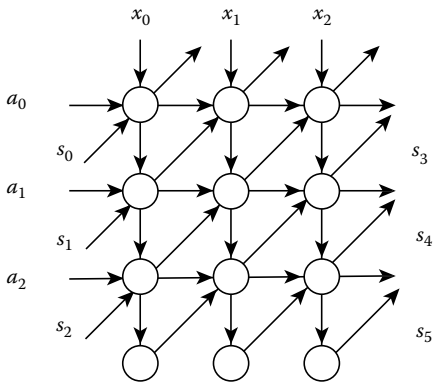

FIGURE 9.108 Bit-level dependence graph corresponding to the multiply-and-add operation.

The data flows are fully compatible at both word and bit levels. At this point, a full two-dimensional bit-level systolic array can be obtained from the final dependence graph by simply replacing each node with latched full adder cells. Different linear systolic implementations can be obtained by projecting the combined dependence graph along various directions. One possibility is again to keep the coefficients residents in individual cells, and have input data bits and accumulated results propagate in opposite directions. The schematic representation of the systolic array with these features is drawn in Figure 9.109. Judgment about the merits of different projections involves desired data movement, I–O considerations, throughput rate, latency time, efficiency factor (ratio of idle time to busy time per cell), etc.

As discussed previously, the convolution operation can be described at bit level from the very beginning. In this case the expression for the jth bit of the kth output can be expressed as follows:

$$y_{k,j} = \sum_{i=0}^{N-1} \sum_{l=0}^{B-1} a_{i,l} x_{k-i,j-1} + \text{carries} \tag{9.23}$$

By using this expression as a starting point, one is capable of generating a number of feasible systolic realizations potentially much larger than what is attainable from the two-step hierarchical approach. The reason for this can be simply understood by nothing that in this formulation no arbitrary precedence relationship is imposed between the two summations on i and l, whereas earlier we required that the summation on l would always ''precede'' the summation on i. The result is a fairly complicated three-dimensional dependence graph of size $N \times B \times$ number of inputs, as shown in Figure 9.110. Observe that

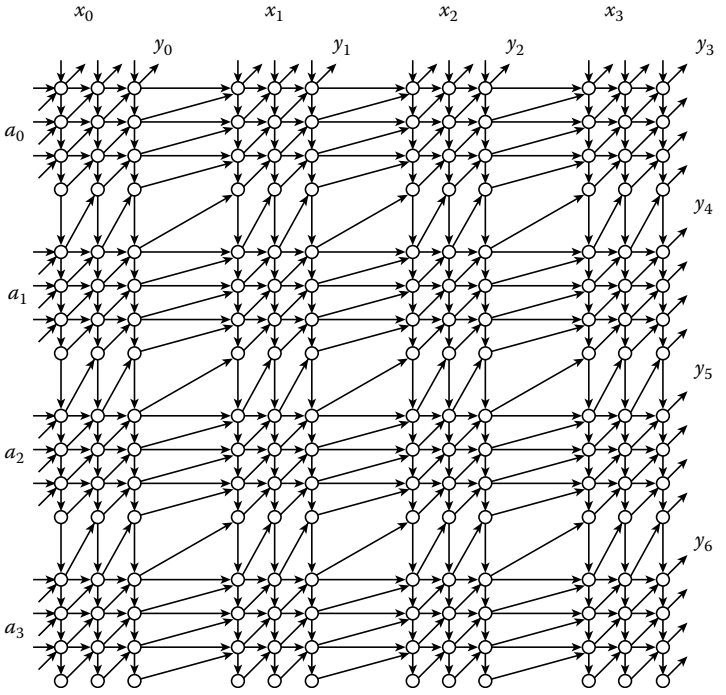

FIGURE 9.109 Bit-level dependence graph for convolution obtained by embedding the bit-level graph into the word-level graph.

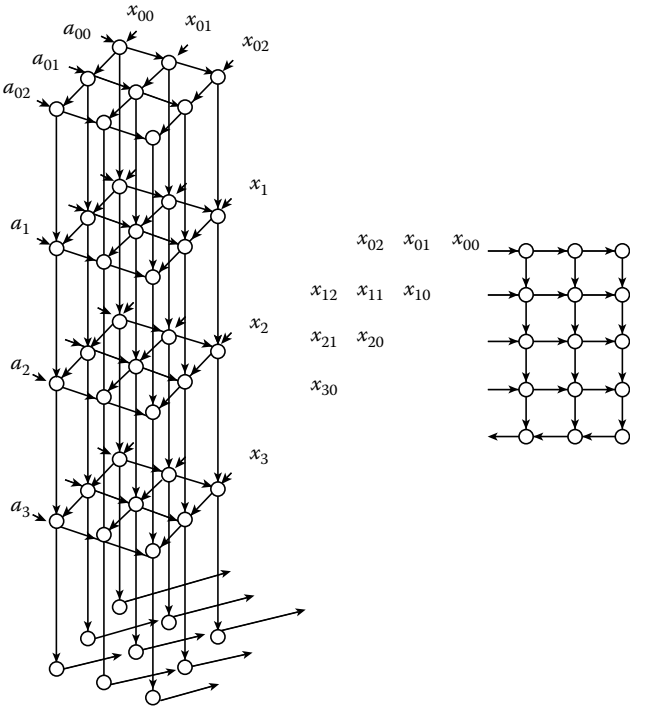

FIGURE 9.110 General three-dimensional bit-level dependence graph for convolution.

the bottom level of the dependence graph corresponds to the summation over l in Equation 9.23. In the same figure a schematic two-dimensional bit-level systolic realization of the algorithm is given, in which the coefficient bits are held in place. Projections along different directions have different characteristics and may be considered preferable in different situations. The choice ultimately must be made according to given design constraints or to efficiency requirements.

The concept of bit-level design, as considered here, can be applied to a large variety of algorithms. Indeed, it has generated a number of architectures, including FIR/IIR filters, arrays for inner product computation, median filtering, image processing, eigenvalue problems, Viterbi decoding, etc.

9.5.4 Recursive LSs Estimation

9.5.4.1 LSs Estimation

The LS technique constitutes one of the most basic components of all modern signal processing algorithms dealing with linear algebraic and optimization of deterministic and random signals and systems. Specifically, some of the most computationally intensive parts of modern spectral analysis, beam formation, direction finding, adaptive array, image restoration, robotics, data compression, parameter estimation, and KF all depend crucially on LS processing.

Regardless of specific application, an LS estimation problem can be formulated as $Ax \approx y$, where the $m \times n$ data matrix A and the $m \times 1$ data vector y are known, and we seek the $n \times 1$ desired solution x. In certain signal processing problems, rows of A are composed of sequential blocks of lengths n taken from a one-dimensional sequence of observed data. In other n-sensor multichannel estimation problems, each column of A denotes the sequential outputs of a given sensor. In all cases, the desired solution x provides the weights on the linear combinations of the columns of A to optimally approximate the observed vector y in the LS sense. When $m = n$ and A is nonsingular, then an exact solution for x exists. The Gaussian elimination method provides an efficient approach for determining this exact solution. However, for most signal processing problems, such as when there are more observations than sensors, and thus $m > n$, then no exact solution exists. The optimum LS solution $\hat{x}$ is defined by $\|A\hat{x} - y\| = \min_x \|Ax - y\|$. The classical approach in LS solution is given by $\hat{x} = A^+ y$, where A^+ is the pseudo-inverse of A defined by $A^+ = (A^{\mathrm{T}} A)^{-1} A^{\mathrm{T}}$. The classical LS approach is not desirable from the complexity, finite precision sensitivity, and processing architecture points of views. This is due to the need for a matrix inversion, the increase of numerical instability from "squaring of the condition number" in performing the $A^{\mathrm{T}}A$ operation, and the block nature of the operation in preventing a systolic update processing and architecture for real-time applications.

The QRD approach provides a numerically stable technique for LS solution that avoids the objections associated with the classical approach. Consider a real-valued $m \times n$ matrix A with $m \geq n$ and all the columns are linearly independent (i.e., rank $A = n$). Then, from the QRD, we can find a $m \times m$ orthogonal matrix Q such that $QA = \overline{R}$. The $m \times n$ matrix $\overline{R} = [R^{\mathrm{T}}, 0^{\mathrm{T}}]^{\mathrm{T}}$ is such that R is an $n \times n$ upper triangular matrix (with nonzero diagonal elements) and 0 is an all-zero $(m - n) \times n$ matrix. This upper triangularity of R is used crucially in the following LS solution problem.

Because the l_2 norm of any vector is invariant with respect to an orthogonal transformation, an application of the QRD to the LS problem yields $\|Ax - y\|^2 = \|Q(Ax - y)\|^2 = \|\overline{R}x - f\|^2$, where f is an $m \times 1$ matrix given by $f = Qy = [u^{\mathrm{T}}, v^{\mathrm{T}}]^{\mathrm{T}}$. Denote $e = Ax - y$ as the "residual" of the LS problem. Then, the previous LS problem is equivalent to $\|e\|^2 = \|Ax - y\|^2 = \|[Rx, 0x]^{\mathrm{T}} - [u^{\mathrm{T}} - v^{\mathrm{T}}]^{\mathrm{T}}\|^2 = \|Rx - u\|^2 + \|v\|^2$. Because R is a nonsingular upper triangular square matrix, the back substitution procedure of the Gaussian elimination method can be used to solve for the exact solution $\hat{x}$ of $R\hat{x} = u$. Finally, the LS problem reduces to $\min_x \|Ax - y\|^2 = \|A\hat{x} - y\|^2 = \|-R\hat{x} - f\|^2 = \|R\hat{x} - u\|^2, + \|v\|^2 = \|v\|^2$. For the LS problem, any QRD technique such as the Gram–Schmidt method, the modified-Gram–Schmidt (MGS) method, the Givens transformation, and the Householder transformation is equally valid for

finding the matrix R and the vector v. For a systolic implementation, the Givens transformation yields the simplest architecture, but the MGS and Householder transformation techniques are also possible with slight advantages under certain finite precision conditions.

9.5.4.2 Recursive LSs Estimation

The complexity involved in the computation of the optimum residual $\hat{e}$ and the optimum LS solution vector $\hat{x}$ can become arbitrarily large as the number of samples in the column vectors of A and y increases. In practice, we must limit m to some finite number greater than the number of columns n. Two general approaches in addressing this problem are available. In the ''sliding window'' approach, we periodically incorporate the latest observed set of data (i.e., ''updating'') and possibly remove an older set of data (i.e., ''downdating''). In the ''forgetting factor'' approach, a fixed scaling constant with a magnitude between 0 and 1 is multiplied against the R matrix and thus exponentially forget older data. In either approach, we find the optimum LS solution weight vector $\hat{x}$ in a recursive LSs manner. As the statistics of the signal change over each window, these $\hat{x}$ vectors change ''adaptively'' with time. This observation motivates the development of a recursive LSs solution implemented via the QRD approach. For simplicity, we consider only the updating aspects of the sliding window recursive LSs problem.

Let m denote the present time of the sliding window of size m. Consider the $m \times n$ matrix $A(m)$, the $m \times 1$ column vector $y(m)$, the $n \times 1$ solution weight column vector $x(m)$, and the $m \times 1$ residual column vector $e(m)$ expressed in terms of their values at time $m-1$ as $A(m) = [\alpha\ (1), \ldots, \alpha\ (m)]^{\mathrm{T}} = [A(m-1)^{\mathrm{T}}, \alpha\ (m)]^{\mathrm{T}}$, $y(m) = [y_1, \ldots, y_m]^{\mathrm{T}}\ [y(m-1)^{\mathrm{T}}, y^{\mathrm{T}}m]^{\mathrm{T}}$, $x(m) = [x_1(m), \ldots, x_n(m)]^{\mathrm{T}}$, and $e(m)\ A(m) \times (m) - y(m) = [e_1(m), \ldots, e_n(m)]^{\mathrm{T}}$. By applying the orthogonal matrix $Q(m) = [Q_1(m)^{\mathrm{T}}, Q_2(m)^{\mathrm{T}}]^{\mathrm{T}}$ of the QRD of the $m \times n$ matrix $A(m)$, we obtain $Q(m)\ A(m) = [R(m)^{\mathrm{T}},\ 0^{\mathrm{T}}]^{\mathrm{T}} = R_0(m)$ and $Q(m)y(m) = [Q_1(m)^{\mathrm{T}}, Q_2(m)^{\mathrm{T}}]^{\mathrm{T}}\ y(m) = [u(m)^{\mathrm{T}},\ v(m)^{\mathrm{T}}]^{\mathrm{T}}$. The square of the l_2 norm of the residual e is then given by $\in(m) = \|e(m)\|^2 = \|A(m)x(m) - y(m)\|^2 = \|Q(m)(A(m)x(m) - y(m))\|^2 = \|R(m)x(m) - u(m)\|^2 + \|v(m)\|^2$. The residual is minimized by using the back substitution method to find the optimum LS solution $\hat{x}(m)$ satisfying $R(m)\hat{x}(m) = u(m) = [u_1(m), \ldots, u_n(m)]^{\mathrm{T}}$. It is clear that the optimum residual $\hat{e}(m)$ is available after the optimum LS solution $\hat{x}(m)$ is available as seen from $\hat{e}(m) = A(m)\hat{x}(m) - y(m)$. It is interesting to note that it is not necessary to first obtain $\hat{x}(m)$ explicitly and then solve for $\hat{e}(m)$ as shown earlier. It is possible to use a property of the orthogonal matrix $Q(m)$ in the QRD of A and the vector $y(m)$, to obtain $\hat{e}(m)$ explicitly. Specifically, note $\hat{e}(m) = A(m)\hat{x}(m) - y(m) = Q_1(m)^{\mathrm{T}}\ R(m)\hat{x}(m) - y(m) = [Q_1(m)^{\mathrm{T}}\ Q_1(m) - I_m]y(m) = -Q_2(m)^{\mathrm{T}}\ Q_2(m)y(m) = -Q_2(m)^{\mathrm{T}}v(m)$. This property is used explicitly in the following systolic solution of the last component of the optimum residual.

9.5.4.3 Recursive QRD

Consider the recursive solution of the QRD. First, assume the decomposition at step $m-1$ has been completed as given by $Q(m-1)A(m-1) = [R(m-1)^{\mathrm{T}}, 0^{\mathrm{T}}]^{\mathrm{T}}$ by using a $(m-1) \times (m-1)$ orthogonal matrix. Next, define a new $m \times m$ orthogonal transformation $T(m) = [Q(m-1), 0; 0, 1]$. By applying $T(m)$ on the new $m \times n$ data $A(m)$, which consists of the previously available $A(m-1)$ and the newly available row vector $\alpha(m)^{\mathrm{T}}$ we have

$$T(m)A(m) = \begin{bmatrix} Q(m-1) & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} A(m-1) \\ \alpha(m)^T \end{bmatrix} = \begin{bmatrix} Q(m-1)A(m-1) \\ \alpha(m)^T \end{bmatrix}$$
$$= \begin{bmatrix} R(m-1) \\ 0 \\ \alpha(m)^T \end{bmatrix} = R_1(m)$$

While $R(m-1)$ is an $n \times n$ upper triangular matrix, $R_1(m)$ does not have the same form as the desired $R_0(m) = [R(m)^{\mathrm{T}}, 0^{\mathrm{T}}]^{\mathrm{T}}$ where $R(m)$ is upper triangular.

9.5.4.4 Givens Orthogonal Transformation

Next, we want to transform $R_1(m)$ to the correct $R_0(m)$ form by an orthogonal transformation $G(m)$. While any orthogonal transformation is possible, we will use the Givens transformation approach due to its simplistic systolic array implementation. Specifically, denote $G(m) = G_n(m)G_{n-1}(m)\ldots G_1(m)$, where $G(m)$ as well as each $G_i(m)$, $i = 1,\ldots n$, are all $m \times m$ orthogonal matrices. Define

$$G_i(m) = \begin{array}{c} \\ 1 \\ \\ i \\ \\ m \end{array} \begin{array}{c} \begin{array}{ccccc} 1 & & i & & m \end{array} \\ \begin{bmatrix} 1 & & 0 & & 0 \\ & 1 & & & \\ 0 & & c_i(m) & & s_i(m) \\ & & & 1 & \\ 0 & & -s_i(m) & & c_i(m) \end{bmatrix} \end{array}, \quad i = 1,\ldots,n$$

as a $m \times m$ identity matrix, except that the (i, i) and (m, m) elements are specified as $c_i(m) = \cos\theta_i(m)$, where $\theta_i(m)$ represents the rotation angle at the ith iteration, the (i, m) element as $s_i(m) = \sin\theta_i(m)$, and the (m, i) element as $-S_i(m)$. By cascading all the $G_i(m)$, $G(m)$ can be reexpressed as

$$G(m) = \begin{bmatrix} k(m) & 0 & d(m) \\ 0 & I_{m-n-1} & 0 \\ h^T(m) & 0 & \gamma(m) \end{bmatrix}$$

where $k(m)$ is $n \times n$, $d(m)$ and $h(m)$ are $n \times 1$, and $\gamma(m)$ is 1×1. In general $k(m)$, $d(m)$, and $h(m)$ are quite involved functions of $c_i(m)$ and $s_i(m)$, but $\gamma(m)$ is given simply as $\gamma(m) = \prod_{i=1}^{n} c_i(m)$ and will be used in the evaluation of the optimum residual.

Use $G(m)$ to obtain $G(m)T(m)A(m) = G(m)R_1(m)$. In order to show the desired property of the n orthogonal transformation operations of $G(m)$, first consider

$$G_1(m)R_1(m) = \begin{bmatrix} c_1(m) & & & & s_1(m) \\ & 1 & & & \\ & & 1 & & \\ & & & 1 & \\ s_1(m) & & & & c_1(m) \end{bmatrix} \begin{bmatrix} x & x & \cdots & x \\ 0 & x & \cdots & x \\ & & \cdots & x \\ 0 & 0 & \cdots & x \\ x & x & \cdots & x \end{bmatrix}$$

$$= \begin{bmatrix} x & x & \cdots & x \\ 0 & x & \cdots & x \\ & & \cdots & x \\ 0 & 0 & \cdots & x \\ 0 & x & \cdots & x \end{bmatrix}$$

In the preceding expression, an x denotes some nonzero valued element. The purpose of $G_1(m)$ operating on $R_1(m)$ is to obtain a zero at the $(m, 1)$ position without changing the $(m-2) \times n$ submatrix from the second to the $(m-1)$st rows of the r.h.s. of the expression. In general, at the ith iteration, we have

$$G_i(m) \begin{bmatrix} x & x & . & . & . & x \\ & x & . & . & . & x \\ & & & & & x \\ & & & \vdots & & \\ 0 & 0 & . & . & . & 0 \\ 0 & 0 & 0 & x & x & x \\ & & & \underset{i-1}{} & & \end{bmatrix} = \begin{bmatrix} x & x & . & . & . & x \\ & x & . & . & . & x \\ & & & & & x \\ & & & \vdots & & \\ 0 & 0 & . & . & . & 0 \\ 0 & 0 & 0 & 0 & x & x \\ & & & \underset{i}{} & & \end{bmatrix}$$

The preceding zeroing operation can be explained by noting that the Givens matrix $G_i(m)$ operates as a $(m-2)\times(m-2)$ identity matrix on all the rows on the right of it except the ith and the mth rows. The crucial operations at the ith iteration on these two rows can be represented as

$$\begin{bmatrix} c & s \\ -s & c \end{bmatrix} \quad \begin{bmatrix} 0 & \cdots & 0 & r_i & r_{i+1} & \cdots & r_n \\ 0 & \cdots & 0 & \underset{i}{a_i} & a_{i+1} & \cdots & a_n \end{bmatrix}$$

$$= \begin{bmatrix} 0 & \cdots & 0 & r_i^T & r_{i+1}^T & \cdots & r_n^T \\ 0 & \cdots & 0 & \underset{i}{0} & a_{i+1}^T & \cdots & a_n^T \end{bmatrix}$$

For simplicity of notation, we suppress the dependencies of i and m on c and s. Specifically, we want to force $a_i^{\mathrm{T}}=0$ as given by $0=a_i^{\mathrm{T}}=-sr_i+ca_i$. In conjunction with $c^2+s^2=1$, this requires $c^2=r_i^2/(a_i^2+r_i^2)$ and $s^2=a_i^2/(a_i^2/r_i^2)$. Then $r_i^{\mathrm{T}}=cr_i+sa_i=\sqrt{(a_i^2+r_i^2)}$, $c=r_i/r_i^{\mathrm{T}}$, and $s=a_i/r_i^{\mathrm{T}}$. This shows from the individual results of $G_1(m)$, $G_2(m),\ldots,$ $G_n(m)$, the overall results yield $Q(m)$ $A(m)=G(m)\overline{R}(m)=[R(m)^{\mathrm{T}}$, $0^{\mathrm{T}}]^{\mathrm{T}}=R_0(m)$, with $Q(m)=G(m)T(m)$.

9.5.4.5 Recursive Optimal Residual and LS Solutions

Consider the recursive solution of the last component of the optimum residual $\hat{e}(m)=[\hat{e}_1(m),\ldots,$ $\hat{e}_m(m)]^{\mathrm{T}}=-Q_2(m)^{\mathrm{T}}\,v(m)=-Q_2(m)^{\mathrm{T}}\,[v_1(m),\ldots,v_m(m)^{\mathrm{T}}]$. Because $Q_2(m)=[Q_2(m-1),\ 0;\ h(m)^{\mathrm{T}}$ $Q_1(m-1),\ \gamma(m)]$, then $\hat{e}(m)=[\hat{e}_1(m),\ldots,\hat{e}_m(m)]^{\mathrm{T}}=Q_2(m)=-[Q_2^{\mathrm{T}}(m-1),\ Q_1^{\mathrm{T}}(m-1)h(m);\ 0,\ \gamma(m)]$ $[v_1(m),\ldots,v_m(m)]$. Thus, the last component of the optimum residual is given by $\hat{e}(m)=-\gamma(m)$ $v_m(m)=-\prod_{i=1}^{n}c_i(m)v_m(m)$, which depends on all the products of the cosine parameters $c_i(m)$ in the Givens QR transformation, and $v_m(m)$ is just the last component of $v(m)$, which is the result of $Q(m)$ operating on $y(m)$.

As considered earlier, the LS solution $\hat{x}$ satisfies the triangular system of equations. After the QR operation on the extended matrix $[A(m),\ Y(m)]$, all the $r_{ij}, j\geq i=1,\ldots,n$ and $u_i, i=1,\ldots,n$ are available. Thus, $\{\hat{x}_1,\ldots,\hat{x}_n\}$ can be obtained by using the back substitution method of $\hat{x}_i=(u_i-\Sigma_{j-i+1}^{n}r_{ij}\hat{x}_j/r_{ij})$, $i=n,\ n-1,\ldots,\ 1$. Specifically, if $n=1$, then $\hat{x}_1=u_1/r_{11}$. If $n=2$, then $\hat{x}_2=u_2/r_{22}$ and $\hat{x}_1=u_1-r_{12}\hat{x}_2/$ $r_{11}=u_1/r_{11}-u_2r_{12}/r_{11}r_{22}$. If $n=3$, then $\hat{x}_3=u_3/r_{33},\hat{x}_2=u_2-r_{23}x_3/r_{22}=u_2/r_{22}-r_{23}u_3/r_{22}r_{23}$, and $\hat{x}_1=u_1-r_{12}\hat{x}_2-r_{13}\hat{x}_3/r_{11}=u_1/r_{11}-r_{12}u_2/r_{11}r_{22}+u_3[-r_{13}/r_{11}r_{33}+r_{12}r_{23}/r_{11}r_{22}r_{33}]$.

9.5.4.6 Systolic Array Implementation for QRD and LS Solution

The recursive QRD considered above can be implemented on a two-dimensional triangular systolic array based on the usage of four kinds of processing cells. Figure 9.111a shows the boundary cell for the generation of the sine and cosine parameters, s and c, needed in the Givens rotations. Figure 9.111b shows the internal cell for the proper updating of the QRD transformations. Figure 9.111c shows the single output cell needed in the generation of the last component of the optimal residual $\hat{e}_m(m)$ as well as the optimal LS solution $\hat{x}(m)$. Figure 9.111d shows the delay cell which performs a unit time delay for proper time skewing in the systolic processing of the data.

Figure 9.112 shows a triangular systolic array capable of performing the recursive QRD for the optimal recursive residual estimation and the recursive LSs solution by utilizing the basic processing cells in Figure 9.111. In particular, the associated LS problem uses an augmented matrix $[A,y]$ consisting of the $m\times n$ observed data matrix A and the $m\times 1$ observed vector y. The number or processing cells in the triangular array consists of n boundary cells, $n(n+1)/2$ internal cells, one output cell, and n delay cells.

The input to the array in Figure 9.112 uses the augmented matrix

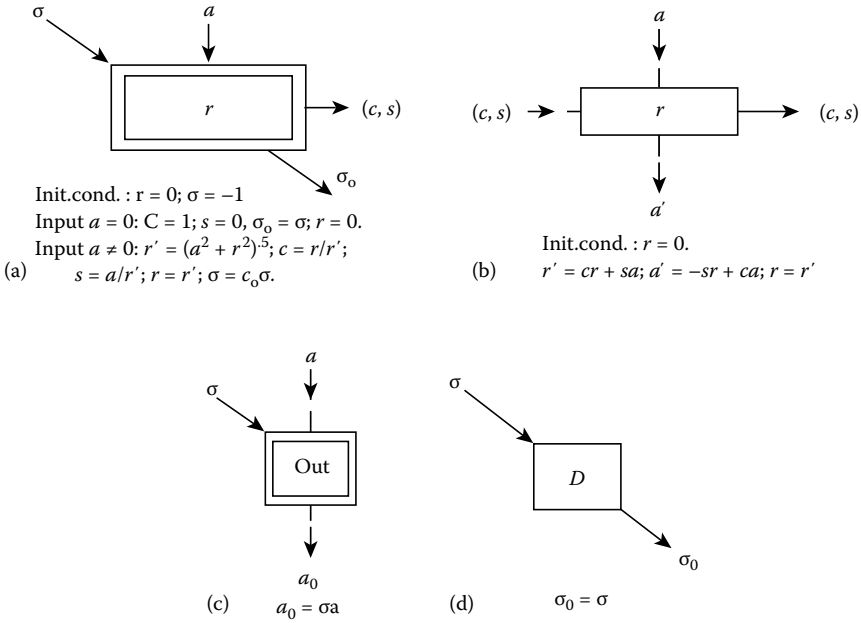

FIGURE 9.111 (a) Boundary cell; (b) internal cell; (c) output cell; and (d) delay cell.

$$[A,Y] = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} & y_1 \\ a_{21} & a_{22} & \cdots & a_{2n} & y_2 \\ & & \vdots & & \\ a_{m1} & a_{m2} & \cdots & a_{mn} & y_m \end{bmatrix}$$

skewed in a manner such that each successive column from left to right is delayed by a unit time as given by

$$\begin{bmatrix} a_{11} & 0 & & \cdots & 0 & 0 \\ a_{21} & a_{12} & 0 & \cdots & 0 & 0 \\ a_{31} & a_{22} & a_{13} & \cdots & 0 & 0 \\ & & & \vdots & & \\ a_{n1} & a_{(n-1)2} & & & a_{1n} & 0 \\ a_{(n+1)1} & a_{n2} & & & a_{2n} & y_1 \\ & & & \vdots & & \\ a_{m1} & a_{(m-1)2} & & & a_{(m-n+1)n} & y_{m-n} \\ & & & \vdots & & \\ 0 & & & & a_{mn} & y_{m-1} \\ 0 & & & & 0 & y_m \end{bmatrix} \begin{matrix} k=1 \\ 2 \\ 3 \\ \vdots \\ n \\ n+1 \\ \vdots \\ m \\ \vdots \\ m+n-1 \\ m+n \end{matrix}$$

We see that at time k, input data consists of the kth row of the matrix, and moves down with increasing time. However, in Figure 9.112, purely for drawing purpose in relation to the position of the array, the relevant rows of data are drawn as moving up with increasing k.

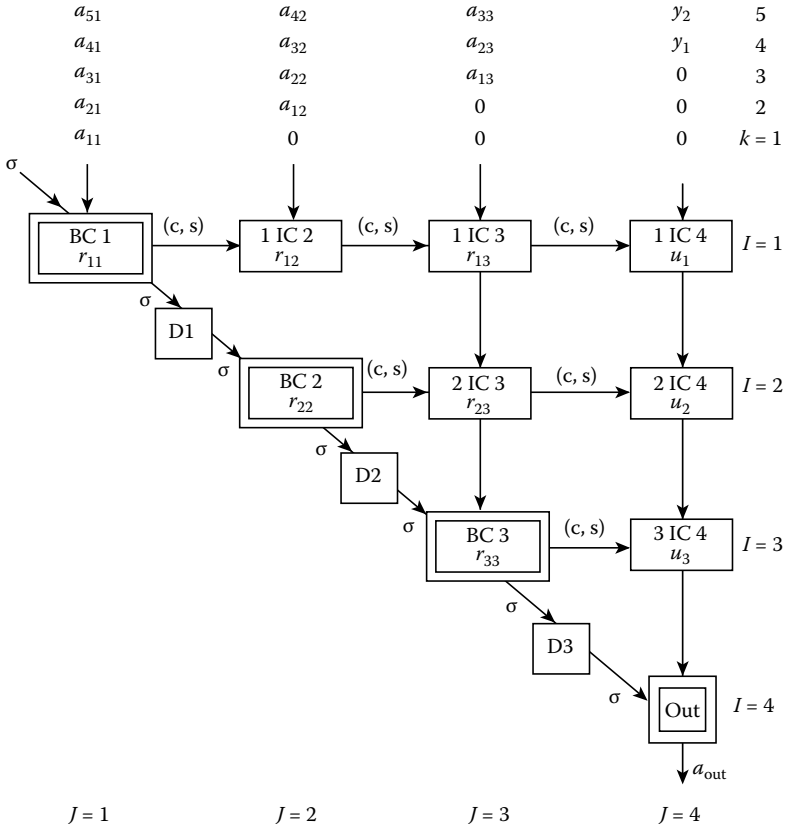

FIGURE 9.112 Triangular systolic array implementation of an $n = 3$, QRD-recursive, LSs solver.

Consider some of the iterative operations of the QRD for the augmented matrix $[A, y]$ for the systolic array in Figure 9.112. At time $k = 1$, a_{11} enters BC 1 and results in $c = 0$, $s = 1$, and $r_{11} = a_{11}$. All other cells are inactive. At $k = 2$, a_{21} enters BC 1, with the results $c = a_{11}\sqrt{(a_{11}^2 + a_{21}^2)}$, $s = a_{21}\sqrt{(a_{11}^2 + a_{21}^2)}$,$r_{11} = \sqrt{a_{11}^2 + a_{21}^2}$. This r_{11} corresponds to that of r_i^{T}, while the preceding c and s correspond to the c and s in the Givens transformation. Indeed, the new a_i^{T} is zero and does not need to be saved in the array. Still, at $k = 2$, a_{12} enters 1 IC 2 and outputs $a^{\mathrm{T}} = 0$ and $r_{12} = a_{12}$. At $k = 3$, a_{13} enters BC 1, and the Givens rotation operation continues where the new r_i is given by the previously processed r_i^T and a_i is now given by a_{13}. Meanwhile, a_{22} enters at 1 IC 2. It outputs $a^{\mathrm{T}} = -a_{21}a_{12}/\sqrt{(a_{11}^2 + a_{21}^2)} + -a_{22}a_{21}/\sqrt{(a_{11}^2 + a_{21}^2)}$, which corresponds to that of a_{i+1}^T, and $r_{12} = a_{11}a_{12}/\sqrt{(a_{11}^2 + a_{21}^2)} + -a_{21}a_{22}/\sqrt{(a_{11}^2 + a_{21}^2)}$, which corresponds to that of r_{i+1}^T. In general, the top (i.e., $I = 1$) row of the processing cells performs Givens rotation by using the first row to operate on the second, third,..., mth rows (each row with $n + 1$ elements), such that the $\{21, 31, \ldots, m1\}$ locations in the augmented matrix are all zeroed. The next row ($I = 2$) of cells uses the second row to operate on the third,..., mth rows (each row with n elements), such that locations at $\{32, 42, \ldots, m2\}$ are zeroed. Finally, at row $I = n$, by using the nth row to operate on the $(n + 1)$st,..., mth rows, elements at locations $\{(n + 1)n, (n + 2)n, \ldots, mn\}$ are zeroed. We also note that the desired cosine values in $\gamma(m)$ are being accumulated by c along the diagonal of the array. Delay cells $\{D_1, D_2, \ldots, D_n\}$ are used to provide the proper timing along the diagonal.

The cell BC 1 (at $I = J = 1$) terminates in the QR operation at time $k = m$, while the cell at $I = 1$ and $J = 2$ terminates at $k = m + 1$. In general, the processing cell at location (I, J) terminates at

$k = I + J + m - 2$. In particular, the last operation in the QRD on the augmented matrix is performed by the cell at $I = n$ and $J = n + 1$ at time $k = 2n + m - 1$. Then, the last component of the optimum residual $e_m(m)$ exits the output cell at time $k = 2n + m$.

After the completion of the QRD obtains the upper triangular system of equation, we can "freeze" the r_{IJ} values in the array to solve for the optimum LS solution $\hat{x}$ by the back substitution method. Specifically, we can append $[I_n, 0]$, where I_n is a $n \times n$ identity matrix and 0 is an $n \times 1$ vector of all zeroes, to the bottom of the augmented matrix $[A, y]$. Of course, this matrix is skewed as before when used as input to the array. In particular, immediately after the completion of the QR operation at BC 1, we can input the unit value at time $k = m + 1$. This is stage 1 of the back substitution method. Due to skewing, a unit value appears at the $I = 1$ and $J = 2$ cell at stage 3. Finally, at stage $(2n - 1)$, which is time $k = m + 2n - 1$, the last unit value appears at the $I = n$ and $J = 1$ cell. For our example of $n = 3$, this happens at stage 5. The desired LS solution $\hat{x}_1$ appears at stage $(2n + 1)$ (i.e., stage 7 for $n = 3$), which is time $k = 2n + m + 1$, while the last solution $\hat{x}_n$ appears at stage $3n$ (i.e., stage 9 for $n = 3$), which is time $k = 3n + m$. The values of$\{\hat{x}_1, \hat{x}_2, \hat{x}_3\}$ at the output of the systolic array are identical to those given by the back substitution method solution of the LS problem.

9.5.5 Kalman Filtering

KF was developed in the late 1950s as a natural extension of the classical Wiener filtering. It has profound influence on the theoretical and practical aspects of estimation and filtering. It is used almost universally for tracking and guidance of aircraft, satellites, GPS, and missiles as well as many system estimation and identification problems. KF is not one unique method, but is a generic name for a class of state estimators based on noisy measurements. KF can be implemented as a specific algorithm on a general-purpose mainframe/mini/microcomputer operating in a batch mode, or it can be implemented on dedicated system using either DSP, ASIC, or custom VLSI processors in a real-time operating mode.

Classically, an analog or a digital filter is often viewed in the frequency domain having some low-pass, bandpass, high-pass, etc. properties. A KF is different from the classical filter in that it may have multiple inputs and multiple outputs with possibly nonstationary and time-varying characteristics performing optimum states estimation based on the unbiased minimum variance estimation criterion.

In the following discussions, we first introduce the basic concepts of KF, followed by various algorithmic variations of KF. Each version has different algorithmic and hardware complexity and implementational implications. Because there are myriad of KF variations, we then consider two simple systolic versions of KF.

9.5.5.1 Basic KF

The KF model consists of a discrete-time linear dynamical system equation and a measurement equation. A linear discrete-time dynamical system with $n \times 1$ state vector $x(k+1)$, at time $k+1$, is given by $x(k+1) = \mathrm{A}(k)x(k) + B(k)u(k) + w(k)$, where $x(k)$ is the $n \times 1$ state vector at time k, $A(k)$ is an $n \times n$ system coefficient matrix, $B(k)$ is an $n \times p$ control matrix, $u(k)$ is a $p \times 1$ deterministic vector, which for some problems may be zero for all k, and $w(k)$ is an $n \times 1$ zero-mean system noise vector with a covariance matrix $W(k)$. The input to the KF is the $m \times 1$ measurement (also called observation) vector $y(k)$, modeled by $y(k) = C(k)x(k) + v(k)$, where $C(k)$ is an $m \times n$ measurement coefficient matrix, and $v(k)$ is a $m \times 1$ zero-mean measurement noise vector with an $m \times m$ positive-definite covariance matrix $V(k)$. The requirement of the positive-definite condition on $V(k)$ is to guarantee the Cholesky (square root) factorization of $V(k)$ for certain KF algorithms. In general, we will have $m \leq n$ (i.e., the measurement vector dimension is less than or equal to that of the state vector dimension). It is also assumed that $w(k)$ is uncorrelated to $v(k)$. That is, $E\{w(i)v(j)^{\mathrm{T}}\} = 0$. We also assume each noise sequence is white in the sense $E\{w(i)w(j)^{\mathrm{T}}\} = E\{v(i)v(j)^{\mathrm{T}}\} = 0$, for all $i \neq j$.

The KF provides a recursive linear estimation of $x(k)$ under the minimum variance criterion based on the observation of the measurement $y(k)$. Let $\hat{x}(k)$ denote the optimum filter state estimate of $x(k)$ given

measurements up to and including $y(k)$, while $\hat{x}_+(k)$ denotes the optimum predicted state estimate of $x(k)$ given measurement up to and including $y(k-1)$. Then the $n \times n$ "optimum estimation error covariance matrix" is given by $P(k) = E\{(x(k) - \hat{x}(k))(x(k) - \hat{x}(k))^{\mathrm{T}}\}$, while the "minimum estimation error variance" is given by $J(k) = \text{Trace } P(k) = E\{(x(k) - \hat{x}(k))^{\mathrm{T}} (x(k) - \hat{x}(k))\}$. The $n \times n$ "optimum prediction error covariance matrix" is given by $P_+(k) = E\{(x(k) - x_+(k))(x(k) - x_+(k))^{\mathrm{T}}\}$.

The original KF recursively updates the optimum error covariance and the optimum state estimate vector by using two sets of update equations. Thus, it is often called the "covariance KF." The "time update equations" for $k = 1, 2, \ldots$, are given by $x_+(k) = A(k-1)\ \hat{x}(k-1) + B(k-1)u(k-1)$ and $P_+(k) = A(k-1)\ P(k-1)A^{\mathrm{T}}(k-1) + W(k-1)$. The $n \times n$ "Kalman gain matrix" $K(k)$ is given by $K(k) = P_+(k)C^{\mathrm{T}}(k)[C(k)P_+(k)C^{\mathrm{T}}(k) + V(k)]^{-1}$. The "measurement update equations" are given by $\hat{x}(k) = x_+(k) + K(k)(y(k) - C(k)x_+(k))$ and $P(k) = P_+(k) - K(k)P_+(k)$. The first equation shows the update relationship of $\hat{x}(k)$ to the predicted state estimate $x_+(k)$, for $x(k)$ based on $\{\ldots, y(k-2), y(k-2), y(k-1)\}$, when the latest observed value $y(k)$ is available. The second equation shows the update relationship between $P(k)$ and $P_+(k)$. Both equations depend on the $K(k)$, which depends on the measurement coefficient matrix $C(k)$and the statistical property of the measurement noise, covariance matrix $V(k)$. Furthermore, $K(k)$ involves an $m \times m$ matrix inversion.

9.5.5.2 Other Forms of KF

The basic KF algorithm considered above is called the covariance form of KF because the algorithm propagates the prediction and estimation error covariance matrices $P_+(k)$ and $P(k)$. Many versions of the KF are possible, characterized partially by the nature of the propagation of these matrices. Ideally, under infinite precision computations, no difference in results is observed among different versions of the KF. However, the computational complexity and the systolic implementation of different versions of the KF are certainly different. Under finite precision computations, especially for small numbers of bits under fixed point arithmetics, the differences among different versions can be significant. In the following discussions we may omit the deterministic control vector $u(k)$ because it is usually not needed in many problems. In the following chol (.) qr (.), and triu (.) stand for Cholesky factor, QRD, and triangular factor, respectively.

1. **Information filter**. The inverse of the estimation error covariance matrix $P(k)$ is called the information matrix and is denoted by $PI(k)$. A KF can be obtained by propagating the information matrix and other relevant terms. Specifically, the information filter algorithm is given by time updates for $k = 1, 2, \ldots,$ of $L(k) = A^{-\mathrm{T}}(k-1)PI(k-1)A^{-1}(k-1) \times [W^{-1}(k-1) + A^{-\mathrm{T}}(k-1)\ PI(k-1)A^{-\mathrm{T}}(k-1)]^{-1}$, $d_+(k) = (I - L(k))A^{-\mathrm{T}}(k-1)PI(k-1)A^{-1}(k-1)$. The measurements updates are given by $d(k) = d_+(k) + C^{\mathrm{T}}(k)V^{-1}(k)y(k)PI(k) = PI_+(k) + C^{\mathrm{T}}(k)V^{-1}(k)C(k)$.
2. **Square-root covariance filter (SRCF)**. In this form of the KF, we propagate the square root of $P(k)$. In this manner, we need to use a lower dynamic range in the computations and obtain a more stable solution under finite precision computations. We assume all three relevant covariance matrices are positive-definite and have the factorized form of $P(k) = S^{\mathrm{T}}(k)S(k)$, $W(k) = S_W^T(k)S_W(k)$, $V(k) = S^{\mathrm{T}}(k)\ S_v(k)$. In particular, $S(k) = \text{chol}(P(k))$, $S_W(k) = \text{chol}(W(k))$, $S_V(k) = \text{chol}(V(k))$, are the upper triangular Cholesky factorizations of $P(k)$, $W(k)$, and $V(k)$, respectively. The time updates for $k = 1, 2, \ldots,$ are given by $x_+(k) = A(k-1)\hat{x}(k-1)$, $U(k) = \text{triu}(\text{qr}([S(k-1)A^{\mathrm{T}}(k-1); S_W(k-1)]))$, $P_{+s}(k) = U(k)(1{:}n;\ 1{:}n)$. The measurement updates are given by $P_+(k) = P_{+s}^{\mathrm{T}}(k)P_{+s}(k)$,/,$K(k) = P_+(k)C^+(k)[C(k)P_+(k)C^+(k) + V(k)]^{-1}$, $\hat{x}(k) + K(k)(y(k) - C(k)x_+(k))$, $Z(k) = \text{triu}(qr([S_v(k),\ 0_{mn}; P_{+s}(k)C^+(k), P_{+s}(k)]))$ and $S(k) = \text{Z}(k)(m+1{:}\ m+n, m+1{:}\ m+n)$.
3. **Square-root information filter (SRIF)**. In the SRIF form of the KF, we propagate the square root of the information matrix. Just as in the SRCF approach, as compared to the conventional covariance form of the KF, the SRIF approach, as compared to the SRIF approach, needs to use a lower dynamic range in the computations and obtain a more stable solution under finite precision computations. First, we denote $SI(k) = (\text{chol}(P(k)))^{-1}$, $SI_W(k) = (\text{chol}(W(k)))^{-1}$, and

$SI_V(k) = (\text{chol}(V(k)))^{-1}$. The time updates for $k = 1, 2, \ldots$, are given by $U(k) = \text{triu}(\text{qr}([SI_W(k-1), 0_{n\times n}, 0_{n\times 1}; SI(k-1)A^{-1}(k-1), SI(k-1)A^{-1}(k-1), b(k-1)]))$, $P_{+S}(K) = U(k)(n+1{:}2n, n+1{:}2n)$ and $b_+(k) = U(k)(n+1{:}\ 2n,\ 2n+1)$. The measurement updates are given by $Z(k) = \text{triu}(\text{qr}([P_{+S}(k), b_+(k); SI_V(k)C(k), SI_V(k)y(k)]))SI(k) = Z(k)(1{:}n, 1{:}n)$, and $b(k) = Z(k)(1{:}\ n, n+1)$. At any iteration, $\hat{x}(k)$ and $P(k)$ are related to $b(k)$ and $SI(k)$ by $\hat{x}(k) = SI(k)b(k)$ and $P(k) = (SI^{\text{T}}(k)SI(k))^{-1}$.

9.5.5.3 Systolic Matrix Implementation of the KF Predictor

The covariance KF for the optimum state estimate $\hat{x}(k)$ includes the KF predictor $x_+(k)$ In particular, if we are only interested in $x_+(k)$ a relatively simple algorithm for $k = 1, 2, \ldots$, is given by $K(k) = P_+(k)C^{\text{T}}(k)[C(k)P_+(k)C^{\text{T}}(k) + V(k)]^{-1}$, $x_+(k+1) = A(k)\ x_+(k) + A(k)\ K(k)\ [y(k) - C(k)x_+(k)]$ and $P_+(k+1) = A(k)P_+(k)A^{\text{T}}(k) - A(k)K(k)C(k)P_+(k)A^{\text{T}}(k) + W(k)$. To start this KF prediction algorithm, we use $\hat{x}(0)$ and $P(0)$ to obtain $x_+(1) = A(0)\hat{x}(0)$ and $P_+(1) = A(0)P(0)A^{\text{T}}(0) + W(0)$. The above operations involve matrix inverse; matrix–matrix and matrix–vector multiplications; and matrix and vector additions. Fortunately, the matrix inversion of $\alpha = C(k)P_+(k)C^{\text{T}}(k) + V(k)$ can be approximated by the iteration of $\beta(i+1) = \beta(i)[2I - \alpha\ \beta(i)]$, $i = 1, \ldots, I$. Here, $\beta(i)$ is the ith iteration estimate of the inverse of the matrix α. While the preceding equation is not valid for arbitrary α and $\beta(i)$, for KF applications, we can use $I = 4$ because a good initial estimate $\beta(1)$ of the desired inverse is available from the previous step in the KF. Clearly, with the use of the above equation for the matrix inversion, all the operations needed in the KF predictor can be implemented on an orthogonal array using systolic matrix operations of the form $D = B \times A + C$, as shown in Figure 9.113.

The recursive algorithm of the KF predictor is decomposed as a sequence of matrix multiplications, as shown in Table 9.14. In step 1 the $n \times n$ matrix $P_+(k)$ and the $m \times n$ matrix $C^{\text{T}}(k)$ are denoted as B and A, respectively. The rows of B (starting from the n, $n-1, \ldots, 1$ row) are skewed and inputted to the $n \times n$ array starting at time 1. By time n (as shown in Figure 9.113), all the elements of the first column of B (i.e., $b_{n1}, \ldots, b_{11}$) are in the first column of the array. At time $n+1, \ldots, 2n-1$, elements of the second to nth columns of B are inputted to the array and remain there until the completion of the BA matrix multiplication. At time $n+1$, a_{11} enters $(1,1)$ cell and starts the BA process. At time $n+m$, a_{1m} enters the $(1,1)$ cell. Of course, additional times are needed for other elements in the second to the nth rows of A to enter the array. Further processing and propagation times are needed before all the elements of $D = BA = P_+(k)C^{\text{T}}(k)$ are outputted. However, in step 2, because B remains as $P_+(k)$, we do not need to input it again, but only append $A(k)$ (denote as $\tilde{A}$ in Figure 9.113) in the usual skewed manner after the previous $A = C^{\text{T}}(k)$. Thus, at time $n+m+1$, $\tilde{a}_{11}$ enters the $(1, 1)$ cell. By time $n+m+n$, $\tilde{a}_{1n}$ enters the $(1, 1)$ cell. Thus, step 1 takes $n+m$ time units, while step 2 takes only n time units. In step 3 m time units are needed to load $C(k)$ and m time units are needed to input $P_+(k)C^{\text{T}}(k)$, resulting in $2m$ time units. Steps 4 and 5 perform one iteration of the inverse approximation. In general, $I = 4$ iterations is adequate, and $16m$ time units are needed. Thus far, all the matrices and vectors are fed continuously into the array with no delay. However, in order to initiate step 13, the $(n, 1)$ component of $A(k) - A(k)K(k)C(k)$ is needed, but not available. Thus, at the end of step 11, an additional $(n-3)$ time units of delay must be provided to access this component. From Table 9.14, a total of $9n + 22m$ time units is needed to perform one complete KF prediction iteration.

9.5.5.4 Systolic KF Based on the Faddeev Algorithm

A form of KF based on mixed prediction error covariance $P_+(k)$ and information matrix $PI\ (k) = P^{-1}(k)$ updates can be obtained from the covariance KF algorithm. For $k = 1, 2, \ldots$, we have $x_+(k) = A(k-1)\hat{x}(k-1) + B(k-1)$, $P_+(k) = A(k-1)PI^{-1}(k-1)A^{\text{T}}(k-1) + W(k-1)$, $PI(k) = P_+^{-1}(k) + C^{\text{T}}(k)V^{-1}(k)C(k)K(k) = PI^{-1}(k)C^{\text{T}}(k)V^{-1}(k)$ and $\hat{x}(k) = x_+(k) + K(k)(y(k) - C(k)x_+(k))$. The algorithm starts with the given $\hat{x}(0)$ and $P(0)$, as usual. Because this algorithm requires the repeated use of matrix inversions for $(PI(k-1))$, $(P_+(k))^{-1}$, $(V(k))^{-1}$ as well as $P(k) = (PI(k))^{-1}$, the following "Faddeev algorithm" is suited for this approach.

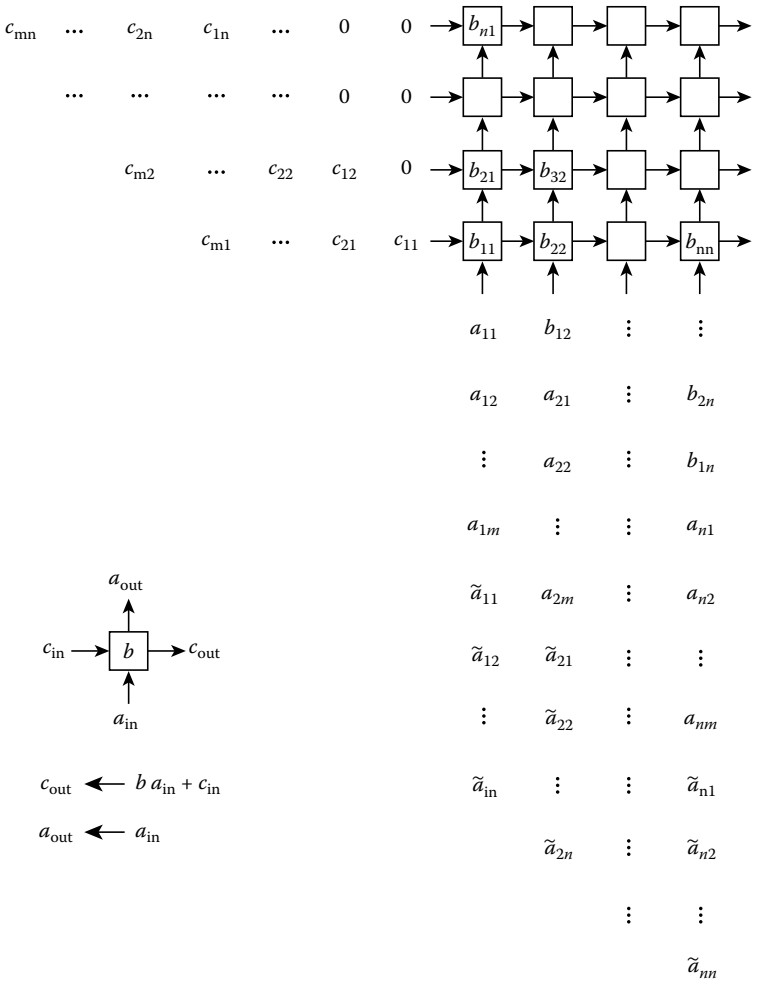

FIGURE 9.113 Systolic matrix multiplication and addition of $B \times A + C$.

TABLE 9.14 Systolic Matrix Operations of a KF Predictor

Step	B	A	C	D	Time

4	α	$-\beta(i)$	$2I$	$2I-\alpha\beta(i)$	$2Im$
5	$\beta(i)$	$2I-\alpha\beta(i)$	0	$\beta(i+1)$	$2Im$
6	$P_+(k)\ C^{\mathrm{T}}(k)$	β	0	$K(k)$	$n+m$
7	$A(k)$	$K(k)$	0	$A(k)K(k)$	$n+m$
8	$A(k)$	$x_+(k)$	0	$A(k)x_+(k)$	1
9	$-C(k)$	$x_+(k)$	$y(k)$	$y(k)-C(k)x_+(k)$	$m+1$
10	$A(k)K)(k)$	$-C(k)$	$A(k)$	$A(k)-A(k)K(k)C(k)$	$2n$
11	$A(k)K(k)$	$y(k)-C(k)x_+(k)$	$A(k)x_+(k)$	$x_+(k+1)$	1
12	$n-3$				
13	$A(k)-A(k)K(k)C(k)$	$P_+(k)A^T(k)$	$W(k)$	$P_+(k)$	$2n$

Consider an $n \times n$ matrix A, an $n \times m$ matrix B, a $p \times n$ matrix C, and a $p \times m$ matrix D arranged in the form of a compound matrix $[A\ B; -C\ D]$. Consider a $p \times n$ matrix W multiplying $[A\ B]$ and added to $[-C\ D]$, resulting in $[A\ B; -C + WAD + WB]$. Assume W is chosen such that $-C + WA = 0$, or $W = CA^{-1}$. Then, we set $D + WB = D + CA^{-1}B$.

In particular, by picking $\{A, B, C, D\}$ appropriately, the basic matrix operations needed above can be obtained using the Faddeev algorithm. Some examples are given by

$$\begin{matrix} A & I \\ -I & 0 \end{matrix} \Rightarrow D + W\ B\ = A^{-1}$$

$$\begin{matrix} I & B \\ -C & 0 \end{matrix} \Rightarrow D + W\ B\ = C\ B$$

$$\begin{matrix} I & B \\ -C & D \end{matrix} \Rightarrow D + W\ B\ = D + C\ B$$

$$\begin{matrix} A & B \\ -I & 0 \end{matrix} \Rightarrow D + W\ B\ = A^{-1}B$$

A modified form of the previous Faddeev algorithm first triangularizes A with an orthogonal transformation Q, which is more desirable from the finite precision point of view. Then, the nullification of the lower left portion can be performed easily using the Gaussian elimination procedure. Specifically, applying a QRD, $Q[A\ B] = [R\ QB]$. Then, applying the appropriate W yields

$$\begin{bmatrix} R & QB \\ -C + W\ Q\ A & D + W\ Q\ B \end{bmatrix} = \begin{bmatrix} R & Q\ B \\ 0 & D + C\ A^{-1}B \end{bmatrix} \tag{9.24}$$

The preceding mixed prediction error covariance and information matrix KF algorithm can be reformulated as a sequence of Faddeev algorithm operations, as given in Table 9.15. The times needed to

TABLE 9.15 Faddeev Algorithm Solution to KF

Step	Compound Matrix		$D + WB$	Time
1	I $-A(k-1)$	$\hat{x}(k-1)$ $B(k-1)u(k-1)$	$x_+(k)$	$n+1$
2	$P^{-1}(k-1)$ $-A(k-1)$	$A^{\mathrm{T}}(k-1)$ $W(k-1)$	$P_+(k)$	$2n$
3	$V(k-1)$ $-C^{\mathrm{T}}(k)$	I 0	$C^{\mathrm{T}}(k)V^{-1}(k-1)$	$m+n$
4	$P_+(k)$ $-I$	I 0	$p_+^{-1}(k)$	$2n$
5	I $-C^{\mathrm{T}}(k)V^{-1}(k)$	$C(k)$ $P_+^{-1}(k)$	$P^{-1}(k)$	N
6	$P^{-1}(k)$ $-I$	$C^{\mathrm{T}(k+1)V^{-1}(k)}$ 0	$K(k)$	$2n$
7	I $C(k)$	$x_+(k)$ $y(k)$	$y(k) - C(k)_{x_+}(k)$	$m+1$
8	I $-K(k)$	$y(k) - C(k)x_+(k)$ $x_+(k)$	$\hat{x}(k)$	$m+1$

perform steps 2, 3, 4, and 6 are clearly just the sum of the lengths of the two matrices in the corresponding steps. Step 1 requires only n times unit to input the second row of matrices because $\hat{x}(k-1)$ is already located in the array from the previous iteration (step 8 output) and one time unit to output $x_+(k)$. Due to the form of $[-I\ 0]$ in step 4, $C(k)$ of step 5 can be inputted before the completion of $P_+^{-1}(k)$ in step 4. Thus, only n time units are needed in step 5. Similarly, $x_+(k)$ of step 7 can be inputted in step 6. Thus, we need only $m+1$ time units to input $[C(k)\ y(k)]$ and complete its operations. In step 8 only $m+1$ time units are needed as in step 1. Thus, a total of $9n+3m+3$ time units are needed for the Faddeev algorithm approach to the KF.

9.5.5.5 Other Forms of Systolic KF and Conclusions

While the operations of a KF can be expressed in many ways, only some of these algorithms are suited for systolic array implementations. For a KF problem with a state vector of dimension n and a measurement vector of dimension m, we have shown the systolic matrix–matrix multiplication implementation of the predictor form of the KF needs $9n+22m$ time steps for each iteration. A form of KF based on mixed update of prediction error covariance and information matrices is developed based on the Faddeev algorithm using matrix–matrix systolic array implementation. It has a total of $9n+3m+3$ time steps per iteration. A modified form of the SRIF algorithm can be implemented as a systolic array consisting of an upper rectangular array of $n(n+1)/2$ internal cells, and a lower n-dimensional triangular array of n boundary cells, and $(n-1)^2/2$ internal cells, plus a row of n internal cells, and $(n-1)$ delay cells. It has a total of n-boundary cells, $((n-1)^2+2n^2+2n)/2$ internal cells, and $(n-1)$ delay cells. Its throughput rate is $3n$ time steps per iteration. A modified form of the SRCF algorithm utilizing the Faddeev algorithm results in a modified SRCF form of a KF consisting of a trapezodial section, a linear section, and a triangular section systolic array. The total of these three sections needs $(n+m)$ boundary cells, n linear cells, and $((m-1)^2+2nm+(n-1)^2)/2$ internal cells. Its throughput rate is $3n+m+1$ time steps per iteration. The operations of both of these systolic KF are quite involved and detailed discussions are omitted here. In practice, in order to compare different systolic KFs, one needs to concern oneself not only with the hardware complexity and the throughput rate, but other factors involving the number of bits needed finite precision computations, data movement in the array, and I–O requirements as well.

9.5.6 Eigenvalue and SVDs

Results from linear algebra and matrix analysis have led to many powerful techniques for the solution of wide range of practical engineering and signal processing problems. Although known for many years, these mathematical tools have been considered too computationally demanding to be of any practical use, especially when the speed of calculation is an issue. Due to the lack of computational power, engineers had to content themselves with suboptimal methodologies of simpler implementation. Only recently, due to the advent of parallel/systolic computing algorithms, architectures, and technologies, have engineers employed these more sophisticated mathematical techniques. Among these techniques are the so-called eigenvalue decomposition (EVD) and the SVD. As an application of these methods, we consider the important problem of spatial filtering.

9.5.6.1 Motivation–Spatial Filtering Problem

Consider a linear array consisting of L sensors uniformly spaced with an adjacent distance d. A number M, $M<L$, of narrowband signals of center frequency f_0, impinging on the array. These signals arrive from M different spatial direction angles $\theta_1,\ldots,\theta_M$, relative to some reference direction. Each sensor is provided with a variable weight. The weighted sensor outputs are then collected and summed. The goal is to compute the set of weights to enhance the estimation of the desired signals arriving from directions $\theta_1,\ldots,\theta_M$.

In one class of beamformation problems, one sensor (sometimes referred to as main sensor) receives the desired signal perturbed by interference and noise. The remaining $L-1$ sensors (auxiliary sensors)

are mounted and aimed in such a way as to collect only the (uncorrelated) interference and noise components. In this scenario the main sensor gain is to be kept at a fixed value, while the auxiliary weights are adjusted in such a way as to cancel out as much perturbation as possible. Obviously, the only difference of this latter cast is that one of the weights (the one corresponding to the main sensor) is kept at a constant value of unity.

Let the output of the ith sensor, $i = 1, \ldots, L$, at discrete time $n = 0, 1, \ldots$, be given by

$$\bar{x}_i(n) = \Re\left\{ [x_i(n) + v_i(n)] e^{j(2\pi f_0 n)} \right\} \quad x_i(n) = a_i(n) \sum_{k=1}^{M} S_k(n) e^{j2\pi(i-1)d \sin\theta_k/\lambda}$$

where

$a_i(n)$ is the antenna gain at time n
S_k is the complex amplitude of the kth signal, inclusive of the initial phase
λ is the signal wavelength

The vectors $x_i(n)$ and $v_i(n)$ are analytic signal representations. The noise $v_i(n)$ is assumed to be uncorrelated white and Gaussian, of power σ_N^2. In order to avoid the ill effects of spatial aliasing, let us also assume that $d \leq \lambda/2$. The outputs of the sensor array for times $n = 0, 1, \ldots, N$, can be collected in matrix form as follows:

$$\underbrace{X}_{N\times L} = \underbrace{S}_{N\times M} = \underbrace{A}_{M\times L} + \underbrace{V}_{N\times L}$$

The matrix A is referred to as the "steering matrix." In the case in which $a_i(n) = 1$ for all i, the matrix A is Vandermonde and full rank, and its kth row can be expressed as $A(\theta) = (1, e^{j2\pi d \sin\theta/\lambda}, \ldots, e^{j2\pi(L-I)d \sin\theta_k/\lambda})$.

The data correlation matrix, $R_X = E\{X^H X\}$, where $E(\cdot)$ is the ensemble average operator, is equal to $R_X = A^H R_s A + \sigma_N^2 I, R_s = \mathrm{E}\{S^H S\}$. We note:

1. The matrix R_s has rank M by definition as does the matrix $A^H R_s A$.
2. The rows of A are in the range space of R_X.
3. The value σ_N^2 is an eigenvalue of R_X with multiplicity $L - M$, given the det $(R_X - \sigma_N^2 I) = 0$, and the rank of $A^H R_s A$ is M.

The EVD of R_X can therefore be written as $R_X = V_S \Lambda_S V_S^H + \sigma_N^2 V_N V_N^H$, where V_S is $L \times M$, V_N is $L \times (L - M)$, $V_S^H V_S = I$ and $V_N^H V_N = 1$, and $V_S^H V_N = 0$. Moreover, we have that $A V_N = 0$. Let $A(\theta)$ be a generic steering vector, defined as $A(\theta) + (1, e^{j2\pi d \sin\theta/\lambda}, \ldots, e^{j2\pi(L-I)d \sin\theta/\lambda})$. Then, the function $\pm(\theta) = 1/|A(\theta) V_N|^2$ has M poles at the angles $\theta = \theta_k k = 1, \ldots, M$. Alternatively, any linear combination, w, of the columns of V_N is such that $E\{\|Xw\|_2\} = \min_z E\{\|Xz\|_2\} = \sigma_N$. In other words, the signals impinging from angular directions $\theta_1, \ldots, \theta_M$ are totally canceled out in the system output.

The desired weighting vector for our spatial filtering problem can consequently be expressed as $w = V_N p$, $p = [p_1, \ldots, p_{L-M}]^{\mathrm{T}}$, for any nonzero vector p. From the above discussion, we see that the solution to the original spatial filtering problem can be obtained from the EVD of the correlation matrix $R_X = E\{X^H X\}$. In practice the sample correlation matrix $\hat{R}_X$ is used instead, where the ensemble average is replaced by a suitable temporal average.

The computation of the covariance matrix implies the computation of the matrix product $X^H X$. Some small elements in X are then squared and the magnitude of the resulting element can become comparable or smaller than the machine precision. Rounding errors can often impair and severely degrade the computed solution. In these cases it is better to calculate the desired quantities (correlation eigenvalues and eigenvectors) directly from the data matrix X using the SVD technique as considered next.

9.5.6.2 EVD of a Symmetric Matrix

Consider an $L \times L$ real symmetric matrix $A = A^{\mathrm{T}}$. In the previous spatial filtering example, $A = R_X$. Let

$$G(i,j,\theta) = \begin{array}{c} \\ i \\ \\ \\ \\ j \\ \\ \end{array} \begin{array}{c} \begin{array}{ccccc} i & & j & & \end{array} \\ \begin{pmatrix} I_{i-1} & & & & \\ & c & & s & \\ & & I_{j-i-1} & & \\ & -s & & c & \\ & & & & I_{L-j} \end{pmatrix} \end{array}$$

be an "orthogonal Givens rotation matrix," where $c = \cos\theta$ and $s = \sin\theta$. Pre- or postmultiplication of A by G leaves A unchanged, except for rows (columns) i and j, which are replaced by a linear combination of old rows (columns) i and j. A "Jacobi rotation" is obtained by simultaneous pre- and postmultiplication of a matrix by a Givens rotation matrix, as given by $G(i, j, \theta)^{\mathrm{T}} A G(i, j, \theta)$, where θ is usually chosen in order to zero out the (i, j) and (j, i) entries of A.

The matrix A can be driven toward diagonal form by iteratively applying Jacobi rotations, as given by $A_0 \leftarrow A$, $A_{k+1} \leftarrow G_k^T A G_k$, where G_k is a Givens rotation matrix. A "sweep" is obtained by applying $L(L-1)/2$ Jacobi rotations, each nullifying a different pair of off-diagonal elements, according to a prespecified order. Given the matrix $A_k = (a_{pq}^{(k)})$ at the kth iteration, and a pair of indices (i, j), the value of $\tan\theta$ can be obtained from the following equations:

$$u = \frac{a_{jj}^{(k)} - a_{ii}^{(k)}}{2a_{ij}^{(k)}}, \quad \tan\theta = \frac{sign(u)}{|u| + \sqrt{1+u^2}} \tag{9.25}$$

It is possible to demonstrate that each Jacobi rotation reduces the matrix off-norm. The matrix A_k indeed tends to diagonal form and for all practical purposes it reaches it after $\mathbb{O}(\log L)$ sweeps.

The matrix V of eigenvectors is obtained by applying the same rotations to a matrix initialized to the identity, as follows: $V_0 \leftarrow I$, $V_{k+1} \leftarrow V_k G_k$. A two-dimensional systolic array implementation of the previous algorithm is shown in Figure 9.114, for the case $L = 8$. At the beginning of iteration k, processor P_{ij} contains elements

$$\begin{pmatrix} a_{2i-1,2j-1}^{(k)} & a_{2i-1,2j}^{(k)} \\ a_{2i,2j-1}^{(k)} & a_{2i,2j}^{(k)} \end{pmatrix} \quad i,j = 1,2,\ldots,L/2,$$

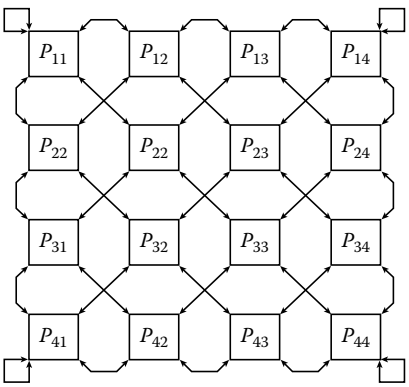

FIGURE 9.114 Systolic array for an EVD of a symmetric matrix based on Jacobi rotations.

The diagonal processors compute the rotation parameters and apply the rotation to the four entries they store. Subsequently, they propagate the rotation parameters horizontally and vertically to their neighbors, which, upon receiving them, apply the corresponding rotation to their stored entries. After the rotation is applied, each processor swaps its entries with its four neighbors along the diagonal connections. The correct data movement at the edges of the array is also shown in Figure 9.114. A correct scheduling of operations requires that each processor be idle for two out of three time steps, which translates into an "efficiency" of 33%. Each sweep takes 3 $(L-1)$ time steps, and the number of sweeps can be chosen on the order of $\log L$.

9.5.6.3 SVD of a Rectangular Matrix via the Hestenes Algorithm

Consider an $N \times L$ real matrix A, $N \geq L$. Its SVD can be written as follows:

$$\underbrace{A}_{N\times L} = \underbrace{U}_{N\times L}\,\underbrace{\Sigma}_{L\times L}\,\underbrace{V^{\mathrm{T}}}_{L\times L}$$

where U and V have orthonormal columns. The matrix $\Sigma = \mathrm{diag}(\sigma_1, \ldots, \sigma_L)$ is the diagonal matrix of singular values, where $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_L \geq 0$. Consider the following recursion $A_0 \leftarrow A$, $A_{k+1} \leftarrow A_k\, G_k$, where the Givens rotations are chosen not to zero out entries of A_k, but to orthogonalize pairs of its columns. A sweep is now defined as a sequence of Givens rotations that orthogonalize all $\binom{L}{2}$ pairs of columns exactly once. Observe the similarity with the algorithm described previously for the calculation of eigenvalues and eigenvectors. If $G(i, j, \theta)$ is the Givens rotation which orthogonalizes columns i and j of A, then $G(i, j, \theta)^{\mathrm{T}} M G(i, j, \theta)$ is the Jacobi rotation that zeroes out the entries (i, j) and (j, i) of $M = A^{\mathrm{T}}A$. A sweep (as defined here) of rotations applied to the rectangular matrix A corresponds exactly to a sweep (as defined earlier) of rotations applied to the symmetric matrix M.

At any time step, the original matrix A can be expressed as follows:

$$A = A_k V_k^T, \quad V_k = \prod_{i=1}^{k} G_k$$

where V_k has orthonormal columns for any k (by definition of Givens rotations). After a number of sweeps (on the order of $\log L$) the matrix A_k approaches a matrix, W, of orthogonal columns, $A_k \rightarrow W$, $V_k \rightarrow V$. If σ_i is the norm of the ith column of W, $i = 1, \ldots, L$, then we have $W = U\ \mathrm{diag}\ (\sigma_1, \ldots, \sigma_L)$, $A = U\Sigma V^{\mathrm{T}}$.

This SVD approach based on the Hestenes algorithm can be realized on a Brent–Luk [58] linear systolic array, as shown in Figure 9.115, for the case $L = 8$. Each processor stores a pair of columns; in particular, the procedure starts by storing columns 2 $k-1$ and $2k$ in processor P_k. Each processor computes the rotation parameters which orthogonalize the pair of columns.

Let x and z be the two stored columns. Let ξ and ζ be their norms, and $\acute{\eta}$ be their inner product. Then the value of $\tan\theta$ from

$$u = \frac{\zeta - \xi}{2\eta}, \quad \tan\theta = \frac{\mathrm{sign}(u)}{|u| + \sqrt{1 + u^2}}$$

After applying the computed rotation, each processor swaps its pair of columns with the two neighboring processors along the connections shown in Figure 9.115. The column indices stored in each processor at the different steps of a single sweep are given in Table 9.16. Note that all the $\binom{L}{2}$ pairs of indices are generated by using the Brent–Luk scheme. The stopping criteria can be set in advance. A possible criterion is by inspecting the magnitude of the rotating angles. When they are all in absolute value below

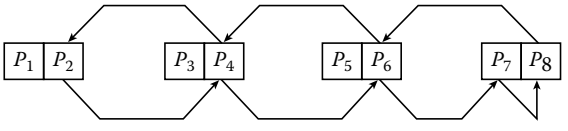

FIGURE 9.115 Linear systolic array for SVD of a rectangular matrix based on the Hestenes algorithm.

a given threshold, then the algorithm can stop. More commonly, a predetermined number of sweeps is chosen ahead of time. Observation shows that a number of sweeps on the order of $\log L$ is sufficient for convergence.

9.5.6.4 SVD of a Rectangular Nonsymmetric Matrix

9.5.6.4.1 Via the Jacobi Algorithm

The SVD algorithm described in the previous section has the drawback of a somewhat complicated updating procedure. In many signal processing applications, continuous updating of the matrix decomposition as new samples are appended to the data matrix is required. Such problems occur in spectral analysis, direction-of-arrival estimation, beam forming, etc. An efficient updating procedure for the SVD of rectangular matrices of growing row size is given by the algorithm described in this section, based on the succession of two basic operations: a QR updating step, followed by a rediagonalization operation. This algorithm is otherwise known as a version of the Kogbetliantz algorithm for triangular matrices.

Given the $m \times L$ data matrix at time m, $A_m = [a_1, \ldots, a_m]^T$, where a_i, $i = 1, \ldots, m$ are the rows of A_m, one defines the exponentially weighted matrix $B_m(\beta)\, A_m$, where $B_m(\beta)$ is the diagonal forgetting matrix $B_m(\beta) + \text{diag}(\beta^{m-1}, \beta^{m-2}, \ldots, \beta, 1)$, and $0 < \beta \leq 1$ is the forgetting factor. The updating problem is to determine the SVD of the updated weighted matrix $B_{m+1}(\beta)\, A_{m+1}$, given the SVD at time m,

$$B_m(\beta) A_m = U_m \sum_m V_m$$

Often only the singular values and right singular vectors are of interest. This is fortunate because the left singular matrix grows in size as time increases, while the sizes of Σ_m and V_m remain unchanged.

The algorithm can be summarized as follows. Given the matrices V_m and Σ_m and the new data sample x_{m+1},

$$\sum\nolimits'_m \leftarrow \begin{pmatrix} \beta & \sum \\ & m \\ x_{m+1} & V_m \end{pmatrix} V'_m \leftarrow V_m,$$

the QR updating step

$$\begin{pmatrix} \sum'_m \\ 0 \end{pmatrix} \leftarrow Q_{m+1} \sum\nolimits'_m$$

the rediagonalization using permuted Jacobi rotations

for $k = 1, \ldots, 1$,
  for $i = 1, \ldots, n-1$, $j = i+1$,
    $\Sigma'_m \leftarrow \prod_{ij} G(i, j, \theta)\Sigma'_m G(i, j, \varphi)^{\mathrm{T}} \prod_{ij}$,
    $V'_m \leftarrow V'_m G(i, j, \varphi)^{T} \prod_{ij}$.
end
end
    $\Sigma_{m+1} \leftarrow \Sigma'_m$,
    $V_{m+1} \leftarrow V'_m$.

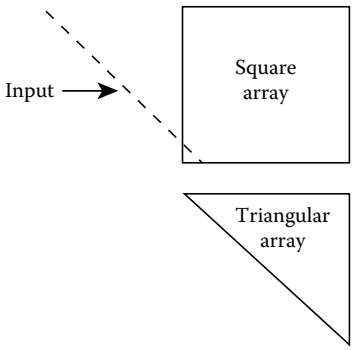

FIGURE 9.116 Two-dimensional systolic array for updating the Jacobi SVD algorithm for a nonsymmetric matrix.

In the preceding algorithm, the parameter l determines both the number of computations between subsequent updates and the estimation accuracy at the end of each update step. When l is chosen equal to the problem order L, then one complete sweep is performed. In practice, the l parameter can be chosen as high as $\sim 10L$ (usually for block computations or slow updates) and as small as 1 (for very high updating rates, with understandable degradation of estimation accuracy). The matrices Σ_m and Σ'_m are upper triangular at all times. This is ensured by the application of the permuted left and right Givens rotations in the rediagonalization step. After the application of any Jacobi rotation, the rotated rows and columns are subsequently permuted. This expedient not only preserves the upper triangularity of the Σ matrices, but also makes it possible for the rotations to be generated on the diagonal and propagated along physically adjacent pairs of rows and columns. All these features make this algorithm a very attractive candidate for a systolic implementation.

A schematic diagram of the systolic array proposed by Moonen et al. [63] is shown in Figure 9.116, where the triangular array stores the matrices Σ_m and Σ'_m, for all m, and the square array stores the V-matrix. The incoming data samples, x_{m+1}, are input into the V-array, where the vector-by-matrix multiplication $x_{m+1}\ V_m$ is performed. The output is subsequently fed into the triangular array. As it propagates through the array, the QR updating step is carried on: left rotations are generated in the diagonal elements of the array and propagated through the corresponding rows of the Σ matrix. One does not need to wait for the completion of the QR step to start performing the Jacobi rotations associated with the diagonalization step. It is known that the two operations (QR update and diagonalization) can be interleaved without compromising the final result. The parameters relative to the left rotations are, as before, propagated along the rows of the triangular matrix, while the right rotation parameters move along the columns of Σ_m, and are passed on to the V-array. Due to the continual modification of the matrix V_m caused by these right rotations, and because of the use of finite precision arithmetic, the computed right singular matrix may deviate from orthogonality. It is also known that in a realistic environment the norm of $V_m V_m^{\mathrm{T}} - I$ grows linearly with m. Reorthogonalization procedures must therefore be included in the overall scheme. A complicated reorthogonalization procedure based on left rotations, which interleaves with the other operations, was described in Moonen et al. [63]. An improved reorthogonalization algorithm was proposed by Vanpoucke and Moonen [66], where the matrix V_m is stored in parametrized form, thereby guaranteeing orthogonality at all times. The resulting triangular array and its modes of operation were also described.

10.1 Digital-to-Analog Converters

Bang-Sup Song

10.1.1 Introduction

Digital-to-analog converters (DACs), referred to as decoders in communications terms, are devices by which digital processors communicate with the analog world. Although DACs are used as key elements in analog-to-digital converters (ADCs), they find numerous applications as stand-alone devices from CRT display systems and voice/music synthesizers to automatic test systems, waveform generators, digitally controlled attenuators, process control actuators, and digital transmitters in modern digital communications systems.

The basic function of the DAC is the conversion of input digital numbers into analog waveforms. An N-bit DAC provides a discrete analog output level, either voltage or current, for every level of 2^N digital words, $\{D_i;\ i = 0, 1, 2, \ldots, 2^N - 1\}$, that is applied to the input. Therefore, an ideal voltage DAC generates 2^N discrete analog output voltages for digital inputs varying from $000\ldots00$ to $111\ldots11$ as illustrated in Figure 10.1 for the 4 bit example. The output has a one-to-one correspondence with the input

$$V_{\text{out}}(D_i) = V_{\text{ref}}\left(\frac{b_N}{2} + \frac{b_{N-1}}{2^2} + \cdots + \frac{b_2}{2^{N-1}} + \frac{b_1}{2^N}\right) \tag{10.1}$$

where V_{ref} is a reference voltage setting the output range of the DAC and $b_N, b_{N-1}, \ldots, b_1$ is the binary representation of the input digital word D_i. In the unipolar case, as shown, the reference point is 0 when the digital input D_0 is $000\ldots00$, but in bipolar or differential DACs, the reference point is the midpoint of

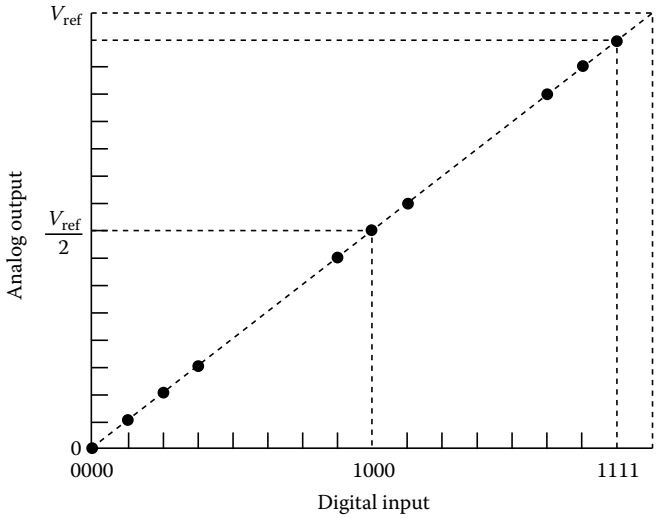

FIGURE 10.1 Transfer characteristics of a unipolar DAC.

the full scale when the digital input is 100 . . . 00, and the range is defined from $-V_{ref}/2$ to $V_{ref}/2$. Although purely current-output DACs are possible, voltage-output DACs are common in most applications.

10.1.1.1 Signal-to-Noise Ratio and Dynamic Range

The resolution is a term used to describe a minimum voltage or current that a DAC can resolve. The fundamental limit of a DAC is the quantization noise due to the finite resolution of the DAC. If the input digital word is N bits long, the minimum step that a DAC can resolve is $V_{ref}/2^N$. If output voltages are reproduced with this minimum step of uncertainty, an ideal DAC should have a maximum signal-to-noise ratio (SNR) of

$$\text{SNR} = \frac{3}{2}2^{2N} \approx 6N + 1.8 \text{ (dB)} \tag{10.2}$$

where SNR is defined as the power ratio of the maximum signal to the inband uncorrelated noise. For example, an ideal 16 bit DAC has an SNR of about 97.8 dB. The spectrum of the quantization noise is evenly distributed up to the Nyquist bandwidth (half the sampling frequency). Therefore, this inband quantization noise decreases by 3 dB when the oversampling ratio (OSR) is doubled. This implies that when oversampled, the SNR within the signal band can be made lower than the quantization noise limited by Equation 10.2.

The resolution of a DAC is usually characterized in terms of SNR, but the SNR accounts only for the uncorrelated noise. The real noise performance is better represented by TSNR, which is the ratio of the signal power to the total inband noise, including harmonic distortion (HD). Also, a slightly different term is often used in place of the SNR. The useful signal range or dynamic range is defined as the power ratio of the maximum signal to the minimum signal. The minimum signal is defined as the smallest input, for which the TSNR is 0 dB, while the maximum signal is the full-scale input. Therefore, the SNR of nonideal DACs can be lower than the ideal dynamic range because the noise floor can be higher with a large signal present. In practice, DACs are limited not only by the quantization noise, but also by nonideal factors such as noises from circuit components, power supply coupling, noisy substrate, timing jitter, insufficient settling, and nonlinearity.

10.1.2 Basic Converter Design Issues

The performance of a DAC can be specified in terms of its linearity, monotonicity, and conversion speed. In most conventional DACs, except for the oversampling DACs the linearity and monotonicity are limited by how accurately the reference voltage/current is divided using passive/active components.

10.1.2.1 Linearity

Differential nonlinearity (DNL). The output range of an N-bit DAC is equally divided into 2^N small units, as shown in Figure 10.1, and one least significant bit (LSB) change in the input digital word makes the analog output voltage change by $V_{\text{ref}}/2^N$. The DNL is a measure of the deviation of the actual DAC output voltage step from this ideal voltage step for 1 LSB. The DNL is defined as

$$\text{DNL} = \frac{V_{\text{out}}(D_{i+1}) - V_{\text{out}}(D_i) - V_{\text{ref}}/2^N}{V_{\text{ref}}/2^N} \quad \text{for } i = 0, 1, \ldots, 2^N - 2 \text{ (LSB)} \tag{10.3}$$

and the largest positive and negative numbers are usually quoted to specify the static performance of a DAC.

Integral nonlinearity (INL). The overall linearity of a DAC can be specified in terms of the INL, which is a measure of deviation of the actual DAC output voltage from the ideal straight line drawn between two endpoints, 0 and V_{ref}. Because the ideal output is $i \times V_{\text{ref}}/2^N$ for any digital input D_i, the INL is defined as

$$\text{INL} = \frac{V_{\text{out}}(D_i) - i \times V_{\text{ref}}/2^N}{V_{\text{ref}}/2^N} \quad \text{for } i = 0, 1, \ldots, 2^N - 1 \text{ (LSB)} \tag{10.4}$$

and the largest positive and negative numbers are usually quoted to specify the static performance of a DAC.

However, several definitions of INL may result depending on how two endpoints are defined. In some DAC architectures the two endpoints are not exactly 0 and V_{ref}. The nonideal reference point causes an offset error, while the nonideal full-scale range gives rise to a gain error. In most DAC applications, these offset and gain errors resulting from the nonideal endpoints do not matter, and the integral linearity can be better defined in a relative measure using a straight line linearity concept rather than the end point linearity in the absolute measure. The straight line can be defined as two endpoints of the actual DAC output voltages or as a theoretical straight line adjusted to best fit the actual DAC output characteristics. The former definition is sometimes called endpoint linearity, while the latter is called best straight line linearity.

10.1.2.2 Monotonicity

The DAC output should increase over its full range as the digital input word to the DAC increases. That is, the negative DNL should be <-1 LSB for a DAC to be monotonic. Monotonicity is critical in most applications, in particular, in digital control applications. The source of nonmonotonicity is an inaccuracy in binary weighting of a DAC. For example, the most significant bit (MSB) has a weight of one half of the full range. If the MSB weight is smaller than the ideal value, the analog output change can be smaller than the ideal step $V_{\text{ref}}/2^N$ when the input digital word changes from $0111\ldots11$ to $1000\ldots00$ at the midpoint of the DAC range. If this decrease in the output is >1 LSB, the DAC becomes nonmonotonic. The similar nonmonotonicity can take place when switching the second or lower MSB bits in binary-weighted multibit DACs.

Monotonicity is inherently guaranteed if an N-bit DAC is made of 2^N elements for thermometer decoding. However, it is impractical to implement high-resolution DACs using 2^N elements because the number of elements grows exponentially as N increases. Therefore, to guarantee monotonicity in practical applications, DACs have been implemented using either a segmented DAC or an

integrator-type DAC. Oversampling interpolative DACs also achieve monotonicity using a pulse-density modulated bitstream converted into analog voltages by a lossy integrator or by a low-pass filter.

Segmented DACs. Applying a two-step conversion concept, a DAC can be made in two levels using coarse and fine DACs. The fine DAC divides one coarse MSB segment into fine LSBs. If one fixed MSB segment is subdivided to generate LSBs, matching among MSB segments creates a nonmonotonicity problem. However, if the next MSB segment is subdivided instead of the fixed segment, the segmented DAC can maintain monotonicity regardless of the MSB matching. This is called ''next-segment approach.'' Unless the next segment approach is used to make a segmented DAC with a total $M+N$ bits, the MSB DAC should have a resolution of $M+N$ bits for monotonicity, while the LSB DAC requires an N-bit resolution. Using the next-segment approach, an MSB DAC made of 2^M identical elements guarantees monotonicity, although INL is still limited by the MSB matching.

To implement a segmented DAC using two resistor-string DACs, voltage buffers are needed to drive the LSB DAC without loading the MSB DAC. Although the resistor-string MSB DAC is monotonic, overall monotonicity is not guaranteed due to the offsets of the voltage buffers. The use of a capacitor-array LSB DAC eliminates a need for voltage buffers. The most widely used segmented DAC is a current-ratioed DAC, whose MSB DAC is made of identical elements for the next-segment approach, but the LSB DAC is a current divider. A binary-weighted current divider can be used as an LSB DAC, as shown in Figure 10.2. For monotonicity, the MSB M-bits are selected by a thermometer code, but one of the MSB current sources corresponding to the next segment of the thermometer code is divided by a current divider for fine LSBs.

Integrator-type DACs. As mentioned, monotonicity is guaranteed only in a thermometer-coded DAC. The thermometer coding of a DAC output can be implemented either by repeating identical DAC elements many times or by repeatedly using the same element. The former requires more hardware, but the latter more time. In the continuous time integrator-type DAC the integrator output is a linear ramp and the time to stop integrating can be controlled by the digital codes. Therefore, monotonicity can be maintained. Similarly, the discrete time integrator can integrate a constant amount of charge repeatedly and the number of integrations can be controlled by the digital codes. The integration approach can give high accuracy, but its disadvantage is its slow speed limiting its applications.

Although it is different in concept, oversampling interpolative DACs modulate the digital code in to a bitstream, and its pulse density represents the DAC output. Due to the incremental nature of the pulse density modulation, oversampling DACs are monotonic. A DAC for the pulse-density modulated

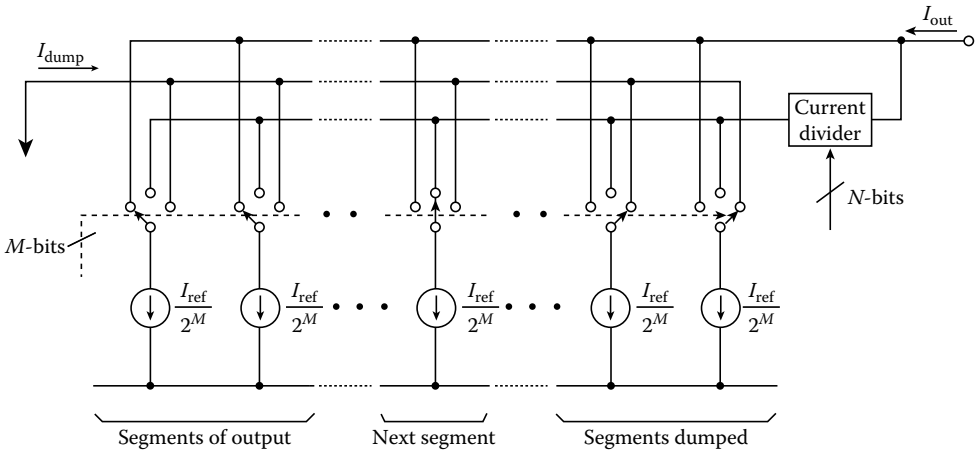

FIGURE 10.2 Segmented DAC for monotonicity.

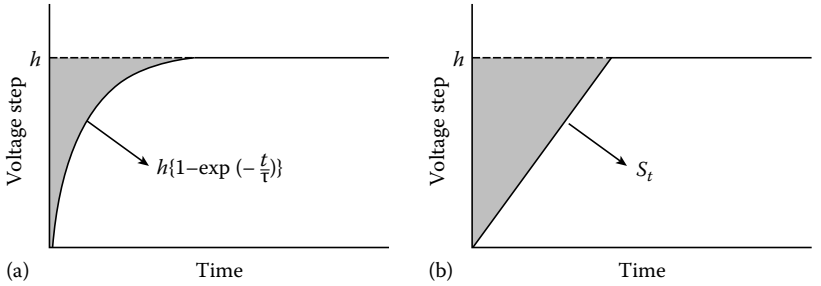

FIGURE 10.3 Errors in step response: (a) settling and (b) slewing.

bitstream is a lossy integrator. The integrator integrates a constant charge if the pulse is high, while it subtracts the same charge if the pulse is low. In principle, it is equivalent to the discrete time integrator DAC, but the output is represented by the average charge on the integrator.

10.1.2.3 Conversion Speed

The output of a DAC is a sampled-and-held step waveform held constant during a word clock period. Any deviation from the ideal step waveform causes an error in the DAC output. High-speed DACs usually have a current output, but even current-output DACs are either terminated with a 50 to 75 Ω low-impedance load or buffered by a wideband transresistance amplifier. Therefore, the speed of a DAC is limited either by the RC time constant of the output node or by the bandwidth of the output buffer amplifier. Figure 10.3 illustrates two step responses of a DAC when it settles with a time constant of τ and when it slews with a slew rate of S, respectively. The transient errors given by the shaded areas of Figure 10.3 are $h\tau$ and $h^2/2S$, respectively. This implies that a single time-constant settling of the former case only generates a linear error in the output, which does not effect the DAC linearity, but the slew-limited settling of the buffer generates a nonlinear error. Even in the single-time constant case (the former), the code-dependant time constant in settling can introduce a nonlinearity error because the settling error is a function of the time constant τ. This is true for a resistor-string DAC, which exhibits a code-dependent settling time because the output resistance of the DAC depends on the digital input.

The slew rate limit of the buffer is a significant source of nonlinearity since the error is proportional to the square of the signal, as shown in Figure 10.3b. The height and the width of the error term change with the input. The worst-case HD when generating a sinusoidal signal with a magnitude V_0 with a limited slew rate of S is [1]

$$\mathrm{HD}_k = 8\frac{\sin^2\frac{\omega T_c}{2}}{\pi k(k^2-4)} \times \frac{V_0}{ST_c}, \quad k = 1, 3, 5, 7, \ldots \tag{10.5}$$

where T_c is the clock period. For a given distortion level, the minimum slew rate is given. Any exponential system with a bandwidth of ω_0 gives rise to signals with the maximum slew rate of $2\omega_0 V_0$. Therefore, by making $2\omega_0 V_0 > S_{\min}$, no slew rate is limited and the DAC system will exhibit no distortion.

10.1.3 Converter Architectures

Many circuit techniques are used to implement DACs, but a few popular techniques used widely today are of the parallel type, in which all bits change simultaneously upon applying an input code word. Serial DACs, on the other hand, produce an analog output only after receiving all digital input data in a sequential form. When DACs are used as stand-alone devices, their output transient behavior limited by

glitch, slew rate, word clock jitter, settling, etc. are of paramount importance, but are used as subblocks of ADCs, DACs need only to settle within a given time interval. In stand-alone DAC applications, the digital input word made of *N*-bits should be synchronously applied to the DAC with a precise timing accuracy. Thus, the input data latches are used to hold the digital input during the conversion. The output analog sample-and-hold (S/H), usually called deglitcher, is often used for the better transient performance of a DAC. The three most popular architectures in integrated circuits are DACs using a resistor string, ratioed current sources, and a capacitor array. The current-ratioed DAC finds the greatest application as a stand-alone DAC, while the resistor-string and capacitor-array DACs are used mainly as ADC subblocks.

10.1.3.1 Resistor-String DACs

The simplest voltage divider is a resistor string. Reference levels can be generated by connecting 2^N identical resistors in series between V_{ref} and 0. Switches to connect the divided reference voltages to the output can be either a 1-out-of-2^N decoder or a binary tree decoder as shown in Figure 10.4 for the 3 bit example. Because it requires a good switch, the stand-alone resistor-string DAC is easier to implement using CMOS. However, the lack of switches does not limit the application of the resistor string as a voltage reference divider subblock for ADCs in other process technologies.

Resistor strings are used widely as reference dividers, an integral part of the flash ADC. All resistor-string DACs are inherently monotonic and exhibit good differential linearity. However, they suffer from a poor integral linearity and also have the drawback that the output resistance depends on the digital input code. This causes a code-dependent settling time when charging the capacitive load of the output bus. The code-dependent settling time has no effect on the reference divider performance as an ADC subblock, but the performance is severely degraded as a stand-alone DAC. This nonuniform settling time problem can be alleviated by adding low-resistance parallel resistors and by compensating the MOS switch overdrive voltages.

In bipolar technology, the most common resistors are thin-film resistors made of tantalum, Ni–Cr, or Cr–SiO, which exhibit very low voltage and temperature coefficients. In CMOS either diffusion or undoped poly resistors are common. Four of the most frequently used resistors are listed in Table 10.1. Conventional trimming or adjustment techniques are impractical to be applied to all 2^N resistor elements. The following four methods are often used to improve the integral linearity of resistor-string DACs.

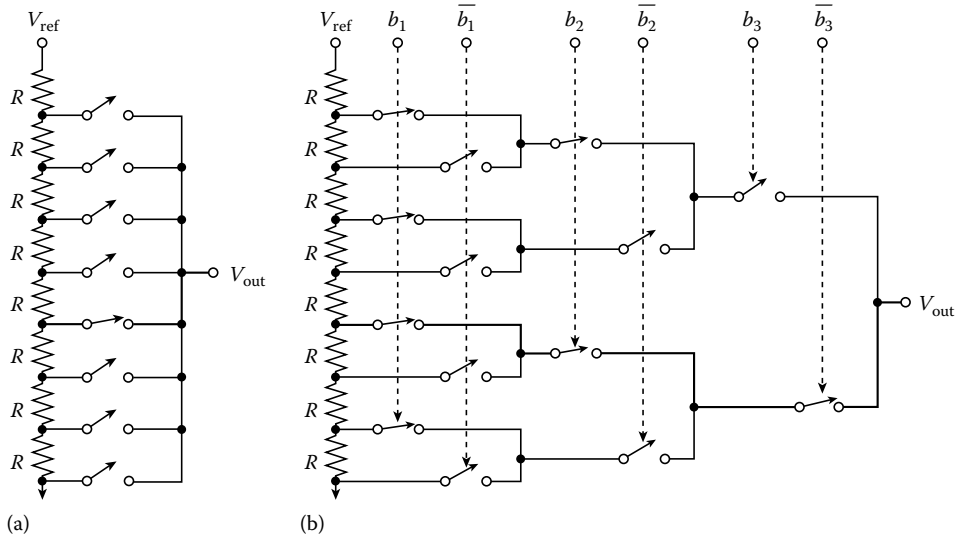

FIGURE 10.4 Resistor-string DAC: (a) with 1-out-of-2^N decoder and (b) with a binary tree decoder.

TABLE 10.1 Resistor in IC Processes

Resistor Type	Sheet R (Ω/sq)	Tolerance (%)	10–20 μm Matching (%)	T.C. (ppm/°C)
Diffusion	100–200	±20	±0.2–0.5	1500
Ion implantation	500–1 k	±5	±0.1	200
Thin film	1 k	±5	±0.1	10–100
Undoped poly	100–500	±20	±0.2	1500

Layout techniques. The use of large geometry devices and/or careful layout is effective in improving the matching marginally. Large geometry devices reduce the random edge effect, and the layout using a common centroid or geometric averaging can reduce the process gradient effect. However, typical matching of resistors in integrated circuits is still limited to an 8–10 bit level due to the mobility and resistor thickness variations. Differential resistor DACs with large feature sizes are reported to exhibit a higher matching accuracy of an 11–12 bit level.

Off-chip adjustment. It is possible to set tap points of a resistor-string to specified voltages by connecting external voltage sources to them, as shown in Figure 10.5a for the 3 bit example. Simply put, the more taps adjusted, the better the integral linearity obtained. An additional benefit of this method is the reduced RC time constant due to the voltage sources at the taps. Instead of using voltage sources, the required voltages can be obtained using parallel trimming, resistors, as shown in Figure 10.5b. However, in addition to external components for trimming, fine adjustments and precision measurement instruments are needed to ensure that voltage levels are correct. Furthermore, due to mismatch in the temperature coefficients between the external components and the on-chip components, retrimming is often required when temperature changes.

Postprocess trimming. The most widely used methods are laser trimming [2], Zener zapping [3], and other electrical trimming using PROM. The trimming method is the same as the parallel resistor trimming shown in Figure 10.5b except for the fact that external trimming resistors are now integrated on the chip. While being trimmed, the resistor string is biased with a constant current. Individual

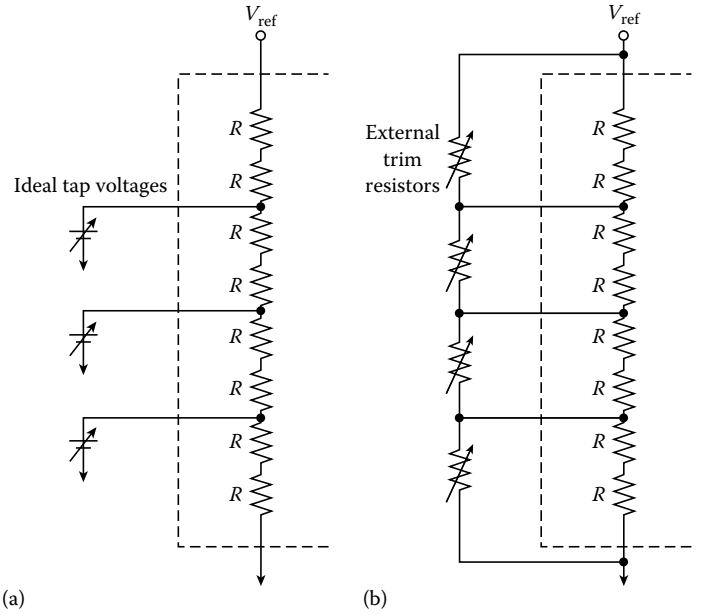

FIGURE 10.5 INL improvements by (a) external voltage sources and (b) parallel resistors.

segments are trimmed to have the same voltage drop. However, during normal conversion, the current source is replaced by a reference voltage source. The focused laser beam for trimming has a finite diameter, and the resistor to be trimmed occupies a large chip area. Both the laser trimming and the Zener zapping processes are irreversible. The long-term stability of trimmed resistors is a major concern, although the electrical and the PROM trimming (if PROM is replaced by EPROM) can be repeated. All trimming methods in this category are time consuming and require precision instruments.

On-chip buffers. The voltage at intermediate taps of the resistor string can be controlled by another resistor string through on-chip unity-gain buffers. This is actually an improved version of the off-chip method. The controlling resistors can be either laser trimmed or electronically controlled by switches. Laser-trimmed controlling resistors have the same problems mentioned earlier. The trimming network can be implemented to electronically control resistor values. In either case buffers with a high open-loop gain, a low output resistance, a large current driving capability, and a wide bandwidth for accurate and fast settling are required.

10.1.3.2 Current-Ratioed DACs

The most popular stand-alone DACs in use today are current-ratioed DACs, of which the two types are a weighted current DAC and an *R*-2*R* DAC.

Binary-weighted current DACs. The weighted current DACs shown in Figure 10.6 are made of an array of switched binary-weighted current sources and the current summing network. In bipolar

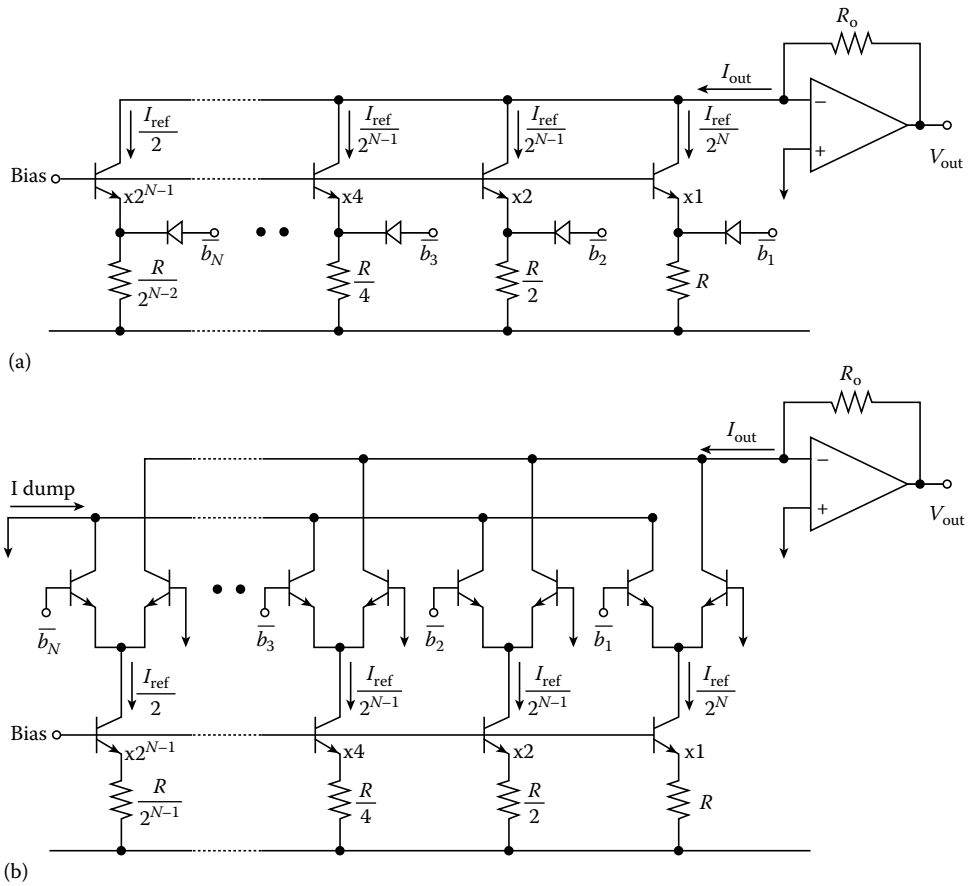

FIGURE 10.6 Binary-weighted current DAC: (a) diode switching and (b) differential pair switching.

technology binary weighting is achieved by ratioed transistors and emitter resistors with binary-related values of R, $R/2$, $R/4$, and so on, while in MOS technology, only ratioed transistors are used. One example is a video random access memory DAC in CMOS, which is made of simple PMOS differential pairs with binary-weighted tail currents. DACs relying on active device matching can achieve an 8 bit level performance with a 0.2%–0.5% matching accuracy using a 10–20 μm device feature size while degeneration with thin-film resistors gives a 10 bit level performance. The current sources are switched on or off by means of switching diodes or emitter-coupled differential pairs (source-coupled pairs in CMOS), as shown in Figure 10.6. The output current summing is done by a wideband transresistance amplifier, but in high-speed DACs, the output current is used directly to drive a resistor load for a maximum speed but with a limited output swing. The weighted current design has the advantage of simplicity and high speed, but it is difficult to implement a high-resolution DAC because a wide range of emitter resistors and transistor sizes is used and very large resistors cause problems with both temperature stability and speed.

***R*-2*R* ladder DACs.** This large resistor ratio problem is alleviated by using a resistor divider known as an *R*-2*R* ladder, as shown in Figure 10.7. The *R*-2*R* network consists of series resistors of value *R* and shunt resistors of value 2*R*. The top of each shunt resistor 2*R* has a single-pole double-throw electronic switch which connects the resistor either to ground or to the output current summing node. The operation of the *R*-2*R* ladder network is based on the binary division of current as it flows down the ladder. At any junction of series resistor *R*, the resistance looking to the right side is 2*R*. Therefore, the input resistance at any junction is *R*, and the current splits into two equal parts at the junction because it sees equal resistances in either direction. The result is binary-weighted currents flowing into each shunt resistor in the ladder. The digitally controlled switches direct the current to either ground or to the summing node. The advantage of the *R*-2*R* ladder method is that only two values of resistors are used, greatly simplifying the task of matching or trimming and temperature tracking. In addition, for high-speed applications relatively low resistor values can be used. Excellent results can be obtained using laser-trimmed thin-film resistor networks. Because the output of the *R*-2*R* DAC is the product of the reference voltage and the digital input word, the *R*-2*R* ladder DAC is often called a multiplying DAC (MDAC).

Both the weighted current DAC and the *R*-2*R* DAC can be used as a current divider to make a sub-DAC. To make a segmented DAC for monotonicity based on the next-segment approach, as discussed earlier, the MSB should be made of thermometer-coded equal currents. Once the MSB is selected, the next segment should be divided further into LSBs as shown in Figure 10.2. INL can be improved by dynamically matching or by self-calibrating the MSB current sources as discussed later.

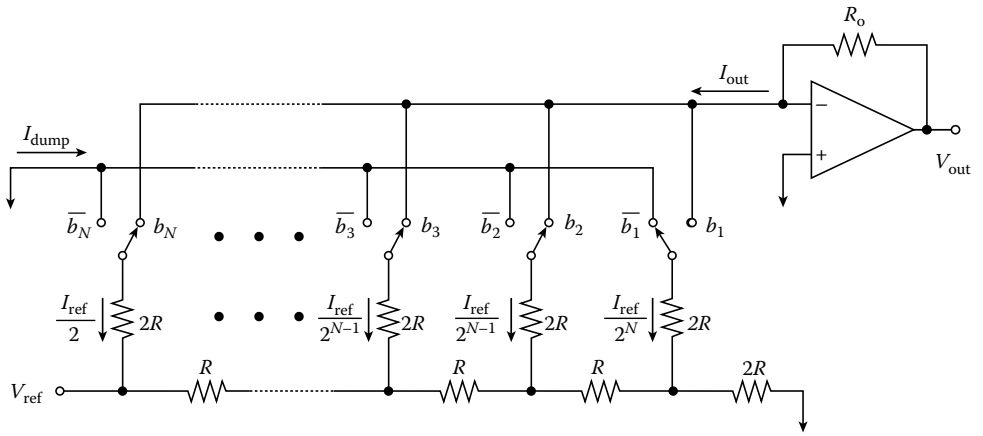

FIGURE 10.7 *R*-2*R* ladder DAC.

Capacitor-array DAC. Capacitors made of double-poly or poly-diffusion in MOS technology are considered one of the most accurate passive components comparable to thin-film resistors in bipolar process, both in the matching accuracy and voltage and temperature coefficients [4]. The only disadvantage in the capacitor-array DAC implementation is the use of a dynamic charge redistribution principle. A switched-capacitor counterpart of the resistor-string DAC is a parallel capacitor array of 2^N unit capacitors (C) with a common top plate. The capacitor-array DAC is not appropriate for stand-alone applications without a feedback amplifier virtually grounding the top plate and an output S/H or deglitcher. The operation of the capacitor-array DAC in Figure 10.8 is based on the thermometer-coded DAC principle, and has a distinct advantage of monotonicity if the system is implemented properly. However, due to the complexity of handling the thermometer-coded capacitor array, a binary-weighted capacitor array is often used, as shown in Figure 10.9, by grouping unit capacitors in binary ratio values. A common centroid layout of the capacitor array is known to give a 10 bit level matching for this application when the unit capacitor size is over 12×12 μm. The matching accuracy of the capacitor in MOS technology depends on the geometry sizes of the capacitor width and length and the dielectric thickness.

As a stand-alone DAC, the top plate of the DAC is precharged either to the offset of the feedback amplifier or to the ground. One smallest capacitor is not necessary for this application. However, as a subblock of an ADC, the total capacitor should be 2^NC, as drawn in Figure 10.9, and the top plate of the

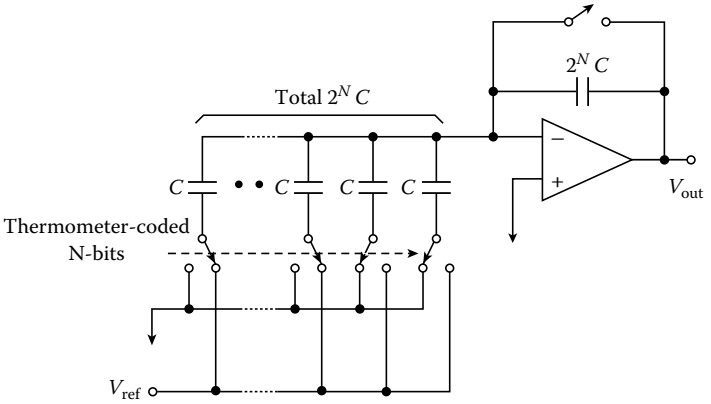

FIGURE 10.8 Thermometer-coded capacitor-array DAC.

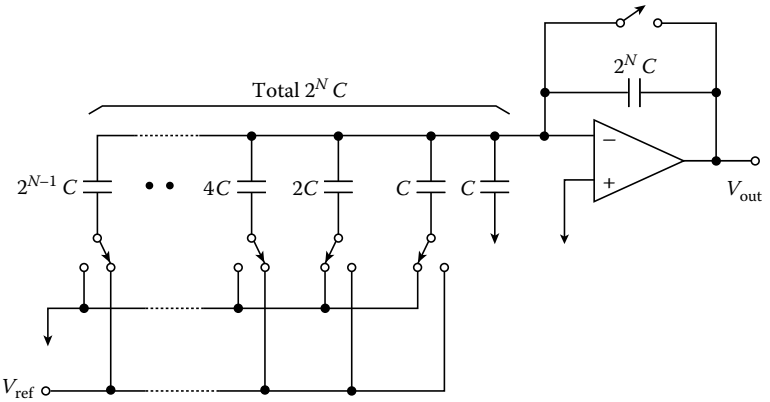

FIGURE 10.9 Binary-weighted capacitor-array DAC.

array is usually connected to the input nodes of comparators or high-gain operational amplifiers, depending on the ADC architectures. As a result, the top plate has a parasitic capacitance, but its effect on the DAC performance is negligible. The capacitor-array DAC requires two-phase nonoverlapping clocks for proper operation. Initially, all capacitors should be charged to ground. After initialization, depending on the digital input, the bottom plates are connected either to V_{ref} or to ground. Consider the case in which the top plate is floating without the feedback amplifier. If the charge at the top plate finishes its redistribution the top plate voltage neglecting the top plate parasitic effect becomes

$$V_0 = \sum_{i=1}^{N} \frac{b_k}{2^i} V_{\text{ref}} \tag{10.6}$$

where $b_N\, b_{N-1}, \ldots, b_2\, b_1$ is the input binary word. For example, switching the MSB capacitor bottom to V_{ref} changes the output voltage by

$$\frac{2^{N-1}C}{\sum_{i=1}^{N} C_i} V_{\text{ref}} = \frac{V_{\text{ref}}}{2} \tag{10.7}$$

where the capacitor C_i, for the ith bit is nominally scaled to $2^{i-1}C$. Therefore, the nonlinearity at the midpoint of the full range is limited by the ratio mismatch of the half sum of the capacitor array to the total sum of the array. Similarly, the nonlinearity at one fourth of the range is limited by the ratio of one fourth of the capacitor array to the total array, and so on.

One important application of the capacitor-array DAC is as a reference DAC for ADCs. As in the case of the *R*-2*R* MDAC, the capacitor-array DAC can be used as an MDAC to amplify residue voltages for multistep ADCs. As shown in Figure 10.9, if the input is sampled on the bottom plates of capacitors instead of the ground, the voltage amplified is the amplified input voltage minus the DAC output. By varying the feedback capacitor size, the MDAC can be used as an interstage residue amplifier in multistep pipelined ADCs. For example, if the feedback capacitor is C and the digital input is the coarse N-bit decision of the sampled analog voltage, the amplifier output is a residue voltage amplified by 2^N for the subsequent LSB conversion.

10.1.3.3 $R + C$ or $C + R$ Combination DACs

Both resistor-string and capacitor-array DACs need 2^N unit elements for N-bits, and the number grows exponentially. Splitting arrays into two, one for MSBs and the other for the LSBs, requires a buffer amplifier to interface between two arrays. Although a floating capacitor connects two capacitors arrays, the parasitic capacitance of the floating node is not well controlled. A more logical combination for high-resolution DAC is between resistor and capacitor DACs. This combination does not require any coupling capacitors or interface buffer amplifiers.

In the $R + C$ combination, the MSB is set by the resistor string, and next segment of the resistor-string DAC supplies the reference voltage of the LSB capacitor DAC, as shown in Figure 10.10. When the top plate is initialized, all capacitor bottom plates are connected to the lower voltage of the next segment of the resistor-string DAC. During the next clock phase, the bottom plates of capacitors are selectively connected to the higher voltage of the segment if the digital bit is ONE, but stays switched to the lower voltage if ZERO. This segmented DAC approach gives an inherent monotonicity as far as the LSB DAC is monotonic within its resolution. Although INL is poor, the fully differential implementation of this architecture benefits from the lack of the even-order nonlinearity, thereby achieving improved INL. On the other hand, in the $C + R$ combination shown in Figure 10.11, the operation of the capacitor DAC is the same. The MSB side reference voltage is fixed, but the reference voltage of the smallest capacitor is supplied by the LSB resistor-string DAC. This approach exhibits nonmonotonicity due to the capacitor

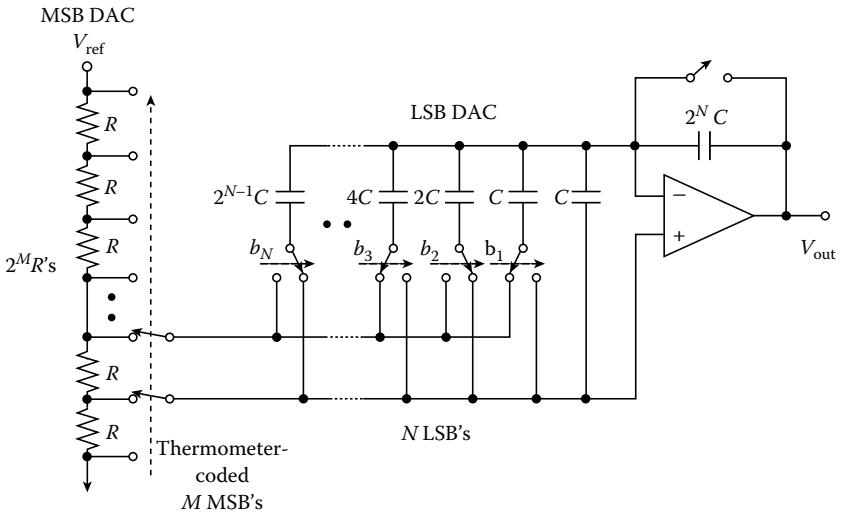

FIGURE 10.10 $R + C$ combination DAC.

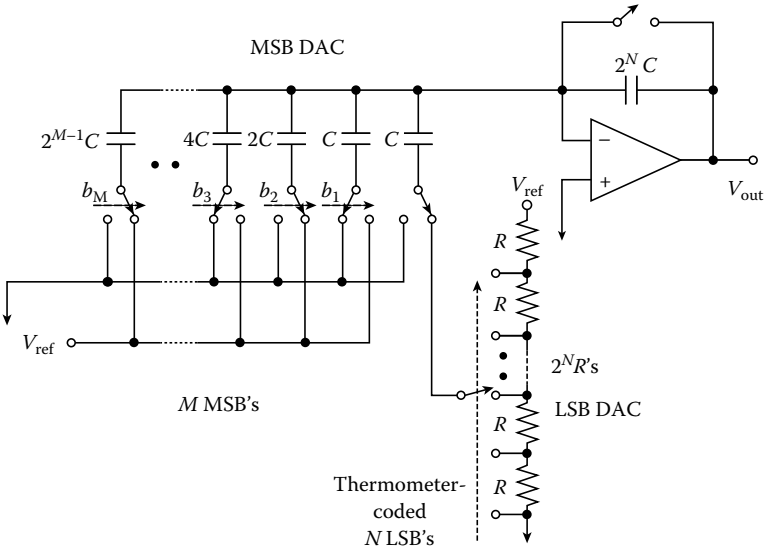

FIGURE 10.11 $C + R$ combination DAC.

DAC matching. Both combination DACs are seldom used as stand-alone DACs due to their limited speed, but are used frequently as subblocks of high-resolution ADCs.

10.1.4 Techniques for High-Resolution DACs

Most DACs are made of passive or active components such as resistors, capacitors, or current sources, and their linearity relies on the matching accuracy of those components. Among frequently used DAC components, diffused resistors and transistors are in general known to exhibit an 8 bit level matching while thin-film resistors and capacitors are matched to a 10 bit level. Trimming or electronic calibration is needed in order to obtain a higher linearity than what is achievable with bare component matching.

The traditional solutions to this have been the wafer-level trimming methods such as laser trimming and Zener zapping. Although many other promising trimming or matching techniques such as polysilicon fuse trimming, electrical trimming techniques using PROM, and large device matching by geometrical averaging have been proposed, conventional factory-set trimming or matching techniques give no flexibility of retrimming. How successfully these techniques can be applied to large-volume production of high-resolution DACs and how the factory-trimmed components will perform over the long term are still in question.

The future trend is toward more sophisticated and intelligent electronic solutions that overcome and complement some of the limitations of conventional trimming techniques. The methods recently developed are dynamic circuit techniques [5] for component matching, switched-capacitor integration [6], electronic calibration [7] of a DAC nonlinearity, and oversampling interpolation techniques [8] which trade speed with resolution. In particular, the oversampling interpolative DACs are used widely in stand-alone applications such as digital audio playback systems or digital communications due to their inherent monotonicity.

10.1.4.1 Dynamic Matching Techniques

In general, a dynamic element matching to improve the accuracy of the binary ratio is a time-averaging process. For simplicity, consider a simple voltage or current divide-by-two element, as shown in Figure 10.12. Due to mismatches in the ratio of resistors, transistors, and capacitors, the divided voltage or current is not exactly $V_{ref}/2$ or $I_{ref}/2$, but their sum is V_{ref} or I_{ref}. The dynamic matching concept is to multiplex these two outputs with complementary errors of Δ and $-\Delta$ so that the errors Δ and $-\Delta$ can be averaged out over time while the average value of $V_{ref}/2$ or $I_{ref}/2$ remains. It is in effect equivalent to the suppressed carrier balanced modulation of the error component Δ. The high-frequency energy can be filtered out using a post low-pass filter. This technique relies on the accurate timing of the duty cycle. Any duty cycle error or timing jitter results in inaccurate matching. The residual matching inaccuracy becomes a second-order error proportional to the product of the original mismatch and the timing error.

The application of dynamic element matching to the binary-weighted current DAC is a straightforward switching of two complementary currents. Its application to the binary voltage divider using two identical resistors or capacitors requires exchanging of resistors or capacitors. This can be achieved easily by reversing the polarity of the reference voltage for the divide-by-two case. However, in the general case of N element matching the current division is inherently simpler in implementation than the voltage division. In general, to match the N independent elements, a switching network with N inputs and N outputs is required. The function of the switching network is to connect any input out of N inputs to

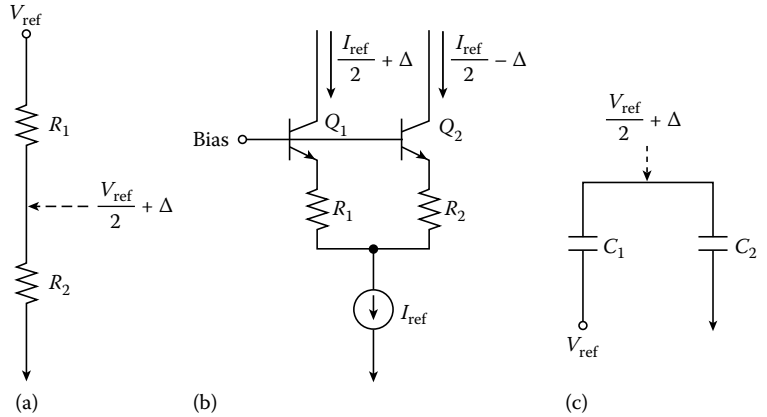

FIGURE 10.12 Divide-by-two elements: (a) resistor, (b) current, and (c) capacitor.

one output with an average duty cycle of $1/N$. The simplest one is a barrel shifter rotating the I–O connections in a predetermined manner [5]. This barrel shifter generates a low-frequency modulated error when N becomes larger because the same pattern repeats every N clocks. A more sophisticated randomizer with the same average duty can distribute the mismatch error over the wider frequency range. The latter technique finds applications as a multibit DAC in the multibit noise-shaping sigma-delta data converter, whose linearity relies on the multibit DAC.

Voltage or current sampling. The voltage or current sampling concept is an electronic alternative to direct mechanical trimming. To sample voltage or current using a voltage or current sampler is equivalent to trimming individual voltage or current sources. The voltage sampler is usually called a S/H circuit, while the current sampler is called a current copier. The voltage is usually sampled on the input capacitor of a buffer amplifier and the current is usually sampled on the input capacitor of a transconductance amplifier such as an MOS transistor gate. Therefore, both voltage and current sampling techniques are ultimately limited by their sampling accuracy.

The idea behind the voltage or current sampling DAC is to use one voltage or current element repeatedly. One example of the voltage sampling DAC is a discrete-time integrator-type DAC with many S/H amplifiers for sampling output voltages. The integrator integrates a constant charge repeatedly, and its output is sampled on a new S/H amplifier every time the integrator finishes an integration as shown in Figure 10.13a. This is equivalent to generating equally spaced reference voltages by stacking identical unit voltages [6]. The fundamental problem associated with this sampling voltage DAC approach is the accumulation of the sampling error and noise in generating larger voltages. Similarly, the current sampling DAC can sample a constant current on current sources made of MOS transistors, as shown in Figure 10.13b [7]. Because one reference current is copied on other identical current samplers, the matching accuracy can be maintained as far as the sampling errors are kept constant. It is not practical to make a high-resolution DAC using voltage or current sampling alone. Therefore, this approach is limited to generating MSB DACs for the segmented DAC or for the subranging ADCs.

10.1.4.2 Electronic Calibration Techniques

Electronic calibration is a general term to describe various circuit techniques, which usually predistort the DAC transfer characteristic so that the DAC linearity can be improved. One such technique is a

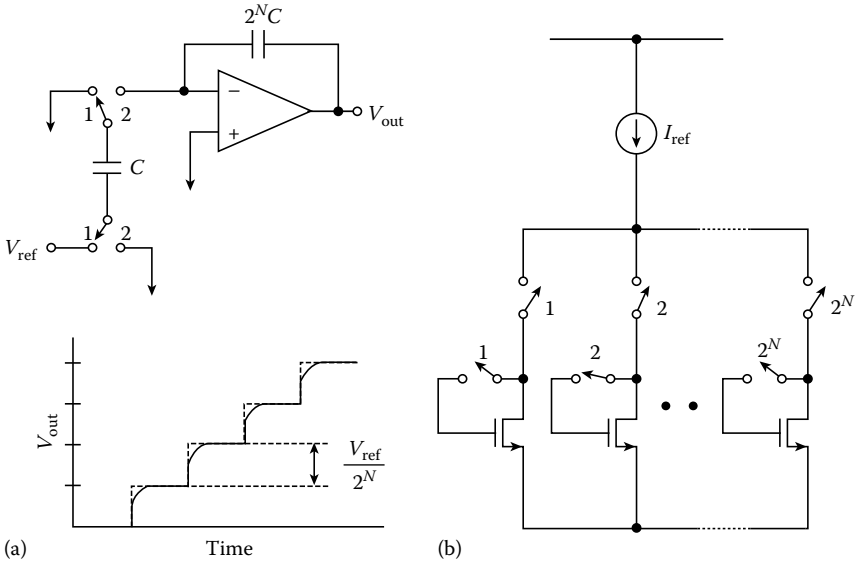

FIGURE 10.13 Voltage and current sampling concepts: (a) integrator and (b) current copier.

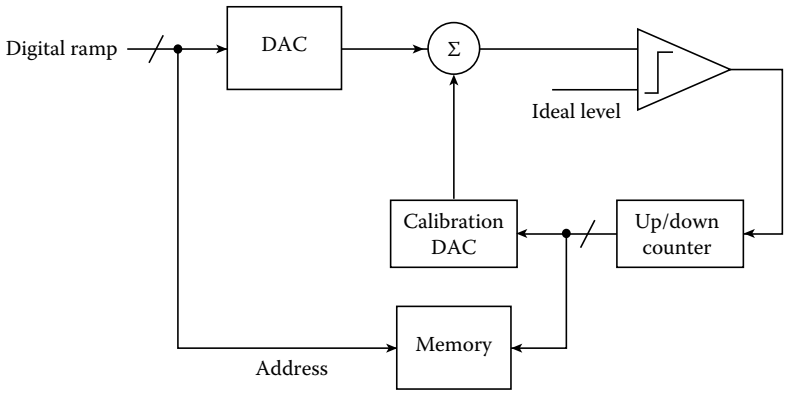

FIGURE 10.14 Code mapping with a calibration DAC.

straightforward code mapping, and the other is a self-calibration. The code-mapping calibration is a very limited technique only for the factory because it requires a precision measurement setup and a large digital memory. The self-calibration is to incorporate all the calibration mechanisms and hardware on the DAC as a built-in function so that users can recalibrate whenever calibrations are needed. The self-calibration is based on an assumption that the segmented DAC linearity is limited by the MSB DAC so that only errors of MSBs may be measured, stored in memory, and recalled during normal operation. There are two ways of measuring the MSB errors. In one method individual-bit nonlinearities, usually appearing as component mismatch errors, are measured digitally [9], and a total error, which is called a code error, is computed from individual-bit errors depending on the output code during normal conversion. On the other hand, the other method measures and stores digital code errors directly and eliminates the digital code-error computation during normal operation [10]. The former requires less digital memory during normal conversion while the latter requires fewer digital computations.

Direct code mapping. The simplified code mapping of a DAC can be done with a calibration DAC, digital memory, and a precision instrument to measure the DAC output, as shown in Figure 10.14. The idea is to measure the DAC error using a calibration DAC so that the DAC output corrected by the calibration DAC can produce an ideal DAC output. The input code of the calibration DAC is stored as a code error in digital memory addressed by the DAC input code. This code error is recalled to predistort the DAC output during normal operation. This technique needs a 2^N memory with a word length corresponding to the number of bits of the calibration DAC. This method can correct any kinds of DAC nonlinearities as long as the calibration DAC has an output range wide enough to cover the whole range of nonlinearity. However, the same method can be implemented without the use of a calibration DAC if the main DAC is monotonic with extra bits of resolution. In this case, the calibration is a simple code mapping, selecting correct input digital codes for correct DAC output voltages among redundant input digital codes.

Self-calibration for individual capacitor errors. The idea of measuring the individual bit errors using a calibration DAC is to quantize the difference Δ in the divide-by-two elements in Figure 10.12 because the ideal divide ration is 1/2. For example, the MSB should be half of the whole range of a DAC, the second MSB is half of the MSB, and so on. Unless buffer amplifiers are used, the ideal calibration DACs for *R* and *C* DACs are *C* and *R* DACs, respectively. The ratio error measurement cycle of 2 bit *C* DAC is illustrated in Figure 10.15. Errors can be quantized using a successive approximation method, but the up/down converter is shown here for simplicity. Initially, the top plate is charged to the comparator offset and the bottom plates of C_1 and C_2 sample 0 and V_{ref}. At the same time, the bottom plate of C_C samples $V_{\text{ref}}/2$ and the up/down counter is reset to make $V_{\text{cal}} = 0$. In the next clock period the charge is redistributed by swapping 0 and V_{ref} on the bottom plates of C_1 and C_2. Then the top plate residual error V_x will be from the charge conservation

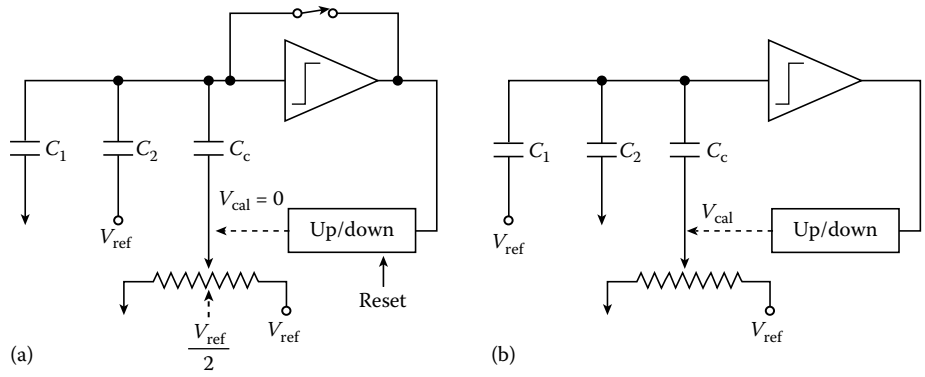

FIGURE 10.15 Capacitor ratio error measurement cycles: (a) initialization and (b) error quantization.

$$V_x = \frac{C_1}{C_1 + C_2 + C_C} V_{ref} - \frac{C_2}{C_1 + C_2 + C_C} V_{ref} = \frac{\Delta C}{2C + C_C} V_{ref} \tag{10.8}$$

If $V_{cal} = 0$, $C_1 = C + \Delta C/2$, and $C_2 = C - \Delta C/2$. This top plate residual voltage can be nulled out by changing the calibration DAC voltage V_{cal}. The measured calibration voltage is approximately

$$V_{cal} = -\frac{\Delta C}{C_C} V_{ref} \tag{10.9}$$

As the actual error V_x is half of the measured value when the V_{ref} is applied to C_1, the actual calibration DAC voltage to be subtracted during normal operation becomes $V_{cal}/2$. Similarly, the multibit calibration can start from the MSB measurement and move down to the LSB side [9].

The extension of this calibration technique to current DACs is straightforward. For example, two identical unipolar currents, I_1 and I_2, can be compared using a voltage comparator and a calibration DAC, as shown in Figure 10.16. After I_1 is switched in, the calibration DAC finds an equilibrium as a null. Then the difference can be measured by interchanging I_1 and I_2 and finding a new equilibrium. Therefore, the current difference error is obtained as

$$I_{cal} = I_2 - I_1 \tag{10.10}$$

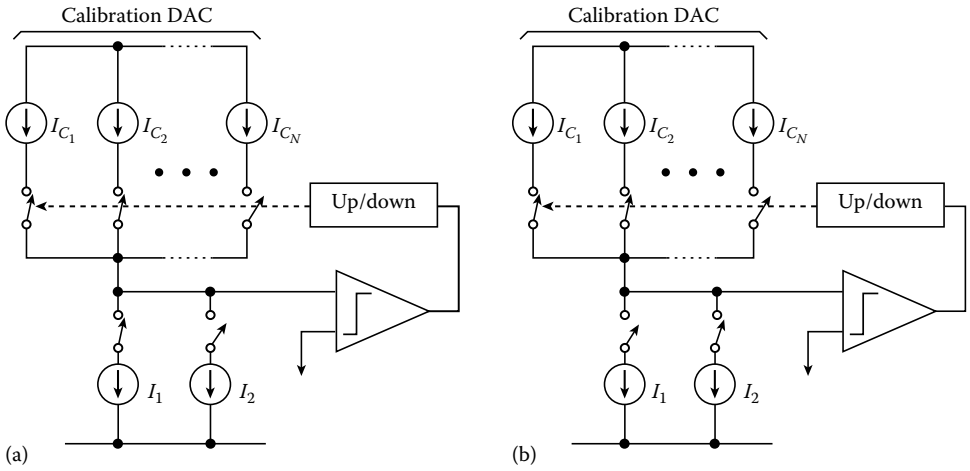

FIGURE 10.16 Current difference measurement cycles: (a) initialization and (b) error quantization.

During normal operation, half of this value should be added to the DAC output using the same calibration DAC every time the current I_1 is switched to the DAC output. Similarly, the same amount is subtracted if I_2 is switched to the output.

Code-error calibration. The code-error calibration is based on the simple fact that the thermometer-coded MSBs of a DAC are made of segments of equal magnitude [10]. Any nonuniform segment will contribute to the overall nonlinearity of a DAC. The segment error between two adjacent input codes is measured by comparing the segment with the ideal segment. Starting from the reference point, 0 or $V_{ref}/2$, the same procedure is repeated until all the segment errors are measured. Therefore, the current code error, Error(j), is obtained by adding the current segment error to the accumulated sum of all the previous segment errors:

$$\text{Error}(j) = \sum_{k=1}^{j} \text{Seg}(k) \tag{10.11}$$

where Seg(k) is the kth segment error from the reference point. These measured code errors are stored in memory addressed by digital codes so that they can be subtracted from uncalibrated raw digital outputs during normal conversion.

The segment error measurement of a current-ratioed DAC thermometer-coded MSBs is similar to the current difference measurement in Figure 10.16. The only difference in measurement is the use of the reference segment current in place of one of the two currents to be compared. That is, each MSB current source is compared to the reference segment. For the capacitive DAC, the kth segment error can be measured in two cycles. After the output of the DAC is initialized to have a negative ideal segment voltage with the input digital code corresponding to $k-1$, the input code is increased by 1 as shown in Figure 10.17. Applying digital codes to the capacitor-array DAC means connecting the bottom plates to either V_{ref} or ground depending on the corresponding digital bits. Then the kth segment error is generated at the output and can be measured digitally using subsequent ADC stages or using a calibration DAC as shown in Figure 10.15.

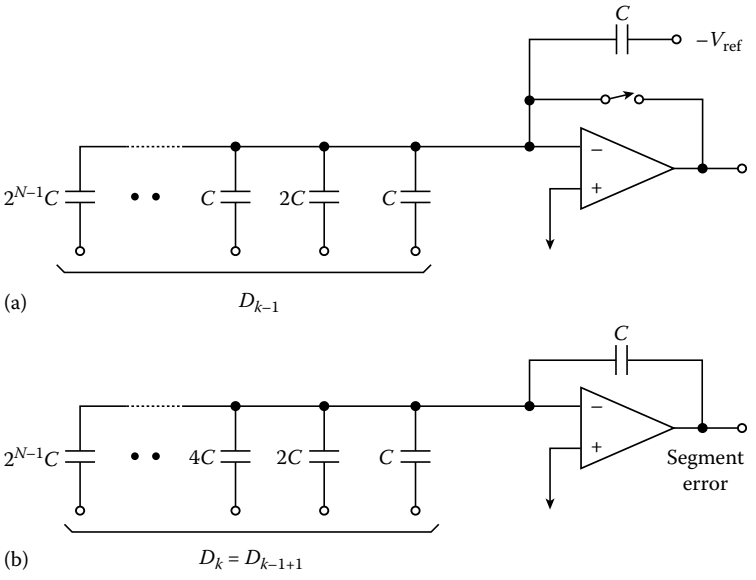

FIGURE 10.17 Code-error measurement cycle: (a) initialization and (b) error quantization.

Digital truncation errors. All calibration methods need extra bits of resolution in the error measurements because digital truncation errors are accumulated during code-error computations. For example, if the truncation errors are random, the additions of n digital numbers will increase the standard deviation of the added number by $n^{1/2}$. This accumulated truncation error affects both DNL and INL of the converter self-calibrated using measured errors of individual bits. On the other hand, if calibrated using measured segment errors, the DNL of the converter is always guaranteed to be within $\pm\frac{1}{2}$ LSB of a target resolution because all segment errors are measured with one extra bit of resolution, but the INL will still be affected by the digital truncation because code errors are obtained by accumulating segment errors. The effect of the digital truncation errors due to n repeated digital additions on the INL can be modeled using uncorrelated and independent random variables, and the standard deviation of INL is calculated in LSB units as

$$\sigma_{\text{INL}} = \sqrt{\frac{(n-i)(i-1)}{12(n-1)}}(\text{LSB}) \quad \text{for } i = 1, 2, \ldots, n \tag{10.12}$$

For example, when $n = 16$, the maximum standard deviation of the INL at the midpoint is about 0.56 LSB.

10.1.4.3 Interpolative Oversampling Techniques

Ordinary DACs generate a discrete output level for every digital word applied to their input, and it is difficult to generate a large number of distinct output levels for long words. The oversampling interpolative DAC achieves fine resolution by covering the signal range with a few widely spaced levels and interpolating values between them. By rapidly oscillating between coarse output levels, the average output corresponding to the applied digital code can be generated with reduced noise in the signal band [8]. The general architecture of the interpolative oversampling DAC is shown in Figure 10.18. A digital filter interpolates sample values of the input signal in order to raise the word rate to a frequency well above the Nyquist rate. The core of the technique is a digital truncator to truncate the input words to shorter output words. These shorter words are then converted into analog form at the high sample rate so that the truncation noise in the signal band may be satisfactorily low. The sampling rate upconversion for this is usually done in stages using two upsampling digital filters. The first filter, usually a two to four times oversampling FIR, is to shape the signal band for sampling rate upconversion and to equalize the passband droop resulting from the second SINC filter for higher-rate oversampling.

A noise-shaping sigma-delta-sigma modulator can be built in digital form to make a digital truncator as shown in Figure 10.19. Using a linearized model, the z-domain transfer function of the modulator is

$$Y(z) = \frac{\alpha H(z)}{1 + \alpha H(z)} X(z) + \frac{1}{1 + \alpha H(z)} Q(z) \tag{10.13}$$

where

$Q(z)$ is the quantization noise

α is the quantizer gain

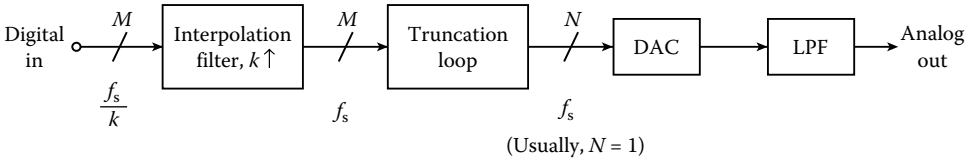

FIGURE 10.18 Interpolative oversampling DAC.

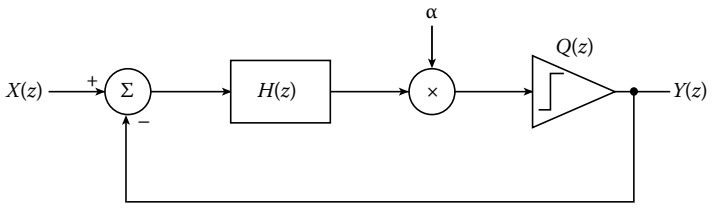

FIGURE 10.19 Delta-sigma modulation as a digital truncator.

The loop filter $H(z)$ can be chosen so that the quantization noise may be high-pass filtered while the input signal is low-pass filtered. For the first-order modulator, the loop filtered is just an integrator with a transfer function of

$$H(z) = \frac{z^{-1}}{1 - z^{-1}} \tag{10.14}$$

while for the second-order modulator, the transfer function is

$$H(z) = \frac{z^{-1}(2 - z^{-1})}{(1 - z^{-1})^2} \tag{10.15}$$

However, the standard second-order modulator is implemented, as shown in Figure. 10.20, using a double integration loop. In general, first-order designs tend to produce correlated idling patterns. Second-order designs are vastly superior to first-order designs both in terms of the required OSR to achieve a particular SNR as well as in the improved randomness of the idling patterns. However, even the second-order loop is not entirely free of correlated fixed patterns in the presence of small DC inputs. The second-order loop needs dithering to reduce fixed pattern noises, but loops of a higher order than third do not exhibit fixed pattern noises.

Stability. The quantizer gain α plays an important role in keeping the modulator stable. Considering α, the transfer function of the second-order loop shown in Figure 10.20 becomes

$$Y(z) = \frac{\alpha z^{-2} X(z) + (1 - z^{-1})^2 Q(z)}{1 - 2(1 - \alpha)z^{-1} + (1 - \alpha)z^{-2}} \tag{10.16}$$

The root locus of the transfer function in the z-domain is shown in Figure 10.21. As shown, the second-order loop becomes unstable for $\alpha > 4/3$ because one pole moves out of the unit circle. This in turn implies that the signal at the input of the quantizer becomes too large. Most delta-sigma modulators become unstable if the signal to the quantizer exceeds a certain limit. Higher-order modulators tend to be

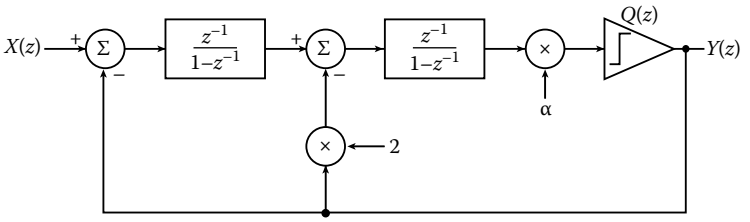

FIGURE 10.20 Second-order 1 bit modulator.

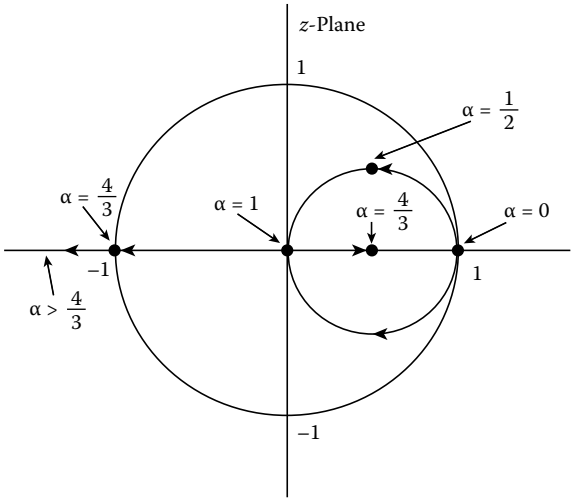

FIGURE 10.21 Root locus of the second-order loop transfer function.

overloaded easily at higher quantizer gain than first-or second-order modulators. Therefore, for the stability reason, the integrator outputs of the loop filter are clamped so that the signal at the input of the quantizer is limited for linear operation. Digital truncators of a higher order than second are feasible in digital circuits because signal levels can be easily detected and controlled. The straightforward third order or higher loop using multiple loops is unstable, but higher order modulators can be built using either the cascaded MASH [11] or the single-bit higher order [12] architecture.

Dynamic range. In general, for the Nth order loop, the noise falls by $6N + 3$ dB for every doubling of the sampling rate, providing $N + 0.5$ extra bits of resolution. Because the advantage of oversampling begins to appear when the OSR is >2, a practically achievable dynamic range by oversampling is approximately

$$\mathrm{DR} > (6N + 3)(v)\mathrm{dB} \tag{10.17}$$

where M is the OSR. For example, a second-order loop with 256 times oversampling can give a dynamic range of >105 dB, but the same dynamic range can be obtained using a third-order loop with only 64 times oversampling. The dynamic range is not a limit in the digital modulator. In practice, the dynamic range is limited in the rear-end analog DAC and postfilter.

One-bit or multibit DAC. The rear end of the interpolative oversampling DAC is an analog DAC. Because the processing in the interpolation filter and truncator is digital instead of analog, achieving precision is easy. Therefore, the oversampling DAC owes its performance to the rear-end analog part because the conversion of the truncated digital words into analog form takes place in the rear-end DAC. The 1 bit quantizer can be easily overloaded and needs clamping to be stable, while multibit quantizers are more stable due to their small quantization errors. However, the multibit system is limited by the accuracy of the multibit DAC. Although the analog techniques such as dynamic matching or self-calibration can improve the performance of the multibit DAC, the 1 bit DAC is simpler to implement and its performance is not limited by component matching. It is true that a continuous time filter can convert the 1 bit digital bitsteam into an analog waveform, but it is difficult to construct an ideal undistorted digital waveform without clock jitter. However, if the bitstream is converted into a charge packet, a high linearity is guaranteed due to the uniformity of the charge packets.

A typical differential 1 bit switched-capacitor DAC with one-pole roll-off can be built as shown in Figure 10.22 using two-phase nonoverlapping clocks 1 and 2. There are many advantages in a fully

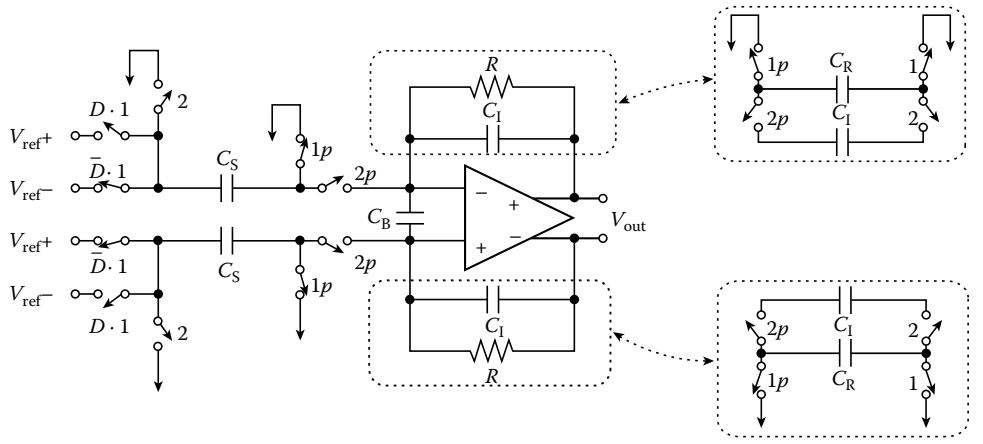

FIGURE 10.22 Switched-capacitor 1 bit DAC/filter.

differential implementation. The dynamic range increases by 3 dB because the signal is doubled (6 dB) but the noise gains by 3 dB. It also rejects most noisy coupling through power supplies or through the substrate as a common-mode signal. Furthermore, the linearity is improved because the even-order nonlinearity components of the capacitors and the op-amp are canceled. In the implementation of Figure 10.22, a resistor as a loss element can be replaced by a capacitor switched in and out at f_c as illustrated. The bandwidths of these filters in both cases are set by $1/RC_I$ and f_cC_R/C_I, respectively, Also, the filter DC gains are defined by Rf_c C_S and C_S/C_R, respectively. The digital bitstream is converted into a charge packet by sampling the reference voltage on the bottom plates of the sampling capacitors (C_S). If the digital bit is ZERO, $-V_{ref}$ is sampled during the clock phase 1 and the charge on C_S is dumped on the lossy integrator during phase 2. On the other hand, if the digital bit is ONE, V_{ref} is sampled instead. To reduce the input-dependent switch-feedthrough component, the switches connected to the top plates should be turned off slightly earlier than the bottom plate switches using $1p$ and $2p$. Alternatively, a slightly different 1 bit DAC is possible by sampling a constant reference voltage by inverting the polarity of the integration depending on the digital bit as shown in Figure 10.23.

The op-amp for this application should have a high DC gain and a fast slew rate. The op-amp DC gain requirement is a little alleviated considering the linear open-loop transfer characteristic of most op-amps

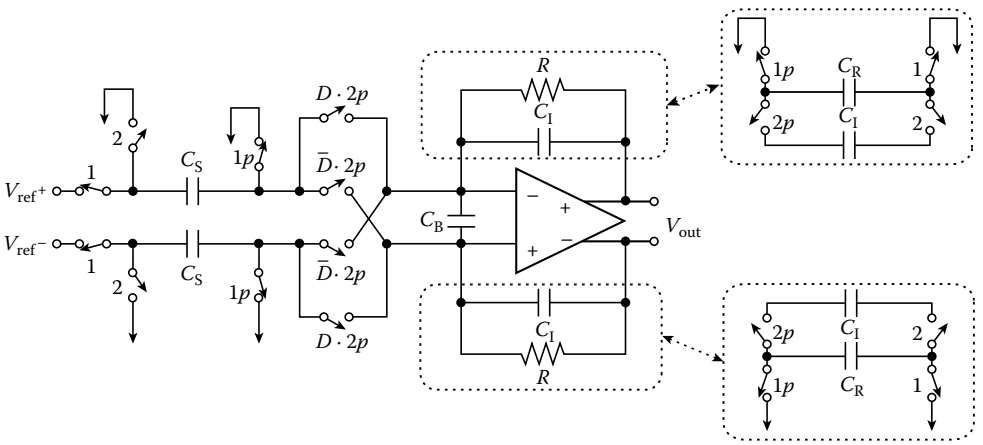

FIGURE 10.23 Alternative 1 bit DAC sampling constant V_{ref}.

within a limited swing range. As discussed earlier, the slew-limited settling generates an error proportional to the square of the magnitude. Therefore, a nonslewing op-amp such as a class AB input op-amp performs better for this application. The op-amp starts to slew when a larger voltage than its linear input range is applied. When the charge packet of the sampled reference voltage is dumped onto the input summing node, it causes a voltage step on the summing node. The bypass capacitor C_B between two summing nodes helps to reduce this voltage step to prevent the op-amp from slewing. The large the C_B, the smaller the voltage step. However, a too-large C_B will narrowband the feedback amplifier, and the settling will take longer as a result.

Postfiltering requirement. Although the one-pole roll-off will substantially attenuate high-frequency components around f_c, the 1 bit DAC should be followed by a continuous time postfilter so that the charge packets can be smoothed out. Unlike the delta-sigma modulator which filters out the out-of-band-shaped noise using digital filters, the demodulator output noise can be filtered only by analog filters. Because the shaped noise is out-of-band, it does not affect the inband performance directly, but the large out-of-band high-frequency noise tends to generate inband intermodulation components and limit the dynamic range of the system. Therefore, the shaped high-frequency noise needs to be filtered with a low-pass filter one order higher than the order of the modulator. It is challenging to meet this postfiltering requirement with analog filtering techniques. Analog filters for this application are often implemented in continuous time using a cascade of Sallen–Key filters made of emitter follower unity-gain buffers, but both switched-capacitor and continuous time filtering techniques have improved significantly to be applied to this application. The other possibility is the hybrid implementation of an FIR filter using digital delays and an analog current swimming network. Because the output is a bitstream, current sources weighted using coefficients of an FIR filter are switched to the current summer depending on the digital bit to make a low-pass FIR filter.

10.1.5 Sources of Conversion Errors

10.1.5.1 Glitch

The basic function of the DAC is the conversion of digital numbers into analog waveforms. A distortion-free DAC creates instantaneously an output voltage that is proportional to the input digital number. In reality, DACs cannot achieve this impossible goal. If the input digital number changes from one value to a different one, the DAC output voltage always reaches a new value sometime later. For DACs, the shape of the transient response is a function governed in large part by two mechanisms, glitch and slew rate limit. The ideal transient response of a DAC to a step is a single-time constant exponential function, which only generates an error growing linearly with the input signal, as explained in Figure 10.3. Any other transient responses give rise to errors that have no bearing on the input signal. The glitch impulse is described in terms of a picovolts times seconds or equivalent unit.

Glitches are caused by small time differences between some current sources turning off and others turning on. Take, for example, the major code transition at half scale from 011 . . . 11 to 100 . . . 00. Here, the MSB current source turns on while all other current sources turn off. The small difference in switching times results in a narrow half-scale glitch, as shown in Figure 10.24. Such a glitch, for example, can produce distorted characters in CRT display applications. To alleviate both glitch and slew-rate problems related to transients, a DAC is followed by a S/H amplifier, usually called a deglitcher. The deglitcher stays in the hold mode while the DAC changes its output value. After the switching transients have settled, the deglitcher is changed to the sampling mode. By making the hold time suitably long, the output of the deglitcher can be made independent of the DAC transient response. Thus, the distortion during transients can be circumvented by using a fast S/H amplifier. However, the slew rate of the deglitcher is on the same order as that of the DAC, and the transient distortion will still be present, now as an artifact of the deglitcher.

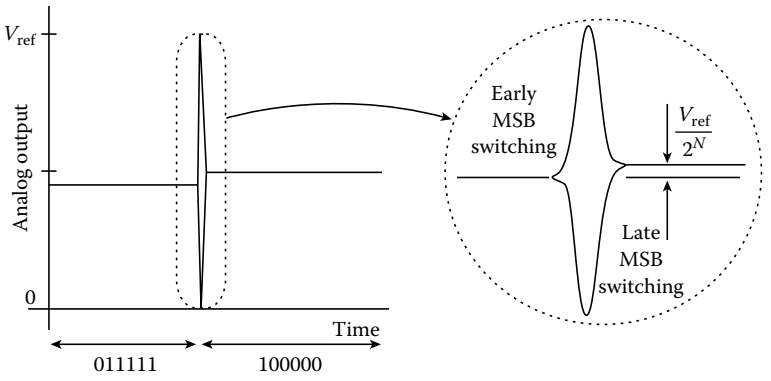

FIGURE 10.24 Glitch impulse at a major carry.

10.1.5.2 Timing Error-Word Clock Jitter

Although a DAC is ideally linear, it needs precise timing to correctly reproduce an analog output signal. If the samples do not generate an analog waveform with the identical timing with which they were taken, distortion will result, as explained in Figure 10.25. Jitter can be loosely defined as timing errors in analog-to-digital and digital-to-analog conversion. When the analog voltage is reconstructed using a DAC with timing variations in the word clock, the sample amplitudes, the ONEs and ZEROs are correct, but they come out at the wrong time. Because the right amplitude at the wrong time is the wrong amplitude, a timing jitter in the word clock produces an amplitude variation in the DAC output, causing the waveform to change shape. This in turn introduces either spurious components related to the jitter frequency or raises the noise floor of a DAC, unless the jitter is periodic. If the jitter has a Gaussian distribution with a root mean square jitter of Δt, the worst-case SNR resulting from this random word clock jitter is

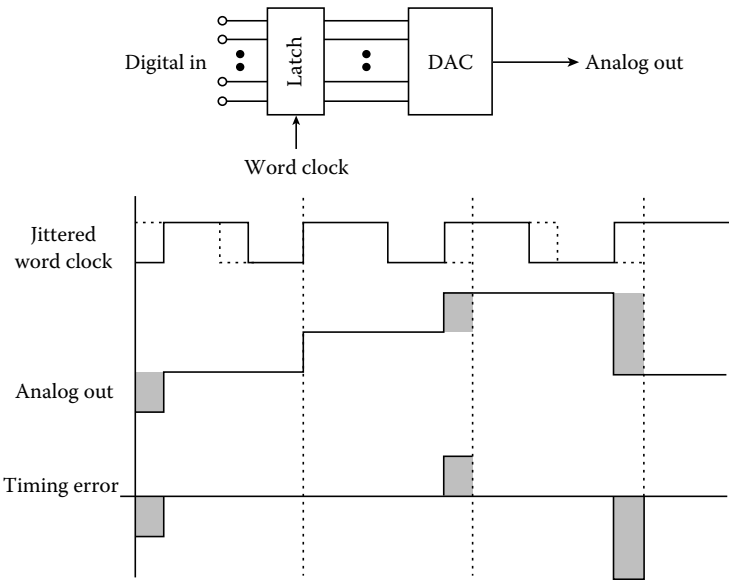

FIGURE 10.25 Word clock jitter effect.

$$\text{SNR} = -20 \times \log \frac{2\pi f \Delta t}{M^{1/2}} \tag{10.18}$$

where f is the signal frequency and M is the OSR. The OSR M is defined as

$$M = \frac{f_c}{2f_n} \tag{10.19}$$

where
f_c is the word clock frequency
f_n is the noise bandwidth

The timing jitter error is more critical in reproducing high-frequency components. In other words, to make an N-bit DAC, an upper limit for the tolerable word clock jitter is

$$\Delta t < \frac{1}{2\pi B 2^N} \left(\frac{2M}{3}\right)^{1/2} \tag{10.20}$$

where B is the bandwidth of the baseband. This implies that the error power induced in the baseband by clock jitter should be no larger than the quantization noise resulting from an ideal N-bit DAC. For example, a Nyquist-sampling 16 bit DAC with a 22 kHz bandwidth should have a word clock jitter of <90 ps.

These timing errors are caused by variation in the clock signal that controls the time when the DAC converts each digital word to an analog voltage. Usually, the term ''clock jitter'' results from everything inside a digital processor (noise from digital circuitry, inductance and capacitance of a clock bus or of a printed circuit board trace) as well as the instability of the clock source. For example, noise in digital circuitry causes the zero-crossing points to shift slightly. If the digital signal has an average slope of 10 V/μs, just 1 mV_{rms} of noise will cause 100 ps of root mean square jitter.

10.1.5.3 Voltage Reference

Ideally, the voltage reference V_{ref} is a constant temperature- and supply-independent voltage with a zero output resistance. The most common voltage reference source is a silicon bandgap voltage reference of about 1.2 V. Depending on the process used, the bandgap reference voltage has a temperature coefficient of typically 20–100 ppm/°C at room temperature when it is set to a voltage ranging from 1.2 to 1.3 V. To generate a different reference voltage other than 1.2 V, op-amps are often used to make inverting and noninverting amplifiers with trimmable feedback gains. Because the bandgap voltage for zero temperature coefficient is not clearly defined and process dependent, it is common to trim this voltage at a wafer level, and it is extremely difficult to achieve an absolute accuracy over a wide range of temperature. However, most DAC applications, except for precision instruments, do not require an absolute accuracy of the reference voltage, and the load-driving capability of the op-amp used in the voltage reference is of paramount interest.

When a DAC is used as a subblock of an ADC, the DAC has only to settle to a final value within a given clock period. In such applications it is not important how the DAC settles. However, the DAC as a stand-along device should have a single-pole response without a glitch and a slew limit. Except for the current-ratioed DAC, the voltage reference is periodically loaded and disturbed by a switched-in load at the clock rate, and the reference output should be restored immediately so that the DAC can settle fast. When disturbed, the voltage reference needs to settle with a time-constant shorter than that of the DAC with an unlimited slew rate. Figure 10.26 illustrates this situation when the voltage reference periodically refreshes the loading capacitor. If the op-amp unity-gain bandwidth is $1/\tau_0$ rad/s, the op-amp restores the output with a time constant $(1 + R_2/R_1)\,\tau_0$ of the feedback amplifier. The large capacitor C_D helps to prevent the op-amp from slewing because the voltage dip of $V_{\text{ref}} C_L/(C_D + C_L)$ decreases as C_D increases.

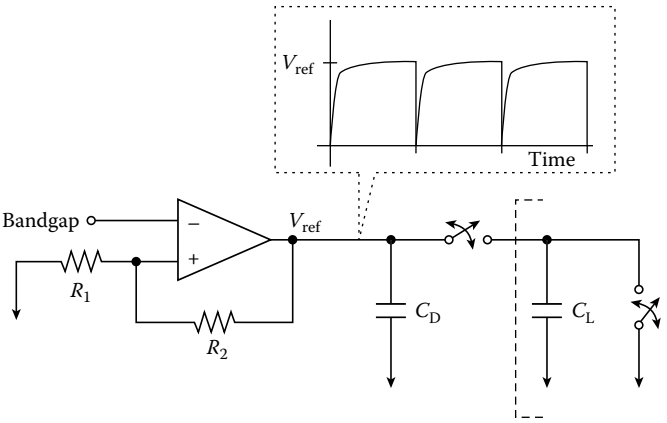

FIGURE 10.26 Voltage reference periodically charging a load capacitor.

10.1.5.4 Noise

Noise is a fundamental limit in high-resolution DACs. The resolution of a DAC is limited by a quantization noise given by Equation 10.2, unless the circuit contributes higher noise. There are many noise sources in real DACs. The DAC output is corrupted by noises directly coupled from bouncing power supplies, bias lines, and ground, as well as the noise sources such as thermal noise, flicker noise, and shot noise. To reduce the former noise sources, it is necessary to carefully separate analog and digital supplies and to eliminate sets of ground loops using a star-ground configuration. The use of a fully-differential architecture helps to reduce such coupling noises. However, the latter set of noise sources is predictable and can be reduced by a low-noise design.

The dominant noise source of a resistor-string DAC shown in Figure 10.4 is a white thermal noise of resistors. If the output resistance of the DAC is R_{out}, the root mean square output noise of the DAC is $(4kTR_{out})^{1/2}$ V/Hz$^{1/2}$, where k is the Boltzman constant and T is the absolute temperature. The thermal noise is about 4 nV/Hz$^{1/2}$ if R_{out} is 1 kΩ. The output resistance of this DAC depends on the digital input code. The worst-case R_{out} is one quarter of the total resistance of the string when the output is connected to the center tap. For lower noise, the total resistance should be minimized at the cost of high power consumption. The noise of the voltage reference appears at the output after being divided by the resistor string. The voltage noise of the output buffer, if used, is directly added to this noise.

On the other hand, the noise source of the current-ratioed DAC of Figures 10.6 and 10.7 is the current noise contributed either by the shot noise of the current source or by the parallel resistor connected to the output node. If the total output current is I_{out} and the total output shunt resistance is R_p, the root mean square output shot noise is 2 qI_{out} A/Hz$^{1/2}$ and the root mean square current noise contributed by the shunt resistor is 4 kT/R_p A/Hz$^{1/2}$, where q is 1.6×10^{-19} C. The shot noise of a 50 μA current and the current noise of a 1 kΩ shunt resistor give the same root mean square noise of 4 pA/Hz$^{1/2}$. The shunt feedback resistance of the transresistance amplifier also contributes to the total noise. If the current DAC is terminated by a low-impedance source of 50–75 Ω, the current noise is usually dominated by this termination resistor.

The main source of the capacitor-array DAC shown in Figures 10.8 and 10.9 is a well-known kT/C noise. The sampled root mean square noise voltage of the capacitor of C is $(kT/C)^{1/2}$ V without regard to the switch-on resistance. The 1 pF sampling capacitor gives a 64 μV sampled noise. This noise is evenly distributed over the Nyquist band (half the sampling frequency), and puts a lower limit on the smallest signal the DAC can handle. Furthermore, the reference and ground noises are divided by the C divider and appear at the output of the DAC. When applied to the oversampling converters either in delta-sigma modulators or in a 1 bit DAC, shown in Figures 10.22 and 10.23, the kT/C noise in the signal band is lower than the Nyquist-rate converters by the OSR of M given by Equation 10.19.

10.1.6 Low-Spurious DAC Design Examples

Modern broadband digital communication systems such as cable modem, cellular baseband, and wireless local area network consist of multiple channels. For high bit rate transmission of 54 Mbit/s over 20 MHz bandwidth, the RF standards such as IEEE 802.11a and Hyperlan2 use the orthogonal frequency division multiplexing scheme that divides the signal band into 52 of 300 kHz narrowband channels. It is challenging to preserve signal integrity of such a complex waveform. Multiple channels are mixed in many different ways when analog signal processing is nonlinear. For example, the multichannel spectrum is perfect when digitally generated, but it is degraded while being converted into analog waveform due to the DAC nonlinearity. To generate an accurate multichannel spectrum without mixing, DAC should be linear both in static and dynamic performance. High spurious-free dynamic range is the most important for frequency-domain applications. Recently, a few techniques such as spatial averaging [13–15], self-trimming [16], and dynamic linearity enhancement [16,17] are reported.

10.1.6.1 Spatial Averaging for Static Linearity

DAC static linearity measured in terms of DNL and INL depends on how DAC components are arranged. In most stand-alone DACs, an array of current sources is predominantly used. It is well known that the binary-weighted array is simple to decode but exhibits poor DNL, while the thermometer-coded array is complex to decode but exhibits good DNL. In fact, the complexity of the thermometer-coded current DAC grows exponentially. Therefore, in typical applications above 8–10 bits, the MSB part is coded in thermometer while the LSB part is coded in binary. The thermometer-coded DAC array occupies a large area, and current source matching is limited by overall gradient effect. In a large thermometer-coded array, systematic and graded errors are far greater in effect than random device mismatch errors. They result from many factors such as edge effect, current source output resistance, supply voltage drop, thermal gradient, and process gradients of doping and thickness across the die, etc. In integrated circuit design, the common-centroid layout scheme has been used to effectively match devices when limited by the gradient effect.

Since the thermometer-coded array is physically large, a two-dimensional common-centroid scheme should be used. To improve INL, the two-dimensional array can be split into four quadrants biased separately using common-centroid bias circuits [13]. To improve INL further, each current source can be split into four small slices connected in parallel, and each slice is placed in one of the four different quadrants [14]. This results in the first-order spatial averaging of the systematic and gradient errors. In general, the gradient effect is first-order, but the second-order effect limits DAC INL performance at 14 bit level or higher. Further partitioning the unit current source into 16 small slices connected in parallel can remove the residual gradient effect [15]. Unlike the first-order centroid scheme, the second-order spatial averaging scheme uses four common-centroid slices placed in four different quadrants. In theory, the matching improves as the array is split into many smaller pieces and the common-centroid scheme is used in each small piece. However, the complexity grows significantly, and the operating speed is inevitably reduced.

10.1.6.2 Self-Trimming for Static Linearity

The two-dimensional geometric averaging is very costly in terms of chip area and the operating speed as the array gets larger. Calibration techniques as discussed are effective in overcoming device mismatch and gradient effects in IC process. One recent trend is self-trimming. The concept is to adjust the current source values electronically like laser trimming. Although laser trimming is a one-time adjustment, the self-trimming is adaptive and continuously engaged. A trimmable floating current source is shown in Figure 10.27, which can be used as one MSB current source in the thermometer-coded array [16]. The floating current source made of transistors N_4 and P_2 is switched from the top side by transistors N_6 and N_7. When the current source needs trimming, the bottom transistor N_2 is turned on, and the current is switched to the measuring resistor R_2. This arrangement of trimming is transparent to the normal

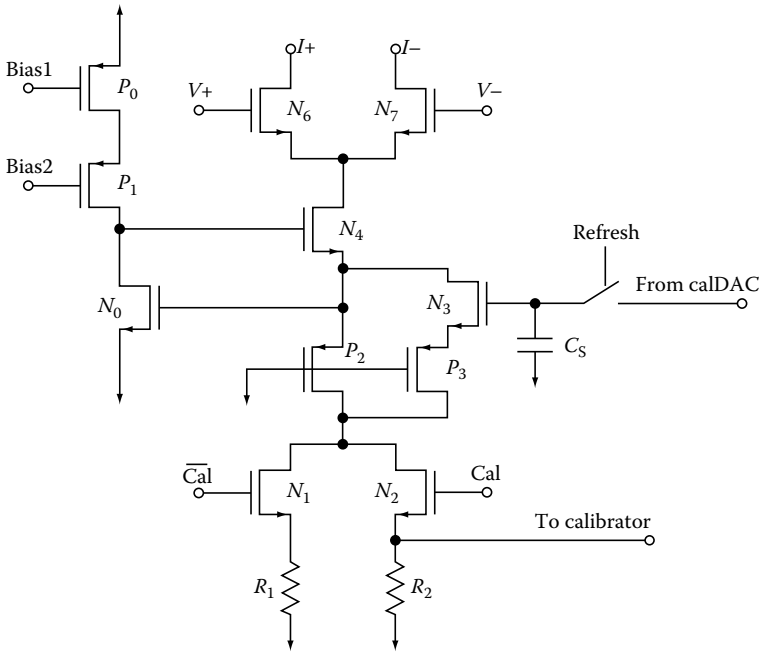

FIGURE 10.27 Trimmable floating current source.

operation and is performed in background. An oversampling calibrator based on delta-sigma modulation repeatedly monitors the voltage across R_2, accurately compares it with the preset reference voltage, and constantly feedbacks the error signal that periodically updates the capacitor C_s to adjust the current source.

10.1.6.3 Dynamic Linearity Enhancement

The static linearity up to over 14 bits can be achieved either with spatial averaging or with self-trimming, but the dynamic linearity heavily depends on how the DAC output settles. For example, the wireless baseband spectrum covers over 20 MHz bandwidth, but generating such a wideband signal with high static and dynamic linearity is not a trivial task. Furthermore, in scaled CMOS, devices are more nonlinear and low supply voltage often limits the DAC linearity. In standard current DACs, each current source is switched to the output at different times due to clock skew, and adds parasitic capacitance to the output node, which results in code-dependent output settling. The clock skew and the code-dependent settling are most prominent among many factors limiting dynamic DAC linearity. Isolating the output node from current sources and synchronizing the code transitions are simple solutions for these, but the clock skew is difficult to deal with high precision. It is often suggested that the DAC's dynamic linearity can be improved if its output is sampled and held using a deglitcher. In fact, the deglitcher is functionally a track and hold circuit, but it is also difficult to implement at high frequencies with high precision.

The return-to-zero (RZ) scheme solves the deglitcher problem as explained in Figure 10.28a [17]. While the error in the track and hold stays for the half period, the error in the RZ exponentially decays. The logic behind this is that rather than sampling analog voltage accurately, it is easier to let the output keep on changing exponentially. Exponential settling is a linear process. The same effect as RZ can be achieved in a simpler manner, called track and attenuate [16]. Rather than resetting the DAC output, just attenuating it achieves the same goal. Figure 10.28b illustrates the DAC output stage performing the track and attenuate function. The differential DAC output current comes into the folded-cascode node V_x, which is isolated from the output node. The output nodes track the signal during the half clock period,

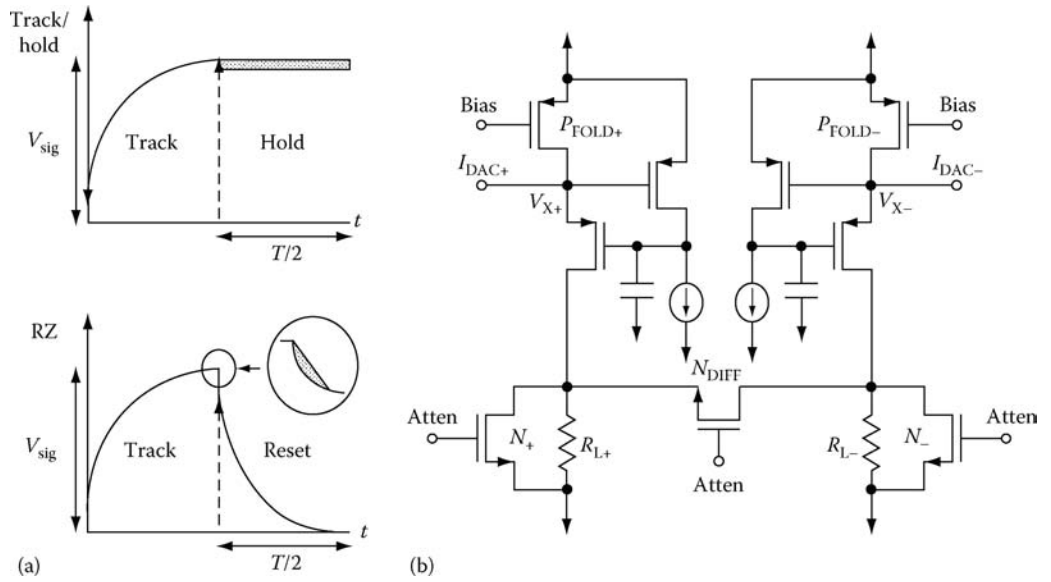

FIGURE 10.28 (a) Track and hold vs. RZ and (b) track/attenuate output stage.

but are bypassed by three transistors N_+, N_-, and N_{DIFF} for attenuation during the remaining half clock period. The difference of the RZ DAC from the conventional DAC is that the output spectrum nulls at multiples of twice the sampling frequency, which in turn provides less attenuation in the passband.

10.2 Analog-to-Digital Converters

Ramesh Harjani

10.2.1 Introduction

With the increased complexity possible in modern-day integrated circuits, analog-to-digital converter (ADC) and digital-to-analog converter (DAC) have become ubiquitous components of mixed-signal integrated circuits. ADCs transform an analog signal, V_A, into an N-bit digital representation, V_d. Such a converter is said to have a resolution of N bits. The digital signal V_d is an approximation of the original analog signal, V_A, and the maximum error during this conversion process for an N-bit converter is equal to $1/2^N$ of the full-scale value. This error is called the quantization error.

A number of topologies exist for ADC. They can be classified as Nyquist rate converters or oversampled converters. Nyquist rate converters sample the input at the minimum sampling rate, i.e., two times the maximum signal frequency. As the name implies, oversampled converters take more samples than is mandated by the Nyquist criterion to generate extremely high resolution. Nyquist rate converters are usually classified as (1) high-speed, (2) medium-speed, and (3) high-resolution converters. However, the different architectures are better categorized by evaluating the number of clock cycles they use to perform the analog-to-digital conversion. For example, for N bits of resolution a high-speed converter performs the conversion in one or two clock cycles, a medium-speed converter performs the conversion in N clock cycles, and a high-resolution converter performs the conversion in 2^N clock cycles. Thus, we classify them here as 1-, N-, and 2^N-clock converters.

Before describing the details of the various ADC architectures we discuss some of the performance characteristics of ADCs in general and describe some test techniques that are used to measure these characteristics.

10.2.1.1 ADC Test Techniques

ADCs are primarily tested using parametric techniques. That is, a key set of parameters that characterize an ADC are verified. An ADC is characterized by its static and dynamic performance. In static performance, we are primarily concerned about the linearity of the I–O transfer characteristics, and in dynamic performance we are concerned about the operation of the converter at full operating speed.

Figure 10.29 shows the transfer characteristics for an ideal 3 bit converter. The dashed line shows the transfer characteristics of an infinite precision converter and the bold line shows the transfer characteristics of a 3 bit version. We note that the least significant bit (LSB) value is equal to $1/2^N$ of the full-scale value. Figures 10.30 through 10.33 show examples of the static performance characteristics of an ADC.

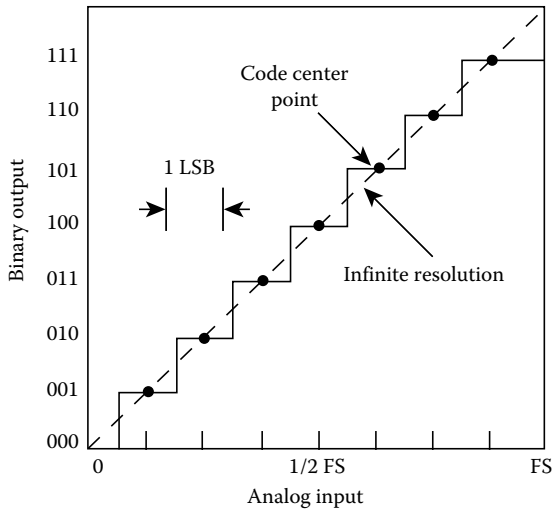

FIGURE 10.29 Transfer characteristics for an ideal 3 bit ADC.

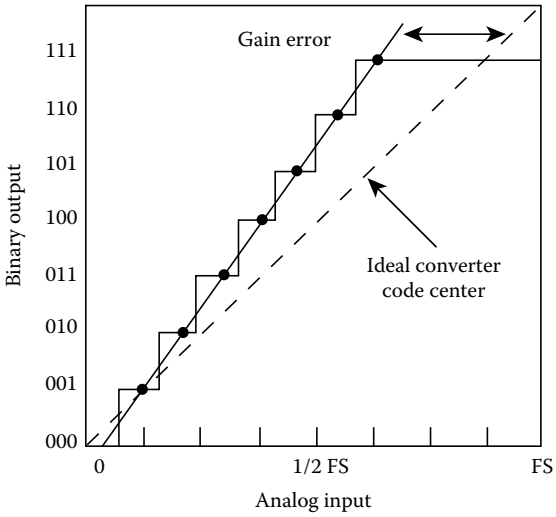

FIGURE 10.30 Gain error in an ADC.

A gain error is said to be present when the maximum digital value does not correspond to the full-scale analog value. An offset error corresponds to a horizontal shift in the transfer characteristics. The integral nonlinearity error specifies the maximum deviation of the transfer characteristics from the ideal code center. Differential nonlinearity specifies the deviation of each stepsize from $1/2^N$ of the full-scale value.

Dynamic ADC performance characteristics include signal-to-noise ratio (SNR), effective bits, aperture errors, and input signal bandwidth. During full-speed operation some additional errors become evident because of the finite settling time and bandwidth limitations of the circuits within the ADC. The SNR and effective bits are dynamic ways of measuring the minimum resolution and errors in the transfer characteristics. Different terms are used to specify similar performance parameters largely because different measurement techniques are used to generate them. The input signal bandwidth specifies the maximum frequency of the input signal.

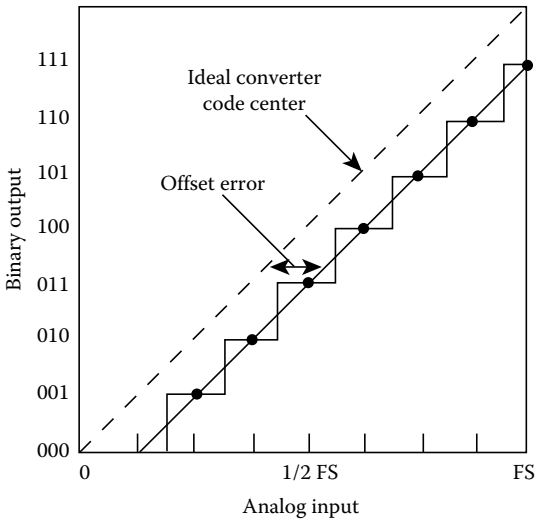

FIGURE 10.31 Offset error in an ADC.

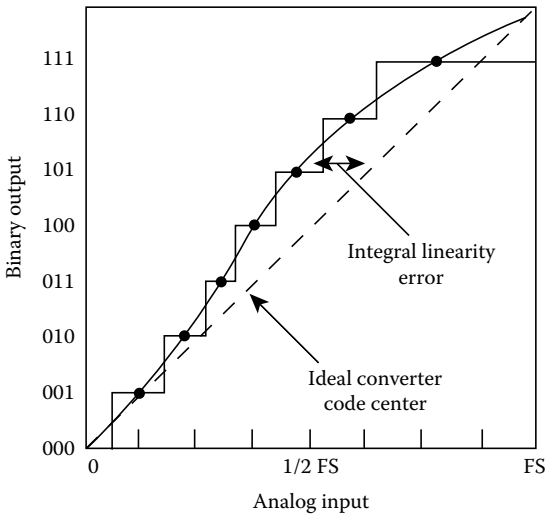

FIGURE 10.32 Integral nonlinearity error.

Because of the large number of performance specifications for ADCs, quite a few techniques are used to test them as well. These testing techniques also reflect the different types of performance characteristics, i.e., static and dynamic. The more traditional methods of testing ADC are primarily concerned with checking the static characteristics of these converters. Examples of such test techniques include analog difference signal methods, crossplot methods, and servo loop code transition measurement methods [3]. Dynamic techniques to test linearity are based on using a well-known and near-full-scale input signal and evaluating the output code probability over a large input sample size. This technique is called the ''code density test'' or the ''histogram test.'' The output code probability for a linear ramp input is uniform for all codes. However, it is difficult to generate extremely accurate ramp signals at high speed, therefore, sine-wave signals are used. Unfortunately, with a sine wave the output code probability is no longer uniform but is instead ''cusp-shaped''. An estimate of the differential nonlinearity can be

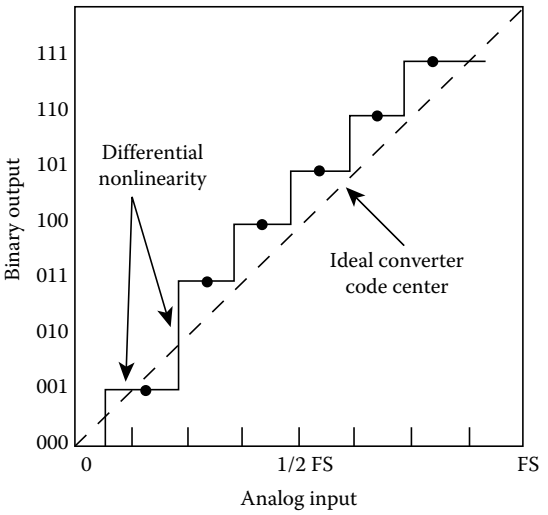

FIGURE 10.33 Differential nonlinearity error.

generated by evaluating the difference between the expected code probability and measured values. The code density test requires a large number of data samples in the range of several hundreds of thousands. Additionally, a small number of large magnitude errors are easily masked in this technique. More recently, frequency domain-based techniques have been used to measure the harmonic content of the converted signal to provide an estimate of the SNR and effective number of bits. In this technique, a discrete time Fourier transform (DTFT) is performed on the output data sequence and is used to measure the data converter performance characteristics. Although the number of data samples required are fewer than the code density approach, this approach still requires a few thousand data samples. Additionally, proper windowing functions and synchronized sampling may be required to reduce spectral leakage.

Data converters are relatively time-consuming to test. However, rather than explain all the techniques that can be used to test data converters, we concentrate on a single method, the crossplot method, to provide the reader with some insight into the complexity of testing ADCs. For additional details about the other methods, readers are referred to [3]. A block diagram for the crossplot method is shown in Figure 10.34. In the crossplot technique, the output of the lowest 2 or 3 bits of an ADC are fed to the

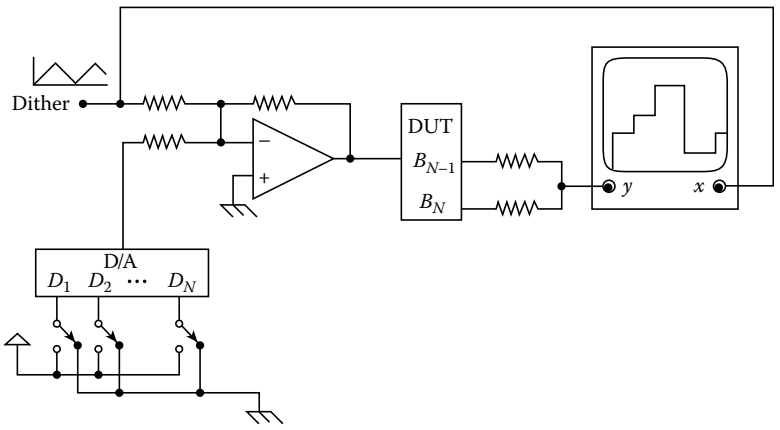

FIGURE 10.34 Crossplot technique used to test ADC static characteristics. (From Demler, M.J., *High-Speed Analog-to-Digital Conversion*, Academic Press, New York, 1991, 162.)

Y input of an oscilloscope and a separate triangular dither signal is fed to the *X* input of the oscilloscope. The input to the ADC is generated using a discrete summing amplifier that adds the output of a DAC, which is itself swept through its input space at a much slower rate, and the dither signal, mentioned earlier. This technique generates a staircase waveform on the oscilloscope. Therefore, the linearity of the last 2 or 3 bits around a fixed bias voltage, which is generated by the DAC, can be seen easily on an oscilloscope. The primary advantage of this technique is that it uses fairly inexpensive equipment. However, it is extremely time consuming to evaluate all 2^N combinations and the technique provides no information about the integral linearity, offset, and gain errors. In general, techniques that are used to test ADCs are fairly complex and either require a large sample size, i.e., high cost, or use extremely complex equipment to perform the tests.

Having described the basic characteristics of ADC, we now describe of the different ADC architectures in detail. We first consider Nyquist rate converter topologies and then describe oversampled converters.

10.2.2 Nyquist Rate Converters

As mentioned earlier, Nyquist rate converters are classified as 1-clock converters, *N*-clock converters, and 2^N-clock converters. Examples of 1-clock converters include the flash architecture, the pipelined architecture [11,12], and the voltage folding architecture. Examples of *N*-clock converters include the successive-approximation architecture [9] and the algorithmic architecture [6]. Examples of 2^N-clock converters include the single-slope and dual-slope architectures [4].

10.2.2.1 1-Clock Converters

Flash converters. Flash or parallel converters are the highest rate converters and are sometimes also called ''video rate converters'' because they operate at rates necessary for video signals. Parallel converters are O(1)-clock converters in that they require one or two clock cycles to perform an *N*-bit conversion. The basic principle of operation is fairly simple and is easily explained with the help of Figure 10.35. This figure is a block diagram for a 3 bit flash converter. The input is compared to $(2^3 - 1)$ comparators. The comparison voltage for the *i*th comparators is set to be equal to $(iV_{FS})/(2^3)$, where V_{FS} is the full-scale voltage. The resulting outputs are then converted from thermometer code to binary code. In general, the time required to perform the analog-to-digital conversion is equal to the comparator resolution time plus the time taken to perform the digital code conversion, i.e., one clock cycle. The reference voltages for the comparators are usually generated using an equally spaced resistor string that is offset by $R/2$, as shown in Figure 10.36. The primary advantage of providing the $R/2$ offset is that it allows the code center to pass through the origin. The resolution of integrated MOS flash converters is limited to approximately 8 bits. This is primarily due to the matching constraints placed on the resistors and also because of the exponential increase in the number of components ($\approx 2^N$) required for higher resolution. The speed for MOS flash converters is usually limited to about 50 MHz. However, if higher speed operation is required, then the process of time interleaving may be employed. Here, *M* (*N*-bit) ADCs are operated in parallel, but each is delayed somewhat, as shown in Figure 10.37 [1]. By starting the conversion operation for A/D_2 before the operation of A/D_1 is complete allows the complete interleaved converter to operate at *M* times the speed of each individual converter. Although the technique allows for higher operating speed, the number of parallel paths has increased. Therefore, due to size limitations the resolution is usually lower than for simple flash converters.

Subranging converters. The exponential area penalty ($\alpha\ 2^N$) for flash converters can be mitigated by using subranging techniques without incurring severe speed penalties. Here, instead of deciding all *N*-bits at one time, only a subset of these is decided during the first clock phase, and the rest are decided in the following clock phases. If two clock phases are used to decide all *N*-bits, this is called a two-step subranging converter topology.

A block diagram for a two-step subranging converter is shown in Figure 10.38. In this converter topology the α most significant bits (MSBs) are decided by the coarse ADC, the results of which are then

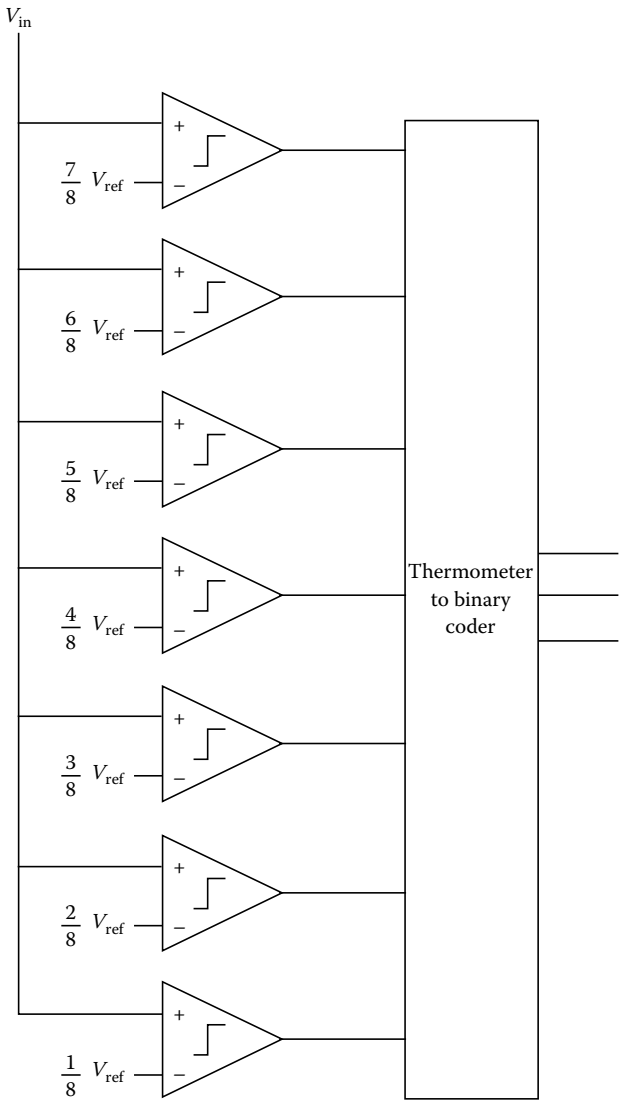

FIGURE 10.35 Three bit flash converter block diagram.

passed on to an α-bit DAC. The output voltage of the DAC is subtracted from the input signal. The resulting voltage is amplified 2α times and then a $(N-\alpha)$-bit fine converter is used to resolve the remaining bits. The entire process—coarse conversion, digital-to-analog subtraction, amplification, and fine conversion—is performed in one clock period. The coarse and fine converters are usually implemented as simple flash converters. Therefore, the operating speed of a pure subranging converter is at least twice as slow as that of a flash converter. However, the total number of comparators (and associated circuits) is reduced from 2^N to $2\alpha + 2^{N-\alpha}$. The savings in area can be substantial. Usually, the value of α is selected to be roughly equal to $N/2$. For example, for $N = 10$ and selecting $\alpha = 5$, the number of comparators reduce from $2^{10} = 1024$ to $2^6 = 64$, which is a savings of 93.75%. This subranging process can be extended further to a larger number of sequential stages; however, the total propagation delay usually limits the operation speed fairly significantly.

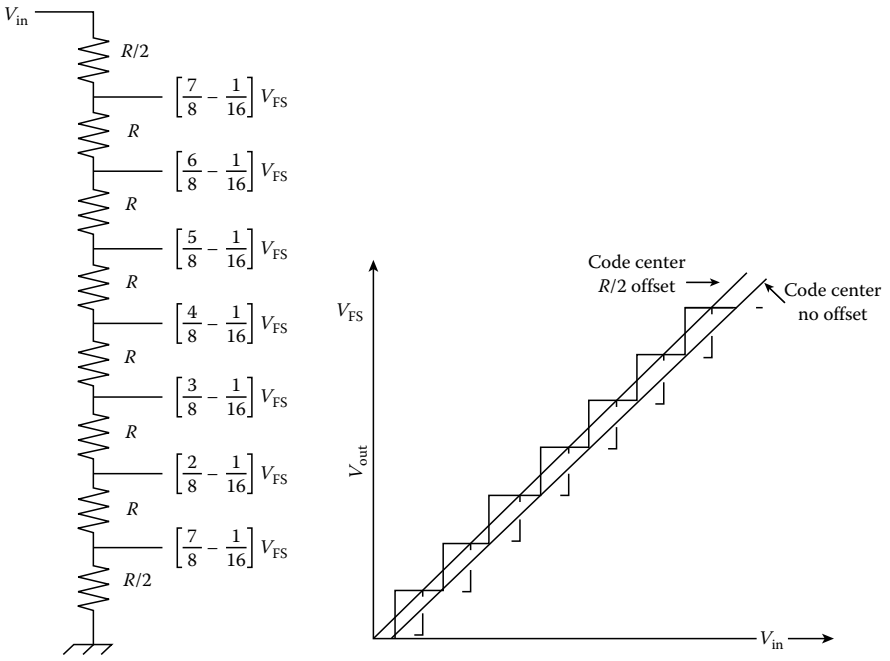

FIGURE 10.36 Flash converter 1/2 LSB offset.

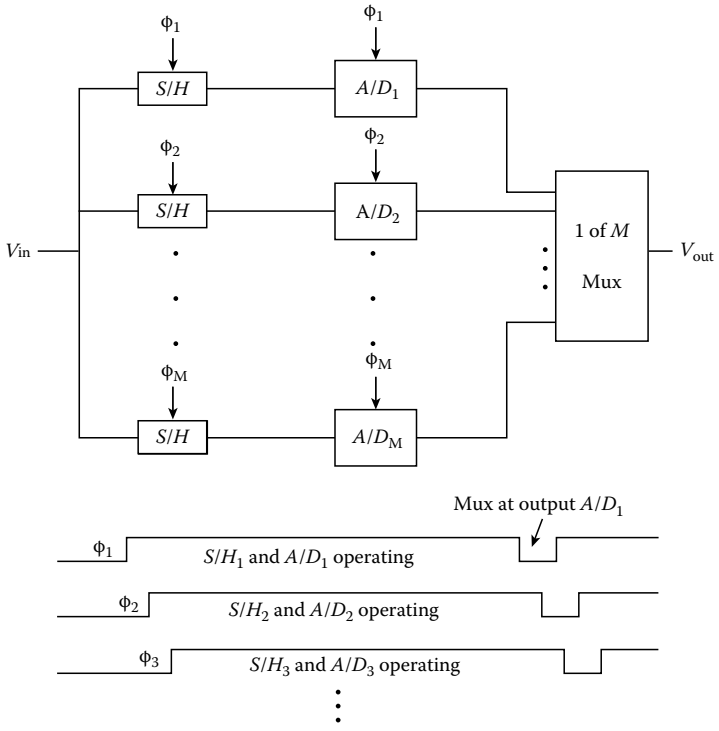

FIGURE 10.37 Time interleaved converter block diagram.

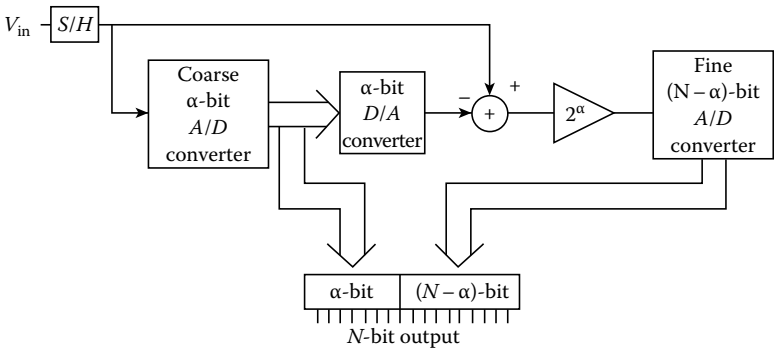

FIGURE 10.38 Subranging converter block diagram.

Pipelined converters. Instead of operating both the coarse and fine converter in the same clock period, a sample-and-hold (S/H) could be added to the circuit in Figure 10.38, such that when the fine converter is resolving the lower $(N-\alpha)$ bits for the first input sample the coarse converter can begin resolving the upper α bits for the next input sample. This kind of converter can be made to operate at speeds comparable to flash converters and is called a pipelined converter. A block diagram for a two-stage pipelined converter is shown in Figure 10.39. Because the α MSBs are decided during the previous clock period, the results from the fine and coarse converters need to be synchronized by delaying the output of the coarse converter by a single clock period. As with the subranging converter the number of comparators have decreased from 2^N to $2^{N-\alpha}+2\alpha$.

Unlike the subranging topology, the pipeline methodology can easily be extended to N sequential stages, each resolving only 1 bit, because of the sample-and-held circuits between each of the stages. The block diagram for such an N-step converter is shown in Figure 10.40. In this figure, note that only one comparator is used per stage and the interstage gain block (also performing the S/H function) has a gain of two. Once again for synchronization purposes, shift registers are used. This pipelined converter [11,12] operates as follows. The input is first compared to see if it is greater than V_{ref}. If the input is greater than V_{ref}, then we set the MSB bit. If the MSB is set, then V_{ref} is subtracted from the input voltage. However, if the MSB is not set, nothing is done. The resulting voltage is then doubled. During the next clock cycle, the resulting voltage is once again compared to V_{ref} to give the MSB-1 bit. While the second stage generates the second MSB for the first input, the first stage processes a new input. When the pipeline is filled, N inputs are being processed simultaneously. Several shift registers are used to ensure that all the data bits

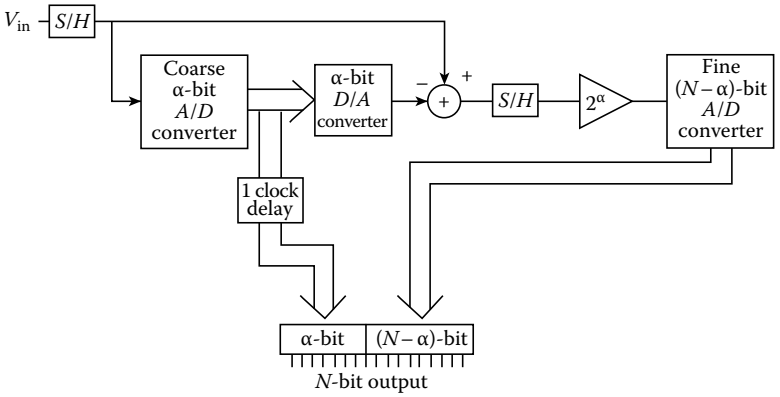

FIGURE 10.39 Two-stage pipelined converter block diagram.

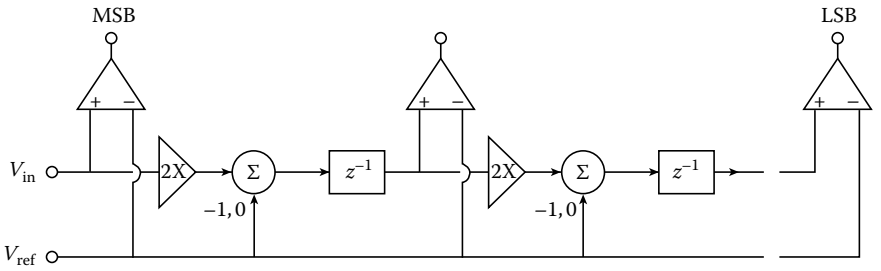

FIGURE 10.40 *N*-stage pipelined converter.

corresponding to a single input are output simultaneously. This process continues until we finally generate the LSB. The analog output of the *i*th stage can be written as

$$V_i = 2[V_{i-1} - b_i V_{\text{ref}}]z^{-1} \tag{10.21}$$

where b_i is equal to 1 if the *i*th bit is set and equal to 0 otherwise.

Figure 10.41 is a simple circuit realization for a pipelined ADC [13]. Other more advanced topologies [12] reduce some of the problems associated with this topology, but operate on the same principle. Only one stage of an *N*-bit converter is shown in this figure. In this first stage, the amplifier A_1 performs the comparison function and the amplifier A_2 performs the 2× multiplication and the conditional subtraction function. Both amplifiers, along with the associated capacitors and switches, also implement a S/H function. Let us first concentrate on the comparison function. For a sufficiently large gain, during ϕ_1 the capacitor C_h is charged to $V_a - V_{off}$, where V_{off} is equal to the amplifier offset voltage. During ϕ_2 the reference voltage, V_{ref}, is connected to the positively charged terminal of capacitor C_h and the feedback around the amplifier is removed. During this period the amplifier A_1 acts as a comparator and compares the voltage $[V_{ref} - (V_a - V_{off})]$ against V_{off}; i.e., the effect of the amplifier offset voltage is completely

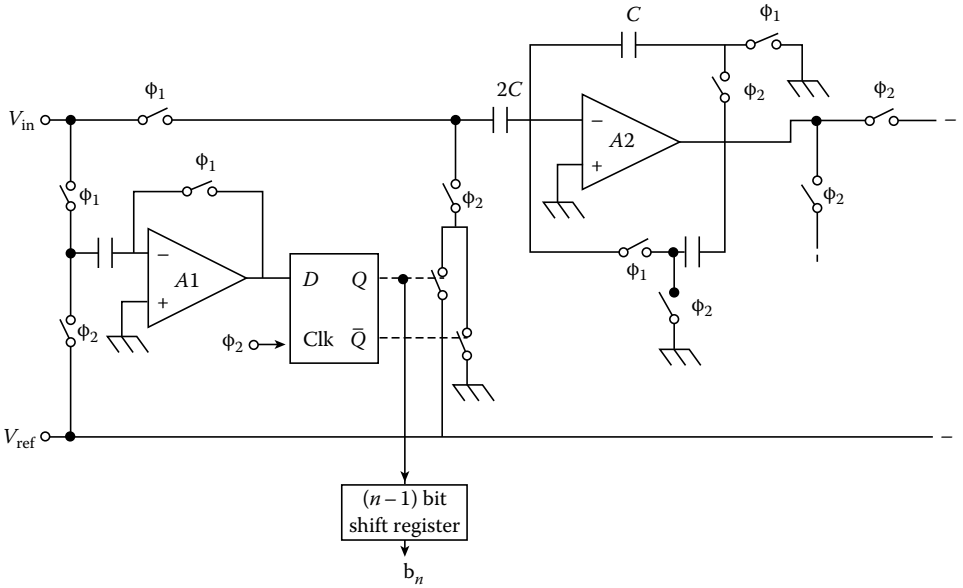

FIGURE 10.41 Circuit realization of an *N*-stage pipelined converter.

canceled. The preceding discussion is valid only for sufficiently large gain. However, if the gain of amplifier A_1 is not sufficiently large then the charge transfer is not complete and an error is introduced in the comparison; i.e., the effective comparison is not with V_{ref} but with $V_{\text{ref}} + \Delta V$. The error in the comparison is dependent on the input signal voltage. Note that the first stage samples the input at ϕ_1 while the next stage samples the input at ϕ_2. Likewise, the third stage samples the input at ϕ_1 and the fourth stage samples the input at ϕ_2, and so forth.

Digital-error correction in multistep converters. Pipelined and subranging converters that have an interstage gain >1 can utilize digital-error correction [14] to improve linearity. We shall illustrate the principle of digital-error correction with the help of a 4 bit two-stage pipelined converter. Each of the stages resolves 2 bits. Digital-error correction can be used to correct for linearity errors in all except the last stage. Additionally, it is unable to correct for digital-to-analog linearity and op-amp settling time errors. Therefore, for our two-stage example we will only be able to correct for errors in the first stage and we shall assume an ideal DAC.

Figure 10.42 is the block diagram for the 4 bit two-stage pipelined converter without digital-error correction. This circuit is a 4 bit version of Figure 10.39. The input signal is sample-and-held by S/H_1. The course MSB bits for the overall converter are generated by the first-stage subconverter (A/D_1). The analog value corresponding to these bits is then generated by the first-stage digital-to-analog subconverter (D/A_1). The difference between the input signal and the digital-to-analog output is called the residue. This residue is amplified by the interstage gain stage ($G = 4$) and passed on to the second-stage analog-to-digital subconverter. The second-stage analog-to-digital subconverter (A/D_1) then generates the lower 2 bits. Because the second stage is working on the signal after one clock delay, an intermediate delay stage is added to synchronize the outputs of the two stages.

The residue for an ideal converter varies from $-\frac{1}{2}$ LSB to $+\frac{1}{2}$ LSB of the first-stage subconverter resolution, as shown in Figure 10.43. In the case of nonlinearity in the first subconverter the residue will have excursions above and below the $\pm\frac{1}{2}$ LSB value, as shown in Figure 10.44. For an ideal digital-to-analog conversion, the residue corresponding to each digital code is still accurate and no data have been lost as yet. In the traditional pipelined converter shown in Figure 10.42 any residue value from the first converter that is greater than $\pm\frac{1}{2}$ LSB of the first stage saturates the second stage and produces errors.

If, however, we change the overall converter topology such that the resolution of the second subconverter is increased by 1 bit, i.e., we double the number of levels, and reduce the interstage gain by half, then we can detect when the residue exceeds the $\pm\frac{1}{2}$ LSB levels and correct for its effect digitally. Figure 10.45 is a block diagram for the pipelined converter in Figure 10.42 with digital-error correction. Whenever the residue from the first stage exceeds $+\frac{1}{2}$ LSB it implies that the digital output of the first

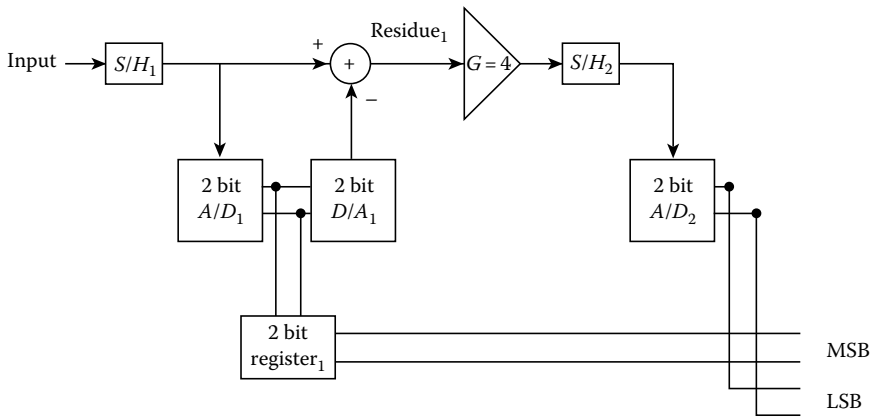

FIGURE 10.42 Four bit, two-stage, pipelined converter block diagram without error correction.

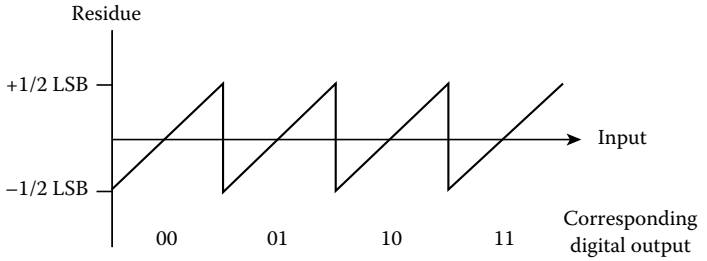

FIGURE 10.43 Ideal subconverter residue.

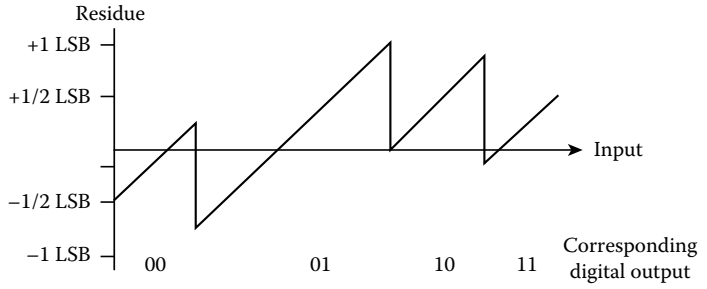

FIGURE 10.44 Nonideal subconverter residue.

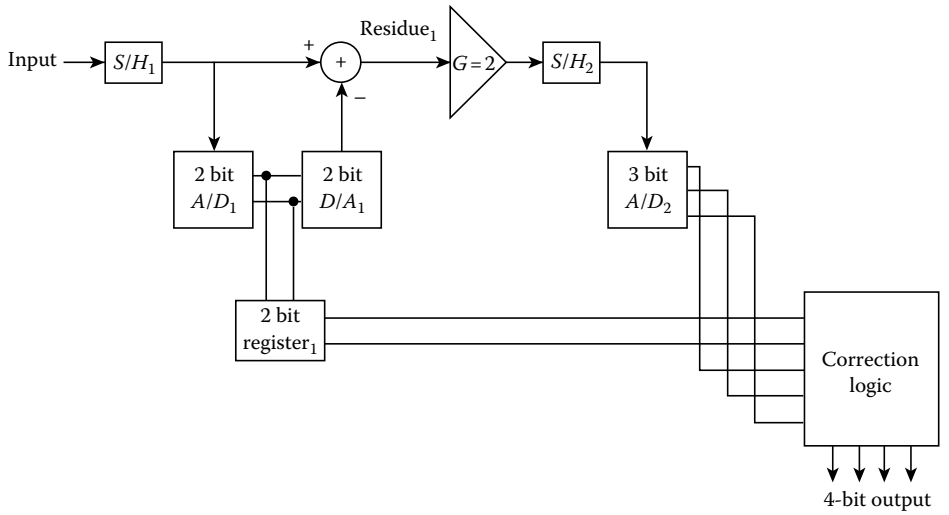

FIGURE 10.45 Four bit, two-stage, pipelined converter block diagram with error correction.

stage subconverter is too small. Likewise, whenever the residue is less than $-\frac{1}{2}$ LSB it implies that the digital output of the first stage is too large. By adding a $\frac{1}{2}$ LSB offset at the input of the first analog-to-digital subconverter and at the output of the first DAC the input to the second subconverter for an ideal first subconverter is restricted between $\frac{1}{4}$ full-scale and $\frac{3}{4}$ full-scale. Any excursion outside this region implies an error in the first analog-to-digital subconverter. The approximate value for this error is measured by the second-stage subconverter and is then subtracted digitally from the final value.

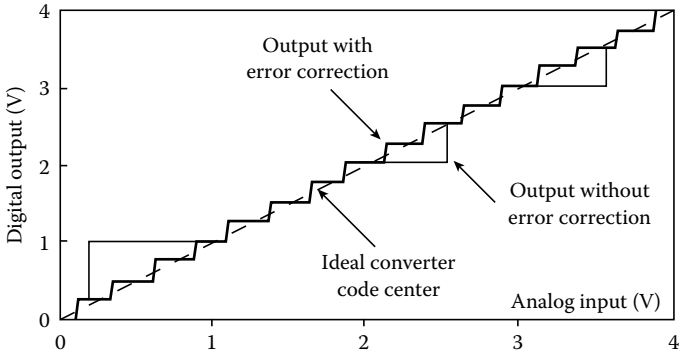

FIGURE 10.46 Digital-error correction simulation results.

Nonlinearities from the second stage are not corrected via this scheme; however, as the interstage gain is greater than 1 the effect of the nonlinearities in the second stage will have a much lower effect than those resulting from the first stage. Nonlinearities in the DAC can be reduced substantially by utilizing reference feedforward compensation [15]. Here, the reference for the second stage changes dynamically and is obtained by amplifying the first-stage digital-to-analog subconverter segment voltage that corresponds to the most current digital output code of the first-stage analog-to-digital subconverter. Figure 10.46 presents the simulation results for the 4 bit two-stage pipelined converter with and without digital error correction. For purposes of clarity the second-stage subconverter is made ideal. In a real converter some nonlinearity would still exist, but would be limited to that introduced by the last stage. Traditionally, even though the resolution of the first subconverter is only 2 bits, it needs to be linear to the overall converter resolution. Digital-error correction can reduce the linearity requirements such that it is commensurate with its resolution.

10.2.2.2 *N*-Clock Converters

Both the successive approximation and algorithmic analog-to-digital topologies require N clock cycles to perform an N-bit conversion. They both perform 1 bit of conversion per clock cycle. The successive approximation converter is a subclass of the subranging converter, in which during each clock cycle only 1 bit of resolution is generated. The algorithmic converter is a variation of the pipelined converter, in which the pipeline is folded back into a loop. Both topologies essentially perform a binary search to generate the digital value. However, in the case of the successive approximation converter the binary search is performed on the reference voltage, while in the case of the algorithmic converter the search is performed on the input signal.

Successive approximation converters. A block diagram for the successive approximation converter is shown in Figure 10.47. Because the conversion requires N clock cycles a S/H version of the input signal is provided to the negative input of the comparator. The comparator controls the digital logic circuit that performs the binary search. This logic circuit is called the successive approximation register (SAR). The output of the SAR is used to drive the DAC that is connected to the positive input of the comparator.

During the first clock period, the input is compared with the MSB, i.e., the MSB is temporarily raised high. If the output of the comparator remains high, then the input lies somewhere between 0 and $V_{ref}/2$, and the MSB is reset to 0. However, if the comparator output is low, then the input signal is somewhere between $V_{ref}/2$ and V_{ref}, and the MSB is set high. During the next clock period the MSB-1 bit is evaluated in the same manner. This procedure is repeated such that at the end of N clock periods all N-bits have been resolved. Figure 10.48 is the binary search procedure for a 4 bit converter and shows the comparator output sequence that corresponds to an input equal to 72% of V_{ref}.

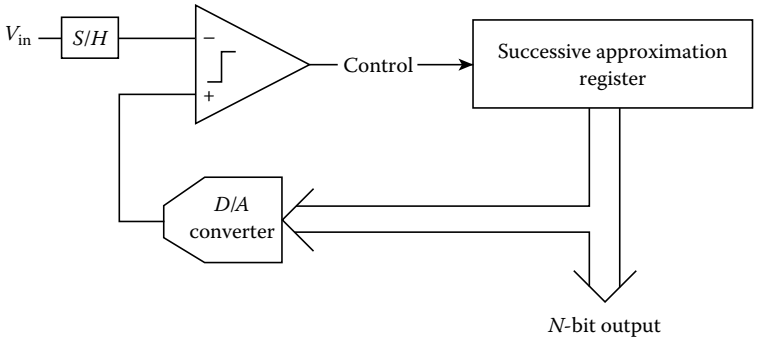

FIGURE 10.47 Successive approximation converter block diagram.

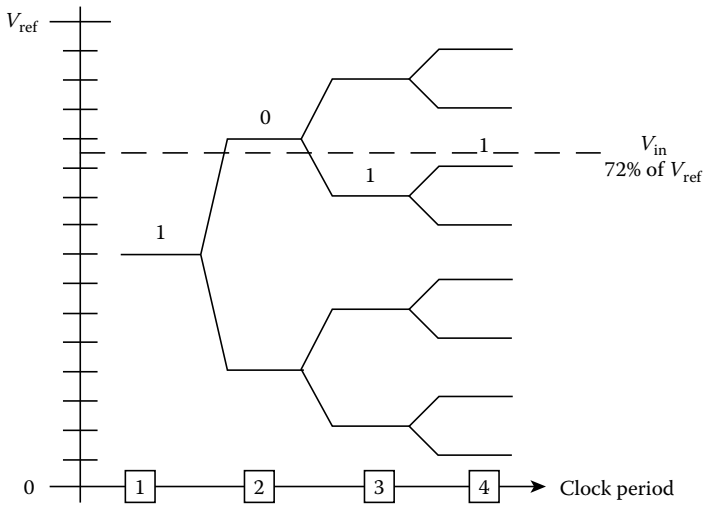

FIGURE 10.48 Binary search process for successive approximation.

The successive approximation converter is one of the most popular topologies in both MOS and bipolar technologies. In MOS technologies the charge-redistribution implementation [9] of the successive approximation methodology is the most commonly used. The circuit diagram of a 4 bit charge redistribution converter is shown in Figure 10.49. In this circuit, the binary weighted capacitors $\{C, C/2, \ldots, C/8\}$ and the switches $\{S_1, S_2, \ldots, S_5\}$ form the 4 bit scaling DAC. For each conversion the circuit operates as a sequence of three phases. During the first phase (sample) switch S_0 is closed and all the other switches $\{S_1, S_2, \ldots, S_6\}$ are connected such that the input voltage V_{in} is sampled onto all the capacitors. During the next phase (hold) S_0 is open and the bottom plates of all the capacitors are connected to ground; i.e., switches $\{S_1, S_2, \ldots, S_5\}$ are switched to ground. The voltage, V_x, at the top plate of the capacitors at this time is equal to $-V_{in}$ and the total charge in all the capacitors is equal to $-2CV_{in}$. The final phase (redistribution) begins by testing the input voltage against the MSB. This is accomplished by keeping the switches $\{S_1, S_2, \ldots, S_5\}$ connected to ground and switching S_1 and S_6 such that the bottom plate of the largest capacitor is connected to V_{ref}. The voltage at the top plate of the capacitor is equal to

$$V_x = \frac{V_{ref}}{2} - V_{in} \tag{10.22}$$

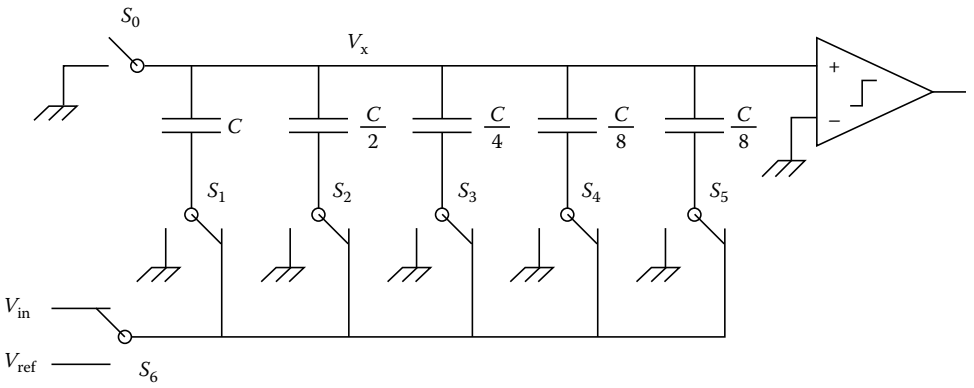

FIGURE 10.49 Charge-distribution implementation of the successive approximation architecture.

If $V_x > 0$ then the comparator output goes high, signifying that $V_{in} < (V_{ref}/2)$ and switch S_1 is switched back to ground. If the comparator output is low, then $V_{in} > (V_{ref}/2)$ and the switch S_1 is left connected to V_{ref} and the MSB is set high. In a similar fashion the next bit, MSB-1, is evaluated. This procedure is continued until all N-bits have resolved. After the conversion process the voltage at the top plate is such that

$$V_x = -V_{in} + \left\{ b_3 \frac{V_{ref}}{2^1} + b_2 \frac{V_{ref}}{2^2} + b_1 \frac{V_{ref}}{2^3} + b_0 \frac{V_{ref}}{2^0} \right\} \tag{10.23a}$$

$$-1 \text{ LSB} < V_x < 0 \tag{10.23b}$$

where b_i is {0, 1} depending upon if bit$_i$ was set to 0 or 1.

One of the advantages of the charge-redistribution topology is that the parasitic capacitance from the switches has little effect on the accuracy. Additionally, the clock feedthrough from switch S_0 only causes an offset and the clock feedthrough from switches $\{S_1, S_2, \ldots, S_5\}$ is input signal independent because they are always connected to either ground or V_{ref}. However, any mismatch in the binary ratios of the capacitors in the array causes nonlinearity, which limits the accuracy to 10 or 12 bits.

Self-calibration successive approximation converters. Fortunately, self-calibrating [7] techniques have been introduced that correct for errors in the binary ratios of the capacitors. Figure 10.50 is the block diagram for a successive approximation-based self-calibrating ADC. The circuit consists of an N-bit binary weighted capacitor array main DAC, an M-bit resistor string sub-DAC, and a calibration DAC. Digital logic is used to control the circuit during calibration and also to store the error voltages.

Let each weighted capacitor C_i have a normalized error in its ratio $(1 + \varepsilon_i)$ from its ideal value:

$$C_i = 2^{i-1} C(1 + \varepsilon_i) \tag{10.24}$$

Each capacitor contributes an error voltage at the top plate which is equal to

$$V_{e_i} = \frac{V_{ref}}{2^N} 2^{i-1} \varepsilon_i \quad i = 1B, 2, \ldots, N \tag{10.25}$$

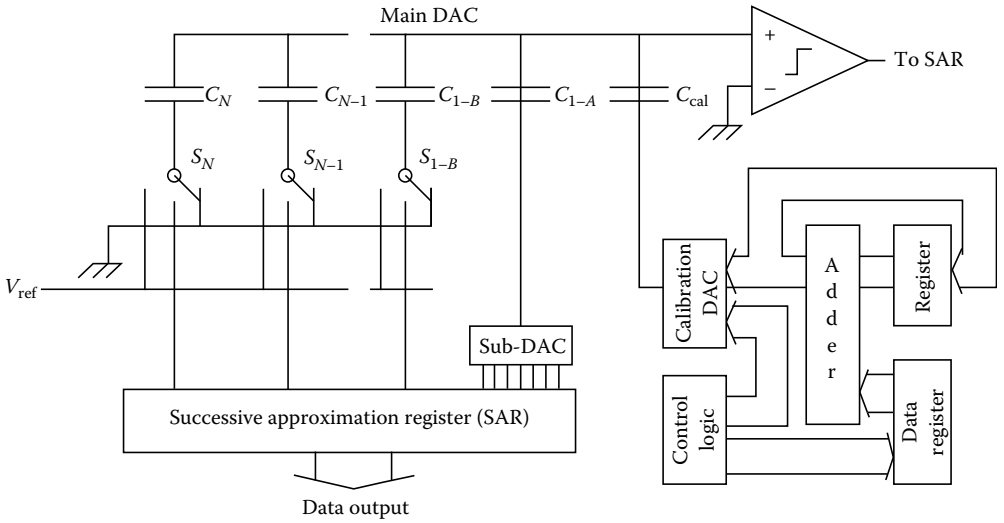

FIGURE 10.50 Self-calibration charge redistribution converter.

Therefore, the total linearity error is equal to

$$V_{\text{error}} = \sum_{i=1B}^{N} V_{\varepsilon_i} b_i \tag{10.26}$$

where b_i is the logic value of the ith bit.

The calibration cycle begins by measuring the error contribution from the largest capacitor and progressing to the smallest. The error from the MSB capacitor is evaluated by closing S_0 and setting switches $\{S_1, S_2, \ldots, S_5\}$ such that all the capacitors except C_{MSB} are charged to V_{ref}. Next, the switch S_0 is opened and switches $\{S_1, S_2, \ldots, S_5\}$ are switched to connect the bottom plates to ground. Under ideal conditions, i.e., $C_{\text{MSB}} = 2^{N-1}C$, the voltage at the top plate is equal to zero. It should be noted that the total capacitance is equal to $2C$. However, because $C_{\text{MSB}} = 2^{N-1}C(1 + \varepsilon_{\text{MSB}})$, the top plate voltage $V_x = (V_{\text{ref}}/2)\varepsilon_{\text{MSB}}$, such that $V_{x_{\text{MSB}}} = 2V_{\varepsilon_{\text{MSB}}}$ Therefore, the error voltage at the top plate is a direct measure of the corresponding error in the capacitor ratio. A successive approximation search using the sub-DAC is used to measure these voltages. The relationship between the measured residual voltage and the error voltage is equal to

$$V_{\varepsilon_i} = \frac{1}{2}\left\{ V_{x_i} - \sum_{j=i+1}^{N} V_{\varepsilon_i} \right\} \tag{10.27}$$

which corresponds to the equivalent error terms on the digital side. These digital correction terms are stored and subsequently added or subtracted during the normal operation cycle. Self-calibration improves the resolution of successive approximation converters to approximately 15 or 16 bits.

Algorithmic converters. As stated earlier, the algorithmic ADC is formed by modifying a pipelined converter. Here, the pipeline has been closed to form a loop. All N-bits are evaluated by a single stage, therefore implying that a N-bit conversion requires N clock cycles. A block diagram for the algorithmic converter is shown in Figure 10.51 [6] and consists of a S/H, a $2\times$ amplifier, a comparator, and a reference subtraction circuit. The circuit operates as follows. The input is first sampled and held by

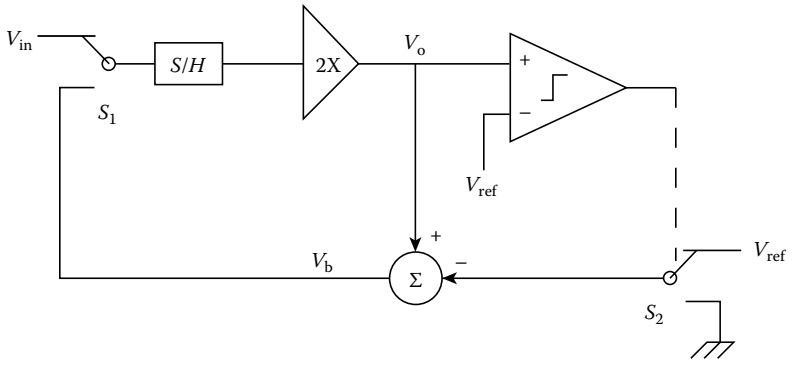

FIGURE 10.51 Algorithmic ADC block diagram.

setting S_1 to V_{in}. This signal is then multiplied by 2 (by the 2× amplifier). The result of this multiplication, V_o, is compared to V_{ref}. If $V_{o_N} > V_{ref}$ then the MSB, b_N, is set to 1 or it is set to 0. If b_N is equal to 1, then S_2 is connected to V_{ref} such that V_{b_N} is equal to

$$V_{b_N} = 2V_{0_N} - b_N V_{ref} \quad b_N = \{0, 1\} \tag{10.28}$$

This voltage is then sample-and-held and used to evaluate the MSB-1 bit. This procedure continues until all N-bits are resolved. The general expression for V_o is equal to

$$V_{0_i} = [2V_{0_{i-1}} - b_i V_{ref}]z^{-1} \tag{10.29}$$

where b_i is the comparator output for the ith evaluation and z^{-1} implies a delay of one clock period.

A circuit implementation for this ADC topology is shown in Figure 10.52 [10]. This circuit uses three amplifiers, five ratio-matched capacitors (C_1 to C_5), an arbitrary valued capacitor, C_6, and a comparator. Two implifiers and the capacitors (C_1 to C_5) form the recirculating register and the gain of two amplifiers. The amplifier A_3 and capacitor C_6 form an offset compensated comparator. The switches controlled by V_3, V_4, and V_5 load the input or selectively subtract the reference voltage. The conversion is started by setting V_1, V_2, and V_3 high. This forces V_x and V_y to 0 and loads V_{in} into C_1. Then, V_1 is set low and V_5 is set high. Therefore, the charge $V_{in} * C_1$ is transferred from C_1 to C_2. C_1 is made to be equal to C_2, therefore, $V_x = V_{in}$(C_3 is also charged to V_x). Because V_1 has been set low the comparator output goes high if $V_{in} > 0$, or else it remains low. This determines the MSB. The MSB-1 is determined by setting V_2 low and setting V_1 high. This forces the charge from C_3 to transfer to C_4($V_4 = V_x$; C_5 is also charged to V_4). During the same period C_1 is connected to ground if MSB = 1, or it is connected to V_{ref}. Next, V_2 is set low and V_1 is set high, while C_1 is switched from ground to V_{ref} for V_{ref} to ground. This transfers a charge equivalent to $C_1 \pm V_{ref}$ from C_1 to C_2 and transfers the charge in C_5, $C_5 * V_y$, to C_2. The capacitor C_5 is made to be twice as large as C_2, therefore, the voltage at V_x is equal to $2 * V_{in} \pm V_{ref}$. This process is repeated and the comparator determines bit MSB-1. This circuit has been shown to provide up to 10 bits of resolution at a maximum conversion rate of 200 kHz.

The maximum resolution of the algorithmic converter is limited by the ratio matching of the capacitors, clock feedthrough, capacitor voltage coefficient, parasitic capacitance, and offset voltages. The previous topology solves the problem of parasitic capacitances and amplifier offset voltage, however, its maximum resolution is limited by the ratio matching of the capacitors that are used to realize the gain of two amplifiers. This problem is partially resolved by using a ratio-independent multiply-by-two algorithm [6] to increase the maximum resolution to the 12 bit level. The ratio-independent multiply-by-two algorithm is easily explained by the circuit shown in Figure 10.53. During ϕ_1, capacitor C_1 is

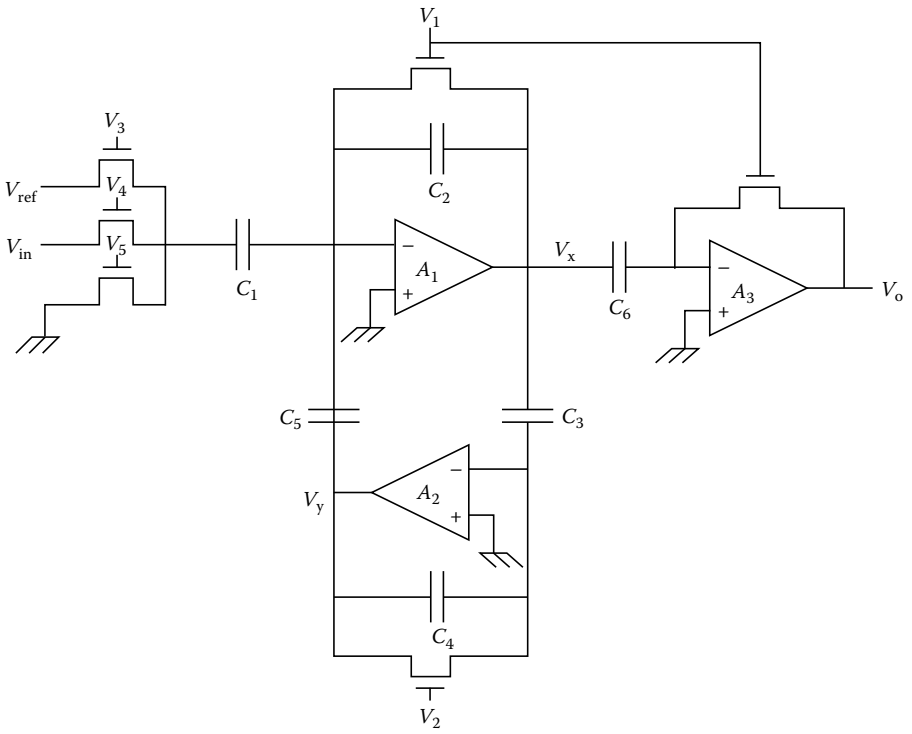

FIGURE 10.52 Example circuit implementation of the algorithmic converter.

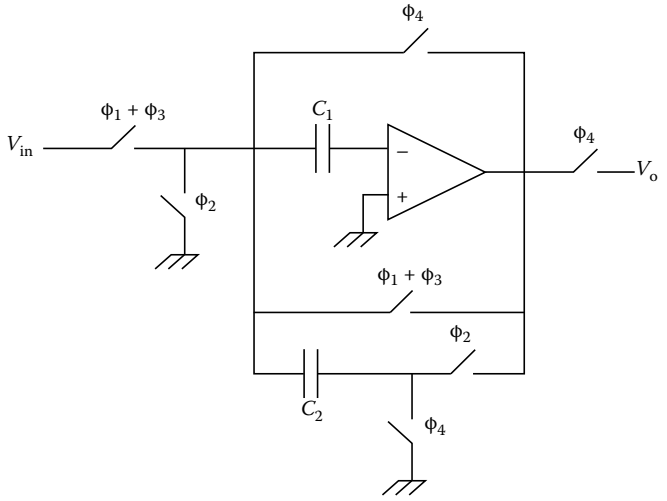

FIGURE 10.53 Ratio-independent multiply-by-two circuit.

charged to V_{in}. This charge is then transferred onto C_2 during ϕ_2. The charge on C_2 is equal to $V_{in} * C_1$. During ϕ_3 C_2 is disconnected from the feedback path and V_{in} is once again sampled onto C_1. During ϕ_4 the charge in C_2 is added to C_1. The total charge in C_1 is now equal to $C_1\ V_{in} + C_1\ V_{in} = 2C_1V_{in}$ and is completely independent of the value of C_2. Therefore, the voltage at the output at ϕ_4 is equal to $2V_{in}$. The only constraint is that the input voltage be held steady, i.e., S/H during ϕ_1 and ϕ_3.

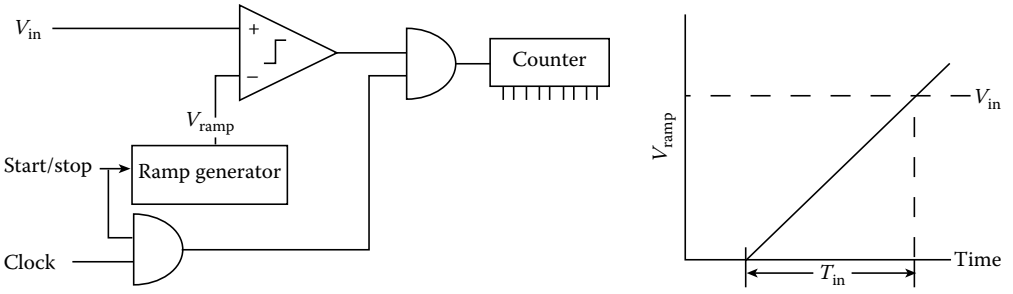

FIGURE 10.54 Single-slope integrating converter.

10.2.2.3 2^N-Clock Converters

The basic principle of the integrating converter can be explained with the help of Figure 10.54. A comparator compares the input signal with the output of a ramp voltage generator. The ramp voltage generator is zeroed after each measurement. The output of this comparator is used to gate the clock to an interval counter. The counter output corresponding to the ramp time T_{in} provides an accurate measure of the input voltage. The input voltage V_{in} is equal to $T_{in} * U$, where U is the ramp rate. Because the absolute values of components are not well controlled and also because of the large offset voltages associated with MOS amplifiers and comparators, a calibration or a reference cycle is usually added to calculate the ramp rate and the offset voltage. A simple circuit for a single-slope integrating converter that includes the calibration cycle is shown in Figure 10.55 [4].

The ramp voltage is generated using a constant current source to charge a capacitor. The ramp voltage, V_{ramp}, is equal to $\int_0^t (I/c)dt$, which is equal to $(I\Delta t)/c$ for a constant current I. The ramp voltage is compared against the analog ground voltages, V_{in} and V_{ref}, respectively. The addition of the third calibration cycle eliminates any offset errors. The final resolution is dependent only on the linearity of the ramp generator, i.e., the linearity of the current source. In the single-slope approach just described, the calibration is done in digital. However, the complete calibration can be performed in analog as well, as in the dual-slope approach. Further improvements include a charge balancing technique [4] that

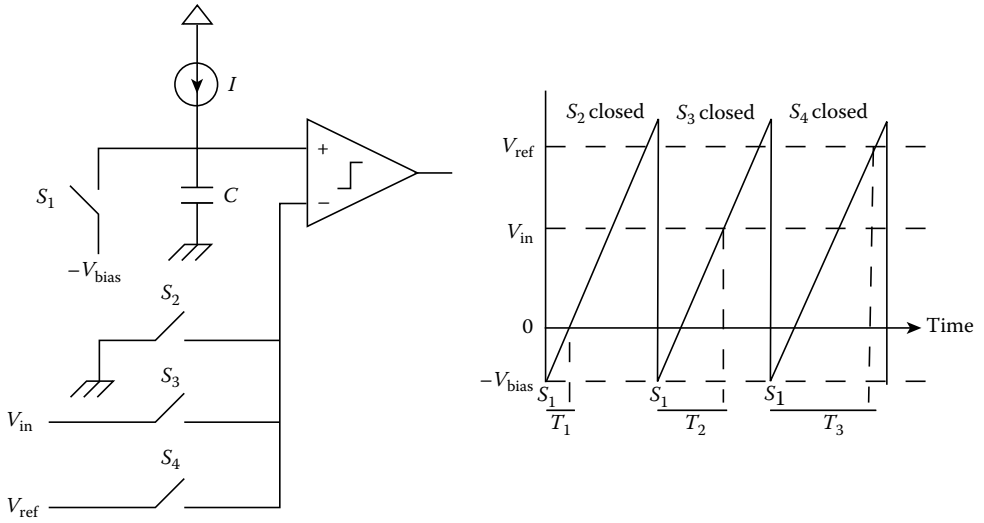

FIGURE 10.55 Single-slope integrating converter with calibration cycle.

uses an oscillating integration process to keep the voltage across the capacitor closer to zero, thereby reducing the linearity constraints on the ramp generator. The primary advantage of the integrating converter is the small number of precision analog components that are required to generate extremely high resolution. However, the primary disadvantage is the conversion time required. It takes 2^N clock cycles to generate a N-bit conversion.

10.2.3 Oversampled Converters

Oversampling converters have the advantage over Nyquist rate converters in that they do not require very tight tolerances from the analog components and also because they simplify the design of the anti-alias filter. Examples of oversampling converters include the noise-shaping architecture and the interpolative architecture. Our discussion centers around noise-shaping converters.

If the analog input signal V_{in} has a frequency spectrum from 0 to f_0 then $2f_0$ is defined as the Nyquist rate. Oversampling converters sample the input at a rate larger than the Nyquist frequency. If f_s is the sampling rate, then $(f_s)/(2f_0) = \text{OSR}$ is called the oversampling ratio. Oversampling converters use "signal averaging" along with a low-resolution converter to provide extremely high resolution. This technique can best be understood by considering the following example in Figure 10.56.

Let the input be exactly in the middle of V_n and V_{n+1} and let it be sampled a number of times. If, in addition to the input signal, we add some random noise, then for a large number of samples the output would fall on V_n 50% of the time and on V_{n+1} the other 50% of the time. If the signal was a littler closer to V_{n+1}, then the percentage of times the output falls on V_{n+1} would increase. Using this averaging technique we can get a better estimate of the input signal. However, in simple oversampling the resolution only increases by $\sqrt{n}$, where n is the number of samples of V_{in} that are averaged. Therefore, to increase the resolution of the converter by one additional bit we are required to increase the number of samples by 4×.

Noise-shaping converters use feedback to generate the necessary noise and additionally perform frequency shaping of the noise spectrum to reduce the amount of oversampling necessary. This can be illustrated with the help of Figure 10.57. The output from H_1 is quantized by an N-bit ADC. This digital value is then converted to an analog value by the N-bit DAC. This value is subtracted from the input and the result is sent to H_1. Here, we assume an N-bit converter for simplicity, however, for the special case in which $N = 1$ the noise-shaping converter is called a sigma-delta converter. The quantization process approximates an analog value by a finite-resolution digital value. This step introduces a quantization error, Q_n. Further, if we assume that the quantization error is not correlated to the input, the system can now be modeled as a linear system, as shown in Figure 10.58. Here, we note that the error introduced by the analog-to-digital process is modeled by Q_n. The output voltage for this system can now be written as

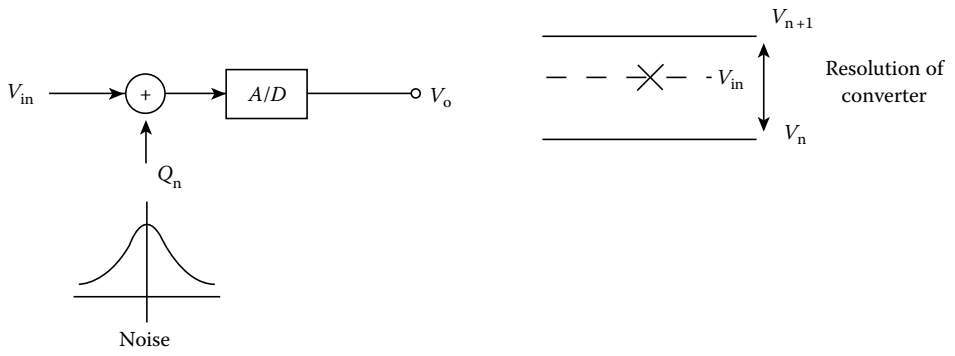

FIGURE 10.56 Higher resolution provided by oversampling.

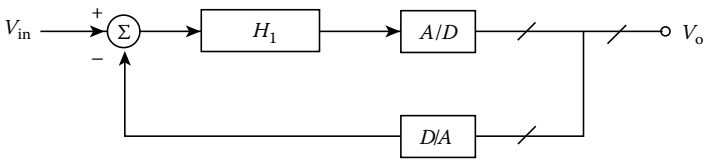

FIGURE 10.57 Noise-shaping oversampling converters.

$$V_0 = \frac{Q_n}{[1+H_1]} + \frac{V_{in}H_1}{[1+H_1]} \tag{10.30}$$

Data converters are sampled data systems, and as such are easier to analyze in the Z-domain. For most sigma-delta converters H_1 has the characteristics of a low-pass filter and is usually implemented as a switched-capacitor integrator. MOS switched-capacitor integrators can be implemented with either a delay in the forward signal path or a delay in the feedback path, and can be modeled in the Z-domain by Figures 10.59 and 10.60, respectively.

We use the first integrator architecture because it simplifies some of the algebra. For a first-order sigma-delta converter H_1 is realized as a simple switched-capacitor integrator, i.e., $H_1 = (z^{-1})/(1-z^{-1})$. Therefore, Figure 10.58 can now be drawn as Figure 10.61. Replacing H_1 by $(z^{-1})/(1-z^{-1})$ in Equation 10.30 we can write the transfer function for the first-order sigma-delta converter as

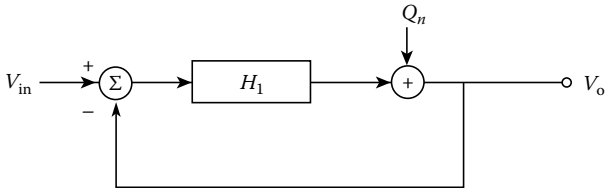

FIGURE 10.58 Linear system model of noise-shaping converter.

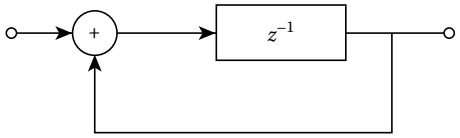

FIGURE 10.59 Forward path delay integrator.

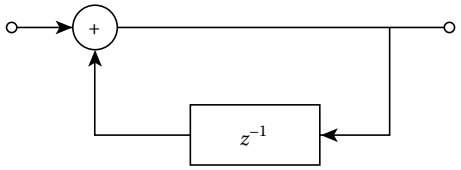

FIGURE 10.60 Feedback path delay integrator.

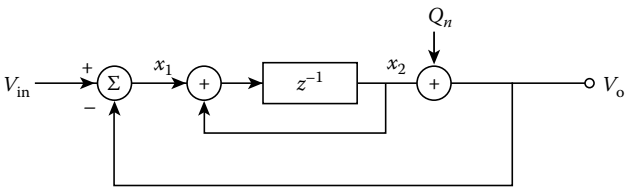

FIGURE 10.61 First-order noise-shaping converter.

$$V_o = V_{in}z^{-1} + Q_n(1 - z^{-1}) \tag{10.31}$$

As can be seen from Equation 10.31, the output is a delayed version of the input plus the quantization noise multiplied by the factor $(1 - z^{-1})$. This function has a high-pass characteristic, as shown in Figure 10.62. We note here that the quantization noise is substantially reduced at lower frequencies and increases slightly at higher frequencies. In this figure, f_o is the input signal bandwidth and $f_s/2 = \pi$ corresponds to the Nyquist rate of the oversampling converter. For simplicity the quantization noise is usually assumed to be white* with a spectral density equal to $e_{rms}\sqrt{2/f_s}$. Therefore, the magnitude of the output noise spectrum can be written as

$$N(f) = e_{rms}\sqrt{\frac{2}{f_s}}\left|1 - z^{-1}\right| = 2e_{rms}\sqrt{\frac{2}{f_s}}\sin\left(\frac{\pi f}{f_s}\right) \tag{10.32}$$

Further, if $f_o \ll f_s$ we can approximate the root mean square noise in the signal band, $(0 < f < f_o)$, by

$$N_{f_0} \approx e_{rms}\frac{\pi}{3}\left(\frac{2f_0}{f_s}\right)^{3/2} \tag{10.33}$$

As the OSR increases the quantization noise in the signal band decreases; i.e., for a doubling of the OSR the quantization noise drops by 20 $\log(2)^{3/2} \approx 9$ dB. Therefore, for each doubling of the OSR we effectively increase the resolution of the oversampling converter by an additional 1.5 bits.

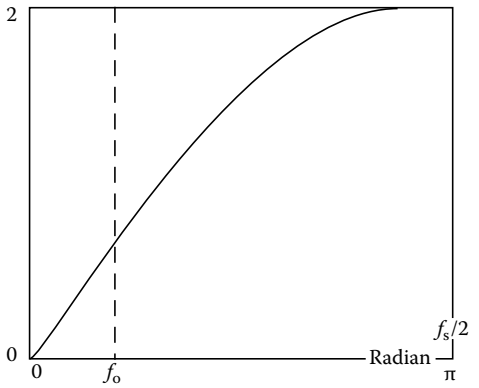

FIGURE 10.62 Magnitude response of the function $(1 - z^{-1})$.

* Quantization noise is clearly not uncorrelated or white for the first-order sigma-delta modulator, but becomes increasingly so for the higher-order systems.

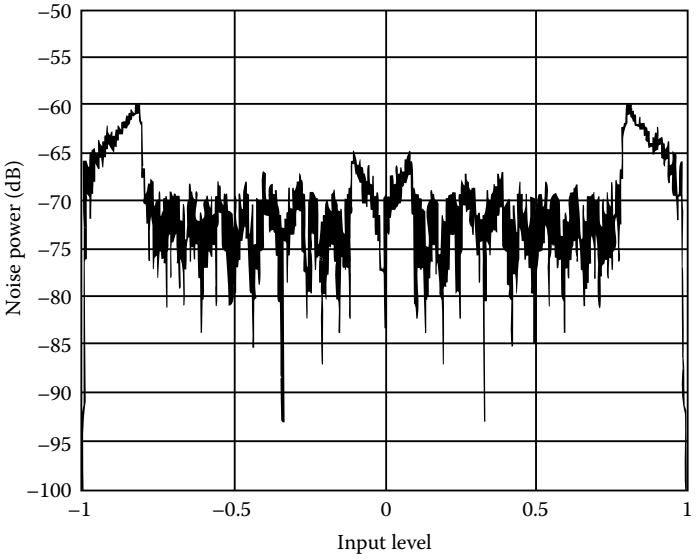

FIGURE 10.63 Pattern noise for a first-order sigma-delta modulator for DC inputs.

The previous analysis was based on the assumption that the quantization noise was not correlated to the input and uniformly distributed across the Nyquist band. We now reexamine these assumptions. The assumption that the quantization noise is not correlated with the input only holds for extremely busy input signals. This is particularly not true for the first-order modulator assumed in the analysis above, such that for extremely low frequency or DC inputs the first-order modulator generates pattern noise (also called tones), as shown in Figure 10.63. The peaks of the pattern noise occur at input voltages that are integer divisors of the quantization step. It is possible to provide a conceptual explanation for this occurrence. For example, for an input that is an integer divisor of the quantization level the digital output of the quantizer repeats itself at an extremely low frequency. This low-frequency repetition causes noise power to be introduced into the signal band. The quantization noise for second- and higher-order models is significantly more uncorrelated and is usually assumed to be white.

The quantization error has a value that is limited to $+\frac{1}{2}$ LSB of the quantizer (the ADC in Figure 10.47). If we assume that the quantization noise is white and uniformly distributed over the quantization level, then the average noise quantization is equal to

$$\int_{-\frac{1}{2}\mathrm{LSB}}^{+\frac{1}{2}\mathrm{LSB}} x^2 \mathrm{d}x = \frac{\mathrm{LSB}^2}{12} = P_n \tag{10.34}$$

Because the quantization noise is sampled at the clock frequency f_s, the entire noise power is aliased back into the overall converter Nyquist ban $[0-(f_s/2)]$. Therefore, the spectral density of the quantization noise is equal to

$$P_n = \frac{\mathrm{LSB}^2}{12} = \int_0^{f_s/2} n_e(f)^2 \delta f = n_e(f)^2 \frac{f_s}{2} \tag{10.35a}$$

$$n_e(f) = P_n\sqrt{\frac{2}{f_s}} \tag{10.35b}$$

The SNR for an ADC is defined as $10\log(P_s/P_n)$, where P_s is the signal power. The signal power is highly waveform dependent. For example, the P_s for a full-scale sine wave input, $(A/2)\sin(\omega T)$, which is applied to an N-bit quantizer, can be written in terms of the quantization level as

$$\frac{A^2}{8} = \frac{[(2^N - 1)\text{LSB}]^2}{8} \tag{10.36}$$

Therefore,

$$\text{SNR} = 10\log\left(\frac{P_s}{P_n}\right) = 10\log\left[\frac{12(2^N - 1)^2}{8}\right] \tag{10.37}$$

10.2.3.1 Higher-Order Modulators

In Figure 10.61, we replaced H_1 for Figure 10.58 with a first-order integrator. Clearly, H_1 can be replaced by other higher-order functions that have a low-pass characteristic.* For example, in Figure 10.64 we show a second-order modulator. This modulator uses one forward delay integrator and one feedback delay integrator to avoid stability problems. The output voltage for this figure can be written as

$$V_0 = V_{\text{in}}z^{-1} + Q_n(1 - z^{-1})^2 \tag{10.38}$$

Note that the quantization noise is shaped by the second-order difference equation. This serves to further reduce the quantization noise at low frequencies. However, a further increase in the noise occurs at higher frequencies. A comparison of the noise shaping offered by the first and second-order modulators is shown in Figure 10.65. Once again, assuming that $f_o \ll f_s$ we can write an expression for the root mean square noise in the signal band for the second-order modulator as

$$N_{f_0} \approx e_{\text{rms}}\frac{\pi^2}{\sqrt{5}}\left(\frac{2f_0}{f_s}\right)^{5/2} \tag{10.39}$$

The noise power in the signal bandwidth falls by 15 dB for every doubling of the OSR. One of the added advantages of the second-order modulator over the first-order modulator is that quantization noise has been shown to be less correlated to the input, therefore, less pattern noise.

From our analysis so far, it would seem that increasing the order of the filter would reduce the necessary OSR for a given resolution. This is true, however, the simple Candy-style modulator (shown in

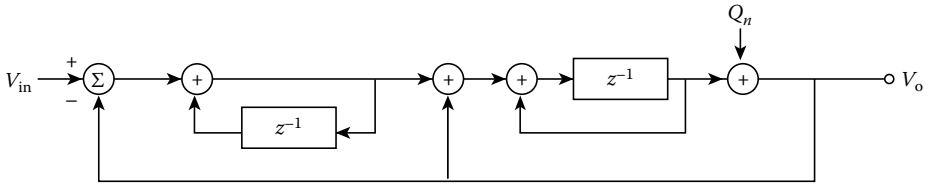

FIGURE 10.64 Second-order modulator block diagram.

* Actually, it is not necessary that they have low-pass characteristics. Bandpass characteristics may be preferred if the input signal is to be bandlimited.

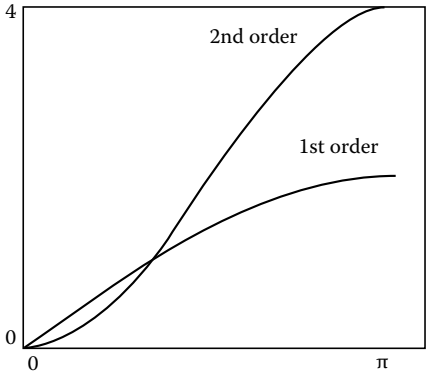

FIGURE 10.65 Noise shaping due to the second-order modulator in Figure 10.62.

Figures 10.61 and 10.64) with orders >2 results in stability problems. This is because for higher-order modulators the later integrator stages are easily overloaded and saturated. This in turn increases the noise in the signal band. However, higher-order modulators can be realized by using a cascade of lower order modulators in the MASH architecture [8]. In the cascaded MASH technique, both the digital output and the output of the integrator of each lower-order modulator is passed on to the next module. A second-order MASH architecture using two cascaded first-order sections is shown in Figure 10.66. It can be shown that the output is equal to

$$Y = z^{-2}X - Q_{n_2}(1 - z^{-1})^2 \tag{10.40}$$

Once again, we note that the quantization noise is multiplied by the second-order difference equation. The sign in front of the noise term is not important. However, for complete cancellation of the quantization noise from the first integrator the gain of the first loop needs to be identical to the gain of the second loop. Therefore, the amplifier gain and capacitor matching become extremely important. It has been shown that a 1% matching and an op-amp gain of 80 dB are sufficient for 16 bits of accuracy [8].

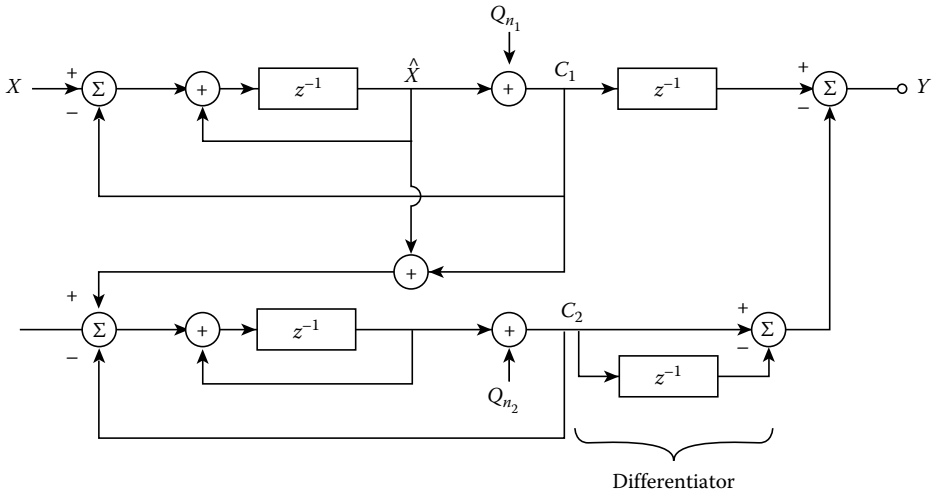

FIGURE 10.66 MASH architecture for a second-order modulator.

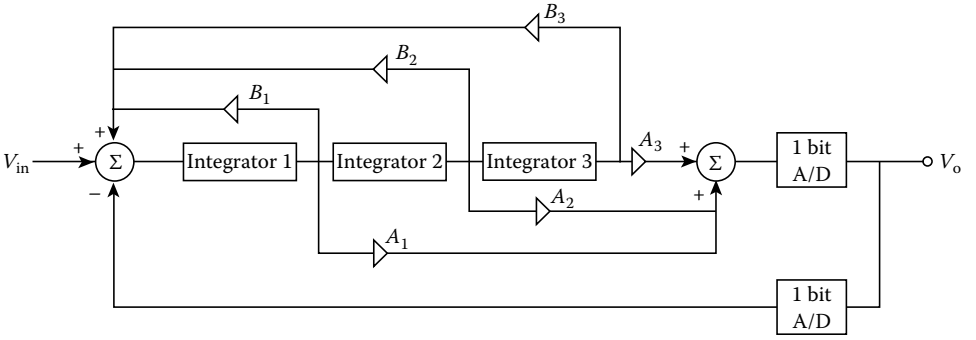

FIGURE 10.67 Finite pole-zero loop filter higher-order modulator.

An alternate methodology to stabilize higher-order oversampled coders is the use of finite poles and zeroes for the loop filter [16], H_1 in Figure 10.57. Up until now, all the loop filters have been integrators with poles at DC and zeroes at extremely high frequencies. The loop filter can be realized using additional feedback and feedforward paths as shown in Figure 10.67. A third-order modulator is shown in this figure. Having finite poles and zeroes serves two purposes: (1) the nonzero poles function to reduce the in-band noise by flattering the quantization noise transfer function at low frequencies, (2) the finite zeroes function to reduce the magnitude of the quantization noise at high frequencies. By reducing the magnitude of the quantization noise at high frequencies, even higher-order modulators can be made stable. Additionally, these modulators have been shown to be devoid of pattern noise artifacts.

10.2.3.2 Multibit Quantizers

The primary reason for using single-bit or two-level quantizers is their inherent perfect linearity. Because only two levels can exist, a straight line can always be drawn between these two levels. On the other hand number of advantages are found in using multibit quantizers in oversampling converters. The quantization noise generated in the multibit-based noise-shaping converter is significantly more "white" and uncorrelated with the input signal, thereby reducing the probability of pattern noise. Additionally, the quantization noise power goes down exponentially as the number of bits in the quantizer increases. However, the primary problem associated with multilevel quantizers is the nonlinearity errors present with the DAC in the modulator loop. This problem can be illustrated with the help of Figure 10.68.

In Figure 10.68, the error resulting from the nonlinearity in the multibit ADC is included as AD_{NL} and the error resulting from the nonlinearity in the multibit DAC is included as DA_{NL}. The output voltage is given by Equation 10.43. Here, note that the analog-to-digital nonlinearity is suppressed by the loop filter, while the digital-to-analog nonlinearity is only subjected to a unit delay. Therefore, any

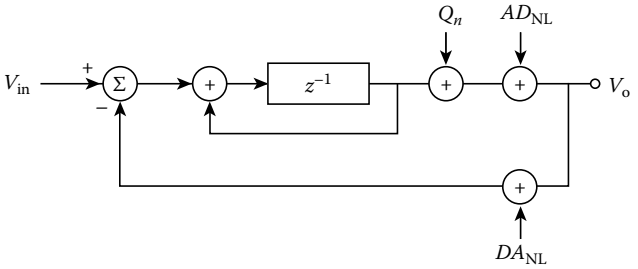

FIGURE 10.68 Model for nonlinearity associated with multibit quantizers.

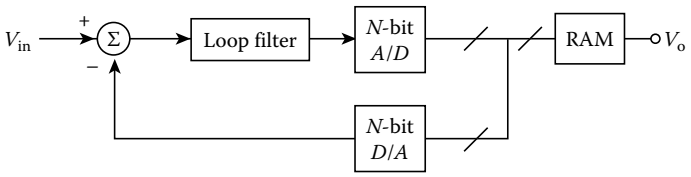

FIGURE 10.69 Digital error correction for multibit quantizers.

digital-to-analog nonlinearity directly appears in the output. A number of methods have been applied to reduce the effects of nonlinearity associated with multibit quantizers. The two most promising methods that have emerged are digital error correction [18] and dynamic element matching [17,19].

$$V_0 = V_{in}z^{-1} - DA_{NL}z^{-1} + Q_n(1 - z^{-1}) + AD_{NL}(1 - z^{-1}) \tag{10.41}$$

A block diagram for digital error correction for multibit quantizer-based noise-shaping converters is shown in Figure 10.69. The random access memory (RAM) and the multibit DAC have the same input signal. Because of the high gain in the loop at low frequencies the output of the DAC is almost identical to the input voltage, V_{in}. Now, if the digital RAM is programmed to generate the exact digital equivalent of the digital-to-analog output for any digital input, then the RAM output and the digital-to-analog output will be identical to each other. Because the output of the DAC is almost identical to the input voltage, the output voltage will also be the exact digital equivalent of the analog input. The RAM can be programmed by reconfiguring the modulator stages and feeding the system with a multibit digital ramp [18].

In the dynamic element matching approach, the various analog elements that are used to generate the different analog voltage levels are dynamically swapped around. The various elements can be swapped randomly [17] or in a periodic fashion [19]. The use of random permutations translates the nonlinearity of the DAC into random noise that is distributed throughout the oversampling converter Nyquist range. This method virtually eliminates errors due to nonlinearity, but unfortunately it also increases the noise level in the signal band. In a variation of this basic technique, the various analog elements are swapped in a periodic fashion such that the nonlinearity in the DAC is translated into noise at higher frequencies. Individual level averaging further eliminates the possibility of pattern noise within the signal band [19].

10.2.3.3 Technology Constraints

One of the primary reasons for using sigma-delta converters is that they do not require good matching among the analog components. Therefore, for the two-level sigma-delta converter the nonidealities are introduced primarily by the integrator loop. To aid in the analysis of the various technology constraints we shall consider a particular implementation of an integrator (Figure 10.70). The ideal transfer function for this circuit is given by $-1/(1 - z^{-1})$. To realize this ideal transfer function the circuit relies on the virtual ground generated at the negative input of the integrator to accomplish complete charge transfer during each clock period. However, limited amplifier gain does not generate a perfect virtual ground,

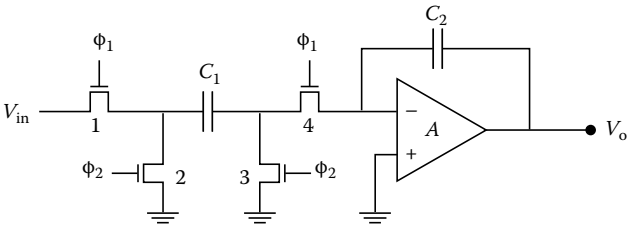

FIGURE 10.70 Example circuit implementation for a switched-capacitor integrator.

thereby not accomplishing the complete transfer of charge during each clock period. The effect of the limited gain is similar to a leaky integrator and the transfer function for the leaky integrator can be written as

$$H(z) = \frac{-1}{1 - \alpha z^{-1}} \tag{10.42a}$$

where

$$\alpha = \frac{1}{1 - \frac{1}{A}\left(1 + \frac{C_1}{C_2}\right)} \approx \frac{1}{1 - \frac{2}{A}} \tag{10.42b}$$

The net effect of finite gain is to increase the modulation noise in the signal band as illustrated by Figure 10.71 for the first-order modulator. In this figure, the *X*-axis is plotted from 0 to 1 rather than the complete Nyquist band to emphasize the signal band. The noise transfer function has been plotted for a number of amplifier gains. When compared to Figure 10.62, note the increase in the noise level in the signal band. The effect of finite gain is felt throughout the input signal magnitude range as shown in Figure 10.72. The graph for Figure 10.71 was generated using the linearized model for the modulator

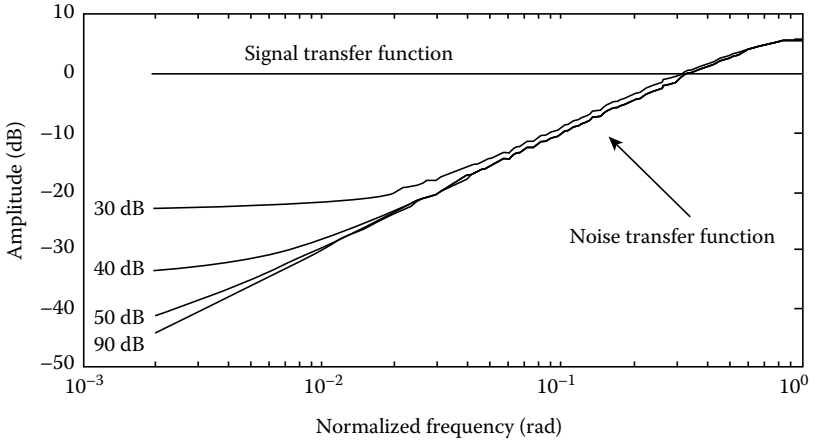

FIGURE 10.71 Effect of finite amplifier gain on noise transfer function using a linear model.

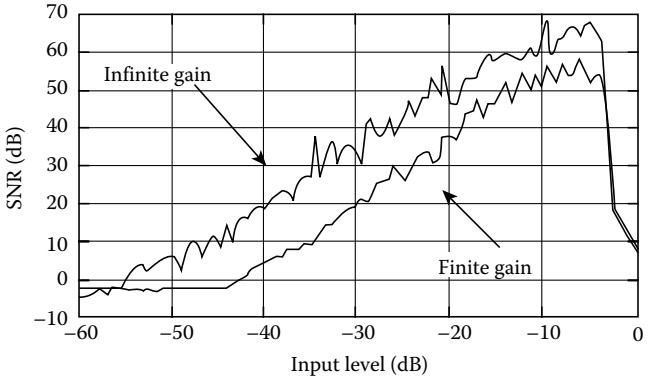

FIGURE 10.72 Effect of finite amplifier gain using difference equation simulations.

presented in Equation 10.21 and the graph in Figure 10.72 was generated using the difference equation method. The difference equation method does not make any assumptions about linearity nor does it assume that the input is uncorrelated with the quantization noise, however, it requires considerably more simulation time. Because of oversampling the bandwidth requirements for the op-amps in the integrators are usually large. Unfortunately, it is extremely difficult to realize extremely high gain and extremely high bandwidth amplifiers in MOS. One solution that attempts to mitigate the finite gain effect is to estimate the amount of incomplete charge transfer and compensate for it [5].

Circuit noise provides additional limitations to the maximum resolution realizable by an oversampled converter. The primary noise sources are the thermal noise generated by the switches in the integrator, amplifier noise, charge injection, and clock feedthrough from the switches. Because of sampling, the thermal noise associated with the finite on resistance of the switches is aliased back into the Nyquist band of the oversampling converter. The total noise aliased into the baseband for large bandwidth amplifiers is equal to kT/C for each switch pair, where k is the Boltzmann constant, T is the temperature in degrees Kelvin, and C is the value of the sampling capacitor in the integrator. For the parasitic insensitive integrator in Figure 10.70, the total noise from this source is equal to $2kT/C$. This noise is evenly spread across the Nyquist band, but only the fraction $2f_o/f_s$ of this noise appears in the signal band. The rest is filtered out by the digital LPF. Using this constraint, for a full-scale sine wave input the minimum sampling capacitance is given by

$$C_{\min} = 16 \cdot k\mathrm{T} \cdot \mathrm{SNR}_{\mathrm{desired}} \tag{10.43}$$

The inband portion of the amplifier noise is also added to the output signal. In general, only the noise of the first amplifier is important for higher-order converters. For MOS amplifiers the flicker noise component is significantly more important as it tends to dominate in the signal band. When necessary, correlated double sampling techniques [5] can be used to reduce the effect of this noise source. Correlated double sampling, or autozeroing as it is sometimes called, has the added benefit that it eliminates any amplifier offset voltages. It is usually important to remove this offset voltage only for data acquisition applications.

Because tight component matching is not required of the analog components, sigma-delta converters are particularly well suited for mixed-signal applications. However, having digital circuits on the sample chip increases the switching noise that is injected into the substrate and into the power supply lines. Any portion of this noise that lies in the signal band is added to the input signal. Therefore, fully differential integrator topologies should be used for high-resolution converters. Substrate and supply noise are common-mode signals and are reduced by the common-mode rejection ratio of the amplifier when using fully differential circuits.

In addition to the amplifier and the switching noise the charge injection from switches also sets a limit on the maximum resolution attainable component. Charge injection from switches has a signal-dependent component and a signal-independent component. The effect of the signal-independent component is to introduce an additional offset error that can easily be calibrated out, if necessary. However, the signal-dependent component, particularly from the input sampling transistor (transistor M_1 in Figure 10.73), cannot be distinguished from input signal. This signal-dependent component is highly nonlinear and can be reduced substantially by using proper clock phasing. Signal-dependent charge injection from transistors M_1 and M_2 in Figure 10.73 can be canceled to first order by delaying the turn off of ϕ_1' slightly [6].

A number of topologies for the digital low-pass filters have been tried. However, it has been shown that simple finite impulse response (sinc) filters are probably the optimal choice. It has been shown that the number of stages of sinc filtering necessary is equal to the modulator order plus 1 [2]. Noise-shaping converters have the ability to provide extremely high resolution. However, care must be used when using simple linear assumptions. Clearly, for the first-order modulator the white noise assumption

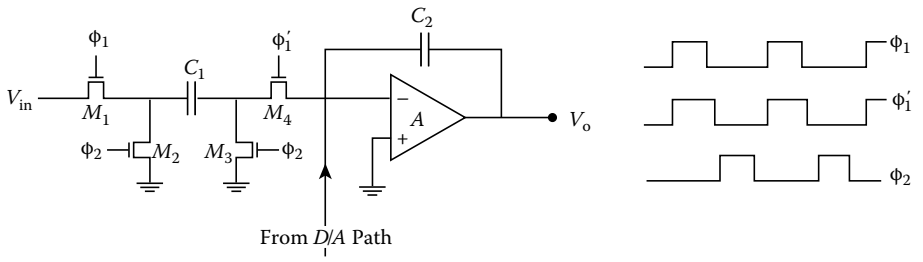

FIGURE 10.73 Proper clock phase to eliminate signal-dependent clock feedthrough.

breaks down. Additionally, it has been shown that the simple linear model overestimates the realizable SNR. For example, the linearized model overestimates the attainable SNR by as much as 14 dB for the second-order modulator.

SPICE model, 1-15–1-16
thermal sensitivity, 1-13–1-14
Bipolar noise
avalanche noise, 3-52–3-53
burst noise–RTS noise, 3-51–3-52
$1/f$ noise, 3-50–3-51
generation–recombination noise, 3-49–3-50
noise characterization
equivalent noise resistance and noise temperature, 3-54–3-55
equivalent noise voltage and current, 3-53–3-54
noise figure, 3-55
noise $1/f^2$, 3-51
shot noise, 3-49
thermal noise, 3-48–3-49
Bipolar transistor, 3-53–3-54

Broadband bipolar networks
bipolar transistor modeling, high frequency
hybrid π model, 3-2–3-3
Miller approximation, 3-3
modified equivalent circuit, 3-4
simplified high-frequency model, 3-3
split current source, 3-4
broadband amplifier stability
classical feedback system review, 3-31
criteria, 3-31–3-32
grounded capacitor compensation, 3-35–3-36
high-frequency performance, 3-36
input capacitance to ground inversion, 3-40
Miller compensation and pole separation, 3-33
op-amp internal compensation strategy, 3-31
phase lag neutralization, 3-38–3-39
power supply impedance, 3-37
resistive and capacitive load effects, 3-37–3-38
single-stage op-amp compensation, 3-34–3-35
two-stage op-amp architecture, 3-32–3-33
C_μ neutralization, 3-9–3-10
current conveyor
applications, 3-12–3-13
broadband analog amplifier, 3-12
current–voltage transfer relationship, 3-12
first-generation current conveyor (CCI), 3-12, 3-15–3-16
second-generation current conveyor (CCII), 3-12, 3-16–3-18
single BJT CCII–, 3-13–3-14
supply-current sensing, voltage op-amp, 3-14–3-15
current-feedback operation amplifier
analysis, 3-22–3-23
architecture, 3-18–3-19
basic current mirror, 3-26–3-28
closed-loop inverting operation, 3-21–3-22
closed-loop noninverting operation, 3-20–3-21
design and development, 3-18
differential-mode operation, 3-19–3-20
feedback current, 3-20
high-speed performance, 3-18
improved broadband current mirror, 3-28–3-29
input stage, 3-44–3-45
phase linearity, 3-29
pole frequency comparison, 3-23–3-24
practical considerations, broadband design, 3-30–3-31
R_2 value, 3-29–3-30
slow rate, 3-24–3-25
wideband and high-gain, 3-25–3-26
Miller's theorem, 3-2
negative feedback, 3-10–3-11
RF bipolar transistor layout, 3-11
single-gain stages
common-base (CB) stage, 3-8–3-9
common-collector (CC) stage, 3-6–3-8
common-emitter (CE) stage, 3-4–3-6
transfer function and bandwidth characteristic
current-feedback, 3-41–3-43
voltage-feedback, 3-43–3-44
Widlar current mirror, 3-45–3-47
Bulk–drain depletion capacitance, 1-54
Bulk-induced modulation, 1-37
Bulk transconductance, 1-60
Butterfly operations, 7-14

C

Cascade voltage switch logic (CVSL) gate, 9-80–9-81
Cauer form, 6-13
CC–CE stage, 3-10
CE–CB cascode stage, 3-9
Channel length modulation effect
drain current equation, 1-88–1-89
JFET technology and device, 1-87
super MOS transistor, 2-90
Circular convolution theorem, 7-11–7-12
Circular spiral inductors
concentric type, 1-127
mutual inductance, 1-129–1-130
self-inductance, 1-127–1-129
total inductance, 1-127
Class *AB* current conveyor, 3-15
Classical feedback system, 3-51
Clocked CMOS logic (C^2MOS), 9-78–9-79
Clocking schemes
current-steered logic and dedicated third-layer, 9-69
distribution
Anceau's PLL scheme, 9-64–9-65
balanced binary tree (BBT), 9-59–9-61
clock ring configuration, 9-56–9-57
clock trunk concepts, 9-53–9-56
delay, skew, and rise time comparison, 9-59
four-quadrant approaches, 9-50
Grover's interval-halving PLL scheme, 9-66–9-68
H-trees, 9-57–9-59

CMOS
amplifier, 2-94–2-95
mixer topology
linear MOS mixers, 4-22–4-23
nonlinearity and LO-feedthrough analysis, 4-23–4-25
switching modulators, 4-21–4-22
RF integration, 4-11
Code-error calibration, DAC, 10-17
Common-base (CB) stage, 3-8–3-9
Common-collector (CC) amplifier
AC schematic diagram, 2-33
active load, 2-35–2-36
driving point input and output resistance, test circuit, 2-34
equivalent circuit, 3-6
equivalent high-frequency model, 3-8
output impedance, 3-7–3-8
Thévenin load resistance, 2-37
transfer function, 3-7
transform property, 3-8
voltage gain, 2-33
Common-emitter (CE) stage
equivalent circuit model, 3-5
high-frequency model, 3-4
Miller approximation, 3-4–3-6
right-hand-plane (RHP) zero, 3-6
second-order characteristic equation, 3-6
Complementary bipolar technology (CBT), 2-6
Complementary pass-transistor logic (CPL) gate, 9-80
Composite super NMOS transistors, 2-91–2-92
Compound semiconductor FET technologies
HEMT device
cross section structure, 1-99
drain current–drain voltage characteristic, GaN, 1-98–1-99
efficiency, 1-99
GaAs MESFET, 1-95–1-96
gate connected field plate, GaN, 1-100
microwave and mm-wave performance, 1-97
microwave power amplifier performance, 1-100
recessed gate AlGaAs/GaAs structure, 1-96
Schottky gate characteristics, 1-96
heterojunctions, AlGaAs and GaAs transition, 1-94–1-95
III–V compound semiconductors, 1-92–1-93
wide bandgap compound semiconductors, 1-97–1-98
Continuous-time Fourier transform
arbitrary aperiodic signal, 7-15
frequency-selective behavior, 7-17–7-18
properties, 7-16
spectral density magnitude, 7-16–7-17
spectral density, sinusoidal pulse, 7-17
Current-controlled current source (CCCS), 1-71–1-72
Current-controlled voltage source (CCVS), 1-72
Current conveyor
applications, 3-12–3-13
broadband analog amplifier, 3-12
current–voltage transfer relationship, 3-12
first-generation current conveyor (CCI), 3-12, 3-15–3-16
second-generation current conveyor (CCII), 3-12, 3-16–3-18
single BJT CCII–, 3-13–3-14
supply-current sensing, voltage op-amp, 3-14–3-15
Current crowding effect, 1-8
Current-feedback operation amplifier
analysis, 3-22–3-23
architecture, 3-18–3-19
basic current mirror, 3-26–3-28
closed-loop inverting operation, 3-21–3-22
closed-loop noninverting operation, 3-20–3-21
design and development, 3-18
differential-mode operation, 3-19–3-20
feedback current, 3-20
high-speed performance, 3-18
improved broadband current mirror, 3-28–3-29
phase linearity, 3-29
pole frequency comparison, 3-23–3-24
practical considerations, broadband design, 3-30–3-31
R_2 value, 3-29–3-30

slow rate, 3-24–3-25
wideband and high-gain, 3-25–3-26
Current-ratioed DAC, 10-8–10-11

D

Data converters
analog-to-digital converters (ADCs)
Nyquist rate type, 10-33–10-47
oversampled type, 10-47–10-57
test techniques, 10-29–10-33
digital-to-analog converters (DACs)
architectures, 10-6–10-12
design issues, 10-3–10-5
error sources, 10-22–10-25
high resolution techniques, 10-13–10-22
low-spurious design examples, 10-26–10-28
signal-to-noise ratio and dynamic range, 10-2
transfer characteristics, 10-1–10-2
Delay-locked loop (DLL)
block diagram, 5-30
modern digital system, synchronous communication, 5-31
PLL bandwidth control, 5-26
timing relationships, 5-31–5-32
voltage-controlled delay line (VCDL), 5-30
Differential amplifier
C_μ neutralization, gain stage, 3-10
voltage gain cells, 2-96–2-97
Differential nonlinearity (DNL), 10-3
Diffused resistors
avalanche breakdown mechanism, 1-107
isolation region, 1-106
n^+ diffusion layer, 1-108–1-109
normalized frequency response, 1-107–1-108
n-type emitter-diffused resistor, 1-107–1-109
p-type resistor and n-type epitaxial (epi) region, 1-106–1-107
Digital circuits and systems
architecture, 9-33
clocking schemes
current-steered logic and dedicated third-layer, 9-69
distribution, 9-48–9-69
mixed technology, 9-69
optoelectronic clock distribution, 9-69–9-70
principles, 9-33–9-48
$\overline{Q}$ elimination, 9-69
reconfigurable clock nets, 9-69–9-70
voltage swing, 9-69
microprocessor-based design
architecture, 9-92–9-95
features, 9-83–9-86
with general purpose microprocessor, 9-95–9-100
guidelines, 9-110–9-111
interfacing, 9-100–9-105
memory, 9-86–9-92
with microcontroller, 9-105–9-110
MOS logic circuits
CMOS inverter, 8-8–8-10
digital inverter, 8-4–8-6
dynamic CMOS logic gates, 8-14–8-15
MOSFET models, 8-1–8-4
nMOS logic gates, 8-6–8-8
static CMOS logic gates, 8-11–8-13
MOS storage circuits
dynamic charge storage, 9-72–9-75
dynamic CMOS logic, 9-78–9-82
shift register, 9-75–9-77
programmable logic devices (PLDs)
combinational logic (CL) PAL devices, 9-11–9-16
combinational logic (CL) PLD classification, 9-10
complexity device ladder, 9-1–9-2
design process, 9-24–9-27
FPGA architectures, 9-22–9-25
notation, 9-4–9-5
programmable array logic (PAL), 9-8–9-10
programmable logic array (PLA), 9-5–9-6
programmable macrocell outputs, 9-18–9-21
programmable read only memory (PROM), 9-7–9-8
sequential PAL devices, 9-16–9-18
state machines synthesis, 9-30–9-31
technologies, 9-2–9-4
VHDL synthesis style, FPGA, 9-27–9-30
systolic arrays
concurrency, parallelism, pipelining, 9-111–9-117
digital filters, 9-117–9-122
eigenvalue and SVDs, 9-137–9-142
Kalman filtering (KF), 9-132–9-137
recursive LSs estimation, 9-126–9-132
systolic word and bit-level designs, 9-122–9-126
transmission gates (TG)
analog processing, 8-24–8-33
complementary transistor version, 8-17–8-18
continuous time filters, 8-27–8-28
digital processing, 8-15–8-24
MOS operational amplifier compensation, 8-24–8-26
pass-transistor logic, 8-18–8-24
single transistor version, 8-15–8-17
switched-capacitor circuits, 8-28–8-33
transimpedance compensation, 8-26–8-27
Digital signal processing
bilateral z-transform (BZT), 7-30–7-31
continuous-time Fourier transform
arbitrary aperiodic signal, 7-15
frequency-selective behavior, 7-17–7-18

properties, 7-16
sinusoidal pulse, spectral density, 7-17
spectral density magnitude, 7-16–7-17
convolution operation, 7-26
discrete Fourier transform (DFT)
aliasing error, 7-9–7-11
applications, 7-11–7-12
discrete Fourier series (DFS) pair, 7-8
Hann window, 7-11
inverse DFT (IDFT), 7-7–7-8
leakage error, 7-10
magnitude spectrum, bandlimited signal, 7-8
periodic discrete-time signal, 7-6
quantization error, 7-6
rectangular window, 7-11
sampling frequency, 7-9
spectral properties, continuous-time periodic signal, 7-8
X(k) magnitude spectrum, 7-9–7-10
discrete-time Fourier transform (DTFT)
Dirac impulse function, 7-20
periodic function and FS coefficients, 7-19
properties, 7-23
sampling process model, 7-18, 7-20
discrete-time signals, 7-5
fast Fourier transform, 7-13–7-14
Fourier series, continuous-time periodic signals
approximation error, 7-2
complex FS coefficients, 7-3–7-4
cyclical phenomena, 7-4
Dirichlet conditions, 7-2
Euler's identity, 7-3
fundamental frequency, 7-2
Gibbs oscillation, 7-4–7-5
mean square error minimization, 7-2
periodic signal, 7-1–7-2
frequency response, 7-26–7-28
ideal digital filters, 7-29–7-30
linear and time invariant discrete-time systems
block diagram, 7-23–7-24
characteristic equation, 7-25
initial conditions, 7-24–7-25
off-line processing, 7-24
unit pulse response, 7-25–7-26
sampling theorem
aliasing error, 7-21–7-22
antialiasing filter, 7-21–7-22
data reconstruction formula, 7-21
DTFT magnitude, 7-20–7-22
exponentially weighted sinusoidal pulse, 7-22
FT magnitude, 7-22
low-pass filter magnitude frequency response, 7-21
sampling frequency, 7-20–7-21
spectral density magnitude, bandlimited signal, 7-20
stability, 7-26
transfer function, 7-33
unilateral *z*-transform, 7-33–7-35
z-plane, 7-31–7-32
Digital-to-analog converters (DACs)
architectures
current-ratioed type, 10-8–10-11
R+C/C+R combination type, 10-11–10-12
resistor-string type, 10-6–10-8
design issues
conversion speed, 10-5
linearity, 10-3
monotonicity, 10-3–10-5
error sources
glitch, 10-22–10-23
noise, 10-25
timing error-word clock jitter, 10-23–10-24
voltage reference, 10-24–10-25
high resolution techniques
dynamic matching type, 10-13–10-14
electronic calibration type, 10-14–10-18
interpolative oversampling type, 10-18–10-22
low-spurious design examples
dynamic linearity enhancement, 10-27–10-28
self-trimming, 10-26–10-27
spatial averaging, 10-26
signal-to-noise ratio and dynamic range, 10-2
transfer characteristics, 10-1–10-2
Digital truncation errors, 10-18
Diode equation, 1-2
Direct code mapping, 10-15
Direct frequency synthesizer, 4-17
Discrete-time index, 7-4
Discrete-time transfer functions, 5-21
Down converter, 4-15–4-16
Drain–source channel resistance, 1-60

E

Ebers–Moll model, 1-2–1-3
Edge detection, NRZ data, 5-29
Electronic calibration type, DAC
capacitor ratio error measurement cycles, 10-16
code-error calibration, 10-17
current difference measurement cycles, 10-16–10-17
digital truncation errors, 10-18
direct code mapping, 10-15
self-calibration for individual capacitor errors, 10-15–10-16
Elmore's approach, 6-15
Emitter follower, *see* Common-collector (CC) amplifier
Epitaxial resistors, 1-111–1-112
Extended RF transistor model, 4-9–4-10

F

Fast Fourier transform (FFT), 7-13–7-14
FET/current mirror bias circuit, 2-63
Fialkov condition, 6-12
Field programmable gate arrays (FPGAs)
architectures
high-level layout, 9-22
LUT, 9-24
minimal CLB, 9-23–9-24
programmable elements, 9-23

XC4010XL chip, CLB, 9-24–9-25
technologies, 9-22
VHDL synthesis style
combinational logic, 9-29
latches, 9-30
registers and flip-flops, 9-27–9-29
Finite impulse response (FIR) filters, 7-28, 9-117–9-118
First-order infinite impulse response filter, 5-22
1/*f* noise, 3-50–3-51
Folded cascode amplifiers, biasing circuits, 2-72–2-73
Forward transconductance, 1-60
Fourier series, 5-7
Fractional-*N* synthesizers, 4-19–4-20
Frequency locked-loop (FLL), 5-9
Frequency synthesizer
block diagrams, 5-32–5-33
dual-modulus prescalar, 5-33–5-34
output frequency, 5-32

G

Gain-boosting principle, 2-90–2-91
Generation–recombination noise, 3-49–3-50
Generation–recombination phenomena, 1-4
Gibbs oscillation, 7-4–7-5
Grover's interval-halving PLL scheme, 9-66–9-68
Gummel–Poon model, 1-4–1-5

H

Hestenes algorithm, 9-140–9-141
High-speed voltage buffer, 3-37

I

Ideal digital filters, 7-29–7-30
Indirect convolution method, 7-12
Infinite impulse response (IIR) filters, 7-28–7-29
bidirectional systolic arrays, 9-121
clustered look-ahead, 9-119–9-120
I–O relationship, 9-118
overlapped subfilter scheme, 9-122
scattered look-ahead, 9-120–9-121
systolic ring scheme, 9-122
Input-referred third-order intercept point (IIP3), 4-5
Integral nonlinearity (INL), 10-3
Integrated PNP transistors, 1-12
Integrator-type DACs, 10-4–10-5
Intermodulation distortion (IMD), 4-4–4-5
Interpolative oversampling technique
alternative 1 bit DAC sampling constant, 10-21–10-22
delta-sigma modulation, 10-18–10-19
dynamic range, 10-20
one-bit/multibit, 10-20
postfiltering requirement, 10-22
stability, 10-19–10-20
switched-capacitor 1 bit DAC/filter, 10-20–10-21
Ion-implanted resistors, 1-112–1-113

J

JFET technology and devices
channel-length modulation effect, 1-87
ion implanted silicon JFET, IC process, 1-91
large-signal model, drain current equations, 1-88–1-89
operating regions
cutoff and subthreshold current regions, 1-86–1-87
ohmic and pinch-off region, 1-85–1-86
static current–voltage characteristics, 1-85
small-signal model, 1-89–1-90
static *I–V* characteristics, 1-84
temperature effects, 1-87–1-88
JK-flipflop PD, 5-13–5-14
Junction capacitors
abrupt pn junction, 1-115–1-116
base–collector capacitor structure, 1-117–1-118
base–emitter capacitor structure, 1-117–1-119
depletion width, 1-116–1-117
permittivity, 1-116

K

Kalman filtering (KF)
Faddeev algorithm, 9-134–9-137
model, 9-132–9-133
other forms, 9-133–9-134
systolic matrix implementation, 9-134
Kirchhoff's current law, 1-3, 3-21
Kirchhoff's voltage law, 2-5
Kirk effect, 1-7–1-8

L

Linear bipolar technology, canonic cells
balanced differential amplifier
engineering constraints, 2-45–2-47
generalized system diagram, 2-44–2-45
monolithic fabrication process, 2-45
single-ended output voltage, 2-44
common-base amplifier
circuit broadbanding, 2-32
common-emitter–common-base cascode, 2-30–2-32
current buffering purpose, 2-26–2-27
diode resistance, 2-28
driving point input/output resistance, 2-29–2-30
equivalent circuit, 2-27–2-28
Kirchhoff's current law constraint, 2-27
Miller multiplication, 2-32
Norton transconductance, 2-31
NPN and PNP AC schematic diagrams, 2-26–2-27
small-signal analysis, 2-27
voltage divider, 2-31

common-collector amplifier
AC schematic diagram, 2-33
active load, 2-35–2-36
driving point input and output resistance, test circuit, 2-34
Thévenin load resistance, 2-37
voltage gain, 2-33
common-emitter amplifier
active current source load, 2-24–2-26
driving point output resistance, 2-23
macromodel, 2-19–2-20, 2-23
Norton current and equivalent circuit, 2-19
NPN and PNP AC schematic diagrams, 2-17, 2-20–2-21
operation, 2-17
output coupling capacitance, 2-24
small-signal test structure, 2-18–2-19
Thévenin source voltage, 2-18
common-mode input voltage, 2-41–2-42
Darlington connection
forward transconductance, 2-41
schematic diagram, 2-38–2-39
small-signal equivalent circuit, 2-39–2-40
transconductance amplifier, 2-38
transconductance frequency response, 2-38–2-39
voltage gain, 2-40–2-41
Wilson mirror load, 2-39
differential input source voltage, 2-41
diode-connected transistor
KVL analysis, 2-15
small-signal transistor model, 2-14–2-15
static common-base current gain, 2-15–2-16
subject diagram, 2-14
V_{BE} multiplier, 2-15–2-17
volt–ampere characteristics, 2-14
performance index, 2-43
small-signal model, 2-11–2-14
system-level diagram, differential amplifier, 2-41–2-42
Thévenin equivalent I/O circuits
balanced bipolar differential amplifier, 2-52–2-53
driving point common-mode/differential mode output resistance, 2-49–2-50
Kirchhoff's current and voltage laws, 2-47
open-circuit differential-mode gain, 2-51
pertinent test cell, 2-48–2-49
test circuit, 2-47–2-49
Thévenin model, 2-51
two-port model, 2-54
zero input signal excitation, 2-49
Linear convolution method, 7-12
Load capacitance neutralization, 3-38–3-39
Long-tail pair input transconductance, 3-24–3-25
Loop filter (LF) gain, 5-8
Low-noise amplifier (LNA)
cutoff frequency, 4-14
drain current equation, 4-14
IIP2 and IIP3 plots, 4-15–4-16
noise and source impedance matching, 4-14
noise figure, 4-12–4-14
third-order intermodulation, 4-14
topology, 4-12–4-13
transit voltage, 4-15

NORA, 9-81–9-82
precharge–evaluate logic gate, 9-78
shift register
clocked barrel shifter, 9-76–9-77
parallel type, 9-76
simple type, 9-75–9-76
MOS transistor, 4-15

N

Natural frequency, PLL, 5-23–5-24
N-channel MOSFET (NMOS), 1-22
Network realization, 6-4–6-5
NMOS amplifier
common-source, enhancement load, 2-92–2-93
gain, 2-94
small-signal equivalent circuit, 2-94
Noise spectral density, 3-50–3-51
Noise temperature, 3-55
Noninverting amplifier, voltage-feedback op-amp, 3-23–3-24
Non-return-to-zero (NRZ)
data format, 5-27–5-28
phase and frequency detectors, 5-15

NORA CMOS dynamic logic, 9-81–9-82
Nyquist equation, 3-48
Nyquist rate converters
1-clock type
digital-error correction, 10-38–10-40
flash/parallel type, 10-33–10-35
pipelined type, 10-36–10-38
subranging converters, 10-33–10-34, 10-36
N-clock type
algorithmic type, 10-43–10-46
self-calibration successive approximation type, 10-42–10-43
successive approximation type, 10-40–10-42
2^N-clock type, 10-46–10-47

O

Ohmic regime
channel potential, 1-39–1-40
cross section, 1-38–1-39
drain saturation voltage, 1-38
pinched off channel, 1-40–1-41
static circuit model, 1-41–1-42
transconductance coefficient, 1-40
Operational amplifier (op-amp), rail-to-rail operation, 2-74
Optoelectronic clock distribution, 9-69–9-70
Output-referred third-order intercept point (OIP3), 4-5
Oversampled converters, ADC
feedback path delay integrator, 10-48
first-order noise-shaping converter, 10-48–10-49
forward path delay integrator, 10-48
higher resolution, 10-47
linear system model, 10-47–10-48
magnitude response, 10-49
noise-shaping type, 10-47–10-48
oversampling ratio (OSR), 10-47
pattern noise, 10-50
SNR, 10-51

P

Passive components
circular spiral inductors
concentric type, 1-127
mutual inductance, 1-129–1-130
self-inductance, 1-127–1-129
total inductance, 1-127
conductivity, 1-103–1-104
diffused resistors
avalanche breakdown mechanism, 1-107
isolation region, 1-106
n^+ diffusion layer, 1-108–1-109
normalized frequency response, 1-107–1-108
n-type emitter-diffused resistor, 1-107–1-109
p-type resistor and n-type epitaxial (epi) region, 1-106–1-107
electron and hole mobility *vs.* impurity concentration, 1-104–1-105
epitaxial resistors, 1-111–1-112
ion-implanted resistors, 1-112–1-113
junction capacitors
abrupt pn junction, 1-115–1-116
base–collector capacitor structure, 1-117–1-118
base–emitter capacitor structure, 1-117–1-119
depletion width, 1-116–1-117
permittivity, 1-116
MOS capacitors, 1-119–1-120
n-type nonuniformly doped resistor, 1-104
parallel-plate capacitor, 1-114
pinched resistors, 1-110–1-111
polysilicon capacitors, 1-120–1-121
rectangular spiral inductors
electrical model, 1-124–1-125
mutual inductance, 1-122–1-124
self-inductance, 1-122–1-123
self-resonant frequency, 1-125
total inductance, 1-122
transformer structure, 1-125–1-126
sheet resistance, 1-103–1-104, 1-106
thin-film resistors, 1-113–1-114
uniformly doped resistor, 1-103
Passive lag filter, 5-4
P-channel MOSFET (PMOS), 1-22–1-23
Phase detector (PD), 5-1–5-2
Phase-error transfer function, 5-4
Phase-frequency detector (PFD), 5-2
Phase-locked loop (PLL) circuits
applications
clock recovery architecture, 5-28–5-30
data conversion, 5-28
data format, 5-27–5-28
delay-locked loop, 5-30–5-32
frequency synthesizer, 5-32–5-34
basic operation concepts, 5-1–5-2
charge-pump

switch settings, 9-20–9-21
programmable read only memory (PROM)
conceptual diagram, 9-7
truth table, 9-7–9-8
sequential PAL devices
implementation range, 9-16, 9-18
PAL16R4 chip logic diagram, 9-16–9-17
state machines synthesis, 9-30–9-31
technologies
process type, 9-2–9-3
programming type, 9-3–9-4
VHDL synthesis style, FPGA
combinational logic, 9-29
latches, 9-30
registers and flip-flops, 9-27–9-29
Pull-in process, 5-8–5-9
Pulse-forming network output response, 6-7

Q

$\overline{Q}$ elimination, 9-69
Q-factor, 4-11–4-12

R

Radio frequency (RF) front-ends, 4-1–4-2
Radix-2 FFT algorithm, 7-13
R+C/C+R combination DAC, 10-11–10-12
Reactance pulse-forming network synthesis
delayed output pulse
algebraic ratio, 6-11
Cauer form, 6-13
delayed quasi-rectangular pulse, 6-9, 6-12
deterioration, 6-13–6-15
Fialkov condition, 6-12
Laplace transform, 6-10–6-11
normalized time, 6-9–6-10
pulse parameter, 6-12
slew rate, fronts, 6-9, 6-11

step response, 6-12–6-13
transfer function realization, 6-13
voltage source efficiency coefficient, 6-9–6-10, 6-13–6-14
non-delayed output pulses, 6-7–6-8
quasi-rectangular output pulse and laplace transform approximation, 6-4
impulse excitation, 6-2
impulse response, 6-4
rise and fall times, 6-3
shift theorem, 6-4
realization requirements, 6-4–6-5
second approximation step impulse response $V_o(s)$, 6-5
spectrum bandwidth ω_m, 6-6
transfer function, 6-5–6-6
sinusoidal pulse forming approximation, realization, 6-21–6-22
transfer function, 6-20–6-21
wideband amplifiers, transfer functions
approximation, 6-16–6-17
design, 6-18–6-19
Elmore's approach, 6-15
step response parameters and Laplace transform, 6-15–6-16
tabulated results, 6-19
Real feedback amplifier, 3-36
Realizable transfer function, 6-18
Rectangular spiral inductors
electrical model, 1-124–1-125
mutual inductance, 1-122–1-124
self-inductance, 1-122–1-123
self-resonant frequency, 1-125
total inductance, 1-122
transformer structure, 1-125–1-126
Region of convergence (ROC), 7-32
Relaxation oscillators, 5-11
Resistor/current mirror bias circuits, 2-63
Resistor-string DAC, 10-6–10-8
RF communication circuits
frequency synthesizer
fractional-*N* synthesis, 4-19–4-20
oscillator, 4-18–4-19
prescaler, 4-19
topology, 4-17–4-18
receiver
down converter, 4-15–4-16
LNA, 4-12–4-15
signal interference, 4-3
system performance metrics
first- and third-order intermodulation, 4-5
gain compression, 4-5
LNA, 4-4
noise figure, 4-3–4-4
nonlinearity performance, 4-4–4-5
receiver sensitivity, 4-3
signal-to-noise and distortion ratio (SNDR), 4-4
signal-to-noise ratio (SNR), baseband, 4-3–4-4
technology
active devices, 4-9–4-10
passive devices, 4-11–4-12
transceiver architectures
direct/zero-IF receiver, 4-7–4-8
down-conversion process, 4-6–4-7
heterodyne receiver, 4-6–4-7
image/mirror signal, 4-6
image rejection, 4-7–4-8
image suppression, 4-7
low output impedance driver, 4-6–4-7
quadrature amplitude modulation (QAM), 4-8
transmission medium, 4-2–4-3
transmitter
CMOS power amplification, 4-25
CMOS RF PA linearization, 4-27–4-29
linear MOS mixers, 4-22–4-23
nonlinearity and LO-feedthrough analysis, 4-23–4-25
switching class E amplifier, 4-25–4-27
switching modulators, 4-21–4-22
up *vs.* down conversion, 4-20–4-21
Ring oscillator jitter, 5-9–5-10

S

Saturation current, 1-4–1-5
Saturation regime
built-in potential, 1-44
channel length modulation voltage, 1-43
common-source volt–ampere characteristic curves, 1-45
drain current, 1-42, 1-44
large-signal circuit model, 1-44
strong inversion, 1-42–1-43
Second-generation current conveyor (CCII), 3-16–3-18
Segmented DACs, 10-4
Self-biased V_{BE} referenced current source, 2-7
Self-biased V_T referenced current source, 2-7–2-8
Self-calibration for individual capacitor errors, DAC, 10-15–10-17
Series R–C snubber, 3-39
Shot noise, 3-49
Signal interference, 4-3, 4-5
Signal-to-noise and distortion ratio (SNDR), 4-4
Simple current mirror, beta helper, 2-2–2-3
Simulation program with integrated circuit emphasis (SPICE) model
bipolar transistor parameters, 1-15–1-16
Gummel–Poon model, 1-5
small-signal model, 1-9
thermal sensitivity, 1-13–1-14
Single-stage op-amp architecture, 3-34–3-35
Sinusoidal envelope, output response, 6-20
Skew and delay, 9-34–9-35
Small-signal model
BJT
Boltzmann voltage, 2-12
emitter–base junction diffusion resistance, 2-13
equivalent circuit, 2-10–2-11
forward Early resistance and transconductance, 2-13
large-signal model, 2-11–2-12
monolithic fabrication process, 2-12

quiescent-operating point, 2-13
static common-emitter current, 2-12
MOSFET technology
analysis, 1-58–1-59, 1-71
bulk-gate transconductance, 1-68
bulk modulation factor, 1-62, 1-69
bulk transconductance, 1-60, 1-62
common-source interconnection, 1-70
equivalent circuit, 1-70

Electrical Engineering

Upon its initial publication, *The Circuits and Filters Handbook* broke new ground. It quickly became **the** resource for comprehensive coverage of issues and practical information that can be put to immediate use. Not content to rest on his laurels, in addition to updating the second edition, editor Wai-Kai Chen divided it into tightly focused texts that made the information easily accessible and digestible. These texts have been revised, updated, and expanded so that they continue to provide solid coverage of standard practices and enlightened perspectives on new and emerging techniques.

Analog and VLSI Circuits draws together international contributors who provide the latest information on analog and VLSI circuits, omitting extensive theory and proofs in favor of numerous examples throughout each chapter. The first part of the text focuses on analog integrated circuits, presenting up-to-date knowledge on monolithic device models, analog circuit cells, high performance analog circuits, RF communication circuits, and PLL circuits. In the second half of the book, well-known contributors offer the latest findings on VLSI circuits, including digital circuits, digital systems, and data converters.

Features

- Presents the fundamental biasing building blocks used in bipolar integrated circuit technology and the refinements of them that have evolved over time
- Provides a tutorial on techniques for integrated circuit amplifiers
- Discusses circuit techniques suitable for developing a single-chip CMOS solution compatible with all standards and capable of adapting itself

This volume will undoubtedly take its place as the engineer's first choice in looking for solutions to problems encountered when working with analog and VLSI circuits.

Preface

As system complexity continues to increase, the microelectronic industry must possess the ability to adapt quickly to the market changes and new technology through automation and simulations. The purpose of this book is to provide in a single volume a comprehensive reference work covering the broad spectrum of computer aided design and optimization techniques, which include circuit performance modeling, design by optimization, statistical design optimization, physical design automation, computer aided analysis and circuit simulations; and design automation, which includes system-level design, performance modeling and analysis, and hardware/software codesign. This book is written and developed for the practicing electrical engineers and computer scientists in industry, government, and academia. The goal is to provide the most up-to-date information in the field.

Over the years, the fundamentals of the field have evolved to include a wide range of topics and a broad range of practice. To encompass such a wide range of knowledge, this book focuses on the key concepts, models, and equations that enable the design engineer to analyze, design, and predict the behavior of large-scale systems. While design formulas and tables are listed, emphasis is placed on the key concepts and theories underlying the processes.

This book stresses fundamental theories behind professional applications and uses several examples to reinforce this point. Extensive development of theory and details of proofs have been omitted. The reader is assumed to have a certain degree of sophistication and experience. However, brief reviews of theories, principles, and mathematics of some subject areas are given. These reviews have been done concisely with perception.

The compilation of this book would not have been possible without the dedication and efforts of Professor Steve Sung-Mo Kang, and most of all the contributing authors. I wish to thank them all.

Wai-Kai Chen

Editor-in-Chief

Wai-Kai Chen is a professor and head emeritus of the Department of Electrical Engineering and Computer Science at the University of Illinois at Chicago. He received his BS and MS in electrical engineering at Ohio University, where he was later recognized as a distinguished professor. He earned his PhD in electrical engineering at the University of Illinois at Urbana–Champaign.

Professor Chen has extensive experience in education and industry and is very active professionally in the fields of circuits and systems. He has served as a visiting professor at Purdue University, the University of Hawaii at Manoa, and Chuo University in Tokyo, Japan. He was the editor-in-chief of the *IEEE Transactions on Circuits and Systems, Series I and II*, the president of the IEEE Circuits and Systems Society, and is the founding editor and the editor-in-chief of the *Journal of Circuits, Systems and Computers*. He received the Lester R. Ford Award from the Mathematical Association of America; the Alexander von Humboldt Award from Germany; the JSPS Fellowship Award from the Japan Society for the Promotion of Science; the National Taipei University of Science and Technology Distinguished Alumnus Award; the Ohio University Alumni Medal of Merit for Distinguished Achievement in Engineering Education; the Senior University Scholar Award and the 2000 Faculty Research Award from the University of Illinois at Chicago; and the Distinguished Alumnus Award from the University of Illinois at Urbana–Champaign. He is the recipient of the Golden Jubilee Medal, the Education Award, and the Meritorious Service Award from the IEEE Circuits and Systems Society, and the Third Millennium Medal from the IEEE. He has also received more than a dozen honorary professorship awards from major institutions in Taiwan and China.

A fellow of the Institute of Electrical and Electronics Engineers (IEEE) and the American Association for the Advancement of Science (AAAS), Professor Chen is widely known in the profession for the following works: *Applied Graph Theory* (North-Holland), *Theory and Design of Broadband Matching Networks* (Pergamon Press), *Active Network and Feedback Amplifier Theory* (McGraw-Hill), *Linear Networks and Systems* (Brooks/Cole), *Passive and Active Filters: Theory and Implements* (John Wiley), *Theory of Nets: Flows in Networks* (Wiley-Interscience), *The Electrical Engineering Handbook* (Academic Press), and *The VLSI Handbook* (CRC Press).

1.1 Introduction

The domain of computer-aided design and optimization for circuits and filters alone is very broad, especially since the design objectives are usually multiple. In general, the circuit design can be classified into

- Electrical design
- Physical design

Physical design deals with concrete geometrical parameters while electrical design deals with the electrical performances of the physical object. Strictly speaking, both design aspects are inseparable since any physical design is a realization of a particular electrical design. On the other hand, electrical design without proper abstraction of the corresponding physical design can be futile in the sense that its implementation may not meet the design goals. Thus, electrical and physical design should go hand in hand. Most literature deals with both designs using weighted abstractions. For example, in the design of a digital or analog filter, various effects of physical layout are first captured in the parasitic models for interconnects and in the electrical performance models for transistors. Then, electrical design is performed using such models to predict electrical performances. In physical design optimization, geometrical parameters are chosen such that the predicted electrical performances can meet the design

objectives. For example, in the timing-driven physical layout of integrated circuits, circuit components will be laid out, placed and interconnected to meet timing requirements. In order to make the optimization process computationally efficient, performance models are used during the optimization process instead of simulation tools. In this chapter, the focus of design optimization is on the electrical performance. The computer-aided electrical design can be further classified into performance analysis and optimization. Thus, this chapter first discusses the modeling of electrical performances, symbolic and numerical analysis techniques, followed by optimization techniques for circuit timing, and yield enhancement with transistor sizing and statistical design techniques.

1.2 Circuit Performance Measures

The performance of a particular circuit can be measured in many ways according to application and design goals. In essence, each performance measure is an indication of the circuit output which the designer is interested in for a particular operating condition. The circuit performance, in general, is dependent on the values of the designable parameters such as the transistor sizes, over which the designer has some degree of control, and the values of the noise parameters such as the fluctuation in power supply voltage or the threshold voltages of the transistors, which are random in nature. Also, the performance measure used is dependent on the type of the circuit. The performance measures of digital circuits are usually quite different from those of analog circuits or filters. Some of the important performance measures of digital circuits are

- Signal propagation delay from an input to an output
- Rise and fall times of signals
- Clock signal skew in the circuit
- Power dissipation
- Manufacturing yield
- Failure rate (reliability)

Important performance measures for analog circuits are

- Small-signal gain and bandwidth in frequency domain
- Sensitivities to various nonideal factors (noise)
- Slew rate of operational amplifiers
- Power dissipation
- Manufacturing yield
- Failure rate (reliability)

The modeling of digital circuit performances is usually more difficult to derive than the modeling of analog circuit performances, mainly due to the nonlinear nature of digital circuits. Thus, simple transistor models have been used often to obtain simple qualitative models for propagation delays, rise and fall times, and power dissipation. On the other hand, due to the small-signal nature, the device models required by analog designers need to be much more accurate. Another important performance measure is the manufacturing yield, which determines the product cost. The yield depends on both the quality of manufacturing process control and the quality of the design. A challenging design problem is how to come up with a design which can be robust to nonideal manufacturing conditions and thereby produce a good manufacturing yield. The model for failure rate is difficult to derive due to several complex mechanisms that determine the lifetime of chips. In such cases, empirical models, which are not physical, have been introduced.

In order to develop models for analog circuits, transistors in the circuit are first DC-biased at the proper biasing points. Then, small-signal circuit models are developed at those DC operating points. The resulting linear circuits can be analyzed by either using mathematical symbols (symbolic analysis) or by using simulators.

1.3 Input–Output Relationships

The circuit functionally depends on the input–output relationships and thus circuit specifications and test specifications are made on the basis of the input–output relationships. For modeling purposes, the input–output relationships can be classified into static relationships and dynamic relationships.

1.3.1 Memoryless (Static) Relationship

A given input–output pair is said to have a memoryless relationship if it can be described statically without the use of any ordinary or partial differential equation. It is important to note that the choice of input and output variables can determine the nature of the relationship. For instance, the relationship between input charge q and the output voltage v in a 1 F capacitor is static. On the other hand, the relationship between an input current i and the output voltage v, in the same capacitor is nonstatic since the voltage is dependent on the integral of the input current. Ideally, basic circuit elements such as resistor, capacitor, inductor, and source should be characterized by using static relationships, so-called constitutive relationships, with proper choice of input and output variables. However, for circuits and systems design, since their input–output relationships are specified in terms of specific variables of interest, such choice of variables cannot be made arbitrarily. Often, both input and output variables are voltages, especially in digital circuits.

1.3.2 Dynamic Relationships

A given input–output pair is said to have a dynamic relationship if the modeling of the relationship requires a differential equation. In most cases, since the circuits contain parasitic capacitors or inductors or both, the input–output relationship is dynamic. For instance, the input–output relationship of an inverter gate with capacitive load C_{load} can be described as

$$C_{\text{load}} \frac{\mathrm{d}V_{\text{out}}}{\mathrm{d}t} = i(V_{\text{out}}, V_{\text{in}}, V_{\text{DD}}) \tag{1.1}$$

where

V_{out} and V_{in} denote the output and input voltages
i denotes the current through the pull-up or pull-down transistor
V_{DD} denotes the power supply voltage

Although the relationship is implicit in this case, Equation 1.1 can be solved either analytically or numerically to find the relationship. Equation 1.1 can be generalized by including noise effects due to variations in the circuit fabrication process.

1.4 Dependency of Circuit Performances on Circuit Parameters

Circuit performances are functions of circuit parameters, which are usually not known explicitly. In order to design and analyze analog or digital circuits, the dependency of the circuit performances on the various circuit parameters need to be modeled.

The actual value of a circuit parameter in a manufactured circuit is expected to be different from the nominal or target value due to inevitable random variations in the manufacturing processes and in the environmental conditions in which the circuit is operated. For example, the actual channel width W of an MOS transistor can be decomposed into a nominal component W^0 and a statistically varying component ΔW, i.e., $W = W^0 + \Delta W$. The nominal component is under the control of the designer and can be set to a particular value. Such a nominal component is said to be designable or controllable, e.g., W^0.

The statistically varying component, on the other hand, is not under the control of the designer and is random in nature. It is called the noise component, and it represents the uncontrollable fluctuation of a circuit parameter about its designable component, e.g., ΔW. For certain circuit parameters, e.g., device model parameters (like the threshold voltages of MOS transistors) and operating conditions (like temperature or power supply voltage), the nominal values are not really under the control of the circuit designer and are set by the processing and operating conditions. For these circuit parameters, the nominal and random components are together called the noise component. In general, therefore, a circuit parameter x_i can be expressed as follows:

$$x_i = d_i + s_i \tag{1.2}$$

where
d_i is the designable component
s_i is the noise component

It is common to group all the designable components to form the set of designable parameters, denoted by **d**. Similarly, all the noise parameters are grouped together to form the noise parameters, denoted by the random vector **s**. Vectorially, Equation 1.2 can be rewritten as

$$\mathbf{x} = \mathbf{d} + \mathbf{s} \tag{1.3}$$

A circuit performance measure is a function of the circuit parameters. For example, the propagation delay of a CMOS inverter circuit is a function of the nominal channel lengths and widths of the NMOS and PMOS transistors. It is also a function of the threshold voltages of the transistors and the power supply voltage. Thus, in general, a circuit performance is a function of the designable as well as the noise parameters:

$$y = y(\mathbf{x}) = y(\mathbf{d}, \mathbf{s}) \tag{1.4}$$

If this function is known explicitly in terms of the designable and noise parameters, then optimization methods can be applied directly to obtain a design which is optimal in terms of the performances or the manufacturing yield. More often than not, however, the circuit performances cannot be expressed explicitly in terms of the circuit parameters. In such cases, the value of a circuit performance for given values of circuit parameters can be obtained by circuit simulation. Circuit simulations are computationally expensive, especially if the circuit is large and transient simulations are required. A compact performance model in terms of the circuit parameters is an efficient alternative to the circuit simulator. Two factors determine the utility of the performance model. First, the model should be computationally efficient to construct and evaluate so that substantial computational savings can be achieved. Second, the model should be accurate.

Figure 1.1 shows the general procedure for constructing the model for a performance measure y in terms of the circuit parameters **x**. The model-building procedure consists of four steps. In the first stem, *m training points* are selected from the **x**-space. The ith training point is denoted by $\mathbf{x}_i$, $i = 1, 2, \ldots, m$. In the second step, the circuit is simulated at these m training points and the values of the performance measure are obtained from the circuit simulation results as $y(\mathbf{x}_1)$, $y(\mathbf{x}_2)$, $\ldots, y(\mathbf{x}_m)$. In the third step, a preassigned function of y in terms of **x** is "fitted" to the data. In the fourth and final step, the model is validated for accuracy. If the model accuracy is deemed inadequate, the modeling procedure is repeated with a larger number of training points or with different models.

The model is called the response surface model (RSM) [1] of the performance and is denoted by $\hat{y}(\mathbf{x})$. The computational cost of modeling depends on the number of training points m, and the procedure of fitting the model to the data. The accuracy of the RSM is quantified by computing error measures which

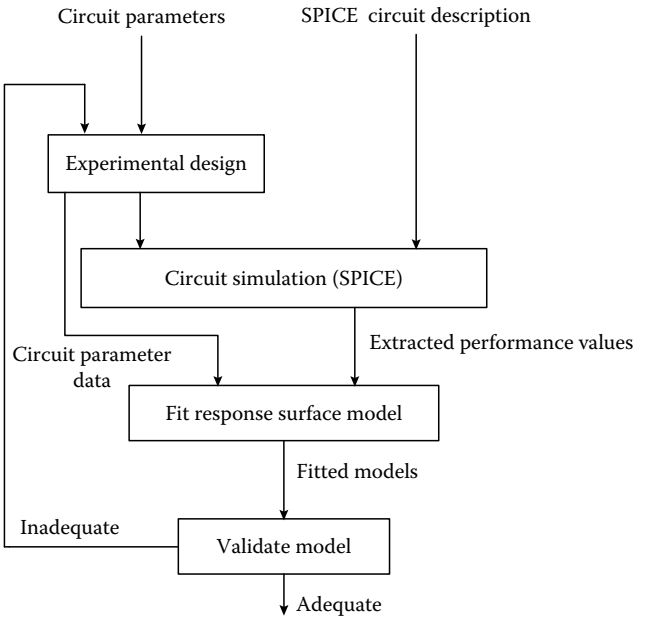

FIGURE 1.1 Performance modeling procedure.

quantify the ''goodness of fit.'' The accuracy of the RSM is greatly influenced by the manner in which the training points are selected from the **x**-space. Design of experiment (DOE) [2] techniques are a systematic means of obtaining the training points such that the maximum amount of information about the model can be obtained from these simulations or experimental runs. In the next section, we review some of the most commonly used experimental design techniques in the context of performance optimization and statistical design. To illustrate certain points in the discussion below, we will assume that the RSM of the performance measure y is the following quadratic polynomial in terms of the circuit parameters:

$$\hat{y}(\mathbf{x}) = \hat{\alpha}_0 + \sum_{i=1}^{n} \hat{\alpha}_i x_i + \sum_{i=1}^{n} \sum_{j=1}^{n} \hat{\alpha}_{ij} x_i x_j \tag{1.5}$$

where the $\hat{\alpha}$s are the coefficients of the model. Note, however, that the discussion is valid for all RSMs in general.

1.5 Design of Experiments

1.5.1 Factorial Design

In this experimental design, each of the circuit parameters $x_1, x_2, \ldots, x_n$ is quantized into two levels or settings, which are denoted by -1 and $+1$. A full factorial design contains all possible combinations of levels for the n parameters, i.e., it contains 2^n training points or experimental runs. The design matrix for the case of $n = 3$ is shown in Table 1.1 and the design is pictorially described in Figure 1.2. The value of the circuit performance measure for the kth run is denoted by y_k.

Much information about the relationship between the circuit performance y and the circuit parameters x_i, $i = 1, 2, \ldots, n$ can be obtained from a full factorial experiment. The main or individual effect of a

TABLE 1.1 Full Factorial Design for $n = 3$

	Parameter Levels			Interaction Levels				
Run	x_1	x_2	x_3	$x_1 \times x_2$	$x_1 \times x_3$	$x_2 \times x_3$	$x_1 \times x_2 \times x_3$	y
1	−1	−1	−1	+1	+1	+1	−1	y_1
2	−1	−1	+1	+1	−1	−1	+1	y_2

7	+1	+1	−1	+1	−1	−1	−1	y_7
8	+1	+1	+1	+1	+1	+1	+1	y_8

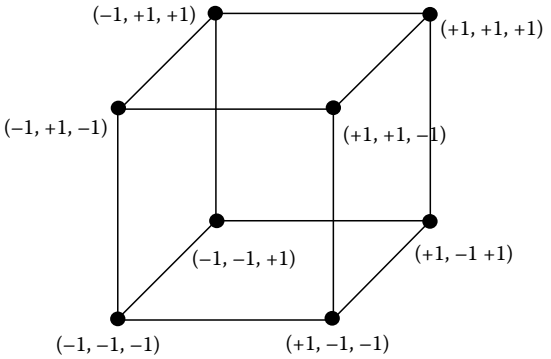

FIGURE 1.2 Pictorial representation of full factorial design for $n = 3$.

parameter quantifies how much a parameter affects the performance singly. The main effect of x_i, denoted by v_i, is given by

$$v_i = \frac{1}{2^n} \sum_{k=1}^{2^n} x_{ik} \times y_k \tag{1.6}$$

where

x_{ik} is the value of x_i in the kth run

y_k is the corresponding performance value

Thus, the main effect is the difference between the average performance value when the parameter is at the high level (+1) and the average performance value when the parameter is at the low level (−1). The main effect of x_i is the coefficient of the x_i term in the polynomial RSM of Equation 1.5. Similarly, the interaction effect of two or more parameters quantities how those factors jointly affect the performance. The two-factor interaction effect is computed as the difference between the average performance value when both factors are at the same level and the average performance value when they are at different levels. The two-factor interaction effect of parameters x_i and x_j, denoted by $v_{i\times j}$, $i \neq j$, is defined as follows:

$$\begin{aligned} v_{i\times j} &= \frac{1}{2}\left\{v_{i|j=+1} - v_{i|j=-1}\right\} \\ &= \frac{1}{2^n} \sum_{k=1}^{2^n} x_{ik} \times x_{jk} \times y_k \end{aligned} \tag{1.7}$$

The two-factor interaction effect of x_i and x_j, $v_{i\times j}$, is the coefficient of the $x_i x_j$ terms in the quadratic RSM of Equation 1.5. Note that $v_{i\times j}$ is the same as $v_{j\times i}$. Moreover, higher-order multifactor interaction effects can be computed recursively as before. Note that the interaction columns of Figure 1.2 are obtained by the aggregated "sign-multiplication" given in Equation 1.7.

Thus, the full factorial design allows us to estimate the coefficients of all the first-order and cross-factor second-order coefficients in the RMS of Equation 1.5. However, it does not allow us to estimate the coefficients of the pure quadratic term x_i^2. Moreover, the number of experimental runs increases exponentially with the number of circuit parameters; this may become impractical for a large number

TABLE 1.2 Half Fraction of a Full Factorial Design for $n = 3$

	Parameter Levels			Interaction Levels				
Run	x_1	x_2	x_3	$x_1 \times x_2$	$x_1 \times x_3$	$x_2 \times x_3$	$x_1 \times x_2 \times x_3$	y
1	−1	−1	+1	+1	−1	−1	+1	y_1
2	−1	+1	−1	−1	+1	−1	+1	y_2
3	+1	−1	−1	−1	−1	+1	+1	y_3
4	+1	+1	+1	+1	+1	+1	+1	y_4

of circuit parameters. In many cases, high-order multifactor interactions are small and can be ignored. In such cases, it is possible to reduce the size of the design by systematically eliminating some interactions and considering only some of the runs. The accuracy with which the main effects and the low-order interaction effects are estimated does not have to be compromised. Such designs are called fractional factorial designs. The most popular class of fractional factorial designs are the 2^{n-p} designs, where a $1/2^p$th fraction of the original 2^n design is used. One of the half fractions of the 2^3 design shown in Table 1.1, i.e., a 2^{3-1} design is shown in Table 1.2.

We observe that some of the columns of Table 1.2 are now identical. It can be seen from Equations 1.6 and 1.7 that we cannot distinguish between effects that correspond to identical columns. Such effects are said to be confounded or aliased with each other. From Table 1.2, we see that v_3, the main effect of x_3, and $v_{1\times2}$, the interaction effects of x_1 and x_2, are confounded with each other. Moreover the three-factor interaction effect $v_{1\times2\times3}$ is confounded with the grand average of the performance (corresponding to a column of 1's). Confounding, however, is not really a problem, since in most applications, high-order interaction effects are negligible. For example, in the quadratic RSM of Equation 1.5, only main effects and two-factor interaction effects are important, and it can be assumed that all higher-order interaction effects are absent.

There is a systematic way of obtaining fractional factorial designs by first isolating a set of basic factors (circuit parameters) and then defining the remaining nonbasic factors in terms of the interaction of the basic factors. These interactions that define the nonbasic factors in terms of the basic factors are called generators. The set of basic factors and the generator functions completely characterize a fractional factorial design. For example, the generator function used in the example of Table 1.2 is

$$x_3 = x_1 \times x_2 \tag{1.8}$$

Note that, once the generator function is known for a fractional design, the confounding pattern is also completely known. Moreover, note that the generator functions are not unique. The generator functions $x_1 = x_2 \times x_3$ and $x_2 = x_1 \times x_3$ also give rise to the design of Table 1.2. This can be understood by realizing that a column corresponding to a parameter sign-multiplied by itself results in a column of all 1s, i.e., the identity column, denoted by I. Thus, multiplying both sides of Equation 1.8 by x_2, we get $x_3 \times x_2 = x_1 \times x_2 \times x_2 = x_1 \times I = x_1$, which is also a generator function. Thus, an appropriate set of generator functions must be defined.

Another important concept related to confounding is called the resolution of a design, which indicates the clarity with which individual effects and interaction effects can be evaluated in a design. A *resolution III* design is one in which no two main effects are confounded with each other (but they may be confounded with two-factor and/or higher-order interaction effects). An important class of resolution *III* designs is the saturated fractional factorial designs. Suppose that the number of factors (parameters), n, can be expressed as $n = 2^q - 1$, for some integer q. Then, a resolution *III* design can be obtained by first selecting q basic factors and then saturating the 2^q design by assigning a nonbasic factor to each of the possible combinations of the q basic factors. There are $p = n - q$ nonbasic factors and generator functions, and these

designs are called 2^{n-p}_{III} designs, since $2^q = n+1$ runs are required for n factors. Note that the fractional factorial design of Table 1.2 is a 2^{n-p}_{III} design, with $n=3$ and $p=1$. In the saturated design for $n=2^q-1$ factors, the confounding patterns for the basic and nonbasic factors are the same, which implies that any of the q factors may be chosen as the basic factors. However, if $n+1$ is not an integral power of 2, then q is chosen as $q=[\log_2(n+1)]$. Next, we define q basic factors and generate a 2^q design. Next, we assign $p=n-q$ nonbasic factors to p generators and form the 2^{n-p}_{III} design. Note that, in this case, only p of the 2^q-q-1 available generators are used, and the confounding pattern depends on the choice of the q basic factors and the p generators. The number of runs in the saturated design is considerably less than 2δ.

Another important class of designs commonly used is called *resolution V* designs. In these designs, no main effect or two-factor interaction effect is confounded with another main effect or two-factor interaction effect. Such designs are denoted by 2^{n-p}_{V} designs, where as before, n is the number of factors and p is the number of generators. These designs can be used to estimate the coefficients of all but the pure quadratic terms in the RSM of Equation 1.5. Since the number of such coefficients (including the constant term) is $C=1+n+n(n-1)/2$, there must be at least C runs. Note that C is still substantially less than 2^n. Another important advantage of the factorial designs is that they are orthogonal, which implies that the model coefficients can be estimated with minimum variances (or errors). An algorithmic method for deriving resolution V designs is given in [3].

1.5.2 Central Composite Design

As mentioned previously, one of the problems of factorial designs in regard to the RMS of Equation 1.5 is that the coefficients of the pure quadratic terms cannot be estimated. These coefficients can be estimated by using a central composite design. A central composite design is a combination of a "cube" and a "star" subdesign. Each factor in a central composite design takes on five values: 0, ± 1, and $\pm\gamma$. Figure 1.3 shows the central composite design for the case of $n=3$. The cube subdesign, shown in dotted lines in Figure 1.3, is a fractional factorial design with the factor levels set to ± 1. This design is of resolution V so that linear and cross-factor quadratic terms in the RSM of Equation 1.5 can be estimated. The star

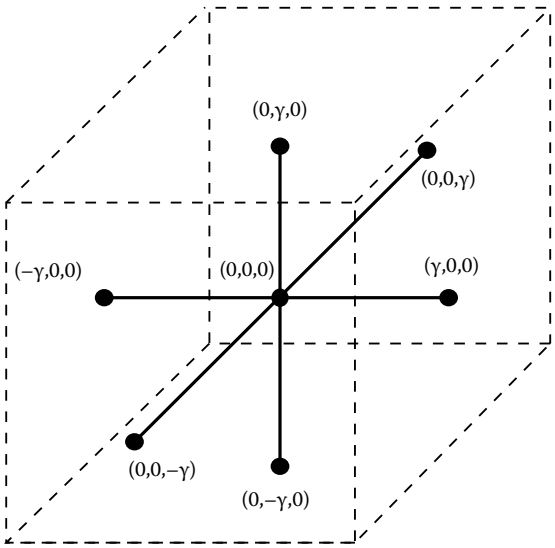

FIGURE 1.3 Central composite design for $n=3$.

subdesign, shown in solid lines in Figure 1.3, is used to estimate the pure quadratic terms, x_1^2, in the RMS, and consists of

- One *center* point, where all the parameters are set to 0
- 2*n Axial* points, one pair for each parameter by setting its value to $-\gamma$ and $+\gamma$ and setting all other parameters to 0

The parameter γ (chosen by the user) is selected so that the composite plan satisfies the rotatability property [1]. The main advantage of the central composite design is that all the coefficients of Equation 1.5 can be estimated using a reasonable number of simulations.

1.5.3 Taguchi's Orthogonal Arrays

Taguchi's method using orthogonal arrays (OA) [4] is another popular experimental design technique. An orthogonal array is a special kind of fractional factorial design. These orthogonal arrays can be classified into two types. The first category of OAs corresponds to two-level designs, i.e., the parameters are quantized to two levels each, while the second corresponds to three-level designs, i.e., the parameters are quantized to three levels each. These arrays are often available as tables in books which discuss Taguchi techniques [4]. As an example, we show the L18 OA in Table 1.3. The number in the designation of the array refers to the number of experimental runs in the design. The L18 OA belongs to the second category of designs, i.e., each parameter has three levels. In the Taguchi technique, the experimental design matrix for the controllable or designable parameters is called the inner array, while that for the noise parameters is called the outer array. The L18 design of Table 1.3 can be used as an inner array as well as an outer array.

1.5.4 Latin Hypercube Sampling

The factorial, central composite, and Taguchi experimental designs described earlier set the parameters to certain levels or quantized values within their ranges. Therefore, most of the parameters space remains

TABLE 1.3 Taguchi's L18 OA

Run	Parameter Levels							
1	1	1	1	1	1	1	1	1
2	1	1	2	2	2	2	2	2

17	2	3	2	1	3	1	2	3
18	2	3	3	2	1	2	3	1

unsampled. It is therefore desirable to have a more "space-filling" sampling strategy. The most obvious method of obtaining a more complete coverage of the parameter space is to perform random or Monte Carlo sampling [5]. In random sampling, each parameter has a particular statistical distribution and the parameters are considered to be statistically independent. The distribution of the circuit parameters can often be obtained from test structure measurements followed by parameter extraction. Often, however, based on previous experience or reasonable expectation, the circuit parameters are considered to be normal (or Gaussian). Since the designable parameters are deterministic variables, they are considered to be independent and uniformly distributed for the purposes of random sampling. Random samples are easy to generate and many inferences can be drawn regarding the probability distribution of the performances. The problem with random sampling, however, is that a large sample is usually required to estimate quantities with sufficiently small errors. Moreover, circuit parameters are usually not statistically independent. In particular, the noise parameters are statistically correlated because of the sequential nature of semiconductor wafer processing. Further, a random sample may not be very space filling either. This can be understood by considering the bell-shaped Gaussian density curve. In random sampling, values near the peak of the bell-shaped curve would be more likely to occur in the sample since such values have higher probability of occurrence. In other words, values away from the central region would not be well represented in the sample.

Latin hypercube sampling (LHS) [6,7] is a sampling strategy that alleviates this problem to a large extent. For each parameter x_i, all portions of its distribution are represented by sample values. If S is the desired size of the sample, then the range of each x_i, $i = 1, 2, \ldots, n$ is divided into S nonoverlapping intervals of equal marginal probability $1/S$. Each such interval is sampled once with respect to the probability density in that interval to obtain S values for each parameter. Next, the S values for one parameter are randomly paired with the S values for another parameter, and so on. Figure 1.4 illustrates this process for the case of two circuit parameters x_1 and x_2, where x_1 is a uniform random variable, and x_2 is a Gaussian random variable, and $S = 5$. The marginal probability in an interval is defined as the area under the probability density curve for that interval. Therefore, intervals with equal probability are intervals with equal areas under the probability density curve. For the uniformly distributed x_1, equal probability intervals are also of equal length. For x_2, however, the intervals near the center are smaller (since the density there is higher) than the intervals away from the center (where the density is lower). Figure 1.4 shows that $S = 5$ values are chosen from each region for x_1 and x_2 (shown as open circles). These values are then randomly paired so as to obtain the sample points (shown as filled dots). If the circuit parameters are correlated, then the pairing of the sample values can be controlled so that

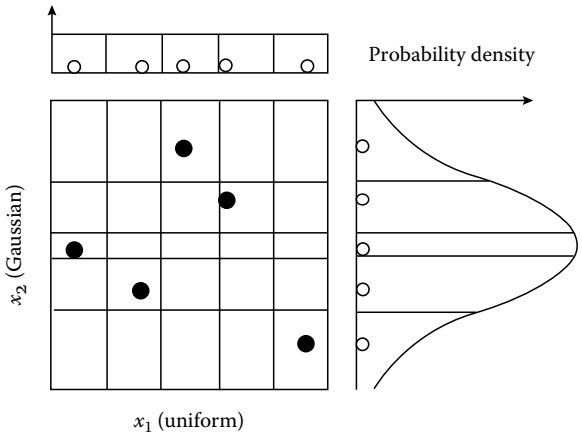

FIGURE 1.4 Latin hypercube sampling for a uniform and a Gaussian random variable.

the sample correlation matrix is close to the user-provided correlation matrix for the circuit parameters. Note that LHS will provide a more uniform coverage of the parameter space than other experimental design techniques. Moreover, a sample of any size can be easily generated and all probability densities are handled.

1.6 Least-Squares Fitting

After the experimental design has been used to select the training points in the parameter space, the circuit is simulated at the training points and the values of the performance measure are extracted from the simulation results. Let S denote the number of experimental runs, and y_k, $k = 1, \ldots, S$ denote the corresponding performance values. The aim in least-squares fitting is to determine the coefficients in the RSM so that the fitting error is minimized. Let C denote the number of coefficients in the RSM. For example, the value of C for the RSM of Equation 1.5 is $C = (n+1)(n+2)/2$, where n is the number of circuit parameters. There are interpolation-based methods that can be used to determine the coefficients when there are a smaller number of data points than coefficients, i.e., when $S < C$. One such method is called maximally flat quadratic interpolation and is discussed later in this chapter. We will restrict our discussion to the case of $S \geq C$. If $S = C$, then there are as many data points as coefficients, and simple simultaneous equation solving will provide the values of the coefficients. In this case, the model interpolates the data points exactly, and there is no fitting error to be minimized. When $S > C$, the coefficients can be determined in such a way that the fitting error is minimized. This method is called least-squares fitting (in a numerical analysis context) or linear regression (in a statistical context). The error measure is called the sum of squared errors and is given by

$$\in = \sum_{i=1}^{S} (y_k - \hat{y}_k)^2 \tag{1.9}$$

where

y_k denotes the simulated performance value
$\hat{y}_k$ denotes the model-predicted value at the kth data point

Least-squares fitting can then be stated as

$$\min_{\hat{\alpha}_i} \in = \sum_{i=1}^{s} (y_k - \hat{y}_k)^2 \tag{1.10}$$

where $\hat{\alpha}_i$ represents the (unknown) coefficients of the RSM. The error ε is used to determine the adequacy of the model. If this error is too large, the modeling procedure should be repeated with a larger number of training points or a different sampling strategy, or a different model of the performance may have to be hypothesized.

From a statistical point of view (linear regression), the actual performance value is considered to be

$$y_i = \hat{y}_i + e_i, \quad i = 1, 2, \ldots, S \tag{1.11}$$

where e_i denotes the random error in the model. In least-squares fitting, this random error is implicitly assumed to be independent and identically distributed normal random variables with zero mean and constant variance. In particular, we assume that

$$\begin{aligned} E(e_i) &= 0 \\ \mathrm{Var}(e_i) &= \sigma^2 \\ \text{and} \quad \mathrm{Cov}(e_i, e_j) &= 0, \quad i \neq j \end{aligned} \tag{1.12}$$

If the RSM of the performance measure is linear, then it can be written as

$$\hat{y}(\mathbf{x}) = \sum_{i=1}^{C} \alpha_i f_i(\mathbf{x}) \tag{1.13}$$

where
$f_i(\mathbf{x})$ are the known basis functions of the circuit parameters
C denotes the number of basis functions

Note that the RSM is said to be linear (and least-squares fitting can be used) if it is linear in terms of the model coefficients α_i. The basis functions $f_i(\mathbf{x})$ need not be linear. For instance, the basis functions used in the quadratic RSM of Equation 1.5 are 1, x_i, and $x_i x_j$.

Let $\mathbf{y}$ and $\mathbf{e}$ be S-vectors: $\mathbf{y} = [y_1, \ldots, y_S]^{\mathrm{T}}$ and $\mathbf{e} = [e_1, \ldots, e_S]^{\mathrm{T}}$, where S is the number of data points. Also, let us define the model coefficients as $\alpha = [\alpha_1, \ldots, \alpha_C]$. Finally, let $\mathbf{X}$ denote the following $S \times C$ matrix:

$$X = \begin{bmatrix} f_1(\mathbf{x}_1) & \cdots & f_C(\mathbf{x}_1) \\ \vdots & \vdots & \vdots \\ f_1(\mathbf{x}_S) & \cdots & f_C(\mathbf{x}_S) \end{bmatrix} \tag{1.14}$$

Then, Equation 1.11 can be vectorially written as

$$\mathbf{y} = \mathbf{X}\alpha + \mathbf{e} \tag{1.15}$$

We choose α to minimize the function

$$\mathrm{RSS}(\alpha) = (\mathbf{y} - \mathbf{X}\alpha)^{\mathrm{T}}(\mathbf{y} - \mathbf{X}\alpha) \tag{1.16}$$

The least squares estimate $\hat{\alpha}$ of α is given by the following formula:

$$\hat{\alpha} = (\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1}\mathbf{X}^{\mathrm{T}}\mathbf{y} \tag{1.17}$$

The function Equation 1.16 evaluated at $\hat{\alpha}$ is called the residual sum of squares, abbreviated RSS, and is given by

$$\mathrm{RSS} = (\mathbf{y} - \mathbf{X}\hat{\alpha})^{\mathrm{T}}(\mathbf{y} - \mathbf{X}\hat{\alpha}) \tag{1.18}$$

It can be shown that an estimate of the variance of the random error is

$$\hat{\sigma}^2 = \frac{\mathrm{RSS}}{S - C} \tag{1.19}$$

and that $\hat{\alpha}$ is unbiased, i.e., $E(\hat{\alpha}) = \alpha$, and the variance of the estimate is

$$\mathrm{var}(\hat{\alpha}) = \hat{\alpha}^2(\mathbf{X}^{\mathrm{T}}\mathbf{X})^{-1} \tag{1.20}$$

Another figure of merit of the linear regression is called the coefficient of determination, denoted by R^2, and given by

$$R^2 = 1 - \frac{\text{RSS}}{\sum_{i=1}^{s} (\text{y}_1 - \bar{y})^2} \tag{1.21}$$

where $\bar{y}$ is the sample average of the y_is, $i = 1, \ldots, S$. The coefficient of determination measures the proportion of variability in the performance that is explained by the regression model. Values of R^2 close to 1 are desirable.

1.7 Variable Screening

Variable screening is used in many performance modeling techniques as a preprocessing step to select the significant circuit parameters that are used as independent variables in the performance model. Variable screening can be used to substantially reduce the number of significant circuit parameters that must be considered, and thereby reduce the complexity of the analysis. The significant circuit parameters are included in the performance model, while the others are ignored. Several variable screening approaches have been proposed; in this chapter, we discuss a simple yet effective screening strategy that was proposed in [8].

The variable screening method of [8] is based on the two-level fractional factorial designs discussed earlier. We assume that the main effects (given by Equation 1.6) of the circuit parameters dominate over the interaction effects and this assumption enables us to use a resolution *III* design. Suppose that there are n original circuit parameters, denoted by $x_1, \ldots, x_n$. Then, we can use the simulation results from the fractional factorial design to compute the following quantities for each of the circuit parameters x_i, $i = 1, \ldots, n$:

1. Main effect v_i computed using Equation 1.6
2. *High deviation* d_i^{h} from the nominal or center point, computed by

$$d_i^{\text{h}} = \frac{2}{n_{\text{r}}} \sum_{k \in K_i^+} y_k - y_{\text{c}} \tag{1.22}$$

   where
   n_{r} is the number of simulations
   K_i^+ is the set of indices where x_i is $+1$
   y_{c} is the performance value at the center point

3. The *low deviation* d_i^{l} from the center point, computed using a formula similar to Equation 1.22, with K_i^+ replaced by K_i^-

Note that only two of the preceding quantities are independent, since the third can be obtained as a linear combination of the other two. A statistical significance test is now used to determine if x_i is significant. To this end, we assume that the quantities v_i, d_i^{h}, and d_i^{l} are sampled from a normal distribution with a sample size of n (since there are n circuit parameters). Denoting any one of the above quantities v_i, d_i^{h}, or d_i^{l} by δ_i, the hypothesis for the significance test is

$$\begin{aligned} &\text{Null hypothesis } H_0: \quad |\delta_i| = 0, \text{ i.e., } x_i \text{ is insignifiant} \\ &\qquad\qquad\qquad\quad H_0 \text{ is rejected if } |\delta_i|/\sigma_\delta > t_{\alpha_s/2, n-1} \end{aligned} \tag{1.23}$$

In Equation 1.23, a two-sided t-test is used [9] with significance level α_s and σ_δ denotes the estimate of the standard deviation of $\delta_i \cdot t_{\alpha_s/2, n-1}$ denotes the value of the t statistic with significance level $\alpha_s/2$ and degrees of freedom $n - 1$. We declare a parameter x_i to be insignificant if it is accepted in the tests for at least two of v_i, d_i^{h}, and d_i^{l}. This screening procedure is *optimistic* in the sense that an insignificant

parameter may be wrongly deemed significant from the preceding significance tests. The values of the *t*-variable can be read off from standard *t*-distribution tables available in many statistics text books.

1.8 Stochastic Performance Models

As stated earlier, the objective of performance modeling is to obtain an inexpensive surrogate to the circuit simulator. This performance model can then be used in a variety of deterministic and statistical optimization tasks in lieu of the expensive circuit simulator. The circuit simulator is a computer model, which is deterministic in the sense that replicate runs of the model with identical inputs will always result in the same values for the circuit performances. This lack of random error makes computer-based experiments fundamentally different from physical experiments. The experimental design and response surface modeling techniques presented earlier have the tacit assumption that the experiments are physical and the difference between the observed performance and the regression model behaves like white noise. In the absence of random error, the rationale for least-squares fitting of a response surface is not clear even though it can be looked upon solely as curve fitting. Stochastic performance modeling [10,11] has been used recently to model the outputs (in our case, the circuit performances) of computer codes or models (in our case, the circuit simulator). The basic idea is to consider the performances as realizations of a stochastic process and this allows one to compute a predictor of the response at untried inputs and allows estimation of the uncertainty of prediction.

The model for the deterministic performance y treats it as a realization of a stochastic process $Y(\mathbf{x})$ which includes a regression model:

$$Y(\mathbf{x}) = \sum_{i=1}^{k} \alpha_i f_i(\mathbf{x}) + Z(\mathbf{x}) \tag{1.24}$$

The first term in Equation 1.24 is the simple regression model for the performance and the second term represents the systematic departure of the actual performance from the regression model as a realization of a stochastic process. This model is used to choose a design that predicts the response well at untried inputs in the parameter space. Various criteria based on functionals of the means square error matrix are used to choose the optimal design. One the design is selected, the circuit simulator is exercised at those design points, and the circuit performance values are extracted. Next, a linear (in the model coefficients $\hat{\alpha}_i s$) predictor is used to predict the values of the performance at untried points. This predicted value can be shown to be the sum of two components: the first component corresponds to the first term in Equation 1.24 and uses the generalized least squares estimate of the coefficients α, and the second component is a smoothing term, obtained by interpolating the residuals at the experimental design points. The main drawback of the stochastic performance modeling approach is the excessive computational cost of obtaining the experimental design and of predicting the performance values.

1.9 Other Performance Modeling Approaches

The most popular performance modeling approach combines experimental design and least-squares-based response surface modeling techniques described previously [8,12–15]. A commonly used assumption valid for MOS circuits that has been used frequently is based on the existence of four critical noise parameters [16–18]. These four critical parameters are the flat-band voltage, the gate-oxide thickness, the channel length reduction, and the channel width reduction.

Several other performance modeling approaches have been proposed, especially in the context of statistical design of integrated circuits. One such approach is based on self-organizing methods [19] and is called the group method of data handling (GMDH) [20]. An interesting application of GMDH for performance modeling is presented in [21,22]. Another interesting approach is called maximally flat

quadratic interpolation (MFQI) [23]. A modeling approach combining the advantages of MFQI and GMDH is presented in [24]. It has been tacitly assumed in the discussion so far that a single RSM is sufficiently accurate to approximate the circuits performances over the entire circuit parameter space. This may not be true for many circuits. In such cases, a piecewise modeling approach may be used advantageously [8]. The circuit parameter space is divided into smaller regions, in each of which a single performance model is adequate. The continuous performance models in the various regions are then *stitched* together to preserve continuity across the regions.

1.10 Example of Performance Modeling

Below, we show an application of performance modeling applied to the clock skew of a clock distribution circuit. Consider the clock driver circuit shown in Figure 1.5. The top branch has three inverters and the lower branch has two inverters to illustrate the problem of signal skew present in many clock trees. We define the clock skew to be the difference between the times at which CLK and its complement cross a threshold of 0.5 V_{DD}. Two skews occur, as shown in Figure 1.6, one corresponding to the rising edge of the CLK, ΔS_r, and another corresponding to the falling edge of CLK, ΔS_f. The performance measure of interest is the signal skew ΔS defined as the larger of the two skews.

The designable circuit parameters of interest in this example are the nominal channel widths of each of the transistors in the second and third inverters in the top branch and the last inverter in the lower

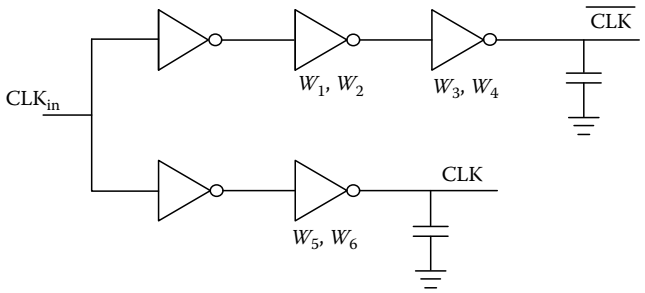

FIGURE 1.5 Clock distribution circuit.

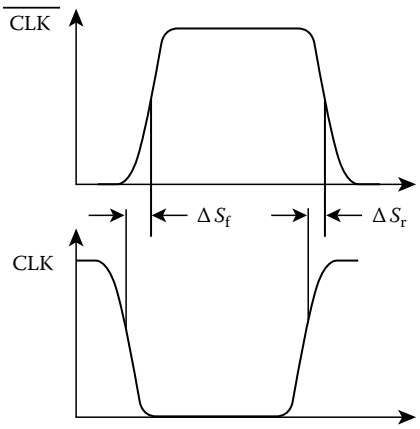

FIGURE 1.6 Definition of rising and falling clock skews.

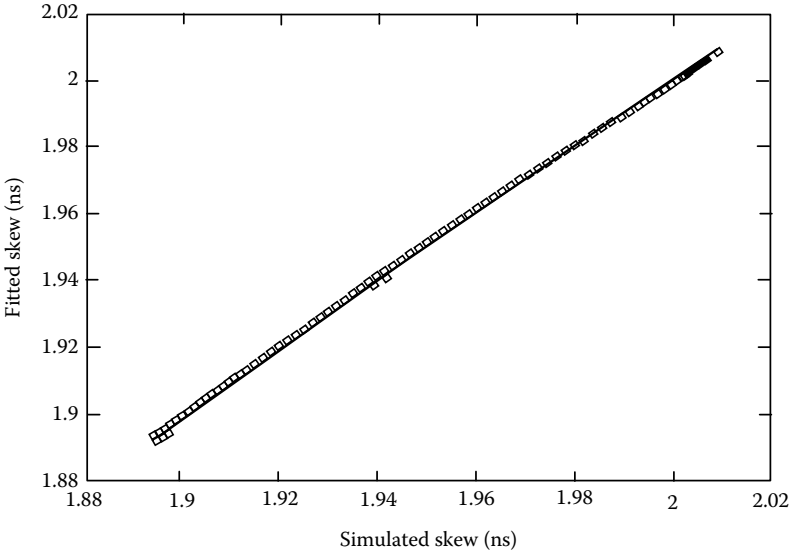

FIGURE 1.7 Plot of predicted versus simulated values for RSM of Equation 1.25.

branch. The designable parameters are denoted by W_1, W_2, W_3, W_4, W_5, and W_6 and are marked in Figure 1.5. The noise parameters of interest are the random variations in the channel widths and lengths of all nMOS and pMOS transistors in the circuit, and the common gate oxide thickness of all the transistors. These are denoted by ΔW_n (channel width variation of nMOS transistors), ΔL_n (channel length variation nMOS transistors), ΔW_p (channel width variation of pMOS transistors), ΔL_p (channel length variation of pMOS transistors), and t_{ox} (gate oxide thickness of all nMOS and pMOS transistors). We hypothesize a linear RSM for the clock skew in terms of the designable and noise parameters of the circuit. To this end, we generate an experimental design of size 30 using Latin hypercube sampling. The circuit is simulated at each of these 30 training points, and the value of the clock skew ΔS is extracted from the simulation results. Then, we use regression to fit the following linear RSM:

$$\begin{aligned}\Delta S = {} & 1.93975 - 0.0106W_1 + 0.0121W_2 + 0.0045W_3 - 0.1793W_4 \\ & + 0.0400W_5 + 0.0129W_6 - 0.0149\Delta W_n - 0.0380\Delta W_p \\ & - 0.0091\Delta L_n + 0.0115\Delta L_p + 0.161t_{ox}\end{aligned} \tag{1.25}$$

This RSM has an R^2 of 0.999. The prediction accuracy for the preceding RSM is in Figure 1.7 where the values of ΔS predicted from the RSM are plotted against the simulated values for a set of checking points (different from the training points used to fit the RSM). Most of the points lie near the 45° line indicating that the predicted values are in close agreement with the simulated values.

2.1 Introduction

The late 1980s and 1990s saw a heightened interest in the development of symbolic analysis techniques and their applications to integrated circuits analysis and design. This trend continues in the new millennium. It resulted in the current generation of symbolic analysis methods, which include several software implementations like ISSAC [Gie89], SCAPP [Has89], ASAP [Fer91], EASY [Som91], SYNAP [Sed88], SAPWIN [Lib95], SCYMBAL [Kon88], GASCAP [Hue89], SSPICE [Wie89], STAINS [Pie01], and Analog Insydes [Hen00]. This generation is characterized by an emphasis on the production of usable software packages and a large interest in the application of the methods to the area of analog circuit design. This includes extensive efforts to reduce the number of symbolic expression generated by the analysis through hierarchical methods and approximation techniques [Fer92,Sed92,Wam92,Hsu94, Yu96]. This generation also includes attempts at applying symbolic analysis to analog circuit synthesis [Gie91,Cab98], parallel processor implementations [Has93b,Mat93,Weh93], time-domain analysis [Has91,Als93,Lib93], and behavioral signal path modeling [Ley00].

The details of traditional symbolic analysis techniques as they apply to linear circuit theory are given in [Rod08]. This chapter addresses symbolic analysis as a computer-aided design tool and its application to integrated circuit design. Modern symbolic analysis is mainly based on either a topological approach or a modified nodal analysis (MNA) approach. The basic topological (graph-based) methodologies are discussed in [Rod08] because the methods are part of traditional symbolic analysis techniques. The methodology addressed in this chapter is based on the concept of MNA [Ho75] as it applies to symbolic analysis.

Traditional symbolic circuit analysis is performed in the frequency domain where the results are in terms of the frequency variable s. The main goal of performing symbolic analysis on a circuit in the frequency domain is to obtain a symbolic transfer function of the form:

$$H(s,\mathbf{x}) = \frac{N(s,\mathbf{x})}{D(s,\mathbf{x})}, \quad \mathbf{x} = \begin{bmatrix} x_1 & x_2 & \dots & x_p \end{bmatrix}, \quad p \leq p_{\text{all}} \tag{2.1}$$

The expression is a rational function of the complex frequency variable s, and the variables x_1 through x_p representing the variable circuit elements, where p is the number of variable circuit elements and p_{all} is the total number of circuit elements. Hierarchical symbolic analysis approaches are based on a decomposed form of Equation 2.1 [Sta86,Has89,Has93a,Pie01]. This hierarchical representation is referred to as a sequence of expressions representation to distinguish it from the single expression representation of Equation 2.1. The major advantage of having a symbolic transfer function in single expression form is the insight that can be gained by observing the terms in both the numerator and the denominator. The effects of the different terms can, perhaps, be determined by inspection. This process is very valid for the cases where there are relatively few symbolic terms in the expression.

The heart of any circuit simulator, symbolic or numeric, is the circuit analysis methodology used to obtain the mathematical equations that characterize the behavior of the system. The circuit must satisfy these equations. These equations are of three kinds: Kirchhoff's current law (KCL), Kirchhoff's voltage law (KVL), and the branch relationship (BR) equations [Chu75]. KCL and KVL are well known and have been discussed earlier in this book. The definition of BR is ''For independent branches, a branch relationship defines the branch current in terms of the branch voltages.'' The most common independent branches are resistors, capacitors, and inductors. For the case of dependent branches, the branch current or voltage is defined in terms of other branches' currents or voltages. The four common types of dependent branches are the four types of controlled sources: voltage-controlled voltage source (VCVS), voltage-controlled current source (VCCS), current-controlled voltage source (CCVS), and current-controlled current source (CCCS). A linear element would produce a BR equation that is linear, and a nonlinear element would produce a nonlinear BR equation. The scope of this section is linear elements. If a nonlinear element is to be included in the circuit, a collection of linear elements could be used to closely model the behavior of that element around a dc operating point (quiescent point) in a certain frequency range [Gie94]. BR equations are not used on their own to formulate a system of equations to characterize the circuit. They are, however, used in conjunction with KCL or KVL equations to produce a more complete set of equations to characterize the circuit. Hybrid analysis [Chu75] uses a large set of BR equations in its formulation.

A system of equations to solve for the circuit variables, a collection of node voltages and branch currents, does not need to include all of the above equations. Several analysis methods are based on these equations or a subset thereof. Mathematically speaking, an equal number of circuit unknowns and linearly independent equations is required in order for a solution for the system to exist. The most common analysis methods used in circuit simulators are as follows:

1. A modification of nodal analysis as used in the numeric circuit simulators SPICE2 [Nag75], and SLIC [Idl71], and in the formulation of the symbolic equations in [Ald73]. Nodal analysis [Chu75] uses KCL to produce the set of equations that characterize the circuit. Its advantage is its relatively small number of equations. This results in a smaller matrix, which is very desirable in computer implementations. Its limitation, however, is that it only allows for node-to-datum voltages as variables. No branch current variables are allowed. Also the only type of independent power sources it allows are independent current sources. However, voltage sources are handled by using their Norton equivalent. A further limitation to this method is that only VCCSs are allowed, none of the other dependent sources are allowed in the analysis. To overcome these limitations, the MNA method was proposed in [Ho75]. It allows branch current as variables in the analysis,

which in turn leads to the ability to include voltage sources and all four types of controlled sources in the analysis. The MNA method is described in more detail in the next section because it is used in symbolic analysis after further modification to it. These modifications are necessary in order for the analysis to accept ideal operational amplifiers (op-amps), and to produce a compact circuit characterization matrix. This matrix is referred to as the reduced MNA matrix (RMNAM).

2. Hybrid analysis [Chu75] is used in the numeric simulators ASTAP [Wee73] and ECAP2 [Bra71]. The method requires the selection of a tree and its associated co-tree. It uses cutset analysis (KCL) and loop analysis (KVL) to formulate the set of equations. The equations produced solve for the branch voltages and branch currents. The method is able to accommodate voltage sources and all four types of dependent sources. It utilizes a much larger matrix than the nodal analysis methods; however, it is a very sparse matrix (lots of zero entries). The main drawback is that the behavior of the equations is highly dependent on the tree selected. A bad tree could easily result in an ill-conditioned set of equations. Some methods of tree selection can guarantee a well-conditioned set of hybrid equations [Nag75]. Therefore, special rules must be observed in the tree selection process that constitutes a large additional overhead on the analysis.
3. Sparse tableau analysis [Hac71] has been used in symbolic analysis to employ the parameter extraction method (this chapter). It uses the entire set of circuit variables: node voltages, branch voltages, and branch currents, for the symbolic formulation in addition to capacitor charges and inductor fluxes in the case of numeric simulations. This results in a huge set of equations and in turn a very large matrix but a very sparse one. This method uses all the above stated equation formulation methods: KCL, KVL and the BR. The entire system of equations is solved for all the circuit variables. The disadvantage of the method is its inherent problem of ill-conditioning [Nag75].

It has been found that the sparse tableau method only produces a very minor improvement in the number of mathematical operations, the nodal analysis methods despite its large overhead, stemming from a large matrix, and the large and rigid set of variables that have to be solved for. The MNA method gives the choice of what branch current variables to be solved for and equations are added accordingly. The tableau method would always have a fixed size matrix and produce unneeded information to the user.

For the purpose of symbolic analysis, as highlighted in this chapter, the entire analysis is performed in the frequency domain with the aid of the complex frequency variable s. The Laplace transform representation of the value of any circuit element is therefore used in the formulation. Also, since a modification of the nodal admittance matrix is used, the elements may be represented by either their admittance or impedance values.

2.2 Symbolic Modified Nodal Analysis

The initial step of MNA is to formulate the nodal admittance matrix **Y** [Chu75] from the circuit. The circuit variables considered here are all the node-to-datum voltages, referred to simply as node voltages; there are n_v of them. They are included in the variable vector **V**. So **V** has the dimensions of $(n_v \times 1)$. The vector **J**, also of dimensions $(n_v \times 1)$, represents the values of all independent current sources in the circuit. The ith entry of **J** is the sum of all independent current sources entering node i. The linear system of node equations can be represented in the following matrix form:

$$\mathbf{YV} = \mathbf{J} \tag{2.2}$$

Row i of **Y** represents the KCL equation at node i. The coefficient matrix, **Y**, called the node admittance matrix, is constructed by writing KCL equations at each node, except for the datum node. The ith

equation then would state that the sum of all currents leaving node *i* is equal to zero. The equations are then put into the matrix form of Equation 2.2. The following example illustrates the process.

Example 2.1

Consider the circuit in Figure 2.1.

Collecting the node voltages would produce the following **V**:

$$\mathbf{V} = \begin{bmatrix} v_1 \\ v_2 \\ v_3 \end{bmatrix} \tag{2.3}$$

Considering all the independent current sources in the circuit, the vector **J** becomes

$$\mathbf{J} = \begin{bmatrix} J_1 \\ J_4 \\ 0 \end{bmatrix} \tag{2.4}$$

Notice that the last entry of **J** is a zero because no independent current sources are connected to node 3.

Now, writing KCL equations at the three non-datum nodes produces

$$\begin{aligned} &G_2 v_1 + G_3(v_1 - v_2) + \frac{1}{sL_7}(v_1 - v_3) = J_1 \\ &G_5 v_2 + G_3(v_2 - v_1) + sC_6(v_2 - v_3) = J_4 \\ &sC_6(v_3 - v_2) + \frac{1}{sL_7}(v_3 - v_1) + g_8 V_{R_3} = 0 \end{aligned} \tag{2.5}$$

Substituting $V_{R_3} = v_1 - v_2$ in the third equation of the set Equation 2.5 and rearranging the variables results in

$$\begin{aligned} &\left(G_2 + G_3 + \frac{1}{sL_7}\right)v_1 - G_3 v_2 - \frac{1}{sL_7} v_3 = J_1 \\ &-G_3 v_1 + (G_3 + G_5 + sC_6)v_2 - sC_6 v_3 = J_4 \\ &\left(g_8 - \frac{1}{sL_7}\right)v_1 - (g_8 + sC_6)v_2 + \left(\frac{1}{sL_7} + sC_6\right) = 0 \end{aligned} \tag{2.6}$$

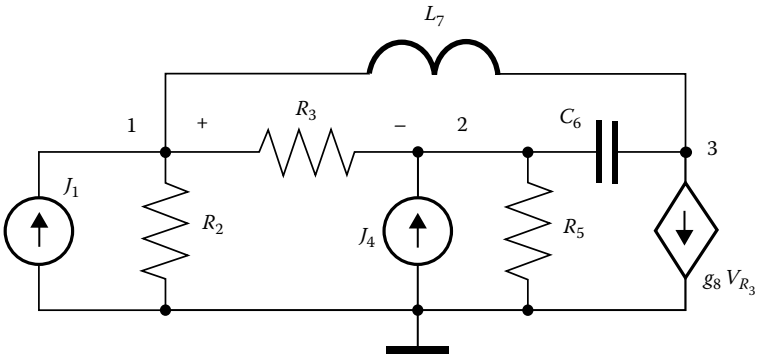

FIGURE 2.1 MNA example circuit.

Finally, rewriting Equation 2.6 in a matrix form of Equation 2.2 yields

$$\begin{bmatrix} G_2+G_3+\dfrac{1}{sL_7} & -G_3 & -\dfrac{1}{sL_7} \\ -G_3 & G_3+G_5+sC_6 & -sC_6 \\ g_8-\dfrac{1}{sL_7} & -(g_8+sC_6) & \dfrac{1}{sL_7}+sC_6 \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ v_3 \end{bmatrix} = \begin{bmatrix} J_1 \\ J_4 \\ 0 \end{bmatrix} \tag{2.7}$$

An automatic technique to construct the node admittance matrix is the element stamp method [Ho75]. The method consists of going through each circuit component and adding its contribution to the nodal admittance matrix in the appropriate positions. It is an easy way to illustrate the impact of each element on the matrix.* Resolving Example 2.1 using the element stamps would produce exactly the same **Y** matrix, **V** vector, and **J** vector as in Equation 2.7.

The MNA technique, introduced in [Ho75], expands on the above nodal analysis in order to readily include independent voltage sources and the three other types of controlled sources: VCVS, CCCS, and CCVS. This is done by introducing some branch currents as variables into the system of equations, which in turn allows for the introduction of any branch current as an extra system variable. Each extra current variable introduced would need an additional equation to solve for it. The extra equations are obtained from the BRs for the branches whose currents are the extra variables. The effect on the nodal admittance matrix is the deletion of any contribution in it due to the branches whose currents have been declared as variables. This matrix is referred to as $\mathbf{Y}_n$. The addition of new variables and a corresponding number of equations to the system results in the need to append extra rows and columns to $\mathbf{Y}_n$. The augmented $\mathbf{Y}_m$ matrix is referred to as the MNA matrix (MNAM). The new system of equations, in matrix form, is

$$\begin{bmatrix} \mathbf{Y}_n & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{bmatrix} \begin{bmatrix} \mathbf{V} \\ \mathbf{I} \end{bmatrix} = \begin{bmatrix} \mathbf{J} \\ \mathbf{E} \end{bmatrix} \tag{2.8}$$

where

I is a vector of size n_i whose elements are the extra branch current variables introduced
E contains the values of the independent voltage sources
C and **D** correspond to BR equations for the branches whose currents are in **I**

An important feature of the MNAM approach is its ability to include impedance elements in the formulation. Let Z_x be an impedance connected between nodes i and j. Introduce the current through Z_x as new variable i_x. The extra equation needed is provided by the corresponding BR: $v_i - v_j - Z_x i_x = 0$. The usefulness of this approach can be appreciated when one needs to handle short circuits ($R = 0$) or inductors at dc. It becomes indispensable in approximation techniques that require the circuit matrix to contain only entries of the type $a = \alpha + s\beta$.

According to [Ho75], the MNA current variables should include all branch currents of independent voltage sources, controlled voltage sources, and all controlling currents. Further modifications of this procedure, like RMNA formulations [Has89], compacted MNA (CMNA) formulations [Gie89], and supernode analysis [Som93] relax these constraints and result in fewer MNA equations.

Example 2.2

As an example of a MNAM formulation, consider the circuit of Figure 2.2. The extra current variables are the branch currents of the independent voltage source E_1 (branch 1), the CCVS (branch 5), and the

* Program STAINS has the animate option that allows viewing the animated process of matrix formulation.

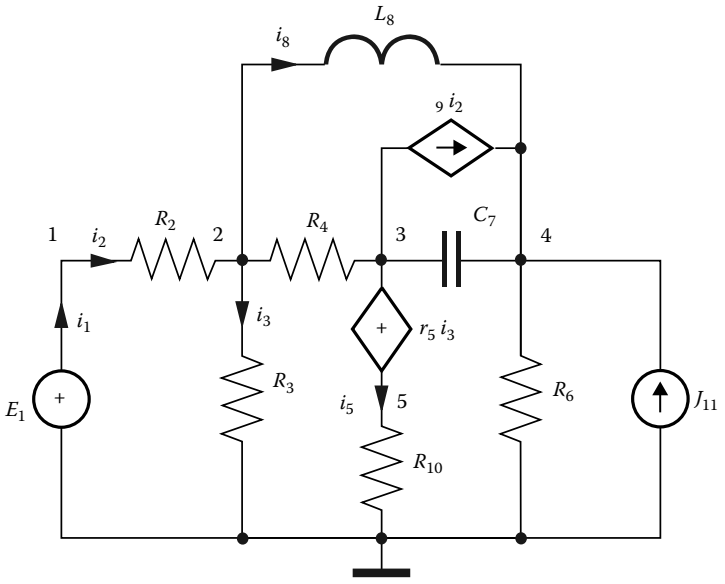

FIGURE 2.2 Circuit of Example 2.2.

inductor L_8 (branch 8). They are referred to as i_1, i_5, and i_8, respectively. The CCCS $\beta_9 i_2$ can be transformed to a VCCS by noticing that $i_2 = G_2(v_1 - v_2)$, so we have $\beta_9 i_2 = \beta_9 G_2(v_1 - v_2)$. Similarly, the CCVS $r_5 i_3$ becomes a VCVS $r_5 G_3 v_2$.

Using element stamps, the MNA system of equations becomes

$$\left[\begin{array}{ccccc|ccc}
G_2 & -G_2 & 0 & 0 & 0 & 1 & 0 & 0 \\
-G_2 & G_2+G_3+G_4 & 0 & 0 & 0 & 0 & 0 & 1 \\
\beta_9 G_2 & -G_4-\beta_9 G_2 & G_4+sC_7 & -sC_7 & 0 & 0 & 1 & 0 \\
-\beta_9 G_2 & \beta_9 G_2 & -sC_7 & G_6+sC_7 & 0 & 0 & 0 & -1 \\
0 & 0 & 0 & 0 & G_{10} & 0 & -1 & 0 \\
\hline
1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\

0 & 1 & 0 & -1 & 0 & 0 & 0 & -sL_8
\end{array}\right]
\left[\begin{array}{c} v_1 \\ v_2 \\ v_3 \\ v_4 \\ v_5 \\ \hline i_1 \\ i_5 \\ i_8 \end{array}\right]
=
\left[\begin{array}{c} 0 \\ 0 \\ 0 \\ J_{11} \\ 0 \\ \hline E_1 \\ 0 \\ 0 \end{array}\right]$$

The above system of linear algebraic equations can be written in the following matrix form:

$$\mathbf{Ax} = \mathbf{b} \tag{2.9}$$

where

A is a symbolic matrix of dimension $n \times n$
x is a vector of circuit variables of length n
b is a symbolic vector of constants of length n
n is the number of circuit variables: currents, voltages, charges, or fluxes

The analysis proceeds by solving Equation 2.9 for **x**.

2.3 Solution Methods

2.3.1 Determinant-Based Solutions

Here the basic idea is to apply an extension of Cramer's rule, symbolically, to find a transfer function from the coefficient matrix of Equation 2.9. According to Cramer's rule, the value of a variable x_i in Equation 2.9 is calculated from the following formula:

$$x_i = \frac{\left|\mathbf{A}^{(i)}\right|}{|\mathbf{A}|} \tag{2.10}$$

where $\mathbf{A}^{(i)}$ is obtained from matrix $\mathbf{A}$ by replacing column i with the vector $\mathbf{b}$ and $|\bullet|$ denotes the determinant. Any transfer function, which is a ratio of two circuit variables, can be found by application of Equation 2.10:

$$\frac{x_i}{x_j} = \frac{\left|\mathbf{A}^{(i)}\right|/|\mathbf{A}|}{\left|\mathbf{A}^{(j)}\right|/|\mathbf{A}|} = \frac{\left|\mathbf{A}^{(i)}\right|}{\left|\mathbf{A}^{(j)}\right|} \tag{2.11}$$

Several symbolic algorithms are based on the concept of using Cramer's rule and calculating the determinants of an MNAM. Most notably is the program ISSAC [Gie89], which uses a recursive determinant expansion algorithm to calculate the determinants of Equation 2.11. Although there are many other algorithms to calculate the determinant of a matrix, like elimination algorithms and nested minors algorithms [Gie91], recursive determinant expansion algorithms were found the most suitable for sparse linear matrices [Wan77]. These algorithms are cancellation-free given that all the matrix entries are different, which is a very desirable property in symbolic analysis.

Let $\mathbf{A}$ be a square matrix of order n. Delete row i and column j from $\mathbf{A}$ and denote the resulting matrix of order $n-1$ by $\mathbf{A}_{-i-j}$. Its determinant, $M_{ij} = |\mathbf{A}_{-i-j}|$, is called a *minor* of $\mathbf{A}$ of order $n-1$. The quantity $\Delta_{ij} = (-1)^{i+j} M_{ij}$ is called a *cofactor* of a matrix element a_{ij}. The determinant of $\mathbf{A}$ can be calculated by recursive application of the following formula:*

$$|\mathbf{A}| = \begin{cases} \sum_{j=1}^{n} a_{ij}\Delta_{ij} = \sum_{j=1}^{n} a_{ji}\Delta_{ji} & \text{for } n > 1 \\ a_{11} & \text{for } n = 1 \end{cases} \tag{2.12}$$

where i is an arbitrary row or column of matrix $\mathbf{A}$.

As an example, the determinant of a 3×3 matrix is calculated by this method as

$$\begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix} = (-1)^{1+1} a_{11} \begin{vmatrix} a_{22} & a_{23} \\ a_{32} & a_{33} \end{vmatrix} + (-1)^{1+2} a_{12} \begin{vmatrix} a_{21} & a_{23} \\ a_{31} & a_{33} \end{vmatrix} + (-1)^{1+3} a_{13} \begin{vmatrix} a_{21} & a_{22} \\ a_{31} & a_{32} \end{vmatrix}$$

$$= a_{11}a_{22}a_{33} - a_{11}a_{23}a_{32} - a_{12}a_{21}a_{33} + a_{12}a_{23}a_{31} + a_{13}a_{21}a_{32} - a_{13}a_{22}a_{31}$$

Here, i was chosen to be, arbitrarily, row 1. The expression is cancellation-free in this example because all the matrix entries are unique. Note that for matrices with duplicated entries, the algorithm is not cancellation-free.

* Single application of Equation 2.12 is known as the Laplace expansion of the determinant.

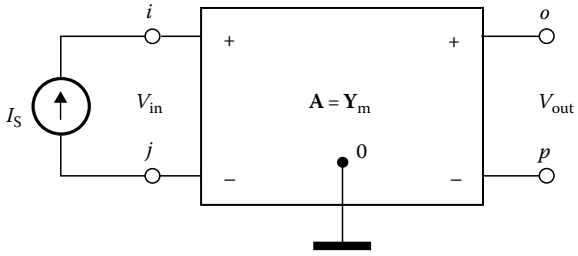

FIGURE 2.3 Two-port representation of a circuit.

Most symbolic analysis problems deal with two-port circuits of the form shown in Figure 2.3, where the signal source, I_S, is the only independent source in the circuit.

Let the two-port be described by the modified nodal equation of the form as in Equation 2.8. The right-hand side of this equation will have only two nonzero entries: $+I_S$ at position i and $-I_S$ at position j. Applying Cramer's rule to calculate potential at any node k, we get

$$v_k = \frac{I_S \Delta_{ik} - I_S \Delta_{jk}}{\Delta} \tag{2.13}$$

Now, if we wish, for example, to calculate the voltage transmittance of the two-port in Figure 2.3, using Equation 2.13, we obtain

$$T_v = \frac{v_o - v_p}{v_i - v_j} = \frac{\Delta_{io} - \Delta_{jo} - \Delta_{ip} + \Delta_{jp}}{\Delta_{ii} - \Delta_{ji} - \Delta_{ij} + \Delta_{jj}} \tag{2.14}$$

Equation 2.14 simplifies considerably if, as it is often the case, nodes j and p are identical with the reference node. We then have

$$T_v = \frac{v_o}{v_i} = \frac{\Delta_{io}}{\Delta_{ii}} \tag{2.15}$$

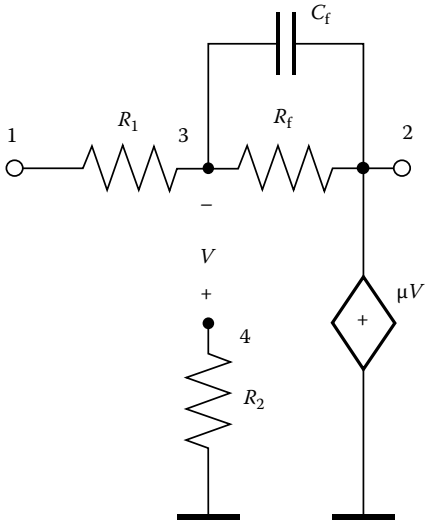

FIGURE 2.4 Circuit for Example 2.3.

Example 2.3

As an example, the voltage transfer function $T_v = v_2/v_1$ for the circuit in Figure 2.4 is to be calculated. The MNAM of this circuit is

$$\mathbf{Y}_m = \left[\begin{array}{cccc|c} G_1 & 0 & -G_1 & 0 & 0 \\ 0 & G_f + sC_f & -G_f - sC_f & 0 & 1 \\ -G_1 & -G_f - sC_f & G_1 + G_f + sC_f & 0 & 0 \\ 0 & 0 & 0 & G_2 & 0 \\ \hline 0 & 1 & \mu & -\mu & 0 \end{array}\right]$$

Using Equation 2.15 and expanding the cofactors according to Equation 2.12, we get

$$T_v = \frac{v_2}{v_1} = \frac{\Delta_{12}}{\Delta_{11}} = \frac{(-1)^{1+2}\begin{vmatrix} 0 & -G_f - sC_f & 0 & 1 \\ -G_1 & G_1 + G_f + sC_f & 0 & 0 \\ 0 & 0 & G_2 & 0 \\ 0 & \mu & -\mu & 0 \end{vmatrix}}{(-1)^{1+1}\begin{vmatrix} G_f + sC_f & -G_f - sC_f & 0 & 1 \\ -G_f - sC_f & G_1 + G_f + sC_f & 0 & 0 \\ 0 & 0 & G_2 & 0 \\ 1 & \mu & -\mu & 0 \end{vmatrix}}$$

$$= \frac{-G_1 G_2 \mu}{-G_2[\mu(-G_f - sC_f) - (G_1 + G_f + sC_f)]} = -\frac{G_1 \mu}{G_1 + G_f + sC_f + \mu(G_f + sC_f)}$$

Note that cancellation of a common term (G_2) in the numerator and denominator occurred. Although not present in the above example, cancellation of terms in each determinant expansion may occur in general if matrix entries are not unique.

2.3.2 Parameter Reduction Solutions

These methods use basic linear algebra techniques, applied symbolically, to find the solution to Equation 2.9. The goal here is to reduce the size of the system of equations by manipulating the entries of matrix **A** down to a 2×2 size. The two variables remaining in **x** are the ones for which the transfer function is to be calculated. The manipulation process, which in simple terms is solving for the two desired variables in terms of the others, is done using methods like Gaussian elimination [Nob77]. This methodology is used in the symbolic analysis programs SCAPP [Has89] and STAINS [Pie01]. Both programs use successive application of a modified Gaussian elimination process to produce the transfer function of the solution. The main difference between the techniques used in SCAPP and STAINS is in pivot selection strategy. While SCAPP selects pivots from the diagonal of **A**, STAINS employs a locally optimal pivot selection [Mar57,Gus70] that minimizes the number of arithmetic operations at each elimination step, thus producing more compact sequences of expressions. The process is applied to the MNAM and the result is a RMNAM ($\mathbf{Y}_R$). The process of reducing a circuit variable, whether a node voltage or a branch current, is referred to as variable suppression.

If the signal (input) source is the only independent source in the circuit, then the reduction process leads to the final RMNAM being identical with the well-known two-port admittance matrix. Its elements are known as the short-circuit admittance parameters or simply the *y*-parameters and have been used in circuit analysis from the 1940s. Since the two-port representation is the most commonly encountered in symbolic analysis problems, for the rest of this section we concern ourselves with terminated two-ports, depicted in Figure 2.5. The advantage of such a representation is the fact that once the *y*-parameters and the terminating admittances, Y_S and Y_L, are known, all other parameters of interest, like input/output impedances and various gains, can be readily calculated (e.g., [Gha65]). With no loss of generality we can assign numbers 1 and 2 to the input and output nodes, respectively. All other circuit variables are numbered from 3 to *n*. To focus our attention, we will only consider a (very typical) case when the input and output ports have a common terminal, which is the reference node.

The circuit of Figure 2.5 can be described by the set of symbolic equations of the form as in Equation 2.9, rewritten here more explicitly:

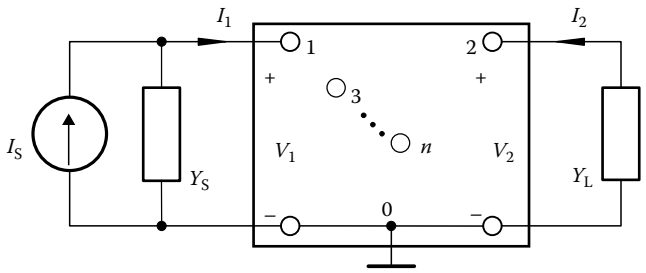

FIGURE 2.5 Terminated two-port for symbolic analysis.

$$\begin{bmatrix} a_{11} & a_{12} & a_{13} & \dots & a_{1n} \\ a_{21} & a_{22} & a_{23} & \dots & a_{2n} \\ a_{31} & a_{32} & a_{33} & \dots & a_{3n} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & a_{n3} & \dots & a_{nn} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ x_3 \\ \vdots \\ x_n \end{bmatrix} = \begin{bmatrix} I_1 \\ I_2 \\ 0 \\ \vdots \\ 0 \end{bmatrix} \tag{2.16}$$

The elements a_{ij} are symbolic entries of general form: $a = \alpha + s\beta$.

Since we are only interested in the relationship between the input and output variables (V_1, I_1 and V_2, I_2 in our case), all other variables can be suppressed. Suppose that we wish to suppress the variable x_p. To achieve this, we can use any equation from the set (Equation 2.16), except the first two equations that has a nonzero coefficient at x_p. Let us choose it to be equation $q > 2$. The qth equation can be written in the expanded form as follows:

$$a_{q1}V_1 + a_{q2}V_2 + \cdots + a_{qp}x_p + \cdots + a_{qn}x_n = 0 \tag{2.17}$$

Provided that $|a_{qp}| \neq 0$, we can calculate x_p from Equation 2.17 as

$$x_p = -\frac{a_{q1}}{a_{qp}}V_1 - \frac{a_{q2}}{a_{qp}}V_2 - \frac{a_{q3}}{a_{qp}}x_3 - \cdots - \frac{a_{qn}}{q_{qp}}x_n \tag{2.18}$$

Substituting Equation 2.18 into Equation 2.16 will eliminate the variable x_p and equation q from the set. During the elimination, each element a_{ij} of **A** undergoes the transformation:

$$a_{ij} \leftarrow a_{ij} - \frac{a_{qj}a_{ip}}{a_{qp}}; \quad i, j = 1, 2, \ldots, n; \quad i \neq q, \quad j \neq p \tag{2.19}$$

This process of suppression of a variable is the very well-known Gaussian elimination. The only difference from the usual appearance of the elimination formula (Equation 2.19) in the literature is the fact that the pivot, a_{qp}, may be off-diagonal ($p \neq q$). In practice, the transformation (Equation 2.19) is only applied to the matrix elements a_{ij} for which $|a_{qj}||a_{ip}| \neq 0$. When any of the updated elements of **A**

is initially zero, a new nonzero element, a fill-in, is created in **A**. The pivot is chosen as to minimize either the number of arithmetic operations* or the number of fill-ins created at each elimination step.

All internal variables are successively eliminated using identical procedure. At the end of this process, we are left with a set of two equations:

$$\begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} I_S - Y_S V_1 \\ -Y_L V_2 \end{bmatrix} \tag{2.20}$$

Note that the two entries in the right-hand side vector, I_1 and I_2, have not been updated during the elimination process, thus coefficients y_{ij} in Equation 2.20 are the short-circuit admittance parameters of the original two-port, described by Equation 2.16. Various gain and immittance relations (network functions) can be expressed in terms of the two-port parameters and the termination admittances [Gha65]. For example, the voltage transmittance, V_2/V_1, and the current transmittance, $-I_2/I_1$, can be calculated as

$$T_v = \frac{V_2}{V_1} = -\frac{y_{21}}{y_{22} + Y_L}, \quad T_i = \frac{-I_2}{I_1} = \frac{-y_{21} Y_L}{y_{11}(y_{22} + Y_L) - y_{12} y_{21}}$$

A simple example serves to illustrate and easily verify the formulation of the RMNAM and advantages of a proper pivoting strategy.

Example 2.4

Consider the circuit in Figure 2.6.

Using element stamps, the modified nodal equation of the circuit in Figure 2.4 can be written as

$$\begin{bmatrix} G_1 & 0 & -G_1 & 0 \\ 0 & G_4 + sC_3 & -sC_3 & 0 \\ -G_1 & -sC_3 & G_1 + sC_3 & 1 \\ -\mu & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ v_3 \\ i_4 \end{bmatrix} = \begin{bmatrix} I_1 \\ I_2 \\ 0 \\ 0 \end{bmatrix} \tag{2.21}$$

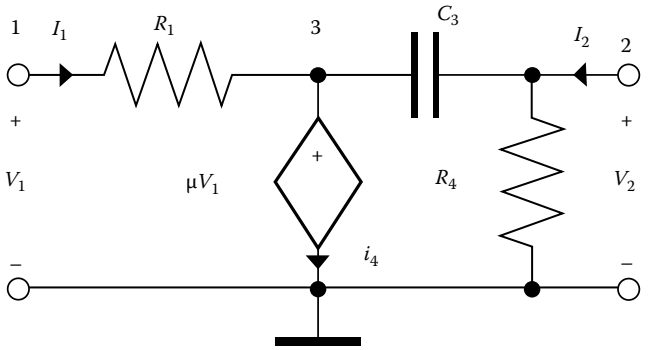

FIGURE 2.6 Circuit of Example 2.4.

* Minimization of the number of arithmetic operations is equivalent with minimization of the number of matrix updates via Equation 2.19. If the numbers of nonzero elements in the pivot row and column are n_q and n_p, respectively, then the number of updates required to suppress x_p using equation q is equal to $(n_q - 1)(n_p - 1)$.

To reduce the coefficient matrix in Equation 2.21 to the two-port admittance matrix, the variables v_3 and i_4 must be eliminated. If we select pivots from the main diagonal only, we have no choice but to first take the element $a_{33} = G_1 + sC_3$. Since row 3 and column 3 have four nonzero elements each, elimination of v_3 using the third equation requires $(4 - 1)(4 - 1) = 9$ updates. Moreover, six fill-ins will be created, making the matrix full. Four more updates are required to suppress the current variable, i_4, increasing the total number of updates to 13. On the other hand, if we are not restricted to diagonal pivots, the best choice for the first one is the element $a_{34} = 1$. Inspection of Equation 2.21 reveals that elimination of the fourth variable (i_4) using equation 3 requires no updates at all ($n_p - 1 = 0$). With no computational effort, we obtain

$$\begin{bmatrix} G_1 & 0 & -G_1 \\ 0 & G_4 + sC_3 & -sC_3 \\ -\mu & 0 & 1 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ v_3 \end{bmatrix} = \begin{bmatrix} I_1 \\ I_2 \\ 0 \end{bmatrix} \tag{2.22}$$

Now, using the element $a_{33} = 1$ of Equation 2.22 as a pivot, only two updates are required to suppress variable v_3. The final equation becomes

$$\begin{bmatrix} G_1 - \mu G_1 & 0 \\ -\mu sC_3 & G_4 + sC_3 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} I_1 \\ I_2 \end{bmatrix}$$

By unrestricted pivot selection, we have achieved the desired result with only 2 updates, compared to 13 updates if the pivot was chosen from the main diagonal only.

2.4 Ideal Operational Amplifiers

Neither the classical nodal analysis, nor the MNA in its original form [Ho75], accounts for ideal op-amps in their equation formulation. The way op-amps have usually been handled in those analyses is by modeling each op-amp by a VCVS with a large gain in an attempt to characterize the infinite gain of the ideal op-amp.

The ideal op-amp is a two-port device for which one of the output terminals is usually assumed to be grounded.* Op-amps are used extensively in the building of a large number of analog circuits, especially analog filters, where symbolic circuit simulators have found extensive applications in obtaining transfer functions for the filters. It is therefore necessary for a modern symbolic analysis program to handle ideal op-amps. Both SCAPP and STAINS include ideal op-amps in their lists of available circuit components.

There are two ways by which the ideal op-amps can be handled in an automatic formulation of circuit equation. The first method is simply an extension of the MNA, which accounts for op-amps by adding the constraining equations to the MNA set, introducing an element stamp for the op-amp [Vla94]. The other approach reduces the size of the MNA set by removing variables that are known to be identical (node voltages at both op-amp inputs) and by removing unnecessary equations (KCL equation at the op-amp output) [Has89,Lin91]. The latter method is known as compacting of the MNAM due to op-amps; the resulting matrix is termed compacted MNA matrix (CMNAM). Both approaches are presented below.

2.4.1 Nullator, Norator, and Nullor

Before the characterization of the ideal op-amp is attempted, the concepts of the nullator, the norator, and the nullor are explored [Bru80]. They are not real elements. These ideal components are tools to introduce some mathematical constraints into a circuit. They are used as an aid to the development of insight into the behavior of ideal devices like the ideal op-amp.

The symbol for the nullator is shown in Figure 2.7. A nullator is defined as follows:

* If neither of the output terminals of the op-amp are grounded, such op-amp is said to be floating [Vla94].

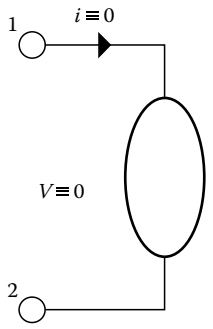

FIGURE 2.7 Nullator.

Definition 2.1: A nullator is a two-terminal element defined by the constraints

$$\begin{aligned} v_1 - v_2 &\equiv 0 \\ i &\equiv 0 \end{aligned} \tag{2.23}$$

The symbol for the norator is presented in Figure 2.8. A norator is defined as follows:

Definition 2.2: A norator is a two-terminal element for which the voltage and current are not constrained. That is,

$$\begin{aligned} v_1 - v_2 &= \text{arbirtary} \\ i &= \text{arbirtary} \end{aligned} \tag{2.24}$$

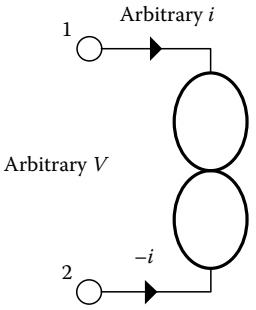

FIGURE 2.8 Norator.

A norator in a circuit introduces freedom from some constraints on the nodes it is connected to.

A circuit must contain an equal number of nullators and norators; in other words, a nullator and a norator must appear in a circuit as a pair. The combination of a nullator and a norator to produce a two-port, as shown in Figure 2.9, is referred to as a nullor. The equations characterizing the nullor are represented then by Equations 2.23 and 2.24.

In the MNA formulation, each nullator introduces additional equation: $v_i - v_j = 0$ into the set. The required extra variable is the corresponding norator's current. Nullor's contribution to the MNAM can be represented as its unique element stamp in similar way as it was done for VCVS, CCVS, etc. This is best illustrated in an example.

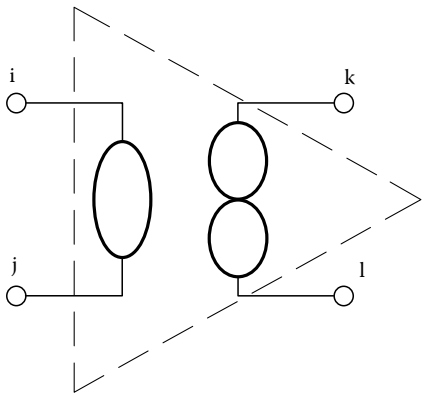

FIGURE 2.9 Nullor.

Example 2.5

Write the MNA equation for the circuit containing a nullor, as shown in Figure 2.10.

To formulate the MNAM, needed in the equation, we start with a 6×6 matrix and use element stamps to include the capacitor and the conductances in the usual manner. The nullator equation, $v_2 - v_5 = 0$, creates two entries in row 6. The norator current, our extra variable i_6, must be included in the KCL equations for the nodes 3 and 4, creating two entries in column 6. This results in the equation

$$\left[\begin{array}{ccccc|c} G_1 + sC_1 & -G_1 & 0 & 0 & -sC_1 & 0 \\ -G_1 & G_1 + G_2 & -G_2 & 0 & 0 & 0 \\ 0 & -G_2 & G_2 & 0 & 0 & 1 \\ 0 & 0 & 0 & G_3 & -G_3 & -1 \\ -sC_1 & 0 & 0 & -G_3 & G_3 + G_4 + sC_1 & 0 \\ \hline 0 & 1 & 0 & 0 & -1 & 0 \end{array}\right] \left[\begin{array}{c} v_1 \\ v_2 \\ v_3 \\ v_4 \\ v_5 \\ i_6 \end{array}\right] = \left[\begin{array}{c} I_S \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{array}\right] \tag{2.25}$$

The sixth row and the sixth column of the MNAM in Equation 2.25 represent the element stamp of the nullor.

2.4.2 Ideal Op-Amp Model

The two characteristics of an ideal op-amp are

1. Zero voltage differential and no current flowing between its input nodes (the virtual short-circuit)
2. Arbitrary current that the output node supplies (to satisfy the KCL at this node)

Both properties are perfectly modeled using a nullor (Figure 2.9), with terminal l grounded. Adding a nullor stamp to our repertoire of element stamps creates a natural extension of the MNA method.

There is, however, another way of looking at ideal op-amp's (nullor's) contribution to the set of nodal equations, describing a circuit. Consider first the input of an ideal op-amp. Due to property 1, potentials at both input nodes must be identical. So, one of the two variables (node potentials) can be eliminated without any loss of information about the circuit. With one less variable, we must also remove one equation, for the system to have a unique solution. Since the ideal op-amp will always supply the exact current required to satisfy the KCL at the output node, the KCL equation at this node is unnecessary and can be simply deleted from the set. This process results in a MNAM that is more compact than the matrix obtained with the use of ideal op-amp stamp. Thus, the resulting matrix is called the CMNAM.

The rules for formulating CMNAM for a circuit containing ideal op-amps are as follows:

1. Remove the ideal op-amps from the circuit.
2. Write the MNAM $\mathbf{Y}_m$ for this circuit; label all columns and rows of $\mathbf{Y}_m$ with numbers corresponding to variables.

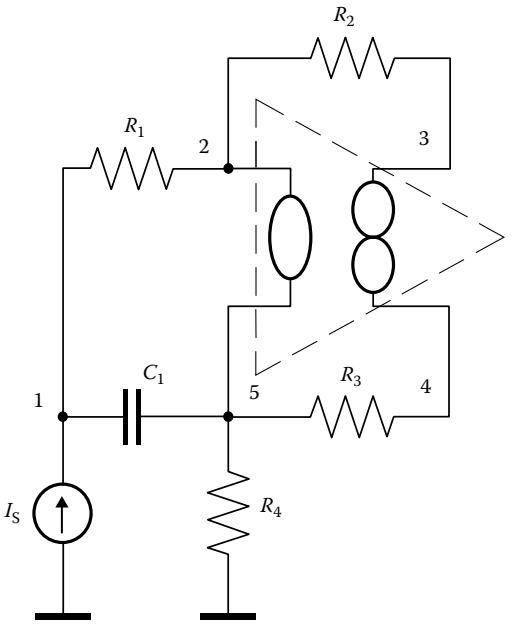

FIGURE 2.10 Circuit with nullor.

3. Repeat for every ideal op-amp in the circuit:
   a. For an ideal op-amp with the input terminals connected to nodes i $(-)$ and j $(+)$, add the column containing label j to the column containing label i and delete the former column; append all labels of the former column to the labels of the latter column. If one of the input nodes is the reference node, simply delete the column and the variable corresponding to the other node.
   b. For an ideal op-amp with the output terminal connected to node k, delete row with label k from the matrix.

Example 2.6

We wish to obtain the CMNAM of the gyrator circuit with two ideal op-amps, as shown in Figure 2.11. Following the compacting rules, we first formulate the NAM of the circuit with op-amps removed and label the rows and columns as shown below:

$$\mathbf{Y}_m = \begin{array}{c} \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \end{array} \begin{array}{c} \begin{array}{ccccc} 1 & 2 & 3 & 4 & 5 \end{array} \\ \begin{bmatrix} G_4 & 0 & 0 & 0 & -G_4 \\ 0 & G_1+G_2 & -G_2 & 0 & 0 \\ 0 & -G_2 & G_2+G_3 & -G_3 & 0 \\ 0 & 0 & -G_3 & G_3+sC_1 & -sC_1 \\ -G_4 & 0 & 0 & -sC_1 & G_4+sC_1 \end{bmatrix} \end{array}$$

Next, according to Rule 3a, for the first op-amp, we add the column containing label 1 to the column containing label 2, delete the former column, and append its labels to the labels of the latter column. Output of O_1 is connected to node 3. Rule 3b requires that we delete row with label 3. This results in the following matrix:

$$\mathbf{Y}_m = \begin{array}{c} \\ 1 \\ 2 \\ 4 \\ 5 \end{array} \begin{array}{c} \begin{array}{cccc} 2,1 & 3 & 4 & 5 \end{array} \\ \begin{bmatrix} G_4 & 0 & 0 & -G_4 \\ G_1+G_2 & -G_2 & 0 & 0 \\ 0 & -G_3 & G_3+sC_1 & -sC_1 \\ -G_4 & 0 & -sC_1 & G_4+sC_1 \end{bmatrix} \end{array}$$

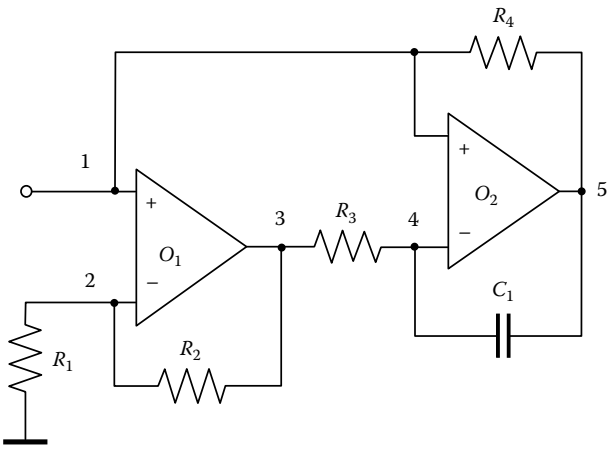

FIGURE 2.11 Gyrator circuit with two ideal op-amps for Example 2.6.

Applying Rule 3 to the op-amp O_2, we add column containing label 1 to the column containing label 4, delete the former column, and append its labels (2,1) to the labels of column 4. According to Rule 3b, we delete row with label 5. The resulting matrix is shown below:

$$\mathbf{Y}_{CM} = \begin{array}{c} \\ 1 \\ 2 \\ 4 \end{array} \begin{array}{c} \begin{array}{ccc} 3 & 4,2,1 & 5 \end{array} \\ \begin{bmatrix} 0 & G_4 & -G_4 \\ -G_2 & G_1+G_2 & 0 \\ -G_3 & G_3+sC_1 & -sC_1 \end{bmatrix} \end{array}$$

It is customary to rearrange the columns of the CMNAM in ascending order of their smallest labels. After exchanging columns 1 and 2, the final matrix becomes

$$\mathbf{Y}_{CM} = \begin{array}{c} \\ 1 \\ 2 \\ 4 \end{array} \begin{array}{c} \begin{array}{ccc} 4,2,1 & 3 & 5 \end{array} \\ \begin{bmatrix} G_4 & 0 & -G_4 \\ G_1+G_2 & -G_2 & 0 \\ G_3+sC_1 & -G_3 & -sC_1 \end{bmatrix} \end{array}$$

2.5 Applications of Symbolic Analysis

There are many specific applications for which symbolic analysis algorithms have been developed over the years. The following is an attempt to categorize the uses of symbolic analysis methods. For a given application, some overlap of these categories might exist. The goal here is to give a general idea of the applications of symbolic analysis methods. It must be noted that most of these applications cover both *s*-domain and *z*-domain analyses.

It is now widely accepted that in all applications where symbolic formula is generated in order to provide means for subsequent repetitive exact numerical calculation, use of sequential formulas is most effective. For the purpose of interpretation, that is, gaining deeper understanding of circuit behavior, only a single formula can be used. Approximate symbolic analysis emerges here as a very promising approach.

2.5.1 Frequency Response Evaluation

This is an obvious application of having the symbolic transfer function stated in terms of the circuit variable parameters. The process of finding the frequency response curve over a frequency range for a given circuit involves the repetitive evaluation of Equation 2.1 with all the parameters numerically specified and sweeping the frequency over the desired range. A numerical simulator would require a simulation run for each frequency point.

2.5.2 Circuit Response Optimization

This process involves the repetitive evaluation of the symbolic function generated by a symbolic simulator [Lin91,Gie94]. The response of the circuit is repetitively evaluated by substituting different values for the circuit parameters in the equation until a desired numerical response is achieved. The concept, of course, requires a good deal of management in order to reduce the search space and the number of evaluations needed. Such a method for filter design by optimization is discussed in [Tem77] and [Bas72], and a method for solving piecewise resistive linear circuits is discussed in [Chu75]. The idea here is that for a given circuit topology, only one run through the symbolic circuit simulator is necessary.

2.5.3 Sensitivity Analysis

Sensitivity analysis is the process of finding the effect of the circuit performance due to changes in an element value [Lin92,Bal98,Bal01]. There are two types of sensitivities of interest to circuit designers: small-change (or differential) sensitivity and large-change sensitivity. The normalized differential sensitivity of a transfer function H with respect to a parameter x is given as

$$S_x^H = \frac{\partial(\ln H)}{\partial(\ln x)} = \frac{\partial H}{\partial x}\frac{x}{H}$$

The above expression can be found symbolically and then evaluated for the different circuit parameter values. For the transfer function H in a single expression form, the differentiation process is quite straightforward. When H is given in a sequence of expressions form, the most compact formula is obtained by the application of the two-port transimpedance concept and an efficient method of symbolic calculations of the elements of the inverse of the reduced modified node admittance matrix [Bal98]. Similar approach is used to obtain the large-change sensitivity [Bal01], defined as

$$\delta_x^H = \frac{\Delta H}{H}\frac{x}{\Delta x}$$

Once the sequence of expressions for the network function has been generated, only a few additional expressions are needed to determine the sensitivity (both differential and large-change). Additional effort to calculate sensitivities is practically independent of circuit size, making this approach attractive for large-scale circuits.

2.5.4 Circuit Sizing

Circuit sizing refers to the process of computing values for the elements of a given circuit topology such that some set of behavioral circuit specifications is satisfied [Hen00]. This process can be supported by symbolic techniques in two ways. Computer algebra can help to solve a system of design equations symbolically for the circuit parameters in order to obtain a set of generic analytic sizing formulas, or to set up and preprocess a system of design equations for subsequent numerical solution.

2.5.5 Parameter Extraction in Device Modeling

This process involves the repeated comparison of measured data from fabricated devices with the simulation results using the mathematical models for these devices [Kon93,Avi98]. The goal of the process is to update the device models to reflect the measured data. The model parameters are incrementally adjusted and the evaluation process is repeated until the difference between the measured and the simulated results are minimized. Such approaches are reported in [Kon89] and [Kon93] (active devices) and [Avi98] (passive devices).

2.5.6 Statistical Analysis

A widely used statistical analysis method is through Monte Carlo simulations [Sty95]. The circuit behavior has to be repetitively evaluated many times in order to evaluate the statistical variation of a circuit output in response to parameter mismatches due to, for instance, integrated circuits process variations.

2.5.7 Fault Diagnosis of Analog Circuits

The process reported in [Man93] takes measurements from the faulty fabricated circuit and compares it to simulation results. The process is continuously repeated with the parameter values in the simulations

changed until the faulty element is detected. Symbolic techniques have also been applied to multiple fault detection [Fed98].

2.5.8 Insight into Circuit Operation

The insight that can be provided by obtaining the symbolic transfer function versus its numerical counterpart is very evident. The simple example in Section 2.5 illustrates this powerful application. The effect of the different elements on the behavior of the circuit can be observed by inspecting the symbolic expression. This, of course, is possible if the number of symbolic parameters is small, that is, the circuit is small. Insight, however, can also be obtained by observing an approximate symbolic expression that reduces the number of symbolic terms to a manageable figure. Several approximation techniques are reported in [Wam92], [Fer92], [Sed92], [Hsu94], [Yu96], and [Hen00].

2.5.9 Education

Symbolic analysis is most helpful for students as a supplement to linear circuit analysis courses. These courses require the derivation of expressions for circuit impedances, gains, and transfer functions. A symbolic simulator can serve as a check for the correctness of the results in addition to aiding instructors in verifying solutions and making up exercises and examples [Hue89].

Symbolic methods in conjunction with mathematical software are used in teaching analog electronics in addition to numerical simulators. This adds another dimension to standard analysis and design process, gives students greater flexibility, and encourages creativeness [Bal00].

2.6 Symbolic Analysis Software Packages

Several stand-alone symbolic simulators available for public use exist nowadays. A comparison of these software packages based on their functionality is given in Table 2.1. The list is by no means exhaustive; it should be treated just as a representative sample. The software packages that were compared are

Add-on packages (toolboxes) that run in symbolic mathematics software environments, like Mathematica, belong to another class of symbolic analysis programs. Analog Insydes [Hen00] is a good example of such an add-on. The toolbox includes approximation algorithms, netlist management, linear and nonlinear device and behavioral modeling, setting up and solving circuit equations, numerical circuit analysis in the frequency and time domains, two- and three-dimensional graphing of analysis results, and data exchange with other circuit simulators. Some routines in the toolbox were written in C to overcome Mathematica's limitations in efficiently handling large sparse systems.

3.1 Equation Formulation

The method by which circuit equations are formulated is essential to a computer-aided circuit analysis program. It affects significantly the setup time, the programming effort, the storage requirement, and the performance of the program.

A linear time-invariant circuit with n nodes and b branches is completely specified by its network topology and branch constraints. The fundamental equations that describe the equilibrium conditions of a circuit are the Kirchhoff's current law (KCL) equations, the Kirchhoff's voltage law (KVL) equations, and the equations which characterize the individual circuit elements. Two methods are popular: the sparse tableau approach and the modified nodal approach.

3.1.1 Implications of KCL, KVL, and the Element Branch Characteristics

Given an example with $n = 4$ and $b = 6$ (as shown in Figure 3.1) we can sum the branch currents leaving each node to zero and obtain

$$\begin{bmatrix} -1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & -1 & 1 & -1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 \\ 1 & -1 & 0 & -1 & 0 & -1 \end{bmatrix} \begin{bmatrix} i_{b_1} \\ i_{b_2} \\ i_{b_3} \\ i_{b_4} \\ i_{b_5} \\ i_{b_6} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

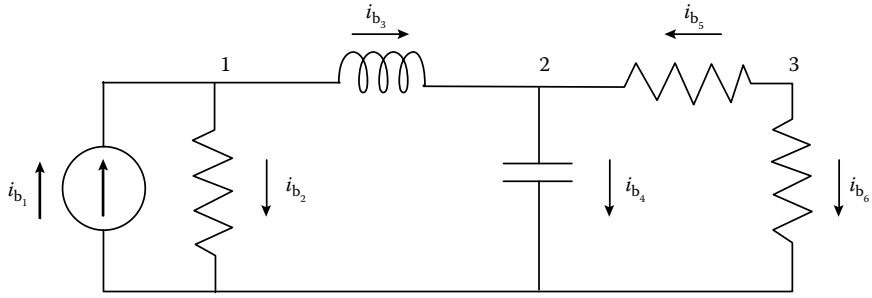

FIGURE 3.1 Network used to illustrate KCL, KVL, and the element branch characteristics.

or

$$A_a \times i_b = 0$$

where

A_a is an $n \times b$ incidence matrix contains $+1$, -1, and 0 entries
i_b is the branch current

Note that A_a is linearly dependent since the entries in each column add up to zero. A unique set of equations can be obtained by defining a datum node and eliminating its corresponding row of A_a. Hence, KCL results in $n-1$ equations and b unknowns. It implies

$$A \times i_b = 0 \tag{3.1}$$

where A is called the *reduced* incidence matrix.

KVL results in b equations with $b+n-1$ unknowns. It implies

$$v_b = A^T \times V_n \tag{3.2}$$

where

A^T is the transpose of the reduced incidence matrix
v_b is the branch voltage
V_n is the node-to-datum (nodal) voltage

Define the convention as follows (Figure 3.2):

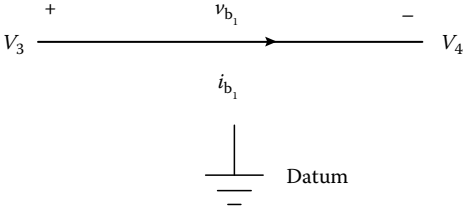

FIGURE 3.2 Reference convention for voltages and current.

One can sum the voltages around the loop using KVL (Figure 3.3):

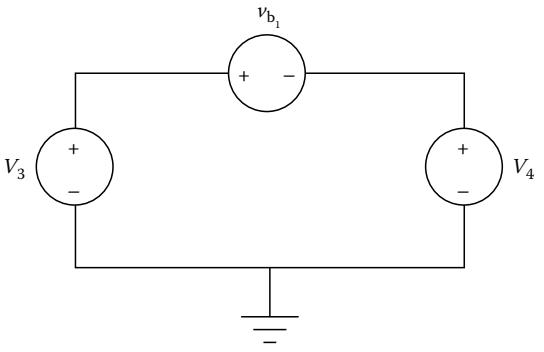

FIGURE 3.3 Voltage around the loop using KVL.

or

$$v_{b_1} = V_3 - V_4$$

Apply KVL to the example above and we obtain

$$\begin{bmatrix} v_{b_1} \\ v_{b_2} \\ v_{b_3} \\ v_{b_4} \\ v_{b_5} \\ v_{b_6} \end{bmatrix} = \begin{bmatrix} -1 & 0 & 0 \\ 1 & 0 & 0 \\ 1 & -1 & 0 \\ 0 & 1 & 0 \\ 0 & -1 & 1 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ V_3 \end{bmatrix}$$

or

$$v_b = A^T \times V_n$$

where v_b and V_n are unknowns.

The element characteristic results in generalized constraints equations in the form of

$$Y_b \cdot v_b + Z_b \cdot i_b = S_b \tag{3.3}$$

For example,
Resistor:

$$\frac{1}{R} v_b - i_b = 0$$

Voltage source:

$$v_b = E$$

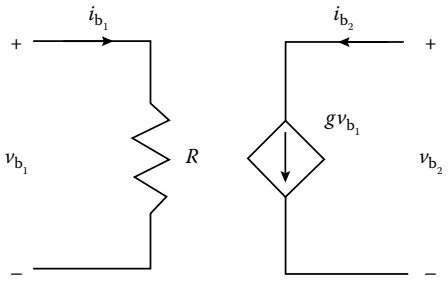

FIGURE 3.4 Voltage-controlled current source (VCCS).

VCCS (Figure 3.4):

$$\begin{bmatrix} 1/R & 0 \\ g & 0 \end{bmatrix} \begin{bmatrix} v_{b_1} \\ v_{b_2} \end{bmatrix} + \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} i_{b_1} \\ i_{b_2} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

3.1.2 Sparse Tableau Formulation

The sparse tableau method simply combines Equations 3.1 through 3.3. The equation and unknown count can be summarized as follows:

	Number of Equations	Number of Unknowns
(3.1)	$n-1$	b
(3.2)	b	$b+n-1$
(3.3)	b	0
Total	$2b+\mathrm{n}-1$	$2b+n-1$

The sparse tableau in the matrix form is shown next:

$$\begin{bmatrix} 0 & A & 0 \\ A^{\mathrm{T}} & 0 & -1 \\ 0 & Z_{\mathrm{b}} & Y_{\mathrm{b}} \end{bmatrix} \begin{bmatrix} V_{\mathrm{n}} \\ i_{\mathrm{b}} \\ v_{\mathrm{b}} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ S_{\mathrm{b}} \end{bmatrix} \tag{3.4}$$

Equation 3.4 is a system of linear equations.

Note that the matrix formulated by the sparse tableau approach is typically sparse with many zero value entries. The main advantage is its generality (i.e., all circuit unknowns including branch current/voltage and node-to-datum voltage can be obtained in one pass). Since the number of equations is usually very large, an efficient sparse linear system solver is essential.

3.1.3 Nodal Analysis

The number of equations in Equation 3.4 can be reduced significantly by manipulating Equations 3.1 through 3.3. Motivated by the fact that the number of branches in a circuit is generally larger than the number of nodes, nodal analysis attempts to reduce the number of unknowns to V_{n}. As we will see, this is achieved by a loss of generality (i.e., not all types of linear elements can be processed).

We can eliminate the branch voltages v_b by substituting Equation 3.2 into Equation 3.3. This yields

$$Y_b A^T V_n + Z_b i_b = S_b \tag{3.5}$$

$$A \times i_b = 0 \tag{3.6}$$

Combining Equations 3.5 and 3.6 to eliminate the branch currents, i_b, we obtain a set of equations with V_n as unknowns:

$$A \cdot Z_b^{-1} \cdot \left(-Y_b A^T V_n + S_b\right) = 0 \tag{3.7}$$

Since the Z_b matrix may be singular, not all elements can be processed. For example, a voltage-controlled voltage source, as shown in Figure 3.5, can be cast in the form of Equation 3.3:

$$\begin{bmatrix} 0 & 0 \\ u & -1 \end{bmatrix} \begin{bmatrix} v_{b_1} \\ v_{b_2} \end{bmatrix} + \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} i_{b_1} \\ i_{b_2} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

Note that Z_b is singular and it cannot be inverted. Consider a special case where Equation 3.3 can be expressed as

$$Y_b v_b - i_b = 0 \tag{3.8}$$

or $-Z_b$ is a unit matrix and $S_b = 0$. This condition is true if the circuit consists of

- Resistor
- Capacitor
- Inductor
- Voltage-controlled current source

For example, Figure 3.6 is a VCCS.

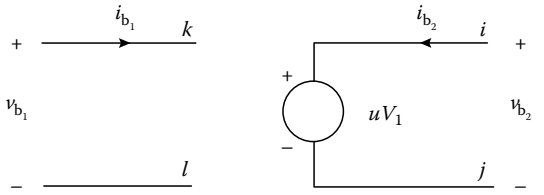

FIGURE 3.5 Voltage-controlled voltage source (VCVS).

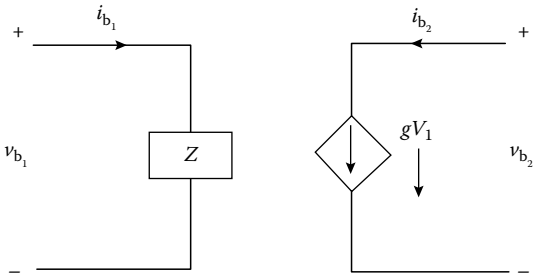

FIGURE 3.6 VCCS.

The branch constraints can be cast as

$$\begin{bmatrix} 1/z & 0 \\ g & 0 \end{bmatrix} \begin{bmatrix} v_{b_1} \\ v_{b_2} \end{bmatrix} + \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} i_{b_1} \\ i_{b_2} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

and $z = 1/j\omega C$ for the capacitor, $z = j\omega L$ for an inductor, and $z = R$ for a resistor. For this type of circuit, the nodal analysis results in $n-1$ equations with V_n as unknowns, or

$$A Y_b A^T \times V_n = 0$$

A circuit of this type contains no excitation (voltage/current source). The current sources can be included in the formulation by letting the corresponding edges of the current sources be numbered last. Hence, we can partition the reduced incidence matrix A into

$$A = [A_b | A_J] \tag{3.9}$$

where A_J corresponds to the subincidence matrix of the current source branches. Then, Equations 3.1, 3.2, and 3.8 can be expressed as

$$A_b i_b + A_J J = 0 \tag{3.10}$$

$$v_b = A_b^T V_n \tag{3.11}$$

$$i_b = Y_b v_b \tag{3.12}$$

Rearranging these equations yields

$$A_b Y_b A_b^T \times V_n = -A_J J \tag{3.13}$$

where J is a vector containing the current source values. Voltage sources can also be included in the formulation by simple source transformation which requires moderate preprocessing. The nodal analysis approach, therefore, can be applied to formulate equations for circuits consisting of

- Resistor
- Capacitor
- Inductor
- Voltage source (with preprocessing)
- Current source
- Voltage-controlled current source

Nodal analysis, however, when applied to an inductor, can cause numerical problems when the frequency is low:

$$\left(\frac{1}{j\omega L}\right)(v_{b_1}) + (-1)(i_{b_1}) = 0$$

or

$$\omega \to 0, \quad \frac{1}{j\omega L} \to \infty$$

To sum up, the nodal analysis must be extended to process the following linear elements (without proprocessing):

- Inductor
- Voltage source
- Current-controlled current source
- Current-controlled voltage source
- Voltage-controlled voltage source

3.1.4 Modified Nodal Analysis

A set of self-consistent modifications to the nodal analysis are proposed and the resultant formulation is called the modified nodal analysis (MNA). The MNA resolves the limitations of the nodal analysis method while preserving its advantages. In this section, we present the basic theory of MNA.

Divide all types of elements into three groups:
Group 1: Elements that satisfy

$$i_b = Y_b v_b$$

such as resistor, capacitor, and VCCS.
Group 2: Elements that satisfy

$$Y_b v_b + Z_b i_b = S_b$$

such as voltage source, inductor, VCVS, CCVS, and CCCS.
Group 3: Current source only.

Apply the partitioning technique to Group 1 and Group 2 elements. We can write

$$[A_1|A_2]\begin{bmatrix} i_1 \\ i_2 \end{bmatrix} = 0 \Rightarrow A_1 i_1 + A_2 i_2 = 0$$

$$\begin{bmatrix} v_1 \\ v_2 \end{bmatrix} = \begin{bmatrix} A_1^T \\ A_2^T \end{bmatrix} V_n \Rightarrow v_1 = A_1^T V_n, \quad v_2 = A_2^T V_n$$

$$i_1 = Y_1 v_1$$

$$Y_2 \cdot v_2 + Z_2 \cdot i_2 = S_2$$

Eliminating v_1, i_1, and v_2 from the preceding equations, we derive a system of linear equations with V_n and i_2 as unknowns:

$$A_1 Y_1 A_1^T V_n + A_2 i_2 = 0 \tag{3.14}$$

$$Y_2 A_2^T V_n + Z_2 i_2 = S_2 \tag{3.15}$$

Casting them in matrix form gives

$$\begin{bmatrix} A_1 Y_1 A_1^T & A_2 \\ Y_2 A_2^T & Z_2 \end{bmatrix}\begin{bmatrix} V_n \\ i_2 \end{bmatrix} = \begin{bmatrix} 0 \\ S_2 \end{bmatrix} \tag{3.16}$$

Finally, we apply the partitioning technique to include the current source (Group 3):

$$\begin{bmatrix} A_1 Y_1 A_1^{\mathrm{T}} & A_2 \\ Y_2 A_2^{\mathrm{T}} & Z_2 \end{bmatrix} \begin{bmatrix} V_{\mathrm{n}} \\ i_2 \end{bmatrix} = \begin{bmatrix} -A_J J \\ S_2 \end{bmatrix} \tag{3.17}$$

or

$$Y_{\mathrm{n}} \times x = J_{\mathrm{n}} \tag{3.18}$$

where

Y_{n} is the node admittance matrix
J_{n} is the source vector
x is the unknown vector

Implementing Equation 3.18 by matrix multiplication is difficult. Stamping methods have been developed to stamp in the entries of Y_{n}, J_{n} *element by element*. It is a very efficient way to implement Equation 3.18 into a network analysis program.

3.1.5 Nodal Formulation by Stamps

In this section, we developed the stamping rules for Group 1 and Group 3 elements only. Given a circuit consisting of Group 1 and Group 3 elements only:

We write the nodal equations at nodes 1, 2, and 3 (Figure 3.7):

$$-I + j\omega C(V_1 - V_3) + 1/R_1(V_1 - V_3) = 0 \qquad \text{(node 1)}$$

$$g(V_1 - V_3) + 1/R_2(V_2 - V_3) = 0 \qquad \text{(node 2)}$$

$$I + j\omega C(V_3 - V_1) + \frac{1}{R(V_3 - V_1)} - g(V_1 - V_3) + \frac{1}{R_2(V_3 - V_2)} = 0 \qquad \text{(node 3)}$$

Cast them in matrix form:

$$\begin{bmatrix} j\omega C + 1/R_1 & 0 & -j\omega C - 1/R_1 \\ g & 1/R_2 & -1/R_2 - g \\ -j\omega C - 1/R_1 - g & -1/R_2 & j\omega C + 1/R_1 + 1/R_2 + g \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ V_3 \end{bmatrix} = \begin{bmatrix} I \\ 0 \\ -I \end{bmatrix}$$

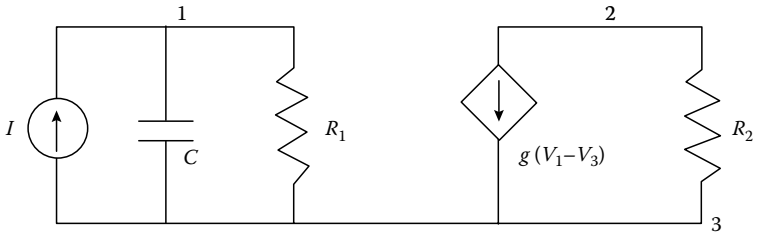

FIGURE 3.7 Network used to illustrate nodal formulation by stamps.

Note that for the left-hand side (LHS), we can write

$$\begin{bmatrix} 1/R_1 & 0 & -1/R_1 \\ 0 & 0 & 0 \\ -1/R_1 & 0 & 1/R_1 \end{bmatrix} + \begin{bmatrix} j\omega C & 0 & -j\omega C \\ 0 & 0 & 0 \\ -j\omega C & 0 & j\omega C \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 \\ g & 0 & -g \\ -g & 0 & g \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1/R_2 & -1/R_2 \\ 0 & -1/R_2 & 1/R_2 \end{bmatrix}$$

Therefore, the sampling rule for a resistor is

$$Y_n(i,i) = Y_n(i,i) + \frac{1}{R}$$

$$Y_n(j,j) = Y_n(j,j) + \frac{1}{R}$$

$$Y_n(i,j) = Y_n(i,j) - \frac{1}{R}$$

$$Y_n(j,i) = Y_n(j,i) - \frac{1}{R}$$

If node i is grounded, the corresponding row and column can be eliminated from the node admittance matrix. We then obtained only

$$Y_n(j,j) = Y_n(j,j) + \frac{1}{R}$$

Similar stamping rules can be derived for a capacitor and a VCCS. The stamping rule for a current source J, flowing from i to j is

$$J_n(i) = J_n(i) - J$$

$$J_n(j) = J_n(j) + J$$

3.1.6 Modified Nodal Formulation by Stamps

Given a circuit including Group 2 elements only:

Let us first define auxiliary branch current unknowns i_v, i_L, and i_β for each type of element in Group 2. From nodal analysis, we obtain the following nodal equations (Figure 3.8):

$$i_v + i_L = 0 \qquad \text{(node 1)}$$

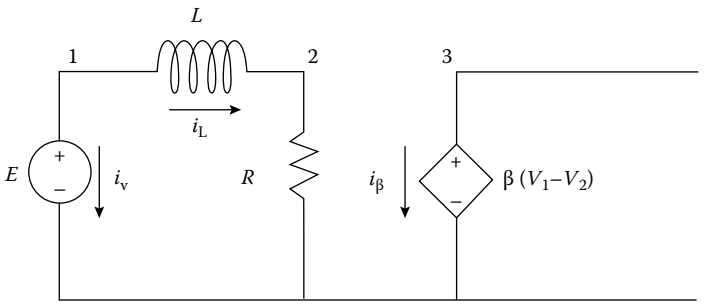

FIGURE 3.8 Network used to illustrate modified nodal formulation by stamps.

$$-i_{\mathrm{L}} + \frac{1}{R(V_2 - V_4)} = 0 \qquad \text{(node 2)}$$

$$i_{\beta} = 0 \qquad \text{(node 3)}$$

$$-i_{\mathrm{v}} + \frac{1}{R(V_4 - V_2)} - i_{\beta} = 0 \qquad \text{(node 4)}$$

For each auxiliary unknown, one auxiliary equation must be provided.

$$\begin{aligned} V_1 - V_4 &= E \\ V_1 - V_2 &= j\omega L i_{\mathrm{L}} \\ V_3 - V_4 &= \beta(V_1 - V_2) \end{aligned}$$

Cast these equations in matrix form:

$$\begin{bmatrix} 0 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1/R & 0 & -1/R & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & -1/R & 0 & 1/R & -1 & 0 & -1 \\ 1 & 0 & 0 & -1 & 0 & 0 & 0 \\ 1 & -1 & 0 & 0 & 0 & -j\omega L & 0 \\ -\beta & \beta & 1 & -1 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ V_3 \\ V_4 \\ i_{\mathrm{v}} \\ i_{\mathrm{L}} \\ i_{\beta} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ E \\ 0 \\ 0 \end{bmatrix}$$

Hence, the following stamping rules are derived:
Voltage source:
LHS:

$$\begin{array}{c} \\ i \\ j \\ i_{\mathrm{v}} \end{array} \begin{array}{c} \begin{array}{ccc} i & j & i_{\mathrm{v}} \end{array} \\ \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & -1 \\ 1 & -1 & 0 \end{bmatrix} \end{array}$$

Right-hand side (RHS):

$$\begin{array}{c} \\ i \\ j \\ i_{\mathrm{v}} \end{array} \begin{bmatrix} 0 \\ 0 \\ E \end{bmatrix}$$

Inductor:
LHS:

$$\begin{array}{c} \\ i \\ j \\ i_{\mathrm{L}} \end{array} \begin{array}{c} \begin{array}{ccc} i & j & i_{\mathrm{L}} \end{array} \\ \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 1 & -1 & -j\omega L \end{bmatrix} \end{array}$$

Note that the numerical problem associated with an inductor is avoided when $\omega \to 0$.

VCVS (Figure 3.5):
LHS:

$$\begin{array}{c} \\ i \\ j \\ i_v \end{array} \begin{array}{c} \begin{array}{ccccc} i & j & k & l & i_v \end{array} \\ \begin{bmatrix} 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & -1 \\ 1 & -1 & -\mu & \mu & 0 \end{bmatrix} \end{array}$$

The stamping rule for a CCVS and a CCCS can be developed following the same arguments. For DC analysis, set $\omega = 0$. In SPICE, the MNA is employed to formulate network equations. To probe a branch current, a user needs to insert a zero value voltage source between the adjacent nodes. The solution i_v is then the branch current. The implementation of MNA can be summarized as follows:

1. Implement an input parser to read in a circuit description file. A ''free'' input format does not restrict a user to follow column entry rules.
2. Build an internal node table which has a one-to-one relationship with user-defined nodes. Hence, a user needs not number the network nodes consecutively.
3. Number the auxiliary nodes for Group 2 elements last. For Group 2 element, one extra node is needed.
4. Solve the system of linear equations to find output voltages and currents.

3.2 Solution of Linear Algebraic Equations

The methods of solving a set of linear equations are basic to all computer-aided network analysis problems. If the network is linear, the equations are linear. Nonlinear networks lead to a system of nonlinear equations which can be linearized about some operating point. Transient analysis involves solving these linearized equations at many iteration points. Frequency domain analysis (small-signal AC analysis) requires the repeated solution of linear equations at specified frequencies.

The discussion in this section will be an introduction to the direct solution method based on *LU* decomposition, a variant of Gaussian elimination. This method is frequently used because of its efficiency, robustness, and ease of implementation. More advanced topics such as the general sparse matrix techniques are not discussed.

Consider a set of n linear algebraic equations of the form:

$$Ax = b \tag{3.19}$$

where
A is an $n \times n$ nonsingular real matrix
x and b are n-vectors

For the system to have a unique solution, A must be nonsingular (i.e., the determinant of A must not be zero). Equation 3.19 can be solved efficiently by first factorizing A into a product of two matrices L and U, which are respectively lower and upper triangular. This so-called *LU* decomposition method for solving a system of linear equations is similar to the Gaussian elimination except b is not required in advance. All operations performed on b using the Gaussian elimination are eliminated to save computation cost. The procedures are expressed as follows:

1. Step 1: Factorization/decomposition
2. Step 2: Forward substitution
3. Step 3: Backward substitution

3.2.1 Factorization

We factor A into a product LU, where L is a lower triangular matrix and U is an upper triangular matrix:

$$A = LU \tag{3.20}$$

Either L or U can have a diagonal of ones. The factors of A, being upper and lower triangular, can be stored in one matrix B, i.e., $B = L + U - I$. In practice, B is stored in place of A to save memory storage. There are two widely used algorithms for factorization: Crout's algorithm (setting the diagonal elements of U to 1) [1] and Doolittle's algorithm (setting the diagonal elements of L to 1) [3]. In the following, we will use a 4×4 matrix to illustrate the direct finding of L and U by the Crout's algorithm:

$$\begin{bmatrix} l_{11} & 0 & 0 & 0 \\ l_{21} & l_{22} & 0 & 0 \\ l_{31} & l_{32} & l_{33} & 0 \\ l_{41} & l_{42} & l_{43} & l_{44} \end{bmatrix} \begin{bmatrix} 1 & u_{12} & u_{13} & u_{14} \\ 0 & 1 & u_{23} & u_{24} \\ 0 & 0 & 1 & u_{34} \\ 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} \\ a_{21} & a_{22} & a_{23} & a_{24} \\ a_{31} & a_{32} & a_{33} & a_{34} \\ a_{41} & a_{42} & a_{43} & a_{44} \end{bmatrix}$$

Multiplying the two matrices on the LHS of the preceding equations gives

$$\begin{bmatrix} l_{11} & l_{11}u_{12} & l_{11}u_{13} & l_{11}u_{14} \\ l_{21} & l_{21}u_{12} + l_{22} & l_{21}u_{13} + l_{22}u_{23} & l_{21}u_{14} + l_{22}u_{24} \\ l_{31} & l_{31}u_{12} + l_{32} & l_{31}u_{13} + l_{32}u_{23} + l_{33} & l_{31}u_{14} + l_{32}u_{24} + l_{33}u_{34} \\ l_{41} & l_{41}u_{12} + l_{42} & l_{41}u_{13} + l_{42}u_{23} + l_{43} & l_{41}u_{14} + l_{42}u_{24} + l_{43}u_{34} + l_{44} \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} \\ a_{21} & a_{22} & a_{23} & a_{24} \\ a_{31} & a_{32} & a_{33} & a_{34} \\ a_{41} & a_{42} & a_{43} & a_{44} \end{bmatrix}$$

The solution sequences, indicated by the superscripts, for solving the 16 unknowns ($n = 4$) are

$$\begin{matrix} l_{11}^{1} & u_{12}^{5} & u_{13}^{6} & u_{14}^{7} \\ l_{21}^{2} & l_{22}^{8} & u_{23}^{11} & u_{24}^{12} \\ l_{31}^{3} & l_{32}^{9} & l_{33}^{13} & u_{34}^{15} \\ l_{41}^{4} & l_{42}^{10} & l_{43}^{14} & l_{44}^{16} \end{matrix}$$

or

1st column: $l_{11} = a_{11}$, $l_{21} = a_{21}$, $l_{31} = a_{31}$, $l_{41} = a_{41}$
1st row: $u_{12} = \frac{a_{12}}{l_{11}}$, $u_{13} = \frac{a_{13}}{l_{11}}$, $u_{14} = \frac{a_{14}}{l_{11}}$

2nd column: $l_{22} = a_{22} - l_{21}u_{12}$, $l_{32} = a_{32} - l_{31}u_{12}$, $l_{42} = a_{42} - l_{41}u_{12}$
2nd row: $u_{23} = \frac{a_{23} - l_{21}u_{13}}{l_{22}}$, $u_{24} = \frac{a_{24} - l_{21}u_{14}}{l_{22}}$

3rd column: $l_{33} = a_{33} - l_{13}u_{13} - l_{32}u_{23}$, $l_{43} = a_{43} - l_{41}u_{13} - l_{42}u_{13}$
3rd row: $u_{34} = \frac{a_{34} - l_{31}u_{14} - l_{32}u_{24}}{l_{33}}$

4th column: $l_{44} = a_{44} - l_{41}u_{14} - l_{42}u_{24} - l_{43}u_{34}$

Note that l_{11}, l_{22}, and l_{33} are elements by which we divide and they are called *pivots*. Division by a zero pivot is not allowed. We now derive the Crout's algorithm for LU decomposition based on the solution procedures described previously:

1. $l_{ji} = a_{ji}$, $j = 1, 2, \ldots, n$ (1st column)
2. $u_{1j} = a_{1j}/l_{11}$, $j = 2, \ldots, n$ (1st row)
3. At the kth step, for column k,

$$l_{jk} = a_{jk} - l_{j1}u_{1k} - l_{j2}u_{2k} - \cdots = a_{jk} - \sum_{m=1}^{k-1} l_{jm}u_{mk}, \quad j = k, \ldots, n$$

4. At the kth step, for row k,

$$u_{kj} = \left(\frac{1}{l_{kk}}\right)(a_{kj} - l_{k1}u_{1j} - l_{k2}u_{2j} - \cdots) = \left(\frac{1}{l_{kk}}\right)\left(a_{kj} - \sum_{m=1}^{k-1} l_{km}u_{mj}\right), \quad j = k+1, \ldots, n$$

The algorithm can be summarized in a compact form:

1. Set $k = 1$
2. $l_{jk} = a_{jk} - \sum_{m=1}^{k-1} l_{jm}u_{mk}, \quad j = k, \ldots, n$
3. If $k = n$, stop
4. $u_{kj} = \left(\frac{1}{l_{kk}}\right)\left(a_{kj} - \sum_{m=1}^{k-1} l_{km}u_{mj}\right), \quad j = k+1, \ldots, n$
5. $k = k+1$, go to step 2

3.2.2 Forward Substitution

Once A has been factored into L and U, the system of equations is written as follows:

$$LUx = b$$

Define an auxiliary vector y, which can be solved by

$$L \cdot y = b \tag{3.21}$$

Due to the special form of L, the auxiliary vector γ can be solved very simply:

$$\begin{bmatrix} l_{11} & 0 & 0 & 0 \\ l_{21} & l_{22} & 0 & 0 \\ l_{31} & l_{32} & l_{33} & 0 \\ l_{41} & l_{42} & l_{43} & l_{44} \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \end{bmatrix}$$

Starting from the first equation we write the solution as follows:

$$\begin{aligned} y_1 &= \frac{b_1}{l_{11}} \\ y_2 &= \frac{(b_2 - l_{21}y_1)}{l_{22}} \\ y_3 &= \frac{(b_3 - l_{31}y_1 - l_{32}y_2)}{l_{33}} \\ y_4 &= \frac{(b_4 - l_{41}y_1 - l_{42}y_2 - l_{43}y_3)}{l_{44}} \end{aligned}$$

and, in general

$$y_i = \frac{\left(b_i = \sum_{j=1}^{i-1} l_{ij}y_i\right)}{l_{ii}}, \quad i = 1, \ldots, n$$

This is called the *forward substitution* process.

3.2.3 Backward Substitution

Once y has been solved, we can proceed to solve for the unknown x by

$$Ux = y \tag{3.22}$$

Again, due to the special form of U, the unknown vector x can be solved very simply:

$$\begin{bmatrix} 1 & u_{12} & u_{13} & u_{14} \\ 0 & 1 & u_{23} & u_{24} \\ 0 & 0 & 1 & u_{34} \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} = \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix}$$

Starting from the first equation, we write the solution as follows:

$$\begin{aligned} x_4 &= y_4 \\ x_3 &= y_3 - u_{34}x_4 \\ x_2 &= y_2 - u_{23}x_3 - u_{24}x_4 \\ x_1 &= y_1 - u_{12}x_2 - u_{13}x_3 - u_{14}x_4 \end{aligned}$$

and, in general,

$$x_i = y_i - \sum_{j=i+1}^{n} u_{ij}x_j, \quad i = n, n-1, \ldots, 1$$

This is called the *backward substitution* process.

3.2.4 Pivoting

If in the process of factorization the pivot (l_{kk}) is zero, it is then necessary to interchange rows and possibly columns to put a nonzero entry in the pivot position so that the factorization can proceed. This is known as *pivoting*.

If $a_{ll} = 0$

1. Need to find another row i which has $a_{il} \neq 0$. This can always be done. Otherwise, all entries of column 1 are zero and hence, det $|A| = 0$. The solution process should then be aborted.
2. Interchange row i and row 1. Note that this must be done for both A and b.

If $l_{kk} = 0$

1. Find another row $r (r = k+1, \ldots, n)$, which has

$$l_{rk} = a_{rk} - \sum_{m=1}^{k-1} l_{rm}u_{mk} \neq 0$$

2. Interchange row r and row k in A and b.

Pivoting is also carried out for numerical stability (i.e., minimize round-off error). For example, one would search for the entry with the maximum absolute value of l_{rR} in columns below the diagonal and perform row interchange to put that element on the diagonal. This is called partial pivoting. Complete

pivoting involves searching for the element with the maximum absolute value in the unfactorized part of the matrix and moving that particular element to the diagonal position by performing both row and column interchanges. Complete pivoting is more complicated to program than partial pivoting. Partial pivoting is used more often.

3.2.5 Computation Cost of *LU* Factorization

In this section, we derive the multiplication/division count for the *LU* decomposition process. As a variation, we derive the computation cost for the Doolittle's algorithm (setting the diagonal elements of L to 1):

$$\begin{bmatrix} 1 & 0 & 0 & 0 \\ l_{21} & 1 & 0 & 0 \\ l_{31} & l_{32} & 1 & 0 \\ l_{41} & l_{42} & l_{43} & 1 \end{bmatrix} \begin{bmatrix} u_{11} & u_{12} & u_{13} & u_{14} \\ 0 & u_{22} & u_{23} & u_{24} \\ 0 & 0 & u_{33} & u_{34} \\ 0 & 0 & 0 & u_{44} \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} \\ a_{21} & a_{22} & a_{23} & a_{24} \\ a_{31} & a_{32} & a_{33} & a_{34} \\ a_{41} & a_{42} & a_{43} & a_{44} \end{bmatrix}$$

LHS after multiplication:

$$\begin{bmatrix} u_{11} & u_{12} & u_{13} & u_{14} \\ l_{21}u_{11} & l_{21}u_{12} + u_{22} & l_{21}u_{13} + u_{23} & l_{21}u_{14} + u_{24} \\ l_{31}u_{11} & l_{31}u_{12} + l_{32}u_{22} & l_{31}u_{13} + l_{32}u_{23} + u_{33} & l_{31}u_{14} + l_{32}u_{24} + u_{34} \\ l_{41}u_{11} & l_{41}u_{12} + l_{42}u_{22} & l_{41}u_{13} + l_{42}u_{23} + l_{43}u_{33} & l_{41}u_{14} + l_{42}u_{24} + l_{43}u_{34} + u_{44} \end{bmatrix}$$

$$\begin{aligned} &\text{Column 1: } (l_{21}, l_{31}, l_{41})u_{11} \\ &\text{Column 2: } (l_{21}, l_{31}, l_{41})u_{12} + (l_{32}, l_{42})u_{22} \\ &\text{Column 3: } (l_{21}, l_{31}, l_{41})u_{13} + (l_{32}, l_{42})u_{23} + l_{43}u_{33} \\ &\text{Column 4: } (l_{21}, l_{31}, l_{41})u_{14} + (l_{32}, l_{42})u_{24} + l_{43}u_{34} \end{aligned} \tag{3.23}$$

Let the symbol $\langle \cdot \rangle$ denote the number of nonzero elements of a matrix or vector. Or

- $\langle U \rangle$: number of nonzeros of U
- $\langle L \rangle$: number of nonzeros of L
- $\langle A_{i\cdot} \rangle$: number of nonzeros in row i of matrix A
- $\langle A_{\cdot j} \rangle$: number of nonzeros in column j of matrix A

From Equation 3.23, the total number of nonzero multiplications and divisions for *LU* factorization is given by

$$(\langle L_{\cdot 1} \rangle - 1)(\langle U_{1\cdot} \rangle) + (\langle L_{\cdot 2} \rangle - 1)(\langle U_{2\cdot} \rangle) + (\langle L_{\cdot 3} \rangle - 1)(\langle U_{3\cdot} \rangle) \tag{3.24}$$

Let α be the total number of multiplications and divisions. Express Equation 3.24 as a summation:

$$\alpha = \sum_{k=1}^{n} (\langle L_{\cdot k} \rangle - 1)(\langle U_{k\cdot} \rangle) \tag{3.25}$$

or for $n = 4$,

$$\alpha = 3 \times 4 + 2 \times 3 + 1 \times 2$$

If L and U are full, Equation 3.25 can be simplified as follows:

$$\begin{aligned}\alpha &= \sum_{k=1}^{n}(n-k)(n-k+1)\\ &= \sum_{k=1}^{n}(n^2+k^2-2kn+n-k)\\ &= n_3 + \sum_{k=1}^{n}k^2 - 2n \times \frac{n(n+1)}{2} + n^2 - \frac{n(n+1)}{2}\\ &= \frac{n(n+1)(2n+1)}{6} - \frac{n(n+1)}{2}\\ &= \frac{n^3-n}{3}\end{aligned} \tag{3.26}$$

The total number of mul/div for forward substitution is equal to the total number of nonzeros for L or $\langle L\rangle$. The total number of mul/div for backward substitution is equal to the total number of nonzeros for U for $\langle U\rangle$. Let β be the mul/div count for the forward and backward substitutions,

$$\beta = \langle L\rangle + \langle U\rangle$$

It follows that

$$\beta = n^2 \tag{3.27}$$

If L and U are full, combining Equations 3.26 and 3.27, we obtain the computation cost of solving a system of linear algebraic equations using direct LU decomposition:

$$\begin{aligned}\text{Total} &= \alpha + \beta\\ \text{Total} &= \alpha + \beta = \frac{n^3}{3} + n^2 - \frac{n}{3}\end{aligned} \tag{3.28}$$

4.1 Introduction

In many integrated circuit (IC) design situations, a designer must make complex trade-offs between conflicting behavioral requirements, dealing with functions that are often nonlinear. The number of parameters involved in the design process may be large, necessitating the use of algorithms that provide qualitatively good solutions in a computationally efficient manner.

The theory and utilization of optimization algorithms in computer-aided design (CAD) of ICs are illustrated here. The form of a general nonlinear optimization problem is first presented, and some of the commonly used methods for optimization are overviewed. It is frequently said that setting up an optimization problem is an art, while (arguably) solving it is an exact science. To provide a flavor for both of these aspects, case studies on the following specific design problems are examined:

- *Transistor sizing*: The delay of a digital circuit can be tuned by adjusting the sizes of transistors within it. By increasing the sizes of a few selected transistors from the minimum size, significant improvements in performance are achievable. However, one must take care to ensure that the area overhead incurred in increasing these sizes is not excessive. The area-delay trade-off here is the transistor size optimization problem. We address the solution of this problem under deterministic and statistical delay models.
- *Analog design centering*: The values of design parameters of an analog circuit are liable to change due to manufacturing variations. This contributes to a deviation in the behavior of the circuit from the norm, and may lead to dysfunctional circuits that violate the performance parameters that they

were designed for. The problem of design centering attempts to ensure that under these variations, the probability of a circuit satisfying its performance specifications is maximized by placing the circuit in the center of its feasible region.

4.2 Optimization Algorithms

4.2.1 Nonlinear Optimization Problems

The standard form of a constrained nonlinear optimization problem is

$$\begin{array}{ll} \text{minimize} & f(\mathbf{x}): \mathbf{R}^n \rightarrow \mathbf{R} \\ \text{subject to} & \mathrm{g}(\mathbf{x}) \leq \mathbf{0} \\ & \mathrm{g}: \mathbf{R}^n \rightarrow \mathbf{R}^m,\ \mathbf{x} \in \mathbf{R}^n \end{array} \tag{4.1}$$

representing the minimization of a function f of n variables under constraints specified by inequalities determined by functions $\mathbf{g} = [g_1 \cdots g_m]^{\mathrm{T}}$. f and g_i are, in general, nonlinear functions, so that the linear programming problem is a special case of the above. The parameters $\mathbf{x}$ may, for example, represent circuit parameters, and $f(\mathbf{x})$ and $g_i(\mathbf{x})$ may correspond to circuit performance functions. Note that "$\geq$" inequalities can be handled under this paradigm by multiplying each side by -1, and equalities by representing them as a pair of inequalities. The maximization of an objective function function $f(\mathbf{x})$ can be achieved by minimizing $-f(\mathbf{x})$.

The set $\mathcal{F} = \{\mathbf{x} \mid \mathbf{g}(\mathbf{x}) \leq 0\}$ that satisfies the constraints on the nonlinear optimization problem is known as the feasible set, or the feasible region. If $\mathcal{F}$ is empty (nonempty), then the optimization is said to be unconstrained (constrained).

Several mathematical programming techniques can be used to solve the optimization problem above; some of these are outlined here. For further details, the reader is referred to a standard text on optimization, such as [1]. Another excellent source for optimization techniques and their applications to IC design is a survey paper by Brayton et al. [2].

The above formulation may not directly be applicable to real-life design problems, where, often, multiple conflicting objectives must be optimized. In such a case, one frequently uses techniques that map on the problem to the form in Equation 4.1 (see Section 4.2.4).

4.2.2 Basic Definitions

In any discussion on optimization, it is virtually essential to understand the idea of a convex function and a convex set, since these have special properties, and it is desirable to formulate problems as convex programming problems, wherever it is possible to do so without an undue loss in modeling accuracy. (Unfortunately, it is not always possible to do so!)

Definition 4.1: A set C in $\mathbf{R}^n$ is said to be a convex set if, for every $\mathbf{x}_1, \mathbf{x}_2 \in C$, and every real number α, $0 \leq \alpha \leq 1$, the point $\alpha\mathbf{x}_1 + (1-\alpha)\mathbf{x}_2 \in C$.

This definition can be interpreted geometrically as stating that a set is convex if, given two points in the set, every point on the line segment joining the two points is also a member of the set. Examples of convex and nonconvex sets are shown in Figure 4.1.

Two examples of convex sets that are referred to later are the following geometric bodies:

1. An ellipsoid $E(\mathbf{x}, \mathcal{B}, r)$ centered at point $\mathbf{x}$ is given by the following equation:

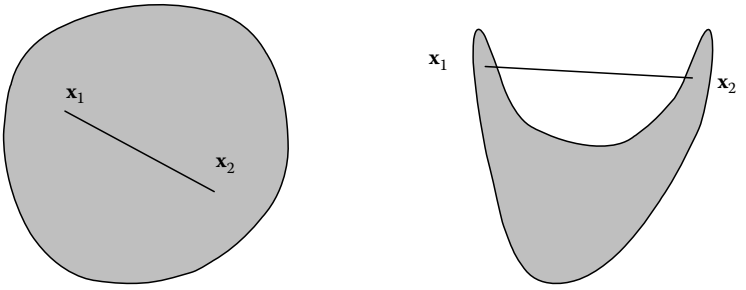

FIGURE 4.1 Convex sets.

$$\{\mathbf{y}|(\mathbf{y}-\mathbf{x})^{\mathrm{T}}\mathcal{B}(\mathbf{y}-\mathbf{x}) \leq r^2\}. \tag{4.2}$$

If $\mathcal{B}$ is a scalar multiple of the unit matrix, then the ellipsoid is called a hypersphere.

2. A (convex) polytope is defined as an intersection of half-spaces, and is given by the following equation:

$$\mathcal{P} \;=\; \{\mathbf{x}|A\mathbf{x} \geq \mathbf{b}\}, A \in \mathbf{R}^{m\times n}, \mathbf{b} \in \mathbf{R}^m, \tag{4.3}$$

corresponding to a set of m inequalities $\mathbf{a}_i^{\mathrm{T}}\,\mathbf{x} \geq b_i$, $\mathbf{a}_i \in \mathbf{R}^n$.

Definition 4.2: The convex hull of m points, $\mathbf{x}_1, \ldots, \mathbf{x}_m \in \mathbf{R}^n$, denoted co $\{\mathbf{x}_1, \ldots, \mathbf{x}_m\}$, is defined as the set of points $\mathbf{y} \in \mathbf{R}^n$ such that

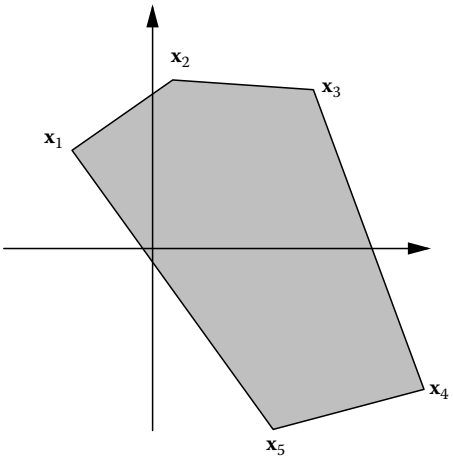

FIGURE 4.2 Convex hull of five points.

$$\mathbf{y} = \sum_{i=1}^{m} \alpha_i \mathbf{x}_i; \quad \alpha_i \geq 0 \;\forall\; i, \quad \sum_{i=0}^{m} \alpha_i = 1. \tag{4.4}$$

The convex hull is the smallest convex set that contains the m points. An example of the convex hull of five points in the plane is shown by the shaded region in Figure 4.2. If the set of points $\mathbf{x}_i$ is of finite cardinality (i.e., m is finite), then the convex hull is a polytope. Hence, a polytope is also often described as the convex hull of its vertices.

Definition 4.3: A function f defined on a convex set Ω is said to be a convex function if, for every $\mathbf{x}_1, \mathbf{x}_2 \in \Omega$, and every α, $0 \leq \alpha \leq 1$,

$$f[\alpha\mathbf{x}_1 + (1-\alpha)\mathbf{x}_2] \leq \alpha f(\mathbf{x}_1) + (1-\alpha) f(\mathbf{x}_2). \tag{4.5}$$

f is said to be strictly convex if the inequality in Equation 4.5 is strict for $0 < \alpha < 1$.

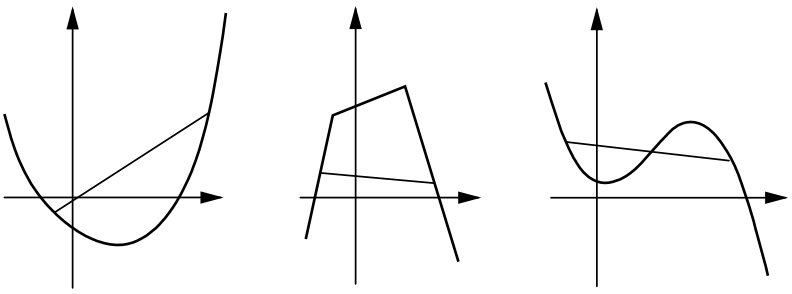

FIGURE 4.3 Convex functions.

Geometrically, a function is convex if the line joining two points on its graph is always above the graph. Examples of convex and nonconvex functions on $\mathbf{R}^n$ are shown in Figure 4.3.

Definition 4.4: A function g defined on a convex set Ω is said to be a concave function if the function $f = -g$ is convex. The function g is strictly concave if $-g$ is strictly convex.

Definition 4.5: The convex programming problem is stated as follows:

$$\text{minimize} \quad f(\mathbf{x}) \tag{4.6}$$

$$\text{such that} \quad \mathbf{x} \in S \tag{4.7}$$

where f is a convex function and S is a convex set. This problem has the property that any local minimum of f over S is a global minimum. An excellent reference on convex programming is [3].

Definition 4.6: A posynomial is a function h of a positive variable $\mathbf{x} \in \mathbf{R}^n$ that has the form

$$h(\mathbf{x}) = \sum_j \gamma_j \prod_{i=1}^{n} x_i^{\alpha_{ij}} \tag{4.8}$$

where the exponents $\alpha_{ij} \in \mathbf{R}$ and the coefficients $\gamma_j > 0$.

For example, the function $3.7x_1^{1.4}x_2^{\sqrt{3}} + 1.8x_1^{-1}x_3^{2.3}$ is a posynomial in the variables x_1, x_2, and x_3. Roughly speaking, a posynomial is a function that is similar to a polynomial, except that the coeffcients γ_j must be positive, and an exponent α_{ij} could be any real number, and not necessarily a positive integer, unlike a polynomial. A posynomial has the useful property that it can be mapped onto a convex function through an elementary variable transformation, $(x_i) = (e^{z_i})$. Such functional forms are useful since in the case of an optimization problem where the objective function and the constraints are posynomial, the problem can easily be mapped onto a convex programming problem.

The family of posynomials is expanded to the superset of generalized posynomials in Ref. [4], and these functions can also be mapped to convex functions under the above transform.

4.2.3 Constrained Optimization Methods

Most problems in IC design involve the minimization or maximization of a cost function subject to certain constraints. In this section, a few prominent techniques for constrained optimization are presented. The reader is referred to [1] for details on unconstrained optimization.

4.2.3.1 Linear Programming

Linear programming is a special case of nonlinear optimization, and is the convex programming problem where the objective and constraints are all linear functions. The problem is stated as

$$\begin{aligned} \text{minimize} \quad & \mathbf{c}^{\mathrm{T}}\,\mathbf{x} \\ \text{subject to} \quad & A\mathbf{x} \leq \mathbf{b} \\ \text{where} \quad & \mathbf{c}, \mathbf{x} \in \mathbf{R}^n,\ \mathbf{b} \in \mathbf{R}^m,\ A \in \mathbf{R}^{m \times n} \end{aligned} \tag{4.9}$$

It can be shown that any solution to a linear program must necessarily occur at a vertex of the constraining polytope. The most commonly used technique for solution of linear programs, the simplex method [1], is based on this principle. The computational complexity of this method can show an exponential behavior for pathological cases, but for most practical problems, it has been observed to grow linearly with the number of variables and sublinearly with the number of constraints. Algorithms with polynomial time worst-case complexity do exist; these include Karmarkar's method and the Shor–Khachiyan ellipsoidal method. The computational complexity of the latter, however, is often seen to be impractical from a practical standpoint.

Some examples of CAD problems that are posed as linear programs include placement, gate sizing, clock skew optimization, layout compaction, etc. In several cases, the structure of the problem can be exploited to arrive at graph-based solutions, for example, in layout compaction.

4.2.3.2 Lagrange Multiplier Methods

These methods are closely related to the first-order Kuhn–Tucker necessary conditions on optimality, which state that given an optimization problem of the form in Equation 4.1, if f and $\mathbf{g}$ are differentiable at $\mathbf{x}^\star$, then there is a vector $\boldsymbol{\lambda} \in \mathbf{R}^m$, $(\boldsymbol{\lambda})_i \geq 0$, such that

$$\nabla f(\mathbf{x}^\star) + \boldsymbol{\lambda}^{\mathrm{T}} \nabla \mathbf{g}(\mathbf{x}^\star) = 0 \tag{4.10}$$

$$\boldsymbol{\lambda}^{\mathrm{T}} \mathbf{g}(\mathbf{x}^\star) = 0 \tag{4.11}$$

These correspond to $m+1$ equations in $m+1$ variables; the solution to these provides the solution to the optimization problem. The variables $\boldsymbol{\lambda}$ are known as the Lagrange multipliers.

Note that since $g_i(\mathbf{x}^\star) \leq 0$, and because of the nonnegativity constraint on the Lagrange multipliers, $\boldsymbol{\lambda}$, it follows from Equation 4.11 that $(\boldsymbol{\lambda})_i = 0$ for inactive constraints (constraints with $g_i(\mathbf{x}) < 0$).

4.2.3.3 Penalty Function Methods

These methods convert the constrained optimization problem in Equation 4.1 into an equivalent unconstrained optimization problem, since such problems are easier to solve than constrained problems, as

$$\text{minimize } h(\mathbf{x}) = f(\mathbf{x}) + c \cdot P(\mathbf{x}) \tag{4.12}$$

where

$P(\mathbf{x})$: $\mathbf{R}^n \rightarrow \mathbf{R}$ is known as a penalty function

c is a constant

The value of $P(\mathbf{x})$ is zero within the feasible region, and positive outside the region, with the value becoming larger as one moves farther from the feasible region; one possible choice when the $g_i(\mathbf{x})$'s are continuous is given by

$$P(\mathbf{x}) = \sum_{i=1}^{m} \max(0, -g_i(\mathbf{x})) \tag{4.13}$$

For large c, it is clear that the minimum point of Equation 4.12 will be in a region where P is small. Thus, as c is increased, it is expected that the corresponding solution point will approach the feasible region and minimize f. As $c \to \infty$, the solution of the penalty function method converges to a solution of the constrained optimization problem.

In practice, if one were to begin with a high value of c, one may not have very good convergence properties. The value of c is increased in each iteration until c is high and the solution converges.

4.2.3.4 Method of Feasible Directions

The method of feasible directions is an optimization algorithm that improves the objective function without violating the constraints. Given a point $\mathbf{x}$, a direction $\mathbf{d}$ is feasible if there is a step size $\bar{\alpha} > 0$ such that $\mathbf{x} + \alpha \cdot \mathbf{d} \in \mathcal{F} \ \forall \ 0 \leq \alpha \leq \bar{\alpha}$, where $\mathcal{F}$ is the feasible region. More informally, this means that one can take a step of size up to $\bar{\alpha}$ along the direction $\mathbf{d}$ without leaving the feasible region. The method of feasible direction attempts to choose a value of α in a feasible direction $\mathbf{d}$ such that the objective function f is minimized along the direction, and α is such that $\mathbf{x} + \alpha \cdot \mathbf{d}$ is feasible.

One common technique that uses the method of feasible directions is as follows. A feasible direction at $\mathbf{x}$ is found by solving the following linear program:

$$\begin{aligned} &\text{minimize} && \varepsilon \\ &\text{subject to} && \langle \nabla f(\mathbf{x}) \cdot \mathbf{d} \rangle \leq \varepsilon && (4.14) \\ & && \langle \nabla g_i(\mathbf{x}) \cdot \mathbf{d} \rangle \leq \varepsilon && (4.15) \\ &\text{and} && \text{normalization requirements on } \mathbf{d} \end{aligned}$$

where the second set of constraints are chosen for all $g_i \geq -b$, where b serves to incorporate the effects of near-active constraints to avoid the phenomenon of jamming (also known as zigzagging) [1]. The value of b is brought closer to 0 as the optimization progresses. One common method that is used as a normalization requirement is to set $\mathbf{d}^{\mathrm{T}}\mathbf{d} = 1$. This constraint is nonlinear and nonconvex, and is not added to the linear program as an additional constraint; rather, it is exercised by normalizing the direction $\mathbf{d}$ after the linear program has been solved. An appropriate step size in this direction is then chosen by solving a one-dimensional optimization problem.

Feasible direction methods are popular in finding engineering solutions because the value of $\mathbf{x}$ at each iteration is feasible, and the algorithm can be stopped at any time without waiting for the algorithm to converge, and the best solution found so far can be used.

4.2.3.5 Vaidya's Convex Programming Algorithm

As mentioned earlier, if the objective function and all constraints in Equation 4.1 are convex, the problem is a convex programming problem, and any local minimum is a global minimum. The first large-scale practical implementation of this algorithm is described in Ref. [5].

Initially, a polytope $\mathcal{P} \in \mathbf{R}^n$ that contains the optimal solution, $\mathbf{x}_{\text{opt}}$, is chosen. The objective of the algorithm is to start with a large polytope, and in each iteration, to shrink its volume while keeping the optimal solution, $\mathbf{x}_{\text{opt}}$, within the polytope, until the polytope becomes sufficiently small. The polytope $\mathcal{P}$ may, for example, be initially selected to be an n-dimensional box described by the set

$$\{\mathbf{x} | x_{\min} \leq x_i \leq x_{\max}\} \tag{4.16}$$

where $x_{\min}$ and $x_{\max}$ are the minimum and maximum values of each variable, respectively. The algorithm proceeds iteratively as follows:

Step 1. A center $\mathbf{x}_c$ deep in the interior of the polytope $\mathcal{P}$ is found.

Step 2. An oracle is invoked to determine whether the center $\mathbf{x}_c$ lies within the feasible region $\mathcal{F}$. This may be done by verifying that all of the constraints of the optimization problem are met at $\mathbf{x}_c$.

If the point $\mathbf{x}_c$ lies outside $\mathcal{F}$, it is possible to find a separating hyperplane passing through $\mathbf{x}_c$ that divides $\mathcal{P}$ into two parts, such that $\mathcal{F}$ lies entirely in the part satisfying the constraint

$$\mathbf{c}^T\mathbf{x} \geq \beta \tag{4.17}$$

where $\mathbf{c} = -[\nabla_{g_p}(\mathbf{x})]^T$ is the negative of the gradient of a violated constraint, g_p, and $\beta = \mathbf{c}^T\mathbf{x}_c$. The separating hyperplane above corresponds to the tangent plane to the violated constraint.

If the point $\mathbf{x}_c$ lies within the feasible region $\mathcal{F}$, then there exists a hyperplane (Equation 4.17) that divides the polytope into two parts such that $\mathbf{x}_{opt}$ is contained in one of them, with

$$\mathbf{c} = -[\nabla f(\mathbf{x})]^T \tag{4.18}$$

being the negative of the gradient of the objective function, and β being defined as $\beta = \mathbf{c}^T\mathbf{x}_c$ once again.

Step 3. In either case, Equation 4.17 is added to the current polytope to give a new polytope that has roughly half the original volume.

Step 4. Go to Step 1; the process is repeated until the polytope is sufficiently small.

Example 4.1

The algorithm is illustrated by using it to solve the following problem:

$$\text{minimize } f(x_1, x_2) \text{ such that } (x_1, x_2) \in S \tag{4.19}$$

where S is a convex set and f is a convex function. The shaded region in Figure 4.4a is the set S, and the dotted lines show the level curves of f. The point $\mathbf{x}_{opt}$ is the solution to this problem.

1. The expected solution region is bounded by a rectangle, as shown in Figure 4.4a.
2. The center, $\mathbf{x}_c$, of this rectangle is found.
3. The oracle is invoked to determine whether or not $\mathbf{x}_c$ lies within the feasible region. In this case, it can be seen that $\mathbf{x}_c$ lies outside the feasible region. Hence, the gradient of the constraint function is used to construct a hyperplane through $\mathbf{x}_c$, such that the polytope is divided into two parts of roughly equal volume, one of which contains the solution $\mathbf{x}_{opt}$. This is illustrated in Figure 4.4b, where the shaded region corresponds to the updated polytope.
4. The process is repeated on the new smaller polytope. Its center lies inside the feasible region; hence, the gradient of the objective function is used to generate a hyperplane that further shrinks the size of the polytope, as shown in Figure 4.4c.
5. The result of another iteration is illustrated in Figure 4.4d. The process continues until the polytope has been shrunk sufficiently.

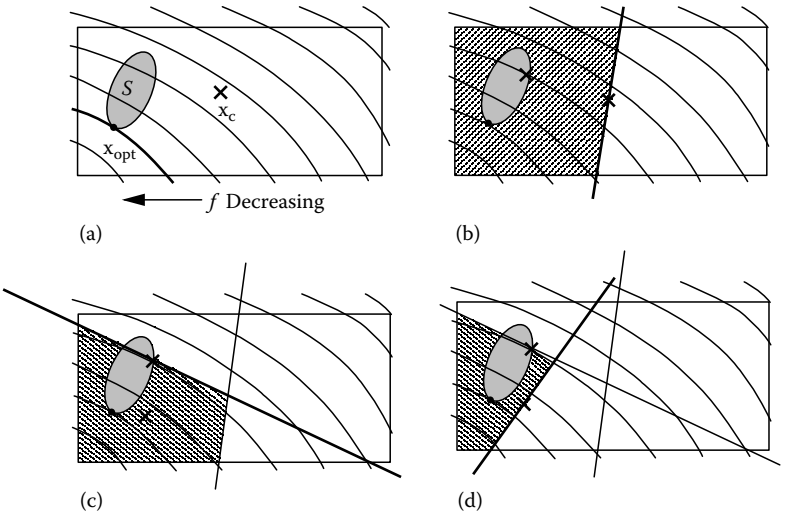

FIGURE 4.4 Example illustrating the convex programming algorithm. (From Sapatnekar, S. S., Rao, V. B., Vaidya, P. M., and Kang, S. M., *IEEE Trans. Comput. Aided Des.*, 12, 1621, 1993. With permission.)

4.2.3.6 Other Methods

The compact nature of this book makes it infeasible to enumerate or describe all of the methods that are used for nonlinear optimization. Several other methods, such as Newton's and modified Newton/quasi-Newton methods, conjugate gradient methods, etc., are often useful in engineering optimization. For these and more, the reader is referred to a standard text on optimization, such as [1].

4.2.4 Multicriterion Optimization and Pareto Criticality

Most IC design problems involve trade-offs between multiple objectives. In cases where one objective can be singled out as the most important one and a reasonable constraint set can be defined in terms of the other objectives, the optimization problem can be stated using the formulation in Equation 4.1. This is convenient since techniques for the solution of a problem in this form have been extensively studied, and a wide variety of optimization algorithms are available.

Let $\mathbf{f}$ be a vector of design objectives that is a function of the design variables $\mathbf{x}$, where

$$\mathbf{f}(\mathbf{x}):\ \mathbf{R}^n \rightarrow \mathbf{R}^m = (f_1(\mathbf{x}), f_2(\mathbf{x}), \ldots, f_m(\mathbf{x})) \tag{4.20}$$

It is extremely unlikely in a real application that all of the f_i's will be optimal at the same point, and hence one must trade off the values of the f_i's in a search for the best design point.

In this context, we note that at a point $\mathbf{x}$, we are interested in taking a step δ in a direction $\mathbf{d}$, $\|\mathbf{d}\| = 1$, so that

$$f_i(\mathbf{x} + \delta \cdot \mathbf{d}) \leq f_i(\mathbf{x}) \ \forall\ 1 \leq i \leq m \tag{4.21}$$

A Pareto critical point is defined as a point $\mathbf{x}$ where no such small step of size less than δ exists in any direction. If a point is Pareto critical for any step size from the point $\mathbf{x}$, then $\mathbf{x}$ is a Pareto point. The notion of a Pareto critical point is, therefore, similar to that of a local minimum, and that of a Pareto point to a global minimum. In computational optimization, one is concerned with the problem of finding a local minimum since, except in special cases, it is the best that one can be guaranteed of finding without

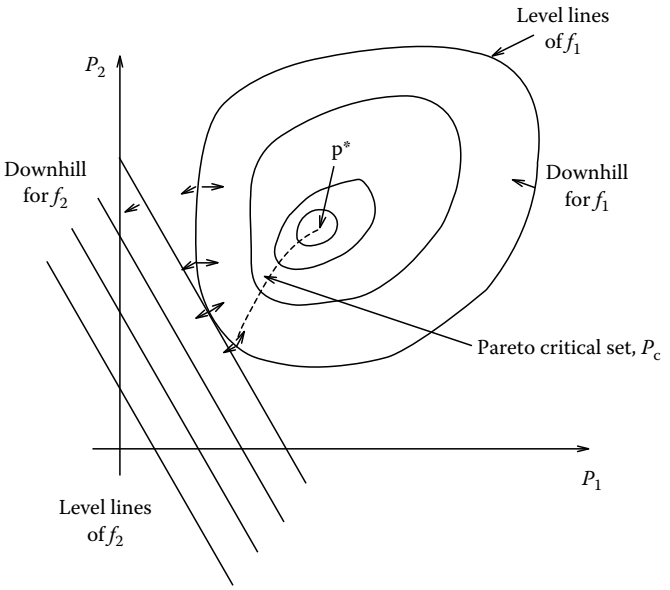

FIGURE 4.5 Exact conflict at a Pareto critical point. (From Brayton, R.K., Hachtel, G.D., and Sangiovanni-Vincentelli, A.L., *Proc. IEEE*, 69, 1334, 1981. With permission.)

an exhaustive search. If the set of all Pareto critical points is P_c, and the set of Pareto points is P, then clearly $P \subset P_c$. In general, there could be an infinite number of Pareto points, but the best circuit design must necessarily occur at a Pareto point $\mathbf{x} \in P$.

In Figure 4.5, the level curves of two objective functions are plotted in $\mathbf{R}^2$. f_1 is nonlinear and has a minimum at $\mathbf{x}^*$. f_2 is linear and decreases as both x_1 and x_2 decrease. The Pareto critical set, P_c, is given by the dashed curve. At few of the points, the unit normal to the level lines of f_1 and f_2, i.e., the negative gradients of f_1 and f_2, is shown. From the figure, it can be seen that if the unit normals at point $\mathbf{x}$ are not equal and opposite, then the unit normals will have a common downhill direction allowing a simultaneous decrease in f_1 and f_2, and hence, $\mathbf{x}$ would not be a Pareto critical point. Therefore, a Pareto critical point is one where the gradients of f_1 and f_2 are opposite in direction, i.e., $\lambda \nabla f_1 = -\nabla f_2$, where λ is some scale factor.

In higher dimensions, a Pareto critical point is characterized by the existence of a set of weights, $w_i > 0$ $\forall$ $1 \leq i \leq m$, such that

$$\sum_{i=1}^{m} w_i \nabla f_i = 0. \tag{4.22}$$

Some of the common methods that are used for multicriterion optimization are discussed below.

4.2.4.1 Weighted Sums Optimization

The multiple objectives $f_1(\mathbf{x}), \ldots, f_m(\mathbf{x})$ are combined as

$$F(\mathbf{x}) = \sum_{i=1}^{m} w_i f_i(\mathbf{x}) \tag{4.23}$$

where $w_i > 0$ $\forall$ $i = 1, \ldots, m$, and the function $F(\mathbf{x})$ is minimized.

At any local minimum point of $F(\mathbf{x})$, the relation in Equation 4.22 is seen to be valid, and hence, $\mathbf{x} \in P_c$. In general, $P \neq P_c$, but it can be shown that when each f_i is a convex function, then $P = P_c$; if so, it can also be shown that all Pareto points can be obtained by optimizing the function F in Equation 4.23. However, for nonconvex functions, there are points $\mathbf{x} \in P$ that cannot be obtained by the weighted sum optimization since Equation 4.22 is only a necessary condition for the minimum of F. A characterization of the Pareto points that can be obtained by this technique is provided in Ref. [2].

In practice, the w_i's must be chosen to reflect the magnitudes of the f_i's. For example, if one of the objectives is a voltage quantity whose typical value is a few volts, and another is a capacitor value that is typically a few picofarads, the weight corresponding to the capacitor value would be roughly 10^{12} times that for the voltage, in order to ensure that each objective has a reasonable contribution to the objective function value. The designer may further weigh the relative importance of each objective in choosing the w_i's. This objective may be combined with additional constraints to give a formulation of the type in Equation 4.1.

4.2.4.2 Minmax Optimization

The following objective function is used for Equation 4.1

$$\text{minimize } F(\mathbf{x}) = \max_{1 \leq i \leq m} w_i f_i(\mathbf{x}) \tag{4.24}$$

where the weights $w_i > 0$ are chosen as in the case of weighted sums optimization.

The above equation can equivalently be written as the following constrained optimization problem:

$$\begin{aligned} &\text{minimize } r \\ &\text{subject to } w_i f_i(\mathbf{x}) \leq r \end{aligned} \tag{4.25}$$

Minimizing the objective function described by Equation 4.24 with different sets of w_i values can be used to obtain all Pareto points [2].

Since this method can, unlike the weighted-sums optimization method, be used to find all Pareto critical points, it would seem to be a more natural setting for obtaining Pareto points than the weighted sum minimization. However, when the f_i's are convex, the weighted sums approach is preferred since it is an unconstrained minimization, and is computationally easier than a constrained optimization. It must be noted that when the f_i's are not all convex, the minmax objective function is nonconvex, and finding all local minima is a nontrivial process for any method.

4.3 Transistor Sizing Problem for CMOS Digital Circuits

4.3.1 Problem Description

Circuit delays in ICs often must be reduced to obtain faster response times. A typical CMOS digital IC consists of multiple stages of combinational logic blocks that lie between latches that are clocked by system clock signals. For such a circuit, delay reduction must ensure that valid signals are produced at each output latch of a combinational block, before any transition in the signal clocking the latch. In other words, the worst-case input–output delay of each combinational stage must be restricted to be below a certain specification.

Given the circuit topology, the delay of a combinational circuit can be controlled by varying the sizes of transistors in the circuit. Here, the size of a transistor is measured in terms of its channel width, since the channel lengths of MOS transistors in a digital circuit are generally uniform. In coarse terms, the circuit delay can usually be reduced by increasing the sizes of certain transistors in the circuit. Hence, making

the circuit faster usually entails the penalty of increased circuit area. The area-delay trade-off involved here is, in essence, the problem of transistor size optimization.

Three formal statements of the problem are stated below:

$$\text{Minimize } \textit{Area} \text{ subject to } \textit{Delay} \leq T_{\text{spec}} \tag{4.26}$$

$$\text{Minimize } \textit{Delay} \text{ subject to } \textit{Area} \leq A_{\text{spec}} \tag{4.27}$$

$$\text{Minimize } \textit{Area} \cdot [\textit{Delay}]^c \tag{4.28}$$

where c is a constant. Of all of these, the first form is perhaps the most useful practical form, since a designer's objective is typically to meet a timing constraint dictated by a system clock.

Depending on the type of analysis, the delay computation may be either deterministic or statistical [6]. In the former case, the problem reduces to a conventional nonlinear optimization problem. In the latter case, the optimization is statistical, though it can be transformed into a deterministic problem.

4.3.2 Delay Modeling

We examine the delay modeling procedure used in TILOS (Timed Logic Synthesizer) [7] at the transistor, gate, and circuit levels. Many transistor sizing algorithms use minor variations on this theme, although some use more exact models. The inherent trade-off here is between obtaining a provably optimal solution under inexact models, versus being uncertain about optimality under more correct models.

4.3.2.1 Transistor Level Model

A MOS transistor is modeled as a voltage-controlled switch with an on-resistance, R_{on}, between drain and source, and three grounded capacitances, C_{d}, C_{s}, and C_{g}, at the drain, source, and gate terminals, respectively, as shown earlier in Figure 4.6. The behaviors of the resistance and capacitances associated with a MOS transistor of channel width x are modeled as

$$R_{\text{on}} \propto 1/x \tag{4.29}$$

$$C_{\text{d}}, C_{\text{s}}, C_{\text{g}} \propto x. \tag{4.30}$$

4.3.2.2 Gate Level Model

At the gate level, delays are calculated in the following manner. For each transistor in a pull-up or pull-down network of a complex CMOS gate, the largest resistive path from the transistor to the gate output is computed, as well as the largest resistive path from the transistor to a supply rail. Thus, for each transistor, the network is transformed into an RC line, and its Elmore time constant [8] is computed and is taken to be the gate delay.

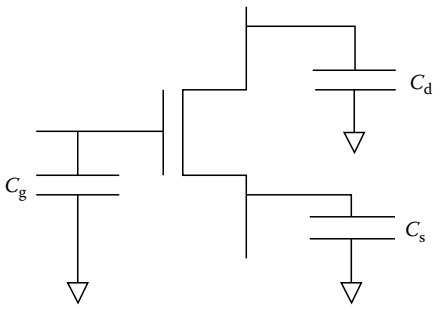

FIGURE 4.6 RC transistor model.

While finding the Elmore delay, the capacitances that lie between the switching transistor and the supply rail are assumed to be at the voltage level of the supply rail at the time of the switching transition, and do not contribute to the Elmore delay. For example, in Figure 4.7, the capacitance at node n_1 is ignored while computing the Elmore delay, the expression for which is

$$(R_1 + R_2)C_2 + (R_1 + R_2 + R_3)C_3. \tag{4.31}$$

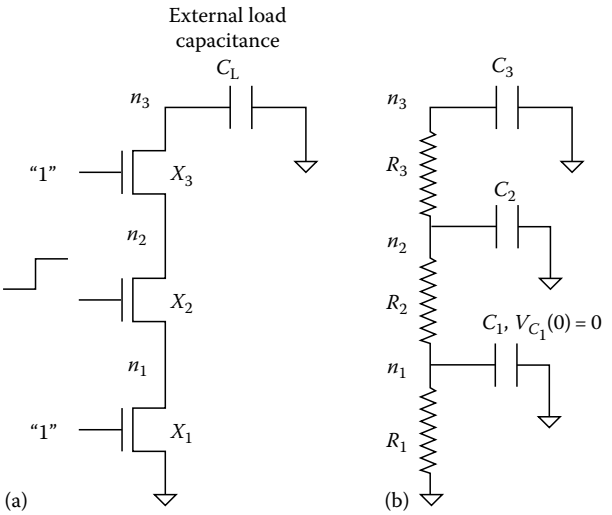

FIGURE 4.7 (a) Sample pull-down network and (b) its RC representation. (From Fishburn, J. and Dunlop, A., *Proceedings of the IEEE International Conference on Computer-Aided Design*, 1985, pp. 326–328. With permission.)

Each R_i is inversely proportional to the corresponding transistor size, x_i, and each C_i is some constant (for wire capacitance) plus a term proportional to the width of each transistor whose gate, drain, or source is connected to node i. Thus, Equation 4.31 can be rewritten as

$$(A/x_1 + A/x_2)(Bx_2 + Cx_3 + D) + (A/x_1 + A/x_2 + A/x_3)(Bx_3 + E),$$

which is a posynomial function (see Section 4.2.2) of x_1, x_2, and x_3. More accurate modeling techniques, using generalized posynomials, are described in Ref. [4].

4.3.2.3 Circuit Level Model

At the circuit level, the program evaluation and review technique (PERT), which will be described shortly, is used to find the circuit delay. The procedure is best illustrated by means of a simple example. Consider the circuit in Figure 4.8, where each box represents a gate, and the number within the box

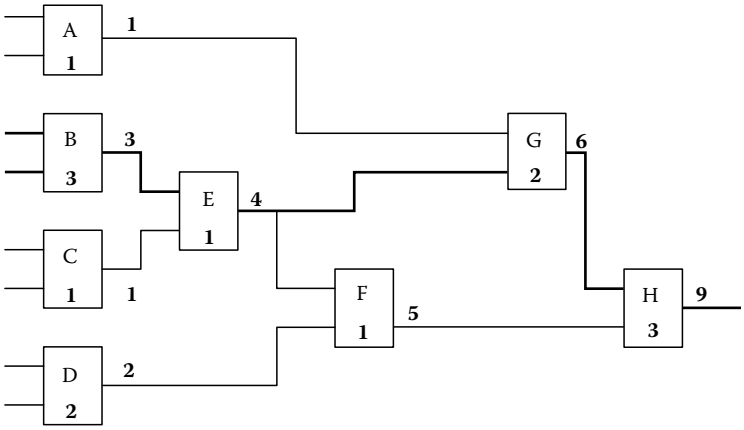

FIGURE 4.8 PERT.

represents its delay. We assume that the worst-case arrival time for a transition at any primary input, i.e., at the inputs to boxes A, B, C, and D, is 0.

A component is said to be ready for processing when the signal arrival time information is available for all of its inputs. Initially, since signal arrival times are known only at the primary inputs, only those components that are fed solely by primary inputs are ready for processing. These are placed in a queue and are scheduled for processing. In the iterative process, the component at the head of the queue is scheduled for processing. Each processing step consists of

- Finding the latest arriving input to the component, which triggers the output transition. This involves finding the maximum of all worst-case arrival times of inputs to the component.
- Adding the delay of the component to the latest arriving input time, to obtain the worst-case transition time at the output.
- Checking all of the components that the current component fans out to, to find out whether they are ready for processing. If so, the component is added to the tail of the queue.

The iterations end when the queue is empty. In the example, the algorithm is executed as follows:

Step 1. Initially, Queue = {A,B,C,D}.

Step 2. Schedule A; $Delay_A = 0 + 1 = 1$. Queue = {B,C,D}.

Step 3. Schedule B; $Delay_B = 0 + 3 = 3$. Queue = {C,D}.

Step 4. Schedule C; $Delay_C = 0 + 1 = 1$. Queue = {D,E}. (E is added to the queue.)

Step 5. Schedule D; $Delay_D = (0 + 2) = 2$. Queue = {E}.

Step 6. Schedule E; $Delay_E = (\max(3,1) + 1) = 4$. Queue = {F,G}.

Step 7. Schedule F; $Delay_F = (\max(4,2) + 1) = 5$. Queue = {G}.

Step 8. Schedule G; $Delay_G = (\max(4,1) + 2) = 6$. Queue = {H}.

Step 9. Schedule H; $Delay_H = (\max(6,5) + 3) = 9$. Queue = {}. The algorithm terminates.

The worst-case delays at the output of each component are shown in Figure 4.8. The critical path, defined as the path between an input and an output with the maximum delay, can now easily be found by successively tracing back, beginning from the primary output with the latest transition time, and walking back along the latest arriving fan-in of the current gate, until a primary input is reached. In the example, the critical path from the input to the output is B-E-G-H.

In the case of CMOS circuits, the rise and fall delay transitions are calculated separately. For inverting CMOS gates, the latest arriving input rise (fall) transition triggers off a fall (rise) transition at the output. This can easily be incorporated into the PERT method described above, by maintaining two numbers, t_r and t_f, for each gate, corresponding to the worst-case rise (high transition) and fall (low transition) delays from a primary input. To obtain the value of t_f at an output, the largest value of t_r at an input node is added to the worst-case fall transition time of the component; the computation of t_r is analogous. For noninverting gates, t_r and t_f are obtained by adding the rise (fall) transition time to the worst-case input rise (fall) transition time.

Since each gate delay is a posynomial, and the circuit delay found by the PERT is a sum of gate delays, the circuit delay is also a posynomial function of the transistor sizes. In general, the path delay can be written as

$$\sum_{i,j=1}^{n} a_{ij} \frac{x_i}{x_j} + \sum_{i=1}^{n} \frac{b_i}{x_i} + K. \tag{4.32}$$

In contrast to deterministic timing, statistical timing analysis techniques model gate delays as statistical functions of the underlying process parameter variations. Instead of propagating delays as fixed numbers, they propagate the probability density functions (PDFs) of delays. Techniques based on Gaussian or non-Gaussian delays, under linear or nonlinear models, with and without correlation, have been presented in the literature [9–12].

4.3.3 Area Model

The exact area of a circuit cannot easily be represented as a function of transistor sizes. This is unfortunate, since a closed functional form facilitates the application of optimization techniques. As an approximation, the following formula is used by many transistor sizing algorithms, to estimate the active circuit area:

$$Area = \sum_{i=1}^{n} x_i \tag{4.33}$$

where
x_i is the size of the ith transistor
n is the number of transistors in the circuit

In other words, the area is approximated as the sum of the sizes of transistors in the circuit that, from the definition Equation 4.8, is clearly a posynomial function of the x_i's.

4.3.4 Sensitivity-Based TILOS Algorithm

4.3.4.1 Steps in the Algorithm

The algorithm that was implemented in TILOS [7] was the first to recognize the fact that the area and delay can be represented as posynomial functions of the transistor sizes. The algorithm proceeds as follows.

An initial solution is assumed where all transistors are at the minimum allowable size. In each iteration, a static timing analysis is performed on the circuit, as explained in Section 4.3.2, to determine the critical path for the circuit.

Let N be the primary output node on the critical path. The algorithm then walks backward along the critical path, starting from N. Whenever an output node of a gate, $Gate_i$, is visited, TILOS examines the largest resistive path between V_{DD} (ground) and the output node if $Gate_i$'s t_r (t_f) causes the timing failure at N. This includes

- Critical transistor, i.e., the transistor whose gate terminal is on the critical path. In Figure 4.7, X_2 is the critical transistor.
- Supporting transistors, i.e., transistors along the largest resistive path from the critical transistor to the power supply (V_{DD} or ground). In Figure 4.7, X_1 is a supporting transistor.
- Blocking transistors, i.e., transistors along the highest resistance path from the critical transistor to the logic gate output. In Figure 4.7, X_3 is a blocking transistor.

TILOS finds the sensitivity, which is the reduction in circuit delay per increment of transistor size, for each critical, blocking, and supporting transistors. (The procedure of sensitivity computation is treated in greater detail shortly.) The size of the transistor with the greatest sensitivity is increased by multiplying it by a constant, BUMPSIZE, a user-settable parameter that defaults to 1.5. The above process is repeated until all constraints are met, implying that a solution is found, or the minimum delay state has been

passed, and any increase in transistor sizes would make it slower instead of faster, in which case TILOS cannot find a solution.

Note that since in each iteration, exactly one transistor size is changed, the timing analysis method can employ incremental simulation techniques to update delay information from the previous iteration. This substantially reduces the amount of time spent in critical path detection.

4.3.4.2 Sensitivity Computation

Figure 4.9 illustrates a configuration in which the critical path extends back along the gate of the upper transistor, which is the critical transistor. The sensitivity for this transistor is calculated as follows: set all transistor sizes, except x, to the size of the critical transistor. R is the total resistance of an RC chain driving the gate and C is the total capacitance of an RC chain being driven by the configuration. The total delay, $D(x)$, of the critical path is

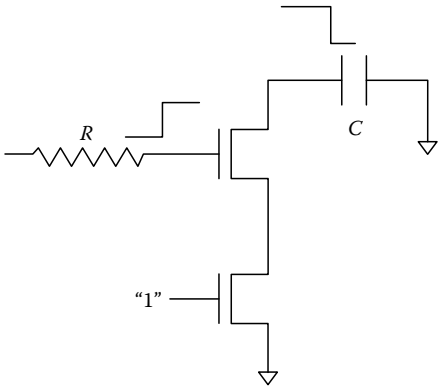

FIGURE 4.9 Sensitivity calculation in TILOS. (From Fishburn, J. and Dunlop, A., *Proceedings of the IEEE International Conference on Computer-Aided Design*, 1985, pp. 326–328. With permission.)

$$D(x) = K + RC_{\mathrm{u}}x + \frac{R_{\mathrm{u}}C}{x} \tag{4.34}$$

where

R_{u} and C_{u} are the resistance and capacitance of a unit-sized transistor, respectively

K is a constant that depends on the resistance of the bottom transistor, the capacitance in the driving RC chain, and the resistance in the driven RC chain

The sensitivity, $D'(x)$, is then

$$D'(x) = RC_{\mathrm{u}} - \frac{R_{\mathrm{u}}C}{x^2}. \tag{4.35}$$

The sensitivities of supporting transistors and blocking transistors can similarly be calculated.

Note that increasing the size of a transistor with negative sensitivity only means that the delay along the current critical path can be reduced by changing the size of this transistor, and does not necessarily mean that the circuit delay can be reduced; the circuit delay is the maximum of all path delays in the circuit, and a change in the size of this transistor could increase the delay along some other path, making a new path critical. This is the rationale behind increasing the size of the most sensitive transistor by only a small factor.

From an optimization viewpoint, the procedure of bumping up the size of the most sensitive transistor could be looked upon in the following way. Let the ith transistor (out of n total transistors) be the one with the maximum sensitivity. Define $\mathbf{e_i} \in \mathbf{R}^n$ as $(\mathbf{e_i})_j = 0$ if $i \neq j$ and $(\mathbf{e_i})_j = 1$ if $i = j$. In each iteration, the TILOS optimization procedure works in the n-dimensional space of the transistor sizes, chooses $\mathbf{e_i}$ as the search direction, and attempts to find the solution to the problem by taking a small step along that direction.

4.3.5 Transistor Sizing Using the Method of Feasible Directions

Shyu et al. proposed a two-stage optimization approach to solve the transistor sizing problem. The delay estimation algorithm is identical to that used in TILOS.

The algorithm can be summarized in the following pseudocode:

```
Use TILOS to size the entire circuit;
While (TRUE) {
    Select G_1, . . . , G_k, the k most critical paths,
    and X = {x_i}, the set of design parameters
    Solve the optimization problem
```

$$\begin{aligned} &\text{minimize} && \sum_{x_i \in X} x_i \\ &\text{such that} && G_i(X) \leq T \ \forall\ i = 1, \ldots, k \\ &\text{and} && x_i \geq \text{minsize} \ \forall\ x_i \in X. \end{aligned}$$

```
    If all constraints are satisfied, exit  }
```

In the first stage, the TILOS heuristic described in Section 4.3.4 is used to generate an initial solution. The heuristic finds a solution that satisfies the constraints, and only the sized-up transistors are used as design parameters. Although TILOS is not guaranteed to find an optimal solution, it can serve as an initial guess solution for an iterative technique.

In the second stage of the optimization process, the problem is converted into a mathematical optimization problem, and is solved by a method of feasible directions (MFD) algorithm described in Section 4.2.3, using the feasible solution generated in the first stage as an initial guess. To reduce the computation, a sequence of problems with a smaller number of design parameters is solved.

At first, the transistors on the worst-delay paths (usually more than one) are selected as design parameters. If, with the selected transistors, the optimizer fails to meet the delay constraints, and some new paths become the worst-delay paths, the algorithm augments the design parameters with the transistors on those paths, and restarts the process. However, while this procedure reduces the run time of the algorithm, one faces the risk of finding a suboptimal solution since only a subset of the design parameters is used in each step.

The MFD optimization method proceeds by finding a search direction **d**, a vector in the n-dimensional space of the design parameters, based on the gradients of the cost function and some of the constraint functions. Once the search direction has been computed, a step along this direction is taken, so that the decrease in the cost and constraint functions is large enough. The computation stops when the length of this step is sufficiently small.

Since this algorithm has the feature that once the feasible region (the set of transistor sizes where all delay constraints are satisfied) is entered, all subsequent improvements will remain feasible, and the algorithm can be terminated at any time with a feasible solution.

4.3.5.1 Practical Implementational Aspects

4.3.5.1.1 Generalized Gradient

For convergence, the MFD requires that the objective and constraint functions be continuously differentiable. However, since the circuit delay is defined as the maximum of all path delays, the delay constraint functions are usually not differentiable. To illustrate that the maximum of two continuously differentiable functions, $g_1(x)$ and $g_2(x)$, need not be differentiable, consider the example in Figure 4.10. The maximum function, shown by the bold lines, is nondifferentiable at x_0.

To cope with the nondifferentiability of the constraint functions, a modification of the MFD is used, which employs the concept of the generalized gradient. The idea is to use a convex combination of the gradients of the active, or nearly active, constraints near a discontinuity.

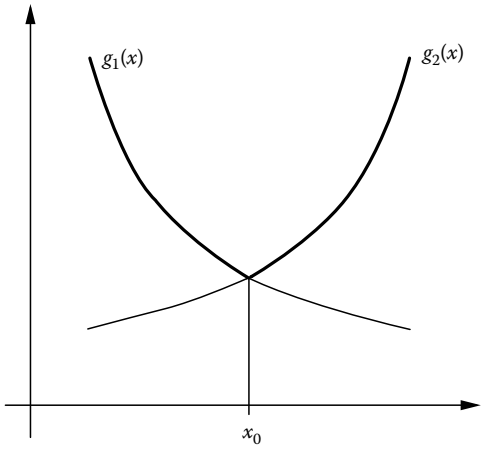

FIGURE 4.10 Nondifferentiability of the max function.

4.3.5.1.2 Scaling

It is important to scale the gradients of the cost and path delay functions since the use of their unscaled values may produce poor descent search directions due to the large difference in magnitude of the gradients of the constraint and objective functions. When a gradient has a magnitude that is much smaller than other gradients, it dominates the search direction. In such a case, the descent direction is unjustly biased away from the other constraints or the cost function.

4.3.6 Lagrangian Multiplier Approaches

As can be seen from the approaches studied so far, the problem of transistor sizing can be formulated as a constrained nonlinear programming problem. Hence, the method of Lagrangian multipliers, described in Section 4.2.3, is applicable.

An early approach by Marple [13] begins with a prespecified layout, and performs the optimization using an area model for that layout. While such an approach has the disadvantage that it may not result in the minimal area over all layouts, it still maintains the feature that the area and delay constraints are posynomials. Apart from the delay constraints, there also exist some area constraints, modeled by constraint graphs that are commonly used in layout compaction. These constraints maintain the minimum spacing between objects in the final layout, as specified by design rules.

The delay of the circuit is modeled by a delay graph, D (V, E) where V is the set of nodes (gates) in D, and E is the set of arcs (connections among gates) in D. This is the same graph on which the PERT analysis is to be carried out. Let m_i represent the worst-case delay at the output of gate i, from the primary inputs. Then for each gate, the delay constraint is expressed as

$$m_i + d_j \leq m_j, \tag{4.36}$$

where gate $i \in$ fan-in (gate j), and d_j is the delay of gate j. Thus, the number of delay constraints is reduced from a number that could, in the worst case, be exponential in $|V|$, to one that is linear in $|E|$, using $|V|$ additional variables.

More recent work [14] recognizes that many of the Lagrange multipliers can be removed to build a relaxed problem, and uses Lagrangian relaxation on the dual to obtain a very fast optimal solution.

4.3.7 Two-Step Optimization

Since the number of variables in the transistor sizing problem, which equals the number of transistors in a combinational segment, is typically too large for most optimization algorithms to handle efficiently, many algorithms choose a simpler route by performing the optimization in two steps. The most successful of these methods is given in Ref. [15], which goes alternately through a D-phase and a W-phase; one of these creates delay budgets for each gate by solving a flow problem, and the other assigns transistor sizes based on these budgets.

4.3.8 Convex Programming-Based Approach

The chief shortcoming of most of the approaches above is that the simplifying assumptions that are made to make the optimization problem more tractable may lead to a suboptimal solution. The algorithm in iCONTRAST solves the underlying optimization problem exactly.

The objective of the algorithm is to solve the transistor sizing problem in Equation 4.28, where both the area and the delay are posynomial functions of the vector **x** of transistor sizes. The procedure described below may easily be extended to solve the formulations in Equations 4.29 and 4.30 as well; however, these formulations are not as useful to the designer. The variable transformation, $(x_i) = (e^{z_i})$, maps the problem in Equation 4.28 to

$$\begin{aligned} &\text{minimize} \quad Area(\mathbf{z}) = \sum_{i=1}^{n} e^{z_i} \\ &\text{subject to} \quad D(\mathbf{z}) \leq T_{\text{spec}}. \end{aligned} \tag{4.37}$$

The delay of a circuit is defined to be the maximum of the delays of all paths in the circuit. Hence, it can be formulated as the maximum of posynomial functions of **x**. This is mapped by the above transformation onto a function $D(\mathbf{z})$ that is a maximum of convex functions; a maximum of convex functions is also a convex function. The area function is also a posynomial in **x**, and is transformed into a convex function by the same mapping. Therefore, the optimization problem defined in Equation 4.28 is mapped to a convex programming problem, i.e., a problem of minimizing a convex function over a convex constraint set. Due to the unimodal property of convex functions over convex sets, any local minimum of Equation 4.28 is also a global minimum.

Vaidya's convex programming method described in Section 4.2.3 is then used to find the unique global minimum of the optimization problem.

4.3.8.1 Gradient Calculations

In an iteration of Vaidya's convex programming algorithm, when the center $\mathbf{z}_c$ of a polytope lies within the feasible region *S*, the gradient of the area function is required to generate the new hyperplane passing through the center. The gradient of the area function (Equation 4.37) is given by

$$\nabla Area(\mathbf{z}) = [e^{z_1}, e^{z_2}, \ldots, e^{z_n}]. \tag{4.38}$$

In the case when the center $\mathbf{z}_c$ lies outside the feasible region *S*, the gradient of the critical path delay function $D_{\text{critpath}}(\mathbf{z}_c)$ is required to generate the new hyperplane that is to be added. Note that transistors in the circuit can contribute to the *k*th component of the gradient of the delay function in either of two ways:

1. If the *k*th transistor is a critical, supporting, or blocking transistor (as defined in Section 4.3.4)
2. If the *k*th transistor is a capacitive load for some critical transistor

Transistors that satisfy neither of these two requirements have no contribution to the gradient of the delay function.

4.3.9 Statistical Optimization

In the presence of statistical variations, it is important to perform timing optimization based on statistical static timing analysis. An obvious way to increase the timing yield of a digital circuit is to pad the specifications to make the circuit robust to variations, i.e., choose a delay specification of the circuit that is tighter than the required delay. This new specification must be appropriately selected to avoid large area or power overheads due to excessively conservative padding.

Early work in Ref. [9] proposes formulation of statistical objective and timing constraints, and solves the resulting nonlinear optimization formulation, but this is highly computational. Other approaches have extended TILOS heuristic to optimize $\mu + 3\sigma$, where μ is the mean of the delay PDF and σ its standard deviation, but while these methods work reasonably in practice, they have no theoretical backing.

More formal optimization approaches have also been used. The work in Ref. [16] presents approaches to optimize the statistical power of the circuit, subject to timing yield constraints under convex formulation of the problem as a second-order conic program. The work in Ref. [17] proposes a gate sizing technique based on robust optimization theory: robust constraints are added to the original constraints set by modeling the intrachip random process parameter variations as Gaussian variables, contained in a constant probability density uncertainty ellipsoid, centered at the nominal values.

4.4 Analog Design Centering Problem

4.4.1 Problem Description

While manufacturing an analog circuit, it is inevitable that process variations will cause design parameters, such as component values, to waver from their nominal values. As a result, the manufactured analog circuit may no longer meet some behavioral specifications, such as requirements on the delay, gain, and bandwidth, that it has been designed to satisfy. The procedure of design centering attempts to select the nominal values of design parameters to move the circuit to the center of the feasible region.

The values of n design parameters may be ordered as an n-tuple that represents a point in $\mathbf{R}^n$. A point is feasible if the corresponding values for the design parameters satisfy the behavioral specifications on the circuit. The feasible region (or the region of acceptability), $R_f \subset \mathbf{R}^n$, is defined as the set of all design points for which the circuit satisfies all behavioral specifications.

The random variations in the values of the design parameters are modeled by a PDF, $\Phi(\mathbf{z})$: $\mathbf{R}^n \rightarrow [0, 1]$, with a mean corresponding to the nominal value of the design parameters. The yield of the circuit, Y, as a function of the mean, $\mathbf{x}$, is given by

$$Y(\mathbf{x}) = \int_{R_f} \Phi_{\mathbf{x}}(\mathbf{z}) d\mathbf{z}. \tag{4.39}$$

The design center is the point $\mathbf{x}$ at which the yield, $Y(\mathbf{x})$, is maximized. There have traditionally been two approaches to solving this problem: one based on geometrical methods and another based on statistical sampling. In addition, several methods that hybridize these approaches also exist. We now provide an exposition of geometrical approaches to the optimization problem of design centering.

A common assumption made by geometrical design centering algorithms is that R_f is a convex-bounded body. Geometrical algorithms recognize that the evaluation of the integral (Equation 4.39) is computationally difficult, and generally proceed as follows: the feasible region in the space of design parameters, i.e., the region where the behavioral specifications are satisfied, is approximated by a known geometrical body, such as a polytope or an ellipsoid. The center of this body is then approximated, and is taken to be the design center.

4.4.2 Simplicial Approximation Method

4.4.2.1 Outline of the Method

The simplicial approximation method [18] is a method for approximating a feasible region by a polytope and finding its center. This method proceeds in the following steps:

1. Determine a set of $m \geq n + 1$ points on the boundary of R_f.
2. Find the convex hull (see Section 4.2.2) of these points and use this polyhedron as the initial approximation to R_f. In the two-dimensional example in Figure 4.11a, the points 1, 2, and 3 are chosen in Step 1, and their convex hull is the triangle with vertices 1, 2, and 3. Set $k = 0$.

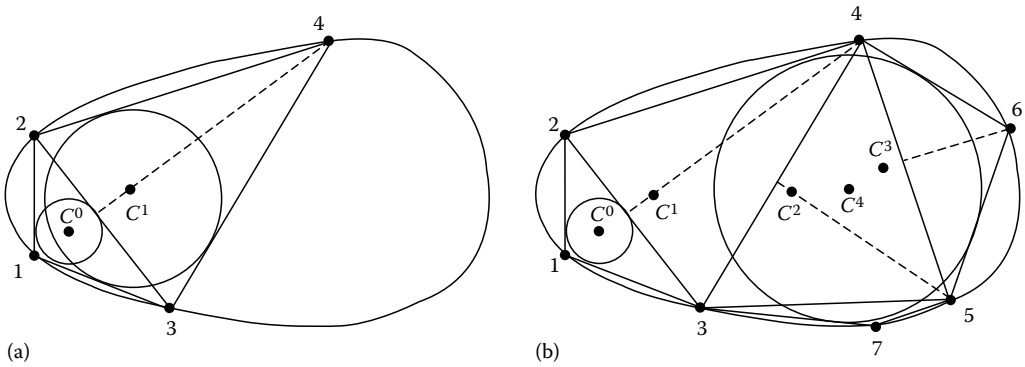

FIGURE 4.11 Simplicial approximation method. (From Director, S.W. and Hachtel, G.D., *IEEE Trans. Circuits Syst.*, CAS-24, 363, 1977. With permission.)

3. Inscribe the largest n-dimensional hypersphere in this approximating polyhedron and take its center as the first estimate of the design center. This process involves the solution of a linear program. In Figure 4.11a, this is the hypersphere C^0.
4. Find the midpoint of the largest face of the polyhedron, i.e., the face in which the largest $n-1$-dimensional hypersphere can be inscribed. In Figure 4.11a, the largest face is 2–3, the face in which the largest one-dimensional hypersphere can be inscribed.
5. Find a new boundary point on R_f by searching along the outward normal of the largest face found in Step 4 extending from the midpoint of this face. This is carried out by performing a line search. In Figure 4.11a, point 4 is thus identified.
6. Inflate the polyhedron by forming the convex hull of all previous points, plus the new point generated in Step 5. This corresponds to the quadrilateral 1, 2, 3, and 4 in Figure 4.11a.
7. Find the center of the largest hypersphere inscribed in the new polyhedron found in Step 6. This involves the solution of a linear program. Set $k = k + 1$, and go to Step 4. In Figure 4.11a, this is the circle C^1.

Further iterations are shown in Figure 4.11b. The process is terminated when the sequence of radii of the inscribed hypersphere converges.

4.4.2.2 Inscribing the Largest Hypersphere in a Polytope

Given a polytope specified by Equation 4.3, if the $\mathbf{a}_i$'s are chosen to be unit vectors, then the distance of a point $\mathbf{x}$ from each hyperplane of the polytope is given by $r = \mathbf{a}_i^{\mathrm{T}}\mathbf{x} - b_i$.

The center $\mathbf{x}$ and radius r of the largest hypersphere that can be inscribed within the polytope $\mathcal{P}$ are then given by the solution of the following linear program:

$$\begin{array}{ll} \text{minimize} & r \\ \text{subject to} & \mathbf{a}_i^{\mathrm{T}}\mathbf{x} - r \geq b_i \end{array} \tag{4.40}$$

Since the number of unknowns of this linear program is typically less than the number of constraints, it is more desirable to solve its dual [1]. A similar technique can be used to inscribe the largest hypersphere in a face of the polytope.

This method has also been generalized for the inscription of maximal norm bodies, to handle joint PDFs with (nearly) convex level contours.

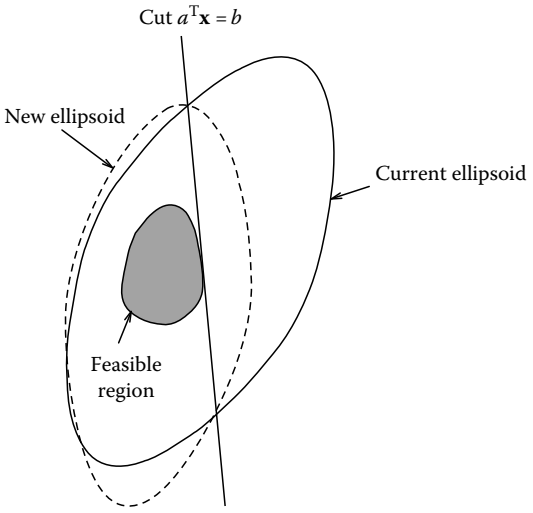

FIGURE 4.12 Ellipsoidal method. (From Abdel-Malek, H.L. and Hassan, A.-K.S.O., *IEEE Trans. Comput. Aided Des.*, 10, 1006, 1991. With permission.)

4.4.2.3 Elongated Feasible Regions

If the design centering procedure outlined earlier is applied to a rectangular feasible region, the best possible results may not be obtained by inscribing a hypersphere. For elongated feasible regions, it is more appropriate to determine the design center by inscribing an ellipsoid rather than a hypersphere. Simplicial approximation handles this problem by scaling the axes so that the lower and upper bounds for each parameter differ by the same magnitude, and one may inscribe the largest ellipsoid by inscribing the largest hypersphere in a transformed polytope. This procedure succeeds in factoring in reasonably the fact that feasible regions may be elongated; however, it considers only a limited set of ellipsoids, which have their axes aligned with the coordinate axis, as candidates for inscription within the polytope.

4.4.3 Ellipsoidal Method

This method [19] is based on principles similar to those used by the Shor–Khachiyan ellipsoidal algorithm for linear programming. This algorithm attempts to approximate the feasible region by an ellipsoid, and takes the center of the approximating ellipsoid as the design center. It proceeds by generating a sequence of ellipsoids, each smaller than the last, until the procedure converges. Like other methods, this procedure assumes that an initial feasible point is provided by the designer. The steps involved in the procedure are as follows (Figure 4.12):

1. Begin with an ellipsoid, E_0, that is large enough to contain the desired solution. Set $j = 0$.
2. From the center of the current ellipsoid, choose a search direction, and perform a binary search to identify a boundary point along that direction. One convenient set of search directions are the parameter directions, searching along the ith, $i = 1, 2, \ldots, n$ in a cycle, and repeating the cycle, provided the current ellipsoid center is feasible. If not, a linear search is conducted along a line from the current center to the given feasible point.
3. A supporting hyperplane [1] at the boundary point can be used to generate a smaller ellipsoid, E_{j+1}, that is guaranteed to contain the feasible region R_f, if R_f is convex. The equation of E_{j+1} is provided by an update procedure.
4. Increment j, and go to Step 1 unless the convergence criterion is met. The convergence criterion is triggered when the volume is reduced by a given factor, ε. Upon convergence, the center of the ellipsoid is taken to be the design center.

4.4.4 Convexity-Based Approaches

4.4.4.1 Introduction

This section describes the approach in Ref. [20]. Here, the feasible region is first approximated by a polytope in the first phase. Next, two geometrical approaches to find the design center are proposed. In the first, the properties of polytopes are utilized to inscribe the largest ellipsoid within the approximating polytope. The second method proceeds by formulating the design centering problem as a convex

programming problem, assuming that the variations in the design parameters are modeled by Gaussian probability distributions, and uses Vaidya's convex programming algorithm described in Section 4.2.3 to find the solution.

4.4.4.2 Feasible Region Approximation

The feasible region, $R_f \subset \mathbf{R}^n$, is approximated by a polytope given by Equation 4.3 in this step. The algorithm begins with an initial feasible point, $\mathbf{z}_0 \in R_f$. An n-dimensional box, namely, $\{\mathbf{z} \in \mathbf{R}^n \mid z_{min} \leq z_i \leq z_{max}\}$, containing R_f is chosen as the initial polytope $\mathcal{P}_0$. In each iteration, n orthogonal search directions, $\mathbf{d}_1, \mathbf{d}_2, \ldots, \mathbf{d}_n$ are chosen (possible search directions include the n coordinate directions). A binary search is conducted from $\mathbf{z}_0$ to identify a boundary point $\mathbf{z}_{\mathbf{b}i}$ of R_f, for each direction $\mathbf{d}_i$. If $\mathbf{z}_{\mathbf{b}i}$ is relatively deep in the interior of $\mathcal{P}$, then the tangent plane to R_f at $\mathbf{z}_{\mathbf{b}i}$ is added to the set of constraining hyperplanes in Equation 4.3. A similar procedure is carried out along the direction $-\mathbf{d}_i$. Once all of the hyperplanes have been generated, the approximate center of the new polytope is calculated. Then $\mathbf{z}_0$ is reset to be this center, and the above process is repeated.

Therefore, unlike simplicial approximation that tries to expand the polytope outward, this method starts with a large polytope and attempts to add constraints to shrink it inward. The result of polytope approximation on an ellipsoidal feasible region is illustrated in Figure 4.13.

4.4.4.3 Algorithm I: Inscribing the Largest Hessian Ellipsoid

For a polytope given by Equation 4.3, the log-barrier function is defined as

$$F(\mathbf{z}) = -\sum_{i=1}^{m} \log_e(\mathbf{a_i}^T\mathbf{z} - b_i). \tag{4.41}$$

The Hessian ellipsoid centered at a point $\mathbf{x}$ in the polytope $\mathcal{P}$ is defined as the ellipsoid E($\mathbf{x}$,$\mathcal{H}(\mathbf{x})$,1) (see Equation 4.2), where $\mathcal{H}(\mathbf{x}_c)$ is the Hessian [1] of the log-barrier function above, and is given by

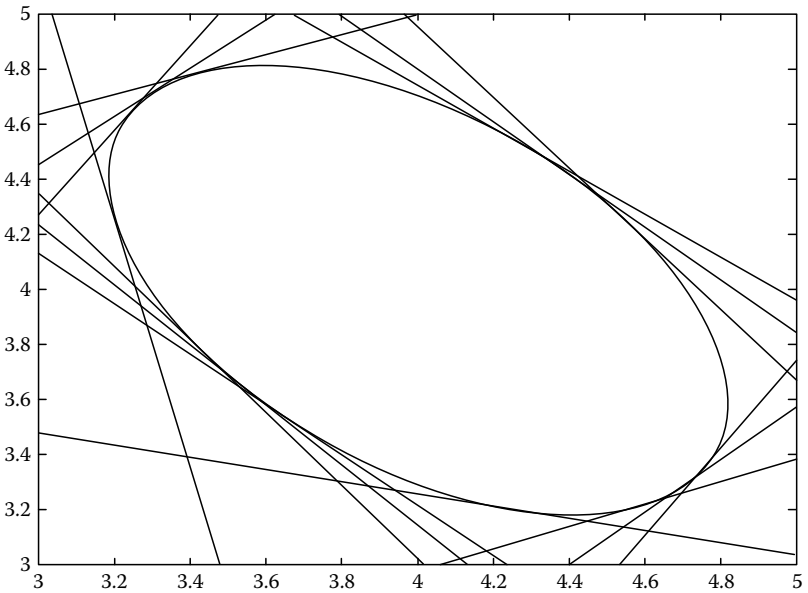

FIGURE 4.13 Polytope approximation for the convexity-based methods. (From Saptnekar, S.S., Vaidya, P.M. and Kang, S.M., *IEEE Trans. Comput. Aided Des.*, 13, 1536, 1994. With permission.)

$$\mathcal{H}(\mathbf{z}) = \nabla^2 F(\mathbf{z}) = \sum_{i=1}^{m} \frac{\mathbf{a_i}\mathbf{a_i}^{\mathrm{T}}}{(\mathbf{a_i}^{\mathrm{T}}\mathbf{z} - b_i)^2}. \tag{4.42}$$

This is known to be a good approximation to the polytope locally around $\mathbf{x}$.

Hence, the goal is to find the largest ellipsoid in the class $\mathbf{E}(\mathbf{x}, \mathcal{H}(\mathbf{x}),\mathrm{r})$ that can be inscribed in the polytope, and its center $\mathbf{x}_c$. The point $\mathbf{x}_c$ will be taken to be the computed design center. An iterative process is used to find this ellipsoid. In each iteration, the Hessian at the current point $\mathbf{x}_k$ is calculated, and the largest ellipsoid $\mathbf{E}(\mathbf{x}, \mathcal{H}(\mathbf{x}_k),\mathrm{r})$ is inscribed in the polytope. The inscription of this ellipsoid is equivalent to inscribing a hypersphere in a transformed polytope. The process of inscribing a hypersphere in a polytope is explained in Section 4.4.2.

4.4.4.4 Algorithm II: Convex Programming Approach

When the PDFs that represent variations in the design parameters are Gaussian in nature, the design centering problem can be posed as a convex programming problem.

The joint Gaussian PDF of n independent random variables $\mathbf{z} = (z_1, \ldots, z_n)$ with mean $\mathbf{x} = (x_1, \ldots, x_n)$ and variance $\sigma = (\sigma_1, \ldots, \sigma_n)$ is given by

$$\Phi_{\mathbf{x}}(\mathbf{z}) = \frac{1}{(2\pi)^{n/2}\sigma_1\sigma_2\cdots\sigma_n} \exp\left[\sum_{i=0}^{i=n} -\frac{(z_i - x_i)^2}{2\sigma_i^2}\right] \tag{4.43}$$

This is known to be a log-concave function of $\mathbf{x}$ and $\mathbf{z}$. Also, note that arbitrary covariance matrices can be handled, since a symmetric matrix may be converted into a diagonal form by a simple linear (orthogonal) transformation. The design centering problem is now formulated as

$$\begin{aligned} &\text{maximize} \quad \mathrm{Y}(\mathbf{x}) = \int_{\mathcal{P}} \Phi_{\mathbf{x}}(\mathbf{z})\mathrm{d}\mathbf{z} \\ &\text{such that} \quad \mathbf{x} \in \mathcal{P}. \end{aligned} \tag{4.44}$$

where $\mathcal{P}$ is the polytope approximation to the feasible region R_f. It is a known fact that the integral of a log-concave function over a convex region is also a log-concave function. Thus, the yield function $\mathrm{Y}(\mathbf{x})$ is log-concave, and the above problem reduces to a problem of maximizing a log-concave function over a convex set. Hence, this can be transformed into a convex programming problem. The convex programming algorithm in Section 4.2.3 is then applied to solve the optimization problem.

4.4.5 Concluding Remarks

The above list of algorithms is by no means exhaustive, but provides a general flavor for how optimization methods are used in geometrical design centering. The reader is referred to [21–24] for further information about statistical design. In conclusion, it is appropriate to list a few drawbacks associated with geometrical methods:

Limitations of the approximating bodies: In the case of ellipsoidal approximation, certain convex bodies cannot be approximated accurately, because an ellipsoid is symmetric about any hyperplane passing through its center, and is inherently incapable of producing a good approximation to a body that has a less symmetric structure. A polytope can provide a better approximation to a convex body than an ellipsoid since any convex body can be thought of as a polytope with an infinite number of faces. However, unlike the ellipsoidal case, calculating the exact center of a polytope is computationally difficult and one must resort to approximations.

Statistical effects are ignored: Methods such as simplicial approximation, ellipsoidal approximation, and Algorithm I of the convexity-based methods essentially approximate the feasible region by means of an ellipsoid, and take the center of that ellipsoid to be the design center, regardless of the probability distributions that define variations in the design parameters. However, the design center could be highly dependent on the exact probability distributions of the variables, and would change according to these distributions.

Nonconvexities: Real feasible regions are seldom convex. While in many cases, they are nearly convex, there are documented cases where the feasible region is not very well behaved. In a large number of cases of good designs, since the joint PDF of the statistical variables decays quite rapidly from the design center, a convex approximation does not adversely affect the result. However, if the nominal design has a very poor yield, a convex approximation will prove to be inadequate.

The curse of dimensionality: Geometrical methods suffer from the so-called curse of dimensionality, whereby the computational complexity of the algorithm increases greatly with the number of variables. However, as noted in Ref. [25], for local circuit blocks within a die, performance variations in digital MOS circuits depend on only four independent statistical variables. Moreover, for this class of circuits, the circuit performance can be modeled with reasonable accuracy by linear functions. For such circuits, the deterministic (i.e., nonstatistical) algorithm in Ref. [25] is of manageable complexity.

5.1 Introduction

Manufacturing process variations and environmental effects (such as temperature) result in the variations of the values of circuit elements and parameters. Statistical methods of circuit design optimization take those variations into account and apply statistical (or statistical/deterministic) optimization techniques to obtain an ''optimal'' design. Statistical design optimization belongs to a general area of statistical circuit design.

5.2 Problems and Methodologies of Statistical Circuit Design

A broad class of problems exists in this area: statistical analysis involves studying the effects of element variations on circuit performance. It applies statistical techniques, such as Monte Carlo simulation [34] and the variance propagation method [39], to estimate variability of performances. Design centering attempts to find a center of the acceptability region [12] such that manufacturing yield is maximized.

Direct methods of yield optimization use yield as the objective function and utilize various statistical (or mixed statistical/deterministic) algorithms to find the yield maximum in the space of designable circuit/process parameters. Design centering and tolerance assignment (used mostly for discrete circuits) attempt to find the design center, with simultaneous optimal assignment of circuit element tolerances, minimizing some suitable cost function and providing 100% yield (worst-case design) [4,6]. To solve this problem, mostly deterministic algorithms of nonlinear programming are used. Worst-case design is often too pessimistic and too conservative, leading to substantial overdesign. This fact motivates the use of statistical techniques, which provide a much more realistic estimation of the actual performance variations and lead to superior designs. Stringent requirements of the contemporary very large scale integration (VLSI) design prompted a renewed interest in the practical application of these techniques. The most significant philosophy introduced recently in this area is statistical Design for Quality (DFQ). It was stimulated by the practical appeal of the DFQ methodologies introduced by Taguchi [30], oriented toward "on-target" design with performance variability minimization. In what follows, mostly the techniques of manufacturing yield optimization and their design for quality generalization are discussed.

5.3 Underlying Concepts and Techniques

5.3.1 Circuit Variables, Parameters, and Performances

5.3.1.1 Designable Parameters

Designable parameters, represented by the n-dimensional vector* $x = (x_1, \ldots, x_n)$, are used by circuit designers as "decision" variables during circuit design and optimization. Typical examples are nominal values of passive elements, nominal MOS transistor mask dimensions, process control parameters, etc.

5.3.1.2 Random Variables

The t-dimensional vector of random variables (or "noise" parameters in Taguchi's terminology [30]) is denoted as $\theta = (\theta_1, \ldots, \theta_t)$. It represents statistical R, L, C element variations, disturbances or variations of manufacturing process parameters, variations of device model parameters such as t_{ox} (oxide thickness), V_{TH} (threshold voltage), and environmental effects such as temperature, supply voltage, etc. Usually, θ represents principal random variables, selected to be statistically independent and such that all other random parameters can be related to them through some statistical models. Probability density function (p.d.f.) of θ parameters will be denoted as $f_\theta(\theta)$.

5.3.1.3 Circuit (Simulator) Variables

These variables represent parameters and variables used in circuit, process, or system simulators such as SPICE. They are represented as the c-dimensional vector $e = (e_1, \ldots, e_c)$. Specific examples of e variables are: R, L, C elements, gate widths W_j and lengths L_j of MOS transistors, device model parameters, or, if a process simulator is used, process-related control, and physical and random parameters available to the user. The e vector contains only those variables that are directly related to the x and θ vectors.† This relationship is, in general, expressed as

$$e = e(x, \theta) \tag{5.1}$$

The p.d.f. of θ is transformed into $f_e(e)$ the p.d.f. of e. This p.d.f. can be singular, i.e., defined in a certain subspace of the e-space (see examples below). Moreover, it can be very complicated, with highly nonlinear statistical dependencies between different parameters, so it is very difficult to represent it directly as

* Vectors are denoted by lowercase letters subscripts or superscripts.
† This means that, e.g., some SPICE parameters will always be *fixed*.

a p.d.f. of e. In the majority of cases, the analytic form of $f_e(e)$ is not known. For that reason, techniques of statistical modeling are used (see the next section).

5.3.1.4 Circuit Performances

The vector of circuit performance function (or simply performances) is defined as the m-dimensional vector $y = (y_1, \ldots, y_m)$. Its elements can be gain, bandwidth, slew rate, signal delay, and circuit response for a single frequency or time, etc. Each of the performances y_j is a function of the vector of circuit elements e: $y_j = y_j(e) = y_j(e(x, \theta))$. These transformations are most often not directly known in analytical form and a circuit simulator (such as SPICE) must be used to find the values of y_j's corresponding to the given values of x and θ. The overall simulator time required for the determination of all the performances y can be substantial for large circuits. This is the major limiting factor for the practical application of statistical circuit design techniques. To circumvent this problem, new statistical macromodeling techniques are being introduced [31] (see example in Section 5.4.9).

5.3.2 Statistical Modeling of Circuit (Simulator) Variables

Statistical modeling is the process of finding a suitable transformation $e = e(x, \theta)$, such that given the distribution of θ, the distribution of e can be generated. The transformation $e = e(x, \theta)$ can be described by closed form analytical formulas or by a computer algorithm.

For discrete active RLC circuits (e.g., such as a common emitter amplifier), vector e is composed of two parts: the first part contains the actual values of statistically perturbed RLC elements: i.e., $e_i = x_i + \theta_i$ for those elements. In this formula, θ represents absolute element spreads and its expected (average) value, $E\{\theta\} = 0$ and x_i is the nominal value of e_i, often selected as the expected value of e_i. This implies that the variance of e_i, $\text{var}\{e_i\} = \text{var}\{\theta_i\}$; $E\{e_i\} = x_i$ and the distribution of e_i is the same as that of θ_i, with the expected value shifted by x_i. Alternatively, if θ_i represents relative element spreads, $e_i = x_i (1 + \theta_i)$, where $E\{\theta_i\} = 0$. Therefore, $E\{e_i\} = x_i$; $\text{var}\{e_i\} = x_i^2\ \text{var}\{\theta_i\}$, i.e., the standard deviations σ_{ei} and $\sigma_{\theta i}$ are related: $\sigma_{ei} = x_i\ \sigma_{\theta i}$, or $\sigma_{ei}/E\{e_i\} = \sigma_{ei}/x_i = \sigma_{\theta i}$. This means that with fixed $\sigma_{\theta i}$, the relative standard deviation of e_i is constant, as it is often the case in practice, where standard deviations of RLC elements are described in percents of the element nominal values. Both forms of e_i indicate that each e_i is directly associated with its corresponding θ_i and x_i, and that there is one-to-one mapping between e_i and θ_i. These dependencies are important, since many of the yield optimization algorithms were developed assuming that $e_i = x_i + \theta_i$. A typical p.d.f. for discrete elements is shown in Figure 5.1, before "binning" into different categories (the whole curve) and after binning into ±1%, ±5%, and ±10% resistors (the shaded and white areas: e.g., the ±10% resistors will have the distribution characterized by the external shaded areas, with a ±5% "hole" in the middle).

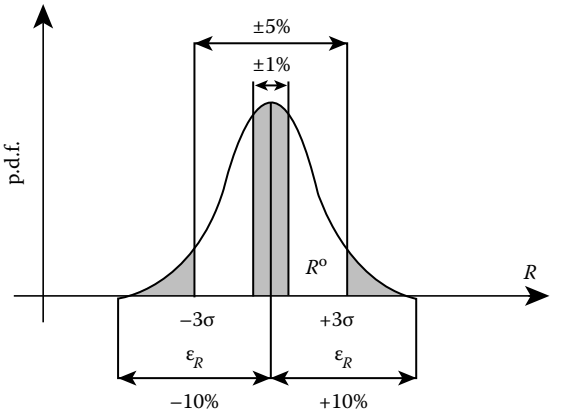

FIGURE 5.1 Typical probability density function (p.d.f.) of a discrete resistor before and after "binning."

Usually, passive discrete elements are statistically independent* as shown in Figure 5.2.

* But, for instance, if R_L (R_C) is a loss resistance of an inductor L (capacitor C) then L and R_L (C and R_C) are correlated.

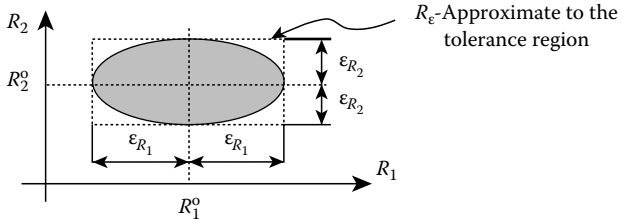

FIGURE 5.2 Level set (cross section) of a p.d.f. function for two discrete resistors after manufacturing.

The cross-section shown is often called a level set, a norm body [12], or a tolerance body. It is defined as a set of element values for which the element p.d.f. is larger than a prescribed value.

This value is selected such that the probability of the element values falling into the tolerance body is equal to e.g., 95%, (i.e., the tolerance body represents 95% of the entire element population). Alternatively, the tolerance body can be represented as a (hyper-) box shown in the figure, with the sides equal to $2\varepsilon_i$ ($2\varepsilon_{R_i}$ in the figure), called the tolerance region and denoted by R_ε. Figure 5.2 also shows that the dependence $e_i = x_i + \theta_i$ is equivalent in this case to $R_i = R_{\mathrm{NOM},i} + \Delta R_i$, where $x_i = R_{\mathrm{NOM},i}$; $\theta = \Delta R_i$).

The second part of e is composed of the parameters representing active device (e.g., BJT, MOS) model parameters. They are usually strongly correlated within each device model (same applies to ICs), but typically, no correlations occur between device model parameters of different devices. Each of the device model parameters e_d is related through a specific model $e_\mathrm{d} = e_\mathrm{d}(x, \theta)$ to the vector θ parameters,* representing principal random variables, which are themselves often some device model parameters (such as oxide thickness t_{ox} of MOS transistors), and/or are some dummy random variables. For example, in the BJT empirical statistical model introduced in [3], the base transient time T_n is modeled as follows:

$$e_\mathrm{d} = e_\mathrm{d}(x_\mathrm{d}, \theta_1, \theta_2) = T_n(\beta, X_{r5}) = \left(a + \frac{b}{\sqrt{\beta}}\right)(1 + cX_{r5}) \tag{5.2}$$

i.e., it is the function of the current gain $\theta_1 = \beta$ (the principal random variable, affecting the majority of the BJT model parameters) and $\theta_2 = X_{r5}$ (a dummy random variable, uniformly distributed in the interval $[-1, 1]$ independent of β and having no physical meaning); a, b, and c are empirically selected constants (Figure 5.3b).

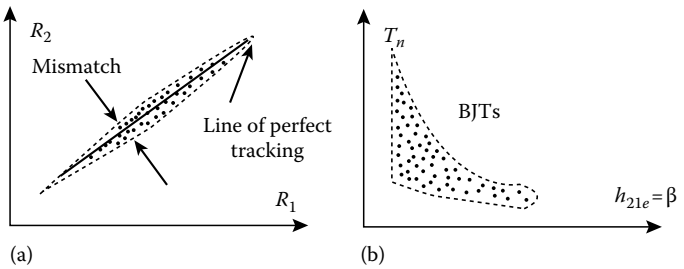

FIGURE 5.3 Dependencies between passive IC elements and between device model parameters: (a) linear, between two resistors R_1 and R_2 and (b) nonlinear, between the base transit time T_n and the current gain $h_{21e} = \beta$ for bipolar junction transistors.

* Observe that these models are parameterized by x: e.g., the MOS transistor model parameters e_i will also depend on the device length L and width W.

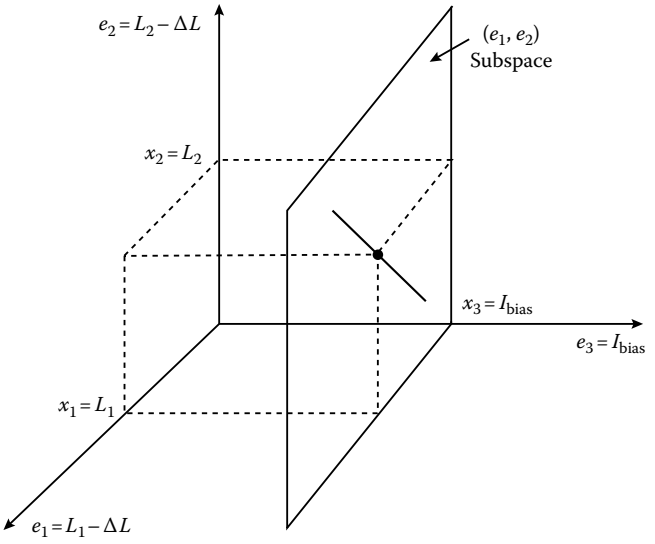

FIGURE 5.4 Singular distribution $f_e(e_1, e_2, e_3)$ in three-dimensional e-space, represented by the thick line in the (e_1, e_2)-subspace (plane). This is due to the perfect matching of $\Delta L \equiv \Delta L_1 \equiv \Delta L_2$ values.

In the discrete circuit case, each designable parameter x_i has a random variable θ_i added to it (i.e., x and θ in the same space in which the p.d.f. $f_e(e) = f_\theta(x + \theta)$ is defined.

For integrated circuits, the passive elements (R's, C's), active dimensions (such as Ws and Ls for MOS transistors), and other transistor model parameters are strongly correlated (see Figure 5.3a). Because of this, the distribution of θ parameters is limited to a certain subspace of the entire e-space, i.e., $f_e(e(x, 0))$ is singular, and the formula $e_i = x_i + \theta_i$ does not hold. As an example, consider a subset of all e parameters representing the gate lengths $x_1 = L_1$, $x_2 = L_2$ (designable parameters) of two MOS transistors T_1, T_2 and an independent designable parameter $x_3 + I_{bias}$, representing the transistor bias current. Assume also (as is frequently the case) that $\theta \equiv \Delta L$, the technological gate length reduction (a common random parameter) changes the same way for T_1 and T_2, i.e., there is ideal matching of $\Delta L \equiv \Delta L_1 = \Delta L_2$,* i.e., $e_1 + x_1 + \theta + L_1 - \Delta L$, $e_2 + x_2 + \theta + L_2 - \Delta L$, $e_3 + x_3 + I_{bias}$. The only random variable in this model is ΔL, as shown in Figure 5.4. The p.d.f. $f_e(e)$ is in this case defined only in the one-dimensional subspace of the e-space (i.e., all the realization of the vector e are located on the thick line in Figure 5.4). The major consequence of this difference is that, in general, many yield optimization algorithms developed for discrete circuits (i.e., using the explicit assumption that $(e_i = e_i + \Delta_i)$, cannot be used for IC design.

Statistical modeling for ICs is concerned with representing global variations and parameter mismatches† occurring between different devices on the same chip. In the last example, mismatch can be modeled by two additional independent local mismatch variables ε_{L_1}, ε_{L_2}, representing small random local deviations of ΔL_1 and ΔL_2 from the ideal value ΔL, i.e., $e_1 + x_1 + \theta + \varepsilon_i + L_1 - \Delta L - \varepsilon_{L_1}$, $e_2 + x_2 + \theta + \varepsilon_i + L_2 - \Delta L - \varepsilon_{L_2}$. With this model, ΔL represents a global or common factor, affecting both channel lengths, and ε_{L_1}, ε_{L_2}, represented *specific* (local) variations. The model just presented is a simple (simple, one-factor) case of the Factor Analysis (FA) [20] model of correlations between e_1 and e_2.

In [8], FA analysis, together with Principal Component Analysis (PCA)‡ and nonlinear regression were used for the determination of linear and nonlinear statistical models for CMOS transistor parameters. The following common factors $F_1, \ldots, F_8$ were identified: t_{ox} (oxide thickness common to n- and p-type

* Such a model is commonly used for digital ICs [9], since it is of sufficient accuracy for digital applications.

† Element mismatches are very important for analog ICs.

‡ Principal component analysis involves coordinate rotation and leads to *uncorrelated principal components*.

transistors) $N_{SUB,n}$, $N_{SUB,p}$ (n- and p-type substrate doping), ΔL_n, ΔL_p (length reduction), ΔW_n, ΔW_p (width reduction—for narrow transistors only), and XJ_p (p-type junction depth). These variables were causing about 96% of the total variability of all parameters. All the other CMOS transistor model parameters were related to the $F_1, \ldots, F_8$ factors through quadratic (or linear in simplified models) regression formulas. The resulting models were able to represent—with a high level of accuracy—the strong nonlinear statistical dependencies existing between some model parameters.

The major theoretical and empirical findings in mismatch modeling are the device area (or length) and distance dependencies of the mismatch level (see [23], where references to other authors can be found). For example, the variance of the difference $e_1 - e_2$ between two MOS transistor model parameters e_1, e_2 is modeled as [3,9]

$$\text{var}(e_1 - e_2) = \frac{a_p}{2W_1L_1} + \frac{a_p}{2W_2L_2} + s_p^2 d_{12}^2 \tag{5.3}$$

where

W_1, L_1, W_2, and L_2 are widths and lengths of the two transistors
d_{12} is the distance between the transistor centers
a_p and s_p are empirical coefficients adjusted individually for each model parameter

Using this model together with PCA, and introducing other concepts, two quite sophisticated linear statistical models in the form $e_i = e(x_i, \theta, W_i, L_i, d)$ were proposed in [23]. They include the transistor separation distance information, collected into the vector d in two different forms. The models, constructed from on-chip measured data, were used for practical yield optimization. θ parameters were divided into two groups: a group of correlated random variables responsible for the common part of each parameter variance and correlations between model parameters of each *individual* transistor, and the second group of local (mismatched related) random variables, responsible for mismatches between different transistors. Additional dependencies, related to transistor spacing and device area related coefficients, maintain proper mismatch dependencies.

5.3.3 Acceptability Regions

The acceptability region A_y is defined as a region in the space of performance parameters y (y-space), for which all inequality and equality constraints imposed on y are fulfilled. In the majority of cases, A_y is a hyperbox, i.e., all the constraints are of the form: $S_j^L \le y_j \le S_j^U$; $j = 1, \ldots, m$, where S_j^L and S_j^U are the (designer defined) lower and upper bounds imposed on y_j, called also designer's specifications. More complicated specifications, involving some relations between y_i parameters, or S_j^L and S_j^U bounds can also be defined.

For the simplest case of the y-space box-constraints, the acceptability region A in the e-space is defined as such a set of e vectors in the c-dimensional space, for which all inequalities $S_j^L \le y_j(e) \le S_j^U, j = 1, \ldots, m$, are fulfilled. Illustration of this definition is shown in Figure 5.5. It can be interpreted as the mapping of the acceptability region A_y from the y-space into the e-space. Acceptability regions A can be very complicated: they can be nonconvex and can contain internal infeasible regions (or "holes"), as shown in Figure 5.6 for a simple active RC filter [25].

For discrete circuits, A is normally represented in the e-space, due to the simple relationship $e_i = x_i + \theta_i$ (or $e_i = x_i(1 + \theta_i)$), between e_i, x_i, and θ_i. For integrated circuits, e is related to x and θ through the statistical model, x and θ are in different spaces (or subspaces), the dimension of θ is lower than the dimension e, and the p.d.f. $f_e(e)$ is singular and usually unknown in analytic form. For these reasons, it is more convenient to represent A in the joint (x, θ)-space, as shown in Figure 5.7. For a fixed x, A can be defined in the θ-space and labeled as $A\theta\ (x)$, since it is parameterized by the actual values of x, as shown in Figure 5.7. The shape and location of $A\theta\ (x)$ change with x, as shown. For a fixed x, $A\theta\ (x)$ is defined as

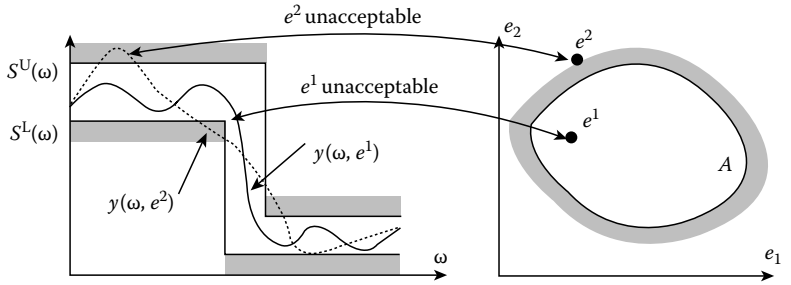

FIGURE 5.5 Illustration of the mapping of the $S^L(\omega)$, $S^U(\omega)$ constraints imposed on $y(\omega, e)$ into the e-space of circuit parameters.

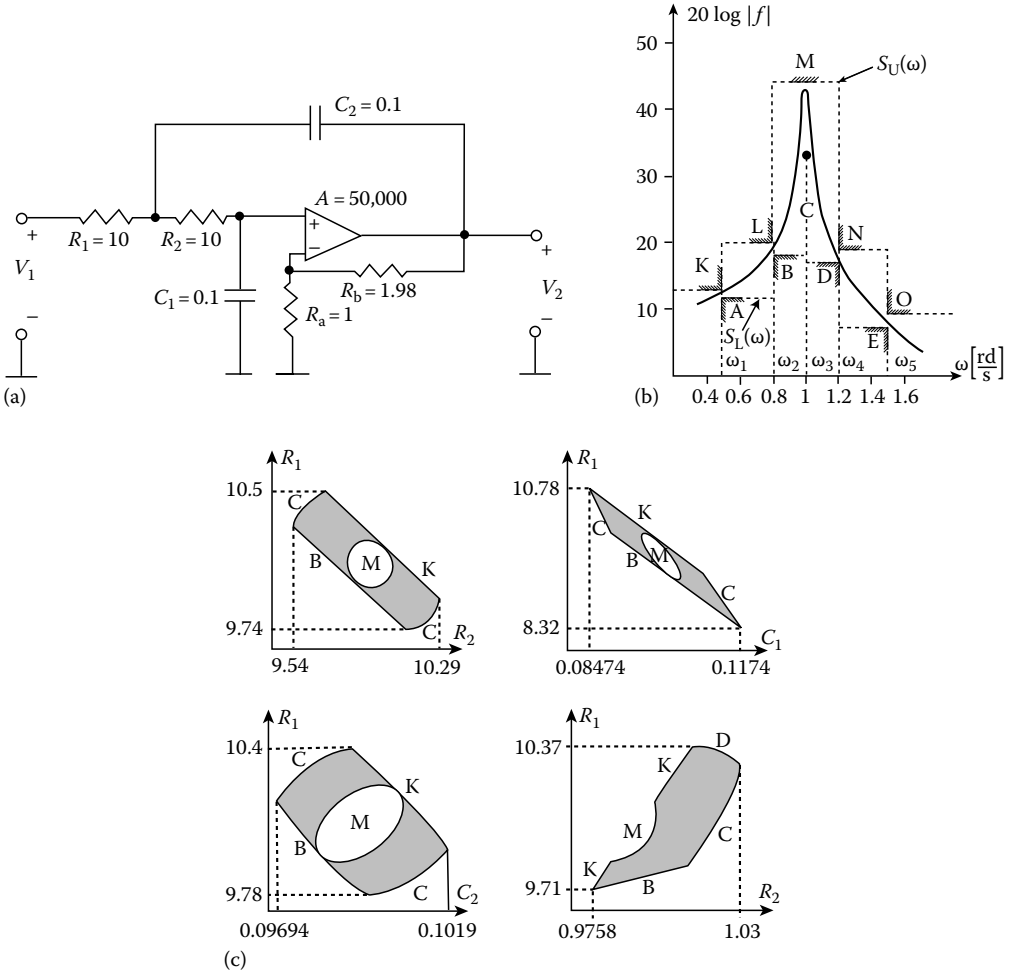

FIGURE 5.6 (a) Sallen–Key active filter, (b) lower and upper bounds imposed in the filter frequency response, and (c) two-dimensional cross sections of the acceptability region A. Capital letters in (b) and (c) indicate the correspondence of constraints to the boundaries of A.

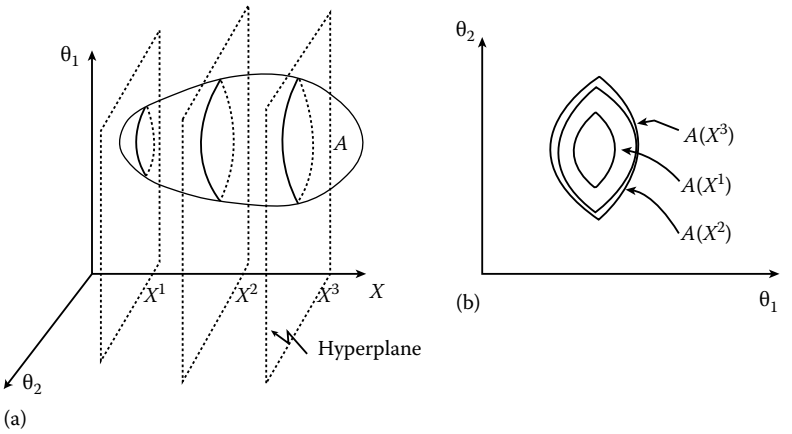

FIGURE 5.7 Acceptability region for integrate circuits: (a) in the joint (x, θ)-space and (b) in the θ-space, parameterized by different values of x. The hyperplanes shown represent t-dimensional subspaces of θ parameters.

such a region in the t-dimensional θ space, for which all the inequalities $S_j^L \leq y_j(e(x, \theta)) \leq S_j^U; j = 1, \ldots, m$, are fulfilled.

In order to recognize if a given point $e(x, \theta)$ in the circuit parameter space belongs to A [or $A\theta$ (x)], an indicator function $\phi(\cdot)$ is introduced:

$$\phi(e(x,\theta)) = \begin{cases} 1 & \text{if } e(x,\theta) \text{ belongs to } A \text{ (a successful, or ''pass point'')} \\ 0 & \text{otherwise (a ''fall point'')} \end{cases} \tag{5.4}$$

A complementary indicator function $\phi_F(e(x, \theta)) = \phi(e(x, \theta)) - 1$ is equal to 1 if $e(x, \theta)$ does not belong to A and 0 otherwise. Both indicator functions will be used in what follows.

5.3.4 Methods of Acceptability Region Approximation

Except for some simple cases, the acceptability region A in the e (or the joint (x, θ))-space is unknown and it is impossible to fully define it. For yield optimization and other statistical design tasks and implicit or explicit knowledge of A and/or its boundary is required. If only the points belonging to A are stored, this can be considered a point-based ''approximation'' to A. Some of the point-based methods are Monte Carlo-based design centering, centers of gravity method, point-based simplicial approximation and yield evaluation (see below), ''parametric sampling-based'' yield optimization [36], yield optimization with ''reusable'' points [39], and others.

The acceptability segment-based method of the A-region approximation was called in [27] a one-dimensional orthogonal search (ODOS) technique leading to several yield optimization methods [25,46]. Its basic principle is shown in Figure 5.8b, where line segments passing through the points e^i randomly sampled in the e-space and parallel to the coordinate axes, are used for the approximation of A. ODOS is very efficient for large linear circuits, since the intersections with A can be directly found from analytical formulas. The two-dimensional cross-sections of A, shown in Figure 5.6, were obtained using this approach. The surface integral-based yield and yield gradient estimation and optimization method proposed in [13] also use the segment approximation to the boundary of A. A variant of this method is segment approximation in one direction, as shown in Figure 5.8c. This method was then extended to plane and hyperplane approximation to A in [42] (Figure 5.8d). In another approach, called ''radial exploration of space'' in [54], the segments approximating A are in radial directions, as shown in Figure 5.8e.

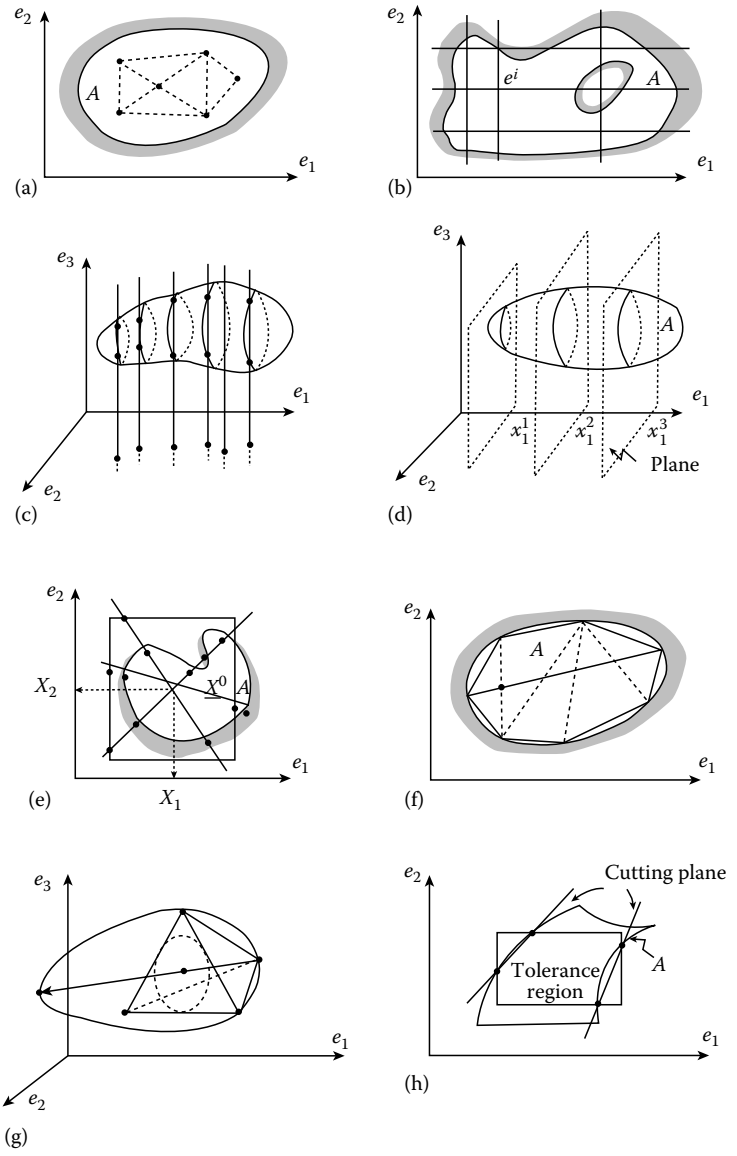

FIGURE 5.8 Various methods of acceptability region approximation: (a) ''point-based'' simplicial approximation to the A-region, (b) segment approximation to A in all directions along e_i axes, (c) segment approximation to A in one direction, (d) (hyper)-plane approximation A, (e) segment approximation to A in radial directions, (f) simplicial approximation to A in two dimensions, (g) simplicial approximation to A in three dimensions, and (h) cutting-plane approximation to A. *Note:* All A-regions are shown in e-space, for the discrete case, i.e., for $e = x + \theta$.

The techniques just described rely on the fact that ''segment'' yields (calculated in the e subspace) can be, for some special cases [27,54], calculated more efficiently than using a standard Monte Carlo method. This leads to higher efficiency and accuracy of yield estimation, in comparison to the point-based yield estimation.

The simplicial approximation proposed in [10] (described in more detail in Section 4.4), is based on approximating the boundary of A in the e-space, by a polyhedron, i.e., by the union of those partitions of a set of c-dimensional hyperplanes which lie inside of the boundary of A or on it. The boundary of

A-region is assumed to be convex (see Figure 5.8f and g). The approximating polyhedron is a convex hull of points. Simplicial approximation is obtained by locating points on the boundary of A, by a systematic expansion of the polyhedron. The search for next vertex is always performed in the direction passing through the center of the largest face of the polyhedron already existing. In the MC-oriented "point-based" version of the method [11] (see Figure 5.8a), subsequent simplicial approximations $\tilde{A}_i$ to A are not based on the points located on the boundary of A (which is computationally expensive) but on the points e^i belonging to A already generated during the MC simulation; after each new point is generated, it is checked if e^i belongs to $\tilde{A}^{i-1}$, (where $\tilde{A}^{i-1}$ is the latest simplicial approximation to A); if yes, the sampled point is considered successful *without* performing the circuit analysis; if e^i does not belong to $\tilde{A}^{i-1}$ and the circuit analysis reveals that e^i belongs to A, the polyhedron is expanded to include this point. Several versions of this general approach, leading to the substantial reduction of the computational effort of yield estimation, are described in the original article.

The method of "cuts" proposed in [5], creates a "cutting-plane" approximation to A in the corners of the tolerance region R_ε assumed to be a hypercube, as shown in Figure 5.8h. The method was combined with discretization of the p.d.f. $f_e(e)$ and multidimensional quadratic approximation to circuit constraints, leading to simplified yield and yield derivative formulas and yield optimization for arbitrary statistical distributors [1].

5.3.5 Manufacturing (Parametric) Yield

Manufacturing yield is defined as the percentage of the total number of products manufactured that fulfill both functional and parametric performance requirements.* Functional circuit performance is the circuit ability to perform desired functions. Catastrophic (or "hard") circuit failures (such as shorts or open circuit faults caused, e.g., by particular wafer contamination) will completely eliminate some of the circuit functions, thus decreasing the part of the overall yield called functional yield. Parametric circuit performance is a measure of circuit quality and is represented by measurable performance functions such as gain, delay, bandwidth, etc., constituting the y-parameter vector. The part of yield related to parametric circuit performance is called parametric yield and is the only type of yield considered in what follows. The actual manufacturing yield is smaller than the parametric yield, since it is equal to the product of the functional or parametric yield [12]. In general, parametric yield is used during circuit electrical design, while functional yield is used during circuit layout design.† Both are used to predict and optimize yield during circuit design.

Parametric yield, therefore, is equal to the percentage of circuits that fulfill all parametric requirements, i.e., it is equal to the probability that e belongs to the acceptability region A. So, it can be calculated as the integral of the p.d.f. of e, $f_e(e)$ over A, for a given vector of designable parameters x. Since $e = e(x, \theta)$ is a function of x, then e, $f_e(e) = f_e(e, x)$ (e.g., $E\{e\}$ and $\mathrm{var}\{e\}$ can be both functions of x). Therefore,‡

$$Y(x) = P\{e \in A\} = \int_A f_e(e, x)\mathrm{d}e = \int_{R^c} \phi(e) f_e(e, x)\mathrm{d}e = E_e\{\phi(e)\} \tag{5.5}$$

where

$P\{\cdot\}$ denotes probability

$\phi(e)$ is the indicator function (Equation 5.4)

$E_e\{\cdot\}$ is expectation with respect to the random variable e

---

* For more detailed yield definitions involving different types of yield, e.g., design yield, wafer yield, probe yield, processing yield, etc., see [12].

† Layout design (i.e., transistor spacing, location, size) has also influence on parameter variations and mismatch, as discussed in Section 5.3.

‡ Multiple integration performed below is over the acceptability region A, or over the entire c-dimensional space R^c of real numbers. ε means "belongs to."

The above formula is useful if $f_e(e, x)$ is a nonsingular p.d.f., which is usually the case for discrete circuits, for which $e_i = x_i + \theta_i$, (or $e_i = x_i\ (1 + \theta_i)$). In a general case, however (e.g., for integrated circuits), the p.d.f. $f_e(e, x)$ is not known, since it has to be obtained from a complicated transformation $e = e\ (x, \theta)$, given the p.d.f. $f_\theta(\theta)$ of θ. Therefore, it is more convenient to integrate directly in the θ-space. Since parametric yield is also the probability that θ belongs to $A\theta(x)$ (the acceptability region in the θ-space for any fixed x), yield becomes

$$\begin{aligned} Y(x) = P\{\theta \in A_\theta(x)\} &= \int_{A_{\theta(x)}} f_\theta(\theta)\mathrm{d}\theta \\ &= \int_{R^t} \phi(e(x,\theta))f_\theta(\theta)\mathrm{d}\theta = E_\theta\{\phi(e(x,\theta))\} \end{aligned} \tag{5.6}$$

Equation 5.6 is general, and is valid for both discrete and integrated circuits. An unbiased estimator of $E_\theta\{\rho(e(x, \theta))\} + E_\theta\{\rho(\theta)\}$ (for fixed x), is the arithmetic mean, based on N points θ^i, sample in θ-space with the p.d.f. $f_\theta(\theta)$, for which the function $\phi(\theta^i)$ is calculated (this involves circuit analyses). Thus, the yield estimator $\hat{Y}$ is expressed as

$$\hat{Y} = \frac{1}{N}\sum_{i=1}^{N} \phi\left(\theta^i\right) = \frac{N_s}{N} \tag{5.7}$$

where N_S is the number of successful trials, i.e., the number of circuits for which $\theta \in A\theta\ (x)$ (all circuit constraints are fulfilled). Integral of Equation 5.6 is normally calculated using Monte Carlo (MC) simulations [34] and Equation 5.7. The MC method is also used to determine statistical parameters of the p.d.f. $f_y(y)$ of $y = y(\mathrm{x}, \theta)$. In order to sample the θ parameters with p.d.f. $f_\theta(\theta)$, special numerical procedures, called random number generators, are used. The basic MC algorithm is as follows:

1. Set $i = 0$, $N_S = 0$ (i is the current index of a sampled point and N_S is the total number of successful trials).
2. Substitute $i = i + 1$, generate the ith realization of $\theta : \theta^i = (\theta_1^i, \ldots, \theta_t^i)$, with the p.d.f. $f_\theta(\theta)$.
3. Calculate the ith realization of $y^i = (y_1^i, \ldots, y_m^i) = y(x, \theta^i)$, with the aid of an appropriate circuit analysis program, and store the results.
4. Check if all circuit constraints are fulfilled, i.e., if $S^L \leq y^i \leq S^U$; if yes, set $N_S = N_S + 1$.
5. If $i \neq N$, go to (2); otherwise, find the yield estimator $\hat{Y} = N_S/N$. If needed, find also some statistical characteristics of y-parameters (e.g., create histograms of y, find statistical moments of y, etc.).

To generate θ^i's with the p.d.f. $f_\theta(\theta)$, the uniformly distributed random numbers are generated first and then transformed to $f_\theta(\theta)$. The most typical random number generator (r.n.g.), generating a sequence of pseudorandom, uniformly distributed integers θ_k in the interval $[0, M]$ (M is an integer), is a multiplicative r.n.g., using the formula [34]: $\theta_{k+1} = c\theta_k \pmod M$ where c is an integer constant and $\theta_k \pmod M$ denotes a remainder from dividing θ_k by M. The initial value θ_0 of θ_k is called the ''seed'' of the r.n.g., and, together with c, should usually be chosen very carefully, to provide good quality of the random sequence generated. Several other r.n.g.s are used in practice [34]. The r_k numbers in the [0, 1) interval are obtained from $r_k = \theta_k/M$. Distributions other than uniform are obtained through different transformations of the uniformly distributed random numbers, such as the inverse of the cumulative distribution function [34]. To generate correlated normal variables $\theta = (\theta_1, \ldots, \theta_n)$, with a given covariance matrix K^θ, the transformation $\theta = CZ$ is used, where $Z = (z_1, z_2, \ldots, z_n)$ is the vector of independent normal variables with $E\{z_i\} = 0$, $\mathrm{var}\{z_i\} = 1$, $i = 1, \ldots, n$, and C is a matrix obtained from the so-called

Cholesky decomposition of the covariance matrix K^{θ} such that $K^{\theta} = CC^{t}$ where t denotes transposition. C is usually lower or upper triangular and can be easily constructed from a given matrix K^{θ} [34].

The yield estimator $\hat{Y}$ is a random variable, since performing different, independent MC simulations, one can expect different values of $\hat{Y} = N_S/N$. As a measure of $\hat{Y}$ variations, variance or standard deviation of $\hat{Y}$ can be used. It can be shown [7] that the standard deviation of $\hat{Y}$, is equal to $\sigma_{\hat{Y}} = Y(1-Y)/N$, i.e., it is proportional to $1/\sqrt{N}$ Hence, to decrease the error of $\hat{Y}$ 10 times, the number of samples has to be increased 100 times. This is a major drawback of the MC method. However, the accuracy of the MC method (measured by $\sigma_{\hat{Y}}$) is independent of the dimensionality of the θ-space, which is usually a drawback of other methods of yield estimation. One of the methods of variance reduction of the $\hat{Y}$ estimator is importance sampling [7,34,39]. Assume that instead of sampling θ with the p.d.f. $f_\theta(\theta)$, some other p.d.f. $g_\theta(\theta)$ is used. Then,

$$Y = \int_{R'} \phi[e(\theta)] \frac{f_\theta(\theta)}{g_\theta(\theta)} g_\theta(\theta)\, d\theta \equiv E\left\{ \phi[e(\theta)] \frac{f_\theta(\theta)}{g_\theta(\theta)} \right\} \tag{5.8}$$

where $g_\theta(\theta) \neq 0$ if $\phi(\theta) = 1$. Yield Y can now be estimated as

$$\tilde{Y} = \frac{1}{N} \sum_{i=1}^{N} \phi\left[e(\theta^i)\right] \frac{f_\theta(\theta^i)}{g_\theta(\theta^i)} \tag{5.9}$$

sampling N points θ^i with the p.d.f. $g_\theta(\theta)$. The variance of this estimator is var $\{\tilde{Y}\} = E\{[\phi(\theta)/g_\theta(\theta) - Y]^2\}/N$. If it is possible to choose $g_\theta(\theta)$ such that it mimics (or is similar to) $\phi(\theta)f_\theta(\theta)/Y$, the variability of $[\phi(\theta)f_\theta(\theta)/g_\theta(\theta) - Y]$ is reduced, and thus the variance of $\hat{Y}$. This can be accomplished if some approximation to $\phi(\theta)$ i.e., to the acceptability region A is known. Some possibilities of using importance sampling techniques were studied, e.g., in [16]. One of such methods, called parametric sampling was used in [36], and other variants of important sampling were used in [2,40] for yield optimization. There are several other methods of variance reduction, such as the method of control variates, correlated sampling, stratified sampling, antithetic variates, and others [7,34,39]. Some of them have been used for statistical circuit design [7,39].

5.4 Statistical Methods of Yield Optimization

The objective of the yield optimization is to find a vector of designable parameters $x = x_{opt}$, such that $Y(x_{opt})$ is maximized. This is illustrated in Figure 5.9 for the case of discrete circuits where $e_1 = x_1 + \theta_1$, $e_2 = x_2 + \theta_2$.* Figure 5.9a corresponds to low initial yield proportional to the weighted (by the p.d.f. $f_e(e)$) area (hypervolume, in general), represented by the dark shaded part of the tolerance body shown. Figure 5.9b corresponds to optimized yield, obtained by shifting the nominal point (x_1, x_2) to the vicinity of the geometric center of the acceptability region A. Because of this geometric property, approximate yield maximization can often be accomplished using methods called deterministic or geometrical design centering. They solve the yield maximization problem indirectly (since yield is not the objective function optimized), using a geometrical concept of maximizing the distance from x_{opt} to the boundary of A. The best known method of this class [10,12] inscribes the largest hypersphere (or other norm-body) into the simplicial approximation to the boundary of A, shown in Figure 5.8g. This approach is described in more detail in Section 4.4, together with other geometrical design centering methods.

A class of methods known as "performance-space oriented design centering methods" is also available. These methods attempt to maximize the scaled distances of the performances y_j from the lower S_j^L

* Alternatively, the model $e_i = x_i(1 + \theta_i)$ can be used, in which case the size of the tolerance body (see Section 5.3) will increase proportionally to x_i.

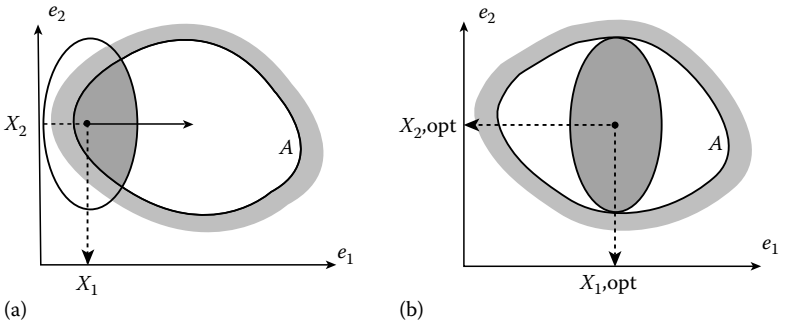

FIGURE 5.9 Interpretation of yield maximization for discrete circuits: (a) initial (low) yield and (b) optimized yield.

and/or upper S_j^U specifications, leading to approximate design centering. Some of these methods are also used for variability minimization and performance tuning, which are the most important tenets of design for quality [30], to be briefly discussed later in this section.

The major feature of statistical yield optimization methods, referred to as statistical design centering, is statistical sampling in either θ-space only or in both θ and x spaces. Sampling can be also combined with some geometrical approximation to the A-region, such as the segment, or radial-segment approximation.

In dealing with various statistical methods of yield optimization, the type of the transformation $e = e(x, \theta)$ from the θ-space to the circuit-parameter space e, has to be considered. The early, mostly heuristic yield optimization methods were based on the simple additive model $e_i = x_i + \theta_i$, valid for discrete circuits. Because of that, the majority of these methods cannot be used for IC or manufacturing process optimization, where θ and x in different spaces, or subspaces, and the distribution of θ is defined over some subspace of the e-space, i.e., it is singular.

The type of the statistical yield optimization algorithm to be used in practice strongly depends on the type of the circuit to be considered and the information available, namely: whether the transformation $e = e(x, \theta)$ is a simple one: $e_i = x_i + \theta_i$ (or $e_i = x_i(1 + \theta_i)$)(for discrete circuits) or general: $e = e(x, \theta)$ (for ICs); whether the values of $\gamma_j(x, \theta)$ for given x and θ only or also the derivatives of y_j with respect to x_k and/or θ_s are available from the circuit simulator; whether some approximation $\tilde{y}(x, \theta)$ to $y(x, \theta)$ is available—either with respect to (w.r.t.) θ only (for a fixed x), or w.r.t. both x and θ; whether the analytical form of $f_\theta(\theta)$ is known and $f_\theta(\theta)$ is differentiable w.r.t. θ, or only samples θ^i of θ are given (obtained from a numerical algorithm or from measurements), so, analytical forms of $f_\theta(\theta)$ and its derivatives w.r.t. θ are not known.

Different combinations of the cases listed above require different optimization algorithms. The more general a given algorithm is, the largest number of cases it is able to cover, but simultaneously it can be less efficient than specialized algorithms covering only selected cases. An ideal algorithm would be the one that is least restrictive and could use the minimum necessary information, i.e., it could handle the most difficult case characterized by the general transformation $e = e(x, \theta)$, with the values of $y = y(x, \theta)$ only available (generated from a circuit simulator) but without derivatives, no approximation to $y(x, \theta)$ available, and unknown analytic form of $f_\theta(\theta)$ (only the samples of θ given). Moreover, under these circumstances such an algorithm should be reasonably efficient even for large problems, and with the presence of some additional information, should become more efficient. The selected yield optimization algorithms discussed below fulfill the criteria of the algorithm ''optimality'' to a quite different level of satisfaction. It has to be stressed that due to different assumptions made during the development of different algorithms and the statistical nature of the results, an entirely fair evaluation of the actual algorithm efficiency is very difficult, and is limited to some specific cases only. Therefore, in what follows, no algorithm comparison is attempted.

5.4.1 Large-Sample vs. Small-Sample Methods

Yield optimization is concerned with the maximization of the regression function $Y(x) = E_\theta\{\phi(x, \theta)\}$ with respect to (w.r.t.) x (see Equation 5.6). In solving general problems of this type, $\phi(\cdot)$ is replaced by an arbitrary function $w(\cdot)$. Large-sample methods of optimizing $E_\theta\{w(x, \theta)\}$ calculate the expectation (average) of w (and/or its gradient) w.r.t. θ for each $x^0, x^1, x^2, \ldots$ from a large number of θ^i samples. Therefore, the averages used in a specific optimization procedure are relatively accurate, following to take relatively large steps $x^{k+1} - x^k$. On the other hand, small-sample methods use just a few (very often just one) samples of $w(x, \theta^i)$ for any given point x, and make relatively small steps in the x-space, but they utilize also a special averaging procedure, which calculates the average of w or its gradient over a certain number of steps. So, in this case, the averaging in θ-space and progression in the x-space are combined, while in the large-sample methods they are separated. Both techniques have proven convergence under certain (different) conditions. The majority of yield optimization methods belong to the large-sample category (but some can be modified to use a small number of samples per iteration). *A* class of small-sample yield optimization methods was proposed in [50] and is based on the well-known techniques of stochastic approximation [34], to be discussed later in this section.

5.4.2 Methods Using Standard Deterministic Optimization Algorithms

The most natural method of yield optimization would be to estimate the yields $Y(x^0), Y(x^1), \ldots$ from a large number of samples (as described in the previous section) for each $x^0, x^1, \ldots$ of the sequence $\{x^k\}$ generated by a standard, nonderivative deterministic search algorithm, such as the simplex method of Nelder and Mead, Powell, or other algorithms discussed in [14]. This is very appealing, since most of the conditions for algorithm's "optimality" are fulfilled: it would work for any $e = e(x, \theta)$ and only the values of $y = y(x, \theta)$ and the samples of θ would be required. However, if no approximation to $y = y(x, \theta)$ was available, the method would require tens of thousands of circuit analyses, which would be prohibitively expensive. Moreover, if the number of samples per iteration was reduced to increase efficiency, the optimizer would be receiving a highly noise-corrupted information leading to poor algorithm convergence or divergence, since standard optimization algorithms work poorly with noisy data (special algorithms, able to work under uncertainly—such as stochastic approximation algorithms—have to be used).

If some approximating functions $\hat{y} = \hat{y}(x^k, \theta)$ are available separately for each x^k, a large number of MC analyses can be cheaply performed, reducing the statistical error. In practice, such an approach is most often too expensive, due to the high cost of obtaining the approximating formulas, if the number of important θ parameters is large. The approximating functions $\hat{y}_{j(x,\theta)}$ for each y_j can be also created in the *joint* (x, θ) space [56,61]. In [45], an efficient new approximating methodology was created, highly accurate for a relatively large range of the x_i values. However, also in this case the dimension of the joint space (x, θ) cannot be too large, since the cost of obtaining the approximating functions $\hat{y}_{j(x,\theta)}$ for becomes itself prohibitively high. Because of these difficulties, several dedicated yield optimization methods have been developed, for which the use of function approximation is not required. Some of these methods are described in what follows.

5.4.3 Large-Sample Heuristic Methods for Discrete Circuits

These methods have been developed mostly for discrete circuits, for which $e_i = x_i + \theta_i$. Only $y^i = y(x + \theta^i)$ function values are required, for the sample θ^i obtained in an arbitrary way. Approximation in the e-space can be constructed to increase efficiency, but for discrete circuits the number of θ parameters can be large (proportional to the number of active devices, since no correlations between different devices exist), so the use of approximation is most often not practical. The most typical representative of this class is the centers of gravity method [39]. The method is based on a simple observation that if $\bar{x}_S$ is the center of gravity of "pass" points (as shown in Figure 5.10), defined as $\bar{x}_S = (x_A^1 + x_A^2 + \cdots + x_A^{N_A})/N_A$,

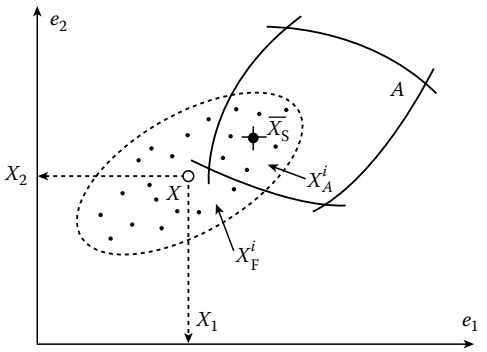

FIGURE 5.10 Interpretation of the original centers of gravity method.

where N_A is the number of points x_A^i falling into the A-region, then a step from x to $\bar{x}_S$ will improve yield. In [37], also the center of gravity of the "fail" points $\bar{x}_F = (x_F^1 + x_F^2 + \cdots + x_F^{N_F})/N_F$ was defined, and the direction of yield increase taken as going from $\bar{x}_F$ through $\bar{x}_A$, as shown in Figure 5.11. Moving in this direction with the step-size equal to $\mu(\bar{x}_S - \bar{x}_F)$, where $\mu \approx 0.2 - 2$ (often taken as $\mu = 1$) leads to a sequence of optimization steps, which is stopped if $\|\bar{x}_S - \bar{x}_F\|$ is less than a predefined small constant. This is based on the property (proved for a class of p.d.f.s in [43] that, under some conditions, at the yield maximum $\|\bar{x}_S - \bar{x}_F\| = 0$ (and $\bar{x}_S - \bar{x}_F = \hat{x}$ where $\hat{x}$ is the point of the yield maximum). It was also shown in [43] that for the normal p.d.f. $f_\theta(\theta)$ with zero correlations and all standard deviations $\sigma_{\theta_i} = \sigma_\theta$, $i = 1, \ldots, t$, equal, the "centers of gravity" direction coincides with the yield gradient direction. However, with correlations and σ_{θ_i}s not equal, the two directions can be quite different. Various schemes, aimed at the reduction of the total required number of analyses were developed based on the concepts of "reusable" points [39].

In [18,19] the original centers of gravity method was significantly improved, introducing a concept of "Gaussian adaptation" of the covariance matrix of the sampled points of θ^i, such that they (temporarily) adopt to the shape of the acceptability region, leading to higher (optimal) efficiently of the algorithm. The method was successfully used on large industrial design examples, involving as many as 130 designable parameters, not only for yield optimization, but also for standard function minimization.

The methods of "radial exploration of space" [54] (see Figure 5.8e) and one-dimensional orthogonal searches (ODOS) [26,27] (see Figure 5.8b and c) discussed in Section 5.3 in the context of Acceptability Region approximation, have also been developed into yield optimization methods: in the "radial exploration" case the asymmetry vectors were introduced, generating a direction of yield increase, and in the ODOS case using a Gauss–Seidel optimization method. Both techniques were especially efficient for linear circuits due to a high efficiency of performing circuit analyses in radial and orthogonal directions.

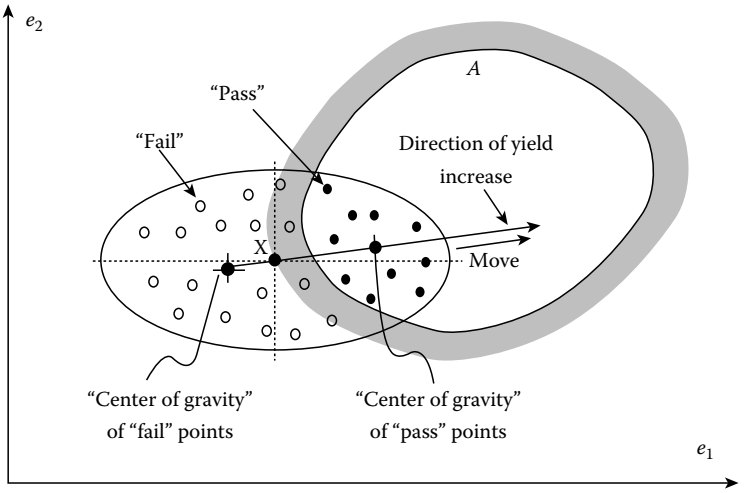

FIGURE 5.11 Interpretation of the modified centers of gravity method.

5.4.4 Large-Sample, Derivative-Based Methods for Discrete Circuits

For discrete circuits, the relation $e_i = x_i + \theta_i$ holds for a part of the entire e vector, so, x_i and θ_i are in the same space. Moreover, the p.d.f. $f_\theta(\theta)$ is most often known. Let x denote the vector of expectations $x \equiv E_\theta\{e(x,\theta)\}$, and $f_e(e, x)$ is the p.d.f. $f_\theta(\theta)$ transformed to the e-space (i.e., of the same shape as $f_\theta(\theta)$, but shifted by x). Then, from Equation 5.5, differentiating w.r.t. x_i, one obtains

$$\frac{\partial Y(x)}{\partial x_i} = \int_{R^n} \phi(e) \frac{\partial f_e(e,x)}{\partial x_i} \frac{f_e(e,x)}{f_e(e,x)} de = E_e\left\{\phi(e) \frac{\partial \ln f_e(e,x)}{\partial x_i}\right\} \tag{5.10}$$

where the equivalence $[\partial f_e(e,x)/f_e(e,x)]/\partial x_i \equiv \partial \ln f_e(e,x)/\partial x_i$ was used. Therefore, yield derivatives w.r.t. x_i can be calculated as the average of the expression in the braces of Equation 5.10, calculated from the same θ^i samples as those used for yield estimation, provided that the p.d.f. $f_e(e, x)$ is differentiable w.r.t x (e.g., the normal or log-normal p.d.f.s are differentiable, but the uniform p.d.f is not). Notice that instead of sampling with the p.d.f. $f_e(e, x)$, some other (better) p.d.f. $g_e(e, x)$ can be used as in the importance sampling yield estimation (see Equation 5.8). Then,

$$\frac{\partial Y(x)}{\partial x_i} = E_e\left\{\phi(e) \frac{\partial f_e(e,x)}{\partial x_i} \left[\frac{f_e(e,x)}{g_e(e,x)}\right]\right\} \tag{5.11}$$

where sampling is performed with the p.d.f. $g_e(e, x) \neq 0$. This technique was used in [2,36,51] (to be discussed next). Consider the multivariate normal p.d.f., with the positive definite covariance matrix K:

$$f_e(e) = \frac{1}{(2\pi)^{t/2}\sqrt{\det K}} \exp\left[-\frac{1}{2}(e-x)^{\mathrm{t}} K^{-1}(e-x)\right] \tag{5.12}$$

where $e - x \equiv \theta$ (discrete circuits), and det K is the determinant of K. Then, it can be shown that the yield gradient $\nabla_x Y(x)$ is expressed by

$$\nabla_x Y(x) = E\{\phi(e) K^{-1}(e-x)\} = Y(x) K^{-1}(\bar{x}_S - x) \tag{5.13}$$

where $\bar{x}_S$ is the center of gravity of "pass" points. If yield $Y(x)$ is a continuously differentiable function of x, then the necessary condition for the yield maximum is $\nabla_x y(\hat{x}) = 0$, which combined with Equation 5.13 means that the stationery point $\hat{x}$ for the yield function (the yield maximum if $Y(x)$ is also concave) is $\hat{x} = \bar{x}_S$, the center of gravity of the pass points. This result justifies (under the assumptions stated previously) the centers of gravity method of yield optimization (since its objective is to make $\hat{x} = \bar{x}_S \equiv \bar{x}_F$).

For $K = \mathrm{diag}\{\sigma_{e_1}^2, \ldots, \sigma_{e_t}^2\}$, i.e., with zero correlations, the yield gradient w.r.t. x is expressed as

$$\nabla_x Y(x) = E_e\left\{\phi(e)\left[\frac{\theta_1}{\sigma_{\theta_1}^2}, \cdots, \frac{\theta_t}{\sigma_{\theta_t}^2}\right]^{\mathrm{t}}\right\} \tag{5.14}$$

where $\sigma_{e_\theta} \equiv \sigma_{e_i}$ was used instead of σ_{e_i}. It can be readily shown that for all $\sigma_{\theta_i} = \cdots = \sigma_{\theta_t} = \sigma_\theta$ equal, the yield gradient direction coincides with the center-of-gravity direction [43] (Figure 5.12).

Since all higher-order derivatives of the normal p.d.f. exist, all higher order yield derivatives can also be estimated from the same sampled points θ^i, as those used for yield estimation. The yield gradient can also be calculated from the "fail" points simply using the $\phi_F(\cdot) = \phi(\cdot) - 1$ indicator function in all the expressions above. Then, the two resulting estimators can be combined as one joint average, as it was done in the $\bar{x}_S$, $\bar{x}_F$-based centers of gravity method. Actually, there exists an optimal weighted combination of the two estimators for any given problem, resulting in the minimum variability of the

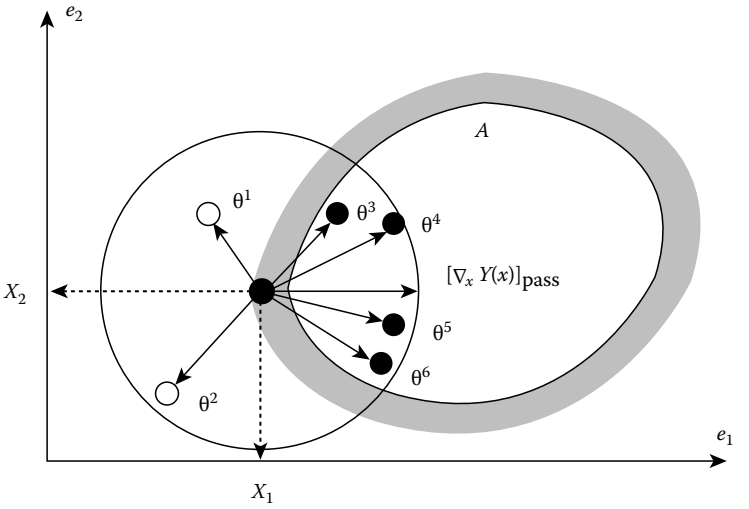

FIGURE 5.12 Interpretation of the yield gradient formula for normal p.d.f., with no correlations and $\sigma_{\theta 1} = \sigma_{\theta 2} = 1$. For the "pass" points (black dots) $[\nabla_x Y(x)]_{\text{pass}} \approx (\theta^3 + \theta^4 + \theta^5 + \theta^6)/4$; for the "fail" points (white dots) $[\nabla_x Y(x)]_{\text{fail}}$ $(-\theta^1 - \theta^2)/2$. The two estimators can be combined together (equal weighting assumed): $\nabla_x Y(x) = -\theta^1 - \theta^2 + \theta^3 + \theta^4 + \theta^5 + \theta^6)/6$. It is clearly seen that the two yield gradient estimators coincide with the center of gravity of the "pass" and "fail" points, respectively.

gradient, but it is difficult to precisely determine in practice. A general rule is that at the beginning of optimization, when x is far away from $\hat{x}$ (the optimal point), the yield gradient estimator based on the "pass" points should be more heavily weighted; the opposite is true at the end of optimization, when the "fail" points carry more precise gradient information. An interpretation of the yield gradient formula Equation 5.14 is shown in Figure 5.12, for the case where $\sigma_{\theta_1} = \sigma_{\theta_2} = 1$.

In the majority of practical applications of large-sample derivative methods, it was assumed that $f_e(e)$ was normal. A typical iteration step is made in the gradient direction:

$$x^{k+1} = x^k + \alpha_k \nabla_x Y(x^k) \tag{5.15}$$

where α_k is most often selected empirically, since yield maximization along the gradient direction is too expensive, unless some approximating functions $\hat{y} = \hat{y}(x + \theta)$ are used (normally, this is not the case for the class of methods discussed). Since the number of points θ^i sampled for each x^k, is large, the main difference between various published algorithms is how to most efficiently use the information already available. The three methods to be discussed introduced almost at the same time [2,36,51]), utilize for that purpose some form of importance sampling, discussed in Section 5.3.

In [36], a "parametric sampling" technique was proposed, in which the θ^i points were sampled with the p.d.f. $g_e(e, x)$ in a broader range than for the original p.d.f. (i.e., all the σ_{θ_i}'s were artificially increased). All points sampled were stored in a database, and the gradient-direction steps made according to Equation 5.15. The importance sampling-based gradient formula (Equation 5.11) was used in subsequent iterations within the currently available database. Then, a new set of points was generated and the whole process repeated.

The methods developed in [2,51] were also based on the importance sampling concept, but instead of using the gradient steps as in Equation 5.15, the yield gradient and Hessian* matrices were calculated

* Matrix of second derivatives.

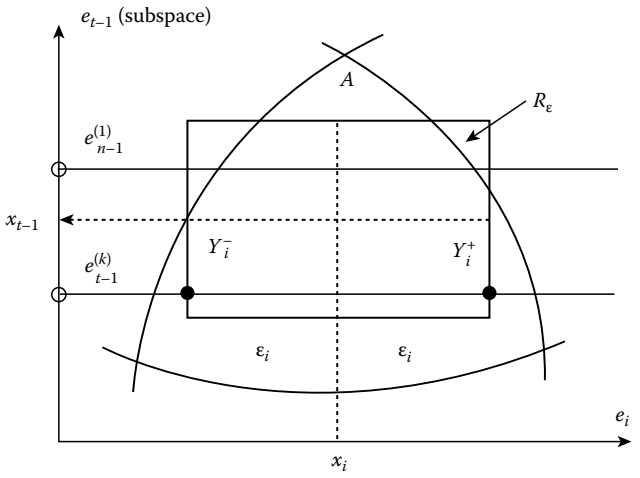

FIGURE 5.13 Yield and yield derivative estimation for uniform distribution. Y^+ and Y^- denote symbolically the "yields" calculated on the $(t-1)$-dimensional faces of the tolerance hypercube R_ε. The $e_{t-1}{}^{(k)}$ points are sampled in the $(t-1)$-dimensional subspaces of e_{t-1} parameters, with the uniform p.d.f. $f_{et-1}(e_{t-1})$.

and updated within a given database. Then, a more efficient Newton's direction was taken in [51] or a specially derived and efficient "yield prediction formula" used in [2]. In order to deal with the singularity or nonpositive definiteness of the Hessian matrix (which is quite possible due to the randomness of data and the behavior of $Y(x)$ itself), suitable Hessian corrections were implemented using different kinds of the Hessian matrix decomposition (Cholesky-type in [51] and eigenvalue decomposition in [2]).

As it was the case for the heuristic methods, the methods just discussed are relatively intensive to the dimensionality of x and θ spaces.

For the uniform p.d.f., centered at $e = x$ (Figure 5.13) and defined within a hyperbox $x_i - \varepsilon_i \le e_i \le x_i + \varepsilon$, $i = 1, \ldots, t$, where ε_i are element tolerances (see Figure 5.2), the yield gradient formula (Equation 5.10) cannot be used, since the uniform p.d.f. is nondifferentiable w.r.t. x_i. It can be shown [26,42,43] that yield can be calculated by sampling in the $(t-1)$-dimensional subspace of the e-space, represented by $e_{t-1} + (e_1, \ldots, e_{i-1}, e_{i+1}, \ldots, e_t)$ and analytical integration in the one-dimensional subspace e_i as shown in Figure 5.13. Using this approach, it can be further proved [43] that the yield derivatives w.r.t. x_i are expressed by

$$\frac{\partial Y(x)}{\partial x_i} = \frac{1}{2\varepsilon_i}\left(Y_i^+ - Y_i^-\right) \tag{5.16}$$

where $Y_i{}^+$, $Y_i{}^-$ are "yields" calculated on the faces of the $t-1$ tolerance hyperbox R_ε, corresponding to $x_i + \varepsilon_i$ and $x_i - \varepsilon_i$, respectively. Calculation of these "yields" is very expensive, so in [43]* different algorithms improving efficiency were proposed. In [53], an approximate method using efficient three-level orthogonal array (OA) sampling on the faces of R_ε was proposed, in which (due to specific properties of OAs) the same sample points were utilized on different faces (actually one-third of all sampled points were available for a single face). This has lead to substantial computational savings and faster convergence.

* In [43], general formulas for gradient calculation for *truncated* p.d.f.s were derived.

5.4.5 Large-Sample, Derivative-Based Method for Integrated Circuits

In this case, which is typical of IC yield optimization, yield gradient calculations cannot be performed in the *e*-space, as was the case for discrete circuits. In general, yield gradient could be calculated by differentiating the $\phi(e(x,\theta)) \equiv \phi(x,\theta)$ term in the θ-space-based yield formula (Equation 5.6), derived for the general case, where the general transformation $e = e(x,\theta)$ is used. Differentiation of $\phi(x, \theta)$ is, however, not possible in the traditional sense, since $\phi(x,\theta)$ is a nondifferentiable unit step function determined over the acceptability region *A*. One possible solution was proposed in [15]. In what follows, a related, but more general method proposed in [13] is discussed.

It was first shown in [13] that yield can be evaluated as a surface-integral rather than the volume-integral (as it is normally done using the MC method). To understand this, observe that yield can be evaluated by sampling in the $t-1$ subspace of the *t*-dimensional θ-subspace, as shown in Figure 5.14, evaluating "local yields" along the lines parallel to the θ_i axis, and averaging all the local yields.* Each "local yield" can be evaluated using the values of the cumulative (conditional) distribution function† along each parallel, at the points of its intersection with the boundary of the acceptability region *A*. This process is equivalent to calculating the surface integral over the value of the cumulative density function calculated (with appropriate signs) on the boundary of the acceptability region.

The next step in [13] was to differentiate the "surface-integral" based yield formula w.r.t. x_i, leading to the following yield gradient formula:

$$\nabla Y(x) = E_{\theta_{t-1}}\left\{\sum_k f_{\theta_i}\left[\theta_i^{(k)}\right] \cdot \frac{\nabla_x y_a(x,\theta)}{\left|\partial y_a(x,\theta)/\partial\theta_i\right|}\bigg|_{x,\theta_{t-1},\theta_i^{(k)}}\right\} \tag{5.17}$$

Where summation is over all intersection points $\theta_i^{(k)}$ of the parallel shown in Figure 5.14 with the boundary of $A_\theta(x)$; y_a is that specific performance function $y_j(x,\theta)$ which, out of all the other performances, actually determines the boundary of the acceptability region at the $\theta_i^{(k)}$ intersection point.‡ The gradient $\nabla_x y_a(x,\theta)$, and the derivative $\partial y_a(x,\theta)/\partial\theta_i$ have to be calculated for every fixed sampled point

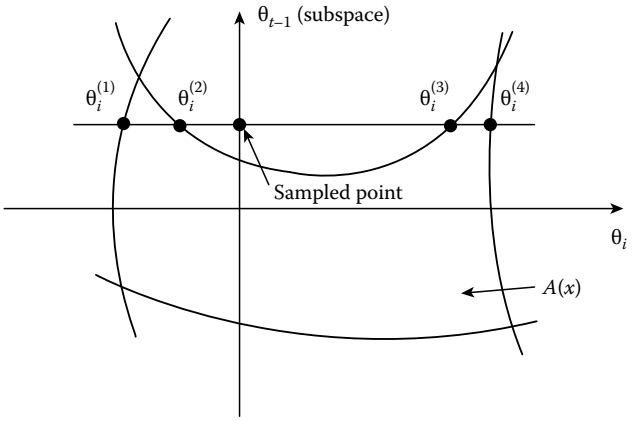

FIGURE 5.14 Interpretation of "local yield" calculation along a parallel.

* Identical technique was used in the previous section [42,43] to derive the yield derivative formula (Equation 5.16) (see Figure 5.13).

† If θ_i's are independent, it is the *marginal* p.d.f. of θ_i, as it was assumed in [13].

‡ At this point, a specific equation $y_a(x, \theta_{t-1}, 1_i^{(k)} = S_a$ (where $S_a + S_a^L$ or $S_a + S_a^U$ or are lower and upper bounds on y_a, respectively) must be *solved* to find $\theta_i^{(k)}$.

(x, θ_{t-1}), at each intersecting point $\theta_i^{(k)}$ shown in Figure 5.14. Observe that the derivative calculations in Equation 5.17 can (and often will have to) be performed in two steps: since $y_a(x, \theta) = y_a(e(x, \theta))$ so, $\partial y_a/\partial x_p = \Sigma_s(\partial y_a/\partial e_s)(\partial e_s/\partial x_p)$, and $\partial y_a/\partial \theta_i = \Sigma_s(\partial y_a/\partial e_s)(\partial e_s/\partial \theta_i)$, where the derivatives appearing in the first parentheses of both formulas are calculated using a circuit simulator and those in the second parentheses from a given statistical model $e = e(x, \theta)$.

In the practical implementation presented in [13], random points θ^r are sampled in the θ-space, in the same way as shown in Figure 5.8b but replacing e by θ, then searches for the intersections $\theta_i^{(k)}$ are performed in all axis directions, the formula in the braces of Equation 5.17 is calculated for each intersection, and averaged out over all outcomes. Searches along the parallel lines in all directions are performed to increase the accuracy of the yield gradient estimator. Observe that this technique requires tens of thousands of circuit analyses to iteratively find the intersection points $\theta_i^{(k)}$, plus additional analyses (if needed) for the calculation of the gradient and the derivatives in Equation 5.17. This problem has been circumvented in [13] by constructing approximating functions $\hat{y} = \hat{y}(x, \theta)$ w.r.t. θ for each x, together with approximating functions for all the derivatives.* Due to a high level of statistical accuracy obtained in evaluating both yield and its gradients, an efficient, gradient-based deterministic optimization algorithm, based on sequential quadratic programming was used, requiring a small number of iterations (from 5 to 11 for the examples discussed in [13]). The gradient $\nabla_x y_a(x, \theta)$ was either directly obtained from circuit simulator, or (if not available) using (improved) finite difference estimators. The method showed to be quit efficient for a moderate size of the θ-space (10–12 parameters).

The resulting yield optimization method is independent of the form of $e = e(x, \theta)$ the derivatives of y_j w.r.t. both x_k and θ_s are required and the analytical form of $f_\theta(\theta)$ and its cumulative function distribution must be known. The method cannot practically work without constructing the approximating functions $\tilde{y} = y(x, \theta)$ (approximating function in the joint space (x, θ) could also be used, if available).

5.4.6 Small-Sample Stochastic Approximation-Based Methods

Standard methods of nonlinear programming perform poorly in solving problems with statistical errors in calculating the objective functions (i.e., yield) and its derivatives.† One of the methods dedicated to the solution of such problems is the stochastic approximation (SA) approach [33] developed for solving the regression equations, and then adopted to the unconstrained and constrained optimization by several authors. These methods are aimed to the unconstrained and (maximum) of a function corrupted by noise (a regression function). The SA methods were first applied to yield optimization and statistical design centering in [49,50]. The theory of SA methods is well established, so its application to yield optimization offers the theoretical background missing, e.g., in the heuristic methods of Section 5.3. As compared to the large-sample methods, the SA algorithms to be discussed use a few (or just one) randomly sampled points per iteration, which is compensated for by a large number of iterations exhibiting a trend toward the solution. The method tends to bring large initial improvements with a small number of circuit analyses, efficiently utilizing the high content of the deterministic information present at the beginning of optimization.

In 1951, in their pioneering work, Robins and Monro [33] proposed a scheme for finding a root of a regression function, which they named the stochastic approximation procedure. The problem was to find a zero of a function, whose ''noise corrupted'' values could be observed only, namely $G(x) = g(x) + \theta(x)$ where $g(x)$ (unknown) function of x, θ is a random variable, such that $E\{\theta\} = 0$ and $\text{var}\{\theta\} \leq L < \infty$. Therefore, a zero of the regression function $g(x) + E\{G(x)\} = 0$ was to be found. The SA algorithm proposed in [33] works as follows: given a point $x^{(k)}$, set the next point as $x^{(k+1)} = x^{(k)} - a^k G[x^{(k)}]$.

* Low-degree polynomials were used with very few terms, generated from a *stepwise regression* algorithm.

† This was the reason a high level of accuracy was required while calculating both yield and its derivatives using the method described in the previous section (and *consistency* between the yield and gradient estimators), otherwise, the deterministic optimization algorithm would often diverge, as observed in [13].

The sequence of $\{x^{(k)}\}$ points converges to the solution $\hat{x}$ under some conditions (one of them is, for instance, that a_k can change according to the harmonic sequence $\left\{\mathbf{1}, \frac{1}{2}, \frac{1}{3}, \frac{1}{4}, \ldots\right\}$). Assuming that $G(x) \equiv \xi^k$ is a "noise corrupted" observation of the gradient of a regression function $f(x) = E_\theta\{w(x, \theta)\}$, the algorithm can be used to find a stationary point (e.g., a maximum) of $f(x)$, since this is equivalent to finding $\hat{x}$ such the $E\{G(\hat{x})\} = E\{\xi(\hat{x})\} = \nabla_x Y(\hat{x}) = 0$. For yield optimization $f(x) \equiv Y(x) = E\{\phi(x, \theta)\}$. This simplest scheme that can be used, if the yield gradient estimator is available is

$$x^{k+1} = x^k + \tau_k \xi^k \tag{5.18}$$

where $\xi^k + \widehat{\nabla_x Y}(x^k)$ is an estimate of the yield gradient, based on one (or more) point θ^i sampled with the p.d.f. $f_\theta(\theta)$ and $\tau_k > 0$ is the step length coefficient selected such that the sequence: $\{\tau_k\} \to 0$, and $\sum_{k=0}^{\infty} \tau_k = \infty, \sum_{k=0}^{\infty} \tau_k^2 < \infty$ (e.g., the harmonic series $\left\{\mathbf{1}, \frac{1}{2}, \frac{1}{3}, \ldots\right\}$ fulfills these conditions). For the convergence with probability 1, it is also required that the conditional expectation $E\{\xi^k | x^1, x^2, \ldots, x^k\} = \nabla Y(x^k)$. The algorithm of Equation 5.18 is similar to the steepest ascent algorithms of nonlinear programming, so, it will be slowly convergent for ill-conditioned problems. A faster algorithm was introduced in [35] and used for yield optimization in [49,50]. It is based on the following iterations:

$$x^{k+1} = x^k + \tau_k d^k \tag{5.19}$$

$$d^k = (1 - \rho_k) d^{k-1} + \rho_k \xi^k, \quad 0 < \rho_k < 1 \tag{5.20}$$

where ξ_k is a (one- or more-point) estimator of $\nabla_x Y(x^k)$ and $\{\tau_k\} \to 0$, $\{\rho_k\} \to 0$ are nonnegative coefficients. $d^{(k)}$ is a convex combination of the previous (old) direction d^{k-1} and the new gradient estimate ξ_k, so the algorithm is an analog of a more efficient, conjugate gradient method. Equation 5.2 provides gradient averaging. The ρ_k coefficient controls the "memory" or "inertia" of the search direction d^k, as shown in Figure 5.15. If ρ_k is small, the "inertia" of the algorithm is large, i.e., the algorithm tends to follow the previous gradient directions. For convergence with probability 1, the same conditions must hold as those for Equation 5.18.

The coefficients τ_k and ρ_k automatically determined based on some heuristic statistical algorithms proposed in [35]. Several other enhancements were used to speed up the convergence of the algorithm, especially in its much refined version proposed in [35]. For solving the optimization problems, the one-or two-point yield gradient estimator is found from Equation 5.10 in general, and from Equation 5.13 or 5.14 for the normal p.d.f.

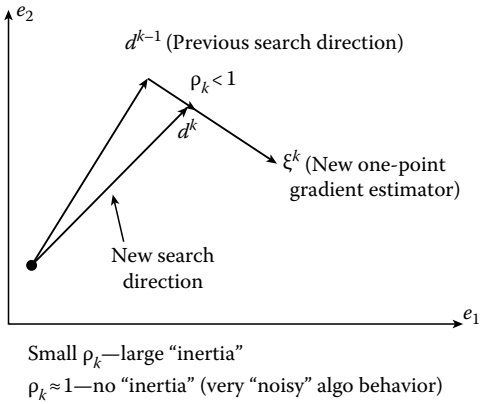

FIGURE 5.15 Illustration of the gradient averaging equation.

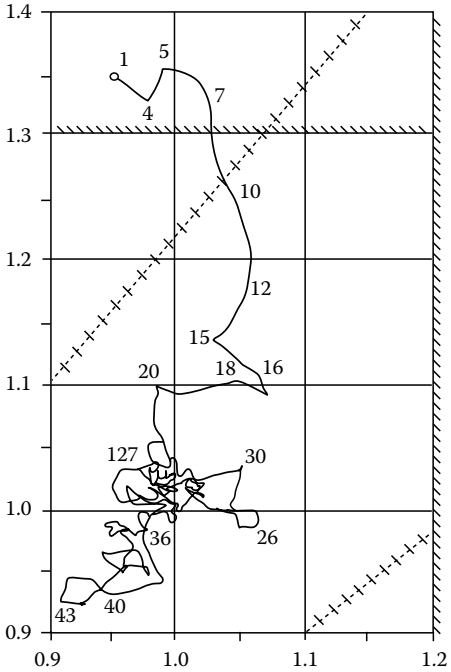

FIGURE 5.16 Typical trajectory of the stochastic approximation algorithm (Example 5.1).

Example 5.1

A simple two-dimensional case is considered in order to illustrate the algorithm properties. The acceptability region (for a voltage divider) [49] is defined in the two-dimensional space (e_1, e_2) by the inequalities:

$$0.45 \leq \frac{e_2}{e_1 + e_2} \leq 0.55 \quad 0 \leq e_1 \leq 1.2 \quad 0 \leq e_2 \leq 1.3 \tag{5.21}$$

where $e_i = x_i + \theta_i$ and the p.d.f. of θ_i is normal with $E\{\theta_1\} = E\{\theta_2\} = 0$ and $\text{Cov}\{\theta_1, \theta_2\} = 0$ (no correlations).

A typical algorithm trajectory is shown in Figure 5.16. The one-sample yield gradient formula (Equation 5.14) was used. The initial yield was low (7.4%). Very few (25–30) iterations (equal to the number of circuit analyses) were required to bring the minimal point close to the final solution. This is due to the fact that at the beginning of optimization, there is a high content of deterministic gradient information available even from a few sampled points, so the algorithm progress is fast. Close to the solution, however, the yield gradient estimator is very noisy, and the algorithm has to filter out the directional information out of noise, which takes the majority of the remaining iterations. After the total of 168 circuit analyses, the yield increases to 85.6%. Other starting points resulted in a similar algorithm behavior. It is also observed that the yield optimum is "flat" in the diagonal direction, reflected in random nominal point movement in this direction (iterations 30–43).

Example 5.2

Parametric yield for the Sallen–Key active filter of Figure 5.6a (often used in practice as a test circuit) with the specifications on its frequency response shown in Figure 5.6b was optimized (recall that the shape of the acceptability region for this case was very complicated, containing internal nonfeasible regions

["holes"]). All *R*, *C* variables were assumed designable. The relative standard deviations were assumed equal to 1% for each element, the p.d.f. was normal with 0.7 correlation coefficient between the like elements (*R*'s or *C*'s) and zero correlations between different elements. The initial yield was 6.61%. Using the SA algorithm as in the previous example, 50 iterations (equal to the number of circuit analyses) brought yield to 46.2%; the next 50 iterations to 60%, while the remaining 132 iterations increased yield to only 60.4% (again the initial convergence was very fast). The algorithm compared favorably with the Hessian matrix-based, large-sample method discussed previously [51], which required about 400 circuit analyses to obtain the same yield level, and whose initial convergence was also much slower. It has to be stressed, however, that the results obtained are statistical in nature and it is difficult to draw strong general conclusions. One observation (confirmed also by other authors) is that the SA-type algorithms provide, in general, fast initial convergence into the neighborhood of the optimal solution, as it was shown in the examples just investigated.

5.4.7 Small-Sample Stochastic Approximation Methods for Integrated Circuits

The methods of yield gradient estimation for discrete circuits cannot be used for ICs because of the form of the $e = e(x, \theta)$ transformation, as discussed at the beginning of Section 5.4. Previously in this section, a complicated algorithm was described for gradient estimation and yield optimization in such situations. In this section, a simple method based on random perturbations in x-space, proposed in [47,48], is described. It is useful in its own merit, but especially in those cases, where the conditions for the application of the yield gradient formula (Equation 5.17) are hard to meet, namely: the cost of constructing the approximating functions $\hat{y} = \hat{y}(x, \theta)$ for fixed x is high and calculating the gradient of y w.r.t. x is also expensive (which is the case, e.g., if the number of important x and θ parameters is large), and the analytical form of $f_\theta(\theta)$ is not available (as it is required in Equation 5.17).

The method applications go beyond yield optimization: a general problem is to find a minimum of a general regression function $f(x) = E_\theta\{w(x, \theta)\}$, using the SA method, in the case where the gradient estimator of $f(x)$ is not directly available. Several methods have been proposed to estimate the gradient indirectly, all based on adding some extra perturbations to x parameters. Depending on their nature, size, and the way the perturbations are changed during the optimization process, different interpretations result, and different problems can be solved. In the simplest case, some extra deterministic perturbations (usually double-sided) are added individually to each x_k (one-at-a-time), while random sampling is performed in the θ-space, and the estimator of the derivative of $f(x)$ w.r.t. x_k is estimated from the difference formula $\hat{\xi}_k = \widehat{\partial f(x)}/\partial x_k = (1/N)\sum_{i=1}^{N}\left\{\left[w\left(x + a_k e_k, \theta_1^i\right) - w\left(x - a_k e_k, \theta_2^i\right)\right]/(2a_k)\right\}$, where $a_k > 0$ is the size of the perturbation step and e_k is the unit vector along the e_k coordinates axis. Usually, $\theta_1^i \equiv \theta_2^1$ to reduce the variance of the estimator. Normally, $N = 1$. Other approaches use random direction derivative estimation by sampling points randomly on: a unit sphere of radius a [34], randomly at the vertices of a hypercube in the x-space [38], or at the points generated by orthogonal arrays [53], commonly used in the design of experiments. Yet another approach, dealing with nondifferentiable p.d.f.s was proposed in [55]. In what follows, the random perturbation approach resulting in convolution function smoothing is described for a more general case, where a *global* rather than a local minimum of $f(x)$ is to be found.

The multi-extremal regression function $f(x)$ defined previously, can be considered a superposition of an uni-extremal function (i.e., having just one minimum) and other multi-extremal functions that add some deterministic "noise" to the uni-extremal function (which itself has also some "statistical noise"—due to θ—superimposed on it). The objective of convolution smoothing can be visualized as "filtering out" but types of noise and performing minimization on the "smoothed" uni-extremal function (or on a family of these functions), in order to reach the global minimum. Since the minimum of the smoothed uni-extremal function does not, in general, coincide with the global function minimum, a sequence of minimization runs is required with the amount of smoothing eventually reduced to zero in the

neighborhood of the global minimum. The smoothing process is performed by averaging $f(x)$ over some region of the n-*dimensional* parameter space x using a proper weighting (or smoothing) function $\hat{h}(x)$, defined below. Let the n-dimensional vector η denote a vector of random perturbations; it is added to x to create the convolution function [34]:

$$\tilde{f}(x,\beta) = \int_{R^n} \hat{h}(\eta,\beta) f(x-\eta)\mathrm{d}\eta$$
$$= \int_{R^n} \hat{h}(x-\eta,\beta) f(\eta)\mathrm{d}\eta = E_\eta\{f(x-\eta)\} \tag{5.22}$$

where $\hat{f}(x,\beta)$ is the smoothed approximation to the original multi-extremal function $f(x)$, and the kernel function $\hat{h}(\eta,\beta)$ is the p.d.f. used to sample η. Note that $f(x,\beta)$ can be interpreted as an averaged version of $f(x)$ weighted by $\hat{h}(\eta,\beta)$. Parameter β controls the dispersion of $\hat{h}$, i.e., the degree of $f(x)$ smoothing (e.g., β can control the standard deviations of $\eta_1 \ldots \eta_n$). $E_\eta\{f(x-\eta)\}$ is the expectation with respect to the random variable η. Therefore, an unbiased estimator $\hat{f}(x,\beta)$ of $\tilde{f}(x,\beta)$ is the average: $\hat{f}(x,\beta) = (1/N)\sum_{i-1}^{N} f(x-\eta^i)$, where η is sampled with the p.d.f. $\hat{h}$ $(\eta-\beta)$. The kernel function $\hat{h}(\eta,\beta)$ should have certain properties discussed in [34], fulfilled by several p.d.f.s, e.g., the Gaussian and uniform. For the function $f(x) = x^4 - 16x^2 + 5x$, which has two distinct minima, smoothed functionals, obtained using Equation 5.22, are plotted in Figure 5.17 for different values of $\beta \to 0$, for (a) Gaussian and (b) uniform kernels. As seen, smoothing is able to eliminate the local minima of $\tilde{f}(x,\beta)$ if β is sufficiently large. If $\beta \to 0$, then $\tilde{f}(x,\beta) \to f(x)$.

The objective now is to solve the following optimization problem: minimize the smoothed functional $\tilde{f}(x,\beta)$ with $\beta \to 0$ as $x \to \hat{x}$, where $\hat{x}$ is the global minimum of the original function $f(x)$. The modified optimization problem can be written as minimize $\tilde{f}(x,\beta)$ w.r.t. x, with $\beta \to 0$ as $x \to \hat{x}$. Differentiating Equation 5.22 and using variable substitution, the gradient formula is obtained:

$$\nabla_x \tilde{f}(x,\beta) = \int_{R^n} \nabla_\eta \hat{h}(\eta,\beta) f(x-\eta)\mathrm{d}\eta = \frac{1}{\beta}\int_{R^n} \nabla_\eta h(\eta) f(x-\beta\eta)\mathrm{d}\eta, \tag{5.23}$$

where $\hat{h}(\cdot)$ is as defined previously, and $h(y)$ is a normalized version of $\hat{h}(y)$ (obtained if $\beta = 1$). For normalized multinormal p.d.f. with zero correlations, the gradient of $\tilde{f}(x,\beta)$ is

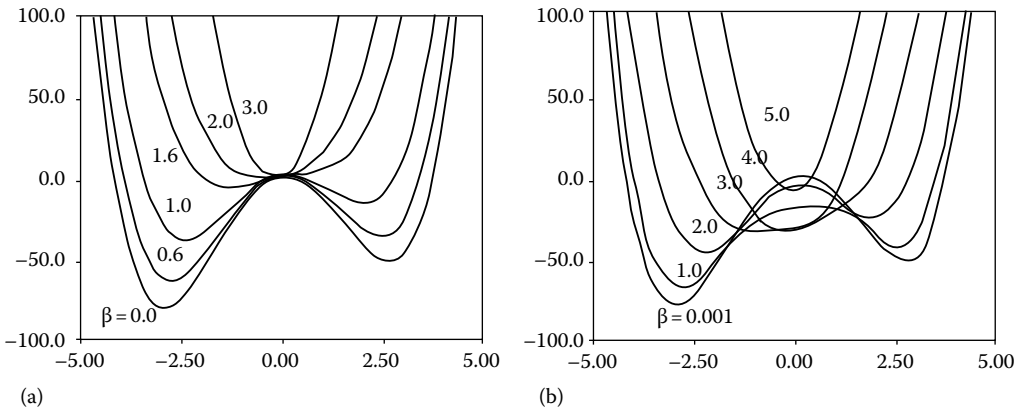

FIGURE 5.17 Smoothed functional $f(x,\beta)$ for different β's using (a) Gaussian kernel and (b) uniform kernel.

$$\nabla_x \tilde{f}(x,\beta) = \frac{-1}{\beta}\int_{R^n} \eta f(x-\beta\eta)h(\eta)d\eta = \frac{-1}{\beta}E_\eta\{\eta f(x-\beta\eta)\}$$
$$= \frac{-1}{\beta}E_{\eta,\theta}\{\eta w(x-\beta\eta,\theta)\} \tag{5.24}$$

where sampling is performed in x-space with the p.d.f. $h(\eta)$, and in θ-space with the p.d.f. $f_\theta(\theta)$; $E_{\eta,\theta}$ denotes expectation w.r.t. *both* η and θ, and it was taken into account for $f(x)$ is a noise corrupted version of $w(x, \theta)$ i.e., $f(x) = E_\theta\{w(x, \theta)\}$. The unbiased single-sided gradient estimator is therefore

$$\hat{\nabla}_x \tilde{f}(x,\beta) = \frac{-1}{\beta}\frac{1}{N}\sum_{i=1}^{N}\eta^i w(x-\beta\eta^i,\theta^i) \tag{5.25}$$

In practice, a double-sided estimator [34] of smaller variance is used

$$\hat{\nabla}_x \tilde{f}(x,\beta) = \frac{1}{2\beta}\frac{1}{N}\sum_{i=1}^{N}\eta^i\left[w(x+\beta\eta^i,\theta_2^i)\right]. \tag{5.26}$$

Normally, $N = 1$ for best overall efficiency. Statistical properties of these two estimators (such as their variability) were studied in [52]. To reduce variability, the same $\theta_1^i = \theta_2^i$ are usually used in Equation 5.26 for positive and negative $\beta\eta^i$ perturbations. For yield optimization, $w(\cdot)$ is simply replaced by the indicator function $\phi(\cdot)$. For multi-extremal problems, β values should be originally relatively large and then systematically reduced to some small number rather than to zero. For single-extremal problems (this might be the case for yield optimization) it is often sufficient to perform just a *single* optimization with a relatively small value of β, as it was done in the examples to follow.

5.4.8 Case Study: Process Optimization for Manufacturing Yield Enhancement

The object of the work presented in [48] was to investigate how to modify the MOS control process parameters together with a simultaneous adjustment of transistor widths and lengths to maximize parametric yield.* To make it possible, both process/device simulators (such as FABRICS, SUPREM, PISCES, etc.) and a circuit simulator must be used. In what follows FABRICS [12,22,24] is used as a process/device simulator. IC technological process parameters are statistical in nature, but variations of some of the parameters (e.g., times of operations, implant doses, etc.) might have small relative variations, and some parameters are common to several transistors on the chip. Because of that, the transformation $e = e(x, \theta)$ (where θ are now process related random variables), is such that standard methods of yield optimization developed for discrete circuits cannot be used. Let $Z_1 = z_1 + \xi_1$ be the process control parameters (doses, times, temperatures), where ξ_1 are random parameter variations, and z_1 are deterministic designable parameters. Let $Z_2 = z_2 + \xi_2$ be the designable layout dimensions, where z_2 are designable and ξ_2 are random variations (common to several transistors on a chip). $P = p + \psi$ are process physical parameters (random, nondesignable) such as diffusivities, impurity concentrations, etc. (as above, p is the nominal value and ψ is random). All random perturbations are collected into the vector of random parameters θ, called also the vector of process disturbances: $\theta = (\xi_1, \xi_2, \psi)$. The vector of designable parameters $x = (z_1, z_2)$ is composed of the process z_1 and layout z_2 designable parameters. Therefore, x and θ are in different spaces (subspaces). There are also other difficulties: the analytical form of the p.d.f. of θ is most often not known, since θ parameters are hierarchically generated from a

* This might be important, e.g., for the process refinement and IC cell *redesign*.

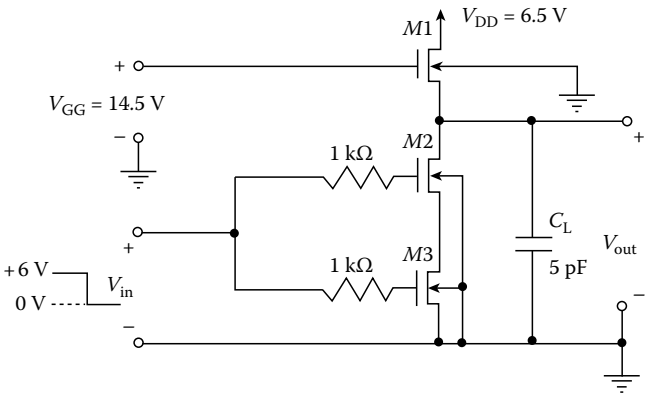

FIGURE 5.18 NMOS NAND gate of Example 5.3.

numerical procedure [12], the derivatives of the performances y w.r.t. x and θ are not known from FABRICS and can only be estimated by finite differences, and the θ and x spaces are very large (see below). So, creating approximation and/or finding derivatives using finite differences is expensive. Because of these difficulties, the smoothed-functional approach discussed in this section will be used, as shown in the following example.

Example 5.3

The objective is to maximize parametric yield for the NMOS NAND gate shown in Figure 5.18 [48], by automated adjustment of process and layout parameters. Specifications are: $V_0 = V_{out}\ (t = 0) \leq 0.7$ V, $V_{out}\ (t_1 = 50$ ns$) > 6.14$ V, circuit area $\leq 2500\ \mu m^2$. There are 45 designable parameters: all 39 technological process parameters, 6 transistor dimensions, and about 40 noise parameters, so it is a large problem suitable for the use of the SA-based random perturbation method described above.

The initial yield was $Y = 20\%$. After the first optimization using the method of random perturbations with 2% relative perturbations of each of the designable parameters involving the total of 110 FABRICS/SPICE analyses, yield increased to 100% and the nominal area decreased to 2138 μm^2. Then, specs were tightened to $V_{out}\ (t_2 = 28$ ns$) > 6.14$ V with the same constraints on V_0 and area, causing yield to drop to 10.1%. After 60 FABRICS/SPICE analyses, using the perturbation method, yield increased to: $Y = 92\%$ and area $= 2188\ \mu m^2$. These much-improved results produced the nominal circuit responses shown in Figure 5.19. Several technological process parameters were changed during optimization in the range between 0.1% and 17%: times of oxidation, annealing, drive-in, partial pressure of oxygen, and others, while the transistor dimensions changed in the range between 0.8% and 6.3%. The cost of obtaining these results was quite reasonable: the total of 170 FABRICS/SPICE analyses, despite the large number of optimized and noise parameters. Other examples are discussed in [48].

5.4.9 Generalized Formulation of Yield, Variability, and Taguchi Circuit Optimization Problems

Parametric yield is not the only criterion that should be considered during statistical circuit design. Equally, and often more important is minimization of performance variability caused by various manufacturing and environmental disturbances. Variability minimization has been an important issue in circuit design for many years [17] (see [17] for earlier reference). It leads (indirectly) to parametric yield improvement. Circuits characterized by low performance variability are regarded as high quality products. Most recently, variability minimization has been reintroduced into practical industrial design

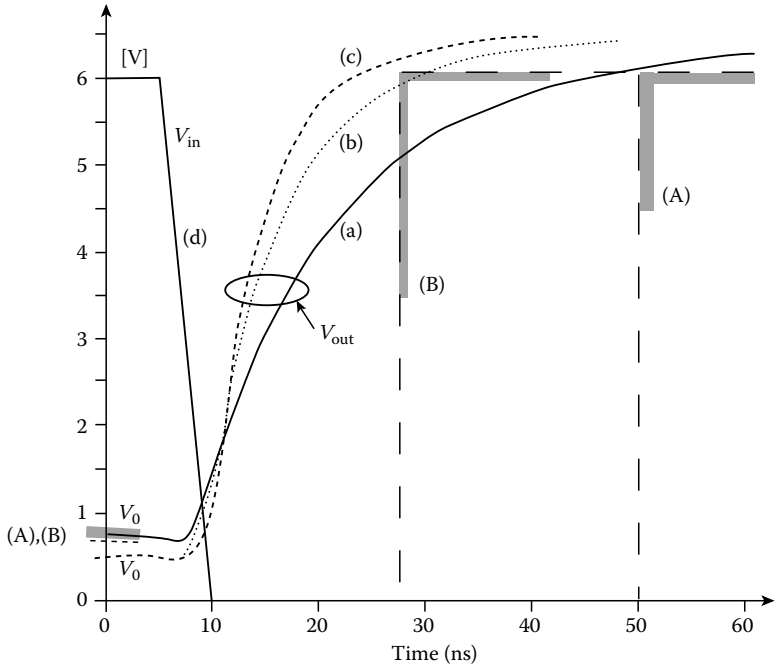

FIGURE 5.19 Nominal transient responses for Example 5.3: (a) initial, (b) after first optimization, and (c) after tightening the specs and second optimization.

due to the work of Taguchi [30]. He has successfully popularized the notion of ''Off-Line Quality Control'' through an intensive practical implementation of his strategy of designing products with low performance variability, tuned to the ''target'' values S_j^T of the performance functions y_j.

In what follows, a generalized approach proposed in [44] is discussed, in which a broad range of various problems, including yield optimization and Taguchi's variability minimization as special cases can be solved, using the SA approach and the general gradient formulas developed previously in this section.

It is convenient to introduce the M-dimensional vector $g(e)$ of scaled constraints, composed of the vectors $g^L(e)$, and $g^U(e)$, defined as

$$g_k^L(e) = \frac{S_k^T - y_k(e)}{S_k^T - S_k^L}, \quad k = 1, \ldots, M_L \tag{5.27}$$

$$g_t^U(e) = \frac{y_t(e) - S_t^T}{S_t^U - S_t^T}, \quad t = 1, \ldots, M_U \tag{5.28}$$

where $e = e(x, \theta)$, $M = M_L + M_U \leq 2$ m (note that in general $M \leq 2$ m, since some of the lower or upper specs might not be defined). These constraints are linear functions of $y_i(\cdot)$; they have important properties: $g^L = g^U = 0$ if $y = S^T$, $g^L = 1$ if $y = S^L$, and $g^U = 1$ if $y = S^U$. For $S^L < y < S^U$ and $y \neq S^T$, either g^L or g^U is greater than zero, but never both.

For any ''good'' design, we would like to make each of the normalized constraints introduced previously equal to zero, which might not be possible due to various existing design trade-offs. Therefore, this is a typical example of a multiobjective optimization problem. The proposed scaling helps to compare various trade-off situations. The Taguchi ''on-target'' design with variability minimization is formulated as follows (for a single performance function $y(e)$)

$$\begin{aligned}\text{minimize}\{M_{\text{TAG}}(x) &= E_\theta\left\{\left[y(e(x,\theta)) - S^{\text{T}}\right]^2\right\} \\ &= var\{y(x)\} + \left[\bar{y}(x) - S^{\text{T}}\right]^2\right\}\end{aligned} \tag{5.29}$$

where

$\bar{y}(x)$ is the mean (average) value of y (w.r.t θ)

M_{TAG} is called the "loss" function (in actual implementations Taguchi uses related but different performance statistics)

Generalization of Equation 5.29 to several objectives can be done in many different ways. One possible approach is to introduce $u(e) = \max_{s=1,\ldots,M}\{g_s(e)\}$ and define the generalized loss function (GLF) as

$$M_{\text{GLF}}(x) = E_\theta\left\{[u(e(x,\theta))]^2\right\} \tag{5.30}$$

This generalization is meaningful, since $u(e) = \max_{s=1,\text{K},M}\{g_s(\text{e})\}$ is a scalar, and for the proposed scaling either $u(\cdot) > 0$, or it is equal to zero if all the performances assume their target values S_i^{T}. Since Equations 5.27 and 5.28 are less or equal to 1 any time $S_i^{\text{T}} \le y_i\ (\text{e}) \le S_i^{\text{U}}$, then $e = e(x,\ \theta)$ belongs to A (the acceptability region in the e-space), if $u(e) < 1$. Let us use the complementary indicator function $\phi_{\text{F}}[u\ (\text{e})] = 1$, if $u(e) \ge 1$, i.e., $e \notin A$ (or $\theta \notin A_\theta(\text{x})$) (failure) and equal to zero otherwise. Maximization of the parametric yield $Y(x)$ is equivalent to the minimization of the probability of failures $F(x) = 1 - Y(x)$, which can be formulated as the following minimization process, w.r.t. x:

$$\left.\begin{aligned}\text{minimize}\{F(x) &= P\{\theta \notin A_\theta(x)\} \\ &= \int_{R^t} \phi_{\text{F}}(u(x,\theta)) f_\theta(\theta)\text{d}\theta = E_\theta[\phi_{\text{F}}(u(x,\theta))]\end{aligned}\right\} \tag{5.31}$$

The scalar "step" function $\phi_{\text{F}}(\cdot)$ (where the argument is also scalar function $u(e) = \max_{s=1,\text{K},M}\{g_s(\text{e})\}$) can now be generalized into a scalar weight function $w(\cdot)$, in the same spirit as in the Zadeh fuzzy set theory [62,63]. For further generalization, the original p.d.f. $f_\theta(\theta)$ used in Equation 5.31 is parameterized, multiplying θ by the smoothing parameters β to control the dispersion of e, which leads to the following optimization problem, utilizing a generalized measure $M_w(\text{x}, \beta)$

$$\text{minimize}\{M_w(x,\beta) = E_\theta\{w[u(e(x,\beta\theta))]\}\} \tag{5.32}$$

where $u(e(x,\ \beta\theta)) = \max_{s=1,\ldots,M}\{g_s(e(x,\ \beta\theta))\}$. If $0 \le w(\cdot) \le 1$, $M_w(\cdot)$ corresponds to the probability measure of fuzzy event introduced by Zadeh [63]. The choice of $w(\cdot)$ and β leads to different optimization problems and different algorithms for yield/variability optimization. The standard yield optimization problem results if $w(\alpha) = \phi_{\text{F}}(\alpha)$ and $\beta = 1$ [Equation 5.31] (Figure 5.20a). Yield can be also approximately optimized indirectly, using a "smoothed" (e.g., sigmoidal) membership function $w(\alpha)$ (Figure 5.20e). For variability minimization, we have a whole family of possible approaches: (1) The generalized Taguchi approach with $w(\alpha) = \alpha^2$ (see Equation 5.30) and $\beta = 1$ (see Figure 5.20c). (2) If $w(\alpha) = \alpha$ and $\beta = 1$ is kept constant, we obtain a statistical mini–max problem, since the expected value of the max function is used; this formulation will also lead to performance variability reduction. (3) If $w(\alpha)$ is piecewise constant (Figure 5.20d), the approach is equivalent to the income index maximization with separate quality classes, introduced in [28], and successfully used there for the increase of the percentage of circuits belonging to the best classes (i.e., those characterized by small values of $u(e)$); this approach also reduces variability of circuit performance functions. For all the cases, optimization is performed using the proposed SA approach. The smoothed functional gradient formulas (Equation 5.25 and 5.26)

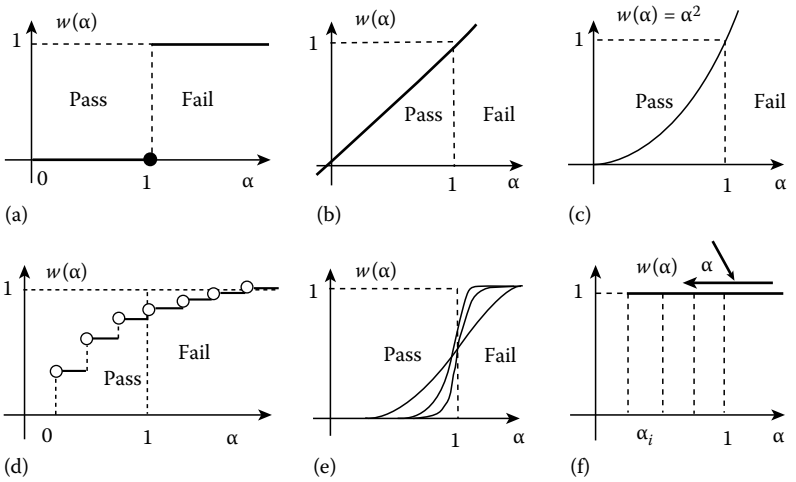

FIGURE 5.20 Various cases of the weight function $w(\alpha)$.

have to be used, in general, since the ''discrete-circuit'' type gradient formulas are valid only for a limited number of situations.

Example 5.4: Performance Variability Minimization for a MOSFET-C Filter

The objective of this example [31] was to reduce performance variability and to tune to target values the performances of the MOSFET-C filter in Figure 5.21. The MOSFETS are used in groups composed of four

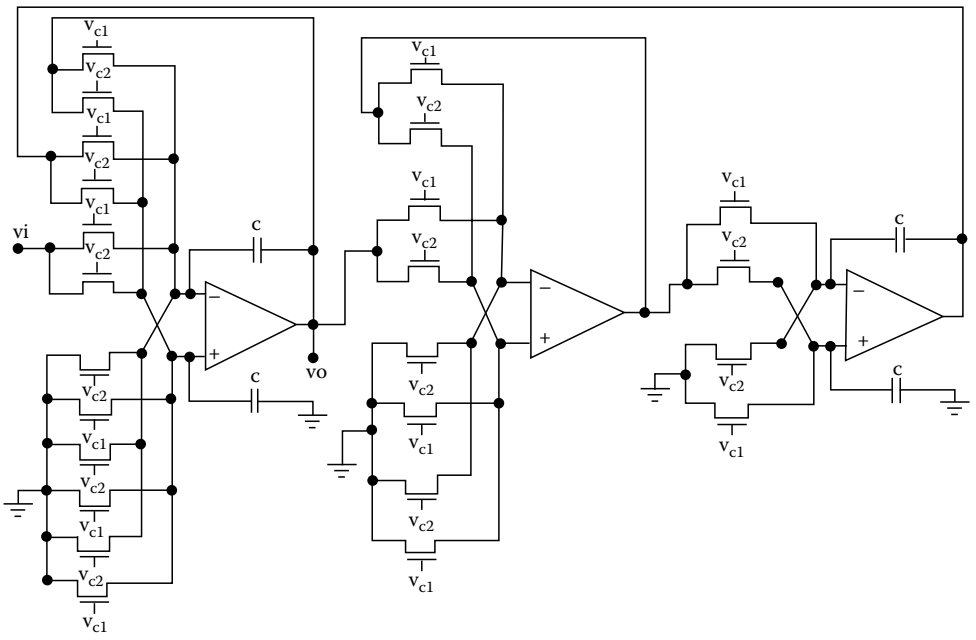

FIGURE 5.21 MOSFET-C bandpass filter optimized in Example 5.4.

transistors implementing equivalent resistors with improved linearity. Design specifications are f_0, the center frequency, with the S^L, S^T, S^U values specified as {45, 50, 55} kHz; H_0, the voltage gain at f_0, with the specs {15, 20, 25} dB; and Q, the pole quality factor, with the specs {8, 10, 12}. The Taguchi-like "on-target" design and tuning was performed by minimizing the generalized measure Equation 5.32 with $w(x) = x^2$, using the SA approach with convolution smoothing, since the designable and random parameters are in different (sub)spaces. The circuit has the total number of 90 transistors so its direct optimization using transistor-level simulation would be too costly. Therefore, in [31] the operational amplifiers (op-amps) shown in Figure 5.21 were modeled by a statistical macromodel, representing the most relevant op-amp characteristics: DC gain A_0, output resistance R_0, and the −20 dB/dec frequency roll-off. Transistor model parameters were characterized by a statistical model developed in [8], based on six common factors (see Section 5.3): t_{ox} (oxide thickness), ΔL_n, ΔL_p (length reduction), $N_{SUB,n}$, $N_{SUB,p}$ (substrate doping), and x_{jp} (junction depth). All other transistor model parameters were calculated from the six common factors using second-order regression formulas developed in [8]. The major difficulty was to create statistical models of the op-amp macromodel parameters A_0, R_0, and f_{3dB} as the functions of the six common factors listed previously. A special extraction procedure (similar in principle to the model of factor analysis [20]) was developed and the relevant models created. Perfect matching between the transistor model parameter of the 22 transistors of each of the op-amps was assumed for simplicity* (correlational dependencies between individual parameters for individual transistors were maintained using the statistical mode of [8], described earlier). Moreover, perfect matching between the three macromodels (for the three op-amps) was also assumed. Mismatches between the threshold voltages and K_p (gain) coefficients of all the transistors in Figure 5.21 were taken into account, introducing 48 additional noise parameters. So, including the 6 global noise parameters discussed previously, the overall number of $\boldsymbol{\theta}$ parameters was 54. Moreover, it was found that even if a large number of noise parameters had small individual effect, their total contributions was significant, so, no meaningful reduction of the dimension of the $\boldsymbol{\theta}$-space was justified. Because of that, it was difficult to use approximating models in the $\boldsymbol{\theta}$-space, and even more difficult in the joint $(x, \boldsymbol{\theta})$ space of $7 + 54 = 61$ parameters. Therefore, no approximation was used.

The Monte Carlo studies showed that the proposed statistical macromodel provided quite reasonably statistical accuracy for f_0 (<1% errors for both the mean and the standard deviation), and <9.5% errors for both, H_0 and Q. The macromodel-based analysis was about 30 times faster than using the full device-level SPICE analysis. Twenty-five designable parameters were selected, including transistor channel length of the "resistor-simulating transistors," four capacitors, and one of the gate voltages. Due to the designable parameter tracking for transistor quadruples, the actual vector of optimized parameters was reduced to 7: $x = (V_{Gs}, C_1, C_2, L_2, L_3, L_4, L_5)$, where V_{Gs} denotes the gate voltage, and C_i, L_j are capacitor and channel length values, respectively. The original yield was 43.5% and relative standard deviations for H_0, f_0, and Q were reduced to 3.98%, 7.24%, and 22.06%, respectively, and all nominal values were close to their target values. After SA optimization with convolution smoothing involving 5% perturbations for each of the x parameters, and the total of about 240 circuit analyses, yield increased to 85.0%, and H_0, f_0, and Q relative standard deviations were reduced to 3.87%, 6.35%, and 13.91%, respectively. Therefore, the largest variability reduction (for Q) was about 37%, with simultaneous significant yield increase.

The preceding example demonstrates a typical approach that has to be taken in the case of large analog circuits: the circuit has to be (hierarchically) macromodeled first† and suitable *statistical* macromodels have to be created, including mismatch modeling.

5.5 Conclusion

Several different techniques of statistical yield optimization were presented. Other approaches to yield estimation and optimization can be found, e.g., in [21] (process optimization), and in [15,57,59,60,61]. It was also shown that yield, variability minimization, Toguchi design, and other approaches can be generalized into one methodology called design for quality‡ (DFQ). DFQ is a quickly growing area [30],

* A more sophisticated model, taking the mismatches into account, was later proposed in [32].

† Behavioral models can also be used.

‡ Other approaches to yield generalization/Design for Quality were presented in [13,28,58].

where the major objective is not to maximize the parametric yield as the only design criterion (yield is often only vaguely defined), but to minimize the performance variability around the designer specified target performance values. This has been a subject of research for many years using a sensitivity-based approach, and most recently, using the Taguchi methodology, based on some of the techniques of Design of Experiments rather than on the use of sensitivities. To increase the efficiency of the (mostly manual) Taguchi techniques [30], some automated methods started to appear, such as the generalized methodology described previously, or the automated approach based on capability indices C_p/C_{pk} (used extensively in process quality control) proposed in [41].

Statistical design optimization is still an active research area, but several mature techniques have been already developed and practically applied to sophisticated industrial IC design. This is of great importance to the overall manufacturing cost reduction, circuit quality improvement, and shortening of the overall IC design cycle.

6.1 Introduction

In the last three decades integrated circuit (IC) fabrication technology has evolved from integration of a few transistors in small-scale integration (SSI) to integration of several million transistors in very large-scale integration (VLSI). This phenomenal progress has been made possible by automating the process of design and fabrication of VLSI chips.

Integrated circuits consist of a number of electronic components, built by layering several different materials in a well-defined fashion on a silicon base called a wafer. The designer of an IC transforms a circuit description into a geometric description, which is known as a layout. A layout consists of a set of planar geometric shapes in several layers. The layout is then checked to ensure that it meets all the design

* The material presented in this chapter was adapted from the author's book *Algorithms for VLSI Physical Design Automation*, Boston: Kluwer Academic, 1993, with editorial changes for clarity and continuity. Copyright permission has been obtained from Kluwer Academic Publishers.

requirements. The result is a set of design files in a particular unambiguous representation, known as an intermediate form, which describes the layout. The design files are then converted into pattern generator files, which are used to produce patterns called masks by an optical pattern generator. During fabrication, these masks are used to pattern a silicon wafer using a sequence of photolithographic steps. The component formation requires very exacting details about geometric patterns and separation between them. The process of converting the specifications of an electrical circuit into a layout is called the physical design. It is an extremely tedious and error-prone process because of the tight tolerance requirements and the minuteness of the individual components. Currently, the smallest geometric feature of a component can be as small as 0.35 μm (1 $\mu m = 1.0 \times 10^{-6}$ m). However, it is expected that the feature size can be reduced to 0.1 μm within 5 years. This small feature size allows fabrication of as many as 4.5 million transistors on a 25×25 mm maximum size chip. Due to the large number of components and the exacting details required by the fabrication process, the physical design is not practical without the help of computers. As a result, almost all phases of physical design extensively use computer-aided design (CAD) tools and many phases have already been partially or fully automated. This automation of the physical design process has increased the level of integration, reduced the turnaround time, and enhanced chip performance.

VLSI physical design automation is essentially the study of algorithms related to the physical design process. The objective is to study optimal arrangements of devices on a plane (or in a three-dimensional space) and efficient interconnection schemes between these devices to obtain the desired functionality. Because space on a wafer is very expensive real estate, algorithms must use the space very efficiently to lower costs and improve yield. In addition, the arrangement of devices plays a key role in determining the performance of a chip. Algorithms for physical design must also ensure that all the rules required by the fabrication are observed and that the layout is within the tolerance limits of the fabrication process. Finally, algorithms must be efficient and should be able to handle very large designs. Efficient algorithms not only lead to fast turnaround time, but also permit designers to iteratively improve the layouts.

With the reduction in the smallest feature size and increase in the clock frequency, the effect of electrical parameters on physical design will play a more dominant role in the design and development of new algorithms.

In this section, we present an overview of the fundamental concepts of VLSI physical design automation. Different design styles are discussed in Section 6.4. Section 6.2 discusses the design cycle of a VLSI circuit. In Section 6.3 different steps of the physical design cycle are discussed. The rest of the sections discuss each step of the physical design cycle.

6.2 Very Large-Scale Integration Design Cycle

Starting with a formal specification, the VLSI design cycle follows a series of steps and eventually produces a packaged chip. A flow chart representing a typical design cycle is shown in Figure 6.1.

1. *System specification*: The specifications of the system to be designed are exactly specified here. This necessitates creating a high-level representation of the system. The factors to be considered in this process include performance, functionality, and the physical dimensions. The choice of fabrication technology and design techniques are also considered. The end results are specifications for the size, speed, power, and functionality of the VLSI system to be designed.
2. *Functional design*: In this step, behavioral aspects of the system are considered. The outcome is usually a timing diagram or other relationships between subunits. This information is used to improve the overall design process and to reduce the complexity of the subsequent phases.
3. *Logic design*: In this step, the functional design is converted into a logical design, typically represented by Boolean expressions. These expressions are minimized to achieve the smallest logic design which conforms to the functional design. This logic design of the system is simulated and tested to verify its correctness.

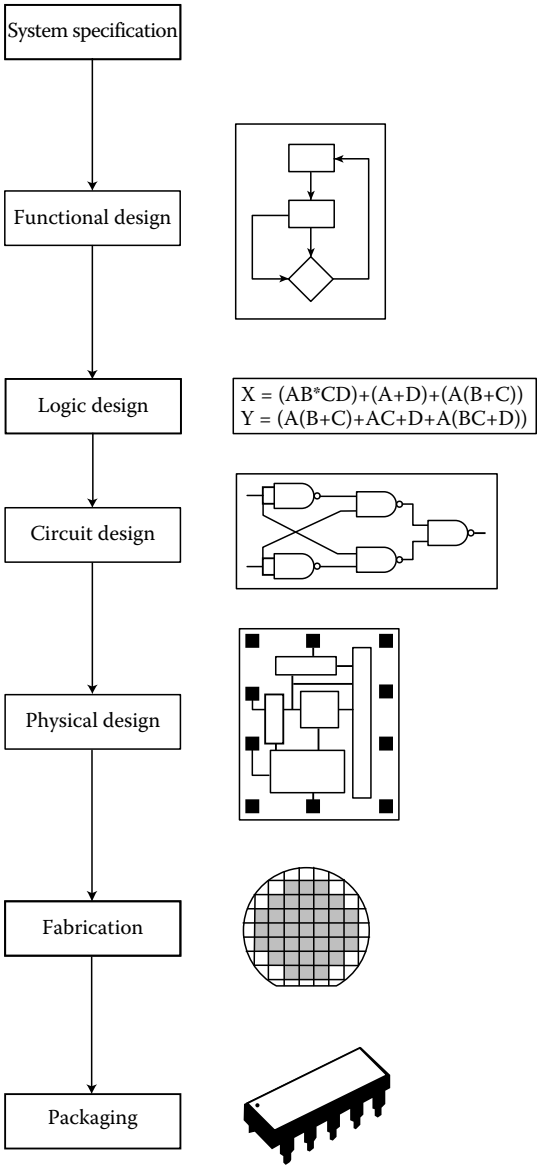

FIGURE 6.1 Design process steps.

4. *Circuit design*: Here, the Boolean expressions are converted into a circuit representation by taking into consideration the speed and power requirements of the original design. The electrical behavior of the various components are also considered in this phase. The circuit design is usually expressed in a detailed circuit diagram.
5. *Physical design*: In this step, the circuit representation of each component is converted into a geometric representation. This representation is in fact a set of geometric patterns which perform the intended logic function of the corresponding component. Connections between different components are also expressed as geometric patterns. As stated earlier, this geometric representation of a circuit is called a layout. The exact details of the layout also depend on design rules, which are guidelines based on the limitations of the fabrication process and the

electrical properties of the fabrication materials. Physical design is a very complex process; therefore, it is usually broken down into various substeps in order to handle the complexity of the problem. In fact, physical design is arguably the most time-consuming step in the VLSI design cycle.

6. *Design verification*: In this step, the layout is verified to ensure that the layout meets the system specifications and the fabrication requirements. Design verification consists of design rule checking (DRC) and circuit extraction. DRC is a process which verifies that all geometric patterns meet the design rules imposed by the fabrication process. After checking the layout for design rule violations and removing them, the functionality of the layout is verified by circuit extraction. This is a reverse engineering process and generates the circuit representation from the layout. This reverse engineered circuit representation can then be compared to the original circuit representation to verify the correctness of the layout.
7. *Fabrication*: After verification, the layout is ready for fabrication. The fabrication process consists of several steps: preparation of wafer, deposition, and diffusion of various materials on the wafer according to the layout description. A typical wafer is 10 cm in diameter and can be used to produce between 12 and 30 chips. Before the chip is mass produced, a prototype is made and tested.
8. *Packaging, testing, and debugging*: In this step, the chip is fabricated and diced in a fabrication facility. Each chip is then packaged and tested to ensure that it meets all the design specifications and that it functions properly. Chips used in printed circuit boards (PCBs) are packaged in a dual-in-line package (DIP) or pin grid array (PGA). Chips which are to be used in a multichip module (MCM) are not packaged because MCMs use bare or naked chips.

The VLSI design cycle is iterative in nature, both within a step and between steps. The representation is iteratively improved to meet system specifications. For example, a layout is iteratively improved so that it meets the timing specifications of the system. Another example may be detection of design rule violations during design verification. If such violations are detected, the physical design step needs to be repeated to correct the error. The objective of VLSI CAD tools is to minimize the number of iterations and thus reduce the time-to-market.

6.3 Physical Design Cycle

Physical design cycle converts a circuit diagram into a layout. This is accomplished in several steps such as partitioning, floorplanning, placement, routing, and compaction, as shown in Figure 6.2.

1. *Partitioning*: The complex task of chip layout is divided into several smaller tasks. A chip may contain several million transistors. Layout of the entire circuit cannot be handled due to the limitation of memory space as well as computation power available. Therefore, it is normally partitioned by grouping the components into blocks (subcircuits/modules). The actual partitioning process considers many factors such as size of the blocks, number of blocks, and number of interconnections between the blocks. The output of partitioning is a set of blocks along with the interconnections required between blocks. The set of interconnections required is referred to as a netlist. Figure 6.2a shows that the input circuit has been partitioned into three blocks. In large circuits the partitioning process is hierarchical and at the topmost level a chip may have between 5 and 25 blocks. Each module is then partitioned recursively into smaller blocks.
2. *Placement*: In this step, good layout alternatives are selected for each block, as well as the entire chip. The area of each block can be calculated after partitioning and is based approximately on the number and the type of components in that block. The actual rectangular shape of the block, which is determined by the aspect ratio may, however, be varied within a prespecified range. Floorplanning is a critical step, as it sets up the groundwork for a good layout. However, it is

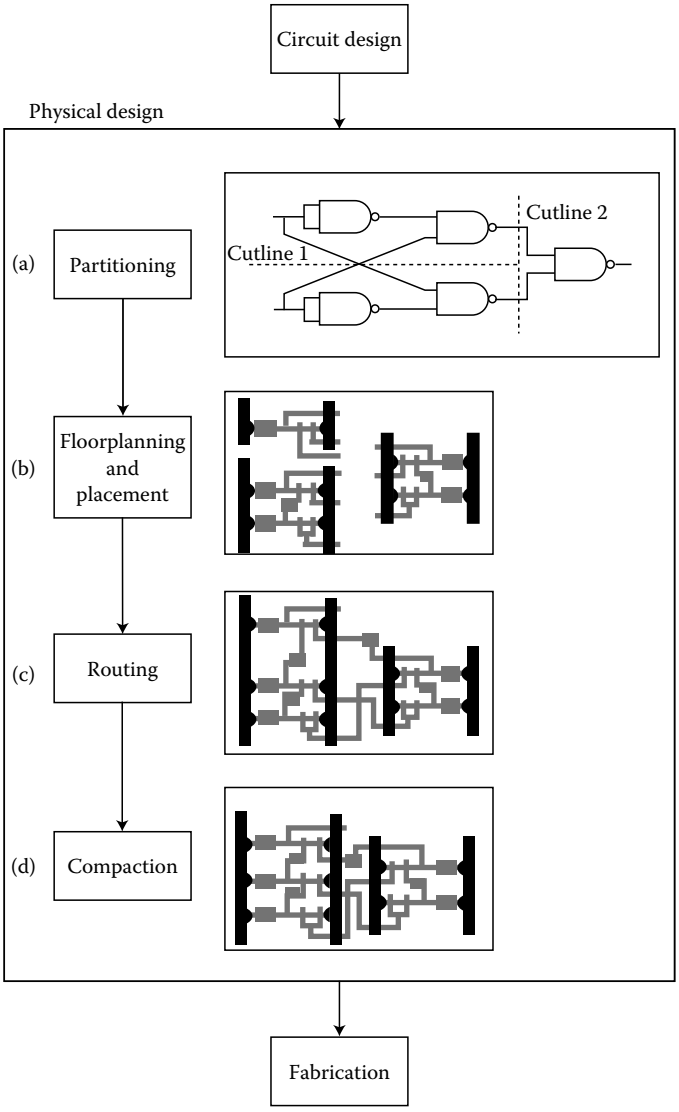

FIGURE 6.2 Physical design cycle.

computationally quite hard. Very often the task of floorplan layout is done by a design engineer, rather than by a CAD tool. This is sometimes necessary as the major components of an IC are often intended for specific locations on the chip. The placement process determines the exact positions of the blocks on the chip, so as to find a minimum area arrangement for the blocks that allows completion of interconnections between the blocks. Placement is typically done in two phases. In the first phase an initial placement is created. In the second phase the initial placement is evaluated and iterative improvements are made until the layout has minimum area and conforms to design specifications. Figure 6.2b shows that three blocks have been placed. It should be noted that some space between the blocks is intentionally left empty to allow interconnections between blocks. Placement may lead to unroutable design, i.e., routing may not be possible in the space provided. Thus, another iteration of placement is necessary. To limit the number of iterations of the placement algorithm, an estimate of the required routing space is used during the placement

phase. A good routing and circuit performance heavily depend on a good placement algorithm. This is due to the fact that once the position of each block is fixed, very little can be done to improve the routing and the overall circuit performance.

3. *Routing*: In this step, the objective is to complete the interconnections between blocks according to the specified netlist. First, the space not occupied by the blocks (called the routing space) is partitioned into rectangular regions called channels and switchboxes. The goal of a router is to complete all circuit connections using the shortest possible wire length and using only the channels and switchboxes. This is usually done in two phases, referred to as the global routing and detailed routing phases. In global routing, connections are completed between the proper blocks of the circuit disregarding the exact geometric details of each wire and pin. For each wire, the global router finds a list of channels which are to be used as a passageway for that wire. In other words, global routing specifies the ''loose route'' of a wire through different regions in the routing space. Global routing is followed by detailed routing, which completes point-to-point connections between pins on the blocks. Loose routing is converted into exact routing by specifying geometric information such as width of wires and their layer assignments. Detailed routing includes channel routing and switchbox routing. Routing is a very well-studied problem and several hundred articles have been published about all its aspects. Because almost all problems in routing are computationally hard, the researchers have focused on heuristic algorithms. As a result, experimental evaluation has become an integral part of all algorithms and several benchmarks have been standardized. Due to the nature of the routing algorithms, complete routing of all the connections cannot be guaranteed in many cases. As a result, a technique called rip-up and reroute is used, which basically removes troublesome connections and reroutes them in a different order. The routing phase of Figure 6.2c shows that all the interconnections between three blocks have been routed.
4. *Compaction*: In this step, the layout is compressed in all directions such that the total area is reduced. By making the chip smaller, wire lengths are reduced, which in turn reduces the signal delay between components of the circuit. At the same time, a smaller area may imply more chips can be produced on a wafer, which in turn reduces the cost of manufacturing. However, the expense of computing time mandates the extensive compaction is used only when large quantities of ICs are produced. Compaction must ensure that no rules regarding the design and fabrication process are violated during the process. The final diagram in Figure 6.2d shows the compacted layout.

Physical design, like VLSI design, is iterative in nature, and many steps such as global routing and channel routing are repeated several times to obtain a better layout. In addition, the quality of results obtained in a step depends on the quality of solutions obtained in earlier steps. For example, a poor quality placement cannot be ''cured'' by high quality routing. As a result, earlier steps have more influence on the overall quality of the solution. In this sense partitioning, floorplanning, and placement problems play a more important role in determining the area and chip performance, as compared to routing and compaction. Because placement may produce an ''unroutable'' layout, the chip might need to be replaced or repartitioned before another routing is attempted. In general, the whole design cycle may be repeated several times to accomplish the design objectives. The complexity of each step varies depending on the design constraints as well as the design style used.

6.4 Design Styles

Even after decomposing physical design into several conceptually easier steps, it has been shown that each step is computationally very hard. Market requirements demand a quick time-to-market and high yield. As a result, restricted models and design styles are used in order to reduce the complexity of

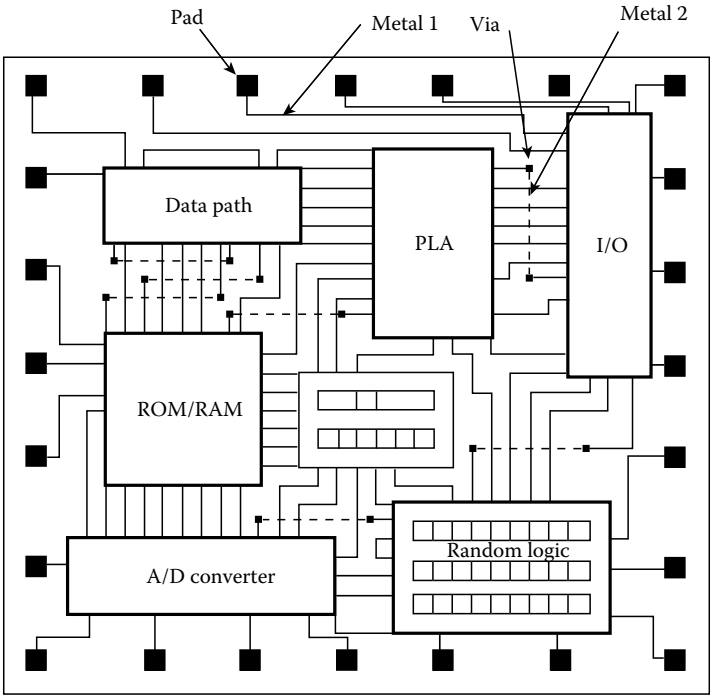

FIGURE 6.3 Full-custom structure.

physical design. This practice began in the late 1960s and led to the development of several restricted design styles [8].

The most general form of layout is called the full-custom design style, in which the circuit is partitioned into a collection of subcircuits according to some criteria such as functionality of each subcircuit. In this design style, each subcircuit is called a functional block or simply a block. The full-custom design style allows functional blocks to be of any size. Figure 6.3 shows an example of very simple circuit with few blocks. Internal routing in each block is not shown for the sake of clarity. Blocks can be placed at any location on the chip surface without restriction. In other words, this style is characterized by the absence of any constraints on the physical design process. This design style allows for very compact designs. However, the process of automating a full-custom design style has a much higher complexity than other restricted models. For this reason, it is used only when final design must have a minimum area and designing time is less of a factor. The automation process for a full-custom layout is still a topic of intensive research. Some phases of physical design of a full-custom chip may be done manually to optimize the layout. Layout compaction is a very important aspect in full-custom. The rectangular solid boxes around the boundary of the circuit are called I–O pads. Pads are used to complete interconnections between chips or interconnections between chip and the board. The space not occupied by blocks is used for routing of interconnecting wires. Initially all the blocks are placed within the chip area, with the objective of minimizing the total area. However, enough space must be left between the blocks to complete the routing. Usually several metal layers are used for routing interconnections. Currently, two metal layers are common for routing and the three-metal layer process is gaining acceptance, as the fabrication costs become more feasible. The routing area needed between the blocks becomes increasingly smaller as more routing layers are used. This is because some routing is done on top of the transistors in the additional metal layers. If all the routing can be done on top of the transistors, the total chip area is determined by the area of the transistors.

In a hierarchical design of circuit each block in full-custom design may be very complex and may consist of several subblocks, which in turn may be designed using the full-custom design style or other design styles. It is easy to see that because any block is allowed to be placed anywhere on the chip, the problem of optimizing area and interconnection of wires becomes difficult. Full-custom design is very time consuming; thus, the method is inappropriate for very large circuits, unless performance is of utmost importance. Full-custom is usually used for the layout of microprocessors.

A more restricted design style is called the standard cell design style. The design process in standard cell design style is simpler than a full-custom design style. Standard cell methodology considers the layout to consist of rectangular cells of the same height. Initially, a circuit is partitioned into several smaller blocks, each of which is equivalent to some predefined subcircuit (cell). The functionality and the electrical characteristics of each predefined cell are tested, analyzed, and specified. A collection of these cells is called a cell library, usually consisting of 200–400 cells. Terminals on cells may be located either on the boundary or in the center of the cells. Cells are placed in rows and the space between two rows is called a channel. These channels are used to perform interconnections between cells. If two cells to be interconnected lie in the same row or in adjacent rows, then the channel between the rows is used for interconnection. However, if two cells to be connected lie in two nonadjacent rows, then their interconnection wire passes through the empty space between any two cells, or feedthrough.

Standard cell design is well suited for moderate-size circuits and medium production volumes. Physical design using standard cells is simpler as compared to full-custom and efficient using modern design tools. The standard cell design style is also widely used to implement the ''random logic'' of the full-custom design, as shown in Figure 6.3. While standard cell designs are developed more quickly, a substantial initial investment is needed in the development of the cell library, which may consist of several hundred cells. Each cell in the cell library is ''handcrafted'' and requires a highly skilled design engineer. Each type of cell must be created with several transistor sizes. Each cell must then be tested by simulation and its performance must be characterized. A standard cell design usually takes more area than a full-custom or a handcrafted design. However, as more metal layers become available for routing, the difference in area between the two design styles will gradually be reduced.

The gate array design style is a simplified version of the standard cell design style. Unlike the cells in standard cell designs, all the cells in gate array are identical. The entire wafer is prefabricated with an array of identical gates or cells. These cells are separated by both vertical and horizontal spaces called vertical and horizontal channels. The circuit design is modified such that it can be partitioned into a number of identical blocks. Each block must be logically equivalent to a cell on the gate array. The name ''gate array'' signifies the fact that each cell may simply be a gate, such as a three-input NAND gate. Each block in the design is mapped or placed onto a prefabricated cell on the wafer during the partitioning/placement phase, which is reduced to a block-to-cell assignment problem. The number of partitioned blocks must be less than or equal to that of the total number of cells on the wafer. Once the circuit is partitioned into identical blocks, the task is to make the interconnections between the prefabricated cells on the wafer using horizontal and vertical channels to form the actual circuit. The uncommitted gate array is taken into the fabrication facility and routing layers are fabricated on top of the wafer. The completed wafer is also called a customized wafer.

This simplicity of gate array design is gained at the cost of rigidity imposed upon the circuit both by the technology and the prefabricated wafers. The advantage of gate arrays is that the steps involved for creating any prefabricated wafer are the same, and only the last few steps in the fabrication process actually depend on the application for which the design will be used. Hence, gate arrays are cheaper and easier to produce than full-custom or standard cell. Similar to standard cell design, gate array is also a nonhierarchical structure. The gate array architecture is the most restricted form of layout. This also means it is the simplest for algorithms to work with. For example, the task of routing in gate array is to determine if a given placement is routable. The routability problem is conceptually simpler as compared to the routing problem in standard cell and full-custom design styles.

The choice of design style for a particular circuit depends on many factors such as functionality of the chip, time-to-market, and the volume of chips to be manufactured. Full-custom is typically reserved for high-performance, high-volume chips, while standard cells are used for moderate performance, where the cost of full-custom cannot be justified. Gate arrays are typically used for low-performance, low-cost applications. A design style may be applicable to the entire chip or a block of the chip.

Irrespective of the choice of the design style, all steps of the physical design cycle need to be carried out. However, the complexity, the effectiveness, and the algorithms used differ considerably depending on the design style. The following sections discuss algorithms for different phases of the physical design cycle.

6.5 Partitioning

As stated earlier, the basic purpose of partitioning is to simplify the overall design process. The circuit is decomposed into several subcircuits to make the design process manageable. This section considers the partitioning phase of the physical design cycle, study constraints, and objective functions for this problem and presents efficient algorithms.

Given a circuit, the partitioning problem is to decompose it into several subcircuits subject to constraints while optimizing a given objective function. The constraints for the partitioning problem include area constraints and terminal constraints. Area constraints are user specified for design optimization and terminal count depends on the area and aspect ratio of the block. In particular, the terminal count for a partition is given by the ratio of the perimeter of the partition to the terminal pitch. The minimum spacing between two adjacent terminals is called terminal pitch and is determined by the design rules. The objective functions for a partitioning problem include the minimization of the number of nets that cross the partition boundaries, and the minimization of the maximum number of times a path crosses the partition boundaries. The constraints and the objective functions used in the partitioning problem vary depending upon the partitioning level and the design style used. The actual objective function and constraints chosen for the partitioning problem may also depend on the specific problem. The number of nets that connect a partition to other partitions cannot be greater than the terminal count of the partition. In addition, the number of nets cut by partitioning should be minimized to simplify the routing task. The minimization of the number of nets cut by partitioning is one of the most important objectives in partitioning.

A disadvantage of the partitioning process is that it may degrade the performance of the final design. During partitioning, critical components should be assigned to the same partition. If such an assignment is not possible, then appropriate timing constraints must be generated to keep the two critical components close together. Usually, several components, forming a critical path, determine the chip performance. If each component is assigned to a different partition, the critical path may be too long. Minimizing the length of critical paths improves system performance.

After a chip has been partitioned, each of the subcircuits must be placed on a fixed plane and the nets between all the partitions must be interconnected. The placement of the subcircuits is done by the placement algorithms and the nets are routed by using routing algorithms.

6.5.1 Classification of Partitioning Algorithms

The partitioning algorithms also may be classified based on the nature of the algorithms, of which two types exist: deterministic algorithms and probabilistic algorithms. Deterministic algorithms produce repeatable or deterministic solutions. For example, an algorithm which makes use of deterministic functions will always generate the same solution for a given problem. On the other hand, the probabilistic algorithms are capable for producing a different solution for the same problem each time they are used, as they make use of some random functions.

The partitioning algorithms also may be classified on the basis of the process used for partitioning. Thus, we have group migration algorithms, simulated annealing and evolution-based algorithms, and other partitioning algorithms.

The group migration algorithms [9,17] start with some partitions, usually generated randomly, and then move components between partitions to improve the partitioning. The group migration algorithms are quite efficient. However, the number of partitions must be specified, which is usually not known when the partitioning process starts. In addition, the partitioning of an entire system is a multilevel operation, and the evaluation of the partitions obtained by the partitioning depends on the final integration of partitions at all levels, from the basic subcircuits to the whole system. An algorithm used to find a minimum cut at one level may sacrifice the quality of cuts for the following levels. The group migration method is a deterministic method that is often trapped at a local optimum and cannot proceed further.

The simulated annealing/evolution algorithms [3,10,18,26] carry out the partitioning process by using a cost function, which classifies any feasible solution, and a set of moves, which allows movement from solution to solution. Unlike deterministic algorithms, these algorithms accept moves which may adversely affect the solution. The algorithm starts with a random solution and as it progresses, the proportion of adverse moves decreases. These degenerate moves act as a safeguard against entrapment in local minima. These algorithms are computationally intensive as compared to group migration and other methods.

Among all the partitioning algorithms, the group migration and simulated annealing/evolution have been the most successful heuristics for partitioning problems. The group migration and simulated annealing/evolution methods are most widely used, and extensive research has been carried out in these two types of algorithms.

6.5.2 Kernighan–Lin Partitioning Algorithm

The Kernighan–Lin (K–L) algorithm is a bisectioning algorithm. It starts by initially partitioning the graph $G = (V, E)$ into two subsets of equal size. Vertex pairs are exchanged across the bisection if the exchange improves the cutsize. The preceding procedure is carried out iteratively until no further improvement can be achieved.

The basic idea of the K–L algorithm is illustrated with the help of an example before presenting the algorithm formally. Consider the example given in Figure 6.4a. The initial partitions are

$$A = \{1,2,3,4\}$$
$$B = \{5,6,7,8\}$$

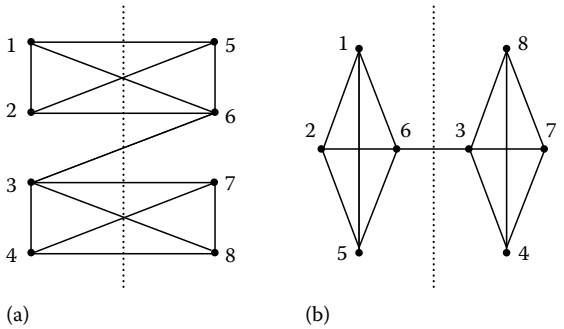

FIGURE 6.4 Graph bisected by K–L algorithm: (a) initial bisections and (b) final bisections.

TABLE 6.1 Log of the Vertex Exchanges

i	Vertex Pair	$g(i)$	$\sum_{j=1}^{i} g(i)$	Cutsize
0	—	—	—	9
1	(3, 5)	3	3	6
2	(4, 6)	5	8	1
3	(1, 7)	−6	2	7
4	(2, 8)	−2	0	9

Notice that the initial cutsize is 9. The next step of the K–L algorithm is to choose a pair of vertices whose exchange results in the largest decrease of the cutsize or results in the smallest increase, if no decrease is possible. The decrease of the cutsize is computed using gain values $D(i)$ of vertices v_i. The gain of a vertex v_i is defined as

$$D(i) = \text{inedge}(i) - \text{outedge}(i)$$

where

inedge(i) is the number of edges of vertex i that do not cross the bisection boundary
outedge(i) is the number of edges that cross the boundary

The amount by which the cutsize decreases, if vertex v_i changes over to the other partition, is represented by $D(i)$. If v_i and v_j are exchanged, the decrease of the cutsize is $D(i) + D(j)$. In the example given in Figure 6.4, a suitable vertex pair is (3, 5), which decreases the cutsize by 3. A tentative exchange of this pair is made. These two vertices are then locked. This lock on the vertices prohibits them from taking part in any further tentative exchanges. The preceding procedure is applied to the new partitions, which gives a second vertex pair of (4, 6). This procedure is continued until all the vertices are locked. During this process, a log of all tentative exchanges and the resulting cutsizes is stored. Table 6.1 shows the log of vertex exchanges for the given example. Note that the partial sum of cutsize decrease $g(i)$ over the exchanges of first i vertex pairs is given in the table; e.g., $g(1) = 3$ and $g(2) = 8$. The value of k for which $g(k)$ gives the maximum value of all $g(i)$ is determined from the table. In this example $k = 2$ and $g(2) = 8$ is the maximum partial sum. The first k pairs of vertices are actually exchanged. In the example the first two vertex pairs (3, 5) and (4, 6) are actually exchanged, resulting in the bisection shown in Figure 6.4b. This completes an iteration and a new iteration starts. However, if no decrease of cutsize is possible during an iteration, the algorithm stops. Figure 6.5 presents the formal description of the K–L algorithm.

The procedure INITIALIZE finds initial bisections, and initializes the parameters in the algorithm. The procedure IMPROVE tests if any improvement has been made during the last iteration, while the procedure UNLOCK checks if any vertex is unlocked. Each vertex has a state of either *locked* or *unlocked*. Only those vertices whose status is *unlocked* are candidates for the next tentative exchanges. The procedure TENT-EXCHGE tentatively exchanges a pair of vertices. The procedure LOCK locks the vertex pair, while the procedure LOG stores the log table. The procedure ACTUAL-EXCHGE determines the maximum partial sum of $g(i)$, selects the vertex pairs to be exchanged, and fulfills the actual exchange of these vertex pairs.

The time complexity of the K–L algorithm is $O(n^3)$. The K–L algorithm is, however, quite robust. It can accommodate additional constraints, such as a group of vertices requiring to be in a specified partition. This feature is very important in layout because some blocks of the circuit are to be kept together due to the functionality. For example, it is important to keep all components of an adder together. However, the K–L algorithm has several disadvantages. For example, the algorithm is not applicable for hypergraphs, it cannot handle arbitrarily weighted graphs and the partition sizes must be specified before partitioning. Finally, the complexity of the algorithm is considered too high even for moderate-size problems.

Algorithm *KL*

```
Begin
    INITIALIZE();
    while (IMPROVE (table) = TRUE) do
    (* if an improvement has been made during last iteration,
    the process is carried out again.*)
        while (UNLOCK(A) = TRUE) do
        (* if there exists any unlocked vertex in A,
        more tentative exchanges are carried out.*)
            for (each a∈A) do
                if (a = unlocked) then
                    for (each b ∈ B) do
                        if (b = unlocked) then
                            if (D_max < D(a) + D(b)) then
                                D_max = D(a) + D(b);
                                a_max = a;
                                b_max = b;
            TENT-EXCHGE(a_max, b_max);
            LOCK(a_max, b_max);
            LOG(table);
            D_max = −∞;
        ACTUAL-EXCHGE(table);
End;
```

FIGURE 6.5 Algorithm K–L.

6.6 Other Partitioning Algorithms

In order to overcome the disadvantages of the K–L algorithm, several extensions of the K–L algorithm such as the Fiduccia–Mattheyses algorithm, the Goldberg and Burstein algorithm, the component replication algorithm, and the ratio cut algorithm were developed. In the class of probabilistic and iterative algorithms simulated annealing and evolution-based algorithms have been developed for partitioning. For details on these partitioning algorithms, refer to Chapter 4 of [29].

6.7 Placement

The placement phase follows the partitioning phase of the physical design cycle. After the circuit has been partitioned, the area occupied by each block (subcircuit) can be calculated and the number of terminals (pins) required by each block is known. Partitioning also generates the netlist which specifies the connections between the blocks. The layout is completed by arranging the blocks on the layout surface and interconnecting their pins according to the netlist. The arrangement of blocks is done in the placement phase, while interconnection is completed in the routing phase. In the placement phase, blocks are assigned a specific shape and are positioned on a layout surface in such a fashion that no two blocks overlap and enough space is left on the layout surface to complete the interconnections between the blocks. The blocks are positioned so as to minimize the total area of the layout. In addition, the locations of pins on each block are also determined.

The input to the placement phase is a set of blocks, the number of terminals for each block, and the netlist. If the layout of the circuit within a block has been completed, then the dimensions of the block are also known. The blocks for which the dimensions are known are called fixed blocks and the blocks for which dimensions are yet to be determined are called flexible blocks. Thus, during the placement phase, we need to determine an appropriate shape for each block (if shape is not known), the location of each block on the layout surface, and determine the locations of pins on the boundary of the blocks. The

problem of assigning locations to the fixed blocks on a layout surface is called the placement problem. If some or all of the blocks are flexible, the problem is called the floorplanning problem. Hence, the placement problem is a restricted version of the floorplanning problem. The terminology is slightly confusing as floorplanning problems are placement problems as well, but these terminologies have been widely used and accepted. It is desirable that the pin locations are identified at the same time the block locations are fixed. However, due to the complexity of the placement problem, the problem of identifying the pin locations for the blocks is solved after the locations of all the blocks are known. This process of identifying pin locations is called pin assignment.

The placement phase is crucial in the overall physical design cycle because an ill-placed layout cannot be improved by high-quality routing. In other words, the overall quality of the layout in terms of area and performance is mainly determined in the placement phase.

6.7.1 Classification of Placement Algorithms

The placement algorithms can be classified on the basis of the input to the algorithms, the nature of output generated by the algorithms, and the process used by the algorithms.

Depending on the input, the placement algorithms can be classified into two major groups: constructive placement and iterative improvement methods. The input to the constructive placement algorithms consists of a set of blocks along with the netlist. The algorithm finds the locations of blocks. On the other hand, iterative improvement algorithms start with an initial placement. These algorithms modify the initial placement in search of a better placement. These algorithms are typically used in an iterative manner until no improvement is possible.

The nature of output produced by an algorithm is another way of classifying the placement algorithms. Some algorithms generate the same solution when presented with the same problem, i.e., the solution produced is repeatable. These algorithms are called deterministic placement algorithms. Algorithms that function on the basis of fixed connectivity rules (or formulas) or determine the placement by solving simultaneous equations are deterministic and always produce the same result for a particular placement problem. Some algorithms, on the other hand, work by randomly examining configurations and may produce a different result each time they are presented with the same problem. Such algorithms are called probabilistic placement algorithms.

The classification based on the process used by the placement algorithms is perhaps the best way of classifying these algorithms. Two important classes of algorithms come under this classification: simulation-based algorithms and partitioning-based algorithms. Simulation-based algorithms simulate some natural phenomenon while partitioning-based algorithms use partitioning for generating the placement. The algorithms which use clustering and other approaches are classified under ''other'' placement algorithms.

6.7.2 Simulated Annealing Placement Algorithm

Simulated annealing is one of the most well-developed methods available [2,10–12,16,19,23,25–28]. The simulated annealing technique has been successfully used in many phases of VLSI physical design, e.g., circuit partitioning. A detailed description of the application of this method to partitioning may be found in Chapter 4 of [29]. Simulated annealing is used in placement as an iterative improvement algorithm. Given a placement configuration, a change to that configuration is made by moving a component or interchanging locations of two components. In the case of the simple pairwise interchange algorithm, it is possible that an achieved configuration has a cost higher than that of the optimum, but no interchange can cause a further cost reduction. In such a situation, the algorithm is trapped at a local optimum, and cannot proceed further. Actually, this happens quite often when this algorithm is used in real-life examples. Simulated annealing avoids getting stuck at a local optimum by occasionally accepting moves that result in a cost increase.

Algorithm *Simulated Annealing*

```
Begin
    temp = INIT-TEMP;
    place = INIT-PLACEMENT;
    while (temp > FINAL-TEMP) do
      while (inner_loop_criterion = FALSE) do
        new_place = PERTURB (place);
        ΔC = COST(new_place) - COST (place);
        if (ΔC < 0) then
          place = new_place;
        else if (RANDOM(0,1) > e^(Δc/T)) then
          place = new_place;
      temp = SCHEDULE(temp);
End;
```

FIGURE 6.6 Algorithm simulated annealing.

In simulated annealing, all moves that result in a decrease in cost are accepted. Moves that result in an increase in cost are accepted with a probability that decreases over the iterations. The analogy to the actual annealing process is heightened with the use of a parameter called temperature T. This parameter controls the probability of accepting moves that result in an increased cost. Additional moves are accepted at higher values of temperature than at lower values. The acceptance probability can be given by $e^{\Delta C/T}$, where ΔC is the increase in cost. The algorithm starts with a very high value of temperature, which gradually decreases so that moves that increase cost have a lower probability of being accepted. Finally, the temperature reduces to a very low value which causes only moves that reduce cost to be accepted. In this way the algorithm converges to an optimal or near-optimal configuration.

In each stage, the configuration is shuffled randomly to obtain a new configuration. This random shuffling could be achieved by displacing a block to a random location, an interchange of two blocks, or any other move that can change the wire length. After the shuffle, the change in cost is evaluated. If a decrease in cost occurs, the configuration is accepted; otherwise, the new configuration is accepted with a probability that depends on the temperature. The temperature is then lowered using some function which, for example, could be exponential in nature. The process is stopped when the temperature has dropped to a certain level. The outline of the simulated annealing algorithm is shown in Figure 6.6.

The parameters and functions used in a simulated annealing algorithm determine the quality of the placement produced. These parameters and functions include the cooling schedule consisting of initial temperature (*init_temp*), final temperature (*final_temp*), and the function used for changing the temperature (SCHEDULE), *inner_loop_criterion*, which is the number of trials at each temperature, the process used for shuffling a configuration (PERTURB), acceptance probability (F), and the cost function (COST). A good choice of these parameters and functions can result in a good placement in a relatively short time.

6.7.3 Other Placement Algorithms

Several other algorithms which simulate naturally occurring processes have been developed for routing. The simulated evolution algorithm is analogous to the natural process of mutation of species as they evolve to better adapt to their environment. The force directed placement explores the similarity between the placement problem and the classical mechanics problem of a system of bodies attached to springs. The partitioning-based placement techniques include Breuer's algorithm and the terminal propagation algorithm. Several other algorithms, such as the cluster growth algorithm, the quadratic assignment algorithm, the resistive network optimization algorithm, and the branch and bound algorithm, also exist. For more details on these algorithms, refer to Chapter 5 of [29].

6.8 Routing

The exact locations of circuit blocks and pins are determined in the placement phase. A netlist is also generated which specifies the required interconnections. Space not occupied by the blocks can be viewed as a collection of regions. These regions are used for routing and are called routing regions. The process of finding the geometric layouts of all the nets is called routing. Each routing region has a capacity, which is the maximum number of nets that can pass through that region. The capacity of a region is a function of the design rules and dimensions of the routing regions and wires. Nets must be routed within the routing regions and must not violate the capacity of any routing region. In addition, nets must not short circuit; that is, nets must not intersect each other. The objective of routing is dependent on the nature of the chip. For general-purpose chips, it is sufficient to minimize the total wire length. For high-performance chips, total wire length may not be a major concern. Instead, we may want to minimize the longest wire to minimize the delay in the wire and therefore maximize its performance. Usually routing involves special treatment of such nets as clock nets, power, and ground nets. In fact, these nets are routed separately by special routers.

Channels and switchboxes are the two types of routing regions. A switchbox is a rectangular area bounded on all sides. A channel is a rectangular area bounded on two opposite sides by the blocks. The capacity of a channel is a function of the number of layers (l), height (h) of the channel, wire width (w), and wire separation (s); i.e., $capacity = (l \times h)/(w + s)$. For example, if for channel C (Figure 6.7), $l = 2$, $h = 18\lambda$, $w = 3\lambda$, $s = 3\lambda$, then the capacity is $(2 \times 18)/(3 + 3) = 6$.

A VLSI chip may contain several million transistors. As a result, tens of thousands of nets must be routed to complete the layout. In addition, several hundred routes are possible for each net. This makes the routing problem computationally hard. In fact, even when the routing problem is restricted to channels, it cannot be solved in polynomial time; i.e., the channel routing problem is NP-complete [30]. Therefore, routing traditionally is divided into two phases. The first phase is called global routing and generates a ''loose'' route for each net. In fact, it assigns a list of routing regions to each net without specifying the actual geometric layout of wires. The second phase, which is called detailed routing, finds the actual geometric layout of each net within the assigned routing regions (Figure 6.8b). Unlike global routing, which considers the entire layout, a detailed router considers just one region at a time. The exact layout is produced for each wire segment assigned to a region, and vias are inserted to complete the layout. Detailed routing includes channel routing and switchbox routing. Another approach to routing is called area routing, which is a single-phase routing technique. However, this technique is computationally infeasible for general VLSI circuits and is typically used for specialized problems.

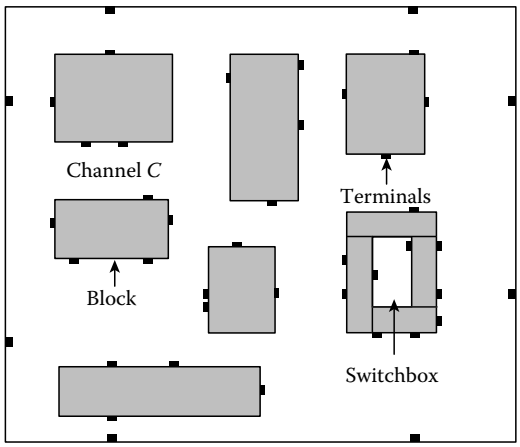

FIGURE 6.7 Layout of circuit blocks and pins after placement.

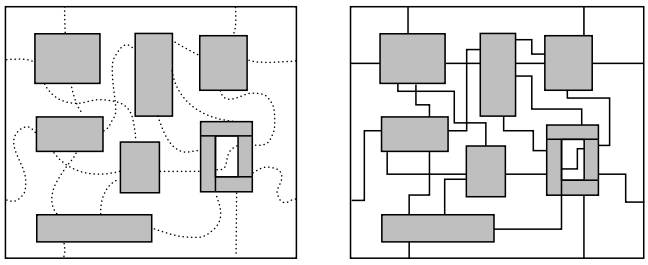

FIGURE 6.8 (a) Global routing and (b) detailed routing.

6.9 Classification of Global Routing Algorithms

Two approaches solve the global routing problem: the sequential and the concurrent:

1. *Sequential approach*: As the name suggests, nets are routed one by one. However, once a net has been routed it may block other nets which are yet to be routed. As a result, this approach is very sensitive to the order in which the nets are considered for routing. Usually, the nets are sequenced according to their criticality, perimeter of the bounding rectangle, and the number of terminals. The criticality of a net is determined by the importance of the net.
2. *Concurrent approach*: This approach avoids the ordering problem by considering routing of all the nets simultaneously. The concurrent approach is computationally hard and no efficient polynomial algorithms are known, even for two-terminal nets. As a result, integer programming methods have been suggested. The corresponding integer program is usually too large to be employed efficiently. Hence, hierarchical methods that work from the top down are employed to partition the problem into smaller subproblems, which can be solved by integer programming.

6.10 Classification of Detailed Routing Algorithms

Many ways are possible for classifying the detailed routing algorithms. The algorithms could be classified on the basis of the routing models used. Some routing algorithms use grid-based models, while some other algorithms use the gridless model. The gridless model is more practical as all the wires in a design do not have the same width. Another possible classification scheme could be to classify the algorithms based on the strategy they use. Thus, we could have greedy routers or hierarchical routers to name two. We classify the algorithms based on the number of layers used for routing. Single-layer routing problems frequently appear as subproblems in other routing problems which deal with more than one layer. Two-layer routing problems have been thoroughly investigated because until recently, due to limitations of the fabrications process, only two metal layers were allowed for routing. A third metal layer is now allowed, thanks to improvements in the fabrication process, but it is expensive compared to the two-layer metal process. Several multilayer routing algorithms also were developed recently, which can be used for routing MCMs, which have up to 32 layers.

6.10.1 Lee's Algorithm for Global Routing

This algorithm, which was developed by Lee in 1961 [20], is the most widely used algorithm for finding a path between any two vertices on a planar rectangular grid. The key to the popularity of Lee's maze router is its simplicity and its guarantee of finding on optimal solution, if one exists.

The exploration phase of Lee's algorithm is an improved version of the breadth-first search. The search can be visualized as a wave propagating from the source. The source is labeled ''0'' and the wavefront

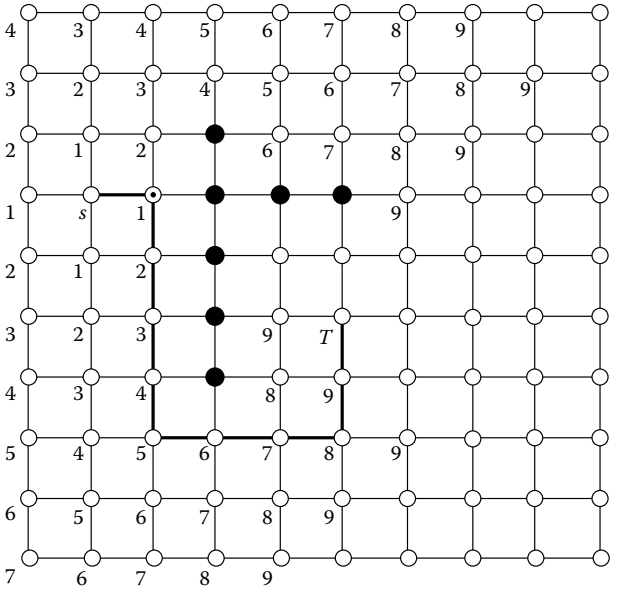

FIGURE 6.9 Net routed by Lee's algorithm.

propagates to all the unblocked vertices adjacent to the source. Every unblocked vertex adjacent to the source is marked with a label "1." Then, every unblocked vertex adjacent to vertices with a label "1" is marked with a label "2," and so on. This process continues until the target vertex is reached or no further expansion of the wave can be carried out. An example of the algorithm is shown in Figure 6.9. Due to the breadth-first nature of the search, Lee's maze router is guaranteed to find a path between the source and the target, if one exists. In addition, it is guaranteed to be the shortest path between the vertices.

The input to Lee's algorithm is an array B, the source, s, and target, t, vertex. $B[v]$ denotes if a vertex v is blocked or unblocked. The algorithm uses an array, L, where $L[v]$ denotes the distance from the source to the vertex v. This array will be used in the procedure RETRACE that retraces the vertices to form a path, P, which is the output of Lee's algorithm. Two linked lists, *plist* (propagation list) and *nlist* (neighbor list), are used to keep track of the vertices on the wavefront and their neighbor vertices, respectively. These two lists are always retrieved from tail to head. We also assume that the neighbors of a vertex are visited in counterclockwise order, that is, top, left, bottom, and then right.

The formal description of Lee's algorithm appears in Figure 6.10. The time and space complexity of Lee's algorithm is $O(h \times w)$ for a grid of dimension $h \times w$.

Lee's routing algorithm requires a large amount of storage space and its performance degrades rapidly when the size of the grid increases. Numerous attempts have been made to modify the algorithm to improve its performance and reduce its memory requirements.

Lee's algorithm requires up to $k+1$ bits per vertex, where k bits are used to label the vertex during the exploration phase and an additional bit is needed to indicate whether the vertex is blocked. For an $h \times w$ grid, $k = \log_2(h \times w)$. Aker [1] noticed that in the retrace phase of Lee's algorithm, only two types of neighbors of a vertex need to be distinguished; vertices toward the target and vertices toward the source. This information can be coded in a single bit for each vertex. The vertices in wavefront, L, are always adjacent to the vertices in wavefront $L-1$ and $L+1$. Thus, during wave propagation, instead of using a sequence 1, 2, 3, . . . , the wavefronts are labeled by a sequence such as 0, 0, 1, 1, 0, 0, ... The predecessor of any wavefront is labeled differently from its successor. Thus, each scanned vertex is either labeled "0" or "1." Besides these two states, additional states ("block" and "unblocked") are needed for each vertex. These four states of each vertex can be represented by using exactly 2 bits, regardless of the problem size.

```
Algorithm Lee-Router (B, s, t, P)

Input: B, s, t
Output: P

Begin
    plist = s;
    nlist = ϕ;
    temp = 1;
    path_exists = FALSE;
    while plist ≠ ϕ do
        for each vertex v_i in plist do
            for each vertex v_j neighboring v_i do
            if B[v_j] = UNBLOCKED then
                L[v_j] = temp;
                INSERT (v_j, nlist);
                if v_j = t then
                    path_exists = TRUE;
                    exit while;
        temp = temp + 1;
        plist = nlist;
        nlist = ϕ;
    if path_exists = TRUE then RETRACE (L, P);
    else path does not exist;
End;
```

FIGURE 6.10 Lee's routing algorithm.

Compared with Acker's scheme, Lee's algorithm requires at least 12 bits per vertex for a grid size of 2000×2000.

It is important to note that Acker's coding scheme only reduces the memory requirement per vertex. It inherits the search space of Lee's original routing algorithm, which is $O(h \times w)$ in the worst case.

6.10.2 Greedy Channel Router for Detailed Routing

Assigning the complete trunk of a net or a two-terminal net segment of a multiterminal net severely restricts LEA and dogleg routers. Optimal channel routing can be obtained if for each column it can be guaranteed that only one horizontal track per net exists. Based on this observation, one approach to reduce channel height could be to route nets column by column trying to join split horizontal tracks (if any) that belong to the same net as much as possible.

Based on the preceding observation and approach, Rivest and Fiduccia [24] developed the greedy channel router. This makes fewer assumptions than LEA and dogleg routers. The algorithm starts from the leftmost column and places all the net segments of a column before proceeding to the next right column. In each column the router assigns net segments to tracks in a greedy manner. However, unlike the dogleg router, the greedy router allows the doglegs in any column of the channel, not necessarily where the terminal of the doglegged net occurs.

Given a channel routing problem with m columns, the algorithm uses several steps while routing a column. In the first step the algorithm connects any terminal to the trunk segment of the corresponding net. This connection is completed by using the first empty track, or the track that already contains the net. In other words, minimum vertical segment is used to connect a trunk to a terminal. For example, net 1 in Figure 6.11a in column 3 is connected to the same net. The second step attempts to collapse any split nets (horizontal segments of the same net present on two different tracks) using a vertical segment as shown in Figure 6.11b. A split net will occur when two terminals of the same net are located on different

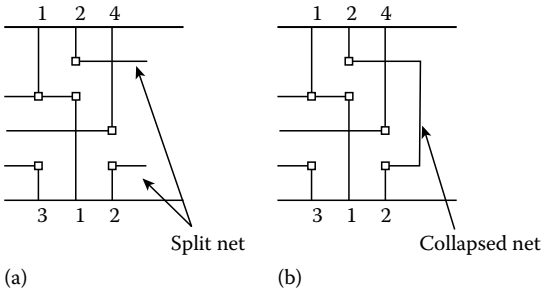

FIGURE 6.11 (a) Split net and (b) collapsed split net.

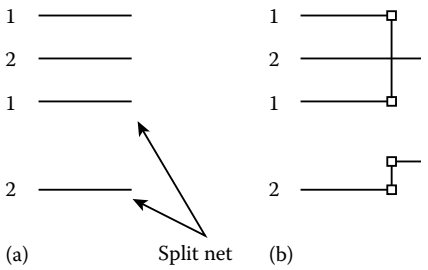

FIGURE 6.12 (a) Reducing the distance between split nets and (b) its result.

sides of the channel and cannot be connected immediately because of existing vertical constraints. This step also brings a terminal connection to the correct track if it has stopped on an earlier track. If two sets of split nets overlap, the second step will only be able to collapse one of them.

In the third step, the algorithm tries to reduce the range or the distance between two tracks of the same net. This direction is accomplished by using a dogleg, as shown in Figure 6.12a and b. The fourth step attempts to move the nets closer to the boundary which contains the next terminal of that net. If the next terminal of a net being considered is on the top (bottom) boundary of the channel, then the algorithm tries to move the net to the upper (lower) track. In case no track is available, the algorithm adds extra tracks and the terminal is connected to this new track. After all five steps have been completed, the trunks of each net are extended to the next column and the steps are repeated. A detailed description of the greedy channel routing algorithm is shown in Figure 6.13.

The greedy router sometimes gives solutions which contain an excessive number of vias and doglegs. It does, however, have the capability of providing a solution even in the presence of cyclic vertical constraints. The greedy router is more flexible in the placement of doglegs due to fewer assumptions about the topology of the connections. An example routed by the greedy channel router is shown in Figure 6.14.

6.10.3 Other Routing Algorithms

Soukup proposed an algorithm that basically cuts down the search time of Lee's algorithm by exploring in the direction toward the target, without changing the direction until it reaches the target or an obstacle. An alternative approach to improve upon the speed was suggested by Hadlock. One class of algorithm is called the line-probe algorithms. The basic idea of the line-probe algorithms is to reduce the memory requirement by using line segments instead of grid notes in the search. Several algorithms based on Steiner trees have been developed. The main advantage of these algorithms is that they can be used for routing multiterminal nets. For further details on these global routing algorithms, refer to Chapter 6 of [29].

Extensive research has been carried out in the area of detailed routing and several algorithms exist for channel and switchbox routing. There are LEA-based algorithms which use a reserved layer model and do not allow any vertical constraints or doglegs. The YACR2 algorithm can handle vertical constraint

```
Algorithm Greedy-Channel-Router (N)

Input: N

Begin
    d = DENSITY (N);
  (* calculate the lower bound of channel density *)
    insert d tracks to channel;
    for i = 1 to m do
      T1 = GET-EMPTY-TRACK;
      if T1 = 0 then
        ADD-TRACK(T1);
        ADD-TRACK(T2);
      else
        T2 = GET-EMPTY-TRACK;
        if T2 = 0 then
          ADD-TRACK(T2);
      CONNECT(T_i,T1);
      CONNECT(B_i,T2);
      join split nets as much as possible;
      bring split nets closer by jogging;
      bring nets closer to either top or bottom boundary;
    while split nets exists do
      increase number of column by 1;
      join split nets as much as possible;
End;
```

FIGURE 6.13 Algorithm greedy channel router.

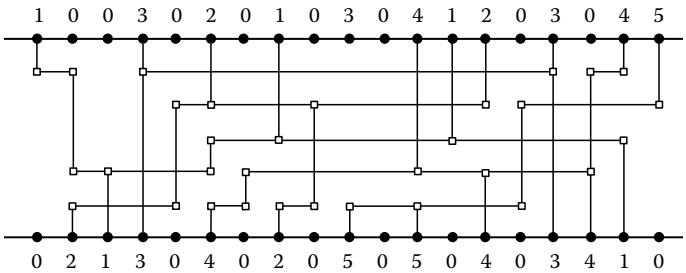

FIGURE 6.14 Channel routed using a greedy router.

violations. The net merge channel router works for two-layer channel routing problems and it exploits the graph theoretic structure of channel routing problems. Glitter is an algorithm for gridless channel routing and can handle nets of varying widths. The hierarchical channel router divides the channel routing problem into smaller problems, each of which is solved in order to generate the complete routing for the nets in the channel. Several algorithms such as the extended net merge channel routing algorithm, HVH routing from the HV solution, and the hybrid HVH–VHV channel routing algorithm exist for the three-layer channel routing problem. For further details on these detailed routing algorithms, refer to Chapter 7 of [29].

6.11 Compaction

After completion of detailed routing, the layout is functionally complete. At this stage, the layout is ready to be used to fabricate a chip. However, due to nonoptimality of placement and routing algorithms, some vacant space is present in the layout. In order to minimize the cost, improve performance, and yield, layouts are reduced in size by removing the vacant space without altering the functionality of the layout. This operation of layout area minimization is called layout compaction.

The compaction problem is simplified by using symbols to represent primitive circuit features, such as transistors and wires. The representation of layout using symbols is called a symbolic layout. Special languages [4,21,22] and special graphic editors [13,14] are available to describe symbolic layouts. To produce the actual masks, the symbolic layouts are translated into actual geometric features. Although a feature can have any geometric shape, in practice only rectangular shapes are considered.

The goal of compaction is to minimize the total layout area without violating any design rules. The area can be minimized in three ways:

1. *By reducing the space between features*: This can be performed by bringing the features as close to each other as possible. However, the spacing design rules must be met while moving features closer to each other.
2. *By reducing the size of each feature*: The size rule must be met while resizing the features.
3. *By reshaping the features*: Electrical characteristics must be preserved while reshaping the feature.

Compaction is a very complex phase in the physical design cycle. It requires understanding many details of the fabrication process such as the design rules. Compaction is critical for full-custom layouts, especially for high-performance designs.

6.11.1 Classification of Compaction Algorithms

Compaction algorithms can be classified in two ways. The first classification scheme is based on the direction of movements of the components (features): one-dimensional (1-D) and two-dimensional (2-D). In 1-D compaction components are moved only in x- or the y-direction. As a result, either the x- or the y-coordinate of the components is changed due to the compaction. If the compaction is done along the x-direction, then it is called x-compaction. Similarly, if the compaction is done along the y-direction, then it is called y-compaction. In 2-D compaction the components can be moved in both the x- and y-directions simultaneously. As a result, in 2-D compaction both x- and y-coordinates of the components are changed at the same time in order to minimize the layout area.

The second approach to classify the compaction algorithms is based on the technique for computing the minimum distance between features. In this approach, we have two methods: constraint graph-based compaction and virtual grid-based compaction. In the constraint graph method, the connections and separations rules are described using linear inequalities which can be modeled using a weighted directed graph (constraint graph). This constraint graph is used to compute the new positions for the components. On the other hand, the virtual grid method assumes the layout is to be drawn on a grid. Each component is considered attached to a grid line. The compaction operation compresses the grid along with all components placed on it, keeping the grid lines straight along the way. The minimum distance between two adjacent grid lines depends on the components on these grid lines. The advantage of the virtual grid method is that the algorithms are simple and can be easily implemented. However, the virtual grid method does not produce compact layouts as does the constraint graph method.

In addition, compaction algorithms can be classified on the basis of the hierarchy of the circuit. If compaction is applied to different levels of the layout, it is called hierarchical compaction. Any of the above-mentioned methods can be extended to hierarchical compaction. A variety of hierarchical compaction algorithms have been proposed for both constraint graph and virtual grid methods. Some compaction algorithms actually ''flatten the layout'' by removing all hierarchy and then

perform compaction. In this case it may not be possible to reconstruct the hierarchy, which may be undesirable.

6.11.2 Shadow-Propagation Algorithm for Compaction

A widely used and one of the best known techniques for generating a constraint graph is the shadow-propagation used in the CABBAGE system [15]. The ''shadow'' of a feature is propagated along the direction of compaction. The shadow is caused by shining an imaginary light from behind the feature under consideration (see Figure 6.15). Usually the shadow of the feature is extended on both sides of the features in order to account for diagonal constraints. This leads to greater than minimal Euclidean spacings because an enlarged rectangle is used to account for corner interactions. (See shadow of feature in Figure 6.15.)

When the shadow is obstructed by another feature, an edge is added to the graph between the vertices corresponding to the propagating feature and the obstructing feature. The obstructed part of the shadow is then removed from the front and no longer propagated. The process is continued until all of the shadow has been obstructed. This process is repeated for each feature in the layout. The algorithm shadow-propagation, given in Figure 6.16, presents an overview of the algorithm for *x*-compaction of a single feature from left to right.

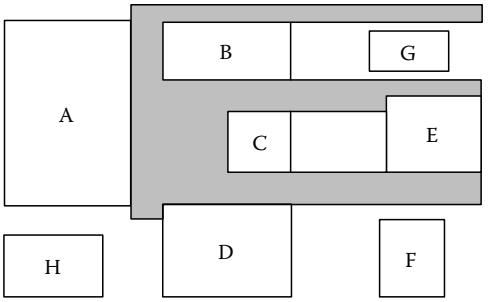

FIGURE 6.15 Example of shadow propagation.

The shadow-propagation routine accepts the list of components (*Comp_list*), which is sorted on the *x*-coordinates of the left corner of the components and the component (*component*) for which the constraints are to be generated. The procedure, INITIALIZE-SCANLINE, computes the total length of the interval in which the shadow is to be generated. This length includes the design rule separation distance. The *y*-coordinate of the top and the bottom of this interval are stored in the global variables, *top* and *bottom*, respectively. The procedure, GET-NXT-COMP, returns the next component (*curr_comp*) from *Comp_list*. This component is then removed

Algorithm *Shadow-Propagation* (*Comp_list, component*)

Input: *Comp_list, component*

```
Begin
    INITIALIZE-SCANLINE (component);
  I = ϕ;
   while ( (LENGTH-SCANLINE(I) < (top – bottom))
         and (Comp_list ≠ ϕ))
      curr_comp = GET-NXT-COMP (Comp_list);
      I_i = LEFT-EDGE (curr_comp);
      if (IN-RANGE (I_i, top, bottom))
         I' = UNION (I_i, I);
         if(I' ≠ I)
            ADD-CONSTRAINT (component, curr_comp);
            I = UNION(I_i, I);
End;
```

FIGURE 6.16 Shadow-propagation algorithm.

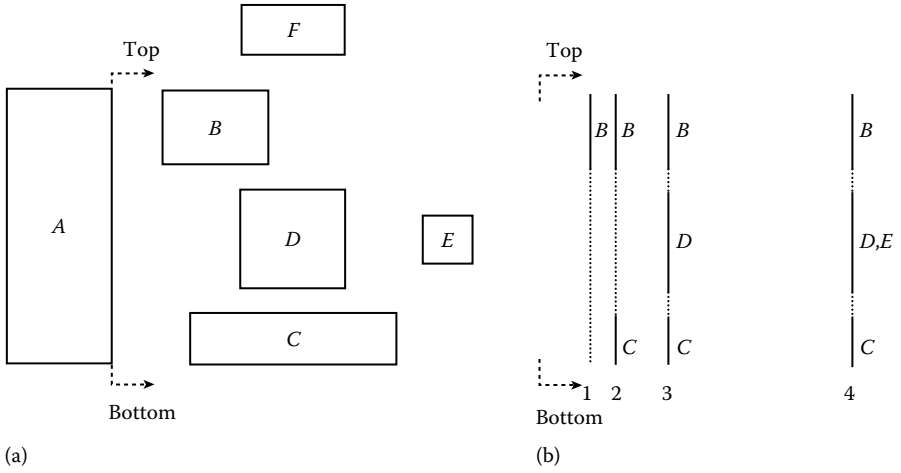

FIGURE 6.17 Interval generation for shadow propagation. (a) The layout of components and (b) the intervals in the interval set.

from the list. Procedure LEFT-EDGE returns the vertical interval of component, *curr_comp*. If this interval is within the *top* and *bottom* then *curr_comp* may have a constraint with *component*. This check is performed by the procedure IN-RANGE. If the interval for *curr_component* lies within *top* and *bottom* and if this interval is not already contained within one of the intervals in the interval set, $\mathcal{I}$, then the component lies in the shadow of *component*, and hence a constraint must be generated. Each interval represents the edge at which the shadow is blocked by a component. The constraint is added to the constraint graph by the procedure ADD-CONSTRAINT. The procedure UNION inserts the interval corresponding to *curr_comp* in the interval set at the appropriate position. This process is carried out until the interval set completely covers the interval from *top* to *bottom* or no more components are in *Comp_list*. Figure 6.17a shows the layout of components. The constraint for component *A* with other components is being generated. Figure 6.17b shows the intervals in the interval set as the shadow is propagated. From Figure 6.17b it is clear that the constraints will be generated between components *A* and components *B*, *C*, and *D* in that order. As component *F* lies outside the interval defined by *top* and *bottom* it is not considered for constraint generation. The interval generated by component *E* lies within one of the intervals in the interval set. Hence, no constraint is generated between components *A* and *E*.

6.11.3 Other Compaction Algorithms

Several algorithms such as constraint graph-based compaction algorithms, scanline algorithm, and grid-based compaction algorithms exist for the 1-D compaction problem. An algorithm based on a simulation of the zone-refining process also was developed. This compactor is considered a $1\frac{1}{2}$-D compactor, as the key idea is to provide enough lateral movements to blocks during compaction to resolve interferences. For further details on these algorithms, refer to Chapter 10 of [29].

6.12 Summary

The sheer size of the VLSI circuit, the complexity of the overall design process, the desired performance of the circuit, and the cost of designing a chip dictate that the whole design process must be automated. Also, the design process must be divided into different stages because of the complexity of the entire process. Physical design is one of the steps in the VLSI design cycle. In this step each component of a circuit is converted into a set of geometric patterns which achieves the functionality of the component.

The physical design step can be divided further into several substeps. All the substeps of the physical design step are interrelated. Efficient and effective algorithms are required to solve different problems in each of the substeps. Despite significant research efforts in this field, the CAD tools still lag behind the technological advances in fabrication. This calls for the development of efficient algorithms for physical design automation.

7.1 Introduction

The field of *design automation* technology, also commonly called computer-aided design (CAD) or computer-aided engineering (CAE), involves developing computer programs to conduct portions of product design and manufacturing on behalf of the designer. Competitive pressures to produce in less time and use fewer resources, new generations of products having improved function and performance are motivating the growing importance of design automation. The increasing complexities of microelectronic technology, shown in Figure 7.1, illustrate the importance of relegating portions of product development to computer automation [1,3]. Advances in microelectronic technology enable over 1 million devices to be manufactured on an integrated circuit substrate smaller in size than a postage stamp, yet the ability to exploit this capability remains a challenge. Manual design techniques are unable to keep pace with product design cycle demands and are being replaced by automated design techniques [2,4].

Figure 7.2 summarizes the historical development of design automation technology and computer programs. Design automation programs are also called ''applications'' or ''tools.'' Design automation efforts started in the early 1960s as academic research projects and captive industrial programs, focusing on individual tools for physical and logical design. Later developments extended logic simulation to more detailed *circuit* and *device* simulation and more abstract *functional* simulation. Starting in the mid to the

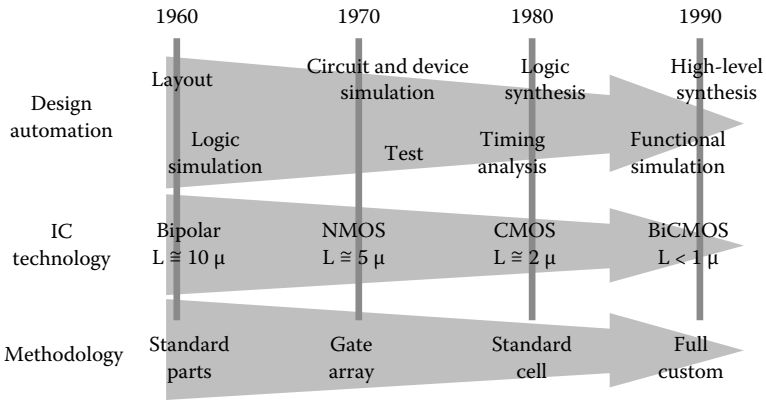

FIGURE 7.2 Development of design automation technology.

late 1970s, new areas of test and synthesis emerged and commercial design automation products appeared. Today, the electronic design automation industry is an international business with a well-established and expanding technical base [5]. The electronic design automation technology base will be examined by presenting an overview of the following topical areas:

- Design entry
- Conceptual design
- Synthesis
- Verification
- Testing
- Frameworks

7.2 Design Entry

Design entry, also called design capture, is the process of communicating with a design automation system. Design entry involves describing a system design to a design automation system, invoking applications to analyze and/or modify the system design, and querying the results. In short, design entry is how an engineer ''talks'' to a design automation application and/or system.

Any sort of communication is composed of two elements: language and mechanism. Language provides common semantics; mechanism provides a means by which to convey the common semantics. For example, two people communicate via a language such as English, French, or German, and a mechanism, such as a telephone, electronic mail, or facsimile transmission. For design, a digital system can be described in many ways, involving different perspectives or abstractions. An abstraction is a model for defining the behavior or semantics of a digital system, i.e., how the outputs respond to the inputs. Figure 7.3 illustrates several popular levels of abstractions and the trends toward higher levels of design entry abstraction to address greater levels of complexity [10,12].

The physical level of abstraction involves geometric information that defines electrical devices and their interconnection. Geometric information includes the shaped objects and where objects are placed relative to each other. For example, Figure 7.4 shows the geometric shapes defining a simple complementary metal–oxide semiconductor (CMOS) inverter. The shapes denote different materials, such as aluminum and polysilicon, and connections, called *contacts* or *vias*.

The design entry mechanism for physical information involves textual and graphic techniques. With textual techniques, geometric shape and placement are described via an artwork description language, such as Caltech Intermediate Form or Electronic Design Intermediate Form. With graphical techniques, geometric shape and placement are described by drawing the objects on a display terminal [13].

The electrical level abstracts geometric information into corresponding electrical devices, such as capacitors, transistors, and resistors. For example, Figure 7.5 shows the electrical symbols denoting a CMOS inverter. Electrical information includes the device behavior in terms of terminal or pin current and voltage relationships. Device behavior also may be defined in terms of manufacturing parameters, such as resistances or chemical compositions.

The logical level abstracts electrical information into corresponding logical elements, such as `and` gates, `or` gates, and inverters. Logical information includes truth table and/or characteristic switching algebra equations and active level designations. For example, Figure 7.6 shows the logical symbol for a CMOS inverter. Notice how the amount of information decreases as the level of abstraction increases.

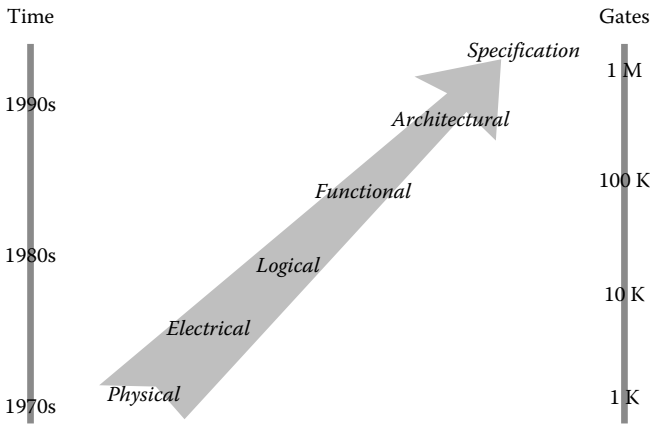

FIGURE 7.3 Design automation abstractions.

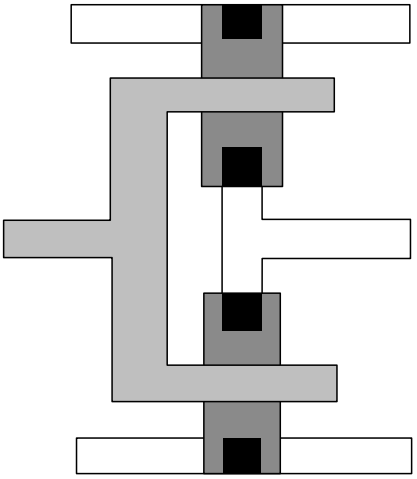

FIGURE 7.4 Physical information.

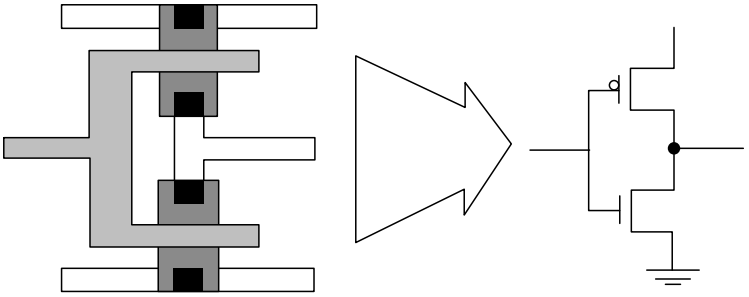

FIGURE 7.5 Electrical information.

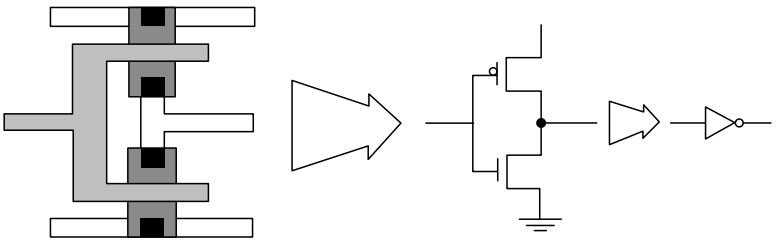

FIGURE 7.6 Logical information.

Design entry mechanisms for electrical and logical abstractions are commonly collectively called *schematic* capture techniques. Schematic capture defines hierarchical structures, commonly called *netlists*, of components. A designer creates instances of components supplied from a library of predefined components and connects component pins or ports via wires [9,11].

The functional level abstracts logical elements into corresponding computational units, such as registers, multiplexers, and arithmetic logic units (ALUs). The architectural level abstracts functional

information into computational algorithms or paradigms. Some examples of common computational paradigms are

- State diagrams
- Petri nets
- Control/data flow graphs
- Function tables
- Spreadsheets
- Binary decision diagrams

These higher levels of abstraction support a more expressive ''higher bandwidth'' communication interface between an engineer and design automation programs. An engineer can focus his or her creative, cognitive skills on concept and behavior, rather than the complexities of detailed implementation. Associated design entry mechanisms typically use hardware description languages with a combination of textual and graphic techniques [6].

Figure 7.7 shows a simple state diagram. The state diagram defines three states, denoted by circles. State-to-state transitions are denoted by labeled arcs; state transitions depend on the present state and the input *X*. The output, *Z*, per state is given within each state. Because the output is dependent on only the present state, the digital system is classified as a *Moore finite state machine*. If the output is dependent on the present state and input, then the digital system is classified as a *Mealy finite state machine*. The state table corresponding to the state diagram in Figure 7.7 is given in Table 7.1. A hardware description language model written in VHDL of the Moore finite state machine is given in Figure 7.8. The VHDL model, called a *design entity*, uses a ''date flow'' description style to describe the state machine [7,8]. The

FIGURE 7.8 VHDL model.

entity statement defines the interface, i.e., the ports. The ports include two input signals, *X* and *CLK*, and an output signal, *Z*. The ports are of type BIT, which specifies that the signals may only carry the values "0" or "1." The architecture statement defines the I–O transform via two concurrent signal assignment statements. The internal signal STATE holds the finite state information and is driven by a guarded, conditional concurrent signal assignment statement that executes when the associated block expression (*CLK* = "1" and not CLK'STABLE) is true, which is only on the rising edge of the signal *CLK*. STABLE is a predefined attribute of the signal *CLK*; CLK'STABLE is true if *CLK* has not changed value. Thus, if not CLK'STABLE is true, meaning that *CLK* has just changed value, and *CLK* = "1", then a rising transition has occurred on *CLK*. The output signal *Z* is driven by a nonguarded, selected concurrent signal assignment statement that executes anytime STATE changes value.

7.3 Conceptual Design

Figure 7.9 shows that the conceptual design task generally follows the design entry task. Conceptual design addresses the initial decision-making process by assisting the designer to conduct initial feasibility studies, determine promising design alternatives, and obtain preliminary indication of estimated performance [16].

During early stages of the electronic design process, one typically makes a number of high-level decisions that can have a significant impact on the outcome of a design. For example, consider the early decisions usually made when designing a memory subsystem. The designer must choose a configuration (e.g., ×1, ×4, ×8, etc.), memory technology (e.g., static RAM, dynamic RAM, mask programmable ROM, etc.), package style (e.g., dual-in-line, chip carrier, pin grid array, etc.), and so on. Taken collectively, these decisions may be referred to as the design plan. The design plan then guides the ensuing, more detailed design process, acting as a high-level road map.

In general, many different plans may result in designs that satisfy the same set of functional specifications, but have varying trade-offs in terms of performances, such as area or power dissipation. For example, Figure 7.10 shows relative area and speed performance trade-offs for six combinational multiplier designs. Figure 7.10 shows the typical trend that increasing speed implies increasing area.

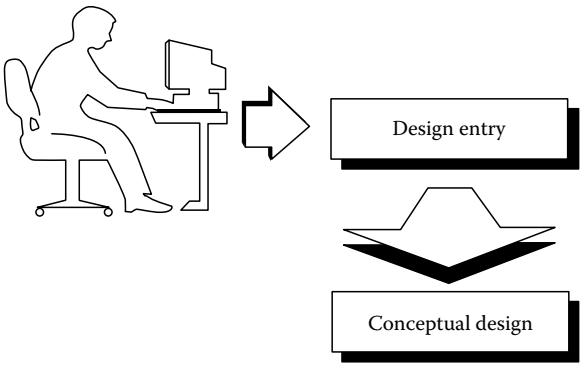

FIGURE 7.9 Design process.

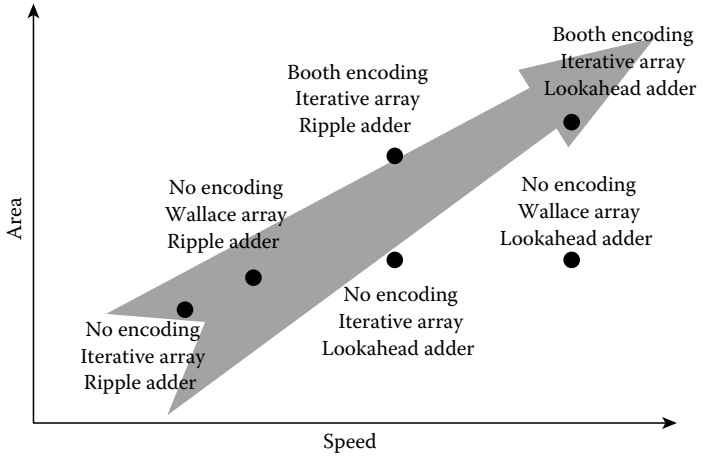

FIGURE 7.10 Performance trade-offs.

More importantly, the chart indicates how various multiplier designs relate to each other and which designs present the best area/speed trade-offs for a particular application.

Given this large set of possible design plans to consider, it is easy to imagine getting hopelessly lost in analyzing the various design plans and keeping track of the trade-offs and decision interdependencies. Choosing the most appropriate design plan is important because it is usually not economically feasible to choose an alternative plan and repeat the detailed design process if the final design does not meet the desired specifications. To aid the designer during the early stages of the design process in maximizing his or her chances that certain high-level decisions will result in a design that meets the desired specifications, conceptual design tools assist the designer in analyzing possible ramifications of high-level design decisions before actually undertaking the detailed design and fabrication process.

During conceptual design, the engineer has a global view of the design process in considering the key decisions associated with each lower level of abstraction. Thus, the engineer can undertake a breadth-first design methodology. Costly errors can be avoided by investing time at the outset in thoroughly thinking through a particular plan, the result being a more complete and credible specification that better guides the ensuing actions. In addition, the unnecessary use of detailed design CAD tools is minimized because conceptual design acts as a ''coarse filter'' eliminating infeasible design plans.

7.3.1 Design Planning

To discuss conceptual design, it is convenient to introduce the following terms:

- *Design issue*—Pertinent aspect of a design for which a decision must be made.
- *Design option*—Possible choice that can be made for a design issue.
- *Design decision*—Particular option chosen for a design issue.
- *Design plan*—Set of design decisions that identifies a high-level approach for implementing the design.

Conceptual design begins with the identification of the set of relevant design issues that must be considered before detailed design begins. For example, for the design of an analog amplifier, the design issues include selection of a type of amplifier (e.g., current, voltage, etc.), selection of a class of operation (e.g., A, B, AB, etc.), selection of a biasing scheme, etc. For the design of a digital signal processing filter, the design issues include selection of an algorithm (e.g., infinite impulse response or finite impulse response), selection of an architecture (e.g., direct, cascade, parallel, etc.), selection of a multiplier logic design, etc. Having identified the relevant design issues, conceptual design proceeds to develop a design plan in the step-by-step fashion outlined in Figure 7.11. For each design issue, the various associated options are examined, and the most appropriate option is selected. To make this selection, the designer chooses some method of discrimination and may need expert advice about the possible options or may desire a prediction about the effect a particular option has on performance. Such a conceptual design approach implies several important features, which are considered in more detail next.

Designers often structure design issues in a hierarchical fashion to control the complexity of the conceptual design process. Complex design issues are decomposed into sets of design subissues or subplans [22]. For example, an expanded, hierarchical listing of candidate design issues for digital signal processing filters is given next [14,20]:

1. Selection of a filter algorithm
2. Selection of a polynominal approximation technique
3. Selection of a filter architecture
   a. Selection of a filter structure
   b. Selection of a pipelining strategy
4. Selection of a logic design
   a. Selection of a multiplier logic design
   b. Selection of an encoding technique

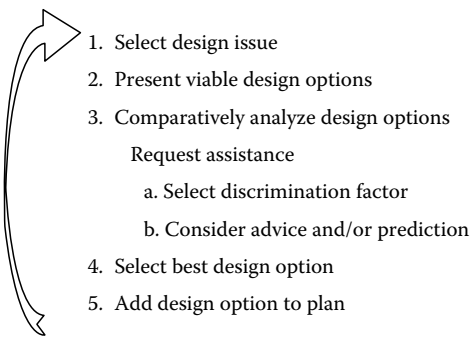

FIGURE 7.11 Constructing a design plan.

   c. Selection of an array design
   d. Selection of a final adder design
   e. Selection of an adder design style
5. Selection of a fabrication technology
6. Selection of a layout design style

The selection of a multiplier logic design can be decomposed into three design subissues: selection of an encoding technique, selection of a combinational array design, and selection of a final adder design. Notice that many details about digital filter design are not listed because conceptual design is typically not concerned with every design issue required to eventually fully design and fabricate the initial specification. Hierarchical design issues provide for a more intuitive representation of the conceptual design process, enabling the designer to better comprehend the overall magnitude and composition of the design domain.

Each design issue has associated commonly used options or selections. For example, the possible digital filter polynomial approximation techniques are

1. Equiripple
2. Frequency sampling
3. Windowing
4. Beta
5. Elliptic
6. Butterworth
7. Chebyshev

During conceptual design, the order in which the designer examines the various issues may not be completely arbitrary because the options available for a design issue may depend on which options were chosen for other design issues. Hence, a partial ordering may be imposed on addressing design issues. As an example, equiripple, frequency sampling, windowing, and beta digital filter approximations apply only to the finite impulse response algorithm, while elliptic, Butterworth, and Chebyshev digital filter approximations apply only to the infinite impulse response algorithm. Hence, the polynomial approximation technique depends on the choice of the filter algorithm and thus, the choice of a filter algorithm must precede the choice of a polynomial approximation technique. Similarly, if the designer chooses a bipolar logic family, then the Manchester carry adder logic design is not a viable option because this option requires pass transistor technology that exists only in MOS-related logic families. Hence, the adder's logic design depends on the choice of the logic family and thus, the choice of a logic family must precede the choice of a logic design style.

Conceptual design supports such ordering of design issues via ordering constraints, enforcing that the more pervasive design issues be addressed first [23]. In specifying the interdependencies between design issues, as many or as few ordering constraints may be imposed as is warranted by the particular design domain. At one extreme, a strict sequential ordering of design issues may be required. At the other extreme, no ordering may occur, signifying that the design issues have no interdependencies and that each issue may be examined independently of the others. Partial orderings may also occur in which some design issues typically arise that may be examined and some design issues that may not be examined, owing to interdependencies. Hence, ordering constraints provide a general mechanism within the conceptual design methodology for encoding various design strategies, such as top-down, bottom-up, or meet-in-the-middle.

In addition to interdependencies between design issues (ordering constraints), there may be interdependencies between options. For the digital adder design example, in which the designer investigates the logic design style issue, only the options that are consistent with the selected logic family option are viable. Interdependencies between design options are supported via consistency constraints. Using

consistency constraints, a system planner helps to determine, for a particular design issue, which options are consistent with earlier decisions. The designer is not presented with an option (step 2 in Figure 7.11) that is inconsistent with his or her earlier decisions. As such, the designer is prevented from developing an incorrect or inconsistent plan.

7.3.2 Decision Assistance

It may be the situation for complex conceptual designs that the designer consults an expert on a particular issue. The expert offers assistance in understanding the relative advantages and disadvantages of the available options in order to select the most appropriate option(s). Two general forms of assistance, advice and prediction, are available.

Advice describes the qualitative advantages and/or disadvantages that should be considered before accepting or rejecting a design option. On the other hand, prediction describes the quantitative advantages and/or disadvantages. Prediction is a valuable tool for reaching down through several levels of the design hierarchy to obtain quantitative insights into the implications of high-level design decisions. Such advice is given in lieu of the more expensive route of actually executing the detailed design process in order to determine the effects of a decision on design performance. While the predicted performance is only an approximation, it is often sufficient to allow the designer to choose a particular option, or at least to rule out an option.

Different types of prediction techniques are summarized in the taxonomy presented in Figure 7.12. Heuristic models use general guidelines or empirical studies to model the design process [15]. Analytical models employ a more rigorous, mathematical approach to model the design process. Some such models may be based on probability theory, e.g., wirability theory, and capture the particulars of a design activity in a set of random variables [17,18], while other analytical models may be based on graph and information theory, e.g., very large scale integration (VLSI) complexity theory [19,24,25]. Finally, simulation models include the judicious partial execution of a design activity on critical portions of the design. The use of previous designs serves to capture the experience or ''corporate history'' factor used by an expert designer in attempting to predict the performance of a new function based on previous similar designs.

As an example, Figure 7.13 shows how performance estimates for digital filters can be obtained in a hierarchical, incremental fashion, employing a variety of prediction models that cooperate to yield the

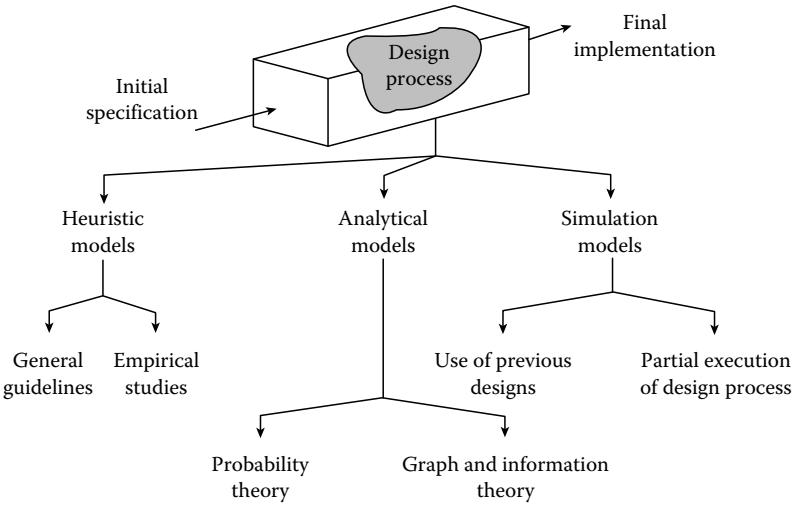

FIGURE 7.12 Types of prediction techniques.

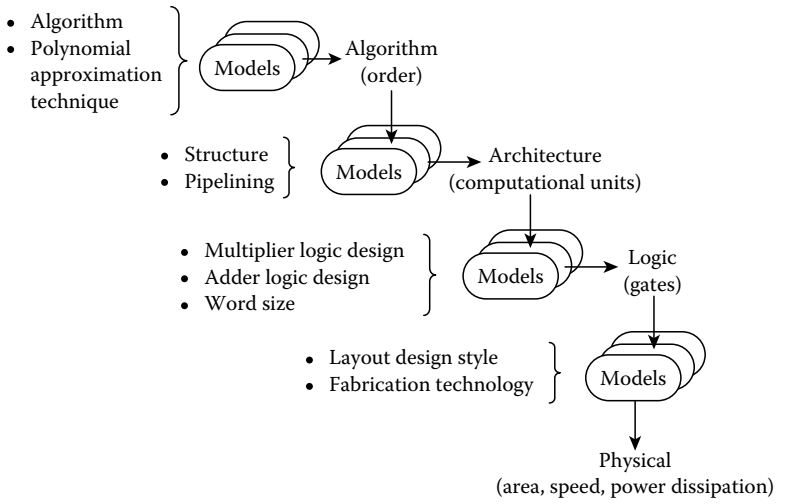

FIGURE 7.13 Hierarchical structure of filter performance prediction.

desired results. The prediction task is performed by incrementally translating the initial specifications into a series of complexity measures. Each succeeding complexity measure is a refinement of the performance estimate, starting with a performance estimate in terms of the filter order and ending with the performance estimate in terms of the physical units of area, speed, and power dissipation. Each prediction model draws its required input information from higher-level prediction models, the initial functional specifications, and the applicable decisions from the conceptual plan. Incrementally generating a prediction allows the flexibility to use different types of prediction techniques as the situation warrants to model the implications of different parts of the design plan.

The starting point in the prediction methodology is the initial functional specifications. For digital filters, functional specifications are usually given in terms of the desired frequency response, involving the following:

- Frequency bands of importance
- Widths of the transition bands between the desired frequency bands
- Levels of amplification or attenuation per frequency band
- Allowable tolerance or deviation from the specified levels of amplification and/or attenuation

An extensive set of prediction models has been developed for predicting the performance of linear, shift-invariant digital filters having the general I–O behavior given by the difference equation

$$y(n) = \sum_{k=1}^{N} a_k(n-k) + \sum_{k=0}^{M} b_k x(n-k) \tag{7.1}$$

The variables $x(n)$ and $y(n)$ denote the values of signals $x(t)$ and $y(t)$ at time t_n. As an example of an algorithm-level prediction model, the order of a low-pass filter using the equiripple polynomial approximation technique is given by the empirical model shown in Equation 7.2 [21].

$$N \approx \frac{\left\{ \begin{array}{c} \left[5.309 \times 10^{-3}(\log_{10}\delta_1)^2 + 0.07114\log_{10}\delta_1 - 0.4761\right]\log_{10}\delta_2 \\ + \left[-2.66 \times 10^{-3}\left(\log_{10}\delta_1^2\right) - 0.5941\log_{10}\delta_1 - 0.4278\right] \end{array} \right\}}{\Delta F} - \left[0.51244(\log_{10}\delta_1 - \log_{10}\delta_2) + 11.01217\right]\Delta F + 1 \tag{7.2}$$

where N is the filter order, δ_1 is the passband tolerance, δ_2 is the stopband tolerance, and ΔF is the width of the transition band. As another example of an algorithm prediction model, the order of a low-pass filter using the elliptic polynomial approximation technique is given by

$$N = \frac{\Psi(\alpha)\Psi\left(\sqrt{1-\beta^2}\right)}{\Psi(\beta)\Psi\left(\sqrt{1-\alpha^2}\right)}$$
$$\alpha = \frac{\omega_p}{\omega_s} \tag{7.3}$$
$$\beta = \frac{\sqrt{\delta_1}\sqrt{2-\delta_1\delta_2}}{\sqrt{1-\delta_2^2}(1-\delta_1)}$$

where ω_p is the cutoff frequency or the high end of the passband, ω_s is the start or low end of the stopband, and $\Psi(\cdot)$ denotes the complete elliptic integral of the first kind.

As an example of a logic level prediction model, filter word size can be estimated to be the maximum of the required data word size and coefficient word size. Equation 7.4 estimates the data word size ($data_{ws}$), i.e., number of bits required to represent the filter input data samples to ensure an adequate signal:noise ratio:

$$data_{ws} = \left\lceil \frac{SNR_q - 4}{6} \right\rceil \tag{7.4}$$

where $[\cdot]$ denotes the ''smallest integer not less than'' and SNR_q denotes the root mean square signal: quantization noise ratio in decibels. Equation 7.5 estimates the coefficient word size ($coeff_{ws}$), i.e., number of bits required to represent the filter coefficients to ensure that finite precision coefficient quantization and arithmetic round-off errors do not appreciably deteriorate filter frequency response:

$$coeff_{ws} = \left\lceil \log_2\left(\frac{\omega_s + \omega_p}{\omega_s - \omega_p}\right) + \log_2\left(\frac{1}{\min(\delta_1, \delta_2)}\right) - \frac{1}{2}\log_2\left(\frac{\omega_S}{\omega_s - \omega_p}\right) + 3 \right\rceil \tag{7.5}$$

where ω_S denotes the sampling frequency.

7.3.3 Exploring Alternative Designs

After analyzing the viable options, the final steps in Figure 7.11 involve making the design decision. Sometimes designers want to delay making a decision during a conceptual design session until other aspects of the design can be explored. If more than one option for a particular design issue looks equally viable, then the designer may elect to consider all of the viable options. For example, returning to digital filters, the designer may wish to investigate the implications of using both the lookahead carry and block lookahead carry logic design styles for the adder. Later in the conceptual design session, when the competing adder design plans have been more fully developed and their relative merits more clearly understood, the designer may have the information necessary to select one logic design style over the other. Such an approach is often referred to as ''nonlinear planning'' or adopting a ''least-commitment strategy.''

Multiple, alternative plans support delaying design decisions. New plans are created each time more than one option is chosen for a design issue. For example, if the designer wishes to investigate both adder logic designs, then the planner records the decision by generating two plans. One design plan uses the lookahead carry adder logic design, and the other plan uses the block lookahead carry logic design. Having generated alternative plans, the designer can then further develop each plan independently by requesting that the planner switch the focus of the conceptual design session between the competing

plans. It should be noted that a consequence of creating alternative plans is that the conceptual design process may not always yield one plan. Rather, the conceptual design process may yield multiple plans that appear roughly equally promising. The conceptual design methodology is not intended to always possess the ability to definitively differentiate between alternative plans due to the general nature of the plans or the approximate nature of the predictions. In cases in which the conceptual design process yields more than one candidate plan, the designer could invoke more detailed synthesis and analysis design automation tools to further investigate and resolve the plans.

In a lengthy conceptual design session, a designer may want to reconsider and possibly change an earlier decision; this situation is supported via backtracking. When the designer requests a reconsideration of an earlier decision for a particular design issue, the planner must back up the state of the conceptual design session and reactivate the associated viable options. The designer may then reexamine the options and possibly select a different option. The backtracking process also involves checking the rest of the plan to see if any of the designer's other, earlier decisions might be affected by the new decision. If any other design decisions depend on the decision that the designer wants to change, then these decisions must be similarly undone. In this manner only the appropriate part of the conceptual design session is backed up; the decisions that are not dependent on the desired change are left unaffected.

7.3.4 Applications

Conceptual design involves well-defined, algorithmic-based knowledge and ill-defined, heuristic-based knowledge. For instance, maintaining alternative plans involves primarily algorithmic-based knowledge. For each plan, the available design issues are determined in accordance with the ordering constraints. For each available design issue, the viable options are determined in accordance with the decisions made thus far and the consistency constraints. As the conceptual design session progresses, new design decisions are recorded, or possibly, previous design decisions are changed.

In contrast, providing advice involves primarily heuristic-based knowledge. Based on the state of the plan, the appropriate piece of advice or prediction model is identified, guidance is formulated, and the results are supplied to the designer. Advice and predictions serve as knowledge sources working to solve the conceptual design ''problem.'' The knowledge sources opportunistically invoke themselves to address an applicable portion of the advice or prediction request, taking their input from the system plan(s), and posting their results back to the system plan(s) in an attempt to refine and develop a conceptual design.

Domain-dependent information concerning design issues, options, trade-offs, and interdependencies is typically specified as part of the knowledge acquisition process involved in initially constructing a system planner, and is separate from domain-independent information to facilitate creating planners for different design tasks and moving existing planners to new design tasks. If alternative plans are developed during conceptual design, multiple versions of the domain-dependent information are correspondingly created. Each version of the domain-dependent information, also called contexts, worlds, or belief spaces, contains a plan's state information, such as which design issues have been addressed, which options have been chosen, and which advice has been given. When a designer changes the focus of the conceptual design session between alternative plans, a context switch is performed between the associated versions of the domain-dependent information. An analogous situation is an operating system that allows multiple jobs. Each time the computer switches to a new job, the state of the current job must be saved, and the state of the new job must be restored.

Clearly, for complex design domains, the amount of domain-dependent information can be sizable. To limit the search time required to find applicable options or appropriate advice, the domain-dependent information can be segmented or partitioned by design issue. Such an organization allows for dynamically limiting the portion of information searched. For instance, in searching for appropriate advice, only the advice that is associated with the current design issue is made accessible. Thus, any search is confined to the advice associated with the current design issue; a search is never executed over the entire domain-dependent information.

Conceptual design is an emerging area of design automation that demonstrates the potential for significantly improving our design capability. Conceptual design involves studying a design process, modeling the process as a hierarchy of design issues, delineating the options, and identifying the associated interdependencies and discriminating characteristics. A conceptual design plan realizes the initial specifications by delineating the important design decisions. Such a methodology emphasizes spending more time at the initial stage of the design process in obtaining a more credible system specification. In addition to beginning an expensive design process with a careful definition of what is required of the design, conceptual design emphasizes the need for a general plan for how to realize the design.

Associated applications play a supporting role of managing and presenting the large and complex amount of information typically involved in conceptual design to assist the designer in making the decisions that constitute the conceptual design plan. Plans are developed incrementally and interactively. In a breadth-first fashion, conceptual design guides the designer through a myriad of alternative plans, allowing the designer to explore differences and seek optimal solutions. The advantage of conceptual design is that expensive design resources are not wasted in trying plans that eventually prove unsatisfactory. Applications also provide performance estimation, which can be useful in coordinating between groups involved with a design. For example, an early estimate of chip area can be used to check with the manufacturing group that the design will be within acceptable fabrication yield margins or will adhere to any packaging or printed circuit board size restrictions. An early estimate of chip performance also can be used to coordinate with marketing and management in projecting potential applications, probable costs, and future business.

7.4 Synthesis

Figure 7.14 shows that the synthesis task generally follows the conceptual design task. The designer describes the desired system via design entry, generates a conceptual plan of major design decisions, and then invokes synthesis design automation programs to assist in generating the required implementation [32].

Synthesis translates or transforms a design at one level of abstraction to another, more detailed level of abstraction. The more detailed level of abstraction may be only an intermediate step in the entire design process or it may be the final implementation. Synthesis programs that yield a final implementation are sometimes called ''silicon compliers'' because the programs generate sufficient detail to proceed directly to silicon fabrication [26,29].

Similar to design abstractions, synthesis techniques can be hierarchically categorized, as shown in Figure 7.15. The higher levels of synthesis offer the advantage of less complexity, but also the disadvantage of less control over the final implementation.

Algorithmic synthesis also called ''behavioral synthesis,'' addresses ''multicycle'' behavior, which means behavior that spans more than one control step. A control step equates to a clock cycle of a synchronous, sequential digital system, i.e., a state in a finite state machine controller or a microprogram step in a microprogrammed controller. Algorithmic synthesis typically accepts sequential design descriptions using a procedural or imperative modeling style. Such descriptions define the I–O transform, but provide little information about the parallelism of the implementation [28,30].

Partitioning decomposes the design description into smaller behaviors. Partitioning is an example of a

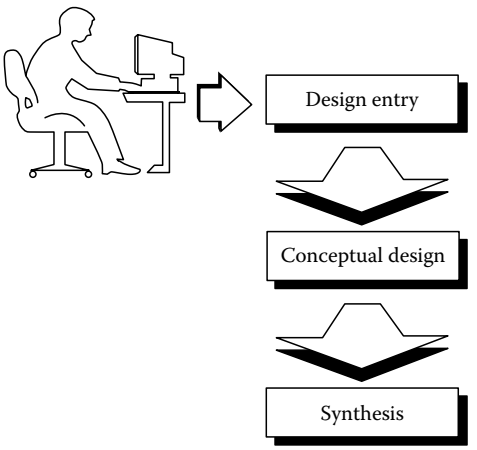

FIGURE 7.14 The design process.

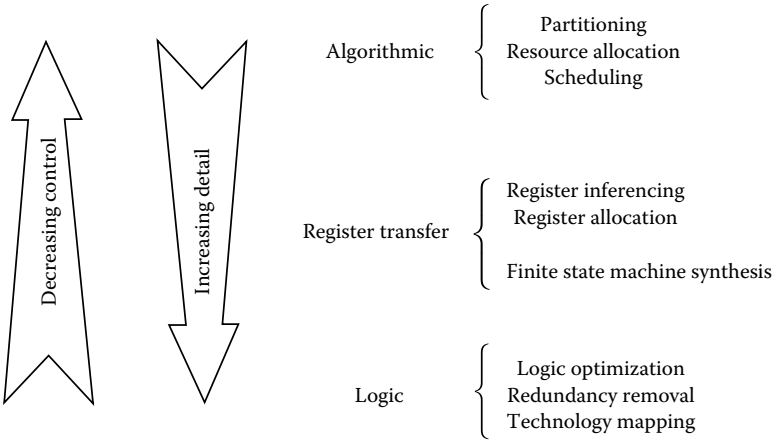

FIGURE 7.15 Taxonomy of synthesis techniques.

high-level transformation that modifies the initial sequential design description to optimize a hardware implementation. High-level transformations include several common software programming complier optimizations, such as loop unrolling, subprogram in-line expansion, constant propagation, and common subexpression elimination.

Resource allocation associates behaviors with hardware computational units and scheduling determines the order in which behaviors execute. Behaviors that are mutually exclusive can potentially share computational resources. Allocation is performed using a variety of graphic clique covering or node coloring algorithms. Allocation and scheduling are interdependent and different synthesis strategies perform allocation and scheduling in different ways. Sometimes scheduling is performed first, followed by allocation; sometimes allocation is performed first, followed by scheduling; and sometimes allocation and scheduling are interleaved.

Scheduling assigns computational units to control steps, thereby determining which behaviors execute in which clock cycles. At one extreme, all computational units can be assigned to a single control step, exploiting maximum concurrency. At the other extreme, computational units can be assigned to individual control steps, exploiting maximum sequentiality. Figure 7.16 illustrates two possible schedules

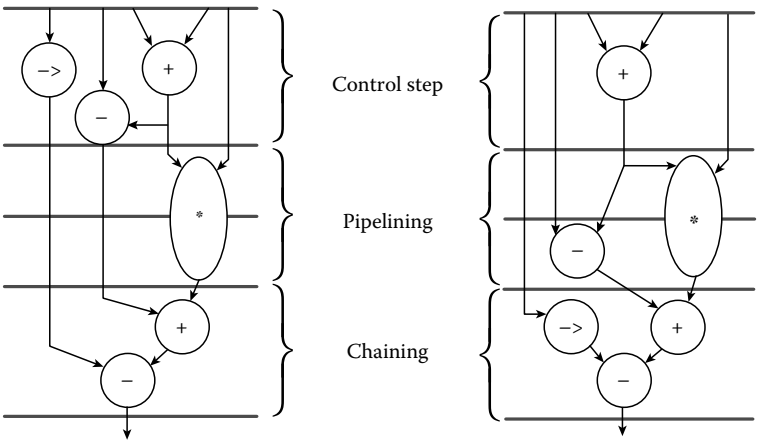

FIGURE 7.16 Scheduling.

of the same behavior. *Pipelining* schedules an operation across multiple control steps, whereas *chaining* combines multiple operations within a single control step.

Several popular scheduling algorithms are

- As soon as possible (ASAP)
- As late as possible (ALAP)
- List scheduling
- Force directed scheduling
- Control step splitting/merging

ASAP and ALAP scheduling algorithms order the computational units based on data dependencies. List scheduling is based on ASAP and ALAP scheduling, but can consider additional global constraints, such as a maximum number of control steps. Force-directed scheduling computes the probabilities of computational units being assigned to control steps and attempts to evenly distribute computation activity among all control steps. Control step splitting scheduling starts with all computational units assigned to one control step and generates a schedule by splitting the computational units into multiple control steps. Control step merging scheduling starts with all computational units assigned to individual control steps and generates a schedule by merging or combining units and steps [28,31].

Register transfer synthesis takes as input the results of algorithmic behavior and addresses ''per-cycle'' behavior, which means the behavior during one clock cycle. Register transfer synthesis selects logic to realize the hardware computational units generated during algorithmic synthesis, such as realizing an addition operation with a carry-save adder or realizing addition and subtraction operations with an ALU. Data that must be retained across multiple clock cycles are identified and registers are allocated to hold these data. Finally, state machine synthesis involves classical state minimization and state assignment techniques. State minimization seeks to eliminate redundant or equivalent states and state assignment assigns binary encodings for states to minimize combinational logic [27,33].

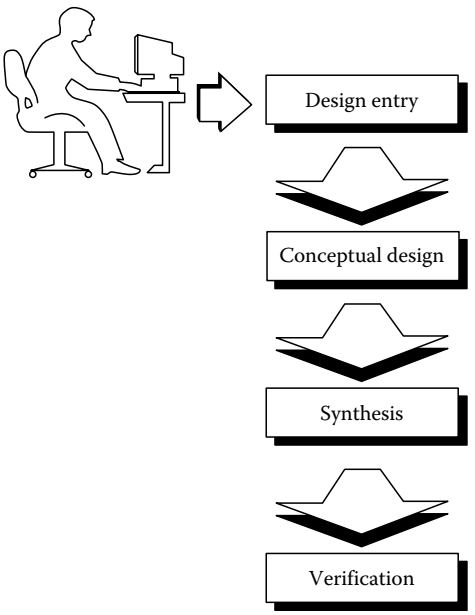

FIGURE 7.17 Design process.

Logic synthesis optimizes the logic generated by register transfer synthesis and maps the minimized logic operations onto physical gates supported by the target fabrication technology. Technology mapping considers the foundry cell library and associated electrical restrictions, such as fanin/fanout limitations.

7.5 Verification

Figure 7.17 shows that the verification task generally follows the synthesis task. The verification task checks the correctness of the function and performance of a design to ensure that an intermediate or final implementation faithfully realizes the initial, desired specification.

Several common types of verification are

- Timing analysis
- Simulation
- Emulation
- Formal verification

These types of verification are examined in more detail in the following sections [42].

7.5.1 Timing Analysis

As the name implies, timing analysis checks that the overall design satisfies operating speed requirements and individual signals within design satisfy transition requirements. Common signal transition requirements, also called timing hazards, include rise and fall times, propagation delays, clock times, race conditions, glitch detection, and setup and hold times. Set and hold timing checks are illustrated in Figure 7.18. For synchronous sequential digital systems, memory devices (level-sensitive latches or edge-sensitive flip-flops) require that the data and control signals obey setup and hold timings to ensure correct operation, i.e., that the memory device correctly and reliably stores the desired data. The control signal is typically a clock signal and Figure 7.18 assumes that a control signal transition, rising or falling, triggers activation of the memory device. The data signal carrying the information to be stored in the memory device must be stable for a period equal to the setup time prior to the control signal transition to ensure the correct value is sensed by the memory device. Also, the data signal must be stable for a period equal to the hold time after the control signal transition to ensure the memory device has enough time to store the sensed value.

Another class of timing transition requirements, commonly called ''signal integrity checks,'' include reflections, cross talk, ground bounce, and electromagnetic interference. Signal integrity checks are typically required for high-speed designs operating at clock frequencies above 75 MHz. At such high frequencies, the transmission line behavior of wires must be analyzed. A wire must be properly terminated, i.e., connected, to a port having an impedance matching the wire characteristic impedance to prevent signal reflections. Signal reflections are portions of an emanating signal that ''bound back'' from the destination to the source. Signal reflections reduce the power of the emanating signal and can damage the source. Cross talk refers to unwanted reactive coupling between physically adjacent signals, providing a connection between signals that are supposed to be electrically isolated. Cross talk causes information carried on a signal to interfere or corrupt information carried on a neighboring signal. Ground bounce is another signal integrity problem. Because all conductive material has finite impedance, a ground signal network does not in practice offer the same electrical potential throughout an entire design. These potential differences are usually negligible because the distributive impedance of the ground signal network is small compared to other finite component impedances. However, when many signals switch value simultaneously, a substantial current can flow through the ground signal network. High intermittent currents yield proportionately high intermittent potential drops, i.e., ground bounces, which can cause unwanted circuit behavior. Finally, electromagnetic interference refers to signal harmonics radiating from design components and interconnects. This harmonic radiation may interfere with other electronic equipment or may exceed applicable environmental safety regulatory limits [38].

Timing analysis can be done dynamically or statically. Dynamic timing analysis exercises the design via simulation or emulation for a period of time with a set of input stimuli and records the timing

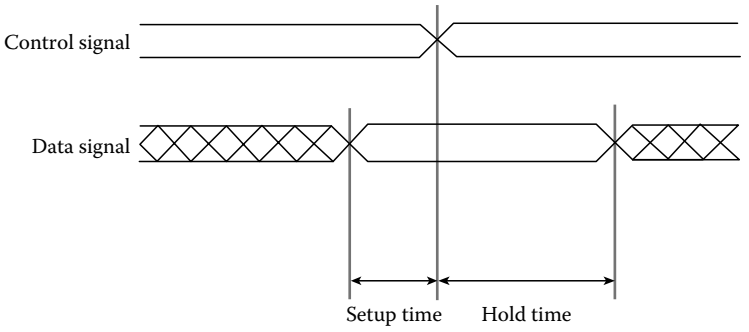

FIGURE 7.18 Signal transition requirements.

behavior. Dynamic timing analysis generally requires simulating many input test vectors to extensively exercise the design to ensure that signal paths are sufficiently identified and characterized. Static timing analysis does not exercise the design via simulation or emulation. Rather, static analysis records timing behavior based on the timing behavior (e.g., propagation delay) of the design components and their interconnection. With static timing analysis, the complexity of the verification task is partitioned into separate functional and performance checks.

Static timing analysis techniques are primarily *block oriented* or *path oriented*. Block-oriented timing analysis generates design input, also called primary input, to design output, also called primary output, propagation delays by analyzing the design, ''stage-by-stage'' and summing up the individual stage delays. All devices driven by primary inputs constitute stage 1, all devices driven by the outputs of stage 1 constitute stage 2, and so on. Starting with the first stage, all devices associated with a stage are annotated with worst-case delays. A worst-case delay is the propagation delay of the device plus the delay of the last input to arrive at the device, i.e., the signal path with the longest delay leading up to the device inputs. For example, the device labeled ''H'' in stage 3 in Figure 7.19 is annotated with the worst-case delay of 13, representing the device propagation delay of 4 and the delay of the last input to arrive through devices ''B'' and ''C'' of 9 [39]. When the devices associated with the last stage, i.e., the devices driving the primary outputs, are processed, the accumulated worst-case delays record the longest delay from primary inputs to primary outputs, also called the critical paths. The critical path for each primary output is highlighted in Figure 7.19.

Path-oriented timing analysis generates primary input to primary output propagation delays by traversing all possible signal paths one at a time. Thus, finding the critical path via path-oriented timing analysis is equivalent to finding the longest path through a directed acyclic graph, where devices are graph vertices and interconnections are graph edges [41].

A limitation of static timing analysis concerns detecting *false violations* or *false paths*. False violations are signal timing conditions that may occur due to the static structure of the design, but do not occur due to the dynamic nature of the design's response to actual input stimuli.

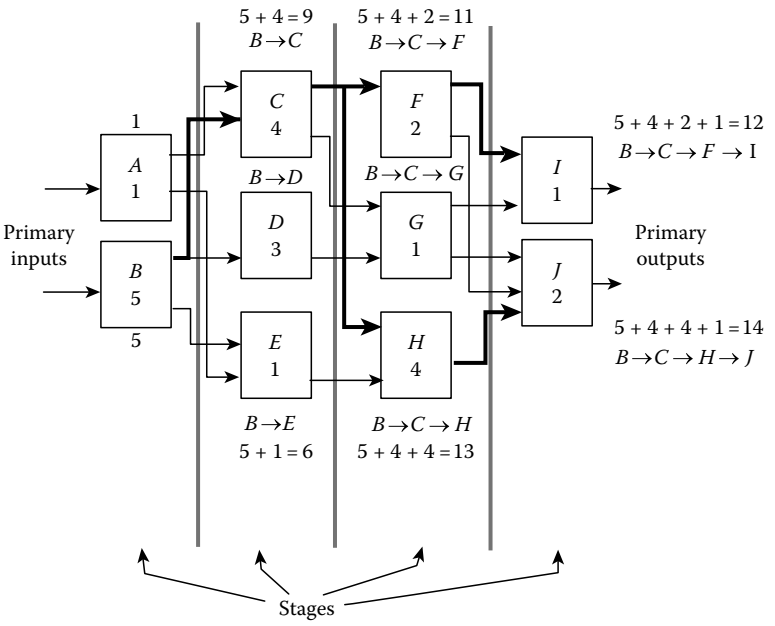

FIGURE 7.19 Block-oriented static timing analysis.

To account for realistic variances in component timing due to manufacturing tolerances, aging, or environmental effects, timing analysis often provides stochastic or statistical checking capabilities. Statistical timing analysis uses random number generators based on empirically observed probabilistic distributions to determine component timing behavior. Thus, statistical timing analysis describes design performance and the likelihood of the design performance.

7.5.2 Simulation

Simulation exercises a design over a period of time by applying a series of input stimuli and generating the associated output responses. The general event-driven, or schedule-driven, stimulation algorithm is diagrammed in Figure 7.20. An event is a change in signal value. Simulation starts by initializing the design; initial values are assigned to all signals. Initial values include starting values and pending values which constitute future events. Simulation time is advanced to the next pending event(s), signals are updated and sensitized models are evaluated. Sensitized models refer to models having outputs dependent on the updated signals [35,40]. The process of evaluating the sensitized model yields new, potentially different values for signals, i.e., a new set of pending events. These new events are added to the list of pending events, time is advanced to the next pending event(s), and the simulation algorithm repeats. Each pass through the loop of evaluating sensitized models at a particular time step is called a simulation cycle (see Figure 7.20). Simulation ends when the design yields no further activity, i.e., no more pending events exist to process.

Logic simulation is a computational intensive task for large, complex designs. Prior to committing to manufacturing, processor designers often simulate bringing up or "booting" the operating system. Such simulation tasks require sizable simulation computational resources. As an example, consider simulating 1s of a 200K gate, 20 MHz processor design. Assuming that on average only 10% of the total 200K gates are active or sensitized on each processor clock cycle, Equation 7.6 shows that simulating 1 s of actual processor time equates to 400 billion events.

$$\begin{aligned} 400\text{ B events} &= (20\text{ M clock cycles})(200\text{K gates})(10\%\text{ activity}) \\ 140\text{ h} &= (400\text{ B events})\left(\frac{50\text{ instructions}}{\text{event}}\right)\left(\frac{50\text{ M instruction}}{\text{s}}\right) \end{aligned} \tag{7.6}$$

Assuming that on average a simulation program executes 50 computer instructions per event on a computer capable of processing 50 million instructions per second, Equation 7.6 also shows that

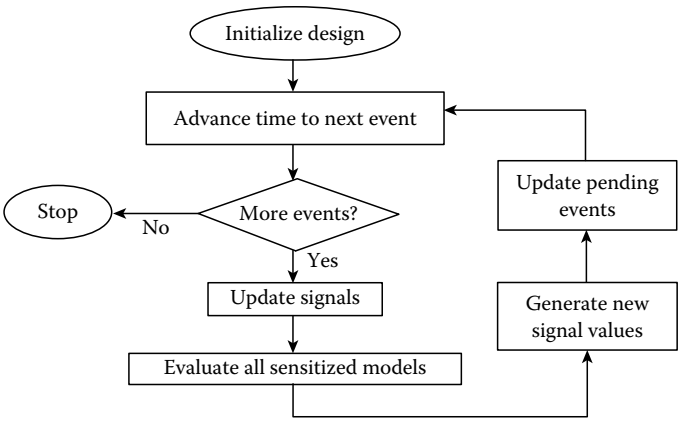

FIGURE 7.20 General event-driven simulation algorithm.

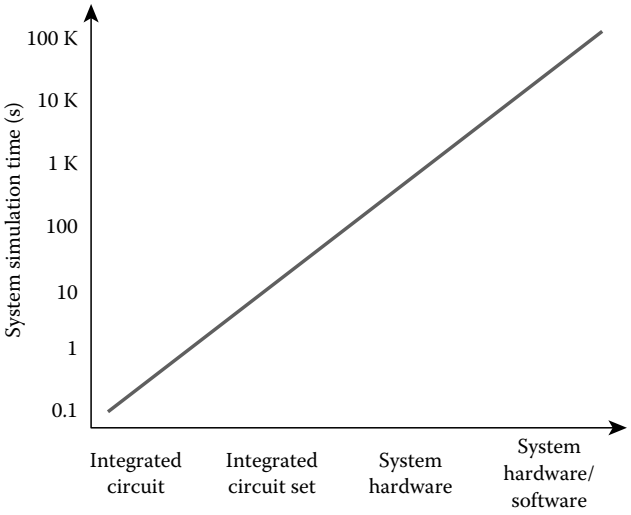

FIGURE 7.21 Simulation requirements.

processing 400 billion events requires 140 h or just short of 6 days. This simple example demonstrates the sizable computational properties of simulation. Figure 7.21 shows how simulation computation scales with design complexity.

To address the growing computational demands of simulation, several simulation acceleration techniques have been introduced. Schedule or event-driven simulation (explained previously) can be accelerated by removing layers of interpretation and running simulation as a native executable image; such an approach is called complied, scheduled-driven simulation. Schedule-driven simulation can be accelerated also by using more efficient event management schemes. In a conventional, central event management scheme all events are logged into a time-ordered list. As simulation time advances, pending events become actual events and the corresponding sensitized devices are executed to compute the response events. One the other hand, in a dataflow event management scheme events are ''self-empowered,'' active agents that flow through networks and trigger device evaluations without registering with a central time-order list and dispatcher [37].

Instead of evaluating a device in a stimulus–response manner, *cycle-driven* simulation avoids the overhead of event queue processing by evaluating all devices at regular intervals of time. Cycle-driven simulation is efficient when a design exhibits a high degree of concurrency, i.e., a large percentage of the devices are active per simulation cycle. Based on the staging of devices, the devices are *ranked-ordered* to determine the order in which they are evaluated at each time step to ensure the correct causal behavior yielding the proper ordering of events. For functional verification, logic devices are often assigned zero-delay and memory devices are assigned unit-delay. Thus, any number of stages of logic devices may execute between system clock periods.

Another simulation acceleration technique is *message-driven* simulation, also called parallel or distributed simulation. Device execution is divided among several processors, and the device simulations communicate event activity via messages. Messages are communicated using a conservative or an optimistic strategy. Optimistic message passing strategies, such as *time warp* and *lazy cancellation*, make assumptions about future event activity to advance local device simulation. If the assumptions are correct, the processors operate more independently and better exploit parallel computation. However, if the assumptions are incorrect, then local device simulations may be forced to ''roll back'' to synchronize local device simulations [34,36].

Schedule-driven, cycle-driven, and message-driven simulation are software-based simulation acceleration techniques. Simulation also can be accelerated by relegating certain simulation activities to dedicated hardware. For example, *hardware modelers* can be attached to simulators to accelerate the activity of device evaluation. As the name implies, hardware modeling uses actual hardware devices instead of software models to obtain stimulus–response information. In a typical scenario, the hardware modeler receives input stimuli from the software simulator. The hardware modeler then exercises the device and sends the output response back to the software simulator. Using actual hardware devices reduces the expense of generating and maintaining software models and provides an environment to support application software development. However, the hardware device must exist, which means hardware modeling has limited use in the initial stages of design in which hardware implementations are not available. Also, it is sometimes difficult for a slave hardware modeler to preserve accurate real-time device operating response characteristics within a master non-real-time software simulation environment. For example, some hardware devices may not be able to retain state information between invocations, so the hardware modeler must save the history of previous inputs and reapply them to bring the hardware device to the correct state in order to apply a new input.

Another technique for addressing the growing computational demands of simulation is via *simulation engines*. A simulation engine can be viewed as an extension of the simulation acceleration techniques of hardware modeling. With a hardware modeler, the simulation algorithm executes in software, and component evaluation executes in dedicated hardware. With a simulation engine, the simulation algorithm and component evaluation execute in dedicated hardware. Simulation engines are typically two to three orders of magnitude faster than software simulation [43].

7.5.3 Emulation

Emulation, also called ''computer-aided prototyping,'' verifies a design by realizing the design in ''preproduction'' hardware and exercising the hardware. The term preproduction hardware means nonoptimized hardware providing the correct functional behavior, but not necessarily the correct performance. That is, emulation hardware may be slower, require more area, or dissipate more power than production hardware. Presently, preproduction hardware commonly involves some form of *programmable logic devices*, typically *field-programmable gate arrays*. Programmable logic devices provide generic combinational and sequential digital system logic that can be programmed to realize a wide variety of designs [44].

Emulation begins by partitioning the design; each design segment is realized by a programmable logic device. The design segments are then interconnected to realize a preproduction implementation and exercised with a series of input test vectors.

Emulation offers the advantage of providing prototype hardware early in the design cycle to check for errors or inconsistencies in initial functional specifications. Problems can be isolated and design modifications can be accommodated easily by reprogramming the logic devices. Emulation can support functional verification at a computational rate much greater than conventional simulation. However, emulation does not generally support performance verification because, as explained previously, prototype hardware typically does not operate at production clock rates.

7.6 Test

Figure 7.22 shows that the test task generally follows the verification task. Although the verification and test tasks both seek to check for correct function and performance, verification focuses on a model of the design before manufacturing, whereas test focuses on the actual hardware after manufacturing. Thus, the primary objective of test is to detect a faulty device by applying input test stimuli and observing expected results [47,53].

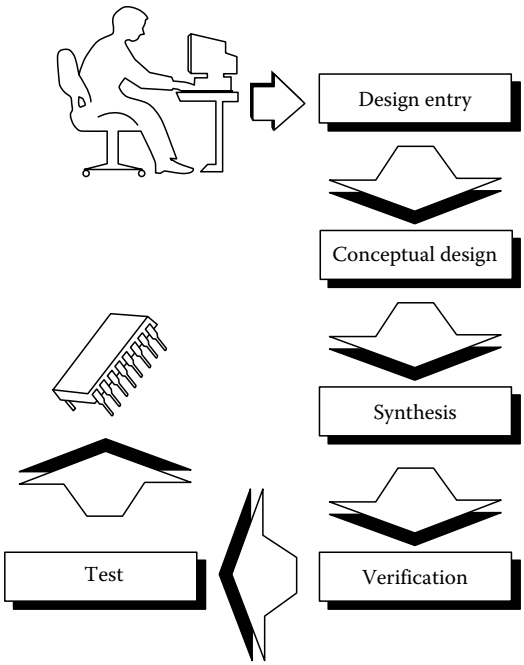

FIGURE 7.22 Design process.

The test task is difficult because designs are growing in complexity; more components provide more opportunity for manufacturing defects. Test is also challenged by new microelectronic fabrication processes having new failure modes which again provides more opportunity for manufacturing defects. New microelectronic fabrication processes also offer higher levels of integration with fewer access points to probe internal electrical nodes. To illustrate the growing demands of test, Table 7.2 shows the general proportional relationship between manufacturing defects and required fault coverage, i.e., quality of testing. Figure 7.23 shows the escalating costs of testing equipment.

Testing involves three general testing techniques or strategies: functional, parametric, and fault. Functional testing checks that the hardware device realizes the correct I–O digital system behavior. Parametric testing checks that the hardware device realizes the correct performance specifications, such as speed or power dissipation, and electrical specifications, such as voltage polarities and current sinking/sourcing limitation. Finally, fault testing checks for manufacturing defects or ''faults.''

TABLE 7.2 Fault Coverage and Defect Rate

	Defect Rate		
Microelectronic Fabrication Process	70% Fault Coverage	90% Fault Coverage	99% Fault Coverage
2 μm			
90% yield	3%	1%	0.1%
1.5 μm			
50% yield	19%	7%	0.7%
1 μm			
10% yield	50%	21%	2%

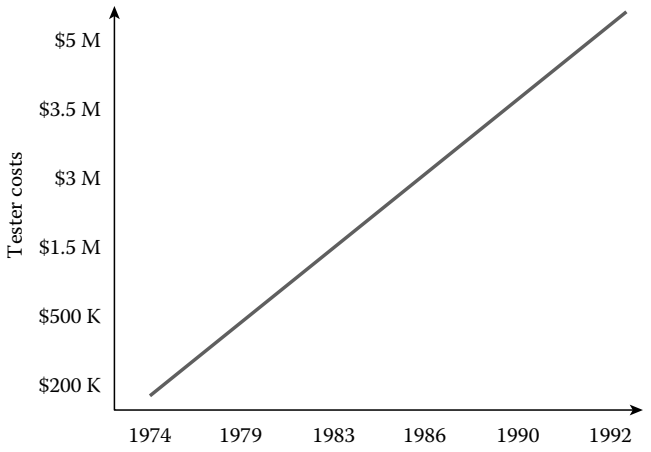

FIGURE 7.23 Integrated circuit tester equipment cost.

7.6.1 Fault Modeling

A fault is a manufacturing or aging defect that causes a device to operative incorrectly or to fail. A sample listing of common integrated circuit physical faults is given next:

- Wiring faults
- Dielectric faults
- Threshold faults
- Soft faults

Wiring faults are unwanted opens and shorts. Two wires or networks that should be electrically connected but are not constitute an open. Two wires or networks that should not be electrically connected but are constitute a short. Wiring faults can be caused by manufacturing defects such as metallization or etching problems, or aging defects, such as corrosion or electromigration. Dielectric faults are electrical isolation defects that can be caused by masking defects, material impurities or imperfections, and electrostatic discharge. Threshold faults occur when the turn-on and turn-off voltage potentials of electrical devices exceed allowed ranges. The faulty devices cannot be properly operated, which results in component failure. Soft faults occur when radiation exposure temporarily changes electrical charge distributions. Such changes can alter circuit voltage potentials, which can, in turn, change logical values, also called ''dropping bits.'' Radiation effects are called ''soft'' faults because the hardware is not permanently damaged [54].

To simplify the task of fault testing, the physical faults described above are translated into logical faults. Typically, a single logical fault covers several physical faults. A popular logical fault model is the *single stuck line* fault model. The single stuck line fault model considers faults where any single signal line or wire is permanently set to a logic 0, ''stuck-at-0,'' or a logic 1, ''stuck-at-1.'' These signal or interconnect faults are assumed to be time invariant.

Building on the single stuck line fault model, the *multiple stuck line* fault model considers multiple signal wire stuck-at-0/stuck-at-1 faults. The multiple stuck line fault model is more expressive and can cover more physical faults than the single stuck line model. However, fault testing for the multiple stuck line fault model is more difficult because of the exponential growth in the possible combinations of multiple signal faults.

Stuck fault models do not address all physical faults because not all physical faults result in signal lines permanently set to low or high voltages, i.e., stuck-at-0 or stuck-at-1 logic faults. Thus, other fault models

have been developed to address specific failure mechanisms. For example, the *bridging* fault model addresses electrical shorts that cause unwanted coupling or spurious feedback loops. As another example, the *pattern-sensitive* fault model addresses wiring and dielectric faults that yield unwanted interference between physically adjacent signals. Pattern-sensitive faults are generally most prevalent in high-density memories incorporating low signal:noise ratios and can be difficult to detect because they are often data-pattern and data-rate dependent. In other words, the part fails only under certain combinations of input stimuli and only under certain operating conditions.

7.6.2 Fault Testing

Having identified and categorized the physical faults that may cause device malfunction or failure and determined how the physical faults relate to logical faults, the next task is to develop tests to detect these faults. When the tests are generated by a computer program, this activity is called ''automatic test program generation.'' Examples of fault testing techniques are listed next:

- Stuck-at techniques
- Scan techniques
- Signature techniques
- Ad hoc techniques
- Coding techniques
- Electrical monitoring techniques

The following paragraphs review these testing strategies.

Basic stuck-at techniques generate input stimuli for fault testing combinational digital systems. Three of the most popular stuck-at fault testing techniques are the D algorithm, the path-oriented decision-making (Podem) algorithm, and the fan algorithm. These algorithms first identify a circuit fault (e.g., stuck-at-0 or stuck-at-1) and then try to generate an input stimulus that detects the fault and makes the fault visible as an output. Detecting a fault is often called ''fault sensitization'' and making a fault visible is often called ''fault propagation.'' To illustrate this process, consider the simple combinational design in Figure 7.24 [46,49,50]. The design is defective because a manufacturing defect has caused the output of the `and` gate to be permanently tied to ground, i.e., stuck-at-0, using a positive logic convention. To sensitize the fault, the inputs A and B should both be set to 1, which should force the `and` gate output to a 1 for a good circuit. To propagate the fault, the inputs C and D should both be set to 0, which will force the `xor` gate output to 1, again for a good circuit. Thus, if $A = 1$, $B = 1$, $C = 0$, and $D = 0$ in Figure 7.24, then a good circuit would yield a 1, but the defective circuit yields a 0 which detects the stuck-at-0 fault at the `and` gate output.

Sequential automatic test program generation is a more difficult task than combinational automatic test program generation because exercising or sensitizing a particular circuit path to detect the presence of a possible manufacturing fault may require a sequence of input test vectors. One technique for testing sequential digital systems is called scan fault testing. Scan fault testing is called a ''design-for-testability'' technique because it modifies or constrains the design in a manner that facilitates fault testing. Scan techniques impose a logic design discipline that all state registers be connected in one or more chains to form ''scan rings,'' as shown in Figure 7.25 [48]. During normal device operation, the scan rings are disabled and the registers serve as conventional memory (state) storage elements. During test operation, the scan rings are enabled and

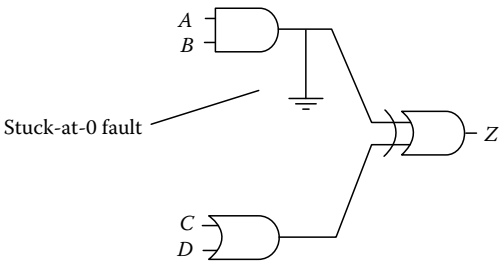

FIGURE 7.24 Combinational logic stuck-at fault testing.

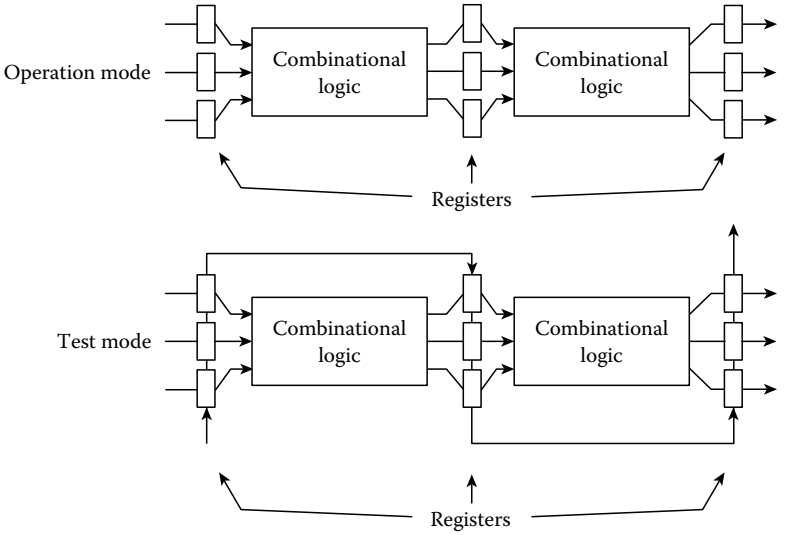

FIGURE 7.25 Scan-based design-for-testability.

stimulus test vectors are shifted into the memory elements to set the state of the digital system. The digital system is exercised for one clock cycle and then the results are shifted out of the scan ring to record the response.

The principal advantage of scan design-for-testability is that the scan ring decouples stages of combinational logic, thereby transforming a sequential design into effectively a combinational design and correspondingly a difficult sequential test task into a simpler combinational test task. However, fault tests must still be generated for the combinational logic, and shifting in stimuli and shifting out response requires time. Also, scan paths require additional hardware resources that can impose a performance (speed) penalty. To address these limitations, ''partial'' scan techniques have been developed that offer a compromise between testability and performance. Instead of connecting every register into scan chains, Figure 7.26 shows that a partial scan selectively connects a subset of registers into scan chains. Registers in critical performance circuit paths are typically excluded and registers providing control and observability to portions of the design are typically included. Similar to full scan test operation, stimulus test vectors are shifted into the memory elements to set the state of the digital system. Then, a partial scan test exercises the digital system for multiple clock cycles (two clock cycles for the partial scan shown in Figure 7.26), and then the results are shifted out of the scan ring to record the response.

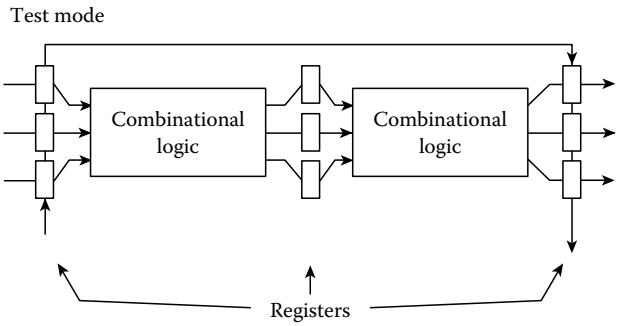

FIGURE 7.26 Partial scan-based design-for-testability.

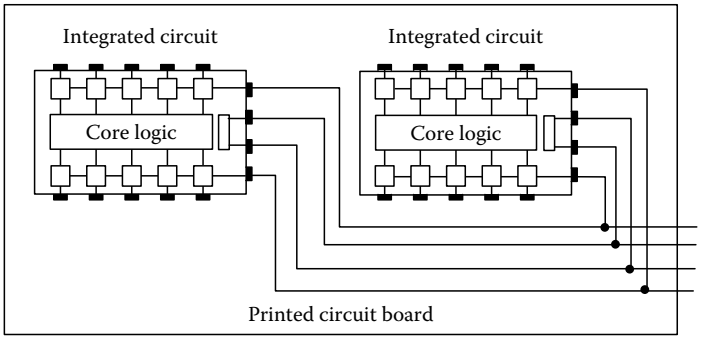

FIGURE 7.27 Boundary scan.

A variation of partial scan design-for-testability, called ''boundary scan,'' has been defined for testing integrated circuits on printed circuit boards. Printed circuit board manufacturing developments, such as fine-lead components, surface mount assembly, and multichip modules, yield high-density boards with fewer access points to probe individual pins. Such printed circuit boards are difficult to test. As the name implies, boundary scan imposes a design discipline on printed circuit board components, typically integrated circuits, such that the I–O pins on the integrated circuits can be connected into scan chains. Figure 7.27 shows that each integrated circuit configured for boundary scan contains scan registers between the I–O pins and the core logic to enable the printed circuit board test bus to control and observe the behavior of individual integrated circuits [51].

Another design-for-testability technique is signature analysis, also called ''built-in-self-test.'' Signature testing techniques use additional logic, typically linear feedback shift registers, to automatically generate pseudorandom test vectors. The output responses are compressed into a single vector and compared to a known good vector. If the output response vector does not exactly match the known good vector, then the design is considered faulty. Matching the output response vector and a known good vector does not guarantee correct hardware; however, if enough pseudorandom test vectors are exercised, then the chances are acceptably small of obtaining a false positive result. Signature analysis is often used to test memories [45].

Ad hoc testing techniques selectively insert test hardware and access points into a design to improve observability and controllability. Typical candidates for additional access points include storage elements (set and reset controls), major system communication buses, and feedback loops. Ad hoc testing techniques, also called behavioral testing techniques, can avoid the performance penalty of more structured, logical fault testing techniques, such as scan testing, and more closely mimics the actions of an expert test engineer. However, the number of access points is often restricted by integrated circuit or printed circuit board I–O pin limitations.

Coding test techniques encode signal information so that errors can be detected and possibly corrected. Although often implemented in software, coding techniques can also be implemented in hardware. For example, a simple coding technique called ''parity checking'' is often implemented in hardware. Parity checking adds an extra bit to multibit data. The parity bit is set such that the total number of logic 1's in the multibit data and parity bit is either an even number (even parity) or an odd number (odd parity). An error has occurred if an even parity encoded signal contains an odd number of logic 1's or an odd parity encoded signal contains an even number of logic 1's. Coding techniques are used extensively to detect and correct transmission errors on system buses and networks, storage errors in system memory, and computational errors in processors [52].

Finally, the electrical monitoring testing technique, also called current/voltage testing, relies on the simple observation that an out-of-range current or voltage often indicates a defective or bad part. Possibly a short or open is present, causing a particular I–O signal to have the wrong voltage or current.

Current testing (I_{ddq} testing) is particularly useful for digital systems using CMOS integrated circuit technology. Normally, CMOS circuits yield very low static or quiescent currents. However, physical faults, such as gate oxide defects, can increase static current by several orders of magnitude. Such a substantial change in static current is straightforward to detect. The principal advantages of current testing are that the tests are simple and the fault models address detailed transistor-level defects. However, current testing requires that enough time be allotted between input stimuli to allow the circuit to reach a static state, which slows down testing and causes problems with circuits that cannot be tested at scaled clock rates.

7.7 Frameworks

The previous sections discussed various types of design automation programs ranging from initial design entry tasks to final manufacturing test tasks. As the number and sophistication of design automation programs increases, the systems aspects of how the tools should be integrated with each other and underlying computing platforms become increasingly important. The first commercial design automation system product offerings in the 1970s consisted primarily of design automation programs and an associated computing platform ''bundled'' together in turnkey systems. These initial product offerings offered little flexibility to ''mix-and-match'' design automation programs and computing products from different source to take advantage of state-of-the-art capabilities and construct a design automation system tailored to particular end-user requirements. In response to these limitations, vendor offerings in the 1980s started to address *open systems*. Vendors ''unbundled'' software and hardware and introduced interoperability mechanisms to enable a design automation program to execute on different vendor systems. The interoperability mechanisms are collectively called ''frameworks'' [56].

Frameworks support design automation systems potentially involving many users, application programs, and host computing environments or platforms. Frameworks manage the complexities of a complete design methodology by coordinating and conducting the logistics of design automation programs and design data. Supporting the entire design cycle, also called ''concurrent engineering,'' improves productivity by globally optimizing the utilization of resources and the minimization of design errors and associated costs.

A general definition of a framework is given next:

> A CAD framework is a software infrastructure that provides a common operating environment for CAD tools. A framework should enable users to launch and manage tools; create, organize, and manage data; graphically view the entire design process; and perform design management tasks such as configuration and version management. Among the key elements of a CAD framework are platform-independent graphics and user interfaces, inter-tool communications, and design data and process management services. (CAD Framework Initiative, CFI)*

Figure 7.28 illustrates that a framework is essentially a domain-specific (i.e., electronic systems) layer of operating system software that facilitates ''plug-compatible'' design automation programs. Framework services are specific to electronic systems design and are mapped into the more generic services provided by general-purpose computing platforms [55].

User interface services provide a common and consistent ''look-and-feel'' to application programs. User interface services include support for consistent information display styles using menus and/or windows. These services also include support for consistent command styles using programming function keys and/or mouse buttons. Application program services provide support for program interactive/batch invocation and normal/abnormal termination. Application services also provide support for

* CAD Framework Initiative is a consortium of companies established to define and promote industry standards for design automation system interoperability.

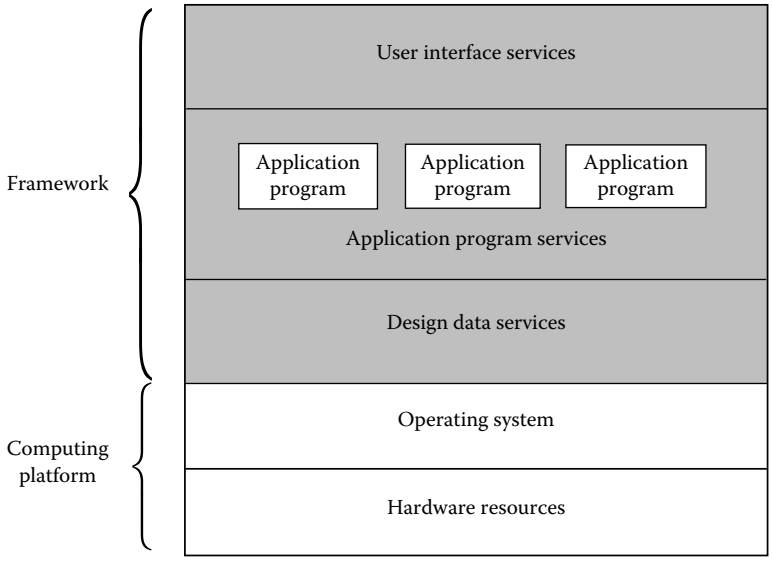

FIGURE 7.28 Framework architecture.

program-to-program communication and process management. Process management implements a design methodology that defines application-to-application and application-to-data dependencies. Process management describes a general sequencing of design automation programs and provisions for iterations. In other words, process management ensures a designer is working with the right tool at the right time with the right data.

Finally, a framework provides design data services to support access, storage, configuration, and integrity operations. Figure 7.29 shows relationships among relational, network, and object-oriented data management schemes. Due to the comparatively large size of design data and the length of design operations, framework data services are evolving toward object-oriented paradigms [57–59].

Object-oriented paradigms match data structures and operations with design automation objects and tasks, respectively. Figure 7.30 shows that hardware devices, components, and products become natural choices for software ''objects.''

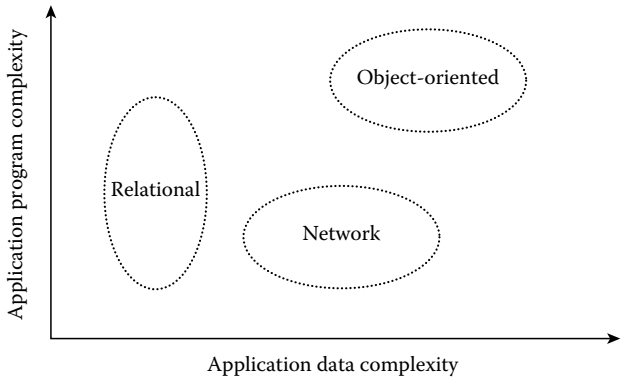

FIGURE 7.29 Data management technology.

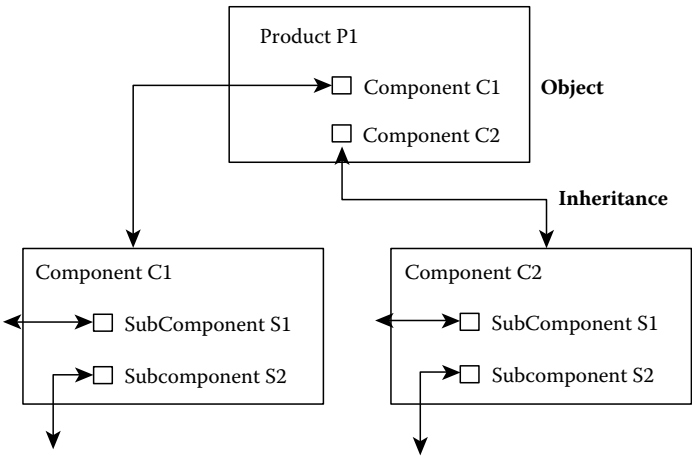

FIGURE 7.30 Object-oriented modeling.

The hierarchical relationships between hardware units become natural choices for software ''inheritance.'' Finally, design automation tasks and subtask that operate on hardware units, such as display or simulate, become natural choices for software ''methods.''

7.8 Summary

Design automation technology offers the potential of serving as a powerful fulcrum in leveraging the skills of a designer against the growing demands of electronic system design and manufacturing. Design automation programs help to relieve the designer of the burden of tedious, repetitive tasks that can be labor intensive and error prone.

Design automation technology can be broken down into several topical areas, such as design entry, conceptual design, synthesis, verification, testing, and frameworks. Each topical area has developed an extensive body of knowledge and experience.

Design entry defines a desire specification. Conceptual design refines the specification into a design plan. Synthesis refines the design plan into an implementation. Verification checks that the implementation faithfully realizes the desired specification. Testing checks that the manufactured part performs functionally and parametrically correctly. Finally, frameworks enable individual design automation programs to operate collectively and cohesively within a larger computing system environment.

8.1 Circuit Simulation Using SPICE and SUPREM

8.1.1 Introduction

Computer-aided simulation is a powerful aid during the design or analysis of electronic circuits and semiconductor devices. The first part of this chapter focuses on analog circuit simulation. The second part covers simulations of semiconductor processing and devices. While the main emphasis is on analog circuits, the same simulation techniques may, of course, be applied to digital circuits (which are, after all, composed of analog circuits). The main limitation will be the size of these circuits because the techniques presented here provide a very detailed analysis of the circuit in question and, therefore, would be too costly in terms of computer resources to analyze a large digital system.

The most widely known and used circuit simulation program is SPICE (simulation program with integrated circuit emphasis). This program was first written at the University of California at Berkeley by Laurence Nagel in 1975. Research in the area of circuit simulation is California at many universities and industrial sites. Commercial versions of SPICE or related programs are available on a wide variety of computing platforms, from small personal computers to large mainframes. A list of some commercial simulator vendors can be found in the Appendix A.

It is possible to simulate virtually any type of circuit using a program like SPICE. The programs have built-in elements for resistors, capacitors, inductors, dependent and independent voltage and current sources, diodes, MOSFETs, JFETs, bipolar junction transistors (BJTs), transmission lines, transformers, and even transformers with saturating cores in some versions. Found in commercial versions are libraries of standard components which have all necessary parameters prefitted to typical specifications.

These libraries include items such as discrete transistors, op-amps, phase-locked loops, voltage regulators, logic integrated circuits (ICs) and saturating transformer cores.

Computer-aided circuit simulation is now considered an essential step in the design of ICs, because without simulation the number of ''trial runs'' necessary to produce a working IC would greatly increase the cost of the IC. Simulation provides other advantages, however:

- Ability to measure ''inaccessible'' voltages and currents. Because a mathematical model is used all voltages and currents are available. No loading problems are associated with placing a voltmeter or oscilloscope in the middle of the circuit, with measuring difficult one-shot wave forms, or probing a microscopic die.
- Mathematically ideal elements are available. Creating an ideal voltage or current source is trivial with a simulator, but impossible in the laboratory. In addition, all component values are exact and no parasitic elements exist.
- It is easy to change the values of components or the configuration of the circuit. Unsoldering leads or redesigning IC masks are unnecessary.

Unfortunately, computer-aided simulation has its own problems:

- Real circuits are distributed systems, not the ''lumped elements models'' which are assumed by simulators. Real circuits, therefore, have resistive, capacitive, and inductive parasitic elements present besides the intended components. In high-speed circuits these parasitic elements are often the dominant performance-limiting elements in the circuit, and must be painstakingly modeled.
- Suitable predefined numerical modes have not yet been developed for certain types of devices or electrical phenomena. The software user may be required, therefore, to create his or her own models which are available in the simulator. (An example is the solid-state thyristor which may be created from a NPN and PNP bipolar transistor.)
- Numerical methods used may place constraints on the form of the model equations used.

The following sections consider the three primary simulation modes: DC, AC, and transient analysis. In each section an overview is given of the numerical techniques used. Some examples are then given, followed by a brief discussion of common pitfalls.

8.1.2 DC (Steady-State) Analysis

DC analysis calculates the state of a circuit with fixed (nontime varying) inputs after an infinite period of time. DC analysis is useful to determine the operating point (*Q*-point) of a circuit, power consumption, regulation and output voltage of power supplies, transfer functions, noise margin and fan-out in logic gates, and many other types of analysis. In addition, DC analysis is used to find the starting point for AC and transient analysis. To perform the analysis the simulator performs the following steps:

1. All capacitors are removed from the circuit (replaced with opens).
2. All inductors are replaced with shorts.
3. Modified nodal analysis is used to construct the nonlinear circuit equations. This results in one equation for each circuit node plus one equation for each voltage source. Modified nodal analysis is used rather than standard nodal analysis because an ideal voltage source or inductance cannot be represented using normal nodal analysis. To represent the voltage sources, loop equations (one for each voltage source or inductor), are included as well as the standard node equations. The node voltages and voltage source currents, then, represent the quantities which are solved for. These form a vector $\mathbf{x}$. The circuit equations can also be represented as a vector $\mathbf{F}(\mathbf{x}) = \mathbf{0}$.
4. Because the equations are nonlinear, Newton's method (or a variant thereof) is used to solve the equations. Newton's method is given by the following equations:

$$J = \left.\frac{\partial \mathbf{F}}{\partial \mathbf{x}}\right|_{\mathbf{x}^i}$$
$$\mathbf{x}^{i+1} = \mathbf{x}^i - J^{-1} \cdot \mathbf{F}(\mathbf{x}^i)$$

Here, if $\mathbf{x}^i$ is an estimate of the solution, $\mathbf{x}^{i+1}$ is a better estimate. The equations are used iteratively, and hopefully the vector **x** converges to the correct solution. The square matrix *J* of partial derivatives is called the Jacobian of the system. Most of the work in calculating the solution is involved in calculating *J* and its inverse J^{-1}. It may take as many a 100 iterations for the process to converge to a solution. Parameters control this process in most simulation programs (see the .OPTIONS statement in SPICE). For example, the maximum number of iterations allowed and error limits which must be satisfied before the process is considered to be converged, but normally the default limits are appropriate.

Example 8.1: Simulation Voltage Regulator

We shall now consider simulation of the type 723 voltage regulator IC, shown in Figure 8.1. We wish to simulate the IC and calculate the sensitivity of the output *IV* characteristic and verify that the output current follows a "fold-back" type characteristic under overload conditions.

The IC itself contains a voltage reference source and operational amplifier. Simple models for these elements are used here rather than representing them in their full form, using transistors to illustrate model development. The use of simplified models can also greatly reduce the simulation effort. (For example, the simple op-amp used here requires only eight nodes and ten components, yet realizes many advanced features.)

Note in Figure 8.1 that the numbers next to the wires represent the circuit nodes. These numbers are used to describe the circuit to the simulator. In most SPICE-type simulators the nodes are represented by numbers, with the ground node being node zero. Referring to Figure 8.2, the 723 regulator and its internal op-amp are represented by subcircuits. Each subcircuit has its own set of nodes and components. Subcircuits are useful for encapsulating sections of a circuit or when a certain section needs to be used repeatedly.

FIGURE 8.2 SPICE input listing of regulator circuit shown in Figure 8.1.

The following properties are modeled in the op-amp:

1. Common mode gain
2. Differential mode gain
3. Input impedance
4. Output impedance
5. Dominant pole
6. Output voltage clipping

The input terminals of the op-amp connect to a "T" resistance network, which sets the common and differential mode input resistance. Therefore, the common mode resistance is RCM + RDIF = 1.1E6 and the differential mode resistance is RDIF1 + RDIF2 = 2.0E5.

Dependent current sources are used to create the main gain elements. Because these sources force current into a $1-\Omega$ resistor, the voltage gain is Gm*R at low frequency. In the differential mode, this gives (GDIF*R1 = 100). In the common mode, this gives (GCM*R1*(RCM/(RDIF1 + RCM = 0.0909). The two diodes D1 and D2 implement clipping by preventing the voltage at node 6 from exceeding VCC or going below VEE. The diodes are made "ideal" by reducing the ideality factor n. Note that the diode current is $I_d = I_s[\exp(V_d/(nV_t)) - 1]$, where V_t is the thermal voltage (0.026 V). Thus, reducing n makes the diode turn on at a lower voltage.

A single pole is created by placing a capacitor (C1) in parallel with resistor R1. The pole frequency is therefore given by 1.0/2 * π * R1 * C1). Finally, the output is driven by the voltage-controlled voltage source E1 (which has a voltage gain of unity), through the output resistor R4. The output resistance of the op-amp is therefore equal to R4.

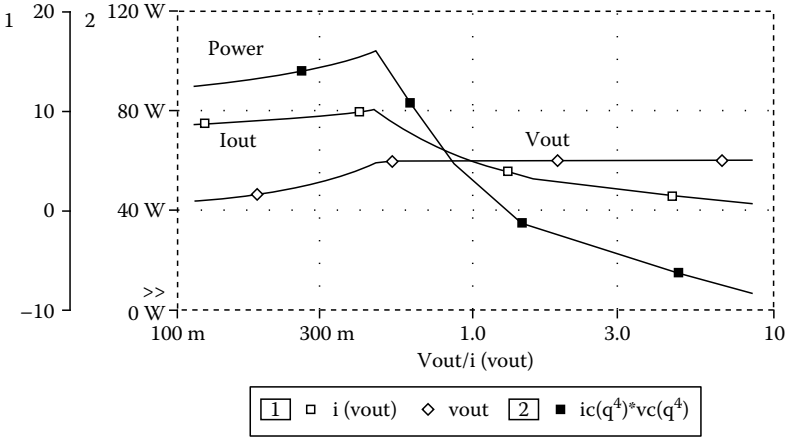

FIGURE 8.3 Output characteristics of regulator circuit using PSPICE.

To observe the output voltage as a function of resistance, the regulator is loaded with a voltage source (VOUT) and the voltage source is swept from 0.05 to 6.0 V. A plot of output voltage vs. resistance can then be obtained by plotting VOUT vs. VOUT/I(VOUT) (using PROBE in this case; see Figure 8.3). Note that for this circuit, even though a current source would seem a more natural choice, a voltage source must be used as a load rather than a current source because the output characteristic curve is multi-valued in current. If a current source were used it would not be possible to easily simulate the entire curve. Of course, many other interesting quantities can be plotted; for example, the power dissipated in the pass transistor can be approximated by plotting IC(Q3)*VC(Q3).

Several restrictions exist as to what constitutes a valid circuit, and in most cases the simulators will complain if the restrictions are violated:

1. All nodes must have a DC path to ground.
2. Voltage sources must not be connected in a loop.
3. Current sources may not be connected in series.
4. Each node must be connected to at least two elements.

For these simulations, PSPICE was used running on an IBM PC. The simulation took <1 min of CPU time.

Pitfalls. Many SPICE users forget that the first line in the input file is used as the title. Therefore, if the first line of the file is a circuit component, the component name will be used as the title and the component will not be included in the circuit. Convergence problems are sometimes experience if "difficult" bias conditions are created. An example of such a condition is if a diode is placed in the circuit backwards, resulting in a large forward bias voltage, SPICE will have trouble resolving the current. Another difficult case is if a current source were used instead of a voltage to bias the output in the previous example. If the user then tried to increase the output current above 10 A, SPICE would not be able to converge because the regulator will not allow such a large current.

8.1.3 AC Analysis

AC analysis uses phasor analysis to calculate the frequency response of a circuit. The analysis is useful for calculating the gain, 3 dB frequency input and output impedance, and noise of a circuit as a function of frequency, bias conditions, temperature, etc.

8.1.3.1 Numerical Method

1. DC solution is performed to calculate the Q-point for the circuit.
2. Linearized circuit is constructed at the Q-point. To do this, all nonlinear elements are replaced by their linearized equivalents. For example, a nonlinear current source $I = aV_1^2 + bV_2^3$ would be replaced by a linear voltage controlled current source $I = V_1(2aV_{1q}) + V_2(3bV_{2q}^2)$.
3. All inductors and capacitors are replaced by complex impedances, and conductances evaluated at the frequency of interest.
4. Nodal analysis is now used to reduce the circuit to a linear algebraic complex matrix. The AC node voltages may now be found by applying an excitation vector (which represents the independent voltage and current sources) and using Gaussian elimination (with complex arithmetic) to calculate the node voltages.

AC analysis does have limitations and the following types of nonlinear or large signal problems cannot be modeled:

1. Distortion due to nonlinearities such as clipping, etc.
2. Slew rate-limiting effects
3. Analog mixers
4. Oscillators

Noise analysis is performed by including noise sources in the models. Typical noise sources include thermal noise in resistors $I_n^2 = 4kT\Delta f/R$, and shot $I_n^2 = 2qI_d\Delta f$, and flicker noise in semiconductor devices. Here, T is temperature in Kelvin, k is Boltzmann's constant, and Δf is the bandwidth of the circuit. These noise sources are inserted as independent current sources, $\mathrm{In}_j(f)$ into the AC model. The resulting current due to the noise source is then calculated at a user-specified summation node(s) by multiplying by the gain function between the noise source and the summation node $A_{js}(f)$. This procedure is repeated for each noise source, and then the contributions at the reference node are root mean squared (RMS) summed to give the total noise at the reference node. The equivalent input noise is then easily calculated from the transfer function between the circuit input and the reference node $A_{is}(f)$. The equation describing the input noise is therefore:

$$I_i = \frac{1}{A_{is}(f)} \sqrt{\sum_j [A_{js}(f)\mathrm{In}_j(f)]^2}$$

Example 8.2: Cascode Amplifier with Macro Models

Here, we find the gain, bandwidth, input impedance, and output noise of a cascode amplifier. The circuit for the amplifier is shown in Figure 8.5. The circuit is assumed to be fabricated in a monolithic IC process, so it will be necessary to consider some of the parasitics of the IC process. A cross-section of a typical IC bipolar transistor is shown in Figure 8.4 along with some of the parasitic elements. These parasitic elements are easily included in the amplifier by creating a "macro model" for each transistor. The macro model is then implemented in SPICE form using subcircuits.

The PSPICE circuit simulator allows the user to define parameters which are passed into the subcircuits. This capability is very useful in this case because the resistor model will vary, depending on the value of the resistor. It if is assumed for a certain resistor type that the width w (measured perpendicular to current flow) of the resistor is fixed, e.g., to the minimum line width of the process, then the resistance must be proportional to the length (l) of the resistor ($R \propto l/w$). The parasitic capacitance of the resistor, on the other hand, is proportional to the junction area of the resistor, and therefore to the value of the resistance as well ($C \propto lw \propto R$). Using parameterized subcircuits these relations are easily implemented, and one subcircuit can be used to represent many different resistors (see Figure 8.6). Here,

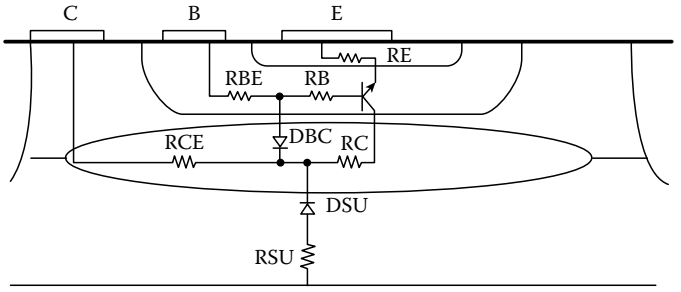

FIGURE 8.4 BJT cross-section with macro model elements.

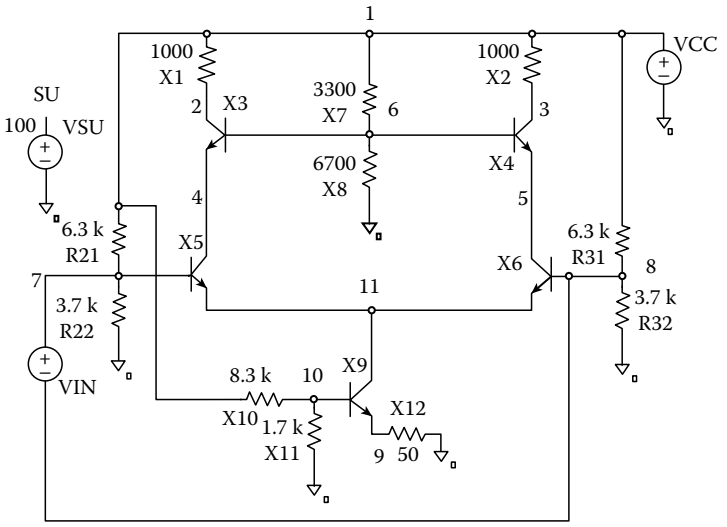

FIGURE 8.5 Cascode amplifier for AC analysis, created using PSPICE.

we represent the capacitance using two diodes one at each end of the resistor. This was done because the resistor junction capacitance is voltage dependent.

The input to the circuit is a voltage source (VIN), applied differentially to the amplifier. The output will be taken differentially across the collectors of the two upper transistors at nodes 2 and 3. The input impedance of the amplifier can be calculated as VIN/I(VIN) or because VIN = 1.0 just as 1/I(VIN). These quantities are shown plotted using PROBE in Figure 8.7. It can be seen that the gain of the amplifier falls off at high frequency as expected. The input impedance also drops because parasitic capacitances shunt the input.

It is also requested in Figure 8.6 that noise analysis be performed at every 20th frequency point. A portion of the noise printout is shown in Figure 8.8. It can be seen that the simulator calculates the noise contributions of each component in the circuit at the specified frequencies and displays them. The total noise at the specified summing node (differentially across nodes 2 and 3) in this case is also calculated as well as the equivalent noise referenced back to the input. This example took <1 min on an IBM PC.

Pitfalls. Many novice users will forget that AC analysis is a linear analysis. They will, for example, apply a 1 V signal to an amplifier with 5 V power supplies and a gain of 1000 and be surprised when SPICE tells them that the output voltage is 1000 V. Of course, the voltage generated in a simple amplifier must be less

FIGURE 8.8 Noise analysis results for cascode amplifier.

than the power supply voltage, but to examine such clipping effects, transient analysis must be used. Likewise, selection of a proper *Q*-point is important. If the amplifier is biased in a saturated portion of its response and AC analysis is performed, the gain reported will be much smaller than the actual large signal gain.

8.1.4 Transient Analysis

Transient analysis is the most powerful analysis capability of a simulator because the transient response is so hard to calculate analytically. Transient analysis can be used for many types of analysis, such as switching speed, distortion, basic operation of certain circuits like switching power supplies. Transient analysis is also the most CPU intensive and can require 100 or 1000 times the CPU time as a DC or AC analysis.

8.1.4.1 Numerical Method

In a transient analysis time is discretized into intervals called time steps. Typically, the time steps are of unequal length, with the smallest steps being taken during portions of the analysis when the circuit voltages and currents are changing most rapidly. The capacitors and inductors in the circuit are then replaced by voltage and current sources based on the following procedure.

The current in a capacitor is given by $I_c = C\mathrm{d}V_c/\mathrm{d}t$. The time derivative can be approximated by a difference equation.

$$I_c^k + I_c^{k-1} = 2C\frac{V_c^k - V_c^{k-1}}{t^k - t^{k-1}}$$

In this equation, the superscript k represents the number of the time step. Here, k is the time step we are presently solving for and $(k-1)$ is the previous time step. This equation can be solved to give the capacitor current at the present time step.

$$I_c^k = V_c^k(2C/\Delta t) - V_c^{k-1}(2C/\Delta t) - I_c^{k-1}$$

Here $\Delta t = t^k - t^{k-1}$, or the length of the time step. As time steps are advanced, $V_c^{k-1} \rightarrow V_c^k; I_c^{k-1} \rightarrow I_c^k$. Note that the second two terms on the right hand side of the above equation are dependent only on the capacitor voltage and current from the previous time step, and are therefore fixed constants as far as the present step is concerned. The first term is effectively a conductance ($g = 2C/\Delta t$) multiplied by the capacitor voltage, and the second two terms could be represented by an independent current source. The entire transient model for the capacitor therefore consists of a conductance in parallel with two current sources (the numerical values of these are, of course, different at each time step). Once the capacitors and inductors have been replaced as indicated, the normal method of DC analysis is used. One complete DC analysis must be performed for each time point. This is the reason that transient analysis is so CPU intensive. The method outlined here is the trapezoidal time integration method and is used as the default in SPICE.

Example 8.3: Phase-Locked Loop Circuit

Figure 8.9 shows the phase-locked loop (PLL) circuit. The first analysis considers only the analog multiplier portion (also called a phase detector). The second analysis demonstrates the operation of the entire PLL. For the first analyses we wish to show that the analog multiplier does indeed multiply its input voltages. To do this, sinusoidal signals of 0.5 V amplitude are applied to the inputs, one at 2 MHz and the second at 3 MHz. The analysis is performed in the time domain and a Fourier analysis is used to analyze the output. Because the circuit functions as a multiplier, the output should be

$$V_{out} = AV_a \sin(2e6\pi t)V_b \sin(3e6\pi t) = AV_aV_b[\cos(1e6\pi t) - \cos(5e6\pi t)]$$

The 1 and 5 MHz components are of primary interest. Feedthrough of the original signal will also occur, which will give 2 and 3 MHz components in the output. Other forms of nonlinear distortion will

give components at higher frequencies. The SPICE input deck is shown in Figure 8.10. The output of the Fourier analysis is shown in Figure 8.11. It can be seen that the components at 1 and 5 MHz dominate and are a factor of 3 larger than the next largest component. The phase of the 1 and 5 MHz component is also offset by approximately 90° from the input (at 0°), as expected.

Simulation of the entire PLL will now be performed. The SPICE input deck is own in Figure 8.12. The phase detector and voltage-controlled oscillator are modeled in separate subcircuits. The phase

FIGURE 8.12 SPICE input listing for phase-locked loop circuit.

detector, or multiplier, subcircuit is the same as that of Figure 8.10 and is omitted from Figure 8.12 for brevity. Examine the VCO subcircuit and note the PULSE-type current source ISTART connected across the capacitor. The source gives a current pulse 0.3E-6 s wide at the start of the simulation to start the VCO running. To start a transient simulation SPICE first computes a DC operating point (to find the initial voltages V_c^{k-1} on the capacitors). As this DC point is a valid, although not necessarily stable, solution, an oscillator will remain at this point indefinitely unless some perturbation is applied to start the oscillations. Remember, this is an ideal mathematical model and no noise sources or asymmetries exist that would start a real oscillator—it must be done manually. The capacitor C1 would have to be placed off-chip, and bond pad capacitance (CPAD1 and CPAD2) have been included at the capacitor nodes. Including the pad capacitances is very important if a small capacitor C1 is used for high-frequency operation.

In this example, the PLL is to be used as a FM detector circuit and the FM signal is applied to the input using a single frequency FM voltage source. The carrier frequency is 600 kHz and the modulation frequency is 60 kHz. Figure 8.13 shows the input voltage and the output voltage of the PLL at the VCO output and at the phase detector output. It can be seen that after a brief starting transient, the PLL locks onto the input signal and that the phase detector output has a strong 60 kHz component. This example took 251 s on a Sun SPARC-2 workstation (3046 time steps, with an average of 5 N iterations per time step).

Pitfalls. Occasionally, SPICE will fail and give the message ''Timestep too small in transient analysis,'' which means that the process of Newton iterations at certain time steps could not be made to converge. One of the most common causes of this is the specification of a capacitor with a value that is much too large, for example, specifying a 1 F capacitor instead of a 1 pF capacitor (an easy mistake to make by not adding the ''p'' in the value specification). Unfortunately, we usually have no way to tell which capacitor is at fault from the type of failure generated other than to manually search the input deck.

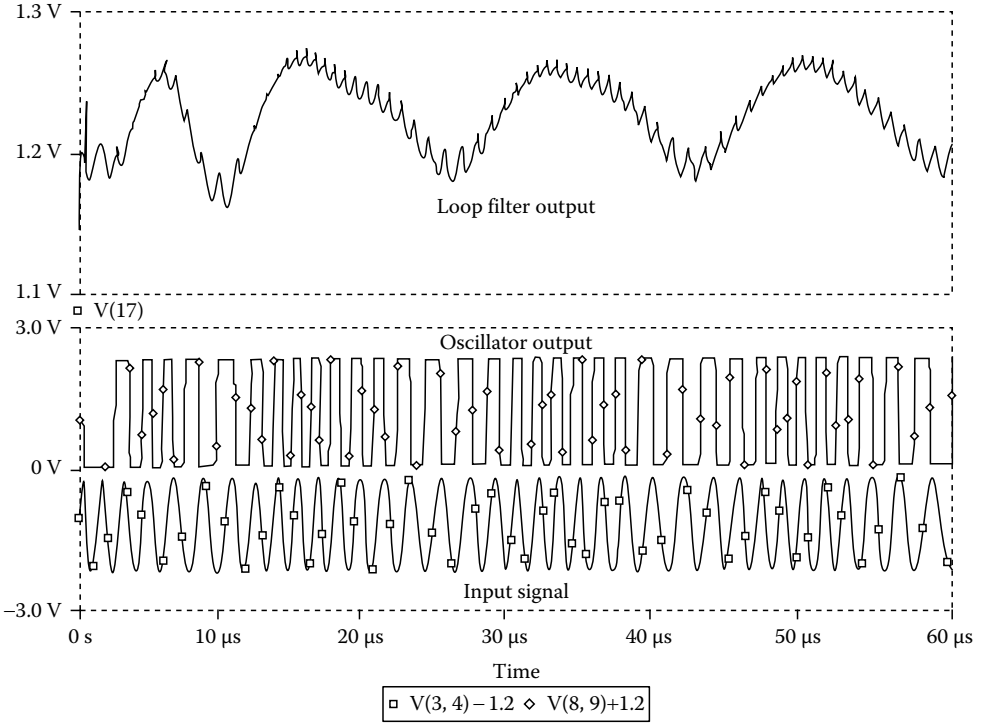

FIGURE 8.13 Transient analysis results of PLL circuit, created using PSPICE.

Other transient failures are caused by MOSFET models. Some models contain discontinuous capacitances (with respect to voltage) and others do not conserve charge. These models can vary from version to version so it is best check the user's guide.

8.1.5 Process and Device Simulation

Process and device simulation are the steps that precede analog circuit simulation in the overall simulation flow (see Figure 8.14). The simulators are also different in that they are not measurement driven as are analog circuit simulators. The input to a process simulator is the sequence of process steps performed (times, temperatures, gas concentrations) as well as the mask dimensions. The output from the process simulator is a detailed description of the solid-state device (doping profiles, oxide thickness, junction depths, etc.). This input to the device simulator is the detailed description generated by the process simulator (or via measurement). The output of the device simulator is the electrical characteristics of the device (I–V curves, capacitances, switching transient curves).

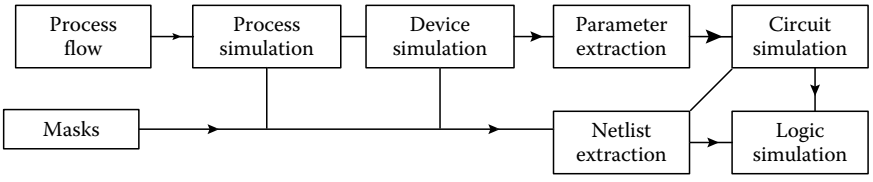

FIGURE 8.14 Data flow for complete process-device-circuit modeling.

Process and device simulation are becoming increasingly important and widely used during the IC design process. A number of reasons exist for this:

- As device dimensions shrink, second-order effects can become dominant. Modeling of these effects is difficult using analytical models.
- Computers have greatly improved, allowing time-consuming calculations to be performed in a reasonable amount of time.
- Simulation allows access to impossible to measure physical characteristics.
- Analytic models are not available for certain devices, for example, thyristors, heterojunction devices, and IGBTS.
- Analytic models have not been developed for certain physical phenomena, for example, single event upset, hot electron aging effects, latchup, and snap-back.
- Simulation runs can be used to replace split lot runs. As the cost of fabricate test devices increases, this advantage becomes more important.
- Simulation can be used to help device, process, and circuit designers understand how their devices and process work.

Clearly, process and device simulation is a topic which can be been the topic of entire texts. The following sections attempt to provide an introduction to this type of simulation, give several examples showing what the simulations can accomplish, and provide references to additional sources of information.

8.1.6 Process Simulation

IC processing involves a number of steps which are designed to deposit (deposition, ion implantation), remove (etching), redistribute (diffusion), or transform (oxidation) the material of which the IC is made. Most process simulation work has been in the areas of diffusion, oxidation, and ion implantation; however, programs are available that can simulate the exposure and development of photo-resist, the associated optical systems, as well as gas and liquid phase deposition and etch.

A number of programs are available (either from universities or commercial vendors) which can model silicon processing. The best known program is SUPREM-IV, which was developed at Stanford University (Stanford, CA). SUPREM-IV is capable of simulating oxidation, diffusion, and ion implantation, and has simple models for deposition and etch. In the following section a very brief discussion of the governing equations used in SUPREM will be given along with the results of an example simulation showing the power of the simulator.

8.1.6.1 Diffusion

The main equation governing the movement of electrically charged impurities (acceptors in this case) in the crystal is the diffusion equation:

$$\frac{\partial C}{\partial t} = \nabla \cdot \left(D\nabla C - \frac{DqC_a}{kT}\mathbf{E} \right)$$

Here

C is the concentration (#/cm^3) of impurities
C_a is the number of electrically active impurities (#/cm^3)
q is the electron charge
k is Boltzmann's constant
T is temperature in Kelvin
D is the diffusion constant
$\mathbf{E}$ is the built-in electric field.

The built-in electric field E in (V/cm) can be found from

$$\mathbf{E} = -\frac{kT}{q}\frac{1}{n}\nabla n$$

In this equation, n is the electron concentration (#/cm^3), which in turn can be calculated from the number of electrically active impurities (C_a). The diffusion constant (D) is dependent on many factors. In silicon the following expression is commonly used:

$$D = F_{IV}\left(D_x + D_+\frac{n_i}{n} + D_-\frac{n}{n_i} + D_=\left(\frac{n}{n_i}\right)^2\right)$$

The four D components represent the different possible charges states for the impurity: (x) neutral, ($+$) positive, ($-$) negative, ($=$) doubly negatively charged. n_i is the intrinsic carrier concentration, which depends only on temperature. Each D component is in turn given by an expression of the type

$$D = A\exp\left(-\frac{B}{kT}\right)$$

Here, A and B are experimentally determined constants, different for each type of impurity (x, +g, $-$, $=$). B is the activation energy for the process. This expression derives from the Maxwellian distribution of particle energies and will be seen many times in process simulation. It is easily seen that the diffusion process is strongly influenced by temperature. The term F_{IV} is an enhancement factor which is dependent on the concentration of interstitials and vacancies within the crystal lattice (an interstitial is an extra silicon atom which is not located on a regular lattice site; a vacancy is a missing silicon atom which results in an empty lattice site) $F_{IV} \propto C_I + C_V$. The concentration of vacancies, C_V, and interstitials, C_I, are in turn determined by their own diffusion equation:

$$\frac{\partial C_v}{\partial t} = +\nabla \cdot D_V \cdot \nabla C_V - R + G$$

In this equation, D_V is another diffusion constant of the form $A\exp(-B/kT)$. R and G represent the recombination and generation of vacancies and interstitials. Note that an interstitial and a vacancy may recombine and in the process destroy each other, or an interstitial and a vacancy pair may be simultaneously generated by knocking a silicon atom off its lattice site. Recombination can occur anywhere in the device via a bulk recombination process $R = A(C_V C_1)\exp(-b/kT)$. Generation occurs where there is damage to the crystal structure, in particular at interfaces where oxide is being grown or in regions where ion implantation has occurred, as the high-energy ions can knock silicon atoms off their lattice sites.

8.1.6.2 Oxidation

Oxidation is a process whereby silicon reacts with oxygen (or with water) to form new silicon dioxide. Conservation of the oxidant requires the following equation:

$$\frac{dy}{dt} = \frac{\mathbf{F}}{N}$$

Here

F is the flux of oxidant (#/cm^2/s)
N is the number of oxidant atoms required to make up a cubic centimeter of oxide
dy/dt is the velocity with which the Si–SiO_2, interface moves into the silicon.

In general, the greater the concentration of oxidant (C_0), the faster the growth of the oxide and the greater the flux of oxidant needed at the Si–SiO_2, interface. Thus, $F = k_s C_0$.

The flux of oxidant into the oxide from the gaseous environment is given by

$$F = h(HP_{ox} - C_0)$$

Here

H is a constant
P is the partial pressure of oxygen in the gas
C_0 is the concentration of oxidant in the oxide at the surface
h is of the form $A \exp(-B/kT)$.

Finally, the moment of the oxidant within the already existing oxide is governed by diffusion: $\mathbf{F} = D_0 \nabla C$ When all these equations are combined, it is found that (in the one-dimensional case) oxides grow linearly $dy/dt \propto t$ when the oxide is thin and the oxidant can move easily through the existing oxide. As the oxide grows thicker $dy/dt \propto \sqrt{t}$ because the movement of the oxidant through the existing oxide becomes the rate-limiting step.

Modeling two-dimensional oxidation is a challenging task. The newly created oxide must "flow" away from the interface where it is being generated. This flow of oxide is similar to the flow of a very thick or viscous liquid and can be modeled by a creeping flow equation:

$$\nabla^2 V \propto \nabla P$$
$$\nabla \cdot \mathrm{V} = 0$$

V is the velocity at which the oxide is moving and P is the hydrostatic pressure. The second equation results from the incompressibility of the oxide. The varying pressure P within the oxide leads to mechanical stress, and the oxidant diffusion constant D_0 and the oxide growth rate constant k_s are both dependent on this stress. The oxidant flow and the oxide flow are therefore coupled because the oxide flow depends on the rate at which oxide is generated at the interface and the rate at which the new oxide is generated depends on the availability of oxidant, which is controlled by the mechanical stress.

8.1.6.3 Ion Implantation

Ion implantation is normally modeled in one of two ways. The first involves tables of moments of the final distribution of the ions that are typically generated by experiment. These tables are dependent on the energy and the type of ion being implanted. The second method involves Monte Carlo simulation of the implantation process. In Monte Carlo simulation, the trajectories of individual ions are followed as they interact with (bounce off) the silicon atoms in the lattice. The trajectories of the ions, and the recoiling Si atoms (which can strike more Si atoms) are followed until all come to rest within the lattice. Typically several thousand trajectories are simulated (each will be different due to the random probabilities used in the Monte Carlo method) to build up the final distribution of implanted ions. Monte Carlo has advantages in that the damage to the lattice can be calculated during the implant process. This damage creates interstitials and vacancies that affect impurity diffusion, as was seen earlier. Monte Carlo can also model channeling, which is a process whereby the trajectories of the ions align with the crystal planes, resulting in greater penetration of the ion than in a simple amorphous target. Monte Carlo has the disadvantage of being CPU intensive.

Process simulation is always done in the transient mode using time steps as was done with transient circuit simulation. Because partial differential equations are involved, rather than ordinary differential equations, spatial discretization is needed as well. To numerically solve the problem, the differential equations are discretized on a grid. Either rectangular or triangular grids in one, two, or

three dimensions are commonly used. This discretization process results in the conversion of the partial differential equations into a set of nonlinear algebraic equations. The nonlinear equations are then solved using a Newton method in a way very similar to the method used for the circuit equations in SPICE.

Example 8.4: NMOS Transistor

In this example, the process steps used to fabricate a typical NMOS transistor will be simulated using SUPREM-4. These steps are

1. Grow initial oxide (30 min at 1000 K).
2. Deposit nitride layer (a nitride layer will prevent oxidation of the underlying silicon).
3. Etch holes in nitride layer.
4. Implant P + channel stop (boron dose = 5e12, energy = 50 keV).
5. Grow the field oxide (180 min at 1000 K wet O_2).
6. Remove all nitride.
7. Perform P channel implant (boron dose = 1e11, energy = 40 keV).
8. Deposit and etch polysilicon for gate.
9. Oxidize the polysilicon (30 min at 1000 K, dry O_2).
10. Implant the light doped drain (arsenic dose = 5e13 energy = 50 keV).
11. Deposit sidewall space oxide.
12. Implant source and drain (arsenic, dose = 1e15, energy = 200 keV).
13. Deposit oxide layer and etch contact holes.
14. Deposit and etch metal.

The top 4 μm of the completed structure, as generated by SUPREM-4, is shown in Figure 8.15. The actual simulation structure used is 200 μm deep to allow correct modeling of the diffusion of the vacancies and interstitials. The gate is at the center of the device. Notice how the edges of the gate have lifted up due to the diffusion of oxidant under the edges of the polysilicon (the polysilicon, as deposited in step 8, is flat). The dashed contours show the concentration of dopants in both the oxide and silicon layers. The short dashes indicate N-type material, while the longer dashes indicate P-type material. This entire simulation requires about 30 min on a Sun SPARC-2 workstation.

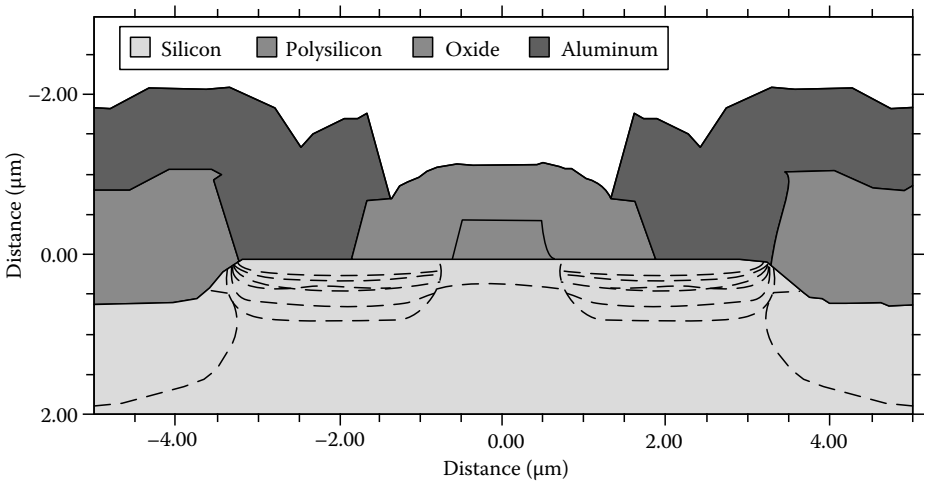

FIGURE 8.15 Complete NMOS transistor cross section generated by process simulation, created with TMA SUPREM-4.

8.1.7 Device Simulation

Device simulation uses a different approach from that of conventional lumped circuit models to determine the electrical device characteristics. Whereas with analytic or empirical models all characteristics are determined by fitting a set of adjustable parameters to measured data, device simulators determine the electrical behavior by numerically solving the underlying set of differential equations. The first of these equations is the Poisson equation, which describes the electrostatic potential within the device.

$$\nabla \cdot \varepsilon \cdot \nabla \Psi = q\left(N_{\mathrm{a}}^{-} - N_{\mathrm{d}}^{+} - p + n - Q_{\mathrm{f}}\right)$$

N_{d} and N_{a} are the concentration of donors and acceptors, i.e., the N- and P-type dopants. Q_{f} is the concentration of fixed charge due, for example, to traps or interface charge. The electron and hole concentrations are given by n and p, respectively, and Ψ is the electrostatic potential.

A set of continuity equations describes the conservation of electrons and holes:

$$\frac{\partial n}{\partial t} = \left(\frac{1}{q}\nabla \cdot J_n - R + G\right)$$

$$\frac{\partial p}{\partial t} = \left(-\frac{1}{q}\nabla \cdot J_p - R + G\right)$$

In these equations, R and G describe the recombination and generation rates for the electrons and holes. The recombination process is influenced by factors such as the number of electrons and holes present as well as the doping and temperature. The generation rate is also dependent upon the carrier concentrations, but is most strongly influenced by the electric field, with increasing electric fields giving larger generation rates. Because this generation process is included, device simulators are capable of modeling the breakdown of devices at high voltage. J_n and J_p are the electron and hole current densities (in amperes per square centimeter). These current densities are given by another set of equations:

$$\mathbf{J}_n = q\mu\left(-n\nabla\Psi + \frac{kT_n}{q}\nabla n\right)$$

$$\mathbf{J}_p = q\mu\left(-p\nabla\Psi - \frac{kT_p}{q}\nabla p\right)$$

In this equation, k is Boltzmann's constant, μ is the carrier mobility, which is actually a complex function of the doping, n, p, electric field, temperature, and other factors. In silicon the electron mobility will range between 50 and 1000 and the hole mobility will normally be a factor of 2 smaller. In other semiconductors such as gallium arsenide the electron mobility can be as high as 5000. T_n and T_p are the electron and hole mean temperatures, which describe the average carrier energy. In many models these default to the device temperature (300 K). In the first term the current is proportional to the electric field ($\nabla\Psi$), and this term represents the drift of carriers with the electric field. In the second term the current is proportional to the gradient of the carrier concentration (∇n), so this term represents the diffusion of carriers from regions of high concentration to those of low concentration. The model is therefore called the drift-diffusion model.

In devices in which self-heating effects are important, a lattice heat equation can also be solved to give the internal device temperature:

$$\sigma(T)\frac{\partial T}{\partial t} = H + \nabla \cdot \lambda(T) \cdot \nabla T$$

$$H = -(J_n + J_p) \cdot \nabla\Psi + H_{\mathrm{R}}$$

where H is the heat generation term, which includes resistive (Joule) heating as well as recombination heating, H_R. The terms $\sigma(T)$, $\lambda(T)$ represent the specific heat and the thermal conductivity of the material (both temperature dependent). Inclusion of the heat equation is essential in many power device problems.

As with process simulation partial differential equations are involved, therefore, a spatial discretization is required. As with circuit simulation problems, various types of analysis are available:

- Steady-state (DC), used to calculate characteristic curves of MOSFETs, BJTs diodes, etc.
- AC analysis, used to calculate capacitances, *Y*-parameters, small signal gains, and *S*-parameters
- Transient analysis, used for calculation of switching and large signal behavior, and special types of analysis such as radiation effects

Example 8.5: NMOS IV Curves

The structure generated in the previous SUPREM-IV simulation is now passed into the device simulator and bias voltages are applied to the gate and drain. Models were included which account for Auger and Shockley Reed Hall recombination, doping and electric field-dependent mobility, and impact ionization. The set of drain characteristics obtained is shown in Figure 8.16. Observe how the curves bend upward at high V_{ds} as the device breaks down. The $V_{gs} = 1$ curve has a negative slope at $I_d = 1.5\text{e-}4$ A as the device enters snap-back. It is possible to model this type of behavior because impact ionization is included in the model.

Figure 8.17 shows the internal behavior of the device with $V_{gs} = 3$ V and $I_d = 3\text{e-}4$ A. The filled contours indicate impact ionization, with the highest rate being near the edge of the drain right beneath the gate. This is to be expected because this is the region in which the electric field is largest due to the drain depletion region. The dark lines indicate current flow from the source to the drain. Some current also flows from the drain to the substrate. This substrate current consists of holes generated by the impact ionization. The triangular grid used in the simulation can be seen in the source, drain, and gate electrodes. A similar grid was used in the oxide and silicon regions.

8.2 Parameter Extraction for Analog Circuit Simulation

Peter Bendix

8.2.1 Introduction

8.2.1.1 Definition of Device Modeling

We use various terms such as device characterization, parameter extraction, optimization, and model fitting to address an important engineering task. In all of these, we start with a mathematical model that describes the transistor behavior. The model has a number of parameters that are varied or adjusted to match the I–V (current–voltage) characteristics of a particular transistor or set of transistors. The act of determining the appropriate set of model parameters is what we call device modeling. We then use the model with the particular set of parameters that represent our transistors in a circuit simulator such as SPICE* to simulate how circuits with our kinds of transistors will behave. Usually, the models are supplied by the circuit simulator we chose. Occasionally, we may want to modify these models or construct our own models. In this case we need access to the circuit simulator model subroutines as well as the program that performs the device characterization.

Most people believe the preceding description covers device modeling. However, we feel this is a very narrow definition. One can obtain much more information by characterizing a semiconductor process than just providing models for circuit simulation. If the characterization is done correctly, it can provide detailed information about the fabrication process. This type of information is useful for process architects as an aid in developing future processes. In addition, the wealth of information from the parameters obtained can be used by process and product engineers to monitor wafers routinely. This provides much more information than what is usually obtained by doing a few crude electrical tests for process monitoring. Finally, circuit designers can use device characterization as a means of optimizing a circuit for maximum performance. Therefore, instead of just being a tool used by specialized device physicists, device characterization is a tool for process architects, process and product engineers, and circuit designers. It is a tool that can and should be used by most people concerned with semiconductor manufacture and design.

8.2.1.2 Steps Involved in Device Characterization

Device characterization begins with a test chip. Without the proper test chip structures, proper device modeling cannot be done from measured data. A good test chip for MOS technology would include transistors of varying geometries, gate oxide capacitance structures, junction diode capacitance structures, and overlap capacitance structures. This would be a minimal test chip. Additional structures might include ring oscillators and other circuits for checking the AC performance of the models obtained. It is very important that the transistors be well designed and their geometries be chosen appropriate for the technology as well as the desired device model. For bipolar technology modeling, the layout of structures used to get *S*-parameter measurements is very critical. Although a complete test chip description is beyond the scope of this book, be aware that even perfect device models cannot correct for a poor test chip.

Next, we need data that represent the behavior of a transistor or set of transistors of different sizes. These data can come from direct measurement or they can be produced by a device simulator such as PISCES.† Typically, one does voltage sweeps on various nodes of the transistor and measures the output current at some or all of these nodes. For example, in an MOS transistor, one might sweep the gate voltage and measure the resulting drain current, holding the drain and bulk voltages fixed. The equipment used to do DC device characterization measurements is usually a DC parametric tester.

---

* SPICE is a circuit simulation program from the Department of Electrical Engineering and Computer Science at the University of California, Berkeley.

† PISCES is a process simulation program from the Department of Electrical Engineering at Stanford University, Stanford, CA.

This equipment usually has a set of SMUs (source/measure units) that can force voltage and measure current, or force current and measure voltage. The measuring equipment can be manually run or controlled by a computer. In either case the measured data must be put onto a hard disk.

For oxide capacitors, junction diodes, and overlap capacitors, a capacitance or inductance, capacitance, resistance (LCR) meter is used to do the measurements. For junction capacitance models, a junction diode (source to bulk, for example) has a reverse bias sweep done and the capacitance is measured at each bias point. For oxide and overlap capacitances, only a single capacitance measurement at one bias voltage is required.

In a more automated environment, switching matrices, semiautomated probers, and temperature-controlled chucks are added. The same equipment is used for bipolar devices. In addition, network analyzers are often used for *S*-parameter characterization to obtain the related AC transit time parameters of bipolar transistors. A typical collection of measuring equipment might look like Figure 8.18.

It is also possible to use a device simulator like PISCES, or a combination of a process simulator like SUPREM-IV* coupled to a device simulator, to provide the simulated results. The process recipe steps are fed into SUPREM-IV, which produces a device structure and associated profiles of all dopants; this information is then fed into the device simulator along with a description of voltage sweeps to be applied to various device electrodes. The output of the device simulator is a set of IV characteristics which closely represent what would have been measured on a real device. The benefits of using simulation over measurement are that no expensive measurement equipment or fabricated wafers are necessary. This can be very helpful when trying to predict the device characteristics of a new fabrication process before any wafers have been produced.

Once the measured (or simulated) data are available, parameter extraction software is used to find the best set of model parameter values to fit the data. This can be done by extraction, optimization, or a combination of the two. Extraction is simpler and quicker, but not as accurate as optimization. In extraction simplifying assumptions are made about the model equations and parameter values are extracted using slope and intercept techniques, for example. In optimization general least-squares curve fitting routines are employed to vary a set or subset of parameters to fit the measured data. Extraction and optimization are covered in more detail in the following sections.

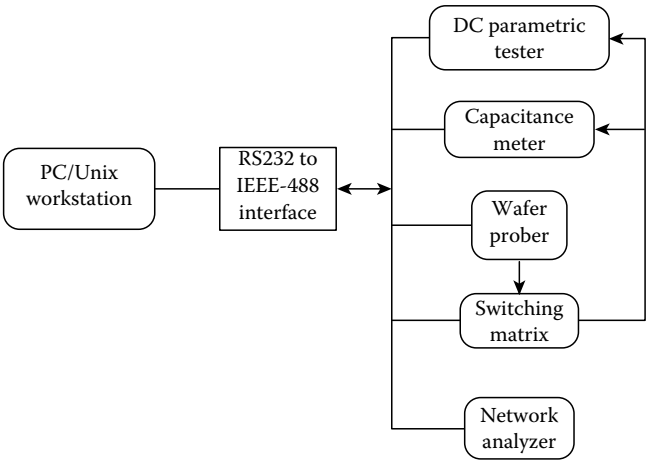

FIGURE 8.18 Typical hardware measuring equipment for device characterization.

* SUPREM-IV is a process simulation program from the Department of Electrical Engineering at Stanford University, Stanford, CA.

8.2.1.3 Least-Squares Curve Fitting (Analytical)

We begin this section by showing how to do least-squares curve fitting by analytical solutions, using a simple example to illustrate the method. We then discuss least-squares curve fitting using numerical solutions in the next section. We can only find analytical solutions to simple problems. The more complex ones must rely on numerical techniques.

Assume a collection of measured data, $m_1, \ldots, m_n$. For simplicity, let these measured data values be functions of a single variable, v, which was varied from v_1 through v_n, measuring each m_i data point at each variable value v_i, i running from 1 to n. For example, the m_i data points might be drain current of an MOS transistor, and the v_i might be the corresponding values of gate voltage. Assume that we have a model for calculating simulated values of the measured data points, and let these simulated values be denoted by $s_1, \ldots, s_n$. We define the least-squares, root mean square (RMS) error as

$$Error_{\text{rms}} = \left[\frac{\sum_{i=1}^{n} \{\text{weight}_i (s_i - m_i)\}^2}{\sum_{i=1}^{n} \{\text{weight}_i m_i\}^2} \right]^{1/2} \tag{8.1}$$

where a weighting term is included for each data point. The goal is to have the simulated data match the measured data as closely as possible, which means we want to minimize the RMS error. Actually, what we have called RMS error is really the relative RMS error, but the two terms are used synonymously. There is another way of expressing the error, called the absolute RMS error, defined as follows:

$$Error_{\text{rms}} = \left[\frac{\sum_{i=1}^{n} \{\text{weight}_i (s_i - m_i)\}^2}{\sum_{i=1}^{n} \{\text{weight}_i \; m_{\min}\}^2} \right]^{1/2} \tag{8.2}$$

where we have used the term $m_{\min}$ in the denominator to represent some minimum value of the measured data. The absolute RMS error is usually used when the measured values approach zero to avoid problems with small or zero denominators in Equation 8.1. For everything that follows, we consider only the relative RMS error. The best result is obtained by combining the relative RMS formula with the absolute RMS formula by taking the maximum of the denominator from Equation 8.1 or 8.2.

We have a simple expression for calculating the simulated data points, s_i, in terms of the input variable, v, and a number of model parameters, $p_1, \ldots, p_m$. That is,

$$s_i = f(v_i, p_1, \ldots, p_m) \tag{8.3}$$

where f is some function. Minimizing the RMS error function is equivalent to minimizing its square. Also, we can ignore the term in the denominator of Equation 8.1 as concerns minimizing, because it is a normalization term. In this spirit, we can define a new error term,

$$\text{Error} = (Error_{\text{rms}})^2 \left[\sum_{i=1}^{n} \{\text{weight}_i m_i\}^2 \right] \tag{8.4}$$

and claim that minimizing Error is equivalent to minimizing $Error_{\text{rms}}$. To minimize Error, we set all partial derivatives of it with respect to each model parameter equal to zero; that is, write

$$\frac{\partial(Error)}{\partial p_j} = 0 \quad \text{for } j = 1, \ldots, m \tag{8.5}$$

Then, solve the preceding equations for the value of p_j.

Least-squares curve fitting. Analytic example**:** Write a simple expression for the drain current of an MOS transistor in the linear region in terms of a single variable, the gate voltage, V_{gs}, and also in terms of two model parameters, β and V_{th};

$$I_{ds} = \beta(V_{gs} - V_{th})V_{ds} \tag{8.6}$$

We denote the measured drain current by I_{meas}. In terms of our previous notation, we have the following substitutions:

$$\begin{aligned} s &\rightarrow I_{ds} \\ v &\rightarrow V_{gs} \\ p_1 &\rightarrow \beta \\ p_2 &\rightarrow V_{th} \end{aligned}$$

We have two conditions to satisfy for minimizing the error:

$$\frac{\partial(Error)}{\partial \beta} = 0 \tag{8.7}$$

$$\frac{\partial(Error)}{\partial V_{th}} = 0 \tag{8.8}$$

Equations 8.7 and 8.8 imply, respectively,

$$\sum_{i=1}^{n} [\beta(V_{gs_i} - V_{th})V_{ds} - I_{meas_i}](V_{gs_i} - V_{th}) = 0 \tag{8.9}$$

$$\sum_{i=1}^{n} [\beta(V_{gs_i} - V_{th})V_{ds} - I_{meas_i}] = 0 \tag{8.10}$$

Solving Equations 8.9 and 8.10 is straightforward but tedious. The result is

$$V_{th} = \frac{[\text{Term}_1\text{Term}_2 - \text{Term}_3\text{Term}_4]}{[n\text{Term}_1 - \text{Term}_2\text{Term}_4]} \tag{8.11}$$

$$\beta = \left(\frac{1}{V_{ds}}\right)\frac{[n\text{Term}_1 - \text{Term}_2\text{Term}_4]}{\left[n\text{Term}_3 - \text{Term}_2^2\right]} \tag{8.12}$$

where n is the number of data points that i is summed over, and

$$\text{Term}_1 = \sum_{i=1}^{n} V_{gs_i} I_{meas_i} \tag{8.13}$$

$$\text{Term}_2 = \sum_{i=1}^{n} V_{\text{gs}_i} \tag{8.14}$$

$$\text{Term}_3 = \sum_{i=1}^{n} V_{\text{gs}_i}^2 \tag{8.15}$$

and

$$\text{Term}_4 = \sum_{i=1}^{n} I_{\text{meas}_i} \tag{8.16}$$

Thus, analytical solutions can become quite messy, even for the simplest model expressions. In fact, it is usually not possible to solve the system of equations analytically for more complicated models. Then, we must rely on numerical solutions.

One further word of caution is required. One may try comparing analytical solutions to those obtained by numerical techniques. They almost always will not match. The reason is that the weighting functions used to calculate $Error_{\text{rms}}$ are different for the two cases. In order to compare the two techniques, one must know the exact algorithm that the numerical least-squares curve fitting routine is using and be able to match the weighting functions. Often weighting is implicit in the numerical least-squares curve fitting algorithm that is not explicitly obvious.

8.2.1.4 Least-Squares Curve Fitting (Numerical)

For almost all practical applications we are forced to do least-squares curve fitting numerically, because the analytic solutions as previously discussed are not obtainable in closed form. What we are calling least-squares curve fitting is more generally known as nonlinear optimization. Many fine references on this topic are available. We highlight only the main features here, and paraphrase parts of [2] in what follows.

Basically, we want to solve the optimization problem whose goal is to minimize the function $F(\mathbf{x})$ where F is some arbitrary function of the vector $\mathbf{x}$. If extra conditions exist on the components of $\mathbf{x}$, we are then solving a constrained, nonlinear optimization problem. When using least-squares fitting for model parameter optimization, we usually constrain the range of the fitting parameters. This type of constraint is a very simple one and is a special case of what is called nonlinear constrained optimization. This or the unconstrained approach are the types normally used for model parameter optimization.

For simplicity, let F be a function of a single variable, x, instead of the vector, $\mathbf{x}$. We state without proof that a necessary condition for a minimum of $F(x)$ to exist is that

$$F' = \frac{\partial F}{\partial x} = 0 \tag{8.17}$$

This means we solve the minimization problem if we can solve for the zeroes of F'. This is exactly what we did when we went through the least-squares analytical method.

One numerical approach to solving for the zeroes of a function, f, is Newton's method. This is an iterative method in which we write

$$x_{k+1} = x_k - \frac{f(x_k)}{f'(x_k)} \tag{8.18}$$

Steepest descents method. Next consider the more general case in which F is now a function of many variables, $\mathbf{x}$; i.e., F is multivariate. We want to consider numerical techniques for finding the minimum of

F by iteration. We also would like to take iteration steps that decrease the value of F at each step. This imposes what is called a descent condition:

$$F(\mathbf{x}_{k+1}) < F(\mathbf{x}_k) \tag{8.19}$$

where k is the iteration number. Solving the minimization problem amounts to choosing a search direction for the vector $\mathbf{x}$ such that at each iteration F decreases until some convergence criterion is satisfied with $\mathbf{x}_k$ as the solution. Let us write F as a Taylor series expanded around the point $\mathbf{x}$, with $\mathbf{p}$ a vector of unit length and h a scalar

$$F(\mathbf{x} + h\mathbf{p}) = F(\mathbf{x}) + hg^{\mathrm{T}}(\mathbf{x})\mathbf{p} + \frac{1}{2}h^2\mathbf{p}^{\mathrm{T}}G(\mathbf{x})\mathbf{p} + \cdots \tag{8.20}$$

where in Equation 8.20, $g(\mathbf{x})$ is the gradient (first derivative in the $\mathbf{p}$ direction) of $F(\mathbf{x})$ and $G(\mathbf{x})$ is the curvature (second derivative in the $\mathbf{p}$ direction) of $F(\mathbf{x})$. The uppercase "T" means matrix transpose.

We want to choose a direction and step length for the next iteration in which

$$\mathbf{x}_{k+1} = \mathbf{x}_k + h_k\mathbf{p}_k \tag{8.21}$$

where in Equation 8.21, $\mathbf{p}$ is a unit vector in the search direction and h is the step size. In the method of steepest descents we set

$$\mathbf{p}_k = -g(\mathbf{x}_k) \tag{8.22}$$

That is, the method of steepest descents chooses the search direction to be opposite the first derivative in the direction $\mathbf{x}_k$.

Newton's method. The method of steepest descents is a first derivative method. Newton's method is a second derivative method (this is not to be confused with the simple Newton's method discussed previously). Referring to Equation 8.20, the Newton direction of search is defined to be the vector $\mathbf{p}$, which satisfies

$$G(\mathbf{x}_k)\mathbf{p}_k = -g(\mathbf{x}_k) \tag{8.23}$$

Finding $\mathbf{p}_k$ from the preceding equation involves calculating second derivatives to compute G.

Gauss–Newton method. We want to modify Newton's method so that second derivative calculations are avoided. To do this, consider the so-called least-squares problem in which F can be written as

$$F(\mathbf{x}) = \sum [f_i(\mathbf{x})]^2 \tag{8.24}$$

In this special case, we can write

$$g(\mathbf{x}) = J^{\mathbf{T}}(\mathbf{x})f(\mathbf{x}) \tag{8.25}$$

$$G(\mathbf{x}) = J^{\mathbf{T}}(\mathbf{x})J(\mathbf{x}) + Q(\mathbf{x}) \tag{8.26}$$

where J is the Jacobian of f and

$$Q(\mathbf{x}) = \sum f_i(\mathbf{x})G_i(\mathbf{x}) \tag{8.27}$$

where G_i is the so-called Hessian of f. Substituting Equations 8.25 and 8.26 into Equation 8.23 gives

$$\left[J^{\mathrm{T}}(\mathbf{x}_k)J(\mathbf{x}_k) + Q_k\right]\mathbf{p}_k = -J^{\mathbf{T}}(\mathbf{x}_k)f(\mathbf{x}_k) \tag{8.28}$$

If we throw away the Q term, Equation 8.28 becomes

$$\left[J^{\mathrm{T}}(\mathbf{x}_k)J(\mathbf{x}_k)\right]\mathbf{p}_k = -J^{\mathrm{T}}(\mathbf{x}_k)f(\mathbf{x}_k) \tag{8.29}$$

a condition for finding the search direction, $\mathbf{p}_k$, which does not involve second derivatives. Solving Equation 8.29 is tantamount to solving the linear least-squares problem of minimizing

$$F(\mathbf{x}) = \sum [\, j_i(\mathbf{x}_k)\mathbf{p}_k + f_i(\mathbf{x}_k)]^2 \tag{8.30}$$

When the search direction, $\mathbf{p}_k$, is found from Equation 8.29, we call this the Gauss–Newton method.

Levenberg–Marquardt algorithm. Both the method of steepest descents and the Gauss–Newton method have advantages and disadvantages. Briefly stated, the method of steepest descents will move toward the correct solution very quickly, but due to the large steps it takes, it can jump past the solution and not converge. The Gauss–Newton method, however, moves more slowly toward the correct solution, but because it tends to take smaller steps, it will converge better as its approaches the solution. The Levenberg–Marquardt algorithm was designed to combine the benefits of both the steepest descents and Gauss–Newton methods.

The Levenberg–Marquardt search direction is found by solving

$$\left[J^{\mathrm{T}}(\mathbf{x}_k)J(\mathbf{x}_k) + \lambda_k I\right]\mathbf{p}_k = -J^{\mathrm{T}}(\mathbf{x}_k)f(\mathbf{x}_k) \tag{8.31}$$

where λ_k is a nonnegative scalar and I is the identity matrix. Note that Equation 8.31 becomes Equation 8.29 when λ_k is zero, so that the Levenberg–Marquardt search direction becomes the Gauss–Newton in this case; as $\lambda_k \to \infty$, $\mathbf{p}_k$ becomes parallel to $-J^{\mathrm{T}}(\mathbf{x}_k)\, f(\mathbf{x}_k)$, which is just $-g(\mathbf{x}_k)$, the direction of steepest descents. Generally speaking, in the Levenberg–Marquardt algorithm the value of λ_k is varied continuously, starting with a value near the steepest descents direction (large λ_k) and moving toward smaller values of λ_k as the solution is approached.

8.2.1.5 Extraction (as Opposed to Optimization)

The terms ''extraction'' and ''optimization'' are, unfortunately, used interchangeably in the semiconductor industry; however, strictly speaking, they are not the same. By optimization, we mean using generalized least-squares curve fitting methods such as the Levenberg–Marquardt algorithm to find a set of model parameters. By extraction, we mean any technique that does not use general least-squares fitting methods. This is a somewhat loose interpretation of the term extraction, but perhaps the following discussion will justify it.

Suppose we have measured the drain current of an MOS transistor in the linear region at zero backbias (the bulk node bias) and we want to find the threshold voltage by extraction (as opposed to optimization). We could plot the drain current vs. gate voltage, draw a tangent line at the point where the slope of I_{ds} is a maximum, and find the V_{gs} axis intercept of this tangent line. This would give us a crude value of the threshold voltage, V_{th} (neglecting terms such as $V_{\mathrm{ds}}/2$). This would be a graphic extraction technique; it would not involve using least-squares optimization.

We could also apply the preceding graphic technique in an equivalent algorithmic way, without drawing any graphs. Let us write a linear region equation for the drain current

$$I_{\mathrm{ds}} = \beta(V_{\mathrm{gs}} - V_{\mathrm{th}})V_{\mathrm{ds}}[1 + Ke^{-\alpha(V_{\mathrm{gs}} - V_{\mathrm{th}})}] \tag{8.32}$$

In Equation 8.32, the exponential term is the subthreshold contribution to the drain current; it becomes negligible for $V_{\mathrm{gs}} \gg V_{\mathrm{th}}$. To find the value of V_{gs} where the maximum slope occurs, we set the derivative of I_{ds} with respect to V_{gs} equal to zero and solve for V_{gs}. The solution is

$$V_{gs}(\text{maximum slope}) = V_{th} + \left[\frac{1+K}{2\alpha K}\right] \tag{8.33}$$

where in obtaining Equation 8.33 we used the approximation

$$e^{-\alpha(V_{gs}-V_{th})} \cong 1 - \alpha(V_{gs} - V_{th}) \tag{8.34}$$

If we rewrite (8.33) for V_{th} in terms of V_{gs} (maximum slope) we have

$$V_{th} = V_{gs}(\text{maximum slope}) - \left[\frac{1+K}{2\alpha K}\right] \tag{8.35}$$

Therefore, the approach is to use a measurement search routine that seeks the maximum slope, $\Delta I_{ds}/\Delta V_{gs}$, where the Δ is calculated as numerical derivatives, and having found V_{gs} (maximum slope) through measurement, use Equation 8.35 to calculate V_{th} from V_{gs} (maximum slope).

We could continue by including the effects of mobility degradation, modifying Equation 8.32 to

$$I_{ds} = \left[\frac{\beta}{1+\theta(V_{gs} - V_{th})}\right](V_{gs} - V_{th})V_{ds}[1 + Ke^{-\alpha(V_{gs}-V_{th})}] \tag{8.36}$$

where we have now included the effects of mobility degradation with the θ term. The extraction analysis can be done again by including this term, with a somewhat different solution obtained using suitable approximations.

The main point is that we write the equations we want and then solve them by whatever approximations we choose, as long as these approximations allow us to get the extracted results in closed form. This is parameter extraction.

8.2.1.6 Extraction vs. Optimization

Extraction has the advantage of being much faster than optimization, but it is not always as accurate. It is also much harder to supply extraction routines for models that are being developed. Each time you make a change in the model, you must make suitable changes in the corresponding extraction routine. For optimization, however, no changes are necessary other than the change in the model itself, because least-squares curve fitting routines are completely general. Also, if anything goes wrong in the extraction algorithm (and no access to the source code is available), almost nothing can be done to correct the problem. With optimization, one can always change the range of data, weighting, upper and lower bounds, etc. A least-squares curve fitting program can be steered toward a correct solution.

Novices at device characterization find least-squares curve fitting somewhat frustrating because a certain amount of user intervention and intuition is necessary to obtain the correct results. These beginners prefer extraction methods because they do not have to do anything. However, after being burned by extraction routines that do not work, a more experienced user will usually prefer the flexibility, control, and accuracy that optimization provides.

Commercial software is available that provides both extraction and optimization together. The idea here is to first use extraction techniques to make reasonable initial guesses and then use these results as a starting point for optimization, because optimization can give very poor results if poor initial guesses for the parameters are used. Nothing is wrong with using extraction techniques to provide initial guesses for optimization, but for an experienced user this is rarely necessary, assuming that the least-squares curve fitting routine is robust (converges well) and the experienced user has some knowledge of the process under characterization. Software that relies heavily on extraction may do so because of the nonrobustness of its optimizer.

These comments apply when an experienced user is doing optimization locally, not globally. For global optimization (a technique we do not recommend), the previous comparisons between extraction and optimization are not valid. The following section contains more detail about local vs. global optimization.

8.2.1.7 Strategies: General Discussion

The most naive way of using an optimization would be to take all the measured data for all devices, put them into one big file, and fit to all these data with all model parameters simultaneously. Even for a very high quality, robust optimization program the chances of this method converging are slight. Even if the program does converge, it is almost certain that the values of the parameters will be very unphysical. This kind of approach is an extreme case of global optimization. We call any optimization technique that tries to fit with parameters to data outside their region of applicability a global approach. That is, if we try to fit to saturation region data with linear region parameters such as threshold voltage, mobility, etc., we are using a global approach. In general, we advise avoiding global approaches, although in the strategies described later, sometimes the rules are bent a little.

Our recommended approach is to fit subsets of relevant parameters to corresponding subsets of relevant data in a way that makes physical sense. For example, in the MOS level 3 model, VT0 is defined as the threshold voltage of a long, wide transistor at zero back-bias. It does not make sense to use this parameter to fit to a short channel transistor, or to fit at nonzero back-bias values, or to fit to anywhere outside the linear region. In addition, subsets of parameters should be obtained in the proper order so that those obtained at a later step do not affect those obtained at earlier steps. That is, we would not obtain saturation region parameters before we have obtained linear region parameters because the values of the linear region parameters would influence the saturation region fits; we should have to go back and reoptimize on the saturation region parameters after obtaining the linear region parameters. Finally, never use optimization to obtain a parameter value when the parameter can be measured directly. For example, the MOS oxide thickness, TOX, is a model parameter, but we would never use optimization to find it. Always measure its value directly on a large oxide capacitor provided on the test chip. The recommended procedure for proper device characterization follows:

1. Have all the appropriate structures necessary on your test chip. Without this, the job cannot be performed properly.
2. Always measure whatever parameters are directly measurable. Never use optimization for these.
3. Fit the subset of parameters to corresponding subsets of data, and do so in physically meaningful ways.
4. Fit the parameters in the proper order so that those obtained later do not affect those obtained previously. If this is not possible, iteration may be necessary.

Naturally, a good strategy cannot be mounted if one is not intimately familiar with the model used. There is no substitute for learning as much about the model as possible. Without this knowledge, one must rely on strategies provided by software vendors, and these vary widely in quality.

Finally, no one can provide a completely general strategy applicable to all models and all process technologies. At some point the strategy must be tailored to suit the available technology and circuit performance requirements. This not only requires familiarity with the available device models, but also information from the circuit designers and process architects.

8.2.2 MOS DC Models

8.2.2.1 Available MOS Models

A number of MOS models have been provided over time with the original circuit simulation program, SPICE. In addition, some commercially available circuit simulation programs have introduced their own proprietary models, most notably HSPICE.* This section concentrates on the standard MOS models

* HSPICE is a commercially available, SPICE-like circuit simulation from Meta Software, Campbell, CA.

provided by UC Berkeley's SPICE, not only because they have become the standard models used by all circuit simulation programs, but also because the proprietary models provided by commercial vendors are not well documented and no source code is available for these models to investigate them thoroughly.

MOS levels 1, 2, and 3. Originally, SPICE came with three MOS models known as level 1, level 2, and level 3. The level 1 MOS model is a very crude first-order model that is rarely used. The level 2 and level 3 MOS models are extensions of the level 1 model and have been used extensively in the past and present [11]. These two models contain about 15 DC parameters each and are usually considered useful for digital circuit simulation down to 1 μm channel length technologies. They can fit the drain current for wide transistors of varying length with reasonable accuracy (about 5% RMS error), but have very little advanced fitting capability for analog application. They have only one parameter for fitting the subthreshold region, and no parameters for fitting the derivative of drain current with respect to drain voltage, G_{ds} (usually considered critical for analog applications). They also have no ability to vary the mobility degradation with back-bias, so the fits to I_{ds} in the saturation region at back-bias are not very good. Finally, these models do not interpolate well over device geometry, e.g., if a fit is made to a wide-long device and a wide-short device, and then one observes how the models track for lengths between these two extremes, they usually do not perform well. For narrow devices, they can be quite poor as well. Level 3 has very little practical advantage over level 2, although the level 2 model is proclaimed to be more physically based, whereas the level 3 model is called semiempirical. If only one can be used, perhaps levels 3 is slightly better because it runs somewhat faster and does not have quite such an annoying kink in the transition region from linear to saturation as does level 2.

***Berkeley short-channel IGFET model* (*BSIM*).** To overcome the many shortcomings of level 2 and level 3, the BSIM and BSIM2 models were introduced. The most fundamental difference between these and the level 2 and 3 models is that BSIM and BSIM2 use a different approach to incorporating the geometry dependence [3,6]. In levels 2 and 3, the geometry dependence is built directly into the model equations. In BSIM and BSIM2, each parameter (except for a very few) is written as a sum of three terms:

$$\text{Parameter} = \text{Par}_0 + \frac{\text{Par}_L}{L_{\text{eff}}} + \frac{\text{Par}_W}{W_{\text{eff}}} \tag{8.37}$$

where

Par_0 is the zero-order term
Par_L accounts for the length dependence of the parameter
Par_W accounts for the width dependence
L_{eff} and W_{eff} are the effective channel width and length, respectively

This approach has a large influence on the device characterization strategy, as discussed later. Because of this tripling of the number of parameters and for other reasons as well, the BSIM model has about 54 DC parameters and the BSIM2 model has over 100.

The original goal of the BSIM model was to fit better than the level 2 and 3 models for submicron channel lengths, over a wider range of geometries, in the subthreshold region, and for nonzero back-bias. Without question, BSIM can fit individual devices better than level 2 and level 3. It also fits the subthreshold region better and it fits better for nonzero back-biases. However, its greatest shortcoming is its inability to fit over a large geometry variation. This occurs because Equation 8.37 is a truncated Taylor series in $1/L_{\text{eff}}$ and $1/W_{\text{eff}}$ terms, and in order to fit better over varying geometries, higher power terms in $1/L_{\text{eff}}$ and $1/W_{\text{eff}}$ are needed. In addition, no provision was put into the BSIM model for fitting G_{ds}, so its usefulness for analog applications is questionable. Many of the BSIM model parameters are unphysical, so it is very hard to understand the significance of these model parameters. This has profound implications for generating skew models (fast and slow models to represent the process corners) and for incorporating temperature dependence. Another flaw of the BSIM model is its wild

behavior for certain values of the model parameters. If model parameters are not specified for level 2 or 3, they will default to values that will at least force the model to behave well. For BSIM, not specifying certain model parameters, setting them to zero, or various combinations of values can cause the model to become very ill-behaved.

BSIM2. The BSIM2 model was developed to address the shortcomings of the BSIM model. This was basically an extension of the BSIM model, removing certain parameters that had very little effect, fixing fundamental problems such as currents varying the wrong way as a function of certain parameters, adding more unphysical fitting parameters, and adding parameters to allow fitting G_{ds}. BSIM2 does fit better than BSIM, but with more than twice as many parameters as BSIM, it should. However, it does not address the crucial problem of fitting large geometry variations. Its major strengths over BSIM are fitting the subthreshold region better, and fitting G_{ds} better. Most of the other shortcomings of BSIM are also present in BSIM2, and the large number of parameters in BSIM2 makes it a real chore to use in device characterization.

BSIM3. Realizing the shortcomings of BSIM2, UC Berkeley recently introduced the BSIM3 model. This is an unfortunate choice of name because it implies BSIM3 is related to BSIM and BSIM2. In reality, BSIM3 is an entirely new model that in some sense is related more to levels 2 and 3 than BSIM or BSIM2. The BSIM3 model abandons the length and width dependence approach of BSIM and BSIM2, preferring to go back to incorporating the geometry dependence directly into the model equations, as do levels 2 and 3. In addition, BSIM3 is a more physically based model, with about 30 fitting parameters (the model has many more parameters, but the majority of these can be left untouched for fitting), making it more manageable, and it has abundant parameters for fitting G_{ds}, making it a strong candidate for analog applications.

It is an evolving model, so perhaps it is unfair to criticize it at this early stage. Its greatest shortcoming is, again, the inability to fit well over a wide range of geometries. It is hoped that future modifications will address this problem. In all fairness, however, it is a large order to ask a model to be physically based, have not too many parameters, be well behaved for all default values of the parameters, fit well over temperature, fit G_{ds}, fit over a wide range of geometries, and still fit individual geometries as well as a model with over 100 parameters, such as BSIM2. Some of these features were compromised in developing BSIM3.

Proprietary models. A number of other models are available from commercial circuit simulator vendors, the literature, etc. Some circuit simulators also offer the ability to add a researcher's own models. In general, we caution against using proprietary models, especially those which are supplied without source code and complete documentation. Without an intimate knowledge of the model equations, it is very difficult to develop a good device characterization strategy. Also, incorporating such models into device characterization software is almost impossible. To circumvent this problem, many characterization programs have the ability to call the entire circuit simulator as a subroutine in order to exercise the proprietary model subroutines. This can slow program execution by a factor of 20 or more, seriously impacting the time required to characterize a technology. Also, if proprietary models are used without source code, the circuit simulator results can never be checked against another circuit simulator. Therefore, we want to stress the importance of using standard models. If these do not meet the individual requirements, the next best approach is to incorporate a proprietary model whose source code one has access to. This requires being able to add the individual model not only to circuit simulators, but also to device characterization programs; it can become a very large task.

8.2.2.2 MOS Level 3 Extraction Strategy in Detail

The strategy discussed here is one that we consider to be a good one, in the spirit of our earlier comments. Note, however, that this is not the only possible strategy for the level 3 model. The idea here is to illustrate basic concepts so that this strategy can be refined to meet particular individual requirements.

In order to do a DC characterization, the minimum requirement is one each of the wide-long, wide-short, and narrow-long devices. We list the steps of the procedure and then discuss them in more detail.

Step 1. Fit the wide-long device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VT0 (threshold voltage), U0 (mobility), and THETA (mobility degradation with V_{gs}).

Step 2. Fit the wide-short device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VT0, LD (length encroachment), and THETA. When finished with this step, replace VT0 and THETA with the values from step 1, but keep the value of LD.

Step 3. Fit the narrow-long device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VT0, DW (width encroachment), and THETA. When finished with this step, replace VT0 and THETA with the values from step 1, but keep the value of DW.

Step 4. Fit the wide-short device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters RS and RD (source and drain series resistance).

Step 5. Fit the wide-long device in the linear region at all back-biases, at V_{gs} values above the subthreshold region, with parameter NSUB (channel doping affects long channel variation of threshold voltage back-bias).

Step 6. Fit the wide-short device in the linear region at all back-biases, at V_{gs} values above the subthreshold region, with parameter XJ (erroneously called the junction depth; affects short-channel variation of threshold voltage with back-bias).

Step 7. Fit the narrow-long device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameter DELTA (narrow channel correction to threshold voltage).

Step 8. Fit the wide-short device in the saturation region at zero back-bias (or all back-biases) with parameters VMAX (velocity saturation), KAPPA (saturation region slope fitting parameter), and ETA (V_{ds} dependence of threshold voltage).

Step 9. Fit the wide-short device in the subthreshold region at whatever back-bias and drain voltage is appropriate (usually zero back-bias and low V_{ds}) with parameter NFS (subthreshold slope fitting parameter). One may need to fit with VT0 also and then VT0 is replaced after this step with the value of VT0 obtained from step 1.

This completes the DC characterization steps for the MOS level 3 model. One would then go on to do the junction and overlap capacitance terms (discussed later). Note that this model has no parameters for fitting over temperature, although temperature dependence is built into the model that the user cannot control.

In Step 1, VT0, U0, and THETA are defined in the model for a wide-long device at zero back-bias. They are zero-order fundamental parameters without any short or narrow channel corrections. We therefore fit them to a wide-long device. It is absolutely necessary that such a device be on the test chip. Without it, one cannot obtain these parameters properly. The subthreshold region must be avoided also because these parameters do not control the model behavior in subthreshold.

In Step 2, we use LD to fit the slope of the linear region curve, holding U0 fixed from step 1. We also fit with VT0 and THETA because without them the fitting will not work. However, we want only the value of LD that fits the slope, so we throw away VT0 and THETA, replacing them with the values from step 1.

Step 3 is the same as step 2, except that we are getting the width encroachment instead of the length.

In Step 1, the value of THETA that fits the high V_{gs} portion of the wide-long device linear region curve was found. Because the channel length of a long transistor is very large, the source and drain series resistances have almost no effect here, but for a short-channel device, the series resistance will also affect the high V_{gs} portion of the linear region curve. Therefore, in step 4 we fix THETA from step 1 and use RS and RD to fit the wide-short device in the linear region, high V_{gs} portion of the curve.

In Step 5, we fit with NSUB to get the variation of threshold voltage with back-bias. We will get better results if we restrict ourselves to lower values of V_{gs} (but still above subthreshold) because no mobility

degradation adjustment exists with back-bias, and therefore the fit may not be very good at higher V_{gs} values for the nonzero back bias curves.

Step 6 is just like step 5, except we are fitting the short-channel device. Some people think that the value of XJ should be the true junction depth. This is not true. The parameter XJ is loosely related to the junction depth, but XJ is really the short-channel correction to NSUB. Do not be surprised if XJ is not equal to the true junction depth.

Step 7 uses DELTA to make the narrow channel correction to the threshold voltage. This step is quite straightforward.

Step 8 is the only step that fits in the saturation region. The use of parameters VMAX and KAPPA is obvious, but one may question using ETA to fit in the saturation region. The parameter ETA adjusts the threshold voltage with respect to V_{ds}, and as such one could argue that ETA should be used to fit measurements of I_{ds} sweeping V_{gs} and stepping V_{ds} to high values. In doing so, one will corrupt the fit in the saturation region, and usually we want to fit the saturation region better at the expense of the linear region.

Step 9 uses NFS to fit the slope of the $\log(I_{ds})$ vs. V_{gs} curve. Often, the value of VT0 obtained from step 1 will prevent one from obtaining a good fit in the subthreshold region. If this happens, try fitting with VT0 and NFS, but replacing the final value of VT0 with that from step 1 at the end, keeping only NFS from this final step.

The preceding steps illustrate the concepts of fitting relevant subsets of parameters to relevant subsets of data to obtain physical values of the parameters, as well as fitting parameters in the proper order so that those obtained in the later steps will affect those obtained in earlier steps minimally. Please refer to Figures 8.19 and 8.20 for how the resulting fits typically appear (all graphs showing levels fits are provided by the device modeling software package Aurora, from Technology Modeling Associates, Inc., Palo Alto, CA).

An experienced person may notice that we have neglected some parameters. For example, we did not use parameters KP and GAMMA. This means KP will be calculated from U0, and GAMMA will be calculated from NSUB. In a sense U0 and NSUB are more fundamental parameters than KP and GAMMA. For example, KP depends on U0 and TOX; GAMMA depends on NSUB and TOX. If one is trying to obtain skew models, it is much more advantageous to analyze statistical distributions of

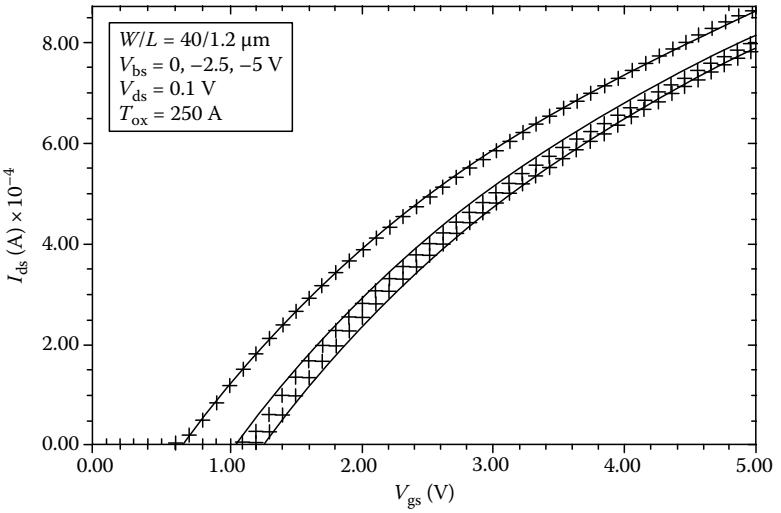

FIGURE 8.19 Typical MOS level 3 linear region measured and simulated plots at various V_{bs} values for a wide-short device.

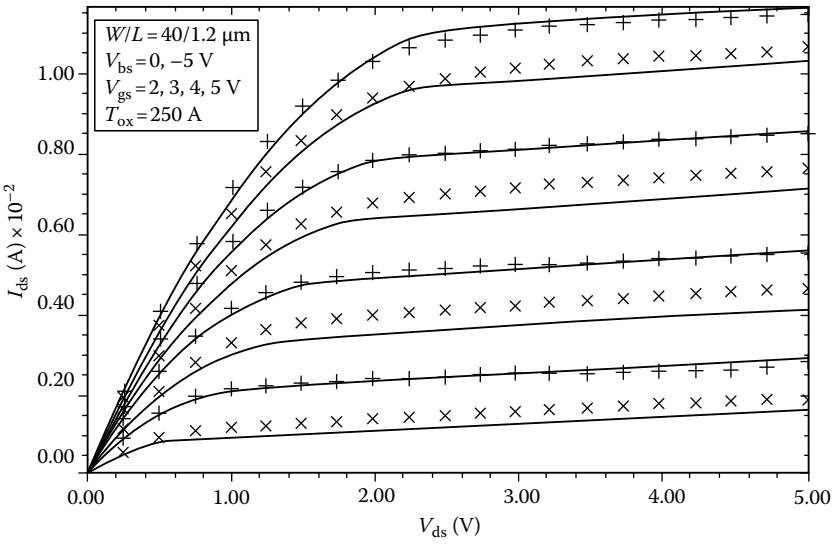

FIGURE 8.20 Typical MOS level 3 saturation region measured and simulated plots at various V_{gs} and V_{bs} values for a wide-short device.

parameters that depend on a single effect than those that depend on multiple effects. KP will depend on mobility and oxide thickness; U0 is therefore a more fundamental parameter. We also did not obtain parameter PHI, so it will be calculated from NSUB. The level 3 model is very insensitive to PHI, so using it for curve fitting is pointless. This illustrates the importance of being very familiar with the model equations. The kind of judgments described here cannot be made without such knowledge.

Test chip warnings. The following hints will greatly assist in properly performing device characterization:

1. Include a wide-long device; without this, the results will not be physically correct.
2. All MOS transistors with the same width should be drawn with their sources and drains identical. No difference should be seen in the number of source/drain contacts, contact spacing, source/drain contact overlap, poly gate to contact spacing, etc. In Figure 8.21, *c* is the contact size, *cs* is the contact space, *cov* is the contact overlap of diffusion, and *c2p* is the contact to poly spacing. All these dimensions should be identical for devices of different *L* but identical *W*. If not, extracting the series resistance will become more difficult.

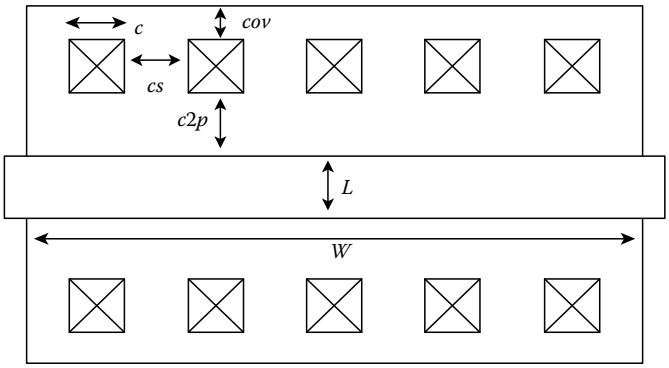

FIGURE 8.21 Mask layers showing dimensions that should be identical for all MOS devices of the same width.

3. Draw devices in pairs. That is, if the wide-long device is $W/L = 20/20$, make the wide-short device the same width as the wide-long device; e.g., make the short device 20/1, not 19/1. If the narrow-long device is 2/20, make the narrow-short device of the same width; i.e., make it 2/1, not 3/1, and similarly for the lengths. (Make the wide-short and the narrow-short devices have the same length.)
4. Draw structures for measuring the junction capacitances and overlap capacitances. These are discussed later in Section 8.2.5.

8.2.3 BSIM Extraction Strategy in Detail

All MOS model strategies have basic features in common; namely, fit the linear region at zero back-bias to get the basic zero-order parameters, fit the linear region at nonzero back-bias, fit the saturation region at zero back-bias, fit the saturation region at nonzero back-bias, and then fit the subthreshold region. It is possible to extend the type of strategy we covered for level 3 to the BSIM model, but that is not the way BSIM was intended to be used.

The triplet sets of parameters for incorporating geometry dependence into the BSIM model, Equation 8.37, allow an alternate strategy. We obtain sets of parameters without geometry dependence by fitting to individual devices without using the Par_L and Par_W terms. We do this for each device size individually. This produces sets of parameters relevant to each individual device. So, for device number 1 of width $W(1)$ and length $L(1)$ we would have a value for the parameter VFB which we will call VFB(1); for device number n of width $W(n)$ and length $L(n)$ we will have VFB(n). To get the Par_0, Par_L and Par_W terms, we fit to the parameters themselves, rather than the measured data. That is, to get VFB_0, VFB_L, and VFB_W, we fit to the "data points" VFB(1),...,VFB(n) with parameters VFB_0, VFB_L, and VFB_W using Equation 8.37, where L_{eff} and W_{eff} are different for each index, 1 through n.

Note that as L and W become very large, the parameters must approach Par_0. This suggests that we use the parameter values for the wide-long device as the Par_0 terms and only fit the other geometry sizes to get the Par_W and Par_L terms. For example, if we have obtained VFB(1) for our first device which is our wide-long device, we would set $\text{VFB}_0 = \text{VFB}(1)$, and then fit to VFB(2),...,VFB(n) with parameters VFB_L and VFB_W, and similarly for all the other triplets of parameters. In order to use a general least-squares optimization program in this way the software must be capable of specifying parameters as targets, as well as measured data points.

We now list a basic strategy for the BSIM model:

Step 1. Fit the wide-long device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VFB (flatband voltage), MUZ (mobility), and U0 (mobility degradation), with DL (length encroachment) and DW (width encroachment) set to zero.

Step 2. Fit the wide-short device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VFB, U0, and DL.

Step 3. Fit the narrow-long device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VFB, U0, and DW.

Step 4. Refit the wide-long device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VFB, MUZ, and U0, now that DL and DW are known.

Step 5. Fit the wide-short device in the linear region at zero back-bias, at V_{gs} values above the subthreshold region, with parameters VFB, RS, and RD. When finished, replace the value of VFB with the value found in step 4.

Step 6. Fit the wide-long device in the linear region at all back-biases, at V_{gs} values above the subthreshold region, with parameters K1 (first-order body effect), K2 (second-order body effect), U0, and X2U0 (V_{bs} dependence of U0).

Step 7. Fit the wide-long device in the saturation region at zero back-bias with parameters U0, ETA (V_{ds} dependence of threshold voltage), MUS (mobility in saturation), U1 (V_{ds} dependence of mobility), and X3MS (V_{ds} dependence cf MUS).

Step 8. Fit the wide-long device in the saturation region at all back-biases with parameter X2MS (V_{bs} dependence of MUS).

Step 9. Fit the wide-long device in the subthreshold region at zero back-bias and low V_{ds} value with parameter N0; then fit the subthreshold region nonzero back-bias low V_{ds} data with parameter NB; and finally fit the subthreshold region data at higher V_{ds} values with parameter ND. Or, fit all the subthreshold data simultaneously with parameters N0, NB, and ND.

Repeat steps 6 through 10 for all the other geometries, with the result of sets of geometry-independent parameters for each different size device. Then follow the procedure described previously for obtaining the geometry-dependent terms Par_0, Par_L, and Par_W.

In the preceding strategy, we have omitted various parameters either because they have minimal effect or because they have the wrong effect and were modified in the BSIM2 model. Because of the higher complexity of the BSIM model over the level 3 model, many more strategies are possible than the one just listed. One may be able to find variations of the above strategy that suit the individual technology better. Whatever modifications are made, the general spirit of the above strategy probably will remain.

Some prefer to use a more global approach with BSIM, fitting to measured data with Par_L and Par_W terms directly. Although this is certainly possible, it is definitely not a recommended approach. It represents the worst form of blind curve fitting, with no regard for physical correctness or understanding. The BSIM model was originally developed with the idea of obtaining the model parameters via extraction as opposed to optimization. In fact, UC Berkeley provides software for obtaining BSIM parameters using extraction algorithms, with no optimization at all. As stated previously, this has the advantage of being relatively fast and easy. Unfortunately, it does not always work. One of the major drawbacks of the BSIM model is that certain values of the parameters can cause the model to produce negative values of G_{ds} in saturation. This is highly undesirable, not only from a modeling standpoint, but also because of the convergence problems it can cause in circuit simulators. If an extraction strategy is used that does not guarantee nonnegative G_{ds}, very little can be done to fix the problem when G_{ds} becomes negative. Of course, the extraction algorithms can be modified, but this is difficult and time consuming. With optimization strategies, one can weight the fitting for G_{ds} more heavily and thus force the model to produce nonnegative G_{ds}. We, therefore, do not favor extraction strategies for BSIM, or anything else. As with most things in life, minimal effort provides minimal rewards.

8.2.3.1 BSIM2 Extraction Strategy

We do not cover the BSIM2 strategy in complete detail because it is very similar to the BSIM strategy, except more parameters are involved. The major difference in the two models is the inclusion of extra terms in BSIM2 for fitting G_{ds} (refer to Figure 8.22, which shows how badly BSIM typically fits $1/G_{ds}$ vs. V_{ds}). Basically, the BSIM2 strategy follows the BSIM strategy for the extraction of parameters not related to G_{ds}. Once these have been obtained, the last part of the strategy includes steps for fitting to G_{ds} with parameters that account for channel length modulation (CLM) and hot electron effects. The way this proceeds in BSIM2 is to fit I_{ds} first, and then parameters MU2, MU3, and MU4 are used to fit to $1/G_{ds}$ vs. V_{ds} curves for families of V_{ds} and V_{bs}. This can be a very time-consuming and frustrating experience, because fitting to $1/G_{ds}$ is quite difficult. Also, the equations describing how G_{ds} is modeled with MU2, MU3, and MU4 are very unphysical and the interplay between the parameters makes fitting awkward. The reader is referred to Figure 8.23, which shows how BSIM2 typically fits $1/G_{ds}$ vs. V_{ds}. BSIM2 is certainly better than BSIM, but it has its own problems fitting $1/G_{ds}$.

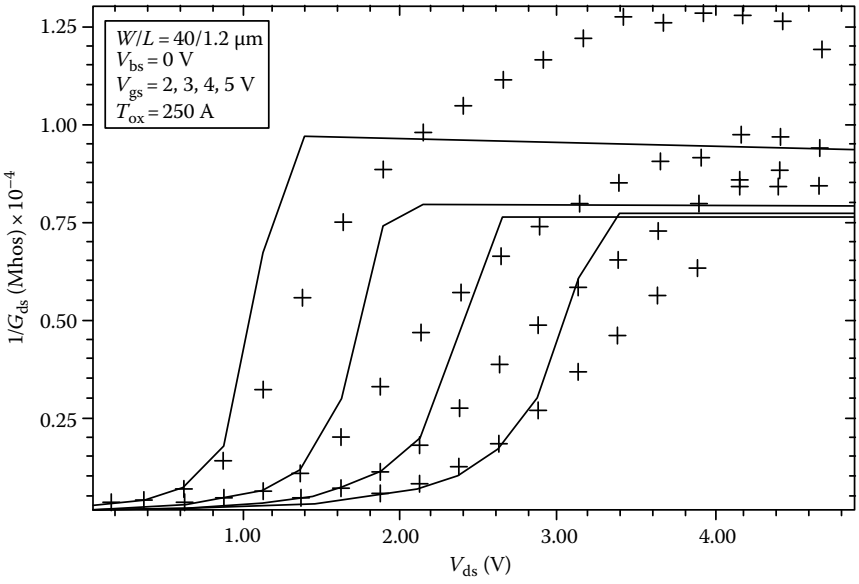

FIGURE 8.22 Typical BSIM $1/G_{ds}$ vs. V_{ds} measured and simulated plots at various V_{gs} values for a wide-short device.

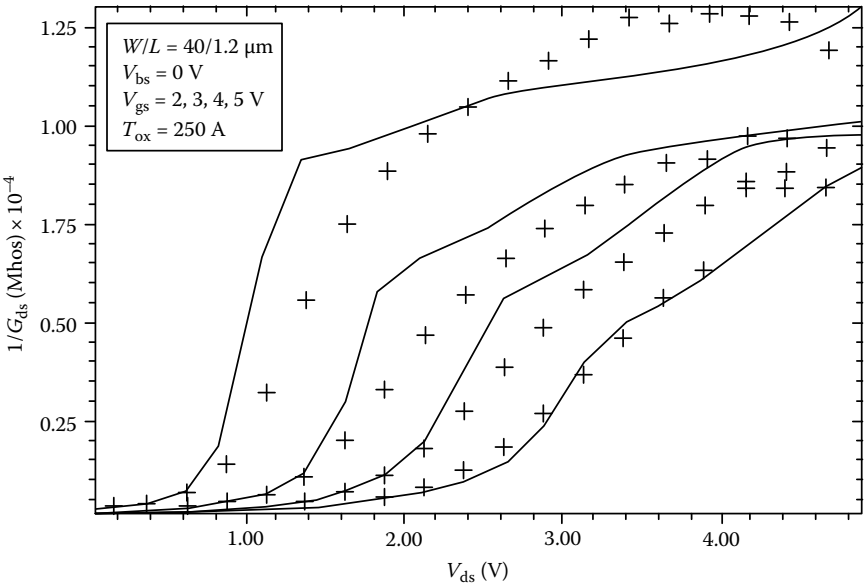

FIGURE 8.23 Typical BSIM2 $1/G_{ds}$ vs. V_{ds} measured and simulated plots at various V_{gs} values for a wide-short device.

8.2.3.2 BSIM3 Comments

The BSIM3 model is very new and will undoubtedly change in the future [5]. We will not list a BSIM3 strategy here, but focus instead on the features of the model that make it appealing for analog modeling.

BSIM3 has terms for fitting G_{ds} that relate to CLM, drain-induced barrier lowering (DIBL), and hot electron effects. They are incorporated completely differently from the G_{ds} fitting parameters of BSIM2.

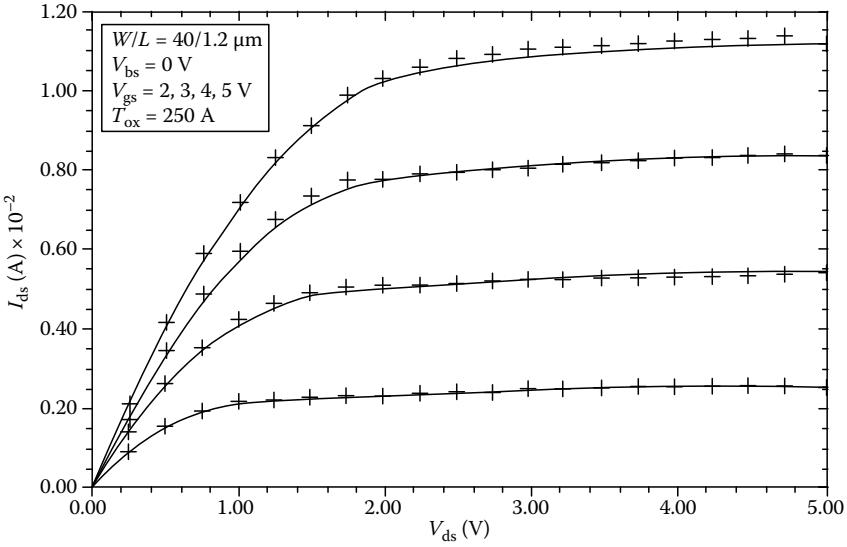

FIGURE 8.24 Typical BSIM3 saturation region measured and simulated plots at various V_{gs} values for a wide-short device.

In BSIM3, these parameters enter through a generalized Early voltage relation, with the drain current in saturation written as

$$I_{ds} = I_{d\,sat}\left[1 + \frac{(V_{ds} - V_{d\,sat})}{V_A}\right] \tag{8.38}$$

where V* is a generalized early voltage made up of three terms as

$$\frac{1}{V_A} = \frac{1}{V_{ACLM}} + \frac{1}{V_{ADIBL}} + \frac{1}{V_{AHCE}} \tag{8.39}$$

with the terms in Equation 8.39 representing generalized early voltages for CLM, DIBL, and hot carrier effects (HCE). This formulation is more physically appealing than the one used in BSIM2, making it easier to fit $1/G_{ds}$ vs. V_{ds}. curves with BSIM2. Figures 8.24 and 8.25 show how BSIM3 typically fits I_{ds} vs. V_{ds} and $1/G_{ds}$ vs. V_{ds}.

Most of the model parameters for BSIM3 have physical significance so they are obtained in the spirit of the parameters for the level 2 and 3 models. The incorporation of temperature dependence is also easier in BSIM3 because the parameters are more physical. All this, coupled with the fact that about 30 parameters exists for BSIM3 as compared to over 100 for BSIM2, makes BSIM3 a logical choice for analog design. However, BSIM3 is evolving, and shortcomings to the model may still exist that may be corrected in later revisions.

8.2.3.3 Which MOS Model to Use?

Many MOS models are available in circuit simulators, and the novice is bewildered as to which model is appropriate. No single answer exists, but some questions must be asked before making a choice:

1. What kind of technology am I characterizing?
2. How accurate a model do I need?

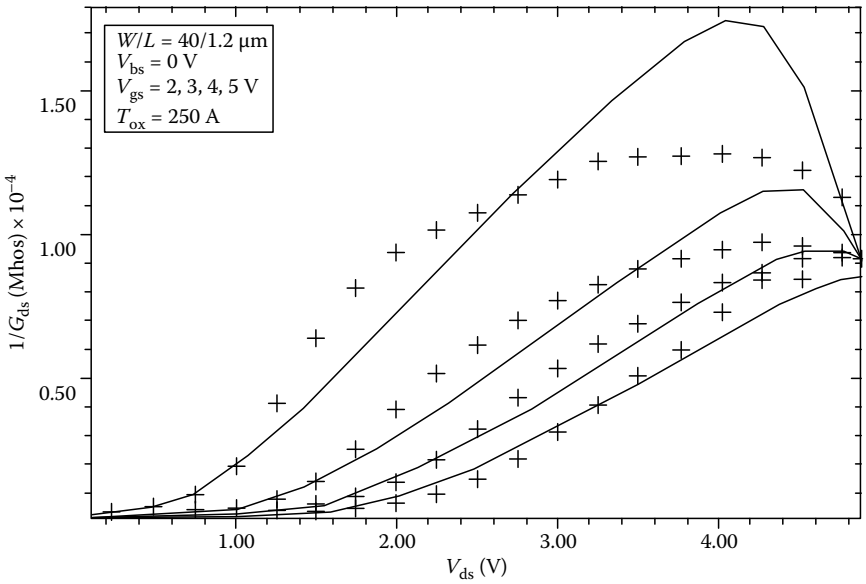

FIGURE 8.25 Typical BSIM3 $1/G_{ds}$ vs. V_{ds} measured and simulated plots at various V_{gs} values for a wide-short device.

3. Do I want to understand the technology?
4. How important are the skew model files (fast and slow parameter files)?
5. How experienced am I? Do I have the expertise to handle a more complicated model?
6. How much time can I spend doing device characterization?
7. Do I need to use this model in more than one circuit simulator?
8. Is the subthreshold region important?
9. Is fitting G_{ds} important?

Let us approach each question with regard to the models available. If the technology is not submicron, perhaps a simpler model such as level 3 is capable of doing everything needed. If the technology is deep submicron, then use a more complicated model such as BSIM, BSIM2, or BSIM3. If high accuracy is required, then the best choice is BSIM3, mainly because it is more physical than all the other models and is capable of fitting better.

For a good physical understanding of the process being characterized, BSIM and BSIM2 are not good choices. These are the least physically based of all the models. The level 2 and 3 models have good physical interpretation for most of the parameters, although they are relatively simple models. BSIM3 is also more physically based, with many more parameters than level 2 or 3, so it is probably the best choice.

If meaningful skew models need to be generated, then BSIM and BSIM2 are very difficult to use, again, because of their unphysical parameter sets. Usually, the simplest physically based model is the best for skew model generation. A more complicated physically based model such as BSIM3 may also be difficult to use for skew model generation.

If the user is inexperienced, none of the BSIM models should be used until the user's expertise improves. Our device is to practice using simpler models before tackling the harder ones.

If time is critical, the simpler models will definitely be much faster for use in characterization. The more complicated models require more measurements over wider ranges of voltages as well as wider ranges of geometries. This, coupled with the larger number of parameters, means they will take some time with which to work. The BSIM2 model will take longer than all the rest, especially if the G_{ds} fitting parameters are to be used.

The characterization results may need to be used in more than one circuit simulator. For example, if a foundry must supply models to various customers, they may be using different circuit simulators. In this case, proprietary models applicable to a single circuit simulator should not be used. Also, circuit designers may want to check the circuit simulation results on more than one circuit simulator. It is better to use standard Berkeley models (level 2, level 3, BSIM, BSIM2, and BSIM3) in such cases.

If the subthreshold region is important, then level 2 or level 3 cannot be used, and probably not even BSIM. BSIM2 or BSIM3 must be used instead. These two models have enough parameters for fitting the subthreshold region.

If fitting G_{ds} is important, BSIM2 and BSIM3 are, again, the only choices. None of the other models have enough parameters for fitting G_{ds}.

Finally, if a very unusual technology is to be characterized, none of the standard models may be appropriate. In this case commercially available specialized models or the user's own models must be used. This will be a large task, so the goals must justify the effort.

8.2.4 Bipolar DC Model

The standard bipolar model used by all circuit simulators is the Gummel–Poon model, often called the BJT (bipolar junction transistor) model [4]. Most circuit simulator vendors have added various extra parameters to this model, which we will not discuss, but they all have the basic parameters introduced by the original UC Berkeley SPICE model.

We now list a basic strategy for the BJT model:

Step 1. Fit a Gummel plot (log(IC) and log(IB) vs. VBE) for the IC curve in the straight line portion of the curve (low to middle VBE values) with parameters IS and NF. Note that it is best if the Gummel plots are done with VCB = 0.

Step 2. Fit plots of IC vs. VCE, stepping IB, in the high VCE region of the curves with parameters VAF, BF, and IKF.

Step 3. Fit plots of IC vs. VCE, stepping IB, in the low VCE region of the curves with parameter RC.

Step 4. Fit a Gummel plot for the IB curve for VBE values in the mid- to high-range with parameter BF.

Step 5. Fit a Gummel plot for the IB curve for low VBE values with parameters ISE and NE.

Step 6. Try to obtain parameter RE by direct measurement or by simulation using a device simulator such as PISCES. It is also best if RB can be obtained as a function of current by measurement on special structures, or by simulation. One may also obtain RB by *S*-parameter measurements (discussed later). Failing this, RB may be obtained by fitting to the Gummel plot for the IB curve for VBE values in the mid- to high-range with parameters RB, RBM, and IRB. This is a difficult step to perform with an optimization program.

Step 7. Fit a Gummel plot for the IC curve for high VBE values with parameter IKF.

Step 8. At this point, all the DC parameters have been obtained for the device in the forward direction. Next, obtain the reverse direction data by interchanging the emitter and collector to get the reverse Gummel and IC vs. VCE data.

Repeat Step 2 on the reverse data to get VAR, BR, IKR.
Repeat Step 4 on the reverse data to get BR.
Repeat Step 5 on the reverse data to get ISC, NC.
Repeat Step 7 on the reverse data to get IKR.

Fitting the reverse direction parameters is very frustrating because the BJT model is very poor in the reverse direction. After seeing how poor the fits can be, one may decide to obtain only a few of the reverse parameters.

8.2.5 MOS and Bipolar Capacitance Models

8.2.5.1 MOS Junction Capacitance Model

The MOS junction capacitance model accounts for bottom wall (area component) and sidewall (periphery component) effects. The total junction capacitance is written as a sum of the two terms

$$\mathrm{CJ(total)} = \frac{A(\mathrm{CJ})}{1 + [(VR/\mathrm{PB})]^{\mathrm{MJ}}} + \frac{P(\mathrm{CJSW})}{1 + [(VR/\mathrm{PB})]^{\mathrm{MJSW}}} \tag{8.40}$$

where

A is the area
P is the periphery of the junction diode capacitor
VR is the reverse bias (a positive number) across the device

The parameters of this model are CJ, CJSW, PB, MJ, and MJSW.

It is very easy to find parameter values for this model. Typically, one designs special large junction diodes on the test chip, large enough so that the capacitances being measured are many tens of picofarads. This means the diodes have typical dimensions of hundreds of microns. Two junction diodes are needed—one with a large area:periphery ratio, and another with a small area:periphery ratio. This is usually done by drawing a rectangular device for the large area:periphery ratio, and a multifingered device for the small area:periphery ratio (see Figure 8.26).

The strategy for this model consists of a single step, fitting to all the data simultaneously with all the parameters. Sometimes it is helpful to fix PB to some nominal value such as 0.7 or 0.8, rather than optimize on PB, because the model is not very sensitive to PB.

8.2.5.2 BJT Junction Capacitance Model

The BJT model is identical to the MOS, except it uses only the bottom wall (area term), not the sidewall. Three sets of BJT junction diodes need to be characterized: emitter–base, collector–base, and collector–substrate. Each of these has three model parameters to fit. For example, for the emitter–base junction diode, the parameters are CJE, VJE, and MJE (CJE corresponds to CJ, VJE to PB, and MJE to MJ of the MOS model). Similarly, for the collector–base junction diode, we have CJC, VJC, and MJC. Finally, for the collector–substrate junction diode, we have CJS, VJS, and MJS.

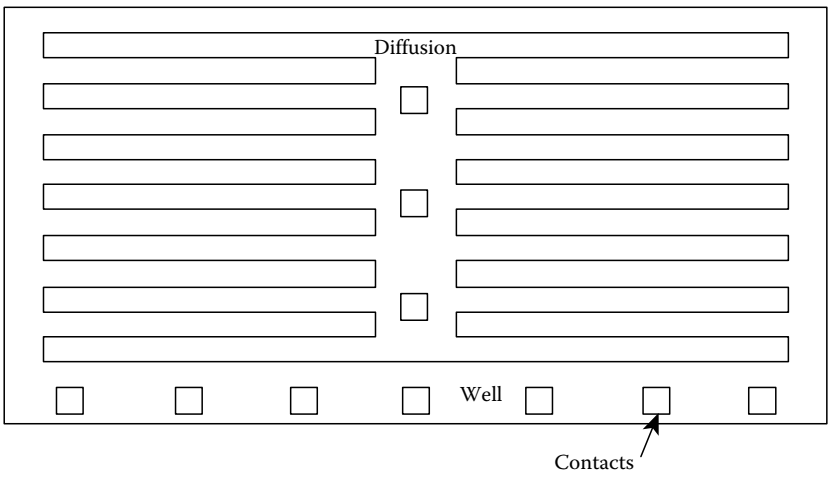

FIGURE 8.26 Mask layers showing the periphery multifingered junction diode structure.

These parameters are all fit in a single strategy step on the relevant data. Again, it is best if large test structures can be drawn rather than the values measured directly on transistor, because the transistor junction diodes have such small areas that the measurements are prone to accuracy problems.

8.2.5.3 MOS Overlap Capacitance Model

In addition to the junction capacitance model, the MOS models include terms for the overlap or Miller capacitance. This represents the capacitance associated with the poly gate overlap over the source and drain regions. As for the junction diodes, special test chip structures are necessary for obtaining the overlap capacitance terms CGS0, CGD0, and CGB0. These structures usually consist of large, multi-fingered devices that look just like the junction capacitance periphery diodes, except that where the junction diodes are diffusion over well structures, the overlap capacitors are poly over diffusion.

8.2.6 Bipolar High-Frequency Model

The SPICE BJT model has five parameters for describing the high-frequency behavior of bipolar devices. These are parameters TF, XTF, ITF, VTF, and PTF, all of which are associated with the base transit time, or equivalently, the cutoff frequency. Parameter TF is the forward transit time, XTF and ITF modify TF as a function of VBE (or IC), and VTF modifies TF as function of VBE (or IC), and VTF modifies TF as a function of VCB. Parameter PTF represents the excess phase at the cutoff frequency. The expression used by SPICE for the transit time is

$$\tau_f = \mathrm{TF}\left[1 + \mathrm{XTF}\left\{\frac{\mathrm{IF}}{\mathrm{IF} + \mathrm{ITF}}\right\}^2\right] e^{[\mathrm{VBC}/\{(1.44(\mathrm{VTF}))\}]} \tag{8.41}$$

where

$$\mathrm{IF} = \mathrm{IS}[e^{\{(q)(V_{\mathrm{be}})\}/\{(NF)(k)(T)\}} - 1] \tag{8.42}$$

SPICE uses the transit time to calculate the diffusion capacitance of the emitter–base junction in forward bias.

Obtaining the bipolar high frequency parameters is very complicated, time consuming, and difficult. It also requires very expensive measuring equipment, including a network analyzer for measuring *S*-parameters, and a quality high-frequency wafer prober with high-frequency probes. Having measured the *S*-parameters, after suitable data manipulation and optimization it is possible to find the high-frequency SPICE parameters.

It is beyond the scope of this book to cover high-frequency bipolar theory completely. We will, however, list the basic steps involved in obtaining the high frequency bipolar transit time parameters:

Step 1. Measure the *S*-parameters over an appropriate frequency range to go beyond the cutoff frequency, f_T. Do these measurements over a large range of IC values and stepping over families of VCB values as well. Be sure to include VCB = 0 in these data. Be sure that the network analyzer being used is well calibrated. These measurements can be done in either common emitter or common collector mode. Each has advantages and disadvantages.

Step 2. De-embed the *S*-parameter measurements by measurements dummy pad structures that duplicate the layout of the bipolar transistors, including pads and interconnect, but with no devices. The de-embedding procedure subtracts the effects of the pads and interconnects from the actual devices. This step is very important if reliable data are desired [10].

Step 3. Calculate the current gain, β from the *S*-parameter data. From plots of β vs. frequency, find the cutoff frequency, f_T. Also calculate parameter PTF directly from these data.

Step 4. Calculate τ_f from f_T by removing the effect of RE, RC, and the junction capacitances. This produces tables of τ_f vs. IC, or equivalently, τ_f vs. VBE, over families of VCB.

Step 5. Optimize on τ_f vs. VBE data over families of VCB with parameters TF, XTF, ITF, and VTF.

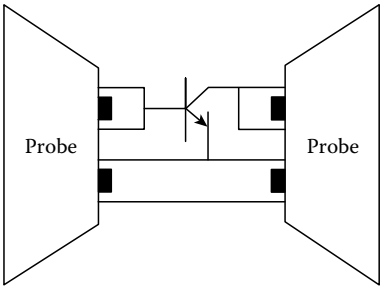

FIGURE 8.27 Typical bipolar transistor test chip layout for measuring *S*-parameters with high-frequency probes. This shows the common emitter configuration.

Note that many of the preceding steps are done automatically by some commercial device modeling programs.

It is very important to have well-designed and appropriate test structures for measuring *S*-parameters. The pad layout and spacing is very critical because of the special size and shape of the high-frequency probes (see Figure 8.27). The test chip structures must be layed out separately for common emitter and common collector modes if measurements are necessary for both these modes.

It is also possible to use the *S*-parameter measurements to obtain the base resistance as a function of collector current. From this information one can optimize to obtain parameters RB, RBM, and IRB. However, the base resistance obtained from *S*-parameters is not a true DC base resistance, and the model is expecting DC values of base resistance.

8.2.7 Miscellaneous Topics

8.2.7.1 Skew Parameter Files

This chapter discusses obtaining model parameters for a single wafer, usually one that has been chosen to represent a typical wafer for the technology being characterized. The parameter values obtained from this wafer correspond to a typical case. Circuit designers also want to simulate circuits with parameter values representing the extremes of process variation, the so-called fast and slow corners, or skew parameter files. These represent the best and worst case of the process variation over time.

Skew parameter values are obtained usually by tracking a few key parameters, measuring many wafers over a long period of time. The standard deviation of these key parameters is found and added to or subtracted from the typical parameter values to obtain the skew models. This method is extremely crude and will not normally produce a realistic skew model. It will almost always overestimate the process spread, because the various model parameters are not independent—they are correlated.

Obtaining realistic skew parameter values, taking into account all the subtle correlations between parameters, is more difficult. In fact, skew model generation is often more an art than a science. Many attempts have been made to utilize techniques from a branch of statistics called multivariate analysis [1]. In this approach, principal component or factor analysis is used to find parameters that are linear combinations of the original parameters. Only the first few of these new parameters will be kept; the others will be discarded because they have less significance. This new set will have fewer parameters than the original set and therefore will be more manageable in terms of finding their skews. The user sometimes must make many choices in the way the common factors are utilized, resulting in different users obtaining different results.

Unfortunately, a great deal of physical intuition is often required to use this approach effectively. To date, we have only seen it applied to the simpler MOS models such as level 3. It is not known if this is a viable approach for a much more complicated model such as BSIM2 [7].

8.2.7.2 Macro Modeling

Sometimes, a device is designed and manufactured that cannot be modeled by a single transistor model. In such cases, one may try to simulate the behavior of a single device by using many basic device elements together, representing the final device. For example, a single real bipolar device might be modeled using a combination of several ideal bipolar devices, diodes, resistors, and capacitors. This would be a macro model representing the real bipolar device.

Macro modeling usually uses least-squares optimization techniques. One chooses model parameter values to represent the ideal devices in the technology, and then optimizes on geometry size, capacitance size, resistance size, etc., to obtain the final macro model. This is similar to the optimization techniques used to find model parameters for a standard model, but in this case we are calling on an entire circuit simulator rather than a model subroutine to provide the output characteristics of our macro model.

Obviously, macro modeling can be very computation intensive. A complex macro model can take a very long time to optimize. Also, it may be impractical to use a macro model for every real device in the circuit. For example, if the circuit in question has 100,000 real transistors and each of these is being represented by a macro model with 10 components, the number of circuit nodes introduced by the macro model ($>10 \times 10{,}000$) might be prohibitive in terms of simulation time. Nevertheless, for critical components, macro modeling can provide tremendous insight.

8.2.7.3 Modeling in a TCAD Environment

Programs that do optimization are part of a larger set of software that is sometimes called TCAD (technology computer-aided design). Typically, TCAD encompasses software for process simulation (doping distributions), device simulation (electrical characteristics), device modeling, and circuit simulation. Other elements of TCAD can include lithography simulation, interconnect modeling (capacitance, resistance, and inductance), etc.

In the past, each of the software components of TCAD were used as stand-alone programs, with very little communication between the components. The trend now is to incorporate all these pieces into a complete environment that allows them to communicate with each other seamlessly, efficiently, and graphically, so that the user is not burdened with keeping track of file names, data, etc. In such a system, one can easily set up split lots and simulate from process steps up through circuit simulation. One will also be able to close the loop, feeding circuit simulation results back to the process steps and run optimization on an entire process to obtain optimal circuit performance characteristics (see Figure 8.28).

The future of device modeling will surely be pushed in this direction. Device modeling tools will be used not only separately, but within a total TCAD environment, intimately connected with process, device, interconnect, and circuit simulation tools.

9.1 Introduction

Analog circuit simulation usually means simulation of analog circuits or very detailed simulation of digital circuits. The most widely known and used circuit simulation program is SPICE (simulation program with integrated circuit emphasis) of which it is estimated that there are over 100,000 copies in use. SPICE was first written at the University of California at Berkeley in 1975, and was based on the combined work of many researchers over a number of years. Research in the area of circuit simulation continues at many universities and industrial sites. Commercial versions of SPICE or related programs are available on a wide variety of computing platforms, from small personal computers to large mainframes. A list of some commercial simulator vendors can be found in the Appendix. The focus of this chapter is the simulators and the theory behind them. Examples are also given to illustrate their use.

9.2 Purpose of Simulation

Computer-aided simulation is a powerful aid for the design or analysis of VLSI circuits. Here, the main emphasis will be on analog circuits; however, the same simulation techniques may be applied to digital circuits, which are composed of analog circuits. The main limitation will be the size of these circuits because the techniques presented here provide a very detailed analysis of the circuit in question and, therefore, would be too costly in terms of computer resources to analyze a large digital system. However, some of the techniques used to analyze digital systems (like iterated timing analysis or relaxation methods) are closely related to the methods used in SPICE.

It is possible to simulate almost any type of circuit SPICE. The programs have built-in elements for resistors, capacitors, inductors, dependent and independent voltage and current sources, diodes, MOSFETs, JFETs, BJTs, transmission lines, and transformers. Commercial versions have libraries of standard components, which have all necessary parameters prefitted to typical specifications. These libraries include items such as discrete transistors, op-amps, phase-locked loops, voltage regulators, logic integrated circuits, and saturating transformer cores. Versions are also available that allow the inclusion of digital models (mixed-mode simulation) or behavioral models that allow the easy modeling of mathematical equations and relations.

Computer-aided circuit simulation is now considered an essential step in the design of modern integrated circuits. Without simulation, the number of ''trial runs'' necessary to produce a working IC would greatly increase the cost of the IC and the critical time-to-market. Simulation provides other advantages, including

- The ability to measure ''inaccessible'' voltages and currents that are buried inside a tiny chip or inside a single transistor.
- No loading problems are associated with placing a voltmeter or oscilloscope in the middle of the circuit, measuring difficult one-shot waveforms or probing a microscopic die.
- Mathematically ideal elements are available. Creating an ideal voltage or current source is trivial with a simulator, but impossible in the laboratory. In addition, all component values are exact and no parasitic elements exist.
- It is easy to change the values of components or the configuration of the circuit.

Unfortunately, computer-aided simulation has it own set of problems, including

- Real circuits are distributed systems, not the ''lumped element models'' which are assumed by simulators. Real circuits, therefore, have resistive, capacitive, and inductive parasitic elements present in addition to the intended components. In high-speed circuits, these parasitic elements can be the dominant performance-limiting elements in the circuit, and they must be painstakingly modeled.
- Suitable predefined numerical models have not yet been developed for certain types of devices or electrical phenomena. The software user may be required, therefore, to create his or her own models out of other models that are available in the simulator. (An example is the solid-state thyristor, which may be created from an npn and pnp bipolar transistor.)
- The numerical methods used may place constraints on the form of the model equations used. In addition, convergence difficulties can arise, making the simulators difficult to use.
- There are small errors associated with the solution of the equations and other errors in fitting the nonlinear models to the transistors that make up the circuit.

9.3 Netlists

Before simulating, a circuit must be coded into a netlist. Figure 9.1 shows the circuit for a simple differential pair. Circuit nodes are formed wherever two or more elements meet. This particular circuit has seven nodes, which are numbered 0–6. The ground or datum node is traditionally numbered as zero. The circuit elements (or branches) connect the nodes.

The netlist provides a description of the topography of a circuit and is simply a list of the branches (or elements) that make up the circuit. Typically, the elements may be entered in any order and each has a unique name, a list of nodes, and either a value or model identifier. For the differential amplifier of Figure 9.1, the netlist is shown in Figure 9.2.

The first line gives the title of the circuit (and is required in many simulators). The next three lines define the three voltage sources. The letter V at the beginning tells SPICE that this is a voltage source element. The list of nodes (two in this case) is next followed by the value in volts. The syntax for the resistor is similar to that of the voltage source; the starting letter R in the names of the resistors tells SPICE that these

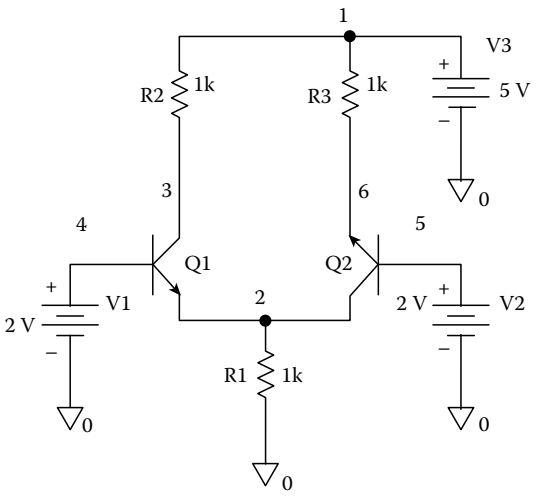

FIGURE 9.1 Circuit for differential pair.

are resistors. SPICE also understands that the abbreviation "k" after a value means 1000. For the two transistors Q1 and Q2, the starting letter Q indicates a bipolar transistor. Q1 and Q2 each have three nodes and in SPICE, the convention for their ordering is collector, base, and emitter. So, for Q1, the collector is connected to node 3, the base to node 4, and the emitter to node 2. The final entry "m2n2222" is a reference to the model for the bipolar transistor (note that both Q1 and Q2 reference the same model). The ".model" statement at the end of the listing defines this model. The model type is npn (for an npn bipolar junction transistor), and a list of "parameter = value" entries follow. These entries define the numerical values of constants in the mathematical models which are used for the

```

bipolar transistor. (Models will be discussed later in more detail.) Most commercial circuit simulation packages come with "schematic capture" software that allows the user to draw the circuit by placing and connecting the elements with the mouse.

9.4 Formulation of the Circuit Equations

In SPICE, the circuits are represented by a system of ordinary differential equations. These equations are then solved using several different numerical techniques. The equations are constructed using Kirchhoff's voltage and current laws (KVL and KCL). The first system of equations pertains to the currents flowing into each node. One equation is written for each node in the circuit (except for the ground node), so the following equation is really a system of N equations for the N nodes in the circuit. The subscript i denotes the node index.

$$0 = F_i(V) = G_i(V) + \frac{\partial Q_i(V)}{\partial t} + W_i(t) \tag{9.1}$$

where

V is an N-dimensional vector that represents the voltages at the nodes

Q is another vector which represents the electrical charge (in Coulombs) at each node

The term W represents any independent current sources that may be attached to the nodes and has units of amperes

The function $G(V)$ represents the currents that flow into the nodes as a result of the voltages V

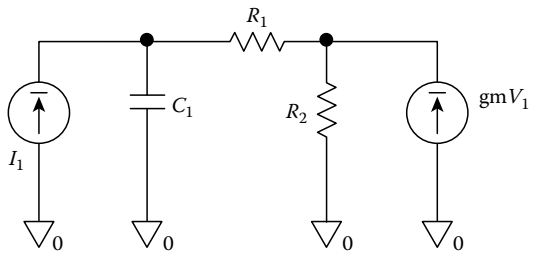

FIGURE 9.3 Example circuit for nodal analysis.

If the equations are formulated properly, a system of N equations in N unknown results.

For example, for the circuit of Figure 9.3 which has two nodes, we need to write two equations. At node 1:

$$0 = (V_1 - V_2)/R_1 + \frac{\mathrm{d}(C_1 V_1)}{\mathrm{d}t} + I_1 \qquad (9.2)$$

We can identify $G(V)$ as $(V_1 - V_2)/R$, the term $Q(V)$ is $C_1 V_1$ and $W(t)$ is simply I_1. Likewise at node 2:

$$0 = (V_2 - V_1)/R_1 + V_2/R_2 + \mathrm{gm}V_1 \qquad (9.3)$$

In this example, G and Q are simple linear terms; however, in general, they can be nonlinear functions of the voltage vector V.

9.5 Modified Nodal Analysis

Normal nodal analysis that uses only KCL cannot be used to represent ideal voltage sources or inductors. This is so because the branch current in these elements cannot be expressed as a function of the branch voltage. To resolve this problem, KVL is used to write a loop equation around each inductor or voltage source. Consider Figure 9.4 for an example of this procedure. The unknowns to be solved for are the voltage V_1 at node 1, V_2 the voltage at node 2, V_3 the voltage at node 3, the current flowing through voltage source V_1 which we shall call I_x, and the current flowing in the inductor L_1 which we shall call I_1 The system of equations is

$$\begin{aligned}
0 &= V_1/R_1 + I_x \\
0 &= V_2/R_2 - I_z + I_l \\
0 &= V_3/R_3 - I_l \\
0 &= V_1 - V_x + V_2 \\
0 &= V_2 + \frac{\mathrm{d}(L_1 I_1)}{\mathrm{d}t} - V_3
\end{aligned} \qquad (9.4)$$

The use of modified nodal analysis does have the disadvantage of requiring that an additional equation be included for each inductor or voltage source, but has the advantage that ideal voltage sources can be used.

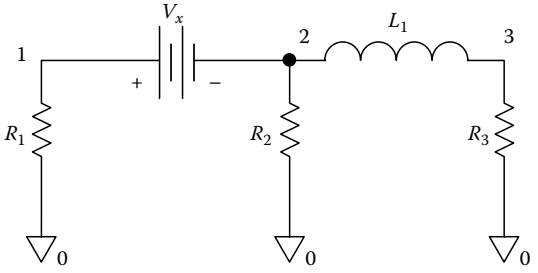

FIGURE 9.4 Circuit for modified nodal analysis.

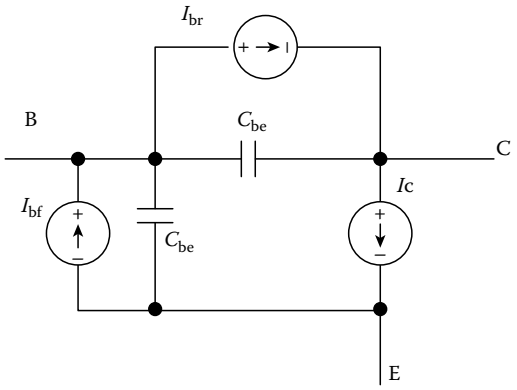

FIGURE 9.5 Ebers–Moll model for the bipolar transistor.

The total number of equations to be solved is therefore the number of nodes plus the number of voltages sources and inductors.

9.6 Active Device Models

VLSI circuits contain active devices like transistors or diodes, which act as amplifiers. These devices are normally described by a complicated set of nonlinear equations. We shall consider a simple model for the bipolar transistor—the Ebers–Moll model. This model is one of the first developed, and while it is too simple for practical application, it is useful for discussion.

A schematic of the Ebers–Moll model is shown in Figure 9.5. The model contains three nonlinear voltage-dependent current sources I_c, I_{bf}, and I_{br} and two nonlinear capacitances C_{be} and C_{bc}. The current flowing in the three current sources are given by the following equations:

$$I_c = I_s(\exp(V_{be}/V_t)) - \exp(V_{ce}/V_t) \tag{9.5}$$

$$I_{bf} = \frac{I_s}{B_f}(\exp(V_{be}/V_t) - 1) \tag{9.6}$$

$$I_{br} = \frac{I_s}{B_r}(\exp(V_{bc}/V_t) - 1) \tag{9.7}$$

The voltages V_{be} and V_{bc} are the voltages between base and emitter and the base and collector, respectively. I_s, B_f, and B_r are three user-defined parameters that govern the DC operation of the BJT. V_t is the "thermal voltage" or kT/q, which has the numerical value of approximately 0.26 V at room temperature. Observe that in the normal forward active mode, where $V_{be} > 0$ and $V_{ce} < 0$, I_{br} and the second term in I_c vanish and the current gain of the BJT, which is defined as I_c/I_b becomes numerically equal to B_f. Likewise, in the reverse mode where $V_{ce} > 0$ and $V_{be} < 0$, the reverse gain (I_e/I_b) is equal to B_r.

The two capacitances in Figure 9.5 contribute charge to the emitter, base, and collector, and this charge is given by the following equations:

$$Q_{be} = \tau_f I_s(\exp V_{be}/V_t - 1) + C_{je}\int_0^{V_{be}} (1 - V/V_{je})^{-m_e} \tag{9.8}$$

$$Q_{bc} = \tau_r I_s(\exp V_{bc}/V_t - 1) + C_{jc}\int_0^{V_{bc}} (1 - V/V_{jc})^{-m_c} \tag{9.9}$$

Q_{be} contributes positive charge to the base and negative charge to the emitter. Q_{bc} contributes positive charge to the base and negative charge to the collector. The first term in each charge expression is due to charge injected into the base from the emitter for Q_{be} and from the collector into the base for Q_{bc}. Observe that the exponential terms in the charge terms are identical to the term in I_c. This is so because the injected charge is proportional to the current flowing into the transistor. The terms τ_f and τ_r are the forward and reverse transit times, respectively, and correspond to the amount of time it takes the electrons (or holes) to cross the base. The second term in the charge expression (the term with the integral)

corresponds to the charge in the depletion region of the base–emitter junction for Q_{be} and in the base–collector junction for Q_{bc}. Recall that the depletion width in a pn junction is a function of the applied voltage. The terms V_{je} and V_{jc} are the "built-in" potentials with units of volts for the base–emitter and base–collector junctions. The terms m_c and m_e are the grading coefficients for the two junctions and are related to how rapidly the material changes from n-type to p-type across the junction.

This "simple" model has eleven constants I_s, B_f, B_r, C_{je}, C_{jc}, M_e, M_c, V_{je}, V_{jc}, T_f, and T_r that must be specified by the user. Typically, these constants would be extracted from measured I–V and C–V data taken from real transistors using a fitting or optimization procedure (typically a nonlinear least-squares fitting method is needed). The Ebers–Moll model has a number of shortcomings that are addressed in newer models like Gummel–Poon, Mextram, and VBIC. The Gummel–Poon model has over 40 parameters that must be adjusted to get a good fit to data in all regions of operation.

Models for MOS devices are even more complicated than the bipolar models. Modeling the MOSFET is more difficult than the bipolar transistor because it is often necessary to use a different equation for each of the four regions of operation (off, subthreshold, linear, and saturation) and the drain current and capacitance are functions of three voltages (V_{ds}, V_{bs}, and V_{gs}) rather than just two (V_{be} and V_{ce}) as in the case of the BJT. If a Newton–Raphson solver is to be used, the I–V characteristics and capacitances must be continuous and it is best if their first derivatives are continuous as well. Furthermore, MOS models contain the width (W) and length (L) of the MOSFET channel as parameters; and for the best utility the model should remain accurate for many values of W and L. This property is referred to as "scalability."

Over the years, literally hundreds of different MOS models have been developed. However, for modern VLSI devices, only three or four are commonly used today. These are the SPICE Level-3 MOS model, the HSPICE Level-28 model (which is a proprietary model developed by Meta Software), the public domain BSIM3 model developed at UC, Berkeley, and MOS9 developed at Phillips. These models are supported by many of the "silicon foundries," that is, parameters for the models are provided to chip designers by the foundries. BSIM3 has been observed to provide a good fit to measured data and its I–V curves to be smooth and continuous (thereby resulting in good simulator convergence). The main drawback of BSIM3 is that it has over 100 parameters which are related in intricate ways, making extraction of the parameter set a difficult process.

A process known as "binning" is used to provide greater accuracy. When binning is used, a different set of model parameters is used for each range of the channel length and width (L and W). An example of this is shown in Figure 9.6. For a given type of MOSFET, 12 complete sets of model parameters are extracted and each is valid for a given range. For example, in Figure 9.6, the set represented by the number "11" would only be valid for channel lengths between 0.8 and 2.0 μm and for channel widths between 0.5 and 0.8 μm. Thus, for a typical BSIM3 model with about 60 parameters, $12 \times 60 = 720$ parameters would need to be extracted in all and this just for one type of device.

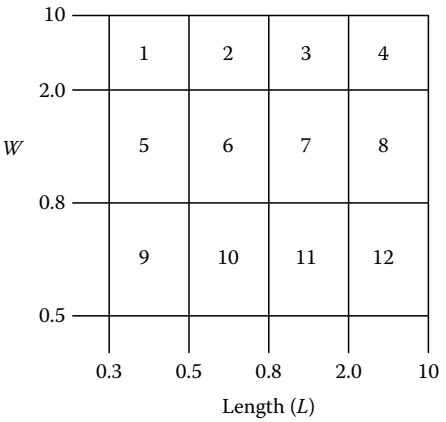

FIGURE 9.6 Binning of MOS parameters.

Many commercial simulators contain other types of models besides the traditional R, L, C, MOS, and BJT devices. Some simulators contain "behavioral" models which are useful for systems design or integration tasks; examples of these are integrators, multipliers, summation, and Laplace operator blocks. Some simulators are provided with libraries of prefitted models for commercially available operational amplifiers, logic chips, and discrete devices. Some programs allow "mixed-mode" simulation, which is a combination of logic simulation (which normally allows only a few discrete voltage states) and analog circuit simulation.

9.7 Types of Analysis

For analog circuits, three methods of analysis are commonly used: DC, AC, and transient analysis. DC analysis is used to examine the steady-state operation of a circuit; that is, what the circuit voltages and currents would be if all inputs were held constant for an infinite time. AC analysis (or sinusoidal steady state) examines circuit performance in the frequency domain using phasor analysis. Transient analysis is performed in the time domain and is the most powerful and computationally intensive of the three. For special applications, other methods of analysis are available such as the harmonic-balance method, which is useful for detailed analysis of nonlinear effects in circuits excited by purely periodic signals (like mixers and RF amplifiers).

9.7.1 DC (Steady-State) Analysis

DC analysis calculates the steady-state response of a circuit (with all inductors shorted and capacitors removed). DC analysis is used to determine the operating point (*Q*-point) of a circuit, power consumption, regulation and output voltage of power supplies, transfer functions, noise margin and fanout in logic gates, and many other types of analysis. In addition, a DC solution must be calculated to find the starting point for AC and transient analysis.

To calculate the DC solution, we need to solve Kirchhoff's equations formulated earlier. Unfortunately, since the circuit elements will be nonlinear in most cases, a system of transcendental equations will normally result and it is impossible to solve this system analytically. The method that has met with the most success is Newton's method or one of its derivatives.

9.7.1.1 Newton's Method

Newton's method is actually quite simple. We need is to solve the system of equations $F(X) = 0$ for X, where both F and X are vectors of dimension N. (F is the system of equations from modified nodal analysis, and X is the vector of voltages and current that we are solving for.) Newton's method states that given an initial guess for X^i, we can obtain a better guess X^{i+1} from the equation:

$$X^{i+1} = X^i - [J(X^i)]^{-1} F(X^i) \tag{9.10}$$

Note that all terms on the right side of the equation are functions only of the vector X^i. The term $J(X)$ is a $N \times N$ square matrix of partial derivatives of F, called the Jacobian. Each term in J is given by

$$J_{i,j} = \frac{\partial F_i(X)}{\partial X_j} \tag{9.11}$$

We assemble the Jacobian matrix for the circuit at the same time that we assemble the circuit equations. Analytic derivatives are used in most simulators.

The -1 in Equation 9.10 indicates that we need to invert the Jacobian matrix before multiplying by the vector F. Of course, we do not need to actually invert J to solve the problem; we only need to solve the linear problem $F = YJ$ for the vector Y and then calculate $X^{i+1} = X^i - Y$. A direct method such as the LU decomposition is usually employed to solve the linear system.

For the small circuit of Figure 9.3, analyzed in steady state (without the capacitor), the Jacobian entries are

$$\begin{array}{ll} J_{1,1} = 1/R_1 & J_{1,2} = -1/R_1 \\ J_{2,1} = 1/R_1 + gm & J_{2,2} = 1/R_1 + 1/R_2 \end{array} \tag{9.12}$$

```

.dc V1  1.0  3.0  0.01
```

FIGURE 9.7 Input file for DC sweep of V_1.

For a passive circuit (i.e., a circuit without gain), the Jacobian will be symmetric and for any row, the diagonal entry will be greater than the sum of all the other entries.

Newton's method converges quadratically, provided that the initial guess X^i is sufficiently close to the true solution. Quadratically implies that if the distance between X^i and the true solution is d, then the distance between X^{i+1} and the true solution will be d^2. Of course, we are assuming that d is small to start with. Still, programs like SPICE may require 50 or more iterations to achieve convergence. The reason for this is that, often times, the initial guess is poor and quadratic convergence is not obtained until the last few iterations. There are additional complications like the fact that the model equations can become invalid for certain voltages. For example, the BJT model will "explode" if a junction is forward-biased by more than 1 V or so since: $\exp(1/Vt) = 5e16$. Special limiting or damping methods must be used to keep the voltages and currents to within reasonable limits.

9.7.1.2 Example Simulation

Most circuit simulators allow the user to ramp one or more voltage sources and plot the voltage at any node or the current in certain branches. Returning to the differential pair of Figure 9.1, we can perform a DC analysis by simply adding a .dc statement (see Figure 9.7). A plot of the differential output voltage (between the two collectors) and the voltage at the two emitters is shown in Figure 9.8. Observe that the output voltage is zero when the differential pair is "balanced" with 2.0 V on both inputs. The output saturates at both high and low values for V_1, illustrating the nonlinear nature of the analysis. This simulation was run using the PSPICE package from MicroSim Corporation. The simulation run is a few seconds on a 486 type PC.

9.7.2 AC Analysis

AC analysis is performed in the frequency domain under the assumption that all signals are represented as a DC component V_{dc} plus a small sinusoidal component V_{ac}

$$V = V_{dc} + V_{ac} \exp(j\omega t) \tag{9.13}$$

where

$j = \sqrt{-1}$

ω is the radial frequency $(2\pi f)$

V_{ac} is a complex number

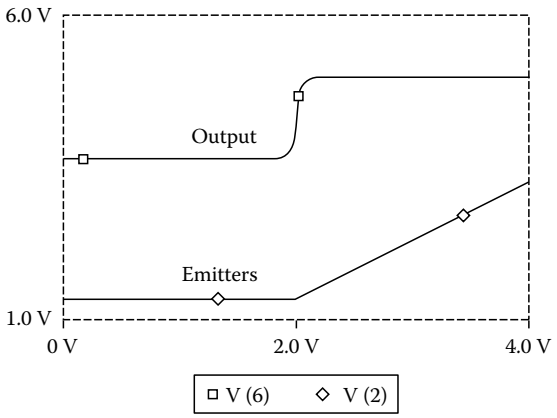

FIGURE 9.8 Output from DC analysis.

Expanding Equation 9.1 about the DC bias point V_{dc} (also referred to as the Q point), we obtain

$$F(V) = F(V_{dc}) + W_{dc} + W_{ac} + \frac{\partial G(V_{dc})}{\partial V_{dc}} V_{ac} + \frac{\partial}{\partial t}\left(\frac{\partial Q(V_{dc})}{\partial V_{dc}}\right) V_{ac} + \alpha V_{ac}^2 \Lambda \tag{9.14}$$

The series has an infinite number of terms; however, we assume that if V_{ac} is sufficiently small, all terms above first order can be neglected. The first two terms on the right-hand side are the DC solution and, when taken together, yield zero. The third term W_{ac} is the vector of independent AC sources which drive the circuit. The partial derivative in the fourth term is the Jacobian element, and the derivative of Q in parentheses is the capacitance at the node. When we substitute the exponential into Equation 9.14, each term will have an exponential term that can be canceled. The result of all these simplifications is the familiar result:

$$0 = W_{ac} + JV_{ac} + j\omega CV_{ac} \tag{9.15}$$

This equation contains only linear terms which are equal to the partial derivatives of the original problem evaluated at the Q point. Therefore, before we can solve the AC problem, we must calculate the DC bias point. Rearranging terms slightly, we obtain

$$V_{ac} = -(J + j\omega C)^{-1} W_{ac} \tag{9.16}$$

The solution at a given frequency can be obtained from a single matrix inversion. The matrix, however, is complex but normally the complex terms share a sparsity pattern similar to the real terms. It is normally possible (in FORTRAN and C++) to create a suitable linear solver by taking the linear solver which is used to calculate the DC solution and substituting ''complex'' variables for ''real'' variables. Since there is no nonlinear iteration, there are no convergence problems and AC analysis is straightforward and foolproof.

The same type of analysis can be applied to the equations for modified nodal analysis. The unknowns will of course be currents and the driving sources voltage sources.

$$I_{ac} = -(J + j\omega L)^{-1} E_{ac} \tag{9.17}$$

The only things that must be remembered with AC analysis are

1. AC solution is sensitive to the Q point, so if an amplifier is biased near its saturated DC output level, the AC gain will be smaller than if the amplifier were biased near the center of its range.
2. This is a linear analysis and therefore ''clipping'' and slew rate effects are not modeled. For example, if a 1 V AC signal is applied to the input of a small signal amplifier with a gain of 100 and a power supply voltage of 5 V, AC analysis will predict an output voltage of 100 V. This is of course impossible since the output voltage cannot exceed the power supply voltage of 5 V. If you want to include these effects, use transient analysis.

9.7.2.1 AC Analysis Example

In the following example, we will analyze the differential pair using AC analysis to determine its frequency response. To perform this analysis in SPICE, we need to only specify which sources are the AC-driving sources (by adding the magnitude of the AC signal at the end) and specify the frequency range on the .AC statement (see Figure 9.9). SPICE lets the user specify the range as linear or ''decade,'' indicating that we desire a logarithmic frequency scale. The first number is the number of frequency points per decade. The second number is the starting frequency, and the third number is the ending frequency.

```

FIGURE 9.9 Input file for AC analysis.

Figure 9.10 shows the results of the analysis. The gain begins to roll off at about 30 MHz due to the parasitic capacitances within the transistor models. The input impedance (which is plotted in kΩ) begins to roll off at a much lower frequency. The reduction in input impedance is due to the increasing current that flows in the base–emitter capacitance as the current increases. SPICE does not have a method of calculating input impedance, so we have calculated it as $Z = V_{\text{in}}/I(V_{\text{in}})$, where $V_{\text{in}} = 1.0$, using the postprocessing capability of PSPICE. This analysis took about 2 s on a 486-type PC.

9.7.2.2 Noise Analysis

Noise is a problem primarily in circuits that are designed for the amplification of small signals like the RF and IF amplifiers of a receiver. Noise is the result of random fluctuations in the currents which flow in the circuit and is generated in every circuit element. In circuit simulation, noise analysis, is an extension of AC analysis. During noise analysis, it is assumed that every circuit element contributes some small noise component either as a voltage V_{n} in series with the element or as a current I_{n} across the element. Since the noise sources are small in comparison to the DC signal levels, AC small signal analysis is an applicable analysis method.

Different models have been developed for the noise sources. In a resistor, thermal noise is the most important component. Thermal noise is due to the random motion of the electrons:

$$I_n^2 = \frac{4kT\Delta f}{R} \tag{9.18}$$

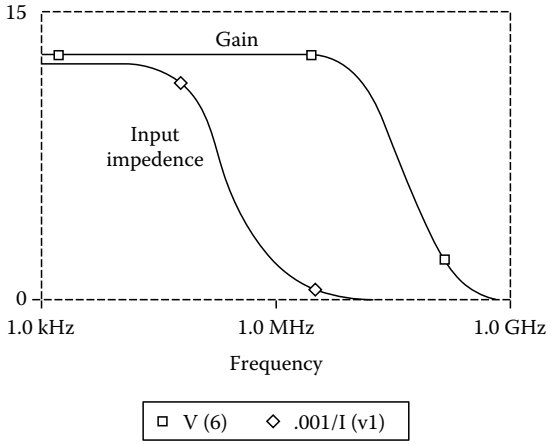

FIGURE 9.10 Gain and input impedance calculated by AC analysis.

where

T is the temperature
k is Boltzman's constant
Δf is the bandwidth of the circuit

In a semiconductor diode, shot noise is important. Shot noise is related to the probability that an electron will surmount the semiconductor barrier energy and be transported across the junction:

$$I_n^2 = 2qI_d\Delta f \tag{9.19}$$

Other types of noise occur in diodes and transistors; examples are flicker and popcorn noise. Noise sources, in general, are frequency-dependent.

Noise signals will be amplified or attenuated as they pass through different circuits. Normally, noise is referenced to some output point called the "summing node." This would normally be the output of the amplifier where we would actually measure the noise. We can call the gain between the summing node and the current flowing in an element j in the circuit $A_j(f)$. Here, f is the analysis frequency since the gain will normally be frequency dependent.

Noise signals are random and uncorrelated to each other so their magnitudes must be root-mean-squared summed rather than simply summed. Summing all noise sources in a circuit yields:

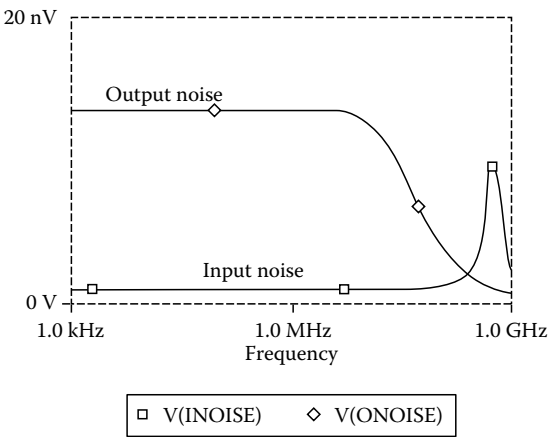

FIGURE 9.11 Noise referenced to output and input.

$$I_n(f) = \sqrt{\sum_j A_j^2(f) I_j^2(f)} \tag{9.20}$$

It is also common to reference noise back to the amplifier input and this is easily calculated by dividing the preceding expression by the amplifier gain. Specifying noise analysis in SPICE is simple. All the user needs to do is add a statement specifying the summing node and the input source. SPICE then calculates the noise at each as a function of frequency

```
.noise  v([6])  V1
```
(9.21)

See Figure 9.11 for example output. Many circuit simulators will also list the noise contributions of each element as part of the output. This is particularly helpful in locating the source of noise problems.

9.7.3 Transient Analysis

Transient analysis is the most powerful analysis capability because the transient response of a circuit is so difficult to calculate analytically. Transient analysis can be used for many types of analysis, such as switching speed, distortion, and checking the operation of circuits such as logic gates, oscillators, phase-locked loops, or switching power supplies. Transient analysis is also the most CPU intensive and can require 100 or 1000 times the CPU time of DC or AC analysis.

9.7.3.1 Numerical Method

In transient analysis, time is discretized into intervals called time steps. Typically, the time steps are of unequal length, with the smallest steps being taken during intervals where the circuit voltages and currents are changing most rapidly. The following procedure is used to discretize the time-dependent terms in Equation 9.1.

Time derivatives are replaced by difference operators, the simplest of which is the forward difference operator:

$$\frac{dQ(t_k)}{dt} = \frac{Q(t_{k+1}) - Q(t_k)}{h} \tag{9.22}$$

where h is the time step given by $h = t_{k+1} - t_k$. We can easily solve for the charge $Q(t_{k+1})$ at the next time point:

$$Q(t_{k+1}) = Q(t_k) - h(G_i(V(t_k)) + W_i(t_k)) \tag{9.23}$$

using only values from past time points. This means that it would be possible to solve the system simply by plugging in the updated values for V each time. This can be done without any matrix assembly or inversion and is very nice. (Note for simple linear capacitors, $V = Q/C$ at each node, so it is easy to get V back from Q.) However, this approach is undesirable for circuit simulation for two reasons: (1) The charge Q, which is a "state variable" of the system, is not a convenient choice since some nodes may not have capacitors (or inductors) attached, in which case they will not have Q values and (2) It turns out that forward (or explicit) time discretization methods like this one are unstable for "stiff" systems, and most circuit problems result in "stiff systems." The term "stiff system" refers to a system that has greatly varying time constants.

To overcome the stiffness problem, we must use implicit time discretization methods which, in essence, mean that the G and W terms in the above equations must be evaluated at t_{k+1}. Since G is nonlinear, we will need to use Newton's method once again.

The most popular implicit method is the trapezoidal method. The trapezoidal method has the advantage of requiring information only from one past time point and, furthermore, has the smallest error of any method requiring one past time point. The trapezoidal method states that if I is the current in a capacitor, then

$$I(t_{k+1}) = \frac{dQ}{dt} = 2\frac{Q(V(t_{k+1})) - Q(V(t_k))}{h} - I(t_k) \tag{9.24}$$

Therefore, we need to only substitute Equation 9.24 into Equation 9.1 to solve the transient problem. Observe that we are solving for the voltages $V(t_{k+1})$, and all terms involving t_k are constant and will not be included in the Jacobian matrix. An equivalent electrical model for the capacitor is shown in Figure 9.12. Therefore, the solution of the transient problem is in effect a series of DC solutions where the values of some of the elements depend on voltages from the previous time points.

All modern circuit simulators feature automatic time step control. This feature selects small time steps during intervals where changes occur rapidly and large time steps in intervals where there is little change. The most commonly used method of time step selection is based on the local truncation error (LTE) for each time step. For the trapezoidal rule, the LTE is given by

$$\varepsilon = \frac{h^3}{12}\frac{d^3x}{dt^3}(\xi) \tag{9.25}$$

and represents the maximum error introduced by the trapezoidal method at each time step. If the error (ε) is larger than some preset value, the step size is reduced. If the error is smaller, then the step size is increased. In addition, most simulators select time points so that they coincide with the edges of pulse-type waveforms.

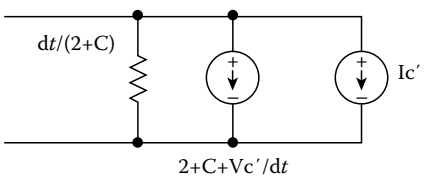

FIGURE 9.12 Electrical model for a capacitor; the two current sources are independent sources. The prime (′) indicates values from a preceding time point.

9.7.3.2 Transient Analysis Examples

As a simple example, we return to the differential pair and apply a sine wave differentially to the input. The amplitude (2 V p-p) is selected to drive the amplifier into saturation.

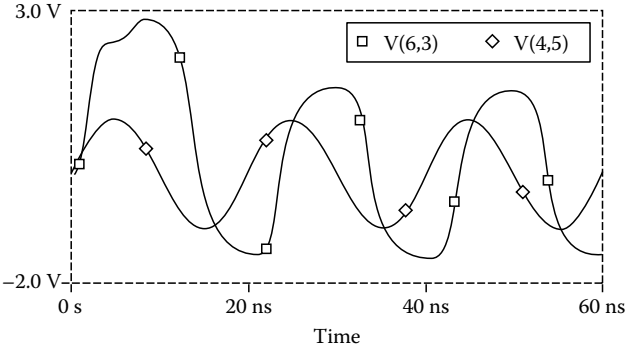

FIGURE 9.13 Transient response V(6,3) of differential amplifier to sinusoidal input at V(4,5).

In addition, we make the frequency (50 MHz) high enough to see phase shift effects. The output signal is therefore clipped due to the nonlinearities and shifted in phase due to the capacitive elements in the transistor models (see Figure 9.13). The first cycle shows extra distortion since it takes time for the ''zero-state'' response to die out. This simulation, using PSPICE, runs in about one second on a 486-type computer.

9.8 Verilog-A

Verilog-A is a new language designed for simulation of analog circuits at various levels. Mathematical equations can be entered directly as well as normal SPICE-type circuit elements.

Groups of equations and elements can be combined into reusable ''modules'' that are similar to subcircuits. Special functions are also provided for converting analog signals into digital equivalents, and vice versa. Systems-type elements such as Laplace operators, integrators, and differentiators are also provided. This makes it possible to perform new types of modeling that were not possible in simulators like SPICE:

- Equations can be used to construct new models for electrical devices (for example, the Ebers–Moll model described earlier could be easily implemented).
- Behavioral models for complex circuits like op-amps, comparators, phase detectors, etc. can be constructed. These models can capture the key behavior of a circuit and yet be simulated in a small fraction of the time it takes to simulate at the circuit level.
- Special interface elements make it possible to connect an analog block to a digital simulator, making mixed-mode simulation possible. Verilog-A is related to and compatible with the popular Verilog-D modeling language for digital circuits.

As an example, consider a phase-locked loop circuit which is designed as an 50X frequency multiplier. A block diagram for the PLL is shown in Figure 9.14 and the Verilog-A input listing is shown in Figures 9.15 and 9.16.

```

FIGURE 9.15 Part one of Verilog-A listing for PLL.

Simulation of this system at the circuit level is very time consuming due to the extreme difference in frequencies. The phase detector operates at a low frequency of 1.0 MHz, while the VCO operates at close to 50 MHz. However, we need to simulate enough complete cycles at the phase detector output to verify that the circuit correctly locks onto the reference signal.

The circuit is broken up into five blocks or modules: the ''top module,'' VCO, divider, phase detector, and loop filter. The VCO has a simple linear dependence of frequency on the VCO input voltage and produces a sinusoidal output voltage. The VCO frequency is calculated by the simple expression freq = center + gain* ($V_{in} - V_{min}$). Center and gain are parameters which can be passed in when the VCO is created within the top module by the special syntax ``#(.gain(2e7),.center(3e7)'' in the top module. If the parameters are not specified when the module is created, then the default values specified within the module are used instead. The special V() operator is used to obtain the voltage at a node (in this case `V(in)` and `V(Vdd)`). The sinusoidal output is created using the SIN and IDT operators. SIN calculates the sine of its argument. I_{dt} calculates the integral of its argument with respect to time. The amplitude of the output is taken from the V_{dd} input, thus making it easy to integrate the VCO block with others. Given that $V_{dd} = 5$ V, gain = 2e7 Hz/V, center = 3e7 Hz, and in = 1.8, the final expression for the VCO output is

$$V_{out} = 2.5 + 2.5\sin\left(3e7 + 2e7\int 2\pi(V_{in} - 1.8)dt\right) \tag{9.26}$$

The phase detector functions as a charge pump which drives current into or out of the loop filter, depending on the phase difference between its two inputs. The `@cross(V1,dir)` function becomes

```
module divide (out, in, vdd);      // Divider module....
        inout out, in;
        electrical out, in;
        parameter real count = 4; // divide by this.
    integer n, state;
        analog begin

                @(cross((V(in) – V(vdd)/2.0),1)) n = n + 1;
                if (n >= count/2) begin
                        if (state == 0) state = 1;
                        else state = 0;
                        n = 0;
                end
                V(out) <+ transition(state*5, 0, 0, 0);
        end

FIGURE 9.16 Part two of Verilog-A PLL listing.

true whenever signal V_1 crosses zero in the direction specified by `dir`. This either increments or decrements the variable STATE. The ''transition'' function is used to convert the STATE signal, which is essentially digital and changes abruptly into a smoothly changing analog signal which can be applied to the rest of the circuit. The ''<+'' (or contribution) operator adds the current specified by the equation on the right to the node on the left. Therefore, the phase detector block forces current into the output node whenever the VCO signal leads the reference signal and forcing current out of the output node whenever the reference leads the VCO signal. The phase detector also has an output resistance which is specified by parameter ROUT.

The loop filter is a simple SPICE subcircuit composed of two resistors and one capacitor. Of course, this subcircuit could contain other types of elements as well and can even contain other Verilog-A modules. The divider block simply counts zero crossings and, when the count reaches the preset divisor, the output of the divider is toggled from 0 to 1, or vice versa. The transition function is used to ensure that a smooth, continuous analog output is generated by the divider.

This PLL was simulated using AMS from Antrim Design Systems. The results of the simulations are shown in Figure 9.17. The top of Figure 9.17 shows the output from the loop filter (V_{cnt}). After a few cycles, the PLL has locked onto the reference signal. The DC value of the loop filter output is

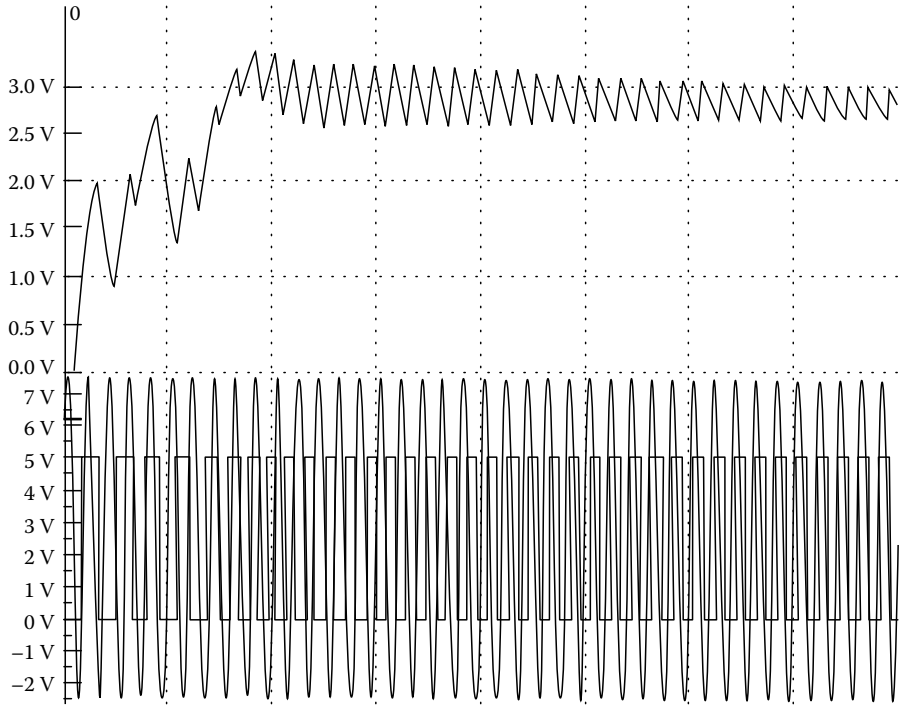

FIGURE 9.17 Loop filter output (top) V_{ref} and divider output (bottom) from PLL simulation.

approximately 2.8 V. Referring back to the VCO model, this gives an output frequency of 2e7* $(2.8 - 1.8) + 3e7 = 50$ MHz, which is as expected. The lower portion of Figure 9.17 shows the divider output (V_{div}) and the reference signal (V_{ref}). It can be seen that the two signals are locked in phase. Figure 9.18 shows the VCO output and the divider output. As expected, the VCO frequency is 50 times the divider frequency.

The behavioral models used in this example are extremely simple ones. Typically, more complex models must be used to accurately simulate the operation of an actual PLL. A better model might include effects such as the nonlinear dependence of the VCO frequency on the input voltage, the effects on signals introduced through power supply lines, delays in the divider and phase detector, and finite signal rise and fall times. These models can be built up from measurements, or transistor-level simulation of the underlying blocks (a process known as characterization). Of course, during the simulation, any of the behavioral blocks could be replaced by detailed transistor-level models or complex Verilog-D digital models.

Another Verilog-A example is shown in Figure 9.19. Here, the Ebers–Moll model developed earlier is implemented as a module. This module can then be used in a circuit in the same way as the normal built-in models. Verilog-A takes care of calculating all the derivatives needed to form the Jacobian matrix. The ''parameter'' entries can be used in the same way as the parameters on a SPICE.MODEL statement. Observe the special ''ddt'' operator. This operator is used to take the time derivative of its argument. In this case, the time derivative of the charge (a current) is calculated and summed in with the other DC components. The ''$limexp'' operation is a special limited exponential operator designed to give better convergence when modeling pn junctions. Of course, this module could be expanded and additional features could be added.

9.9 Fast Simulation Methods

As circuits get larger, simulation times become larger. In addition, as integrated circuit feature sizes shrink, second-order effects become more important and many circuit designers would like to be able to simulate large digital systems at the transistor level (requiring 10,000 to 100,000 nodes). Numerical studies in early versions of SPICE showed that the linear solution time could be reduced to 26% for relatively small circuits with careful coding. The remainder is used during the assembly of the matrix, primarily for model evaluation. The same studies found that the CPU time for the matrix solution was proportional to $n^{1.24}$, where n is the number of nodes. The matrix assembly time on the other hand should increase linearly with node count. Circuits have since grown much bigger, but the models (particularly for MOS devices) have also become more complicated.

Matrix assembly time can be reduced by a number of methods. One method is to simplify the models; however, accuracy will be lost as well. A better way is to precompute the charge and current characteristics for the complicated models and store them into tables. During simulation, the actual current and charges can be found from table lookup and interpolation, which can be done quickly and efficiently. However, there are some problems:

1. To assure convergence of Newton's method, both the charge and current functions and their derivatives must be continuous. This rules out most simple interpolation schemes and means that something like a cubic spline must be used.
2. The tables can become large. A MOS device has four terminals, which means that all tables will be functions of three independent variables. In addition, the MOSFET requires four separate tables (I_d, Q_g, Q_d, Q_b). If we are lucky, we can account for simple parameteric variations (like channel width) by a simple multiplying factor. However, if there are more complex dependencies as is the case with channel length, oxide thickness, temperature, or device type, we will need one complete set of tables for each device.

If the voltages applied to an element do not change from the past iteration to the present iteration, then there is no need to recompute the element currents, charges, and their derivatives. This method is referred to as taking advantage of latency and can result in large CPU time savings in logic circuits, particularly if coupled with a method that only refractors part of the Jacobian matrix. The tricky part is knowing when the changes in voltage can be ignored. Consider, for example, the input to a high-gain op-amp, here ignoring a microvolt change at the input could result in a large error at the output. Use of sophisticated latency-determining methods could also cut into the savings.

Another set of methods are the waveform relaxation techniques which increase efficiency by temporarily ignoring couplings between nodes. The simplest version of the method is as follows. Consider a circuit with n nodes which requires m time points for its solution. The circuit can be represented by the vector equation:

$$F_i(V(t)) + \frac{dQ_i(V(t))}{dt} = 0 \tag{9.27}$$

Using trapezoidal time integration gives a new function:

$$W_i(V(k)) = F_i(V(k)) + F_i(V(k-1)) + 2[Q_i(V(k)) - Q_i(V(k-1))]/dt = 0 \tag{9.28}$$

We need to find the $V(k)$ that makes W zero for all k time points at all i nodes. The normal method solves for all n nodes simultaneously at each time point before advancing k. Waveform relaxation solves for all m time points at a single node (calculates the waveform at that node) before advancing to the next node. An outer loop is used to assure that all the individual nodal waveforms are consistent with each other.

Waveform relaxation is extremely efficient as long as the number of outer loops is small. The number of iterations will be small if the equations are solved in the correct order; that is, starting on nodes which are signal sources and following the direction of signal propagation through the circuit. This way, the waveform at node $i+1$ will depend strongly on the waveform at node i, but the waveform at node i will depend weakly on the signal at node $i+1$. The method is particularly effective if signal propagation is unidirectional, as is sometimes the case in logic circuits. During practical implementation, the total simulation interval is divided into several subintervals and the subintervals are solved sequentially. This reduces the total number of time points which must be stored. Variants of the method solve small numbers of tightly coupled nodes as a group; such a group might include all the nodes in a TTL gate or in a small feedback loop. Large feedback loops can be handled by making the simulation time for each subinterval less than the time required for a signal to propagate around the loop.

The efficiency of this method can be further improved using different time steps at different nodes, yielding a multirate method. This way, during a given interval, small time steps are used at active nodes while large steps are used at inactive nodes (taking advantage of latency).

9.10 Commercially Available Simulators

The simulations in this chapter were performed with the evaluation version of PSPICE from Microsim and AMS from Antrim design systems. The following vendors market circuit simulation software. The different programs have strengths in different areas and most vendors allow you to try their software in-house for an ''evaluation period'' before you buy.

10.1 Introduction

As the complexity of VLSI systems continues to increase, the microelectronic industry must possess an ability to reconfigure design and manufacturing resources and integrate design activities so that it can quickly adapt to the market changes and new technology. Gaining this ability imposes a twofold challenge: (1) to coordinate design activities that are geographically separated and (2) to represent an immense amount of knowledge from various disciplines in a unified format. The Internet can provide the catalyst by abridging many design activities with the resources around the world not only to exchange information but also to communicate ideas and methodologies.

In this chapter, we present a collaborative engineering framework that coordinates distributed design activities through the Internet. Engineers can represent, exchange, and access the design knowledge and carry out design activities. The crux of the framework is the formal representation of process flow using the process grammar, which provides the theoretical foundation for representation, abstraction, manipulation, and execution of design processes. The abstraction of process representation provides mechanisms to represent hierarchical decomposition and alternative methods, which enable designers to manipulate

the process flow diagram and select the best method. In the framework, the process information is layered into separate specification and execution levels so that designers can capture processes and execute them dynamically. As the framework is being executed, a designer can be informed of the current status of design such as updating and tracing design changes and be able to handling exception. The framework can improve design productivity by accessing, reusing, and revising the previous process for a similar. The cockpit of our framework interfaces with engineers to perform design tasks and to negotiate design trade-off. The framework has the capability to launch whiteboards that enable the engineers in a distributed environment to view the common process flows and data and to concurrently execute dynamic activities such as process refinement, selection of alternative process, and design reviews. The proposed framework has a provision for various browsers where the tasks and data used in one activity can be organized and retrieved later for other activities.

One of the predominant challenges for microelectronic design is to handle the increased complexity of VLSI systems. At the turn of the century, it is expected that there will be 100 million transistors in a single chip with 0.1 μm features, which will require an even shorter design time (Spiller and Newton, 1997). This increase of chip complexity has given impetus to trends such as system on a chip, embedded system, and hardware/software codesign. To cope with this challenge, industry uses custom-off-the-shelf (COTS) components, relies on design reuse, and practices outsourcing design. In addition, design is highly modularized and carried out by many specialized teams in a geographically distributed environment. Multifacets of design and manufacturing, such as manufacturability and low power, should be considered at the early stage of design. It is a major challenge to coordinate these design activities (Fairbairn, 1994). The difficulties are caused by due to the interdependencies among the activities, the delay in obtaining distant information, the inability to respond to errors and changes quickly, and general lack of communications. At the same time, the industry must contend with decreased expenditures on manufacturing facilities while maintaining rapid responses to market and technology changes.

To meet this challenge, the U.S. government has launched several programs. The Rapid Prototyping of Application Specific Signal Processor (RASSP) Program was initiated by the Department of Defense to bring about the timely design and manufacturing of signal processors. One of the main goals of the RASSP program was to provide an effective design environment to achieve a four-time improvement in the development cycle of digital systems (Chung et al., 1996). DARPA also initiated a program to develop and demonstrate key software elements for Integrated Product and Process Development (IPPD) and agile manufacturing applications. One of the foci of the earlier program was the development of infrastructure for distributed design and manufacturing. Recently, the program is continued to Rapid Design Exploration & Optimization (RaDEO) to support research, development, and demonstration of enabling technologies, tools, and infrastructure for the next generation of design environments for complex electromechanical systems. The design environment of RaDEO is planned to provide cognitive support to engineers by vastly improving their ability to explore, generate, track, store, and analyze design alternatives (Lyons, 1997).

The new information technologies, such as the Internet and mobile computing, are changing the way we communicate and conduct business. More and more design centers use PCs, and link them on the Internet/intranet. The web-based communication allows people to collaborate across space and time, between humans, humans and computers, and computers in a shared virtual world (Berners-Lee et al., 1994). This emerging technology holds the key to enhance design and manufacturing activities. The Internet can be used as the medium of a virtual environment where concepts and methodologies can be discussed, accessed, and improved by the participating engineers. Through the medium, resources and activities can be reorganized, reconfigured, and integrated by the participating organizations. This new paradigm certainly impacts the traditional means for designing and manufacturing a complex product. Using Java, programs can be implemented in a platform-independent way so that they can be executed in any machine with a Web browser. Common Object Request Broker Architecture (CORBA) (Yang and Duddy, 1996) provides distributed services for tools to communicate through the Internet (Vogel and Duddy). Designers may be able to execute remote tools through the Internet and see the visualization of design data (Erkes et al., 1996; Chan et al., 1998; Chung and Kwon, 1998).

Even though the potential impact of this technology will be great on computer aided design, Electronic Design Automation (EDA) industry has been slow in adapting this new technology (Spiller and Newton, 1997). Until recently, EDA frameworks used to be a collection of point tools. These complete suites of tools are integrated tightly by the framework using their proprietary technology. These frameworks have been suitable enough to carry out a routine task where the process of design is fixed. However, new tools appear constantly. To mix and match various tools outside of a particular framework is very difficult. Moreover, tools, expertise, and materials for design and manufacturing of a single system are dispersed geographically. Now we have reached the stage where a single tool or framework is not sufficient enough to handle the increasing complexity of a chip and emerging new technology. A new framework is necessary which is open and scalable. It must support collaborative design activities so that designers can add new tools to the framework, and interface them with other CAD systems. There are two key functions of the framework: (1) managing the process and (2) maintaining the relationship among many design representations. For design data management, refer to Katz et al. (1987). In this chapter, we will focus on the process management aspect.

To cope with the complex process of VLSI system design, we need a higher level of viewing of a complete process, i.e., the abstraction of process by hiding all details that need not to be considered for the purpose at hand. As pointed out in National Institute of Standards and Technology reports (Schlenoff et al., 1996; Knutilla et al., 1998), a ''unified process specification language'' should have the following major requirements: abstraction, alternative task, complex groups of tasks, and complex sequences.

In this chapter, we first review the functional requirements of the process management in VLSI system design. We then present the Internet-based Microelectronic Design Automation (IMEDA) System. IMEDA is a web-based collaborative engineering framework where engineers can represent, exchange, and access design knowledge and perform the design activities through the Internet. The crux of the framework is a formal representation of process flow using process grammar. Similar to the language grammar, production rules of the process grammar map tasks into admissible process flows (Baldwin and Chung, 1995a). The production rules allow a complex activity to be represented more concisely with a small number of high-level tasks. The process grammar provides the theoretical foundation for representation, abstraction, manipulation, and execution of design and manufacturing processes. It facilitates the communication at an appropriate level of complexity. The abstraction mechanism provides a natural way of browsing the process repository and facilitates process reuse and improvement. The strong theoretical foundation of our approach allows users to analyze and predict the behavior of a particular process. The cockpit of our framework interfaces with engineers to perform design tasks and to negotiate design trade-off. The framework guides the designer in selecting tools and design methodologies, and it generates process configurations that provide optimal solutions with a given set of constraints. The just-in-time binding and the location transparency of tools maximize the utilization of company resources. The framework is equipped with whiteboards so that engineers in a distributed environment can view the common process flows and data and concurrently execute dynamic activities such as process refinement, selection of alternative processes, and design reviews. With the grammar, the framework gracefully handles exceptions and alternative productions. A layered approach is used to separate the specification of design process and execution parameters. One of the main advantages of this separation is freeing designers from the overspecification and graceful exception handling. The framework, implemented using Java, is open and extensible. New process, tools, and user-defined process knowledge and constraints can be added easily.

10.2 Functional Requirements of Framework

Design methodology is defined as a collection of principles and procedures employed in the design of engineering systems. Baldwin and Chung (1995a) define design methodology management as selecting and executing methodologies so that the input specifications are transformed into desired output specifications. Kleinfeldth et al. (1994) state that ''design methodology management provides for the

definition, presentation, execution, and control of design methodology in a flexible, configured way.'' Given a methodology, we can select a process or processes for that particular methodology.

Each design activity, whether big or small, can be treated as a task. A complex design task is hierarchically decomposed into simpler subtasks, and each subtask in turn may be further decomposed. Each task can be considered as a transformation from input specification to output specification. The term *workflow* is used to represent the details of a process including its *structure in terms of all the required tasks and their interdependencies*. Some process may be ill-structured, and capturing it as a workflow may not be easy. Exceptions, conditional executions, and human involvement during the process make it difficult to model the process as a workflow.

There can be many different tools or alternative processes to accomplish a task. Thus, a design process requires design decisions such as selecting tools and processes as well as selecting appropriate design parameters. At a very high level of design, the input specifications and constraints are very general and may even be ill-structured. As we continue to decompose and perform the tasks based on design decisions, the output specifications are refined and the constraints on each task become more restrictive. When the output of a task does not meet certain requirements or constraints, a new process, tools, or parameters must be selected. Therefore, the design process is typically iterative and based on previous design experience. Design process is also a collaborative process, involving many different engineering activities and requiring the coordination among engineers, their activities, and the design results.

Until recently, it was the designer's responsibility to determine which tools to use and in what order to use them. However, managing the design process itself has become difficult, since each tool has its own capabilities and limitations. Moreover, new tools are developed and new processes are introduced continually. The situation is further aggravated because of incompatible assumptions and data formats between tools. To manage the process, we need a framework to monitor the process, carry out design tasks, support cooperative teamwork, and maintain the relationship among many design representations (Katz et al., 1987; Chiueh and Katz, 1990). The framework must support concurrent engineering activities by integrating various CAD tools and process and component libraries into a seamless environment. Figure 10.1 shows the RASSP enterprise system architecture (Welsh et al., 1995). It integrates tools, tool frameworks, and data management functions into an enterprise environment. The key functionality of the RASSP system is managing the RASSP design methodology by ''process automation'', that is, controlling CAD program execution through workflow.

10.2.1 Building Blocks of Process

The lowest level of a building block of a design process is a tool. A *tool* is an unbreakable unit of a CAD program. It usually performs a specific task by transforming given input specifications into output specifications. A *task* is defined as design activities that include information about what tools to use and how to use them. It can be decomposed into smaller subtasks. The simplest form of the task, called an *atomic task*, is the one that cannot be decomposed into subtasks. In essence, an atomic task is defined as an encapsulated tool. A task is called *logical* if it is not atomic. A workflow of a logical task describes the details of how the task is decomposed into subtasks, and the data and control dependencies such as the relationship between design data used in the subtasks. For a given task, there can be several workflows, each of which denotes a possible way of accomplishing the task. A *methodology* is a collection of workflow supported together with information on which workflow should be selected in a particular instance.

10.2.2 Functional Requirements of Workflow Management

To be effective, a framework must integrate many design automation tools and allow the designer to specify acceptable methodologies and tools together with information such as when and how they may be used. Such a framework must not only guide the designer in selecting tools and design methodologies, but also aid the designer in constructing a workflow that is suitable to complete the design under given

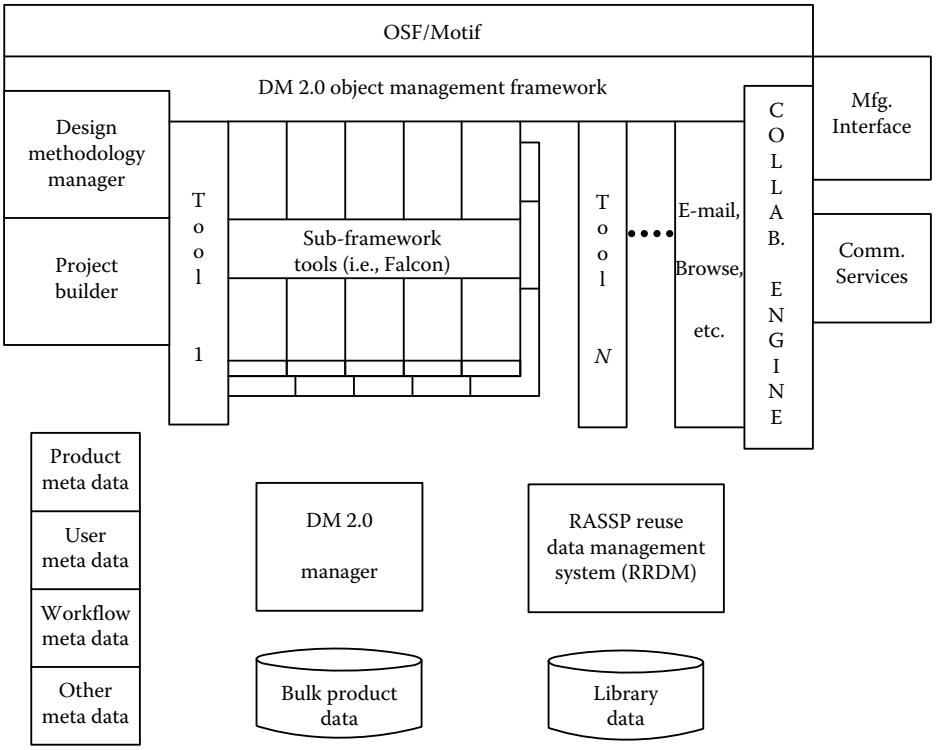

FIGURE 10.1 RASSP enterprise system architecture.

constraints. The constructed workflow should guarantee that required steps are not skipped; built-in design checks are incorporated into the workflow. The framework must also keep the relationships between various design representations, maintain the consistency between designs and support cooperative teamwork, and allow the designer to interact with the system to adjust design parameters or to modify the previous design process. The framework must be extendible to accommodate rapidly changing technologies and emerging new tools. Such a framework can facilitate developing new hardware systems as well as redesigning a system from a previous design.

During a design process, a particular methodology or workflow selected by a designer must be based on available tools, resources (computing and human), and design data. For example, a company may impose a rule that if input is a VHDL behavioral description, then designers should use Model Technology's VHDL simulator, but if the input is Verlig, they must use ViewLogic simulator. Or, if a component uses Xilinx, then all other components must also use Xilinx. Methodology must be driven by local expertise and individual preference, which in turn, are based on the designer's experience.

The process management should not constrain the designer. Instead, it must free designers from routine tasks, and guide the execution of workflow. User interaction and a designer's freedom are especially important when exceptions are encountered during the execution of flows, or when designers are going to modify the workflow locally. The system must support such activities through ''controlled interactions'' with designers.

Process management can be divided into two parts:

- Formal specification of supported methodologies and tools that must show the tasks and data involved in a workflow and their relationships
- Execution environment that helps designers to construct workflow and execute them

10.2.3 Process Specification

Methodology management must provide facilities to specify design processes. Specification of processes involves tasks and their structures (i.e., workflow). The task involved and the flow of process, that is the way the process can be accomplished in terms of its subtasks, must be defined. Processes must be encapsulated and presented to designers in a usable way. Designers want an environment to guide them in building a workflow and to help them execute it during the design process. Designers must be able to browse related processes, and compare, analyze, and modify them.

10.2.3.1 Tasks

Designers should be able to define the tasks that can be logical or atomic, organize the defined tasks, and retrieve them. Task abstraction refers to using and viewing a task for specific purposes and ignoring the irrelevant aspects of the task. In general, object-oriented approaches are used for this purpose. Abstraction of the task may be accomplished by defining tasks in terms of ''the operations the task is performing'' without detailing the operations themselves. Abstraction of tasks allows users to clearly see the behavior of them and use them without knowing the details of their internal implementations. Using the generalization–specialization (GS) hierarchy (Chung and Kim, 1990), similar tasks can be grouped together. In the hierarchy, a node in the lower level inherits its attributes from its predecessors. By inheriting the behavior of a task, the program can be shared, and by inheriting the representation of a task (in terms of its flow), the structure (workflow) can be shared. The Process Handbook (Malone et al., in press) embodies concepts of specialization and decomposition to represent processes.

There are various approaches associated with binding a specific tool to an atomic task. A tool can be bound to a task statically at the compile time, or dynamically at the run time based on available resources and constraints. When a new tool is installed, designers should be able to modify the existing bindings. The simplest approach is to modify the source code or write a script file and recompile the system. The ideal case is plug and play, meaning that CAD vendors address the need of tool interoperability, e.g., the Tool Encapsulation Specification (TES) proposed by CFI (1995).

10.2.3.2 Workflow

To define a workflow, we must specify the tasks involved in the workflow, data, and their relationship. A set of workflows defined by methodology developers enforces the user to follow the flows imposed by the company or group. Flows may also serve to guide users in developing their own flows. Designers would retrieve the cataloged flows, modify them, and use them for their own purposes based on the guidelines imposed by the developer. It is necessary to generate legal flows. A blackboard approach was used in (Lander et al., 1996) to generate a particular flow suitable for a given task. In Nelsis (ten Bosch et al., 1991), branches of a flow are explicitly represented using ''or'' nodes and ''merge'' nodes. A task can be accomplished in various ways. It is necessary to represent alternative methodologies for the task succinctly so that designers can access alternative methodologies and select the best one based on what-if analysis. IDEF3.X (IDEF) is used to graphically model workflow in RASSP environment. Figure 10.2 shows an example of workflow using IDEF3.X. A node denotes a task. It has inputs, outputs, mechanisms, and conditions. IDEF definition has been around for 20 years mainly to capture flat modeling such as a shop floor process. IDEF specification, however, requires complete information such as control mechanisms and scheduling at the specification time, making the captured process difficult to understand. In IDEF, ''or'' nodes are used to represent the alternative paths. It does not have an explicit mechanism to represent alternative workflow. IDEF is ideal only for documenting the current practice and not suitable for executing iterative process which is determined during the execution of the process. Perhaps, the most important aspect missing from most process management systems is the abstraction mechanism (Schlenoff et al., 1996).

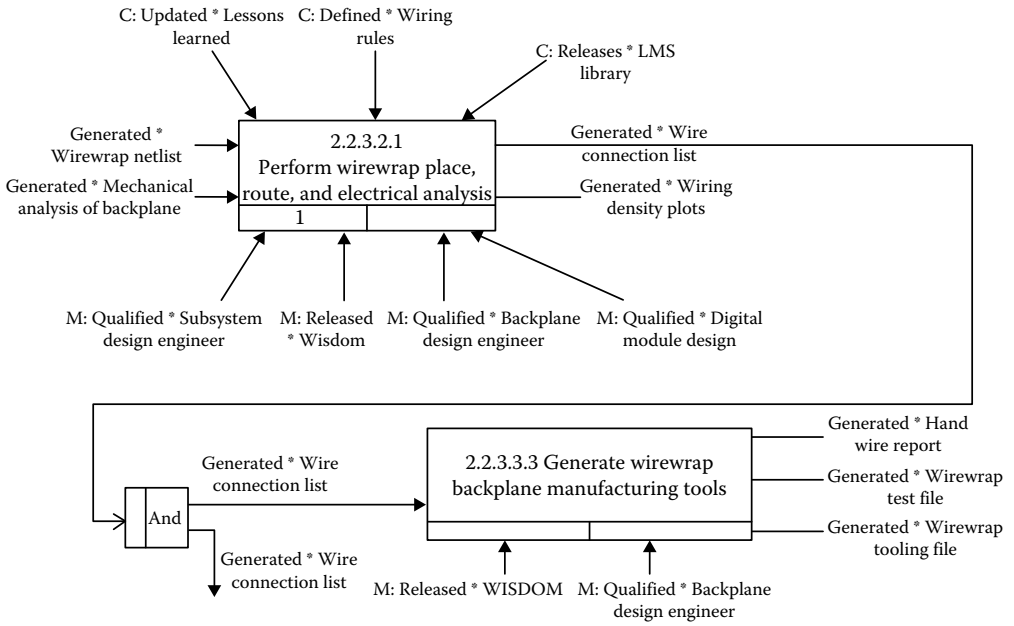

FIGURE 10.2 Workflow example using IDEF definition.

10.2.4 Execution Environment

The execution environment provides dynamic execution of tasks and tools and binds data to tools, either manually or automatically. Few frameworks separate the execution environment from the specification of design process. There are several modes in which a task can be executed (Kleinfeldth et al., 1994): manual mode, manual execution of flow, automatic flow execution, and automatic flow generation. In manual flow execution, the environment executes a task in the context of a flow. In an automatic flow execution environment, tasks are executed based on the order specified on the flow graph. In automatic flow generation, the framework generates workflow dynamically and executes them without the guidance of designers. Many frameworks use blackboard or knowledge-based approaches to generate workflow. However, it is important for designers to be able to analyze the workflow created and share it with others. That is, repeatability and predictability are important factors if frameworks support dynamic creation of workflow.

Each task may be associated with pre and postconditions. Before a task is executed, the precondition of the task is evaluated. If the condition is not satisfied, the framework either waits until the condition is met, or aborts the task and selects another alternative. After the task is executed, its postcondition is evaluated to determine if the result meets the exit criteria. If the evaluation is unsatisfactory, another alternative should be tried.

When a task is complex involving many subtasks and each subtask in turn has many alternatives, generating a workflow for the task that would successfully accomplish the task is not easy. If the first try of an alternative is not successful, another alternative should be tried. In some cases, backtrack occurs which nullifies all the executions of previous workflow.

10.2.5 Literature Surveys

Many systems have been proposed to generate design process (Knapp and Parker, 1991) and manage workflow (Dellen et al., 1997; Lavana et al., 1997; Schurmann and Altmeyer, 1997; Sutton and Director,

1998). Many of them use the Web technology to coordinate various activities in business (Andreoli, 1998), manufacturing (Berners-Lee et al., 1994; Cutkosy et al., 1996; Erkes et al., 1996), and microelectronic design (Rastogi et al., 1993; Chan et al., 1998). WELD (Chan et al., 1998) is a network infrastructure for a distributed design system that offers users the ability to create a customizable and adaptable virtual design system that can couple tools, libraries, design, and validation services. It provides support not only for designing but also for manufacturing, consulting, component acquisition, and product distribution, encompassing the developments of companies, universities, and individuals throughout the world. Lavana et al. (1997) proposed an Internet-based collaborative design. They use Petri nets as a modeling tool for describing and executing workflow. User teams, at different sites, control the workflow execution by selection of its path. Minerva II (Sutton and Director, 1998) is a software tool that provides design process management capabilities serving multiple designers working with multiple CAD frameworks. The proposed system generates design plan and realizes unified design process management across multiple CAD frameworks and potentially across multiple design disciplines. ExPro (Rastogi et al., 1993) is an expert-system-based process management system for the semiconductor design process.

There are several systems that automatically determine what tools to execute. OASIS (1992) uses Unix make file style to describe a set of rules for controlling individual design steps. The Design Planning Engine of the ADAM system (Knapp and Parker, 1986, 1991) produces a plan graph using a forward chaining approach. Acceptable methodologies are specified by listing preconditions and postconditions for each tool in a lisp-like language. Estimation programs are used to guide the chaining. Ulysses (Bushnell and Director, 1986) and Cadweld (Daniel and Director, 1991) are blackboard systems used to control design processes. A knowledge source, which encapsulates each tool, views the information on the blackboard and determines when the tool would be appropriate. The task management is integrated into the CAD framework and Task Model is interpreted by a blackboard architecture instead of a fixed inference mechanism. Minerva (Jacome and Director, 1992) and the OCT task manager (Chiueh and Katz, 1990) use hierarchical strategies for planning the design process. Hierarchical planning strategies take advantage of knowledge about how to perform abstract tasks which involve several subtasks.

To represent design process and workflow, many languages and schema have been proposed. NELSIS (ten Bosch et al., 1991) framework is based on a central, object-oriented database and on a flow management. It uses a dataflow graph as Flow Model and provides the hierarchical definition and execution of design flow. PLAYOUT (Schurmann and Altmeyer, 1997) framework is based on separate Task and Flow Models which are highly interrelated among themselves and the Product Model. In Barthelmann (1996), graph grammar is proposed in defining the task of software process management. Westfechtel (1996) proposed ''process-net'' to generate the process flow dynamically. However, in many of these systems, the relationship between task and data is not explicitly represented. Therefore, representing the case in which a task generates more than one datum and each of them goes to a different task is not easy. In Schurmann and Altmeyer (1997), Task Model (describing the I/O behavior of design tools) is used as a link between the Product Model and the Flow Model. The proposed system integrates data and process management to provide traceability. Many systems use IDEF to represent a process (Chung et al., 1996; Stavas et al.; IDEF). IDEF specification, however, requires complete information such as control mechanisms and scheduling at the specification time, making the captured process difficult to understand.

Although there are many other systems that address the problem of managing process, most proposed system use either a rule-based approach or a hard-coded process flow. They frequently require source code modification for any change in process. Moreover, they do not have mathematical formalism. Without the formalism, it is difficult to handle the iterative nature of the engineering process and to simulate the causal effects of any changes in parameters and resources. Consequently, coordinating the dynamic nature of processes is not well supported in most systems. It is difficult to analyze the rationale how an output is generated and where a failure has occurred. They also lack a systematic way of generating all permissible process flows at any level of abstraction while providing means to hide

the details of the flow when they are not needed. Most systems have the tendency to overspecify the flow information, requiring complete details of a process flow before executing the process. In most real situations, the complete flow information may not be known after the process has been executed: they are limited in their ability to address the underlying problem of process flexibility. They are rather rigid and not centered on users, and do not handle exceptions gracefully. Thus, the major functions for the collaborative framework such as adding new tools and sharing and improving the process flow cannot be realized. Most of them are weak in at least one of the following criteria suggested by NIST (Schlenoff et al., 1996): process abstraction, alternative tasks, complex groups of tasks, and complex sequences.

10.3 IMEDA System

The Internet-based Microelectronic Design Automation (IMEDA) System is a general management framework for performing various tasks in design and manufacturing of complex microelectronic systems. It provides a means to integrate many specialized tools such as CAD and analysis packages, and allows the designer to specify acceptable methodologies and tools together with information such as when and how they may be used. IMEDA is a collaborative engineering framework that coordinates design activities distributed geographically. The framework facilitates the flow of multimedia data sets representing design process, production, and management information among the organizational units of a virtual enterprise. IMEDA uses process grammar (Baldwin and Chung, 1995a) to represent the dynamic behavior of the design and manufacturing process. In a sense, IMEDA is similar to agent-based approach such as Redux (Petrie, 1996). Redux, however, does not provide process abstraction mechanism or facility to display the process flow explicitly.

The major functionality of the framework includes

- Formal representation of the design process using the process grammar that captures a complex sequence of activities of microelectronic design
- Execution environment that selects a process, elaborates the process, invokes tools, pre- and postevaluates the productions if the results meet the criterion, and notifies designers
- User interface that allows designers to interact with the framework, guides the design process, and edits the process and productions
- Tool integration and communication mechanism using Internet Socket and HTTP
- Access control that provides a mechanism to secure the activity and notification and approval that provide the mechanisms to disperse design changes to, and responses from, subscribers

IMEDA is a distributed framework design knowledge, including process information, manager programs, etc., are maintained in a distributed fashion by local servers. Figure 10.3 illustrates how IMEDA links tools and sites for distributed design activities. The main components of IMEDA are

- **System Cockpit:** It controls all interactions between the user and the system and between the system components. The cockpit will be implemented as a Java applet and may be executable on any platform for which a Java-enabled browser is available. It keeps track of the current design status and informs the user of possible actions. It allows users to collaboratively create and edit process flows, production libraries, and design data.
- **Manager Programs:** These encapsulate design knowledge. Using preevaluation functions, managers estimate the possibility of success for each alternative. They invoke tools and call postevaluation functions to determine if a tool's output meets the specified requirements. The interface servers allow cockpits and other Java-coded programs to view and manipulate production, task and design data libraries. Manager programs must be maintained by tool integrators to reflect site-specific information such as company design practices and different ways of installing tools.

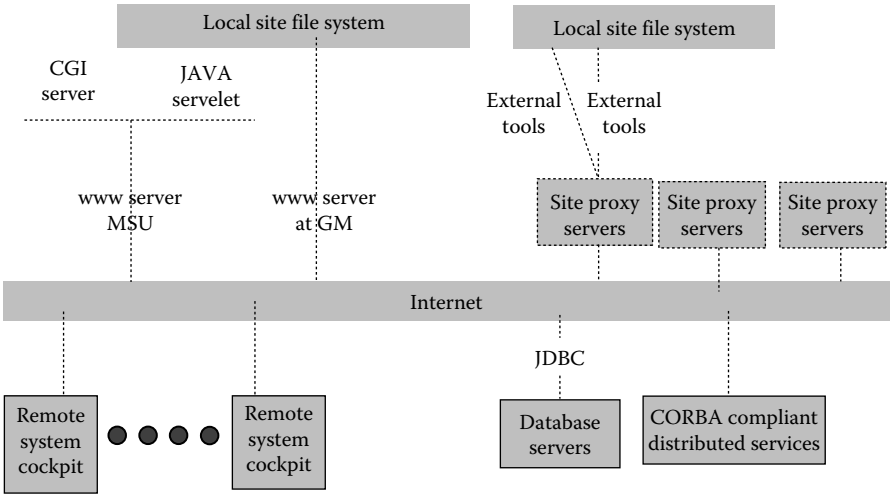

FIGURE 10.3 Architecture of IMEDA.

- **Browsers:** The task browser organizes the tasks in a GS hierarchy and contains all the productions available for each task. The data-specification browser organizes the data-specifications in a GS hierarchy and contains all the children.
- **External Tools:** These programs are the objects invoked by the framework during DM activities. Each atomic task in a process flow is bound to an external tool. External tools are written typically by the domain experts.
- **Site Proxy Server:** Any physical site that will host external tools must have a site proxy server running. These servers provide an interface between the cockpit and the external tools. The site server receives requests from system cockpits, and invokes the appropriate tool. Following the tool completion, the site server notifies the requesting cockpit, returning results, etc.
- **CGI Servers and Java Servlets:** The system cockpit may also access modules and services provided by CGI servers or the more recently introduced Java servlets. Currently, the system integrates modules of this type as direct components of the system (as opposed to external tools that may vary with the flow).
- **Database Servers:** Access to component data is a very important function. Using an API called JDBC, the framework can directly access virtually any commercially available database server remotely.
- **Whiteboard:** The shared cockpit or ''whiteboard'' is a communication medium to share information among users in a distributed environment. It allows designers to interact with the system and guides the design process collaboratively. Designers will be able to examine design results and current process flows, post messages, and carry out design activities both concurrently and collaboratively. Three types of whiteboards are the process board, the chat board, and the freeform drawing board. Their functionality includes (1) process board to the common process flow graph indicating the current task being executed and the intermediate results arrived at before the current task; (2) drawing board to load visual design data, and to design and simulate process; and (3) chat board to allow participants to communicate with each other via text-based dialog box.

IMEDA uses a methodology specification based on a process flow graphs and process grammars (Baldwin and Chung, 1995). Process grammars are the means for transforming high-level process flow graphs into progressively more detailed graphs by applying a set of substitution rules, called productions,

to nodes that represent logical tasks. It provides not only the process aspect of design activities but also a mechanism to coordinate them. The formalism in process grammar facilitates abstraction mechanisms to represent hierarchical decomposition and alternative methods, which enable designers to manipulate the process flow diagram and select the best method. The formalism provides the theoretical foundations for the development of IMEDA.

IMEDA contains the database of admissible flows, called process specifications. With the initial task, constraints, and execution environment parameters, including personal profile, IMEDA guides designers in constructing process flow graphs in a top-down manner by applying productions. It also provides designers with the ability to discover process configurations that provide optimal solutions. It maintains consistency among designs and allows the designer to interact with the system and adjust design parameters, or modify the previous design process. As the framework is being executed, a designer can be informed of the current status of design such as updating and tracing design changes and be able to handling exception.

Real-world processes are typically very complex by their very nature; IMEDA provides designers the ability to analyze, organize, and optimize processes in a way never before possible. More importantly, the framework can improve design productivity by accessing, reusing, and revising the previous process for a similar design.

The unique features of our framework include

Process Abstraction/Modeling: Process grammars provide abstraction mechanism for modeling admissible process flows. The abstraction mechanism allows a complex activity to be represented more concisely with a small number of higher-level tasks, providing a natural way of browsing the process repository. The strong theoretical foundation of our approach allows users to analyze and predict the behavior of a particular process. With the grammar, the process flow gracefully handles exceptions and alternative productions. When a task has alternative productions, backtracking occurs to select other productions.

Separation of Process Specification and Execution Environment: Execution environment information such as complex control parameters and constraints is hidden from the process specification. The information of these two layers is merely linked together to show the current task being executed on a process flow. The represented process flow can be executed in both automatic and manual modes. In the automatic mode, the framework executes all possible combinations to find a solution. In the manual mode, users can explore design space.

Communication and Collaboration: To promote real-time collaboration among participants, the framework is equipped with the whiteboard, a communication medium to share information. Users can browse related processes, compare them with other processes, analyze, and simulate them. Locally managed process flows and productions can be integrated by the framework in the central server. The framework manages the production rules governing the higher level tasks, while lower level tasks and their productions are managed by local servers. This permits the framework to be effective in orchestrating a large-scale activity.

Efficient Search of Design Process and Solution: IMEDA is able to select the best process and generate a process plan, or select a production dynamically and create a process flow. The process grammar easily captures design alternatives. The execution environment selects and executes the best one. If the selected process does not meet the requirement, then the framework backtracks and selects another alternative. This backtrack occurs recursively until a solution is found. If you allow a designer to select the best solution among many feasible ones, the framework may generate many multiple versions of the solution.

Process Simulation: The quality of a product depends on the tools (maturity, speed, and special strength of the tool), process (or workflow selected), and design data (selected from the reuse library). Our framework predicts the quality of results (product) and assesses the risk and reliability. This information can be used to select the best process/workflow suitable for a project.

Parallel Execution of Several Processes and Multiple Versions: To reduce the design time and risk, it is necessary to execute independent tasks in parallel whenever they are available. Sometimes, it is necessary to investigate several alternatives simultaneously to reduce the design time and risk. Or the designer may want to execute multiple versions with different design parameters. The key issue in this case is scheduling the tasks to optimize the resource requirements.

Life Cycle Support of Process Management: The process can be regarded as a product. A process (such as airplane designing or shipbuilding) may last many years. During this time, it may be necessary for the process itself to be modified because of new tools and technologies. Life cycle support includes updating the process dynamically, and testing/validating the design process, version history and configuration management of the design process. Tests and validations of the design processes, the simulation of processes, and impact analysis are necessary tools.

10.4 Formal Representation of Design Process*

IMEDA uses a methodology specification based on a process flow graphs and process grammars (Baldwin and Chung, 1995). The grammar is an extension of graph grammar originally proposed by Ehrig (1979) and has been applied to interconnection network (Derk and DeBrunner, 1998) and software engineering (Heiman et al., 1997).

10.4.1 Process Flow Graph

A process flow graph depicts tasks, data, and the relationships among them, describing the sequence of tasks for an activity. Three basic symbols are used to represent a process flow graph. Oval nodes represent logical tasks, two-concentric oval nodes represent atomic tasks, rectangular nodes represent data specifications and diamond nodes represent selectors. A task that can be decomposed into subtasks is called *logical*. Logical task nodes represent abstract tasks that could be done with several different tools or tool combinations. A task that cannot be decomposed is *atomic*. An atomic task node, commonly called a tool invocation, represents a run of an application program.

A *selector* is a task node that selects data or parameter. Data specifications are design data, where the output specification produced by a task can be consumed by another task as an input specification. Each data specification node, identified by a rectangle, is labeled with a data specification type. Using the graphical elements of the flow graph, engineers can create a process flow in a top-down fashion. These elements can be combined into a process flow graph using directed arcs. The result is a bipartite acyclic directed graph that identifies clearly the task and data flow relationships among the tasks in a design activity. The set of edges indicates those data specifications used and produced by each task. Each specification must have at most one incoming edge. Data specifications with no incoming edges are inputs of the design exercise. $T(G)$, $S(G)$, and $E(G)$ are the sets of task nodes, specification nodes, and edges of graph G, respectively. Figure 10.4 shows a process flow graph that describes a possible rapid prototyping design process, in which a state diagram is transformed into a field-programmable gate array (FPGA) configuration file.

The various specification types form a class hierarchy where each child is a specialization of the parent. There may be several incompatible children. For example, VHDL and Verilog descriptions are both children of simulation models. We utilize these specification types to avoid data format incompatibilities between tools (Figure 10.5a). Process flow graphs can describe design processes to varying levels of detail. A graph containing many logical nodes abstractly describes what should be done without describing how

* Materials in this section are excerpted from Baldwin, R. and Chung, M.J., *IEEE Comput.*, February, 54, 1995a. With permission.

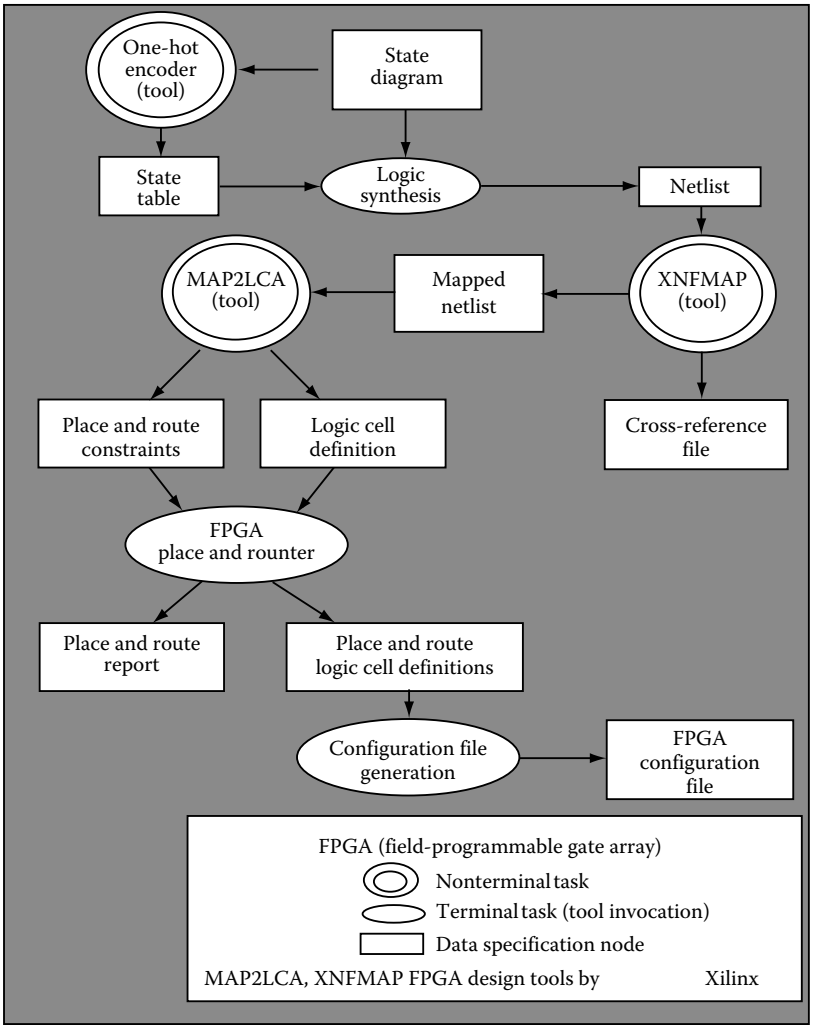

FIGURE 10.4 Sample process flow graph in which a state diagram is transformed into a field-programmable gate array configuration file.

it should be done (i.e., specifying which tools to use). Conversely, a graph in which all task nodes are atomic completely describes a methodology.

In our prototype, we use the following definitions: In(N) is the set of input nodes of node N: In(N) = $\{M \mid (M,N) \in E\}$. Out(N) is the set of output nodes of node N: Out(N) = $\{M \mid (N,M) \in E\}$. $I(G)$ is the set of input specifications of graph G: $\{N \in S(G) \mid \text{In}(N) = \emptyset\}$.

10.4.2 Process Grammars

The designer specifies the overall objectives with the initial graph that lists available input specifications, desired output specifications, and the logical tasks to be performed. By means of process grammars, logical task nodes are replaced by the flows of detailed subtasks and intermediate specifications. The output specification nodes are also replaced by nodes that may have a child specification type.

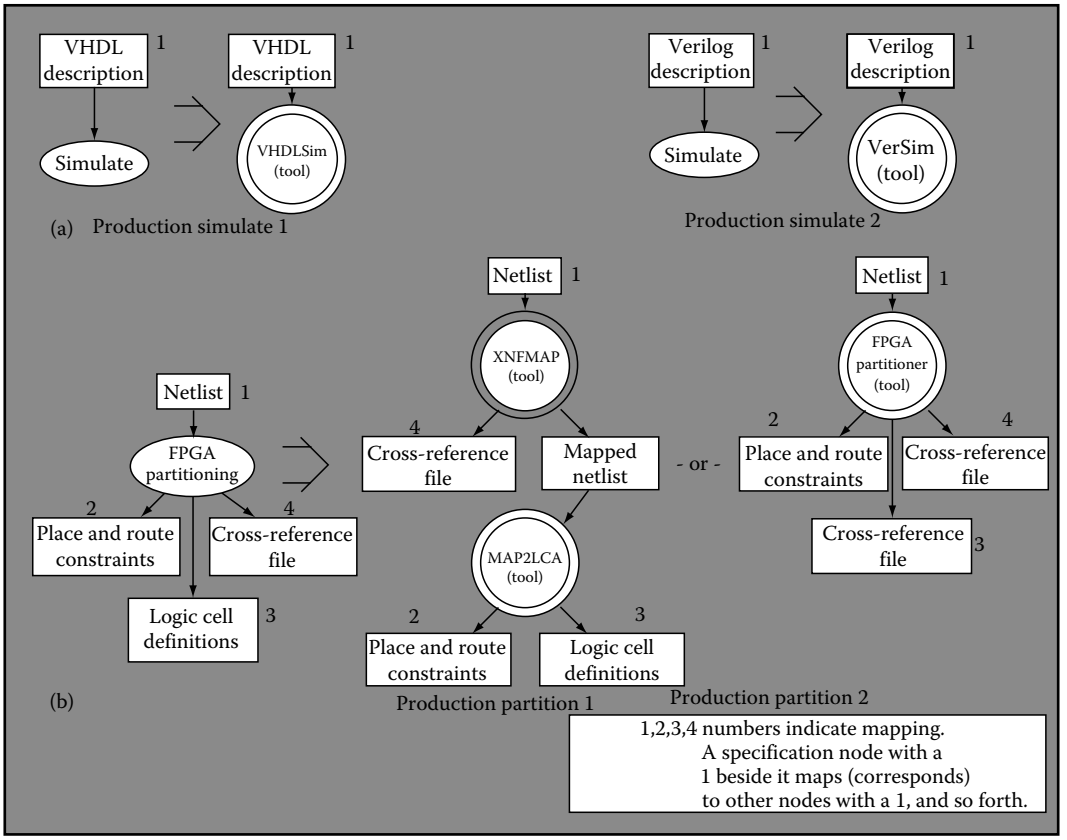

FIGURE 10.5 Graph production from a design process grammar. Two simulation alternatives based on input format are portrayed in (a); two partition alternatives representing different processes for an abstract task are portrayed in (b).

The productions in a graph grammar permit the replacement of one subgraph by another. A production in a design process grammar can be expressed formally as a tuple $P = (G_{LHS}, G_{RHS}, \sigma_{in}, \sigma_{out})$, where G_{LHS} and G_{RHS} are process flow graphs for the left side and the right side of the production, respectively, such that (1) G_{LHS} has one logical task node representing the task to be replaced, (2) σ_{in} is a mapping from the input specifications $I(G_{LHS})$ to $I(G_{RHS})$, indicating the relationship between two input specifications (each input specification of $I(G_{RHS})$ is a subtype of $I(G_{LHS})$), and (3) σ_{out} is a mapping from the output specifications of G_{LHS} to output specifications of G_{RHS} indicating the correspondence between them (each output specification must be mapped to a specification with the same type or a subtype). Figure 10.5 illustrates productions for two tasks, simulate and FPGA partitioning. The mappings are indicated by the numbers beside the specification nodes. Alternative productions may be necessary to handle different input specification types (as in Figure 10.5a), or because they represent different processes—separated by the word "or"—for performing the abstract task (as in Figure 10.5b).

Let A be the logical task node in G_{LHS} and A' be a logical task node in the original process flow graph G such that A has the same task label as A'. The production rule P can be applied to A', which means that A' can be replaced with G_{RHS} only if each input and output specifications of A' matches to input and output specifications of G_{LHS}, respectively. If there are several production rules with the same left side flow graph, it implies that there are alternative production rules for the logical task. Formally, the production matches A' if

1. A' has the same task label as A.
2. There is a mapping ρ_{in}, from In(A) to In(A'), indicating how the inputs should be mapped. For all nodes $N \in$ In(A), $\rho_{in}(N)$ should have the same type as N or a subtype.
3. There is a mapping, ρ_{out}, from Out(A') to Out(A), indicating how the outputs should be mapped. For all nodes $N \in$ Out(A'), $\rho_{out}(N)$ should have the same type as N or a subtype.

The mappings are used to determine how edges that connected the replaced subgraph to the remainder should be redirected to nodes in the new subgraph. Once a match is found in graph G, the production is applied as follows:

1. Insert $G_{RHS} - I(G_{RHS})$ into G. The inputs of the replaced tasks are not replaced.
2. For every N in $I(G_{RHS})$ and edge (N,M) in G_{RHS}, add edge ($\rho_{in}[\sigma_{in}(N)]$,$M$) to G. That is to connect the inputs of A' to the new task nodes that will use them.
3. For every N in Out(A') and edge (N,M) in G, replace edge (N,M) with edge ($\sigma_{out}[\rho_{out}(N)]$,$M$). That is to connect the new output nodes to the tasks that will use them.
4. Remove A' and Out(A') from G, along with all edges incident on them.

Figure 10.6 illustrates a derivation in which the FPGA partitioning task is planned, using a production from Figure 10.5b.

The process grammar provides mechanism of specifying alternative methods for a logical task. A high-level flow graph can then be decomposed into detailed flow graphs by applying *production rules* to a logical task. A *production rule* is a substitution that permits the replacement of a logical task node with a flow graph that represents a possible way of performing the task. The concept of applying productions to

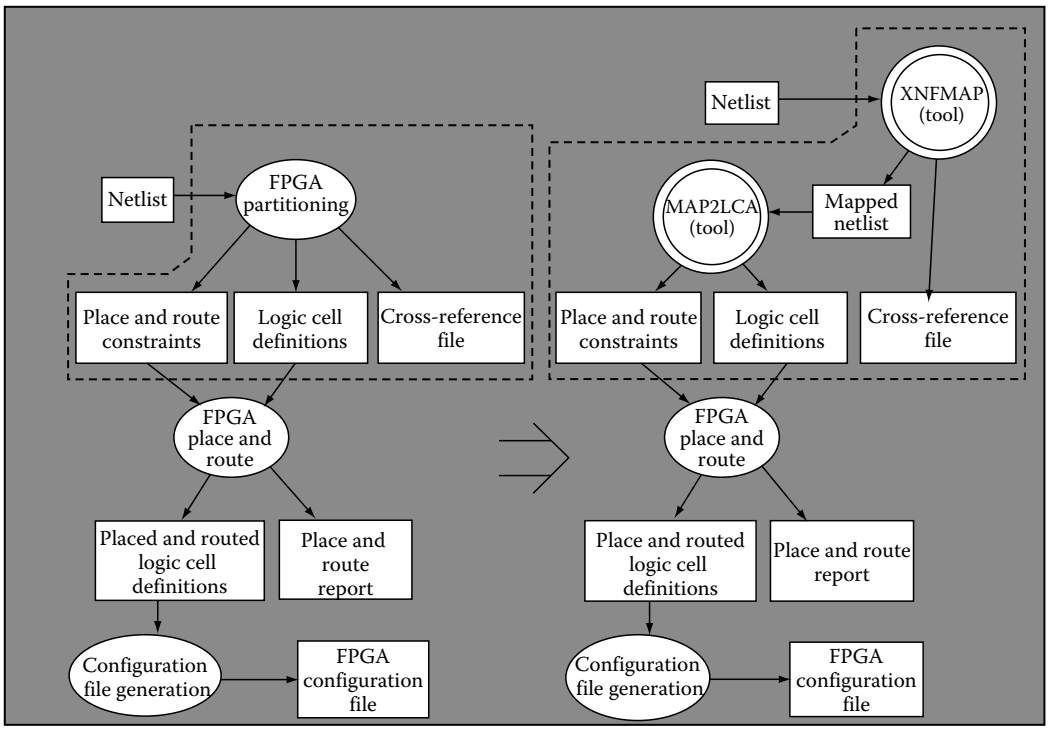

FIGURE 10.6 Sample graph derivation. Nodes in the outlined region, left, are replaced with nodes in the outlined region, right, according to production partition 1 in Figure 10.5.

logical tasks is somewhat analogous to the idea of productions in traditional (i.e., nongraph) grammars. In this sense, logical tasks correspond to *logical symbols* in grammar, and atomic tasks correspond to *terminal symbols*.

10.5 Execution Environment of the Framework

Figure 10.7 illustrates the architecture of our proposed system, which applies the theory developed in the previous section. Decisions to select or invoke tools are split between the designers and a set of manager programs, where manager programs are making the routine decisions and the designers make decisions that requires higher-level thinking. A program called Cockpit coordinates the interaction among manager programs and the designers. Tool sets and methodology preferences will differ among sites and over time. Therefore, our assumption is that each unit designates a person (or group) to act as system integrator, who writes and maintains the tool-dependent code in the system. We provide the tool-independent code and template to simplify the task of writing tool-dependent code.

10.5.1 Cockpit Program

The designer interacts with Cockpit, a program which keeps track of the current process flow graph and informs the designer of possible actions such as productions that could be applied or tasks that could be executed. Cockpit contains no task-specific knowledge; its information about the design process comes entirely from a file of graph productions. When new tools are acquired or new design processes are developed, the system integrator modifies this file by adding, deleting, and editing productions.

To assist the designer in choosing an appropriate action, Cockpit interacts with several manager programs which encapsulate design knowledge. There are two types of manager programs: task managers and production managers. Task managers invoke tools and determine which productions to execute for

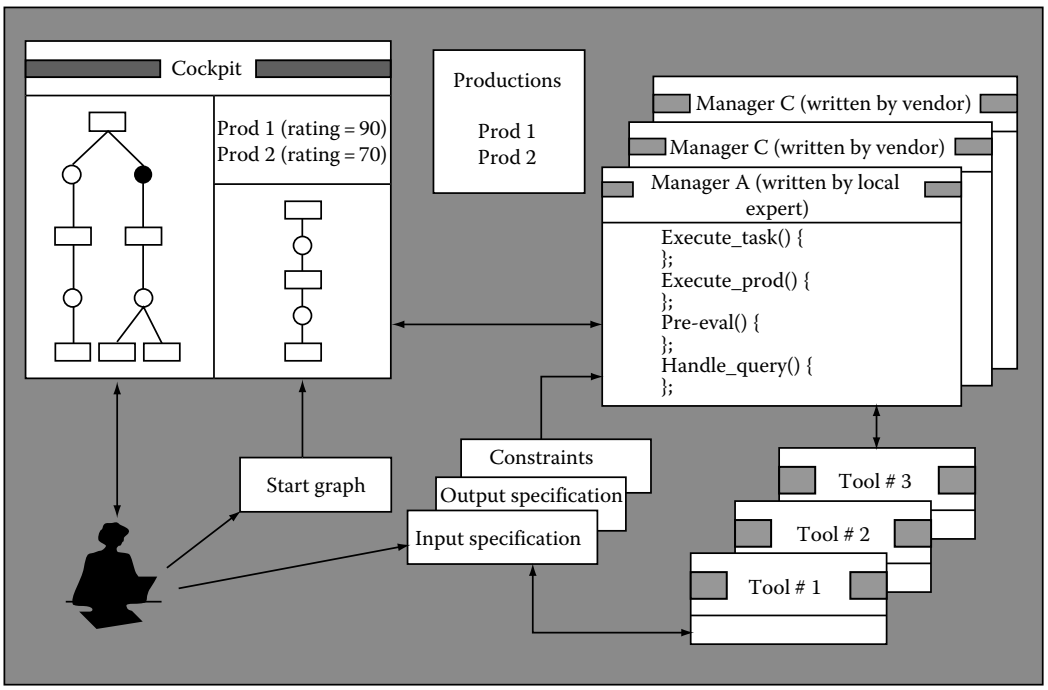

FIGURE 10.7 Proposed system based on Cockpit.

logical task nodes. Production managers provide ratings for the productions and schedule the execution of tasks on the right-hand side of the production. Managers communicate with each other using messages issued by Cockpit.

Our prototype system operates as follows. Cockpit reads the initial process flow graph from an input file generated by using a text editor. Cockpit then iteratively identifies when productions can be applied to logical task nodes and requests that the production managers assign the ratings to indicate how appropriate the productions are for those tasks. The process flow graph and the ratings of possible production applications are displayed for the designer, who directs Cockpit through a graphical user interface to apply a production or execute a task at any time. When asked to execute a task, Cockpit sends a message to a task manager. For an atomic task node, the task manager simply invokes the corresponding tool. For a logical task, the task manager must choose one or more productions, as identified by a Cockpit. The Cockpit applies the production and requests that the production manager executes it.

10.5.2 Manager Programs

Manager programs must be maintained by system integrators to reflect site-specific information, such as company design practices and tool installation methods. Typically, a manager program has its own thread. A Cockpit may have several manager programs, and therefore multithreads. We define a communication protocol between Cockpit and manager programs and provide templates for manager programs. The manager programs provide five operations: preevaluation, tool invocation, logical task execution, production execution, and query handling. Each operation described below corresponds to a C++ or Java function in the templates, which system integrators can customize as needed.

Preevaluation: Production managers assign ratings to help designers and task managers select the most appropriate productions. The rating indicates the likelihood of success from applying this production. The strategies used by the system integrator provide most of the code to handle the rating. In some cases, it may be sufficient to assign ratings statically, based on the success of past productions. These static ratings can be adjusted downward when the production has already been tried unsuccessfully on this task node (which could be determined using the query mechanism). Alternatively, the ratings may be an arbitrarily complex function of parameters obtained through the query mechanism or by examining the input files. Sophisticated manager programs may continuously gather and analyze process metrics that indicate those conditions leading to success, adjust adjusting ratings accordingly.

Tool Invocation: Atomic task mangers must invoke the corresponding software tool when requested by Cockpit, then determine whether the tool completed successfully. In many cases, information may be predetermined and entered in a standard template, which uses the tool's result status to determine success. In other cases, the manager must determine tool parameters using task-specific knowledge or determine success by checking task-specific constraints. Either situation would require further customization of the manager program.

Logical Task Execution: Logical task managers for logical tasks must select productions to execute the logical task. Cockpit informs the task manager of available productions and their ratings. The task manager can either direct Cockpit to apply and execute one or more productions, or it can decide that none of the productions is worthwhile and report failure. The task manager can also request that the productions be reevaluated when new information has been generated that might influence the ratings, such as a production's failure. If a production succeeds, the task manager checks any constraints; if they are satisfied, it reports success.

Production Execution: Production managers execute each task on the right-hand side of the production at the appropriate time and possibly check constraints. If one of the tasks fails or a constraint is violated, backtracking can occur. The production manager can use task-specific knowledge to determine which

tasks to repeat. If the production manager cannot handle the failure itself, it reports the failure to Cockpit, and the managers of higher level tasks and productions attempt to handle it.

Query Handling: Both production and task managers participate in the query mechanism. A production manager can send queries to its parent (the task manager for the logical task being performed) or to one of its children (a task manager of a subtask). Similarly, a task manager can send a query to its parent production manager or to one of its children (a production manager of the production it executed). The manager templates define C functions, which take string arguments, for sending these queries. System integrators call these functions but do not need to modify them. The manager templates also contain functions which are modified by system integrators for responding to queries. Common queries can be handled by template code; for example, a production manager can frequently ask its parent whether the production has already been attempted for that task and whether it succeeded. The manager template handles any unrecognized query from a child manager by forwarding it to the parent manager. Code must be added to handle queries for task-specific information such as the estimated circuit area or latency.

10.5.3 Execution Example

Now we describe a synthesis scenario that illustrates our prototype architecture in use. In this scenario, the objective is to design a controller from a state diagram, which will ultimately be done following the process flow graph in Figure 10.4. There are performance and cost constraints on the design, and the requirement to produce a prototype quickly. The productions used are intended to be representative but not unique. For simplicity, we assume that a single designer is performing the design with, therefore, only one Cockpit.

The start graph for this scenario contains only the primary task, chip synthesis, and specification nodes for its inputs and outputs (like the graph in the left in Figure 10.8). Cockpit tells us that the production of Figure 10.8 can be applied. We ask Cockpit to apply it. The chip synthesis node is then replaced by nodes for state encoding, logic synthesis, and physical synthesis, along with intermediate specification nodes.

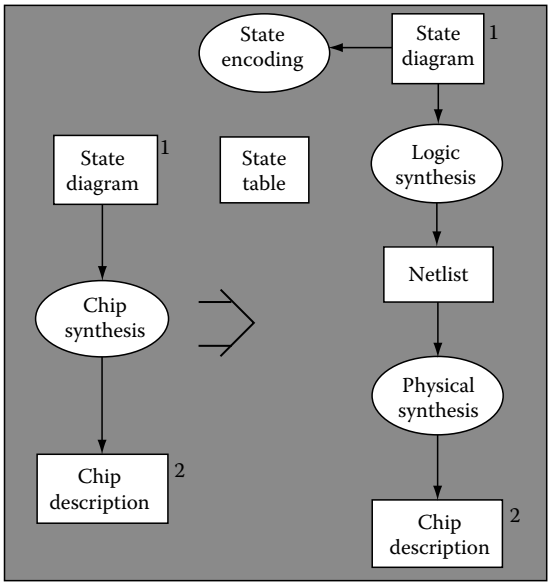

FIGURE 10.8 Productions for chip synthesis.

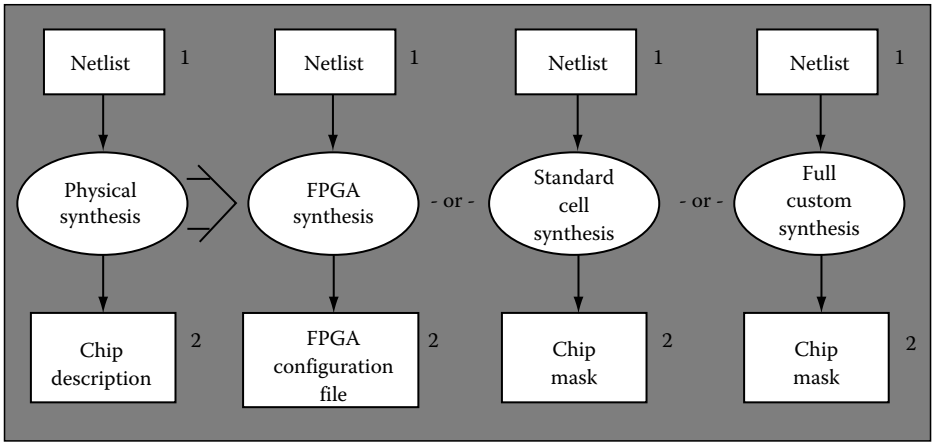

FIGURE 10.9 Productions for physical synthesis.

Next, we want to plan the physical synthesis task. Tasks can be planned in an order other than they are to be performed. Cockpit determines that any of the productions shown in Figure 10.9 may be applied, then queries each production's task manager program asking it to rate the production's appropriateness in the current situation. Based on the need to implement the design quickly, the productions for standard cell synthesis and full custom synthesis are rated low while the production for FPGA synthesis is rated high. Ratings are displayed to help us decide.

When we plan the state encoding task, Cockpit finds two productions: one to use the tool Minbits encoder and the other to use the tool One-hot encoder. One-hot encoder works well for FPGAs, while Minbits encoder works better for other technologies. To assign proper ratings to these productions, their production managers must find out which implementation technology will be used. First, they send a query to their parent manager, the state encoding task manager. This manager forwards the message to its parent, the chip synthesis production manager. In turn, this manager forwards the query to the physical synthesis task manager for an answer. All messages are routed by Cockpit, which is aware of the entire task hierarchy. This sequence of actions is illustrated in Figure 10.10.

After further planning and tool invocations, a netlist is produced for our controller. The next step is the FPGA synthesis task. We apply the production in Figure 10.11 and proceed to the FPGA partitioning task. The knowledge to automate this task has already been encoded into the requisite manager programs, so we direct Cockpit to execute the FPGA partitioning task. It finds the two productions illustrated in Figure 10.5b and requests their ratings, Next, Cockpit sends an execute message, along with the ratings, to the FPGA partitioning task manager. This manager's strategy is to always execute the highest-rated production, which in this case is production Partition 1. (Other task managers might have asked that both productions be executed or, if neither were promising, immediately reported failure.) This sequence of actions is shown in Figure 10.12.

Because the Partition 1 manager used an as-soon-as-possible task scheduling strategy, it asks Cockpit to execute XNFMAP immediately. The other subtask, MAP2LCA, is executed when XNFMAP complete successfully. After both tasks complete successfully, Cockpit reports success to the FPGA partitioning task manager. This action sequence is illustrated in Figure 10.13.

10.5.4 Scheduling

In this section, we describe a detailed description and discussion of auto-mode scheduling, including the implementation of the *linear scheduler*. The ability to search through the configuration space of a design process for a design configuration that meets user-specified constraints is important. For example,

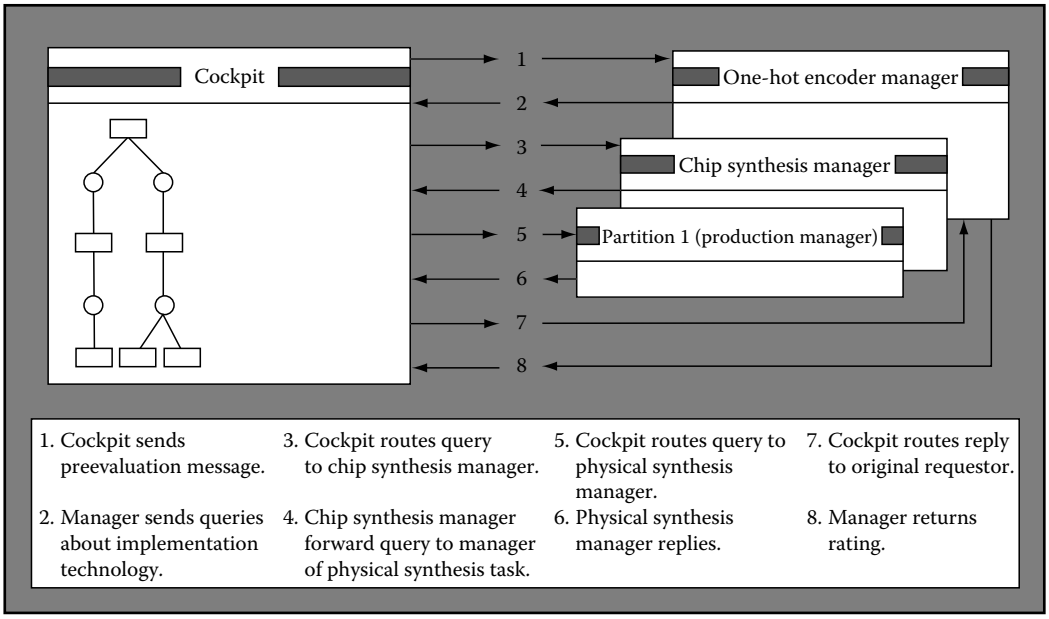

FIGURE 10.10 Sequence of actions for query handling.

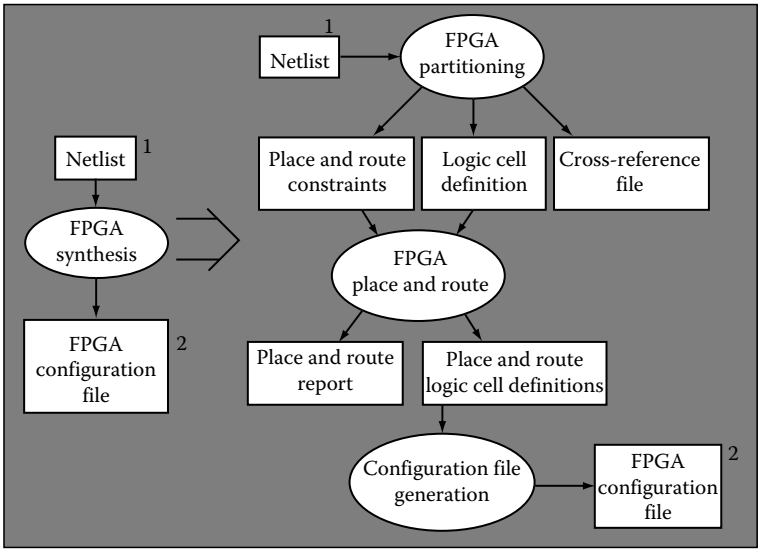

FIGURE 10.11 Production for field-programmable gate array.

assume that a user has defined a process for designing a digital filter with several different alternative ways of performing logical tasks such as ''FPGA Partitioning'' and ''Select the Filter Architecture.'' One constraint that an engineer may wish to place on the design might be: ''Find a process configuration that produces a filter that has maximum delay at most 10 ns.'' Given such a constraint, the framework must search through the configuration space of the filter design process, looking for a sequence of valid atomic tasks that produces a filter with ''maximum delay at most 10 ns.'' We call the framework component that

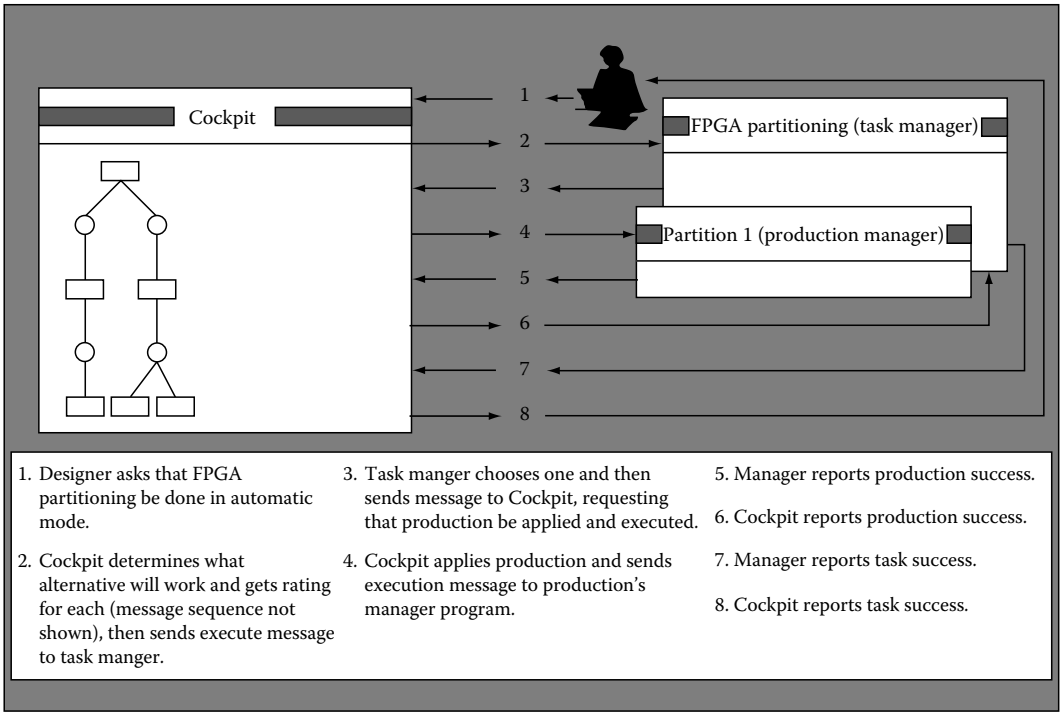

FIGURE 10.12 Sequence of action during automatic task execution.

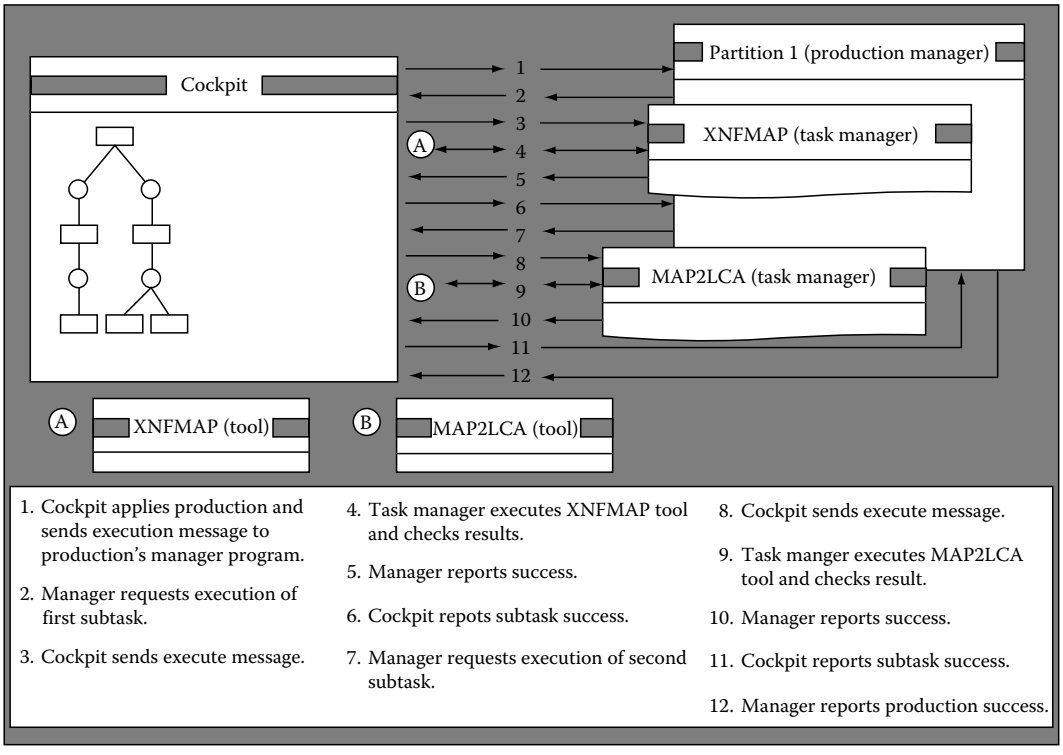

FIGURE 10.13 Sequence of actions during automatic production execution.

performs this search a *scheduler*. There are, of course, many different ways of searching through the design process configuration space. In general, a successful scheduler will provide the following functionality:

- **Completeness (Identification of Successful Configurations):** Given a particular configuration of a process, the correct scheduler will be able to conclusively determine whether the configuration meets user-specified constraints. The scheduler must guarantee that before reporting failure, all possible process configurations have been considered, and if there is a successful configuration, the algorithm must find it.
- **Reasonable Performance:** The configuration space of a process grows exponentially (in the number of tasks). Ideally, a scheduler will be able to search the configuration space using an algorithm that requires less than exponential time.

The Linear Scheduling Algorithm is very simple yet complete and meets most of the above criteria. In this algorithm, for each process flow graph (corresponding to an initial process flow graph or a production), it has a scheduler. Each scheduler is a separate thread with a *Task Schedule List* (TSL) representing the order in which tasks are to be executed. The tasks in a scheduler's TSL are called its children tasks. A scheduler also has a *task pointer* to indicate the child task being executed in the TSL. The algorithm is recursive such that with each new instantiation of a production of a given task, a new scheduler is created to manage the flow graph representing the production selected. A liner scheduler creates a TSL by performing a topological sort of the initial process flow graph and executes its children tasks in order. If a child task is atomic, the scheduler executes the task without creating a new scheduler; otherwise, it selects a new alternative, creates a new child scheduler to manage the selected alternative, and waits for a signal from the child scheduler indicating success or failure. When a child task execution is successful, the scheduler increments the *task pointer* in its TSL and proceeds to execute the next task. If a scheduler reaches the end of its TSL, it signals success to its own parent, and awaits signals from its parent if it should terminate itself (all successful) or rollback (try another to find new configurations). If a child task fails, the scheduler tries another alternative for the task. If there is no alternatives left, it rolls back (by decrementing the task pointer) until it finds a logical task that has another alternative to try. If a scheduler rolls back to the beginning of the TSL and cannot find an alternative, then its flow has failed. In this case, it signals a failure to its parent and terminates itself.

In the linear scheduling algorithm, each scheduler can send or receive any of five signals: PROCEED, ROLLBACK, CHILD-SUCCESS, CHILD-FAILURE, and DIE. These signals comprise scheduler-to-scheduler communication, including self-signaling. Each of the five signals is discussed below.

- **PROCEED:** This signal tells the scheduler to execute the next task in the TSL. It can be self-sent or received from a parent scheduler. For example, a scheduler increments its task pointer and sends itself a PROCEED signal when a child task succeeds, whereas it sends a PROCEED signal to its children to start its execution.
- **ROLLBACK:** This is signaled when a task execution has failed. This signal may be self-sent or received from a parent scheduler. Scheduler self-signals ROLLBACK whenever a child task fails. A Rollback can result in either trying the next alternative of a logical task, or decrementing the task pointer and trying the previous task in the TSL. If rollback results in decrementing the task pointer to point to a child task node which has received a success-signal, the parent scheduler will send a rollback signal to that child task scheduler.
- **CHILD-SUCCESS:** A child scheduler sends a CHILD-SUCCESS to its parent scheduler if it has successfully completed the execution of all of the tasks in its TSL. After sending the child-success signal, the scheduler remains active, listening for possible rollback signals from the parent. After receiving a child-success signal, parent schedulers self-send a proceed signal.
- **CHILD-FAILURE:** A child-failure signal is sent from a child scheduler to its parent in the event that the child's managed flow fails. After sending a child-failure signal, children

schedulers terminate. Upon receiving child-failure signals, parent scheduler self-send a rollback signal.

- **DIE:** This signal may be either self-sent, or sent from parent schedulers to their children schedulers.

10.6 Implementation

In this section, a high level description of the major components of IMEDA and their organization and functionality will be presented. Detailed explanations of the key concepts involved in the architecture of the Process Management Framework will also be discussed, including external tool integration, the tool invocation process, the Java File System, and state properties.

10.6.1 System Cockpit

The System Cockpit, as its name suggests, is shown in Figure 10.14 where nearly all user interaction with the framework takes place. It is here that users create, modify, save, load, and simulate process flow graphs representing design processes. This system component has been implemented as a Java applet. As such, it is possible to run the cockpit in any Java-enabled Web browser such as Netscape's Navigator

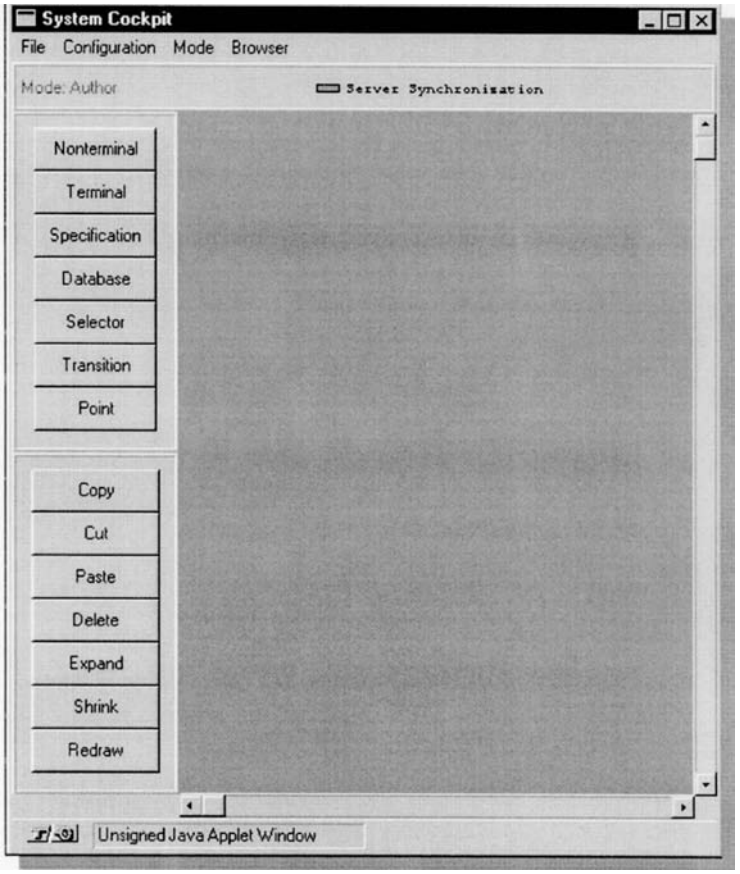

FIGURE 10.14 System Cockpit window.

or Microsoft's Internet Explorer. It is also possible to run the cockpit in some Java-enabled operating systems such as IBM's OS/2.

Each cockpit component also has the following components:

- **Root Flow:** Every cockpit has a Root Flow. The Root Flow is the flow currently being edited in the Cockpit's Flow Edit Panel. Notice that the Root Flow may change as a result of applying a production to a flow graph, in which case the Root Flow becomes a derivation of itself.
- **Flow Edit Panel:** The Flow Edit Panel is the interactive Graphical User Interface for creating and editing process flow graphs. This component also acts as a display for animating process simulations performed by various schedulers such as the manual or auto-mode linear scheduler.
- **Class Directory:** The Cockpit has two Class Directories: Task Directory and the Specification Directory. These directories provide the ''browser'' capabilities of the framework, allowing users to create reusable general-to-specific hierarchies of task classes. Class Directories are implemented using a *tree* structure.
- **Production Database:** The Production Database acts as a warehouse for logical task productions. These productions document the alternative methods available for completing a logical task. Each Production Database has a list of Productions. The Production Database is implemented as a tree-like structure, with Productions being on the root trunk, and Alternatives being leaves.
- **Browser:** Browsers provide the tree-like graphical user interface for users to edit both Class Directories and Databases. There are three Browsers: Database Browser for accessing the Production Database, Directory Browser for accessing the Task Directory, and Directory Browser for accessing the Spec Browser. Both Database Browsers and Directory Browsers inherit properties from object Browser, and offer the user nearly identical editing environments and visual representations. This deliberate consolidation of Browser interfaces allowed us to provide designers with an interface that was consistent and easier to learn.
- **Menu:** A user typically performs and accesses most of the system's key function from the Cockpit's Menu.
- **Scheduler:** The Cockpit has one or more schedulers. Schedulers are responsible for searching the configuration space of a design process for configurations that meet user specified design constraints. The Scheduler animates its process simulations by displaying them in the Flow Edit Panel of the Cockpit.

10.6.2 External Tools

External Tools are the concrete entities to which atomic tasks from a production flow are bound. When a flow task object is expanded in the Cockpit Applet (during process simulation), the corresponding external tool is invoked. The external tool uses a series of inputs and produces a series of outputs (contained in files). These inputs and outputs are similarly bound to specifications in a production flow. Outputs from one tool are typically used as inputs for another. IMEDA can handle the transfer of input and output files between remote sites. The site proxy servers, in conjunction with a remote file server (also running at each site) automatically handle the transfer of files from one system to another. External tools may be implemented using any language, and on any platform that has the capability of running a site server. While performing benchmark tests of IMEDA, we used external tools written in C, Fortran, Perl, csh (a Unix shell script), Java applications, and Mathematica scripts.

10.6.2.1 External Tool Integration

One of the primary functionality of IMEDA is the integration of user-defined external tools into an abstract process flow. IMEDA then uses these tools both in simulating the process flow to find a flow configuration that meets specific constraints, and in managing selected flow configurations during actual design execution.

There are two steps to integrating tools with a process flow defined in IMEDA: *association* and *execution*. Association involves ''linking'' or ''binding'' an abstract flow item (e.g., an atomic task) to an external tool. Execution describes the various steps that IMEDA takes to actually invoke the external tool and process the results.

10.6.2.2 Binding Tools

External tools may be bound to three types of flow objects: atomic tasks, selectors, and multiple version selectors. Binding an external tool to a flow object is a simple and straightforward job, involving simply defining certain properties in the flow object.

The following properties must be defined in an object that is to be bound to an external tool:

- **SITE:** Due to the fact that IMEDA can execute tools on remote systems, it is necessary to specify the site where the tool is located on. Typically, a default SITE will be specified in the system defaults, and making it unnecessary to define the site property unless the default is to be overriden. Note that the actual site ID specified by the SITE property must refer to a site that is running a site proxy server listening on that ID. See the ''Executing External Tools'' section below for more details.
- **CMDLINE:** The CMDLINE property specifies the command to be executed at the specified remote site. The CMDLINE property should include any switches or arguments that will always be sent to the external tool. Basically, the CMDLINE argument should be in the same format that would be used if the command were executed from a shell/DOS prompt.
- **WORKDIR:** The working directory of the tool is specified by the WORKDIR property. This is the directory in which IMEDA will actually execute the external tool, create temporary files, etc. This property is also quite often defined in the global system defaults, and thus may not necessarily have to be defined for every tool.
- **WRAPPERPATH:** The JDK 1.0.2 does not allow Java applications to execute a tool in an arbitrary directory. To handle remote tool execution, a wrapper is provided. It is a ''go-between'' program that would simply change directories and then execute the external tool. This program can be as simple as a DOS/NT batch file, a shell script, or a perl program. The external tool is wrapped in this simple script, and executed. Since IMEDA can execute tools at remote and heterogeneous sites, it was very difficult to create a single wrapper that would work on all platforms (WIN32, Unix, etc.). Therefor, the wrapper program may be specified for each tool, defined as global default, or a combination of the two.

Once the properties above have been defined for a flow object, the object is said to be ''bound'' to an external tool. If no site, directory, or filename is specified for the outputs of the flow object, IMEDA automatically creates unique file names, and stores the files in the working directory of the tool on the site that the tool was run. If a tool uses as inputs data items that are not specified by any other task, then the data items must be bound to static files on some site.

10.6.2.3 Executing External Tools

Once flow objects have been bound to the appropriate external tools, IMEDA can be used to perform process simulation or process management. IMEDA actually has several ''layers'' that lie between the Cockpit (a Java applet) and the external tool that is bound to a flow being viewed by a user in the Cockpit. A description of each of IMEDA components for tool invocations is listed below:

- **Tool Proxy:** The tool proxy component acts as a liaison between flow objects defined in Cockpits and the site proxy server. All communication is done transparently through the communication server utilizing TCP/IP sockets. The tool proxy ''packages'' information from Cockpit objects (atomic tasks, selectors, etc.) into string messages that the proxy server will recognize. It also listens

for and processes messages from the proxy server (through the communications server) and relays the information back to the Cockpit object that instantiated the tool proxy originally.

- **Communications Server:** Due to various security restrictions in the 1.0.2 version of Sun Microsystem's Java Development Kit (JDK), it is impossible to create TCP/IP socket connections between a Java applet and any IP address other than the address from which the applet was loaded. Therefore, it was necessary to create a ''relay server'' in order to allow cockpit applets to communicate with remote site proxy servers. The sole purpose of the communications server is to receive messages from one source and then to rebroadcast them to all parties that are connected and listening on the same channel.
- **Site Proxy Server:** Site proxy servers are responsible for receiving and processing invocation requests from tool proxies. When an invocation request is received, the site proxy server checks to see that the request is formatted correctly, starts a tool monitor to manage the external tool invocation, and returns the exit status of the external tool after it has completed.
- **Tool Monitors:** When the site proxy server receives an invocation request and invokes an external tool, it may take a significant amount of time for the tool to complete. If the proxy server had to delay the handling of other requests while waiting for each external tool to complete, IMEDA would become very inefficient. For this reason, the proxy server spawns a tool monitor for each external tool that is to be executed. The tool monitor runs as a separate thread, waiting on the tool, storing its stdout and stderr, and moving any input or output files that need moving to their appropriate site locations, and notifying the calling site proxy server when the tool has completed. This allows the site proxy server to continue receiving and processing invocation requests in a timely manner.
- **Tool Wrapper:** Tool wrapper changes directories into the specified WORKDIR, and then executes the CMDLINE.
- **External Tool:** External tools are the actual executable programs that run during a tool invocation. There is very little restriction on the nature of the external tools.

10.6.3 Communications Model

The Communications Model of IMEDA is perhaps the most complex portion of the system in some respects. This is where truly *distributed* communications come into play. One system component is communicating with another via network messages rather than function calls.

The heart of the communications model is the Communications Server. This server is implemented as a broadcast server. All incoming messages to the server are simply broadcast to all other connected parties. FlowObjects communicate with the Communications Server via ToolProxys. A ToolProxy allows a FlowObject to abstract all network communications and focus on the functionality of invoking tasks. A ToolProxy takes care of constructing a network message to invoke an external tool. That message is then sent to the Communications Server via a Communications Client. The Communication Client takes care of the low-level socket based communication complexities. Finally, the Communications Client sends the message to the Communications Server, which broadcasts the message to all connected clients. The client for which the message was intended (typically a site proxy server) decodes the message and, depending on its type, creates either a ToolMonitor (for an Invocation Message) or an External Redraw Monitor (for a Redraw Request).

The site proxy server creates these monitors to track the execution of external programs, rather than monitoring them itself. In this way, the proxy server can focus on its primary job—receiving and decoding network messages. When the monitors invoke an external tool, they must do so within a wrapper. Once the monitors have observed the termination of an external program, they gather any output on *stdout* or *stderr* and return these along with the exit code of the program to the site proxy server. The proxy server returns the results to the Communications Server, then the Communications Client, then the ToolProxy, and finally to the original calling FlowObject.

10.6.4 User Interface

The Cockpit provides both the user interface and core functionality of IMEDA. While multiple users may use different instances of the Cockpit simultaneously, there is currently no provision for direct collaboration between multiple users. Developing efficient means of real-time interaction between IMEDA users is one of the major thrusts of the next development cycle.

Currently the GUI of the Cockpit provides the following functionalities:

- **Flow Editing:** Users may create and edit process flows using the flow editor module of the Cockpit. The flow editor provides the user with a simple graphical interface that allows the use of a template of tools for ''drawing'' a flow. Flows can be optimally organized via services provided by a remote Layout Server written in Perl.
- **Production Library Maintenance:** The Cockpit provides functionality for user maintenance of collections of logical task productions, called libraries. Users may organize productions, modify input/output sets, or create/edit individual productions using flow editors.
- **Class Library Maintenance:** Users are provided with libraries of task and specification classes that are organized into a GS hierarchy. Users can instantiate a class into an actual task, specification, selector, or database when creating a flow by simply dragging the appropriate class from a class browser and dropping it onto a flow editor's canvas. The Cockpit provides the user with a simple tree structure interface to facilitate the creation and maintenance of class libraries.
- **Process Simulation:** Processes may be simulated using the Cockpit. The Cockpit provides the user with several scheduler modules that determine how the process configuration space will be explored. The schedulers control the execution of external tools (through the appropriate site proxy servers) and simulation display (flow animation for user monitoring of simulation progress). There are multiple schedulers for the user to choose from when simulating a process, including the manual scheduler, comprehensive linear scheduler, etc.
- **Process Archival:** The Cockpit allows processes to be archived on a remote server using the Java File System (JFS). The Cockpit is enabled by a JFS client interface to connect to a remote JFS server where process files are saved and loaded. While the JFS has its clear advantages, it is also awkward to not allow users to save process files, libraries, etc. on their local systems. Until version 1.1 of the Java Development Kit, local storage by a Java applet was simply not an option—the browser JVM definition did not allow access to most local resources. With version 1.1 of the JDK, however, comes the ability to electronically sign an applet. Once this has been done, users can grant privileged resource access to specific applets after a signature has been verified.

10.6.4.1 Design Flow Graph Properties

Initially, a flow graph created by a user using GUI is not associated with any system-specific information. For example, when a designer creates an atomic task node in a flow graph, there is initially no association with any external tool. The framework must provide a mechanism for users to bind flow graph entities to the external tools or activities that they represent.

We have used the concept of *properties* to allow users to bind flow graph objects to external entities. In an attempt to maintain flexibility, properties have been implemented in a very generic fashion. Users can define any number of properties for flow object. There are a number of key properties that the framework recognizes for each type of flow object. The user defines these properties to communicate needed configuration data to the framework.

A property consists of a *property label* and *property contents*. The label identifies the property, and consists of an alphanumeric string with no white space. The content of a property is any string. Currently users define properties using a freeform text input dialog, with each line defining a property. The first word on a line represents the property label, and the remainder of the line constitutes the property contents.

10.6.4.2 Property Inheritance

To further extend the flexibility of flow object properties, the framework requires that each flow object be associated with a *flow object class*. Classes allow designers to define properties that are common to all flow objects that inherit from that flow object class. Furthermore, classes are organized into a general-to-specific hierarchy, with children classes inheriting properties from parent classes.

Therefore, the properties of a particular class consist of any properties defined locally for that object, in addition to properties defined in the object's inherited class hierarchy. If a property is defined in both the flow object and one of its parent classes, the property definition in the flow object takes precedence. If a property is defined in more than one class in a class hierarchy, the ''youngest'' class (e.g., the child in a parent–child relationship) takes precedence.

Classes are defined in the Class Browsers of IMEDA. Designers that have identified a clear general-to-specific hierarchy of flow object classes can quickly create design flow graphs by dragging and dropping from class browsers onto flow design canvases. The user would then need only to overload those properties in the flow objects that are different from their respective parent classes (Figure 10.15).

For example, consider a class hierarchy of classes that all invoke the same external sort tool, but pass different flags to the tool, based on the context. It is likely that all of these tools will have properties in common, such as a common working directory and tool site. By defining these common properties in a common ancestor of all of the classes, such as *Search*, it is unnecessary to redefine the properties in the children classes.

Of course, children classes can define new properties that are not contained in the parent classes, and may also overload property definitions provided by ancestors. Following these rules, class *Insertion* would have the following properties defined: WORKDIR, SITE, WRAPPERPATH, and CMDLINE (Figure 10.16).

10.6.4.3 Macro Substitution

While performing benchmarks on IMEDA, one cumbersome aspect of the framework that users often pointed out was the need to reenter properties for tasks or specifications if, for example, a tool name or working directory changed. Finding every property that needed to be changed was a tedious job, and prone to errors.

In an attempt to deal with this problem, we came up with the idea of *property macros*. That is, a property macro is any macro that is not a key system macro. A macro is a textual substitution rule that

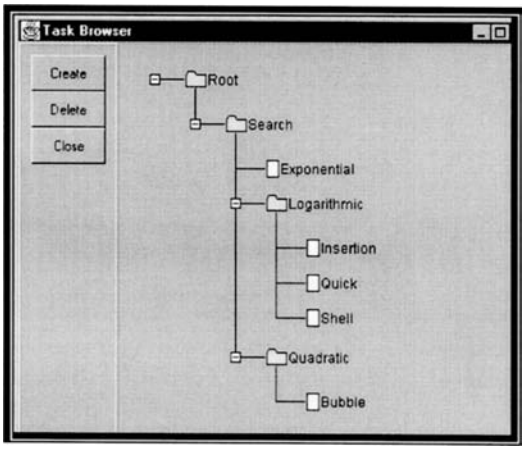

FIGURE 10.15 Task browser.

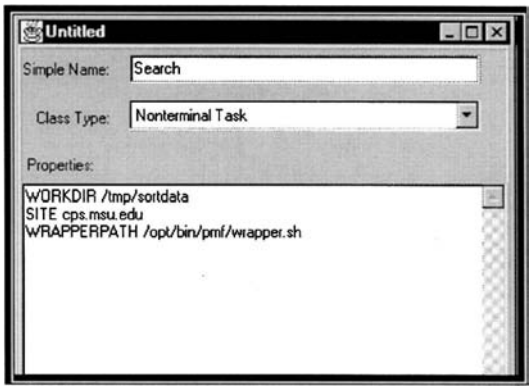

FIGURE 10.16 Property window and property inheritance.

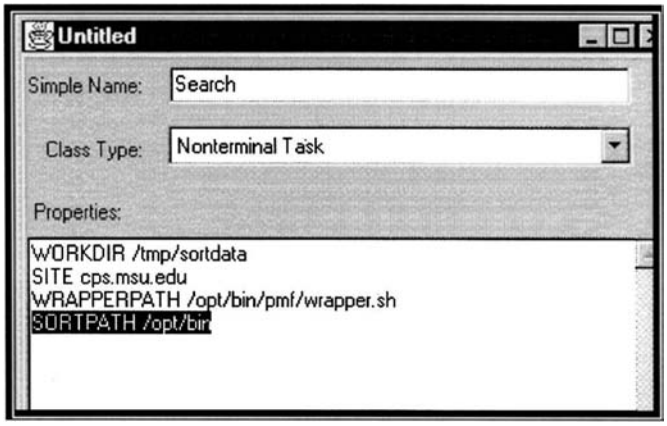

FIGURE 10.17 Macro definition.

can be created by users. By using macros in the property databases of flow objects, design flows can be made more flexible and more amiable to future changes.

As an example, consider a design flow that contains many atomic tasks bound to an external tool. Our previous example using searches is one possible scenario. On one system, the path to the external tool may be ''/opt/bin/sort,'' while on another system the path is ''/user/keyesdav/public/bin/sort.'' Making the flow object properties flexible is easy if a property macro named SORTPATH is defined in an ancestor of all affected flow objects (Figure 10.17). Children flow objects can then use that macro in place of a static path when specifying the flow object properties. As a further example, consider a modification to the previous ''Search task hierarchy'' where we define a macro SORTPATH in the Search class, and then use that macro in subsequent children classes, such as the Insertion class.

In the highlighted portion of the Property Database text area, a macro called ''SORTPATH'' is defined. In subsequent class' Property Databases, this macro can be used in place of a static path. This makes it easy to change the path for all tools that use the SORTPATH property macro—just the property database dialog where SORTPATH is originally defined needs to be modified (Figure 10.18).

10.6.4.4 Key Framework Properties

In our current implementation of IMEDA, there are a number of key properties defined. These properties allow users to communicate needed information to the framework in a flexible fashion. Most importantly,

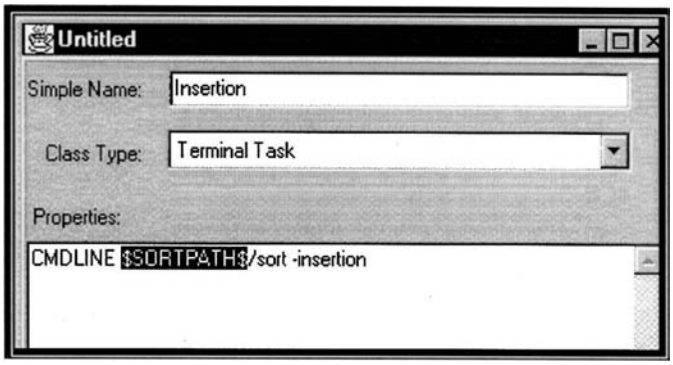

FIGURE 10.18 Macro substitution.

it allows system architects to define or modify system properties quickly. This is an important benefit when working with evolving software such as IMEDA.

10.7 Conclusion

Managing the design process is the key factor to improve the productivity in the microelectronic industry. We have presented an Internet-based Microelectronic Design Automation (IMEDA) framework to manage the design process. IMEDA uses a powerful formalism, called design process grammars, for representing design processes. We have also proposed an execution environment that utilizes this formalism to assist designers in selecting and executing appropriate design processes. The proposed approach is applicable not only in rapid prototyping but also in any environment where a design is carried out hierarchically and many alternative processes are possible.

The primary advantages of our system are

- **Formalism:** A strong theoretical foundation enables us to analyze how our system will operate with different methodologies.
- **Parallelism:** In addition to performing independent tasks within a methodology in parallel, our system also allows multiple methodologies to be executed in parallel.
- **Extensibility:** New tools can be integrated easily by adding productions and manager programs.
- **Flexibility:** Many different control strategies can be used. They can even be mixed within the same design exercise.

The prototype of IMEDA is implemented using Java. We are currently integrating more tools into our prototype system and developing manager program templates that implement more sophisticated algorithms for preevaluation, logical task execution, and query handling. Our system will become more useful as CAD vendors to adapt open software systems and allow greater tool interoperability.

11.1 Introduction

A *system* is a collection of interdependent operational components that together accomplish a complex task. Examples of systems range from cellular phones to camcorders to satellites. Projections point to a continuous increase in the complexity of systems in the coming years.

The term system, when used in the digital design domain, connotes many different entities. A system can consist of a processor, memory, and input/output, all on a single integrated circuit (IC), or can consist of a network of processors, geographically distributed, all performing a specific application. There can be a single clock, with modules communicating synchronously and multiple clocks with asynchronous communication or entirely asynchronous operation. The design can be general purpose, or specific to a given application, i.e., application-specific. The above variations together constitute the *system style*. System style selection is determined to a great extent by the physical technologies used, the environment in which the system operates, designer experience, and corporate culture, and is not automated to any great extent.

System-level design covers a wide range of design activities and design situations. It includes the more specific activity *system engineering*, which involves the requirements, development, test planning,

subsystem interfacing, and end-to-end analysis of systems. System-level design is sometimes called *system architecting*, a term used widely in the aerospace industry.

General-purpose system-level design involves the design of programmable digital systems including the basic modules containing storage, processors, input/output, and system controllers. At the system level, the design activities include determining the following:

- *Power budget* (the amount of power allocated to each module in the system)
- Cost and performance budget allocated to each module in the system
- Interconnection strategy
- Selection of commercial off-the-shelf (COTS) modules
- Packaging of each module
- Overall packaging strategy
- Number of processors, storage units, and input/output interfaces required
- Overall characteristics of each processor, storage unit, and I/O interface

For example, memory system design focuses on the number of memory modules required, how they are organized, and the capacity of each module. A specific system-level decision in this domain can be how to partition the memory between the processor chip and the off-chip memory. At a higher level, a similar decision might involve configuration of the complete storage hierarchy, including memory, disk drives, and archival storage.

For each general-purpose system designed, many more systems are designed to perform specific applications. *Application-specific system design* involves the same activities as described above, but can involve many more decisions, since there are usually more custom logic modules involved. Specifications for application-specific systems contain not only requirements on general capabilities, but also contain the functionality required in terms of specific tasks to be executed. Major application-specific system-level design activities include not only the above general-purpose system design activities, but also the following activities:

- Partitioning an application into multiple functional modules
- Scheduling the application tasks on shared functional modules
- Allocating functional modules to perform the application tasks
- Allocating and scheduling storage modules to contain blocks of data as they are processed
- Determining the implementation styles of functional modules
- Determining the word lengths of data necessary to achieve a given accuracy of computation
- Predicting resulting system characteristics once the system design is complete

Each of the system design tasks given in the two lists above will be described in detail below. Since the majority of system design activities are application-specific, this section will focus on system-level design of application-specific systems. Related activities, hardware–software codesign, verification, and simulation are covered in other sections.

11.1.1 Design Philosophies and System-Level Design

Many design tools have been constructed with a *top-down design* philosophy. Top-down design represents a design process whereby the design becomes increasingly detailed until final implementation is complete. Considerable prediction of resulting system characteristics is required to make the higher-level decisions with some degree of success.

Bottom-up design, on the other hand, relies on designing a set of primitive elements, and then forming more complex modules from those elements. Ultimately, the modules are assembled into a system. At each stage of the design process, there is complete knowledge of the parameters of the lower-level elements. However, the lower-level elements may be inappropriate for the tasks at hand.

System designers in industry describe the design process as being much less organized and considerably more complex than the top-down and bottom-up philosophies suggest. There is a mixture of top-down and bottom-up activities with major bottlenecks of the system receiving detailed design consideration while other parts of the system still exist only as abstract specifications. For this reason, the system-level design activities we present in detail here support such a complex design situation. Modules, elements, and components used to design at the system level might exist, or might only exist as abstract estimates along with requirements. The system can be designed after all modules have been designed and manufactured, prior to any detailed design, or with a mixture of existing and new modules.

11.1.2 System Design Space

System design, like data path design, is quite straightforward as long as the constraints are not too severe. However, most designs must solve harder problems than problems solved by existing systems. Designers must race to produce working systems faster than competitors, systems that are also less expensive. More variations in design are possible than ever before and such variations require a large *design space* to be explored. The dimensions of the design space (its axes) are system properties such as cost, power, design time, and performance. The design space contains a population of designs, each of which possesses different values of these system properties. There are literally millions of system designs for a given specification, each of which exhibits different cost, performance, power consumption, and design time. Straightforward solutions that do not attempt to optimize system properties are easy to obtain, but may be inferior to designs that are produced by system-level design tools and have undergone many iterations of design. The complexity of system design is not because system design is an inherently difficult activity, but because so many variations in design are possible and time does not permit exploration of all of them.

11.2 System Specification

Complete system specifications contain a wide range of information, including

- Constraints on the system power, performance, cost, weight, size, and delivery time
- Required functionality of the system components
- Any required information about the system structure
- Required communication between system components
- Flow of data between components
- Flow of control in the system
- Specification of input precision and desired output precision

Most systems specifications that are reasonably complete exist first in a natural language. However, natural language interfaces are not currently available with commercial system-level design tools.

More conventional system specification methods used to drive system-level design tools include formal languages, graphs, and a mixture of the two. Each of the formal system specification methods described here contains some of the information found in a complete specification, i.e., most specification methods are incomplete. The designer can provide the remaining information necessary for full system design interactively, can be entered later in the design process, or can be provided in other forms at the same time the specification is processed. The required design activities determine the specification method used for a given system design task.

There are no widely adopted formal languages for system-level hardware design although System-Level Design Language (SLDL) was developed by an industry group. Hardware descriptive languages such as VHSIC Verilog Hardware Descriptive Language (VHDL) [1] and Verilog [2] are used to describe the functionality of modules in an application-specific system. High-level synthesis tools can then synthesize

such descriptions to produce register-transfer designs. Extensions of VHDL and Verilog have been proposed to encompass more system-level design properties. Apart from system constraints, VHDL specifications can form complete system descriptions. However, the level of detail required in VHDL and to some extent in Verilog requires the designer to make some implementation decisions. In addition, some information that is explicit in more abstract specifications such as the flow of control between tasks is implicit in HDLs.

Graphical tools have been used for a number of years to describe system behavior and structure. *Block diagrams* are often used to describe system structure. Block diagrams assume that tasks have already been assigned to basic blocks and their configuration in the system has been specified. Block diagrams generally cannot represent the flow of data or control, or design constraints. The processor memory switch (PMS) notation invented by Bell and Newell was an early attempt to formalize the use of block diagrams for system specification [3].

Petri nets have been used for many years to describe system behavior using a *token-flow* model. A token-flow model represents the flow of control with tokens, which flow from one activity of the system to another. Many tokens can be active in a given model concurrently, representing asynchronous activity and parallelism, important in many system designs. Timed Petri nets have been used to model system performance, but Petri nets cannot easily be used to model other system constraints, system behavior, or any structural information.

State diagrams and graphical tools such as *State charts* [4] provide alternative methods for describing systems. Such tools provide mechanisms to describe the flow of control, but do not describe system constraints, system structure, data flow, or functionality.

Task-flow graphs, an outgrowth from the control/data-flow graphs (CDFG) used in high-level synthesis are often used for system specification. These graphs describe the flow of control and data between tasks. When used in a hierarchical fashion, task nodes in the task-flow graph can contain detailed functional information about each task, often in the form of a CDFG. Task-flow graphs contain no mechanisms for describing system constraints or system structure.

Spec charts [5] incorporate VHDL descriptions into state-chart-like notation, overcoming the lack of functional information found in state charts.

Figure 11.1 illustrates the use of block diagrams, Petri nets, task-flow graphs, and spec charts.

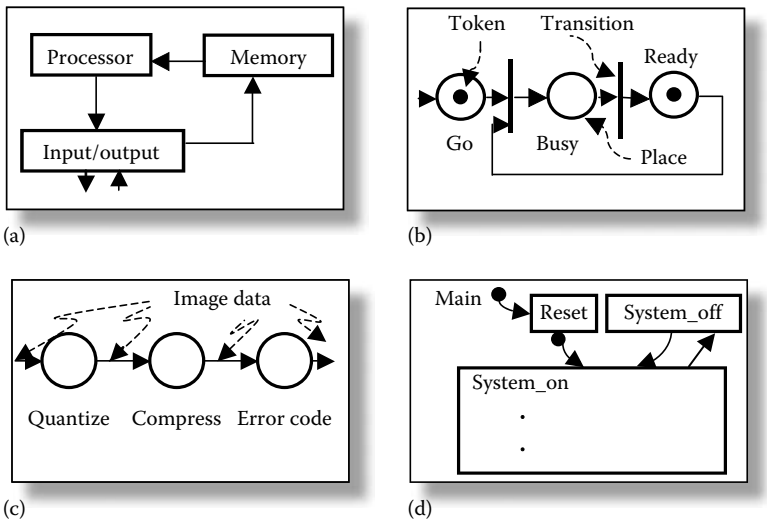

FIGURE 11.1 Use of (a) block diagrams, (b) Petri nets, (c) task-flow graphs, and (d) spec charts, shown in simplified form.

11.3 System Partitioning

Most systems are too large to fit on a single substrate. If the complexity of the system tasks and the capacities of the system modules are of the same order, then partitioning is not required. All other systems must be partitioned so that they fit into the allowed dies, packages, boards, multichip modules (MCMs), and cases. *Partitioning determines the functions, tasks, or operations in each partition of a system*. Each partition can represent a substrate, package, MCM, or larger component. Partitioning is performed with respect to a number of goals, including minimizing cost, design time or power, or maximizing performance. Any of these goals can be reformulated as specific constraints such as meeting given power requirements.

When systems are partitioned, resulting communication delays must be taken into account, affecting performance. Limitations on interconnection size must be taken into account, affecting performance as well. Pin and interconnection limitations force the multiplexing of inputs and outputs, reducing performance and sometimes affecting cost. Power consumption must also be taken into account. Power balancing between partitions and total power consumption might both be considerations. To meet market windows, system partitions can facilitate the use of COTS, programmable components, or easily fabricated components such as gate arrays. To meet cost constraints, functions that are found in the same partition might share partition resources. Such functions or tasks cannot execute concurrently, affecting performance.

Partitioning is widely used at the logic level as well as on physical designs. In these cases, much more information is known about the design properties and the interconnection structure has been determined. System partitioning is performed when information about properties of the specific components might be uncertain, and the interconnection structure undetermined. For these reasons, techniques used at lower levels must be modified to include predictions of design properties not yet known and prediction of the possible interconnection structure as a result of the partitioning.

The exact partitioning method used depends on the type of specification available. If detailed CDFG or HDL specifications are used, the partitioning method might be concerned with which register-transfer functions (e.g., add, multiply, and shift) are found in each partition. If the specification primitives are tasks, as in a task-flow graph specification, then the tasks must be assigned to partitions. Generally, the more detailed the specification, the larger the size of the partitioning problem. Powerful partitioning methods can be applied to problems of small size ($n < 100$). Weaker methods such as incremental improvement must be used when the problem size is larger.

Partitioning methods can be based on *constructive* partitioning or *iterative improvement*. Constructive partitioning involves taking an unpartitioned design and assigning operations or tasks to partitions. Basic constructive partitioning methods include *bin packing* using a first-fit decreasing heuristic, *clustering* operations into partitions by assigning nearest neighbors to the same partition until the partition is full, *random* placement into partitions, and *integer programming* approaches.

11.3.1 Constructive Partitioning Techniques

Bin packing involves creating a number of bins equal in number to the number of partitions desired and equal in size to the size of partitions desired. One common approach involves the following steps: the tasks or operations are sorted by size. The largest task in the list is placed in the first bin, and then the next largest is placed in the first bin, if it will fit, or else into the second bin. Each task is placed into the first bin in which it will fit, until all tasks have been placed in bins. More bins are added if necessary. This simple heuristic is useful to create an initial set of partitions to be improved iteratively later.

Clustering is a more powerful method to create partitions. Here is a simple clustering heuristic. Each task is ranked by the extent of ''connections'' to other tasks either owing to control flow, data flow, or physical position limitations. The most connected task is placed in the first partition and then the tasks connected to it are placed in the same partition, in the order of the strength of their connections to the

first task. Once the partition is full, the task with the most total connections remaining outside a partition is placed in a new partition, and other tasks are placed there in the order of their connections to the first task. This heuristic continues until all tasks are placed.

Random partitioning places tasks into partitions in a greedy fashion until the partitions are full. Some randomization of the choice of tasks is useful in producing a family of systems, each member of which is partitioned randomly. This family of systems can be used successfully in iterative improvement techniques for partitioning, as described later in this section.

The most powerful technique for constructive partitioning is mathematical programming. Integer and mixed integer-linear programming (MILP) techniques have been used frequently in the past for partitioning. Such powerful techniques are computationally very expensive and are successful only when the number of objects to be partitioned is small. The basic idea behind integer programming used for partitioning is the following: an integer, TP(i, j), is used to represent the assignment of tasks to partitions. When TP = 1, task i is assigned to partition j. For each task in this problem, there would be an equation

$$\sum_{j=1}^{\text{Partition total}} \text{TP}(i,j) = 1 \tag{11.1}$$

This equation states that each task must be assigned to one and only one partition. There would be many constraints of this type in the integer program, some of which were inequalities. There would be one function representing cost, performance, or other design property to be optimized. The simultaneous solution of all constraints, given some minimization or maximization goal, would yield the optimal partitioning.

Apart from the computational complexity of this technique, the formulation of the mathematical programming constraints is tedious and error prone if performed manually. The most important advantage of mathematical programming formulations is the discipline it imposes on the CAD programmer in formulating an exact definition of the CAD problem to be solved. Such problem formulations can prove useful when applied in a more practical environment, as described in Section 11.3.2.

11.3.2 Iterative Partitioning Techniques

Of the many iterative partitioning techniques available, two have been applied most successfully at the system level. These are *min-cut partitioning*, first proposed by Kernigan and Lin, and *genetic algorithms*.

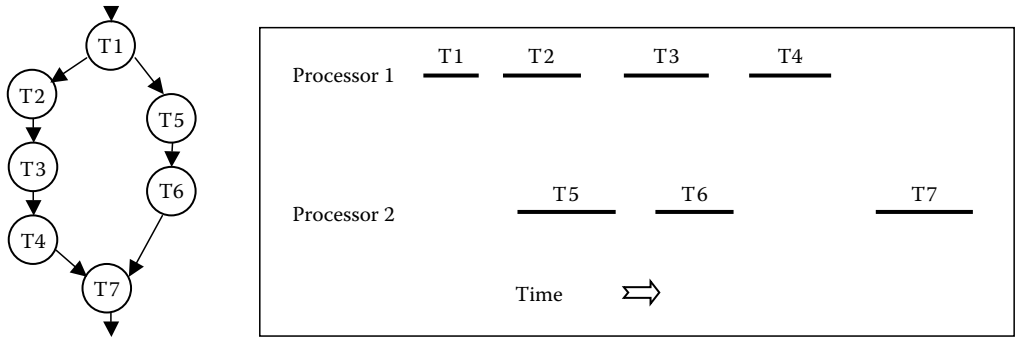
Min-cut partitioning involves exchanging tasks or operations between partitions to minimize the total amount of ''interconnections'' cut. The interconnections can be computed as the sum of data flowing between partitions, or as the sum of an estimate of the actual interconnections that will be required in the system. The advantage of summing the data flowing is that it provides a quick computation, since the numbers are contained in the task-flow graph. Better partitions can be obtained if the required physical interconnections are taken into account since they are related more directly to cost and performance than is the amount of data flowing. If a partial structure exists for the design, predicting the unknown interconnections allows partitioning to be performed on a mixed design, one that contains existing parts as well as parts under design.

Genetic algorithms, highly popular for many engineering optimization problems, are especially suited to the partitioning problem. The problem formulation is similar in some ways to mathematical programming formulations. A simple genetic algorithm for partitioning is described here. In this example, a chromosome represents each partitioned system design, and each chromosome contains genes, representing information about the system. A particular gene TP(i, j) might represent the fact that task i is contained in partition j when it is equal to 1, and is set to 0 otherwise. A family of designs created by some constructive partitioning technique then undergoes mutation and crossover as new designs evolve.

A *fitness function* is used to check the quality of the design and the evolution is halted when the design is considered fit or when no improvement has occurred after some time. In the case of partitioning, the fitness function might include the estimated volume of interconnections, the predicted cost or performance of the system, or other system properties.

The reader might note some similarity between the mathematical programming formulation of the partitioning problem presented here and the genetic algorithm formulation. This similarity allows the CAD developer to create a mathematical programming model of the problem to be solved, find optimal solutions to small problems, and then create a genetic algorithm version. The genetic algorithm version can be checked against the optimal solutions found by the mathematical program. However, genetic algorithms can take into account many more details than can mathematical program formulations, can handle nonlinear relationships better, and can even handle *stochastic parameters*.*

Partitioning is most valuable when there is a mismatch between the sizes of system tasks and the capacities of system modules. When the system tasks and system modules are more closely matched, then the system design can proceed directly to *scheduling* and *allocating* tasks to processing modules.



11.4 Scheduling and Allocating Tasks to Processing Modules

Scheduling and allocating tasks to processing modules involves the determination of how many processing modules are required, which modules execute which tasks, and the order in which the tasks are processed by the system. In the special case where only a single task is processed by each module, the scheduling becomes trivial. Otherwise, if the tasks share modules, the order in which the tasks are processed by the modules can affect system performance or cost. If the tasks are ordered inappropriately, some tasks might wait too long for input data, and performance might be affected. Alternatively, to meet performance constraints, additional modules must be added to perform more tasks in parallel, increasing system cost.

A variety of modules might be available to carry out each task, with differing cost and performance parameters. As each task is allocated to a module, that module is selected from a set of modules available to execute the task. This is analogous to the task *module selection*, which occurs as part of high-level synthesis. For the system design problem considered here, the modules can be general-purpose processors, special-purpose processors (e.g., signal-processing processors), or special-purpose hardware. If all (or most) modules used are general purpose, the systems synthesized are known as heterogeneous application-specific multiprocessors.

A variety of techniques can be used for scheduling and allocation of system tasks to modules. Just as with partitioning, these techniques can be constructive or iterative. Constructive scheduling techniques for system tasks include greedy techniques such as ASAP (as soon as possible) and ALAP (as late as possible). In ASAP scheduling, the tasks are scheduled as early as possible on a free processing module. The tasks scheduled first are the ones with the longest paths from their outputs to final system outputs or system completion. Such techniques, with variations, can be used to provide starting populations of system designs to be further improved iteratively. The use of such greedy techniques for system synthesis differs from the conventional use in high-level synthesis, where the system is assumed to be synchronous, with tasks scheduled into time steps. System task scheduling assumes no central clock, and tasks take a wide range of time to complete. Some tasks could even complete stochastically, with completion time being a random variable. Other tasks could complete basic calculations in a set time, but could perform a finer grain (more accurate) of computations if more time were available. A simple task-flow graph is shown in Figure 11.2, along with a Gantt chart illustrating the ASAP scheduling of tasks onto two processors. Note that two lengthy tasks are performed in parallel with three shorter tasks and that no two tasks take the same amount of time.

* Stochastic parameters represent values that are uncertain. There is a finite probability of a parameter taking a specific value that varies with time, but that probability is less than 1, in general.

(a) Task-flow graph (b) Gantt chart showing schedule

FIGURE 11.2 Example of task-flow graph and schedule.

Similar to partitioning, scheduling, allocation, and module selection, can be performed using mathematical programming. In this case, since the scheduling is asynchronous, time becomes a linear rather than integer quantity. Therefore, MILP is employed to model system-level scheduling and allocation. A typical MILP timing constraint is the following:

$$T_{\mathrm{OA}}(i) + C_{\mathrm{delay}} \leq T_{\mathrm{IR}}(j) \tag{11.2}$$

where

$T_{\mathrm{OA}}(i)$ is the time the output is available from task i
C_{delay} is the communication delay
$T_{\mathrm{IR}}(j)$ is the time the input is required by task j

Unfortunately, the actual constraints used in scheduling and allocation are mostly more complex than this, because the design choices have yet to be made. Here is another example:

$$T_{\mathrm{OA}}(i) \geq T_{\mathrm{IR}}(i) + \sum_{k} \left[P_{\mathrm{delay}}(k) * M(i, k)\right] \tag{11.3}$$

This constraint states that the time an output from task i is available is greater than or equal to the time necessary inputs are received by task i, and a processing delay P_{delay} has occurred. $M(i, k)$ indicates that task i is allocated to module k. P_{delay} can take on a range of values, depending on which of the k modules is being used to implement task i. The summation is actually a linearized select function that picks the value of P_{delay} to use depending on which value of $M(i, k)$ is set to 1.

As with partitioning, mathematical programming for scheduling and allocation is computationally intensive, and impractical for all but the smallest designs, but it does provide a baseline model of design that can be incorporated into other tools.

The most frequent technique used for iterative improvement in scheduling and allocation at the system level is a genetic algorithm. The genes can be used to represent task allocation and scheduling. To represent asynchronous scheduling accurately, time is generally represented as a linear quantity in such genes rather than an integer quantity.

11.5 Allocating and Scheduling Storage Modules

In digital systems, all data require some form of temporary or permanent storage. If the storage is shared by several data sets, the use of the storage by each data set must be scheduled. The importance of this task in system design has been overlooked in the past, but has now become an important system-level task.

Modern digital systems usually contain some multimedia tasks and data. The storage requirements for multimedia tasks sometimes result in systems where processing costs are dwarfed by storage costs, particularly caching costs. For such systems, storage must be scheduled and allocated either during or after task scheduling and allocation. If storage is scheduled and allocated concurrently with task scheduling and allocation, the total system costs are easier to determine and functional module sharing can be increased if necessary to control total costs. Alternatively, if storage allocation and scheduling are performed after task scheduling and allocation, then both programs are simpler, but the result may not be as close to optimal.

Techniques similar to those used for task scheduling and allocation can be used for storage scheduling and allocation.

11.6 Selecting Implementation and Packaging Styles for System Modules

Packaging styles can range from single-chip dual-in-line packages (DIPs) to MCMs, boards, racks, and cases. Implementation styles include general-purpose processor, special-purpose programmable processor (e.g., signal processor), COTS modules, field programmable gate arrays (FPGAs), gate array, standard cell, and custom ICs. System cost, performance, power, and design time constraints determine selection of implementation and packaging styles for many system designs. Tight performance constraints favor custom ICs, packaged in MCMs. Tight cost constraints favor off-the-shelf processors and gate array implementations, with small substrates and inexpensive packaging. Tight power constraints favor custom circuits. Tight design time constraints favor COTS modules and FPGAs. If a single design property has high priority, the designer can select the appropriate implementation style and packaging technology. If, however, design time is crucial, but the system to be designed must process video signals in real time, then trade-offs in packaging and implementation style must be made. The optimality of system cost and power consumption might be sacrificed: the entire design might be built with FPGAs, with much parallel processing and at great cost and large size. Because time-to-market is so important, early market entry systems may sacrifice the optimality of many system parameters initially, and then improve them in the next version of the product.

Selection of implementation styles and packaging can be accomplished by adding some design parameters to the scheduling and allocation program, if that program is not already computationally intensive. The parameters added would include a variable indicating that a particular

- Functional module was assigned a certain implementation style
- Storage module was assigned a certain implementation style
- Functional module was assigned a certain packaging style
- Storage module was assigned a certain packaging style

Some economy of processing could be obtained if certain implementation styles precluded certain packaging styles.

11.7 Interconnection Strategy

Modules in a digital system are usually interconnected in some carefully architected, consistent manner. If point-to-point interconnections are used, they are used throughout the system, or in a subsystem. In the same manner, buses are not broken arbitrarily to insert point-to-point connections or rings. For this reason, digital system design programs usually assume an interconnection style and determine the system performance relative to that style. The most common interconnection styles are bus, point-to-point, and ring.

11.8 Word-Length Determination

Functional specifications for system tasks are frequently detailed enough to contain the algorithm to be implemented. To determine the implementation costs of each system task, knowledge of the word widths to be used is important as system cost varies almost quadratically with word width.

Tools to automatically select task word width are currently experimental, but the potential for future commercial tools exists.

In typical hardware implementations of an arithmetic-intensive algorithm, designers must determine the word lengths of resources such as adders, multipliers, and registers. Wadekar and Parker [6] in a recent publication, present algorithm-level optimization techniques to select distinct word lengths for each computation. These techniques meet the desired accuracy and minimize the design cost for the given performance constraints. The cost reduction is possible by avoiding unnecessary bit-level computations that do not contribute significantly to the accuracy of the final results. At the algorithm level, determining the necessary and sufficient precision of an individual computation is a difficult task since the precision of various predecessor/successor operations can be traded off to achieve the same desired precision in the final result. This is achieved using a mathematical model [7] and a genetic selection mechanism [6]. There is a distinct advantage to word-length optimization at the algorithmic level. The optimized operation word lengths can be used to guide high-level synthesis or designers to achieve an efficient utilization of resources of distinct word lengths and costs. Specifically, only a few resources of larger word lengths and high cost may be needed for operations requiring high precision to meet the final accuracy requirement. Other relatively low-precision operations may be executed by resources of smaller word lengths. If there is no timing conflict, a large word-length resource can also execute a small word-length operation, thus improving the overall resource utilization further. These high-level design decisions cannot be made without the knowledge of word lengths prior to synthesis.

11.9 Predicting System Characteristics

In system-level design, early prediction gives designers the freedom to make numerous high-level choices (such as die size, package type, and latency of the pipeline) with confidence that the final implementation will meet power and energy as well as cost and performance constraints. These predictions can guide power budgeting and subsequent synthesis of various system components, which is critical in synthesizing systems that have low power dissipation, or long battery life. The use by synthesis programs of performance and cost lower bounds allows smaller solution spaces to be searched, which leads to faster computation of the optimal solution.

System cost, performance, power consumption, and design time can be computed if the properties of each system module are known. System design using existing modules requires little prediction. If system design is performed prior to design of any of the contained system modules, however, their properties must be predicted or estimated. Owing to the complexities of prediction techniques, describing these techniques is a subject worthy of an entire chapter. A brief survey of related readings is found in Section 11.10.

The register-transfer and subsequent lower-level power prediction techniques such as gate- and transistor-level techniques are essential for validation before fabricating the circuit. However, these techniques are less efficient for system-level design as a design must be generated before prediction can be done.

11.10 Survey of Research in System Design

Many researchers have investigated the problem of system design, dating back to the early 1970s. This section highlights work that is distinctive, along with tutorial articles covering relevant topics.

Much good research is not referenced here, and the reader is reminded that the field is dynamic, with new techniques and tools appearing almost daily.

Issues in top-down versus bottom-up design approaches were highlighted in the design experiment reported by Gupta et al. [8].

11.10.1 System Specification

System specification has received little attention historically except in the specific area of software specifications. Several researchers have proposed natural language interfaces capable of processing system specifications and creating internal representations of the systems that are considerably more structured. Of note is the work by Granacki [9] and Cyre [10]. One noteworthy approach is the design specification language (DSL), found in the design analysis and synthesis environment [11]. One of the few books on the subject concerns the design of embedded systems—systems with hardware and software designed for a particular application set [12]. In one particular effort, Petri nets were used to specify the interface requirements in a system of communicating modules, which were then synthesized [13]. The SIERA system designed by Srivastava, Richards, and Broderson [14] supports specification, simulation, and interactive design of systems.

The Rugby model [15] represents hardware/software systems and the design process, using four dimensions to represent designs: time, computation, communication, and data. da Silva [16] describes the system data structure (SDS), used for internal representation of systems. da Silva also presents an external language for system descriptions called OSCAR. SDS is general and comprehensive, covering behavior and structure. OSCAR is a visual interface to SDS with a formal semantics and syntax based on a visual coordination language paradigm. It is used to capture the behavior and the coordination aspects of concurrent and communicating processes.

SystemC [17] provides hardware-oriented constructs as a class library implemented in standard C++. Although the use of SystemC is claimed to span design and verification from concept to implementation in hardware and software, the constructs provided are somewhat of lower level than most of the system design activities described in this chapter. Extensions to VHDL and Verilog also support some system design activities at the lower levels of system design.

11.10.2 Partitioning

Partitioning research covers a wide range of system design situations. Many early partitioning techniques dealt with assigning register-level operations to partitions. APARTY, a partitioner designed by Lagnese and Thomas, partitions CDFG designs for single-chip implementation to obtain efficient layouts [18]. Vahid [19] performed a detailed survey of techniques for assigning operations to partitions. CHOP assigns CDFG operations to partitions for multichip design of synchronous, common clocked systems [20]. Vahid and Gajski developed an early partitioner, SpecPart, which assigns processes to partitions [21]. Chen and Parker reported on a process-to-partition technique called ProPart [22].

11.10.3 Nonpipelined Design

Although research on *system design* spans more than two decades, most of the earlier works focus on single aspects of design-like task assignment, and not on the entire design problem. We cite some representative works here. These include graph theoretical approaches to task assignment [23,24], analytical modeling approaches for task assignment [25], and probabilistic modeling approaches for task partitioning [26,27], scheduling [28], and synthesis [29]. Two publications of note cover application of heuristics to system design [30,31].

Other publications of note include mathematical programming formulations for task partitioning [32] and communication channel assignment [33]. Early efforts include those done by soviet researchers since

the beginning of the 1970s such as Linsky and Kornev [34] and others, where each model only included a subset of the entire synthesis problem. Chu et al. [35] published one of the first MILP models for a subproblem of system-level design, scheduling. The program Synthesis of Systems (SOS) including a compiler for MILP models [36,37] was developed, based on a comprehensive MILP model for system synthesis. SOS takes a description of a system described using a task-flow graph, a processor library, and some cost and performance constraints, and generates an MILP model to be optimized by an MILP solver. The SOS tool generates MILP models for the design of nonperiodic (nonpipelined) heterogeneous multiprocessors. The models share a common structure, which is an extension of the previous work by Hafer and Parker for high-level synthesis of digital systems [38].

Performance bounds of solutions found by algorithms or heuristics for system-level design are proposed in many papers, including the landmark papers by Fernandez and Bussel [39], Garey and Graham [40], and more recent publications [41].

The work of Gupta et al. [8] reported the successful use of system-level design tools in the development of an application-specific heterogeneous multiprocessor (ASHM) for image processing. Gupta and Zorian [42] describe the design of systems using cores, silicon cells with at least 5000 gates. The same issue of *IEEE Design and Test of Computers* contains a number of useful articles on the design of embedded core-based systems. Li and Wolf [43] report on a model of hierarchical memory and a multiprocessor synthesis algorithm, which takes into account the hierarchical memory structure.

A major project, RASSP, is a rapid-prototyping approach whose development is funded by the US Department of Defense [44]. RASSP addresses the integrated design of hardware and software for signal-processing applications.

An early work on board-level design, MICON, is of particular interest [45]. Other research results solving similar problems with more degrees of design freedom include the research by Chen [46] and Heo [47]. GARDEN, written by Heo, finds the design with the shortest estimated time-to-market that meets cost and performance constraints.

All the MILP synthesis works cited up to this point address only the nonperiodic case.

Synthesis of ASHMs is a major activity in the general area of system synthesis. One of the most significant system-level design efforts is Lee's Ptolemy project at the University of California, Berkeley. Representative publications include papers by Lee and Bier describing a simulation environment for signal processing [48] and the paper by Kalavede et al. in 1995 [49]. Another prominent effort is the SpecSyn project of Gajski et al. [50] which is a system-level design methodology and framework.

11.10.4 Macropipelined Design

Macropipelined (periodic) multiprocessors execute tasks in a pipelined fashion, with tasks executing concurrently on different sets of data. Most research work on design of *macropipelined* multiprocessors has been restricted to homogeneous multiprocessors having negligible communication costs. This survey divides the previous contributions according to the execution mode: preemptive or *nonpreemptive*.

11.10.4.1 Nonpreemptive Mode

The nonpreemptive mode of execution assumes that each task is executed without interruption. It is used quite often in low-cost implementations. Much research has been performed on system scheduling for the nonpreemptive mode. A method to compute the minimum possible value for the initiation interval for a task-flow graph given an unlimited number of processors and no communication costs was found by Renfors and Neuvo [51].

Wang and Hu [52] use heuristics for the allocation and *full static scheduling* (meaning that each task is executed on the same processor for all iterations) of generalized perfect-rate task-flow graphs on homogeneous multiprocessors. Wang and Hu apply planning, an artificial intelligence method, to the task scheduling problem. The processor allocation problem is solved using a *conflict-graph* approach.

Gelabert and Barnwell [53] developed an optimal method to design macropipelined homogeneous multiprocessors using *cyclic-static scheduling*, where the task-to-processor mapping is not time-invariant as in the full static case, but is periodic, i.e., the tasks are successively executed by all processors. Gelabert and Barnwell assume that the delays for *intraprocessor* and *interprocessor* communications are the same, which is an idealistic scenario. Their approach is able to find an optimal implementation (minimal iteration interval) in exponential time in the worst case.

Tirat-Gefen [54], in his doctoral thesis, extended the SOS MILP model to solve for optimal macropipelined ASHMs. He also proposed an ILP model allowing simultaneous optimal retiming and processor/module selection in high- and system-level synthesis [55].

Verhauger [56] addresses the problem of periodic multidimensional scheduling. His thesis uses an ILP model to handle the design of homogeneous multiprocessors without communication costs implementing data-flow programs with nested loops. His work evaluates the complexity of the scheduling and allocation problems for the multidimensional case, which were both found to be NP-complete. Verhauger proposes a set of heuristics to handle both problems.

Passos et al. [57] evaluate the use of multidimensional retiming for synchronous data-flow graphs. However, their formalism can only be applied to homogeneous multiprocessors without communication costs.

11.10.4.2 Preemptive Mode of Execution

Peng and Shin [58] address the optimal static allocation of periodic tasks with precedence constraints and preemption on a homogeneous multiprocessor. Their approach has an exponential time complexity. Ramamritham [59] developed a heuristic method that has a more reasonable computational cost. Rate-monotonic scheduling (RMS) is a commonly used method for allocating periodic real-time tasks in distributed systems [60]. The same method can be used in homogeneous multiprocessors.

11.10.5 Genetic Algorithms

Genetic algorithms are becoming an important tool for solving the highly nonlinear problems related to system-level synthesis. The use of genetic algorithms in optimization is well discussed by Michalewicz [61] where formulations for problems such as bin packing, processor scheduling, traveling salesman, and system partitioning are outlined.

Research works involving the use of genetic algorithms to system-level synthesis problems are starting to be published, as for example, the results of

- Hou et al. [62]—scheduling of tasks in a homogeneous multiprocessor without communication costs
- Wang et al. [63]—scheduling of tasks in heterogeneous multiprocessors with communication costs, but not allowing cost versus performance trade-off, i.e., all processors have the same cost
- Ravikumar and Gupta [64]—mapping of tasks into a reconfigurable homogeneous array processor without communication costs
- Tirat-Gefen and Parker [65]—a genetic algorithm for design of ASHMs with nonnegligible communications costs specified by a nonperiodic task-flow graph representing both control and data flow
- Tirat-Gefen [54]—introduced a full-set of genetic algorithms for system-level design of ASHMs incorporating new design features such as imprecise computation and probabilistic design

11.10.6 Imprecise Computation

The main results in imprecise *computation* theory are due to Liu et al. [66] who developed polynomial time algorithms for optimal scheduling of preemptive tasks on homogeneous multiprocessors without

communications costs. Ho et al. [67] proposed an approach to minimize the total error, where the error of a task being imprecisely executed is proportional to the amount of time that its optional part was not allowed to execute, i.e., the time still needed for its full completion. Polynomial time-optimal algorithms were derived for some instances of the problem [66].

Tirat-Gefen et al. [68] presented in 1997 a new approach for ASHM design that allows trade-offs between cost, performance, and data-quality through incorporation of imprecise computation into the system-level design cycle.

11.10.7 Probabilistic Models and Stochastic Simulation

Many probabilistic models for solving different subproblems in digital design have been proposed recently. The problem of task and data-transfer scheduling on a multiprocessor when some tasks (data transfers) have nondeterministic execution times (communication times) can be modeled by PERT networks, which were introduced by Malcolm et al. [69] along with the critical path method (CPM) analysis methodology.

A survey on PERT networks and their generalization to conditional PERT networks is done by Elmaghraby [70]. In system-level design, the completion time of a PERT network corresponds to the *system latency*, whose cumulative distribution function (cdf) is a nonlinear function of the probability density distributions of the computation times of the tasks and the communication times of the data transfers in the task-flow graph.

The exact computation of the cdf of the completion time is computationally expensive for large PERT networks, therefore it is important to find approaches that approximate the value of the expected time of the completion time and its cdf. One of the first of these approaches was due to Fulkerson [71], who derived an algorithm in 1962 to find a tight estimate (lower bound) of the expected value of the completion time. Robillard and Trahan [72] proposed a different method using the characteristic function of the completion time in approximating the cdf of the completion time.

Mehrotra et al. [73] proposed a heuristic for estimating the moments of the probabilistic distribution of the system latency t_c. Kulkarni and Adlakha [74] developed an approach based on Markov processes for the same problem. Hagstrom [75] introduced an exact solution for the problem when the random variables modeling the computation and communication times are finite discrete random variables. Kamburowski [76] developed a tight upper bound on the expected completion time of a PERT network.

An approach using random graphs to model distributed computations was introduced by Indurkhya et al. [26], whose theoretical results were improved by Nicol [27]. Purushotaman and Subrahmanyam [77] proposed formal methods applied to concurrent systems with a probabilistic behavior. An example of modeling using queueing networks instead of PERT networks is given by Thomasian and Bay [78]. Estimating errors owing to the use of PERT assumptions in scheduling problems is discussed by Lukaszewicz [79].

Tirat-Gefen developed a set of genetic algorithms using stratified stochastic sampling allowing simultaneous probabilistic optimization of the scheduling and allocation of tasks and communications on ASHM with nonnegligible communication costs [54].

11.10.8 Performance Bounds Theory and Prediction

Sastry [80] developed a stochastic approach for estimation of wireability (routability) for gate arrays. Kurdahi [81] created a discrete probabilistic model for area estimation of VLSI chips designed according to a standard cell methodology. Küçükçakar [82] introduced a method for partitioning of behavioral specifications onto multiple VLSI chips using probabilistic area/performance predictors integrated into a package called BEST (behavioral estimation). BEST provides a range of prediction techniques that can be applied at the algorithm level and includes references to prior research. These predictors provide information required by Tirat-Gefen's system-level probabilistic optimization methods [54].

Lower bounds on the performance and execution time of task-flow graphs mapped to a set of available processors and communication links were developed by Liu and Liu [83] for the case of heterogeneous processors, but no communication costs and by Hwang et al. [84] for homogeneous processors with communication costs. Tight lower bounds on the number of processors and execution time for the case of homogeneous processors in the presence of communication costs were developed by Al-Mouhamed [85]. Yen and Wolf [86] provide a technique for performance estimation for real-time distributed systems.

At the system and register-transfer level, estimating power consumption by the interconnect is important [87]. Wadekar et al. [88] reported ''Freedom,'' a tool to estimate system energy and power that accounts for functional-resource, register, multiplexer, memory, input/output pads, and interconnect power. This tool employs a statistical estimation technique to associate low-level, technology-dependent, physical, and electrical parameters with expected circuit resources and interconnect. At the system level, Freedom generates predictions with high accuracy by deriving an accurate model of the load capacitance for the given target technology—a task reported as critical in high-level power prediction by Brand and Visweswariah [89]. Methods to estimate power consumption prior to high-level synthesis were also investigated by Mehra and Rabaey [90]. Liu and Svensson [91] reported a technique to estimate power consumption in CMOS VLSI chips. The reader is referred to an example of a publication that reports power prediction and optimization techniques at the register-transfer level [92].

11.10.9 Word-Length Selection

Many researchers studied word-length optimization techniques at the register-transfer level. A few example publications are cited here. These techniques can be classified as statistical techniques applied to digital filters [93], simulated annealing-based optimization of filters [94], and simulation-based optimization of filters, digital communication, and signal-processing systems [95]. Sung and Kum reported a simulation-based word-length optimization technique for fixed-point digital signal-processing systems [96]. The objective of these particular architecture-level techniques is to minimize the number of bits in the design that is related to, but not the same as the overall hardware cost.

11.10.10 Embedded Systems

Embedded systems are becoming ubiquitous. The main factor differentiating embedded systems from other electronic systems is the focus of attention on the application rather than on the system as a computing engine. Typically, the I/O in an embedded system is to end users, sensors, and actuators. Sensors provide information on environmental conditions, for example, and actuators control the mechanical portion of the system. In an autonomous vehicle, an embedded system inputs the vehicle's GPS location via a sensor, and outputs control information to actuators that control the acceleration, braking, and steering. Embedded systems are typically real-time systems, falling into the classes hard real-time systems, where failure is catastrophic, and soft real-time systems, where failure is not catastrophic.

In an embedded system, there is typically at least one general-purpose processor or microcontroller, and one or more coprocessors that are COTS chips, DSPs, FPGAs, or custom VLSI chips. The main tasks to be performed for embedded systems are partitioning into hardware/software tasks, assigning tasks to processors, scheduling the tasks, and simulation.

11.10.11 System on Chip and Network on Chip

The level of integration of microelectronics has allowed entire systems to be fabricated on a single IC. The physical design of on-chip processing elements called cores can be obtained from vendors. Thus, along with the traditional system design issues, there are issues of intellectual property (IP) for such cores.

System on Chip (SoC) tend to be used for embedded systems, where hardware/software codesign is a major activity.

Researchers and organizations are also examining the connection of large quantities of cores on a single chip, and proposing to interconnect the cores with various types of interconnection networks. Benini and DeMicheli [97] proposed the use of packet switched on-chip networks, and there has been much publication activity in this area since. Raghavan proposed a hierarchical, heterogeneous approach, and described an alternative network architecture with torus topology and token ring protocol [98].

12.1 Introduction

It has been noted by the digital design community that the greatest potential for additional cost and iteration cycle time savings is through improvements in tools and techniques that support the early stages of the design process [1]. As shown in Figure 12.1, decisions made during the initial phases of a product's development cycle determine up to 80% of its total cost. The result is that accurate, fast analysis tools must be available to the designer at the early stages of the design process to help make these decisions. Design alternatives must be effectively evaluated at this level with respect to multiple metrics, such as performance, dependability, and testability. This analysis capability will allow a larger portion of the design space to be explored yielding higher quality as well as lower cost designs.

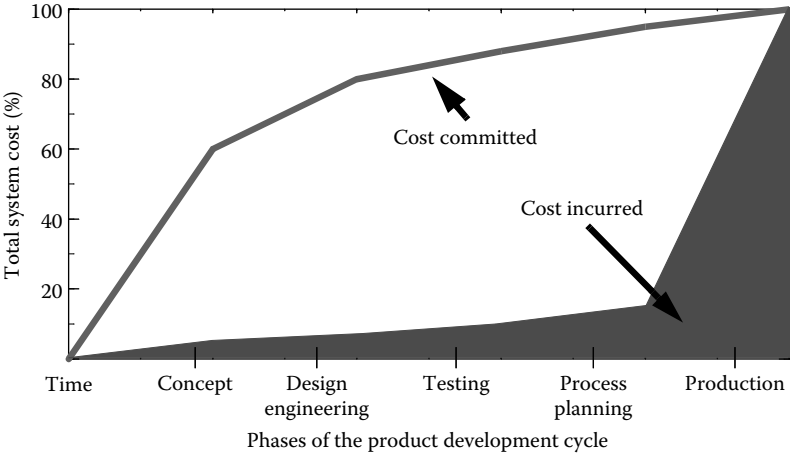

FIGURE 12.1 Product costs over the development cycle.

In 1979, Hill and vanCleemput [2] of the SABLE environment identified three or four stages or phases of design, and noted that each traditionally uses their own simulator. While the languages used have changed and some of the phases can be simulated together these phases still exist in most industry design flows: first an initial high-level simulation, then an intermediate level roughly at the instruction set simulation level, and then a gate-level phase. The authors add a potential fourth stage to deal with custom integrated circuit (IC) simulation. While acknowledging the potential for more efficient simulation at a given level due to potential optimization, they point out five key disadvantages to having different simulators and languages for the various levels. They are

1. Design effort is multiplied by the necessity of learning several simulator systems and recoding a design in each.
2. Possibility of error is increased as more human manipulation enters the system.
3. Each simulator operates at just one level of abstraction. Because it is impossible to simulate an entire computer at a low level of abstraction, only small fragments can be simulated at any one time.
4. Each fragment needs to be driven by a supply of realistic data and its output needs to be interpreted. Often, writing the software to serve these needs is more effortful than developing the design itself.
5. As the design becomes increasingly fragmented to simulate, it becomes difficult for any designer to see how his own particular piece fits into the overall function of the system.

While SABLE was developed almost three decades ago, it is worth noting that today designers are still struggling to address the same basic issues expressed above. Much of the industry has at least two or three design phases requiring separate models and simulators, which still results in a multiplication of design effort. This multiplication of design effort still increases the possibility of error due to inherently fallible human manipulation. While it may not be impossible to simulate an entire computer at one low level of abstraction, it is still impractical and inefficient. Thus, designs are often still fragmented for development and simulation, these fragments still need realistic data, and generating it is still time-consuming. Designers working on a fragment often have difficulty seeing how his or her piece fits into overall function, and this often leads to differing assumptions between fragments and expensive design revision.

There are a number of current tools and techniques that support analysis of these metrics at the system level to varying degrees. A major problem with these tools is that they are not integrated into the engineering design environment in which the system will ultimately be implemented. This problem leads

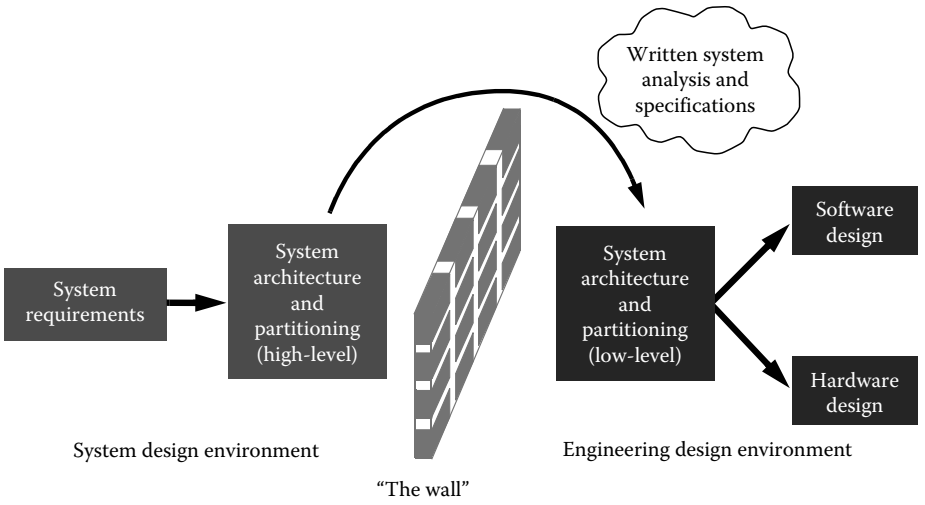

FIGURE 12.2 Disconnect between system-level design environments and engineering design environments.

to a major disconnect in the design process. Once the system-level model is developed and analyzed, the resulting high-level design is specified on paper and thrown ''over the wall'' for implementation by the engineering design team, as illustrated in Figure 12.2. As a result, the engineering design team has to often interpret this specification to implement the system, which often leads to design errors. It also has to develop their own initial ''high-level'' model from which to begin the design process in a top-down manner. Additionally, there is no automated mechanism by which feedback on design assumptions and estimations can be provided to the system design team by the engineering design team.

For systems that contain significant portions of both application-specific hardware and software executing on embedded processors, design alternatives for competing system architectures and hardware/software (HW/SW) partitioning strategies must be effectively and efficiently evaluated using high-level performance models. Additionally, the selected hardware and software system architecture must be refined in an integrated manner from the high-level models to an actual implementation to avoid implementation mistakes and the associated high redesign costs. Unfortunately, most existing design environments lack the ability to model and design a system's hardware and software in the same environment. A similar wall to that between the system design environment and the engineering design environment exists between the hardware and the software design environments. This results in a design path as shown in Figure 12.3, where the hardware and software design process begins with a common system requirement and specification, but proceeds through a separate and isolated design process until final system integration. At this point, assumptions on both sides may prove to be drastically wrong resulting in incorrect system function and poor system performance.

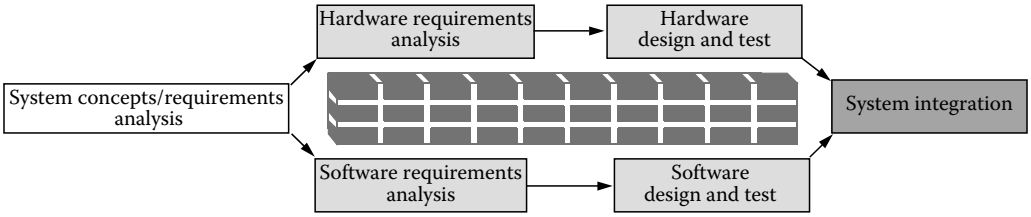

FIGURE 12.3 Current hardware/software system development methodology.

A unified, cooperative approach in which the hardware and software options can be considered together is required to increase the quality and decrease the design time for complex HW/SW systems. This approach is called *hardware/software codesign*, or simply *codesign* [3–5]. Codesign leads to more efficient implementations and improves overall system performance, reliability, and cost-effectiveness [5]. Also, because decisions regarding the implementation of functionality in software can impact hardware design (and vice versa), problems can be detected and changes made earlier in the development process [6].

Codesign can especially benefit the design of *embedded systems* [7], which contain hardware and software tailored for a particular application. As the complexity of these systems increases, the issue of providing design approaches that scale up to more complicated systems becomes of greater concern. A detailed description of a system can approach the complexity of the system itself [8], and the amount of detail present can make analysis intractable. Therefore, decomposition techniques and abstractions are necessary to manage this complexity.

What is needed is a design environment in which the capability for performance modeling of HW/SW systems at a high level of abstraction is fully integrated into the engineering design environment. To completely eliminate the ''over the wall'' problem and the resulting model discontinuity, this environment must support the incremental refinement of the abstract system-level performance model into an implementation-level model. Using this environment, a design methodology based on incremental refinement can be developed.

The design methodology illustrated in Figure 12.4 was proposed by Lockheed Martin Advanced Technology Laboratory as a new way to design systems [9]. This methodology uses the level of the risk of not meeting the design specifications as the metric for driving the design process. In this spiral-based design methodology, there are two iteration cycles. The major cycles (or spirals), denoted as Cycle 1, Cycle 2, . . . , Cycle *N* in the figure, correspond to the design iterations where major architectural changes are made in response to some specification metrics and the system as a whole is refined and more design detail is added to the model. Consistent with the new paradigm of system design, these iterations will actually produce virtual or simulation-based prototypes. A virtual prototype is simply a simulatable model of the system with stimuli described at a given level of design detail or design abstraction that describes the system's operation. Novel to this approach are the mini spirals. The mini spiral cycles, denoted by the levels on the figure labeled Systems, Architecture, and Detailed design, correspond to the refinement of only those portions of the design that are deemed to be ''high risk.'' High risk is obviously defined by the designer but is most often the situation where if one

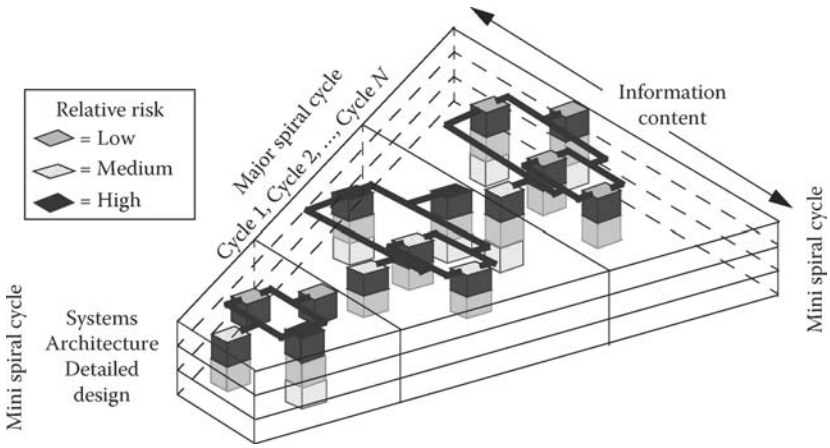

FIGURE 12.4 RDEIM.

or more of these components fail to meet their individual specifications, the system will fail to meet its specifications. The way to minimize the risk is to refine these components to possibly make an implementation so that the actual performance is known. Unlike the major cycles where the entire design is refined, the key to the mini spirals is the fact that only the critical portions of design are refined. For obvious reasons, the resulting models have been denoted as ''Risk Driven Expanding Information Models'' (RDEIMs).

The key to being able to implement this design approach is to be able to evaluate the overall design with portions of the system having been refined to a detailed level, while the rest of the system model remains at the abstract level. For example, in the first major cycle of Figure 12.4 the element with the highest relative risk is fully implemented (detailed design level) while the other elements are described at more abstract levels (system level or architectural level). If the simulation of the model shown in the first major cycle detects that the overall system will not meet its performance requirements, then the ''high risk'' processing element could be replaced by two similar elements operating in parallel. This result is shown in the second major cycle and at this point, another element of the system may become the new ''bottleneck,'' i.e., the highest relative risk, and it will be refined in a similar manner.

Implied in the RDEIM approach is a solution to the ''over the wall'' problem including hardware/software codesign. The proposed solution is to fully integrate performance modeling into the design process.

Obviously, one of the major capabilities necessary to implement a top-down design methodology such as the RDEIM is the ability to cosimulate system models which contain some components that are modeled at an abstract performance level (uninterpreted models) and some that are modeled at a detailed behavioral level (interpreted models). This capability to model and cosimulate uninterpreted models and interpreted models is called *mixed-level modeling* (sometimes referred to as hybrid modeling). Mixed-level modeling requires the development of interfaces that can resolve the differences between uninterpreted models that, by design, do not contain a representation of all of the data or timing information of the final implementation, and interpreted models which require most, or possibly all, data values and timing relationships to be specified. Techniques for systematic development of these mixed-level modeling interfaces and resolution of these differences in abstraction is the focus of some of the latest work in mixed-level modeling.

In addition to the problem of mixed-level modeling interfaces, another issue that may have to be solved is that of different modeling languages being used at different levels of design abstraction. While VHDL, and to some extent various extensions to Verilog, can be used to model at the system level, many designers constructing these types of models prefer to use a language with a more programming language-like syntax. As a result of this and other factors, the SystemC language [10] was developed. SystemC is a library extension to C++ that builds key concepts from existing hardware description languages (HDLs)—primarily a timing model that allows simulation of concurrent events—into an intrinsically object oriented HDL. Its use of objects, pointers, and other standard C++ items makes it a versatile language. Particularly the ability to describe and use complex data types, and the concepts of interfaces and channels make it much more intuitive for describing abstract behaviors than existing HDLs such as VHDL or Verilog. Since SystemC is C++, existing C or C++ code that models behavior can be imported with little or no modification.

12.1.1 Multilevel Modeling

The need for multilevel modeling was recognized almost three decades ago. Multilevel modeling implies that representations at different levels of detail coexist within a model [8,11,12]. Until the early 1990s, the term multilevel modeling was used for integrating behavioral or functional models with lower level models. The objective was to provide a continuous design path from functional models down to implementation. This objective was achieved and the VLSI industry utilizes it today. An example is the tool called Droid, developed by Texas Instruments [13].

The mixed-level modeling approach, as described in this chapter, is a specific type of multilevel modeling which integrates *performance* and *behavioral* models. Thus, only related research on multilevel modeling systems that spans both the performance and the functional/behavioral domains will be described.

Although behavioral or functional modeling is typically well understood by the design community, performance modeling is a foreign topic to most designers. Performance modeling, also called uninterpreted modeling, is utilized in the very early stages of the design process in evaluating such metrics as throughput and utilization. Performance models are also used to identify bottlenecks within a system and are often associated with the job of a system engineer. The term ''uninterpreted modeling'' reflects the view that performance models lack value-oriented data and functional (input/output) transformations. However, in some instances, this information is necessary to allow adequate analysis to be performed.

A variety of techniques have been employed for performance modeling. The most common techniques are Petri nets [14–16] and queuing models [17,18]. A combination of these techniques, such as a mixture of Petri nets and queuing models [19], has been utilized to provide more powerful modeling capabilities. All of these models have mathematical foundations. However, models of complex systems constructed using these approaches can quickly become unwieldy and difficult to analyze.

Examples of a Petri net and a queuing model are shown in Figure 12.5. A queuing model consists of queues and servers. Jobs (or customers) arrive at a specific arrival rate and are placed in a queue for service. These jobs are removed from the queue to be processed by a server at a particular service rate. Typically, the arrival and service rates are expressed using probability distributions. There is a queuing discipline, such as first-come-first-serve, which determines the order in which jobs are to be serviced. Once they are serviced, the jobs depart and arrive at another queue or simply leave the system. The number of jobs in the queues represents the model's state. Queueing models have been used successfully for modeling many complex systems. However, one of the major disadvantages of queuing models is their inability to model synchronization between processes.

As a system modeling paradigm, Petri nets overcome this disadvantage of queuing models. Petri nets consist of places, transitions, arcs, and a marking. The places are equivalent to conditions and hold tokens, which represent information. Thus, the presence of a token in the place of a Petri net corresponds to a particular condition being true. Transitions are associated with events, and the ''firing'' of a transition indicates that some event has occurred. A marking consists of a particular placement of tokens within the places of a Petri net and represents the state of the net. When a transition fires, tokens are removed from the input places and are added to the output places, changing the marking (the state) of the net and allowing the dynamic behavior of a Petri net to be modeled.

Petri nets can be used for performance analysis by associating a time with the transitions. Timed and stochastic Petri nets contain deterministic and probabilistic delays, respectively. Normally, these Petri nets are uninterpreted, since no *interpretation* (values or value transformations) are associated with the tokens or transitions. However, values or value transformations can be associated with the various elements of Petri net models as described below.

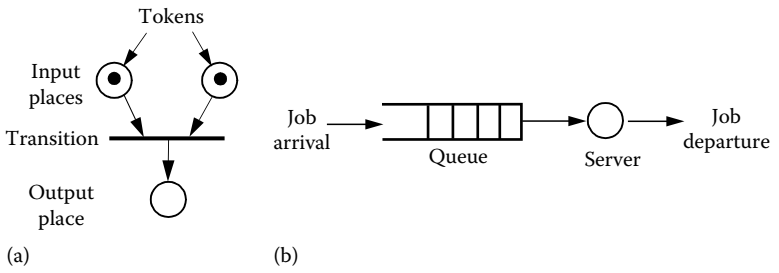

FIGURE 12.5 (a) Petri net and (b) queuing model.

Petri nets that have values associated with tokens are known as colored Petri nets (CPNs). In the colored Petri nets, each token has an attached ''color,'' indicating the identity of the token. The net is similar to the basic definition of the Petri net except that a functional dependency is specified between the color of the token and the transition firing action. In addition, the color of the token produced by a transition may be different from the color of the tokens on the input places. Colored Petri nets have an increased ability to efficiently model real systems with small nets which are equivalent to much larger plain Petri nets due to their increased descriptive powers.

Numerous multilevel modeling systems exist based on these two performance modeling techniques. Architecture Design and Assessment System (ADAS) is a set of tools specifically targeted for high-level design [20]. ADAS models both hardware and software using directed graphs based on timed Petri nets. The flow of information is quantified by identifying discrete units of information called tokens. ADAS supports two levels of modeling. The more abstract level is a dataflow description and is used for performance estimation. The less abstract level is defined as a behavioral level but still uses tokens which carry data structures with them. The functionality is embedded into the models using C or Ada programs. The capability of generating high-level VHDL models from the C or Ada models is provided. These high-level VHDL models can be further refined and developed in a VHDL environment but the refined models cannot be integrated back into the ADAS performance model. The flow of information in these high-level VHDL models is still represented by tokens. Therefore, implementation-level components cannot be integrated into an ADAS performance model. Another limitation is that all input values to the behavioral node must be contained within the token data structure.

Scientific and engineering software (SES)/Workbench is a design specification modeling and simulation tool [21]. It is used to construct and evaluate proposed system designs and to analyze their performance. A graphical interface is used to create a structural model which is then converted into a specific simulatable description (SES/sim). SES/Workbench enables the transition across domains of interpretation by using a *user node*, in which C-language and SES/sim statements can be executed. Therefore, SES/Workbench has similar limitations to ADAS; the inability to simulate a multilevel model when input values of behavioral nodes are not fully specified and the inadequacy of simulating components described as implementation-level HDLs (the capability of integrating VHDL models has been introduced later in the next paragraph). In addition, multiple simulation languages (both SES/sim and C) are required for multilevel models.

The Reveal interactor is a tool developed by Redwood Design Automation [22]. A model constructed in Reveal is aimed at the functional verification of RTL VHDL and Verilog descriptions and, therefore, does not include a separate transaction-based performance modeling capability. However, Reveal can work in conjunction with SES/Workbench. By mixing models created in Reveal and SES/Workbench, a multilevel modeling capability exists. Again, these multilevel models are very limited due to the fact that all the required information at the lower level part of the model must be available within the higher level model.

Integrated Design Automation System (IDAS) is a multilevel design environment which allows for rapid prototyping of systems [23]. Although the behavioral specifications need to be expressed as Ada, C, or FORTRAN programs, IDAS provides the capability of automatically translating VHDL description to Ada. However, the user cannot create abstract models in which certain behavior is unspecified. Also, it does not support classical performance models (such as queuing models and Petri nets) and forces the user to specify a behavioral description very early in the design process.

Transcend claims to integrate multilevel descriptions into a single environment [24,25]. In the more abstract level, T-flow models are used, in which tokens are used to represent flow of data. The capability of integrating VHDL submodels into a T-flow model is provided. However, interfacing between the two models requires a ''C++ like'' language, which map variables to/from VHDL signals, resulting in a heterogeneous simulation environment. Although their approach is geared toward the same objective as mixed-level modeling, the T-flow model must also include all the necessary data to activate the

VHDL submodels. Therefore, the upper-level model cannot be ''too abstract'' and must include lower level details.

Methodology for integrated design and simulation (MIDAS) supports the design of distributed systems via iterative refinement of partially implemented performance specification (PIPS) models [26]. A PIPS model is a partially implemented design where some components exist as simulation models and others as operational subsystems (i.e., implemented components). Although they use the term ''hybrid model'' in this context it refers to a different type of modeling. MIDAS is an ''integrated approach to software design'' [26]. It supports the performance evaluation of software being executed on a given machine. It does not allow the integration of components expressed in an HDL into the model.

The Ptolemy project is an academic research effort being conducted at the University of California at Berkeley [27,28]. Ptolemy, a comprehensive system prototyping tool, is actually constructed of multiple domains. Most domains are geared toward functional verification and have no notion of time. Each domain is used for modeling a different type of system. They also vary in the modeling level (level of abstraction). Ptolemy provides limited capability of mixing domains within one design. The execution of a transition across domains is accomplished with a ''wormhole.'' A wormhole is the mechanism for supporting the simulation of heterogeneous models. Thus, a multilevel modeling and analysis capability is provided. There are two major limitations to this approach compared with the mixed-level modeling approach being described. The first one is the heterogeneity—several description languages. Therefore, translation between simulators is required. The second one is that the interface between domains only translates data. Therefore, all the information required by the receiving domain must be generated by the transmitting domain.

Honeywell Technology Center (HTC) conducted a research effort that specifically addressed the mixed-level modeling problem [29]. This research had its basis in the UVa mixed-level modeling effort. The investigators at HTC developed a performance modeling library (PML) [30,31] and added a partial mixed-level modeling capability to this environment. The PML is used for performance models at a relatively low level of abstraction. Therefore, it assumes that all the information required by the interpreted element is provided by the performance model. In addition, their interface between uninterpreted and interpreted domains allows for bidirectional data flow.

Transaction-level modeling is a model paradigm that combines key concepts from interface-based design [32] with the system-level modeling to develop a refineable model of the system as a whole. Essentially, the system as a whole is represented with the model of computation done in components separated as much as possible from the model of communication between components.

As explained by Cai and Gajski [33],

> In a transaction-level model (TLM), the details of communication among computation components are separated from the details of computational components. Communication is modeled by channels, while transaction requests take place by calling interface functions of these channel models. Unnecessary details of communication and computation are hidden in a TLM and may be added later. TLMs speed up simulation and allow exploring and validating design alternatives at the higher level of abstraction.

There are a number of advantages to such an approach. Of course you get the advantages of a system-level model, but the separation of the modeling of the communication from the modeling of the computation also has a number of advantages. The primary advantage is that it allows the designer to focus on one aspect of the design at a time. The separation limits the complexity that the designer must contend with just as encapsulation and abstraction of component behaviors do. This also allows the designer to develop or refine the communication model of the system in the same way that they would do for the computation model.

To summarize, numerous multilevel modeling efforts exist. However, they are being developed, not addressing the issue of lack of information at the transition between levels of abstraction. The solution of

this problem is essential for true stepwise refinement of the performance models to behavioral models. In addition, integration of performance modeling level and behavioral modeling level was mostly performed by mixing different simulation environments, which results in heterogeneous modeling approach.

12.2 ADEPT Design Environment

A unified end-to-end design environment based solely on VHDL that allows designers to model systems from the abstract level to the gate level as described above has been developed. This environment supports the development of system-level models of digital systems that can be analyzed for multiple metrics like performance and dependability, and can then be used as a starting point for the actual implementation. A tool called Advanced design environment prototype tool (ADEPT) has been developed to implement this environment. ADEPT actually supports both system-level performance and dependability analysis in a common design environment using a collection of predefined library elements. ADEPT also includes the capability to simulate both system- and implementation-level (behavioral) models in a common simulation environment. This capability allows the stepwise refinement of system-level models into implementation-level models.

Two approaches to creating a unified design environment are possible. An evolutionary solution is to provide an environment that ''translates'' data from different models at various points in the design process and creates interfaces for the noncommunicating software tools used to develop these models. With this approach, users must be familiar with several modeling languages and tools. Also, analysis of design alternatives is difficult and is likely to be limited by design time constraints.

A revolutionary approach, the one being developed in ADEPT, is to use a single modeling language and mathematical foundation. This approach uses a common modeling language and simulation environment which decreases the need for translators and multiple models, reducing inconsistencies and the probability of errors in translation. Finally, the existence of a mathematical foundation provides an environment for complex system analysis using analytical approaches.

Simulators for hardware description languages accurately and conveniently represent the physical implementation of digital systems at the circuit, logic, register-transfer, and algorithmic levels. By adding a system-level modeling capability based on extended Petri nets and queuing models to the hardware description language, a single design environment can be used from concept to implementation. The environment would also allow for the mixed simulation of both *uninterpreted* (performance) models and *interpreted* (behavioral) models because of the use of a common modeling language. Although it would be possible to develop the high-level performance model and the detailed behavioral model in two different modeling languages and then develop some sort of ''translator'' or foreign language interface to hook them together, a better approach is to use a single modeling language for both models. A single modeling language that spans numerous design phases is much easier to use, encouraging more design analysis and consequently better designs.

ADEPT implements an end-to-end unified design environment based upon the use of the VHSIC hardware description language (VHDL), IEEE Std. 1076 [34]. VHDL is a natural choice for this single modeling language in that it has high-level language constructs, but unlike other programming languages, it has a built-in timing and concurrency model. VHDL does have some disadvantages in terms of simulation execution time, but techniques have been developed to help address this problem [35].

ADEPT supports the integrated performance and dependability analysis of system-level models and includes the capability to simulate both uninterpreted and interpreted models through mixed-level modeling. ADEPT also has a mathematical basis in Petri nets thus providing the capability for analysis through simulation or analytical approaches [36].

In the ADEPT environment, a system model is constructed by interconnecting a collection of predefined elements called ADEPT modules. The modules model the information flow, both data and control, through a system. Each ADEPT module has a VHDL behavioral description and a corresponding mathematical description in the form of a CPN based on Jensen's CPN model [37]. The modules

communicate by exchanging *tokens*, which represent the presence of information, using a fully interlocked, four-state handshaking protocol [38]. The basic ADEPT modules are intended to be building blocks from which useful modeling functionality can be constructed. In addition, custom modules can be developed by the user if required and incorporated into a system model as long as the handshaking protocol is adhered to. Finally, some libraries of application-specific, high-level modeling modules such as Multiprocessor Communications Network Modeling Library [39] have been developed and included in ADEPT.

The following sections discuss the VHDL implementation of the token data type and transfer mechanism used in ADEPT, and the modules provided in the standard ADEPT modeling library.

12.2.1 Token Implementation

The modules defined in this chapter have been implemented in VHDL, and use a modified version of the token passing mechanism defined by Hady [38]. Signals used to transport tokens must be of the type *token*, which has been defined as a record with two fields. The first field, labeled STATUS, is used to implement the token passing mechanism. The second field, labeled COLOR, is an array of integers that is used to hold user-defined color information in the model. The ADEPT allow the user to select from a predefined number of color field options. The tools then automatically link in the proper VHDL design library so that the VHDL descriptions of the primitive modules operate on the defined color field. The default structure of the *data-type* token used in the examples discussed in this document is shown in Figure 12.6.

There are two types of outputs and two types of inputs in the basic ADEPT modules. *Independent* outputs are connected to *control* inputs, and the resulting connection is referred to as a *control-type* signal. *Dependent* outputs are connected to *data* inputs, and the resulting connection is referred to as a *data-type* signal. To make the descriptions more intuitive, outputs are often referred to as the "source side" of a signal, and inputs are referred to as the "sink side" of a signal.

```
type handshake is (removed, acked, released, present);
type token_fields is (status,
                      tag1, tag2, tag3, tag4, tag5,
                      tag6, tag7, tag8, tag9, tag10,
                      tag11, tag12, tag13, tag14, tag15,
                      boole1, boole2, boole3,
                      fault, module_info,
                      index, act_time, color);
type color_type is array (token_fields range tag1 to act_time) of integer;

type cmp_fields is (lt, le, gt, ge, eq, ne);
type tkf_array is array (1 to 25) of token_fields;-- used in file_read

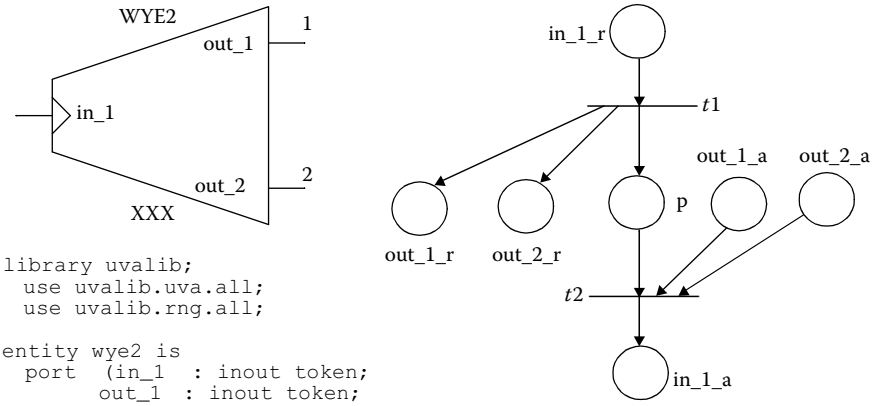
type token_vector is array (integer range <>) of token;

--  resolution function for token
function protocol (input : token_vector) return token;
subtype token_res is protocol token;
```

FIGURE 12.6 Token type definition.

Tokens on *independent* outputs may be written over by the next token, so the ''writing'' process is *independent* of the previous value on the signal. In contrast, new tokens may not be placed on *dependent* outputs until the previous token has been removed, so the ''writing'' process is *dependent* on the previous value on the signal. Data-type signals use the four-step handshaking process to ensure that tokens do not get overwritten, but no handshaking occurs on *control-type* signals.

The STATUS field of a token signal can take on four values. Signals connecting *independent* outputs to *control* inputs (control-type signals) make use of only two of the four values. *Independent* outputs place a value PRESENT on the status field to indicate that a token is present. Since *control* inputs only copy the token but do not remove it, the *independent* output only needs to change the value of the status field to RELEASED to indicate that the token is no longer present on the signal, and the *control* input can no longer consider the signal to contain valid information. The signals connecting *dependent* outputs to *data* inputs (data-type signals) need all four values (representing a fully interlocked handshaking scheme) to ensure that a dependent output does not overwrite a token before the data input to which it is connected has read and removed it. This distinction is important since a token on control-type signals represents the presence or absence of a condition in the network while tokens on data-type signals, in contrast, represent information or data that cannot be lost or overwritten. In addition, fanout is not permitted on *dependent* outputs and is permitted on *independent* outputs.



The signals used in the implementation are of type *token*. The token passing mechanism for data-type signals is implemented by defining a VHDL bus resolution function. This function is called each time a signal associated with a dependent output and a data input changes value. The function essentially looks at the value of the STATUS field at the ports associated with the signal and decides the final value of the signal. At the beginning of simulation the STATUS field is initialized to REMOVED. This value on a signal corresponds to an idle link in the nets defined by Dennis [40]. This state of a signal indicates that a signal is free and a request token may be placed on it. Upon seeing the REMOVED value, the requesting module may set the value of the signal to PRESENT. This operation corresponds to the ready signal in Dennis' definition. The requested module acknowledges a ready signal (PRESENT) by setting the signal value to ACKED, after the requested operation has been completed. Upon sensing the value of ACKED on the signal, the requesting module sets the value of the signal to RELEASED, which in turn causes the requested module to place the value of REMOVED on the signal. This action concludes one request/acknowledge cycle, and the next request/acknowledge cycle may begin.

In terms of Petri Nets, the models described here can be described as one-safe Petri nets since, at any given time, no place in the net can contain more than one token. The correspondence between the signal values and transitions in a Petri net may be defined, in general, in the following manner:

1. *PRESENT*. A token arrives at the input place of a transition.
2. *ACKED*. The output place of a transition is empty.
3. *RELEASED*. The transition has fired.
4. *REMOVED*. The token has been transferred from the input place to the output place.

The modules to be described in this chapter may be defined in terms of Petri nets. As an example, a Petri net description of the Wye module is shown in Figure 12.7.

The function of the Wye module is to copy the input token to both outputs. The input token is not acknowledged until both output tokens have been acknowledged. In the Petri net of Figure 12.7, the ''r'' and ''a'' labels correspond to ''ready'' and ''acknowledge,'' respectively. When a token arrives at the place labeled ''0r,'' the top transition is enabled and a token is placed in the ''1r,'' ''2r,'' and center places. The first two places correspond to a token being placed on the module outputs. Once the output tokens are acknowledged (corresponding to tokens arriving at the ''1a'' and ''2a'' places), the lower transition is enabled and a token is placed in ''0a,'' corresponding to the input token being acknowledged. The module is then ready for the next input token. Note that since this module does not manipulate the color fields, no color notation appears on the net.

```
library uvalib;
  use uvalib.uva.all;
  use uvalib.rng.all;

entity wye2 is
  port  (in_1  : inout token;
         out_1  : inout token;
         out_2  : inout token);
end wye2;

architecture ar_wye2 of wye2 is
begin
  pr_wye2 : process (in_1, out_1, out_2)
  begin
    if token_present (in_1)
      and token_removed (out_1)
      and token_removed (out_2) then
      out_1 <= in_1;
      out_2 <= in_1;
    end if;

    if token_acked (out_1) and token_acked (out_2) then
     ack_token (in_1);
     release_token (out_1);
     release_token (out_2);
    end if;

    if token_released (in_1) then
      remove_token (in_1);
    end if;
  end process pr_wye2;
end ar_wye2;
```

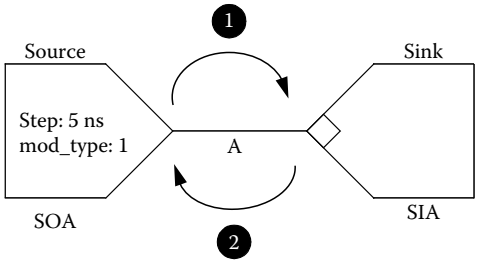


FIGURE 12.7 Wye module ADEPT symbol, its behavioral VHDL description, and its CPN representation.

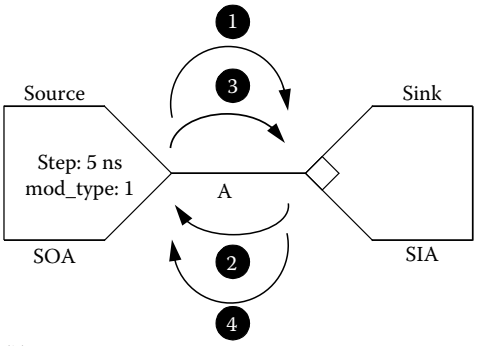
The specific CPN description used is based on the work of Jensen [37]. The complete CPN descriptions of each of the ADEPT building blocks can be found in Ref. [41].

12.2.2 ADEPT Handshaking and Token Passing Mechanism

Recall that the ADEPT standard token has a *status* field which can take on four values: *PRESENT, ACKED, RELEASED,* and *REMOVED*. These values reflect which stage of the token passing protocol is currently in progress. Several examples will now be presented to show how the handshaking and token passing occurs between ADEPT modules. Figure 12.8 illustrates the handshaking process between a Source module connected to a Sink module.

Figure 12.8a describes the ''simplified'' event sequence. Here, we can think of the four-step handshaking as consisting of simply a forward propagation of the token and a backward propagation of the token acknowledgment. Thinking of the handshaking in this simplified manner, Table A in Figure 12.8 shows the simplified event sequence and times. At time 0 ns, the Source module places a token on A, corresponding to Event 1. The token is immediately acknowledged by the Sink module, corresponding



Time between new tokens on A = step + path delay = 5 ns

(a)

TABLE A Simplified Event Sequence

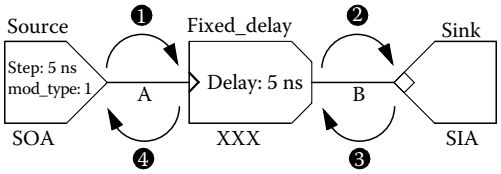
Event	Time (ns)	Description
1	0	Source module places token on signal A
2	0	Sink module acknowledges token on A
1	5	Source module places next token on signal A

(b)

TABLE B Detailed Event Sequence

Event	Time (ns)	Delta	Description	Resolved Signal A
1	0	1	Source module places token on A	*PRESENT*
2	0	2	Sink module acknowledges token on A	*ACKED*
3	0	3	Source module release token on A	*RELEASED*
4	0	4	Sink module removes token on A	*REMOVED*
1	5	1	Source module places token on A	*PRESENT*

FIGURE 12.8 Two module handshaking examples.



to Event 2. Since the Source module has a *step* generic of 5 ns, and there is no other delay along the path to the Sink, the next token will be output by the Source module at time 5 ns.

Figure 12.8b details the entire handshaking process. Table B in Figure 12.8 lists the detailed event sequence for this example. Since handshaking occurs in zero simulation time, the events are listed by *delta cycles* within each simulation time. The function of delta cycles in VHDL is to provide a means for ordering and synchronizing events (such as handshaking) which occur in zero time. The actual event sequence for this example consists of four steps, as shown in Figure 12.8b. Event 1 is repeated at time 5 ns, which starts the handshaking process over again.

12.2.2.1 Three-Module Example

To illustrate how tokens are passed through intermediate modules, a three-module example will now be examined. Consider the case where a Fixed Delay module is placed between a Source and Sink. This situation is illustrated in Figure 12.9.

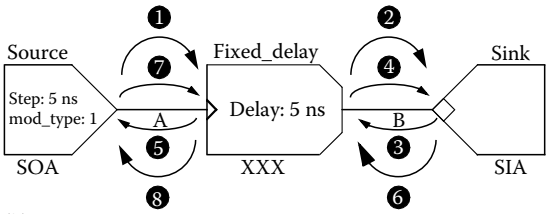


Figure 12.9a shows the simplified event sequence, where we can think of the four-step handshaking as consisting of simply a forward propagation of the token and a backward propagation of the token acknowledgment. Table A in Figure 12.9 lists this simplified event sequence. Notice that since now there is a path delay from the Source to the Sink, the time between new tokens from the Source is *step* + *path_delay* = 5 + 5 = 10 ns. At time 0 ns, the Source module places the first token on Signal A (Event 1). This token is read by the Delay module and placed on Signal B after a delay of 5 ns (Event 2). The Sink module then immediately acknowledges the token on Signal B (Event 3). The Delay module then passes

(a)

TABLE A Simplified Event Sequence

Event	Time (ns)	Description
1	0	Source module places token on signal A
2	5	Delay module places token on signal B
3	5	Sink module acknowledges token on signal B
4	5	Delay module acknowledges token on signal A
1	10	Source module places next token on signal A

(b)

TABLE B Detailed Event Sequence

Event	Time (ns)	Delta	Description	Resolved Signal A	Resolved Signal B
1	0	1	Source module places token on A	*PRESENT*	*REMOVED*
2	5	1	Delay module places token on B	—	*PRESENT*
3	5	2	Sink module acknowledges token on B	—	*ACKED*
4	5	3	Delay module releases token on B	—	*RELEASED*
5			Delay module acknowledges token on A	*ACKED*	—
6	5	4	Sink module removes token on B	—	*REMOVED*
7			Source module relases token on A	*RELEASED*	—
8	5	5	Delay module removes token on A	*REMOVED*	—
1	10	1	Source module places token on A	*PRESENT*	—

FIGURE 12.9 Three-module handshaking examples.

this acknowledgment back through to Signal A (Event 4). At time 10 ns, the Source module places the next token on Signal A, starting the process over again.

Figure 12.9b shows the detailed event sequence for this example. Since there are two signals, there are a total of eight detailed events. Table B in Figure 12.9 lists the detailed event sequence for this example. Again since the handshaking occurs in zero simulation time, the events are listed by delta cycles within each simulation time. Table B lists the resolved values on both Signal A and Signal B, where a value of "—" indicates no change in value. Notice that the sequence of events on each signal proceeds in this order: place the token (*PRESENT*) by the "source side," acknowledge the token (*ACKED*) by the "sink side," release the token (*RELEASED*) by the "source side," and finally remove the token (*REMOVED*) by the "sink side." The important concept to note in this example is the ordering of events. Notice that the Delay module releases the token on its output (Event 4) before it acknowledges the token on its input (Event 5), even though the two events occur in the same simulation time. These actions trigger the Sink module to then remove the token on Signal B (Event 6) and the Source module to release the token on Signal A (Event 7), both in the next delta cycle. Thus Signal B is ready for another token (removed) a full delta cycle before Signal A is ready.

12.2.2.2 Token Passing Example

To illustrate how tokens propagate in a larger system, consider the model shown in Figure 12.10. This figure shows the simplified event sequence, where again we can think of the four-step handshaking as consisting of simply a forward propagation of the token and a backward propagation of the token acknowledgment. In this system, the Source module provides tokens to the Sequence A (SA) module (Event 1), who first passes them to the Sequence B (SB) module (Event 2). The SB module first passes the token to the Fixed Delay A (FDA) module (Event 3), who passes it to the Sink A (SIA) module after a delay of 5 ns (Event 4). The SIA module then immediately acknowledges the token (Event 5), which causes the FDA module to pass the acknowledgment back to the SB module (Event 6). At this point the SB module places a copy of the token on its second output (Event 7), where it is passed through the

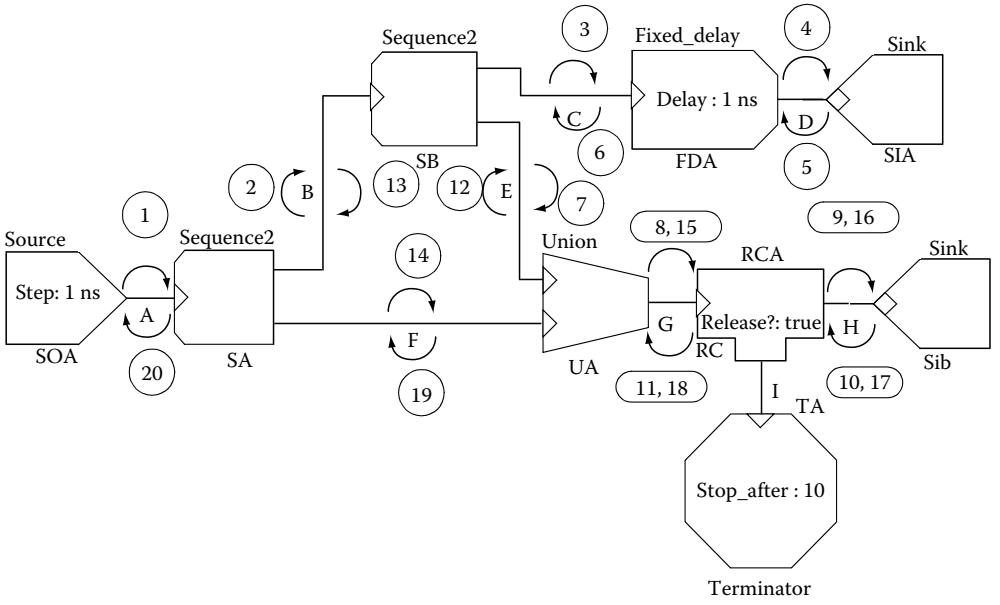

FIGURE 12.10 Token passing example showing simplified event sequence.

Union A and onto its output (Event 8). The Read Color A module then places the token on its out_1 output (Event 9) and simultaneously places the token on its *independent* output. The Sink B module then acknowledges the token on Signal H (Event 10). Upon seeing this acknowledgment, the Read Color A module releases the token on its *independent* output since the Read Color module has no ''memory'' (the *release?* generic equals *true*). The acknowledgment is then propagated back to the SB module (Events 11 and 12). At this point, the SB module acknowledges its input token (Event 13), freeing the SA module to place a token on its second output (Event 14). This token is then passed through the Union A, Read Color A, and Sink module (Events 15 and 16) and the acknowledgment is returned (Events 17–19). The SA module can then acknowledge the token on its input (Event 20), allowing the Source module to generate the next token 5 ns (*step*) later.

If we examine the activity on Signal I (the *independent* output of the Read Color A module), we see that it goes present after Event 8, released after Event 10, present after Event 15, and released again after Event 17. Consider the operation of the Terminator module attached to this signal. Since the Terminator module halts simulation after the number of active events specified by the *stop_after* generic, if we were to simulate this example, the simulation would halt after Event 15 (the second active event).

12.2.3 Module Categories

The ADEPT primitive modules may be divided into six categories: *control modules*, *color modules*, *delay modules*, *fault modules*, *miscellaneous parts modules*, and *mixed-level modules*.

As the name implies, the *control modules* are used to control the flow of tokens through the model. As such, the control modules form the major portion of the performance model. The control modules operate only on the STATUS field of a signal and do not alter the color of a token on a signal. Further, no elapsed simulation time results from the activation of the control modules since they do not have any delay associated with them. There are several control modules whose names end in a numeral, such as ''union2.'' These modules are part of a family of modules that have the same function, but differ in the number of inputs or outputs that they possess. For example, there are eight ''union'' modules, ''union2,'' ''union3,'' ''union4,'' ..., ''union8.'' With the exception of the Switch, Queue, and logical modules, the control modules have been adapted from those proposed by Dennis [40].

The control modules described above process colored tokens but do not alter the color fields of the tokens passing through them. Manipulation of the color field of a token is reserved to the *color modules*. These color modules permit various operations on the color fields such as allowing the user to read and write the color fields of the tokens. The color modules also permit the user to compare the color information carried by the tokens and to control the flow of the tokens based on the result of the comparisons. The use of these color modules enables high-level modeling of systems at different levels of detail. These modules permit the designer to add more detail or information to the model by placing and manipulating information placed on the color fields of tokens flowing through the model. The color fields of these tokens can be set and read by these modules to represent such things as destination or source node addresses, data length, data type (e.g., ''digital'' or ''analog''), or any type of such information that the designer feels is important to the design.

The *delay modules* facilitate the description of data path delays at the conceptual or block level of a design. As an example, the Fixed Delay module, or the FD module, may be used in conjunction with the control modules to model the delay in the control structure of a design which is independent on the type or size of an operation being performed. In contrast, the Data-Dependent Delay module may be used to model processes in which the time to complete a particular operation is dependent on the amount or type of data being processed. The input to the Data-Dependent Delay module is contained on one of the color fields of the incoming token.

The *fault modules* are used to represent the presence of faults and errors in a system model. The modules allow the user to model fault injection, fault/error detection, and error correction processes. The *miscellaneous parts* category contains modules that perform ''convenience'' functions in ADEPT.

Examples include the Collector, Terminator, and Monitor modules. The Collector module is used to write input activation times to a file, and the Terminator module is used to halt simulation after a specified number of events have occurred. The Monitor module is a data-collection device that can be connected across other modules to gather statistical information during a VHDL simulation.

The *mixed-level modules* support mixed-level modeling in the ADEPT environment by defining the interfaces around the interpreted and uninterpreted components in a system model. The functions of these modules and their use in creating mixed-level models are described in more detail in Sections 12.4.2 and 12.4.3.

The complete functionality of each primitive module is defined and the generics associated with each of the modules are described in the *ADEPT Library Reference Manual* [42]. The standard ADEPT module symbol convention is also explained in more detail in the *ADEPT Library Reference Manual.*

In addition to the primitive modules, there are libraries of more complex modules included in ADEPT. In general, these libraries contain modules for modeling systems in a specific applications area. These libraries are also discussed in more detail in the *ADEPT Library Reference Manual.*

12.2.4 ADEPTs

The ADEPT system is currently available on Sun platforms using Mentor Graphics' *Design Architect* as the front end schematic capture system, or on Windows PCs using OrCAD's *Capture* as the front end schematic capture system. The overall architecture of the ADEPT system is shown in Figure 12.11.

The schematic front end is used to graphically construct the system model from a library of ADEPT module symbols. Once the schematic of the model has been constructed, the schematic capture system's netlist generation capability is used to generate an electronic design interchange format (EDIF) 2.0.0 netlist of the model. Once the EDIF netlist of the model is generated, the ADEPT software is used to translate the model into a structural VHDL description consisting of interconnections of ADEPT

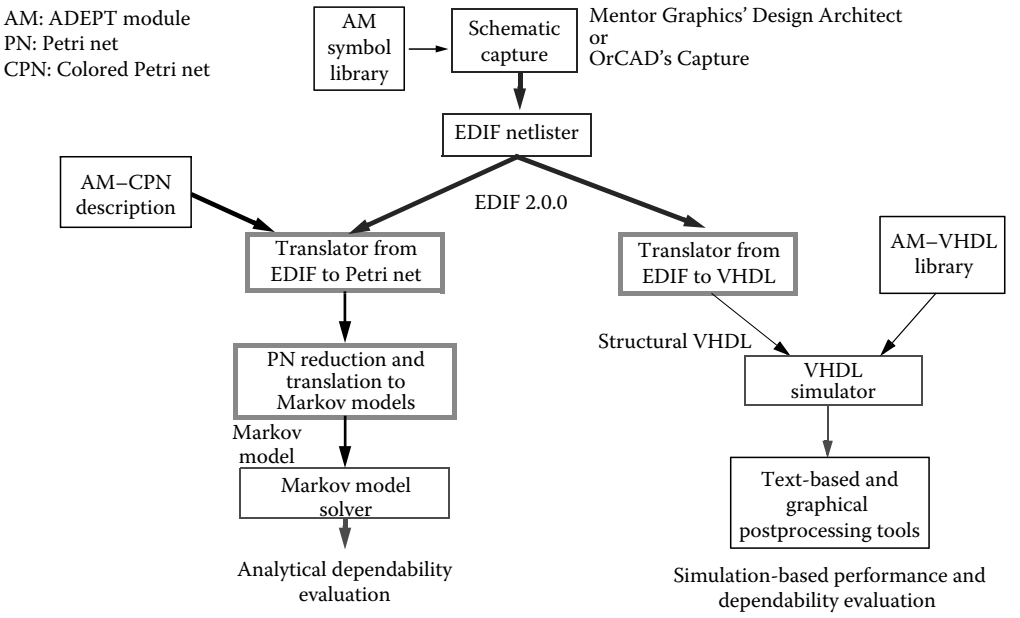

FIGURE 12.11 ADEPT design flow.

modules. The user can then simulate the structural VHDL that is generated using the compiled VHDL behavioral descriptions of the ADEPT modules to obtain performance and dependability measures.

In addition to VHDL simulation, a path exists that allows the CPN description of the system model to be constructed from the CPN descriptions of the ADEPT modules. This CPN description can then be translated into a Markov model using well-known techniques and then solved using commercial tools to obtain reliability, availability, and safety information.

12.3 Simple Example of an ADEPT Performance Model

This section presents a simple example of the usage of the primitive building blocks for performance modeling. The example is a three-computer system wherein the three-computers share a common bus. The example also presents simulation results and system performance evaluations.

12.3.1 Three-Computer System

This section discusses a simple example to illustrate how the modules discussed previously may be interconnected to model and evaluate the performance of a complete system. The system to be modeled consists of three computers communicating over a common bus, as shown in Figure 12.12. Each block representing a computer can be thought to contain its own processor, memory, and peripheral devices. The actual ADEPT schematic for the three-computer system is shown in Figure 12.13.

Computer C1 contains some sensors and preprocessing capabilities. It collects data from the environment, converts it into a more compact form and then sends it to computer C2 via the bus. The computer C2 further processes the data and passes it to computer C3 where the data are appropriately utilized. It is assumed that data are transferred in packets and each packet of data is of varying length. In the example described here, computers C1 and C2 receive packets whose sizes are uniformly distributed between 0 and 100. The packet size of computer C3 is uniformly distributed between 0 and 500. The external environment in this example is modeled by a Source module in C1 and a Sink module in C3.

C1 has an output queue, C2 has both an input queue and an output queue, while C3 has one input queue. All queues in this example are assumed to be of length 8. If the input queues of C2 or C3 are full the corresponding Q_free signal is released (value = *RELEASED*). This interconnection prevents the

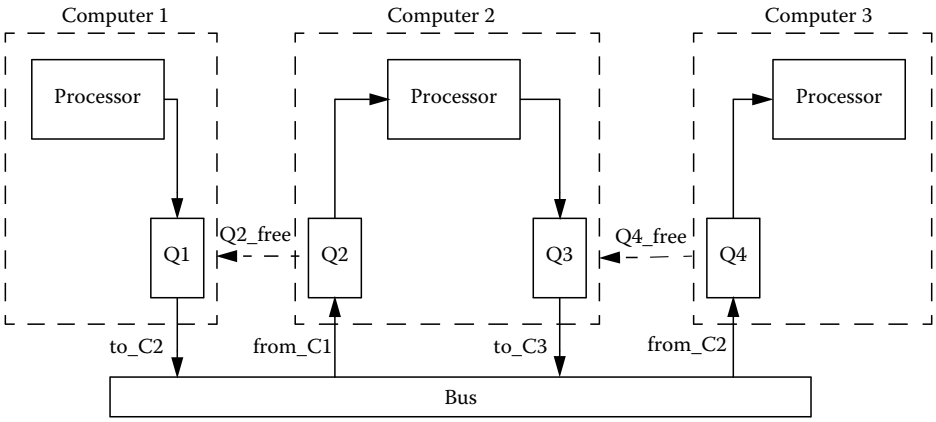

FIGURE 12.12 Three-computer system.

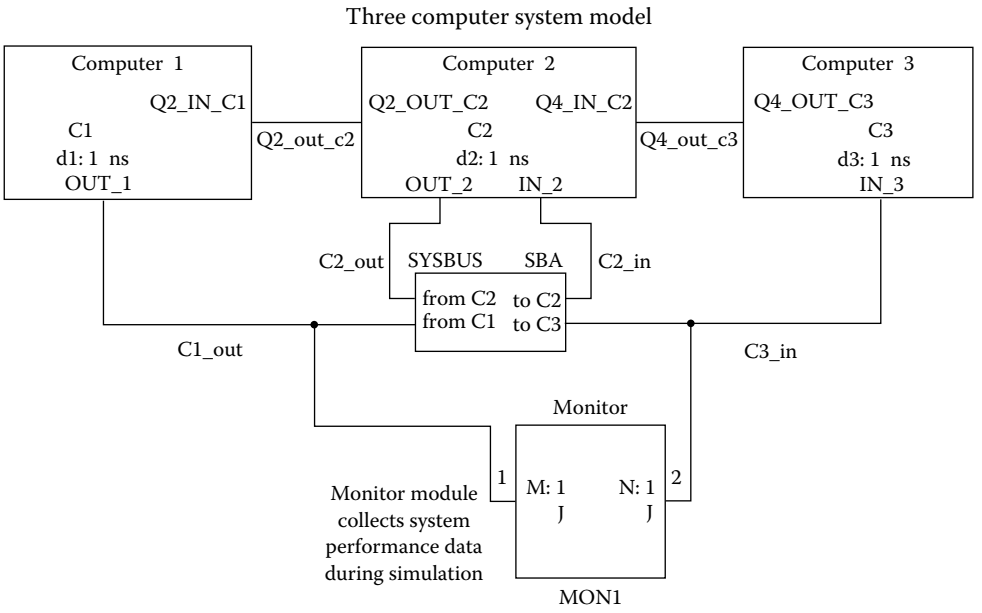

FIGURE 12.13 Three-computer system ADEPT schematic.

computer writing into the corresponding queue from placing data on the bus when the queue is full. This technique not only prevents the bus from being unnecessarily held up but also eliminates the possibility of a deadlock.

The ADEPT model of Computer 1 (C1) is shown in Figure 12.14. The Source A (SOA) module along with the Sequence A (SA), Set_Color A (SCA) and Random A (RA) modules generate tokens whose *tag1* field is set according to a distribution which is representative of the varying data sizes that C1 receives. The Data-Dependent Delay A (DDA) models the processing time of C1 which is directly proportional to the packet size. The *unit_step* delay for the DDA module is passed down as a generic *d1**1 ns. As soon as a token, representing one packet of data, appears at the output of the DDA module, the Sequence B (SB), Set_Color B (SCB), and Random B (RB) modules together set the *tag1* field of the token to represent the packet size after processing. The Constant A (COA) and Set_Color C (SCC) modules set the *tag2* field of the token to 2. This coloring indicates to the bus arbitration unit that the token is to be transferred to C2. The token is then placed in the output Queue (Q1) of C1 and the token is acknowledged. This acknowledge signal is passed back to the Source A module which then produces the next token. The Fixed Delay (FDA and FDB) modules represent the read and write times associated with the Queue. The Switch A (SWA) element is controlled by the Q_free signal from C2 and prevents a token from the output queue of C1 from being placed on the bus if the incoming Q_free signal is inactive.

Figure 12.15 shows the ADEPT model of Computer 2 (C2). When a token arrives at the *data* input of C2 the token is placed at the input of the Queue (Q2). The *control* output of the Queue becomes the Q2_Free output of C2. The remaining modules perform the same function as in C1 except that the tag2 field of the tokens output by C2 is set to 3 which indicates to the bus arbitration unit that the token is to be sent to C3. The DDA module represents the relative processing speed of Computer C2. The *unit_step* delay for the DDA module is passed down as a generic *d2**1 ns.

The modules defining Computer 3 (C3) are shown in Figure 12.16. A token arriving at the input is placed in the queue. The DDA element reads one token at a time and provides the delay associated with

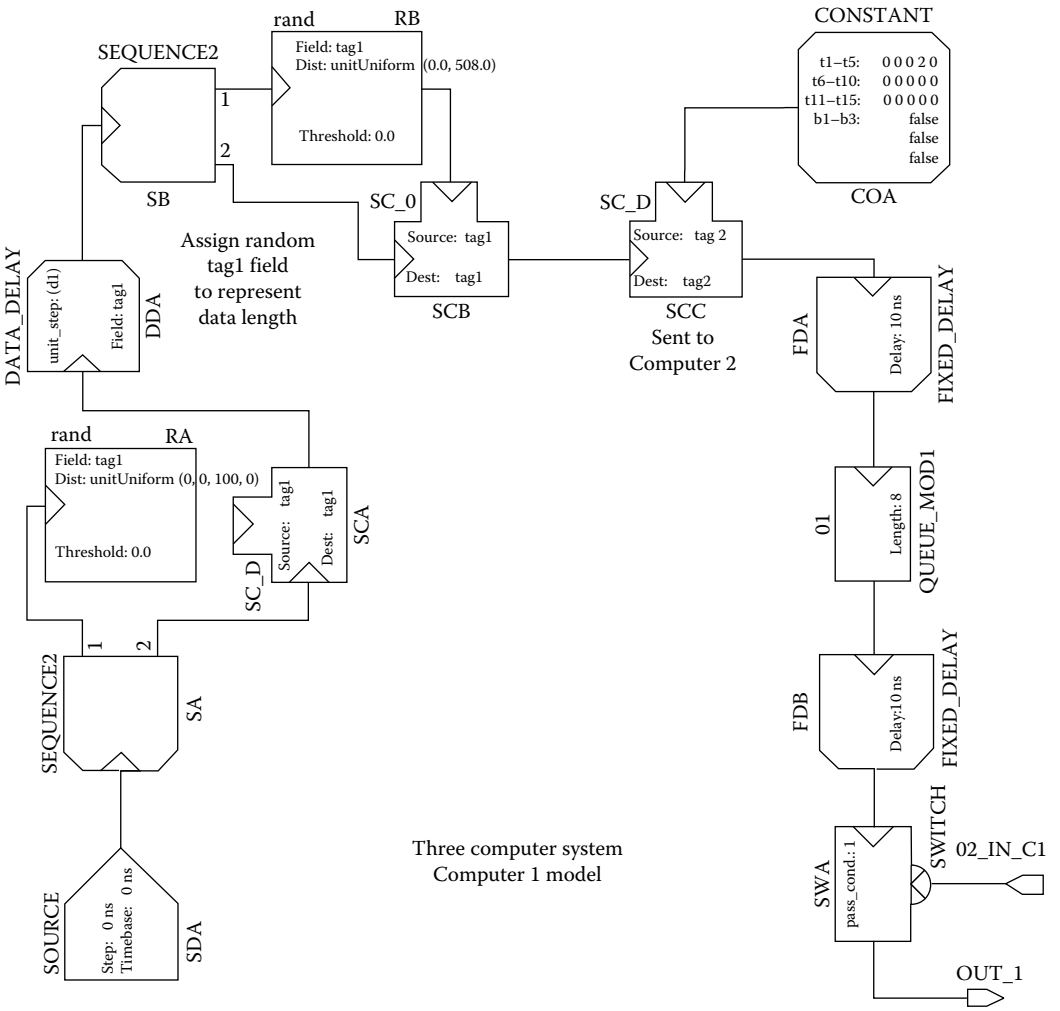

FIGURE 12.14 ADEPT model of Computer 1.

the processing time of C3 before the Sink A (SIA) module removes the token. The *unit_step* delay for the DDA module is passed down as a generic *d3**1 ns.

The bus is shown in Figure 12.17. Arbitration is provided to ensure that both C1 and C2 do not write onto the bus at the same time. The Arbiter A (AA) element provides the required arbitration. Since the output of C2 is connected to the IN_1(1) input of the AA element, it has a higher priority over C1. The Union A (UA) element passes a token present at either of its inputs to its output. The output of the UA element is connected to the Data-Dependent Delay A (DDA) element, which models the packet transfer delay associated with moving packets over the bus. The delay through the bus is dependent on the size of the packet of information being transferred (size stored on the *tag1* field). Note that in this analysis, the bus delay was set to 0. The *independent* output of the Read_Color A(RCA) element is connected to the *control* input of the Decider A (DA) module. The base of the DA element is set to 2. Since the *tag2* field of the token is set to 2 or 3 depending on whether it originated from C1 or C2, the first output of the Decider A module is connected to C2 and the second output is connected to C3. This technique ensures that the tokens are passed on to the correct destination, C2 or C3.

12.3.2 Simulation Results

This section presents simulation results that illustrate the queuing model capabilities of the ADEPT system. The model enables the study of the overall speed of the system in terms of the number of packets of information transferred in a given time. It also allows the study of the average number of tokens present in each queue during simulation, and the effect of varying system parameters on the number of items in the queues and overall throughput of the system. The generic unit_step delay of the DD elements (*d1*, *d2*, and *d3*) associated with the three computers is representative of the processing speed of the computers. The optimal relative speeds of the computers may also be deduced by simulation of this model. Figure 12.18 shows graphs of the number of items in each queue versus simulation time. These graphs were generated using the BAARS postsimulation analysis tool. The upper graph shows the queue lengths when *d1*, *d2*, and *d3* was set to 5, 5, and 2 ns. The lower graph shows the queue lengths when *d1*, *d2*, and *d3* was set to 5, 4, and 1 ns. In the first case, because the processing time of Computer 3 was so much longer than Computer 1 or 2, the queue in Computer 3 became full at ∼4000 ns of simulation time. The filling of the queue in Computer 3 delayed items coming out of Computers 1 and 2 thus causing their queues to also become full. In the second case, the processing time ratios were such that Computer 3 could keep up with the incoming tokens and the queues never got completely full.

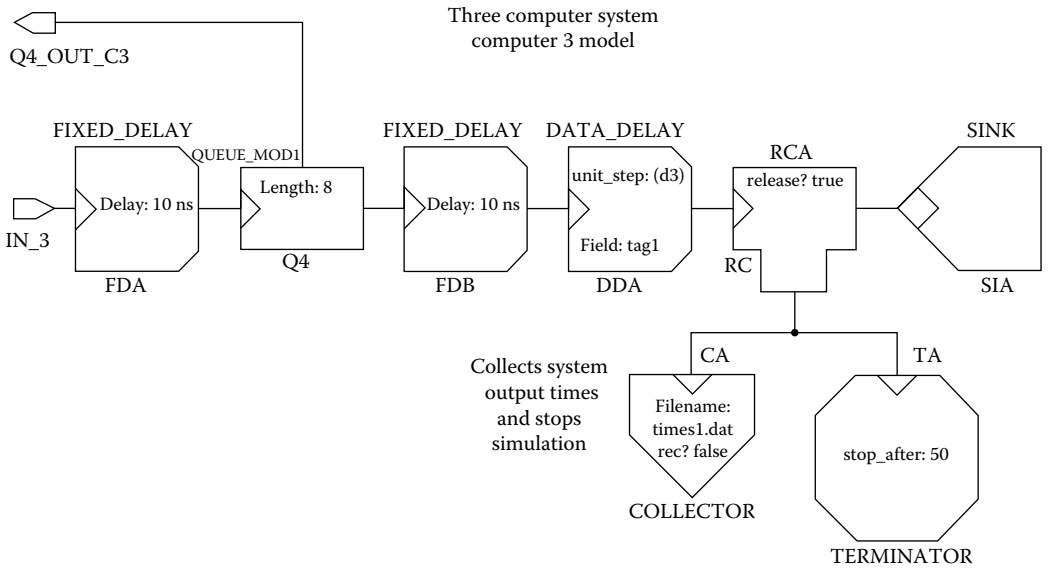

FIGURE 12.16 ADEPT model of Computer 3.

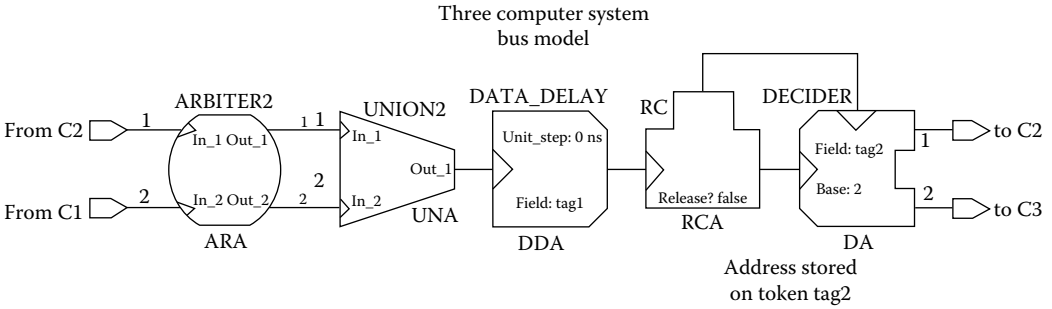

FIGURE 12.17 ADEPT model of system bus.

Table 12.1 summarizes the effect of relative speeds of the computers on the number of packets transferred. Since the size of the packets received by C3 is uniformly distributed between 0 and 500 while the size of the packets received by C1 and C2 is uniformly distributed between 0 and 100, it is intuitively obvious that the overall throughput of the system is largely determined by the speed of Computer C3. The results do indicate this behavior. For example, when the relative instruction execution times for C1, C2, and C3 are 5, 5, and 2, respectively, a total of 197 packets are transferred. By increasing the instruction execution time of C2 by one time unit and decreasing the instruction execution time of C3 by one time unit, it is seen that a total of 321 packets are transferred, an increase of slightly over 60%.

This example has illustrated the use of the various ADEPT modules to model a complete system. Note how the interconnections between modules describing a component of the system are similar to a flow chart describing the behavior of the component. This example also demonstrated that complex systems at varying levels of abstraction and interpretation can easily be modeled using the VHDL-based ADEPTs.

12.4 Mixed-Level Modeling

As described earlier, performance (uninterpreted) modeling has been previously used primarily by systems engineers when performing design analysis at the early stages of the design process. Although most of the design detail is not included in these models since this detail does not yet exist, techniques such as token coloring can be used to include that design detail that is necessary for an accurate model.

However, most of the detail, especially very low-level information such as word widths and bit encoding, are not present. In fact, many additional design decisions must be made before an actual implementation could ever be constructed. In performance models constructed in ADEPT, abstract tokens are used to represent this information (data and control) and its flow in the system. An illustration of such a performance model with its analysis was given the three-computer system described in Section 12.3.1. In contrast, behavioral (interpreted) models can be thought of as including much more design detail often to the point that an implementation could be constructed. Therefore, data values and system timing are available and variables typically take on integer, real, or bit values. For example, a synthesizable model of a carry-lookahead adder would be one extreme of a behavioral model.

It should be obvious that the two examples described above are extremes of the two types of models. Extensive design detail can be housed in the tokens of a performance model and information in a behavioral model can be encapsulated in a very abstract type. However, there is always a difference in the abstraction level of the two modeling types. Therefore, to develop a model that can include both performance and behavioral models, interfaces between the different levels of design abstraction, called *mixed-level interfaces,* must be included in the overall model to resolve differences between these two modeling domains.

The mixed-level interface is divided into two primary parts which function together; the part that handles the transition from the uninterpreted domain to the interpreted domain (U/I) and the part that handles the transition from the interpreted domain to the uninterpreted domain (I/U). The general structure of a mixed-level model is shown in Figure 12.19.

In addition to the tokens-to-values (U/I) and values-to-tokens (I/U) conversion processes, the mixed-level interface must resolve the differences in design detail that naturally exist at the interface between uninterpreted and interpreted elements. These differences in detail appear as differences in data and timing abstraction across the interface. The differences in timing abstraction across the interface arise because the components at different levels model timing events at different granularities. For example, the passing of a token that represents a packet of data being transferred across a network in

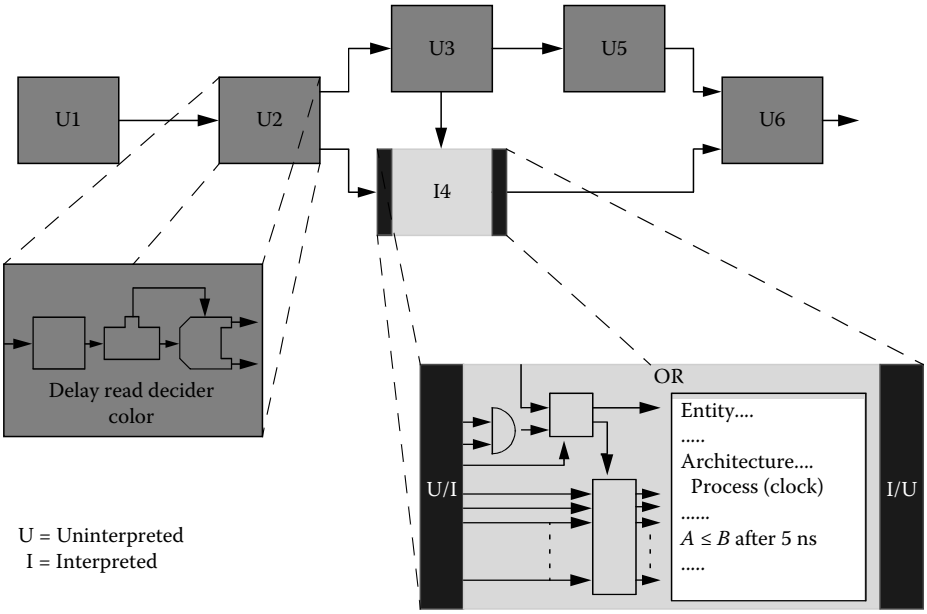

FIGURE 12.19 General structure of a mixed-level model.

a performance model may correspond to hundreds or thousands of bus cycles for a model at the behavioral level.

The differences in data abstraction across the interface are due to the fact that typically, performance models do not include full functional details whereas behavioral models require full functional data (in terms of values on their inputs) to be present before they will execute correctly. For example, a performance level modeling token arriving at the inputs to the mixed-level interface for a behavioral floating point coprocessor model may contain information about the operation the token represents, but may not contain the data upon which the operation is to take place. In this case, the mixed-level interface must generate the data required by the behavioral model and do it in a way that a meaningful performance metric, such as best- or worst-case delays, is obtained.

12.4.1 Mixed-Level Modeling Taxonomy

The functions that the mixed-level interface must perform and the most efficient structure of the interface are affected by several attributes of the system being modeled and the model itself. To partition the mixed-level modeling space and better define the specific solutions, a taxonomy of mixed-level model classes has been developed [43]. The classes of mixed-level modeling are defined by those model attributes which fundamentally alter the development and the implementation of the mixed-level interface. The mixed-level modeling space is partitioned according to three major characteristics:

1. Evaluation *objective* of the mixed-level model
2. *Timing mechanism* of the uninterpreted model
3. *Nature* of the interpreted element

For a given mixed-level model, these three characteristics can be viewed as attributes of the mixed-level model and the analysis effort. Figure 12.20 summarizes the taxonomy of mixed-level models.

Mixed-level modeling objectives. The structure and the functionality of the mixed-level interface are strongly influenced by the objective that the analysis of the mixed-level model will be targeted toward. For the purposes of this work, these objectives were broken down into two major categories:

1. *Performance analysis* and *timing verification*. To analyze the performance of the system (as defined previously) and verify that the specific components under consideration meet system timing constraints. Note that other metrics, such as power consumption, could be analyzed using mixed-level models, but these were outside the scope of this classification.
2. *Functional verification*. To verify that the function (input-to-output value transformation) of the interpreted component is correct within the context of the system model.

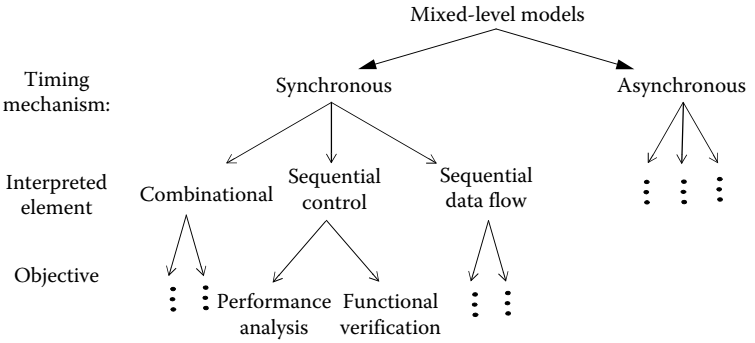

FIGURE 12.20 Mixed-level modeling categories.

Timing mechanisms. Typically, performance (uninterpreted) models are asynchronous in nature and the flow of tokens depends on the handshaking protocol. However, in modeling a system that is globally synchronous (all elements are synchronized to a global clock) a mechanism to synchronize the flow of tokens across the model can be introduced. This synchronization of the performance model will require different mixed-level modeling approaches. Thus the two types of system models that affect the mixed-level interface are

1. *Asynchronous models*. Tokens on independent signal paths within the system model move asynchronously with respect to each other and arrive at the interface at different times.
2. *Synchronous models*. The flow of tokens in the system model is synchronized by some global mechanism and they arrive at the interface at the same time, according to that mechanism.

Interpreted component. The mixed-level modeling technique strongly depends upon the type of the interpreted component that is introduced into the performance model. It is natural to partition interpreted models into those that model combinational elements and sequential elements. Techniques for constructing mixed-level interfaces for models of combinational interpreted elements have been developed previously [44]. In the combinational element case, the techniques for resolving the timing across the interface were more straightforward because of the asynchronous nature of the combinational elements, and the data-abstraction problem was solved using a methodology similar to the one presented here. However, using sequential interpreted elements in mixed-level models requires more complex interfaces to solve the synchronization problem and different specific techniques for solving the data-abstraction problem. Further research into the problem of mixed-level modeling with sequential elements suggested that interpreted components be broken down into three classifications as described below:

1. *Combinational elements*. Unclocked (with no states) elements
2. *Sequential control elements* (SCEs). Clocked elements (with states) that are used for controlling data flow, e.g., a control unit or a controller
3. *Sequential data flow elements* (SDEs). Elements that include datapath elements *and* clocked elements that control the data flow, e.g., control unit and datapath

The major reason for partitioning the sequential elements into SDEs and SCEs is based on the timing attributes of these elements. In a SCE control input values are read every cycle and control output values (that control a datapath) are generated every cycle. In contrast, SDEs have data inputs and may have some control inputs but the output data are usually generated several clock cycles later. This difference in the timing attributes will dictate a different technique for mixed-level modeling. Because the solution for the timing and data-abstraction problem for SDEs is more complex, and the solution for SCEs can be derived from the solution for SDEs, developing a solution for SDEs was the focus of this work.

12.4.2 Interface for Mixed-Level Modeling with FSMD Components

This section describes the interface structure and operation for sequential interpreted elements that can be described as finite state machines with datapaths (FSMDs) [45]. They consist of a finite state machine (FSM) used as a control unit, and a datapath, as shown in Figure 12.21. System models are quite often naturally partitioned to blocks which adhere to the FSMD structure. Each of these FSMDs processes the data and have some processing delays associated with them. These FSMDs indicate the completion of a processing task to the rest of the system either by asserting a set of control outputs or by the appearance of valid data on their outputs. This characteristic of being able to determine when the data-processing task of the FSMD is completed is a key property in the methodology of constructing mixed-level models with FSMD interpreted components.

The functions performed by the U/I operator include placing the proper values on the inputs to the FSMD interpreted model, and generating a clock signal for the FSMD interpreted model. The required

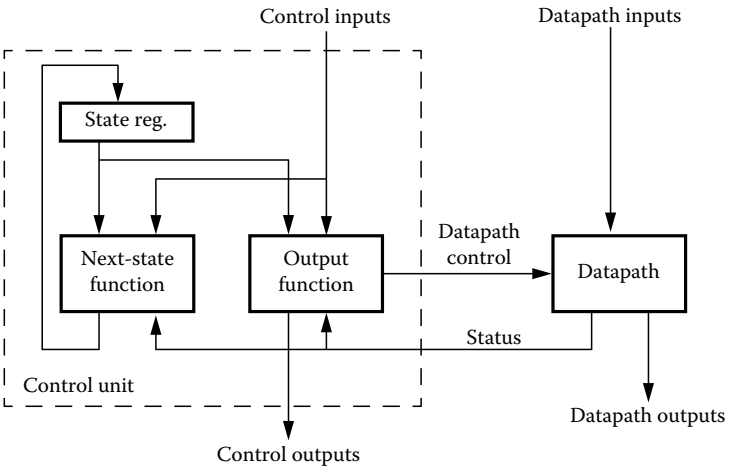

FIGURE 12.21 Generic FSMD block diagram.

values to be placed on the inputs to the FSMD interpreted model are either contained on the incoming token's information, or "color" fields, are supplied by the modeler via some outside source, or are derived using the techniques described in Section 12.4.2.1. The clock signal is either generated locally if the system-level model is globally asynchronous, or converted from the global clock into the proper format if the system-level model is globally synchronous. The functions performed by the I/U operator include releasing the tokens back into the performance model at the appropriate time and, if required, coloring them with new values according to the output signals of the interpreted element. The structure of these two parts of the mixed-level interface is shown in Figure 12.22. The U/I operator is composed of the following blocks: a Driver, an Activator, and a Clock_Generator. The I/U operator is composed of an Output_Condition_Detector, a Colorer, and a Sequential_Releaser.

In the U/I operator, the Activator is used to detect the arrival of a new token (packet of data) to the interpreted element, inform the Driver of a new token arrival, and to drive control input/s of the

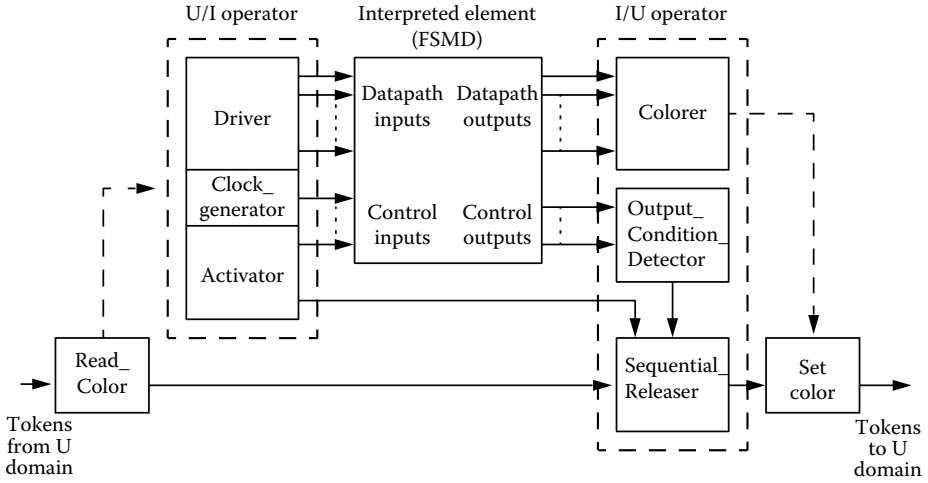

FIGURE 12.22 Mixed-level element structure.

interpreted element. The Activator's output is also connected to the I/U operator for use in gathering information on the delay through the interpreted element. The Driver reads information from the token's color fields and drives the proper input signals to the interpreted element according to predefined assignment properties. The Clock_Generator generates the clock signal according to the overall type of system-level model, either synchronous or asynchronous.

In the I/U operator, the Output_Condition_Detector detects the completion of the interpreted element data-processing operation, as discussed earlier, by comparing the element's outputs to predefined properties. The Colorer samples the datapath outputs and maps them to color fields according to predefined binding properties. The Sequential_Releaser, which "holds" the original token, releases it back to the uninterpreted model upon receiving the signal from the Output_Condition_Detector. The information carried by the token is then updated by the Colorer and the token flows back to the uninterpreted part of the model.

Given this structure, the operation of the mixed-level model can be described using the general example in Figure 12.22. Upon arrival of a new token to the mixed-level interface (U/I operator), the Read_Color module triggers the Activator component and passes the token to the Sequential_Releaser, where it is stored until the interpreted component is finished with its operation. Once triggered by the Read_Color module, the Activator notifies the Driver to start the data-conversion operation on a new packet of data. In the case of a globally asynchronous system-level model, the Activator will notify the Clock_Generator to start generating a clock signal. Since the interpreted element is a sequential machine, the Driver may need to drive sequences of values onto the inputs of the interpreted element. This sequence of values is supplied to the interpreted element, while the original token is held by the Sequential_Releaser. This token is released back to the uninterpreted model only when the Output_Condition_Detector indicates the completion of the interpreted element operation. The Output_Condition_Detector is parameterized to recognize the completion of data processing by the particular FSMD interpreted component. Once the Output_Condition_Detector recognizes the completion of data processing, it signals the Sequential_Releaser to release the token into the performance model. Once the token is released, it passes through the Colorer which maps the output data of the interpreted element onto color fields of the token. The new color information on the token may be used by the uninterpreted model for such things as delays through other parts of the model or for routing decisions.

12.4.2.1 Finding Values for the "Unknown Inputs" in an FSMD-Based Mixed-Level Model

As described previously, because of the abstract nature of a performance model, it may not be possible to derive values for all of the inputs to the interpreted component from the data present in the performance model. Typically, the more abstract the performance model (i.e., the earlier in the design cycle), the higher the percentage of input values that will be unknown. In some cases, particularly during the very early stages of the design process, it is possible that the abstract performance model will not provide any information to the interpreted element, other than the fact that new data has arrived. In this case, the data-abstraction gap will be large. This section describes an analytical technique developed to determine values for these "unknown inputs" such that a meaningful performance metric—best- or worst-case delay—can be derived from the mixed-level model.

If some (or all) inputs are not known from the performance model, some criteria for deriving the values on the unknown inputs must be made. Choosing a criterion is based on the objective of the mixed-level model. For the objective of timing verification, delays (number of clock cycles) through the interpreted element are of interest. The most common criterion in such cases is the worst-case processing delay. In some cases, best-case delay may be desired. If the number of unknown inputs is small, an exhaustive search for worst/best case may be practical. Therefore, it is desirable to minimize the number of unknown inputs which can affect the delay through the interpreted element. The methods for achieving this objective are described conceptually in Section 12.4.2.1.1. By utilizing these methods,

the number of unknown inputs is likely to be reduced but unknown inputs will not be eliminated completely. In this case, the performance metrics of best- and worst-case delay can be provided by a ''traversal'' of the state graph of the SDE component. Section 12.4.2.1.2 describes the traversal method developed for determining the delays through a sequential element.

Note that in the algorithms described below, the function of the SDE component is represented by the state transition graph (STG) or state table. These two representations are essentially equivalent and are easily generated from a behavioral VHDL description of the SDE, either by hand, or using some of the automated techniques that have been developed for formal verification.

12.4.2.1.1 Reducing the Number of Unknown Inputs

Although it is not essential, reducing the number of unknown inputs can simplify the simulation of a mixed-level model significantly. Since the FSMD elements being considered have output signals that can be monitored to determine the completion of data processing as discussed previously, other outputs may not be significant for performance analysis. Therefore, the ''nonsignificant'' (insignificant) outputs can be considered as ''don't cares.'' By determining which inputs do not affect the values on the significant outputs, it is possible to minimize the number of unknown delay affecting inputs (DAIs).

The major steps in the DAI detection algorithm are as follows:

Step 1. Select the ''insignificant'' outputs (in terms of temporal performance).
Step 2. In the state transition graph (STG) of the machine, replace all values for these outputs with a ''don't-care'' to generate the modified state machine.
Step 3. Minimize the modified state machine and generate the corresponding state table.
Step 4. Find the inputs which do not alter the flow in the modified state machine by detecting identical columns in the state table, and combining them by implicit input enumeration.

This method is best illustrated by an example. Consider the state machine which is represented by the STG shown in Figure 12.23. This simple example is a state machine with two inputs, X_1 and X_2, and two outputs, Y_1 and Y_2. This machine cannot be reduced, i.e., it is a minimal state machine. Assume that this machine is the control unit of an FSMD block and that the control output Y_1 is the output which indicates the completion of the ''data processing'' when its value is 1. Thus, output Y_2 is an ''insignificant output'' in terms of delay in accordance with Step 1. Therefore, a ''don't-care'' value is assigned to Y_2 as per Step 2. The modified STG is shown in Figure 12.24. As per Step 3, the modified STG is then reduced. In this example, states A, C, and E are equivalent (can be replaced by a single state, K) and the minimal

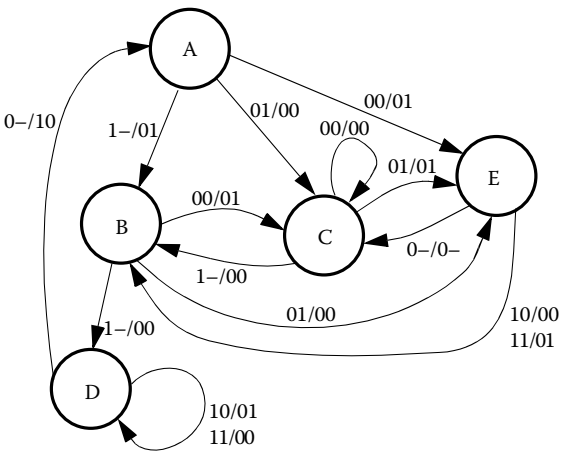

FIGURE 12.23 STG of a two-inputs two-outputs state machine.

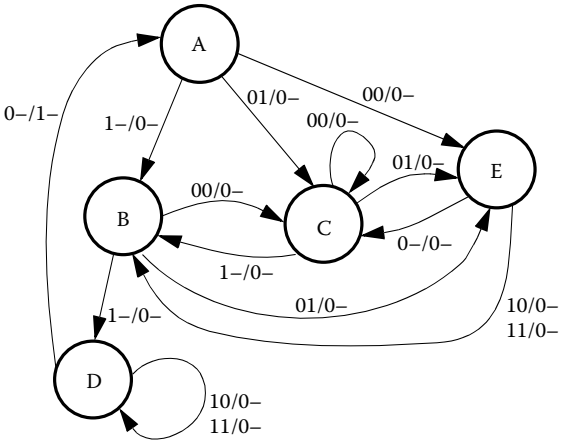

FIGURE 12.24 STG with "significant" output values only.

machine consists of three states, K, B, and D. This minimal machine is described by the state table shown in Table 12.2.

All possible input combinations appear explicitly in Table 12.2. However, it can be seen that the first two columns of the table are identical (i.e., the same next state and output value for all possible present states). Similarly, the last two columns of the table are identical. Therefore, in accordance with Step 4, these columns can be combined yielding the reduced state table shown in Table 12.3.

The reduced state table reveals that the minimal machine does not depend on the value of input X_2. Therefore, the conclusion is that input X_2 is not a DAI. This result implies that by knowing only the value of input X_1, the number of clock cycles (transitions in the original STG) required to reach the condition that output $Y_1 = 1$ can be determined regardless of the values of X_2. This is the case for any given initial state. It is important to emphasize that the paths in the *original* STG and their lengths are those which must be considered during the traversal process and that the modified state machine is used only for the purpose of detecting non-DAIs. The machine which is actually being traversed during the mixed-level simulation is the original state machine with all its functionality.

TABLE 12.2 Next State and Output Y_1 of the Minimal Machine

PS\\X_1X_2	00	01	10	11
K = (ACE)	K, 0	K, 0	B, 0	B, 0
B	K, 0	K, 0	D, 0	D, 0
D	K, 1	K, 1	D, 0	D, 0

TABLE 12.3 Minimal Machine with Implicit Input Enumeration

PS\\X_1X_2	0–	1–
K = (ACE)	K, 0	B, 0
B	K, 0	D, 0
D	K, 1	D, 0

To demonstrate the meaning of an input which is not a DAI, consider the original state machine represented by the graph in Figure 12.23 and assume that the initial state is A. Consider, for example, one possible sequence of values on input X_1 to be 0, 1, 0, 0, 1, 1, 0. By applying this input sequence, the sequence of values on output Y_1 is 0, 0, 0, 0, 0, 0, 1, regardless of the values applied to input X_2. Therefore, two input sequences which differ only in the values of the non-DAI input X_2 will produce the same sequence of values on the "significant" output Y_1. For example, the sequence $X_1X_2 = 00$, 10, 00, 01, 10, 10, 01 will drive the machine from state A to E, B, C, E, B, D, and back to A, and the sequence of values on output Y_1 will be as above. Another input sequence, $X_1X_2 = 01$, 11, 01, 00, 11, 11, 00, in which the values of X_1 are identical to the previous sequence, will drive the machine from state A to C, B, E, C, B, D, and back to A, while the sequence of values on output Y_1 is identical to the previous case. Therefore, the two input sequences will drive the machine via different states but will produce an identical sequence of values on the "significant" output (which also implies that the two paths in the STG have an equal length).

12.4.2.1.2 Traversing the STG for Best and Worst Delays

After extracting all possibilities for minimizing the number of unknown inputs, a method for determining values for those unknown inputs which are DAIs is required. The method developed for mixed-level modeling is based on the traversal of the original STG of the sequential interpreted element. As explained earlier, some combination of output values may signify the completion of processing the data. The search algorithm will look for a minimum or maximum number of state transitions (clock cycles) between the starting state of the machine and the state (Moore machine) or transition (state and input combination—Mealy machine), which generates the output values which signify the completion of data processing. Once this path is found, the input values for the unknown DAIs that will cause the SDE to follow this state transition path will be read from the STG and applied to the interpreted component in the simulation to generate the required best- or worst-case delay. Since the state machine is represented by the STG, this search is equivalent to finding the longest or shortest path between two nodes in a directed graph (digraph).

The search for the shortest path utilizes a well-known algorithm. Search algorithms exist for both single-source shortest path and all-pairs shortest path. One of the first and most commonly used algorithms is Dijkstra's algorithm [46], which finds the shortest path from a specified node to any other node in the graph. The search for all-pairs shortest path is also a well-investigated problem. One such algorithm by Floyd [47] is based on work by Warshall [48]. Its computation complexity is $O(n^3)$ when n is the number of nodes in the graph, which makes it quite practical for moderate-sized graphs. The implementation of this algorithm is based on Boolean matrix multiplication and the actual realization of all-pairs shortest paths can be stored in an $n \times n$ matrix. Utilizing this algorithm required some enhancements to make it applicable to mixed-level modeling. For example, if some of the inputs to the interpreted element are known (from the performance model), then the path should include transitions that include these known input values.

In contrast, the search for the longest path is a more complex task. It is an NP-complete problem that has not attracted significant attention. Since most digraphs contain cycles, the cycles need to be handled during the search to prevent a path from containing an infinite number of cycles. One possible restriction that makes sense for many state machines that might be used in mixed-level modeling is to construct a path that will not include a node more than once. Given a digraph $G(V, E)$ that consists of a set of vertices (or nodes) $V = \{v_1, v_2, \ldots\}$ and a set of edges (or arcs) $E = \{e_1, e_2, \ldots\}$, a *simple path* between two vertices v_{init} and v_{fin} is a sequence of alternating vertices and edges $P = v_{\text{init}}, e_n, v_m, e_{n+1}, v_{m+1}, e_{n+2}, \ldots, v_{\text{fin}}$ in which each vertex does not appear more than once. Although an arbitrary choice was made to implement the search allowing each vertex to appear in the path only once, the same algorithm could be easily modified to allow the appearance of each vertex a maximum of N times.

Given an initial node and a final node, the search algorithm developed for this application starts from the initial node and adds nodes to the path in a depth-first-search (DFS) fashion, until the final node is

reached. At this point, the algorithm backtracks and continues looking for a longer path. However, since the digraph may be cyclic, the algorithm must avoid the possibility of increasing the path due to a repeated cycle, which may produce an infinite path.

The underlying approach for avoiding repeated cycles in the algorithm *dynamically* eliminates the cycles while searching for the longest simple path. Let u be the node that the algorithm just added to the path. All the in-arcs to node u can be eliminated from the digraph at this stage of the path construction. The justification for this dynamic modification of the graph is that, while continuing in this path, the simple path cannot include u again. While searching forward, more nodes are being added to the path and more arcs can be removed temporarily from the graph. At this stage, two things may happen (1) either the last node being added to the path is the final node or (2) the last node has no out-arcs in the dynamically modified graph. These two cases are treated in the same way except that in the first case the new path is checked to see if it is longer than the longest one found so far. If it is, the longest path is updated. However, in both cases the algorithm needs to backtrack.

Backtracking is performed by removing the last node from the path, hence decreasing the path length by one. During the process of backtracking, the in-arcs to a node being removed from the path must be returned to the current set of arcs. This process will enable the algorithm to add this node when constructing a new path. At the same time, whenever a node is removed from the path, the arc that was used to reach that node is marked in the dynamic graph. This process will eliminate the possibility that the algorithm repeats a path that was already traversed. Therefore, by dynamically eliminating and returning arcs from/to the graph, a cyclic digraph can be treated as if it does not contain cycles. The process of reconnecting nodes, i.e., arcs being returned to the dynamic graph, requires that the original graph be maintained. A more detailed description of this search algorithm can be found in Ref. [49].

The restriction that a longest path does not include any *node* in the graph more than once may not be appropriate for all cases. In some mixed-level modeling cases, a more realistic restriction might be that the longest path does not include any *transition* (arc) more than once. A longest-path with no repeated arcs may include a node multiple times as long as it is reached via different arcs. In the case of more than one transition that meets the condition on the output combination, a search for the longest path should check all paths between the initial state and all of these transitions. However, such a path should include any of these transitions only once, and it should be the last one in the path.

Performing a search with the restriction that no arc is contained in the path more than once requires maintaining information on arcs being added or removed from the path. Maintaining this information during the search makes the algorithm and its implementation much more complicated relative to the search for the longest path with no repeated nodes. Therefore, a novel approach to this problem was developed. The approach used is to map the problem to the problem of searching for the longest path with no repeated nodes. This mapping can be accomplished by transforming the digraph to a new digraph, to be referred to as the transformed digraph (or Tdigraph). Given a digraph, $G(V, E)$, which consists of a set of nodes $V = \{v_1, v_2, \ldots, v_k\}$ and a set of arcs $E = \{e_1, e_2, \ldots, e_l\}$ the transformation τ maps $G(V, E)$ into a Tdigraph $TG(N, A)$, where N is its set of nodes and A its set of arcs. The transformation is defined as $\tau(G(V, E)) = TG(N, A)$, and contains the following steps:

Step 1. $\forall(e_i \in E)$ generate a node $n_i \in N$.
Step 2. $\forall(v \in V)$ and $\forall\left(e_p \in d^v_{\text{in}}, e_q \in d^v_{\text{out}}\right)$ generate an arc $a \in A$ such that a: $n_p \rightarrow n_q$.

The first step is used to create a node in the Tdigraph for each arc in the original digraph. This one-to-one mapping defines the set of nodes in the Tdigraph to be $N = \{n_1, n_2, \ldots, n_l\}$, which has the same number of elements found in the set E.

The second step creates the set of arcs, $A = \{a_1, a_2, \ldots, a_u\}$, in the Tdigraph. For each node in the original digraph and for each combination of in-arcs and out-arcs to/from this node, an arc in the Tdigraph is created. For example, given a node v with one in-arc e_i and one out-arc e_j, e_i is mapped to a node n_i, e_j is mapped to a node n_j, and an arc from n_i to n_j is created. In Step 2 of the transformation process, it is guaranteed that all possible connections in the original digraph are preserved as transitions

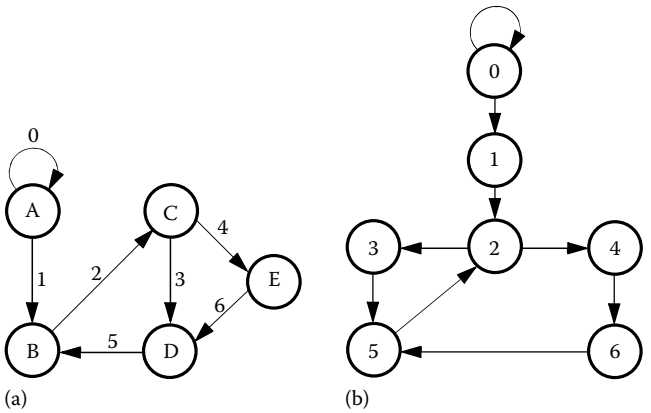

FIGURE 12.25 Transformation of a digraph.

between nodes in the Tdigraph. As a result of this transformation, the restriction on not visiting an arc more than once in the original digraph is equivalent to not visiting a node more than once in the Tdigraph. Therefore, by using this transformation, the problem of searching for the longest path with no repeated arcs in the original digraph is mapped to a search for the longest path with no repeated nodes in the Tdigraph. The algorithm described above can then be used to search the Tdigraph.

This transformation is best illustrated by a simple example. Consider the digraph shown in Figure 12.25a. The arcs in this digraph are labeled by numbers 0–6. The first step of the transformation is to create a node for each arc in the original digraph. Therefore, there will be seven nodes, labeled 0–6, in the Tdigraph as shown in Figure 12.25b. The next step is to create the arcs in the Tdigraph. As an illustration of this step, consider node C in the original digraph. Arc "2" is an in-arc to node C while arcs "3" and "4" are out-arcs from node C. Applying Step 2 results in an arc from node "2" to node "3" and a second arc from node "2" to node "4" in the Tdigraph. Considering node B in the original digraph, the Tdigraph will include an arc from node "1" to node "2" and an arc from node "5" to node "2." This process is repeated for all the nodes in the original digraph until the Tdigraph, as shown in Figure 12.25b, is formed. A search algorithm can now be executed to find the longest path with no repeated nodes.

A mixed-level modeling methodology, which is composed of all the methods described above, has been integrated into the ADEPT environment. The steps for minimizing the unknown inputs can be performed prior to simulating the mixed-level model. On the other hand, the search for longest/shortest possible delay must be performed during the simulation itself. This requirement arises because each token may carry different information which may alter the known input values and, therefore, alter the search of the STG. The STG traversal process has been integrated into the ADEPT modeling environment using the following steps: (1) when a token arrives to the mixed-level interface, the simulation is halted and the search for minimum/maximum number of transitions is performed and (2) upon completion of the search, the simulation continues while applying the sequence of inputs found in the search operation. The transfer of information between the VHDL simulator and the search program, which is implemented in C is done by using the simulator's VHDL/C interface. A component called the Stream_Generator has been created that implements the STG search process via this interface.

Since mixed-level models are part of the design process and are constructed by refining a performance model, it is likely that many tokens will carry identical relevant information. This information may be used for selective application of the STG search algorithm, hence increasing the efficiency of the mixed-level model simulation. For example, if several tokens carry exactly the same information (and assuming the same initial state of the FSM), the search is performed only once, and the results can be used for the following identical tokens.

12.4.2.2 Example of Mixed-Level Modeling with an FSMD Component

This section presents an example of the construction of a mixed-level model with an FSMD interpreted component. The example is based on the performance model of an execution unit of a particular processor. This execution unit is composed of an integer unit (IU), a floating-point unit (FPU), and a load-store unit (LSU). These units operate independently although they receive instructions from the same queue (buffer of instructions). If the FPU is busy processing one instruction and the following instruction requires the FPU, it is buffered, waiting for the FPU to be free again. Meanwhile, instructions which require the IU can be consumed and processed by IU at an independent rate. Both the FPU and the IU have the capability of buffering only one instruction. Therefore, if two or more consecutive instructions are waiting for the same unit, the other units cannot receive new instructions (since the second instruction is held in the main queue). One practical performance metric that can be obtained from this model is the time required for the execution unit to process a given sequence of instructions.

Because the FPU was identified as the most complex and time critical portion of the design, a behavioral description of a potential implementation of it was developed. At this point, a mixed-level model, in which the behavioral description of the FPU is introduced into the performance model, was constructed using the interface described above. The mixed-level model is shown in Figure 12.26. The mixed-level interface is constructed around the interpreted block which is the behavioral description of the FPU. This FPU is an FSMD type of element, and the interpreted model consists of a clock cycle-accurate VHDL behavioral description of this component. The inputs to the FPU include the operation to be performed (Add, Sub, Comp, Mul, MulAdd, and Div), the precision of the operation (single or double), and some additional control information. The number of clock cycles required to complete any instruction depends on these inputs.

Figure 12.27 shows the execution unit performance derived from the mixed-level model for three different instruction traces. In this case, only 40% of the inputs have values that are supplied by the abstract performance model, the remainder of the values for the inputs are derived using the techniques described in Section 12.4.2.1. The performance value is normalized by defining unity to be the amount of time required to process a trace according to the initial uninterpreted performance model. In this example, the benefit of the simulation results of the mixed-level model is clear. It provides performance bounds in terms of best- and worst-case delays, for the given implementation of the FPU.

12.4.3 Interface for Mixed-Level Modeling with Complex Sequential Components

A methodology and components for constructing a mixed-level interface involving general sequential interpreted components that can be described as FSMDs was detailed in the previous section. However, many useful mixed-level models can be constructed that include sequential interpreted components that are too complex to be represented as FSMDs, such as microprocessors, complex coprocessors, network interfaces, etc. In these cases, a more ''programmable'' mixed-level interface that is able to deal with the additional complexity in the timing abstraction problem was needed. This section describes the ''watch-and-react'' interface that was created to be a generalized, flexible interface between these complex sequential interpreted components and performance models.

The two main elements in the watch-and-react interface are the *Trigger* and the *Driver*. Figure 12.28 illustrates how the Trigger and Driver are used in a mixed-level interface. Both elements have ports that can connect to signals in the interpreted components of a model. Collectively, these ports are referred to as the *probe*. The primary job of the Trigger is to detect events on the signals attached to its probe, while the primary job of the Driver is to force values onto the signals attached to its probe. The Driver decodes information carried in tokens to determine what values to force onto signals in the interpreted model (the U/I interface) and the Trigger encodes information about events in the interpreted model onto tokens in the performance model (the I/U interface).

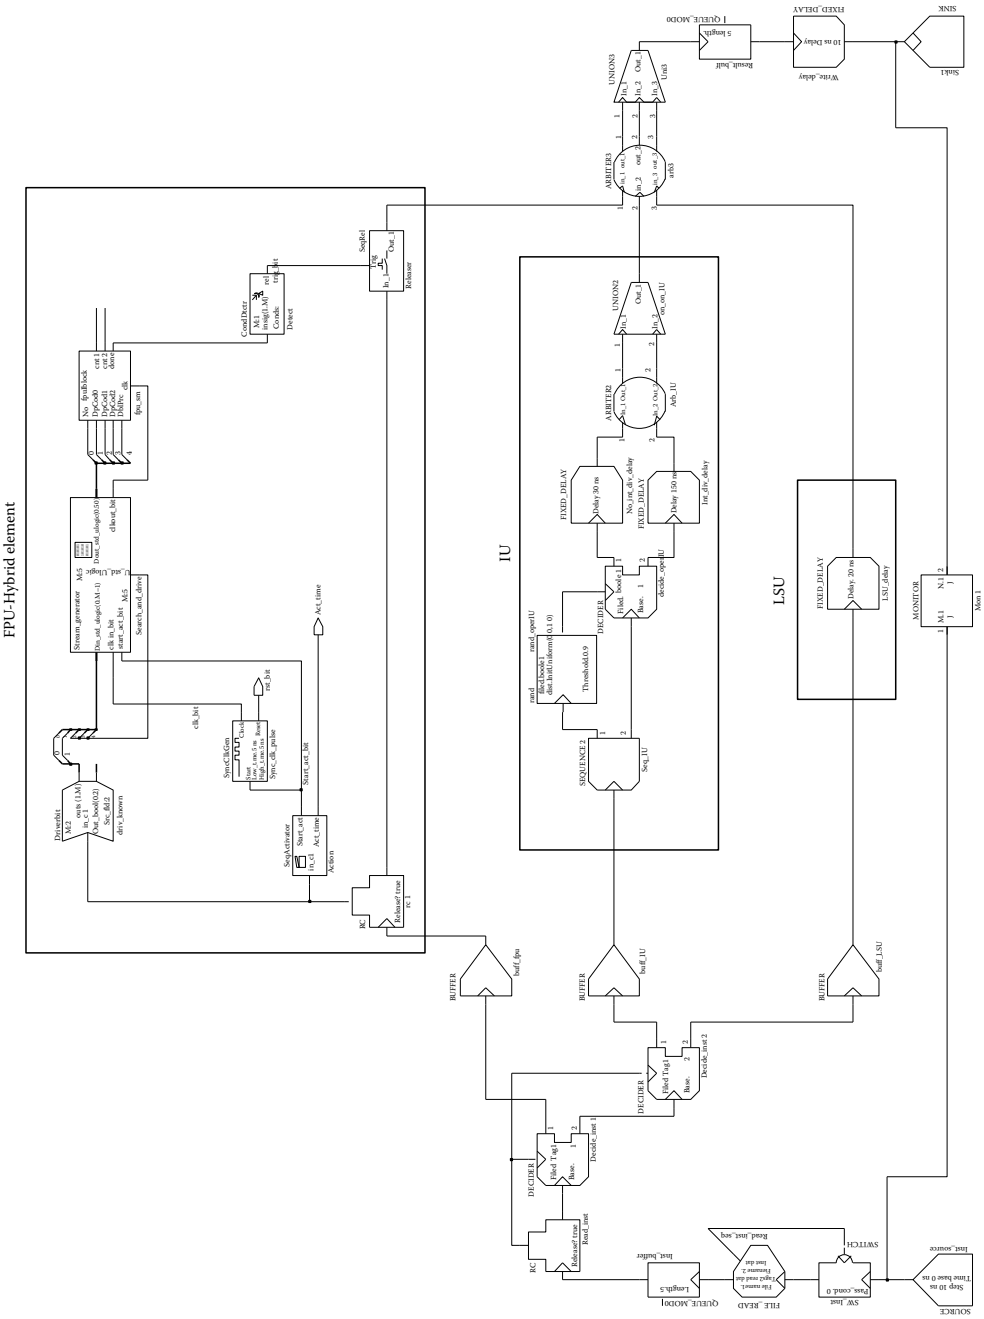

FIGURE 12.26 Mixed-level model with the FPU behavioral description.

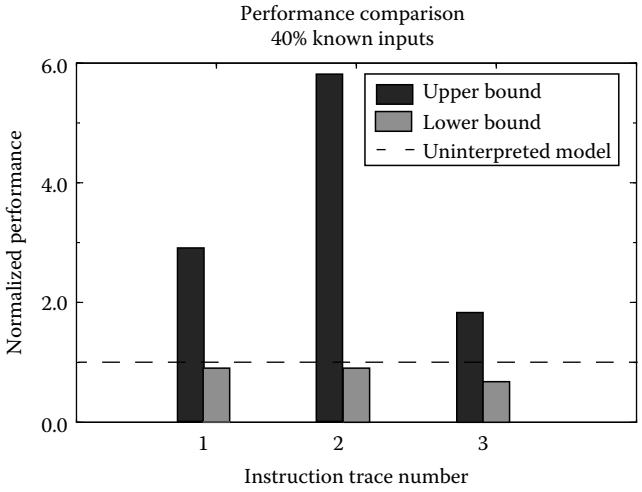

FIGURE 12.27 Performance comparison of the execution unit for three instruction traces.

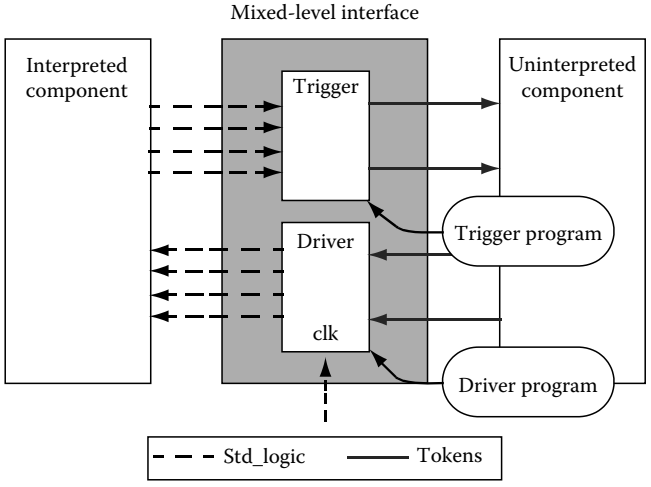

FIGURE 12.28 Watch-and-react mixed-level interface.

The Trigger and Driver were designed to be as generic as possible. A command language was designed that specifies how the Trigger and Driver should behave to allow users to easily customize the behavior of the Trigger and Driver elements without having to modify their VHDL implementation. This command language is interpreted by the Trigger and Driver during simulation. Because the language is interpreted, changes can be made to the Trigger and Driver programs without having to recompile the model, thus minimizing the time required to make changes to the mixed-level model.

The schematic symbol for the Trigger is shown in Figure 12.29. The primary job of the Trigger is to detect events in the interpreted model. The probe on the Trigger is a bus of std_logic signals `probe_size` bits wide, where `probe_size` is a generic on the symbol. There is one token output called `out_event_token` and one token output called `out_color_token`. Tokens generated by the Trigger when events are detected are placed on the `out_event_token` port. The condition number (an integer) of the event that caused the token to be generated is placed on the `condition`

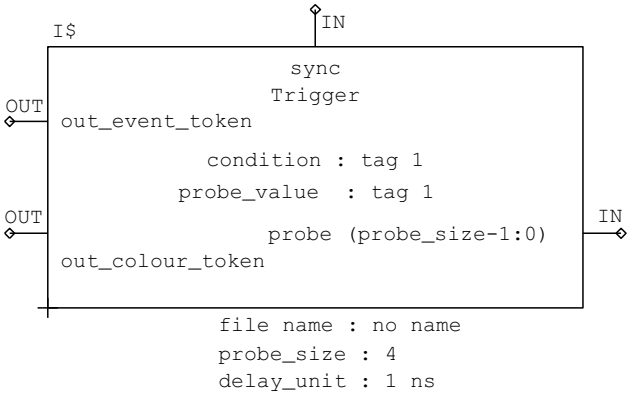

FIGURE 12.29 Schematic symbol for the Trigger.

tag field, which is specified as a generic on the symbol. Also, each time a signal changes on the probe, the color of the token on the `out_color_token` port changes appropriately regardless of whether an event was detected or not. The probe value is placed on the `probe_value` tag field of the `out_color_token` port. The sync port is used to synchronize the actions of the Trigger element with the Driver element as explained below.

The name of the file containing the Trigger's program is specified by the `filename` generic on the symbol. The `delay_unit` generic on the symbol is a multiple that is used to resolve the actual length of an arbitrary number of delay units specified by some of the interface language statements.

The schematic symbol for the Driver element is shown in Figure 12.30. The primary job of the Driver is to create events in the interpreted model by driving values on its probe. These values come from either the command program, or from the values of tag fields on the input tokens to the Driver. The probe on the Driver is a bus of std_logic signals `probe_size` bits wide, where the `probe_size` is a generic on the symbol. There is one token input called `in_event_token`, one token input called `in_color_token`, and a special input for a std_logic type clock signal called `clk`. The `clk` input allows Driver to synchronize its actions with an external interpreted clock source. The `sync` port is used to synchronize the actions of the Driver element with the Trigger element. The `filename` and `delay_unit` generic on the symbol function the same as for the Trigger.

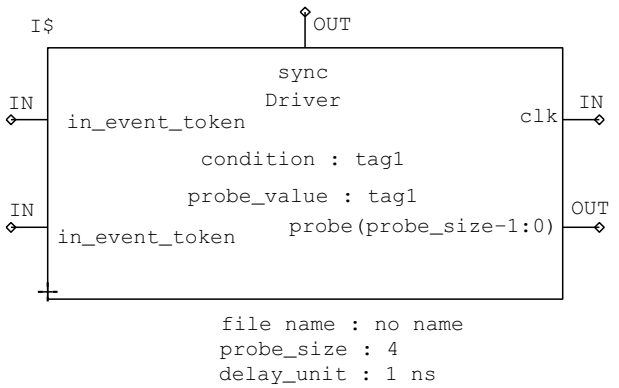

FIGURE 12.30 Schematic symbol for the Driver.

As discussed previously, a command language was developed to allow the user to program the actions of the Trigger and Driver. This command language is read by the Trigger and Driver at the beginning of the simulation. Constructs are available within the command language to allow waiting on events of various signals and driving values or series of values on various signals, either asynchronously, or synchronous with a specified clock signal. In addition, several looping and go-to constructs are available to implement complex behaviors more easily. A summary of the syntax of the command language constructs is shown in Table 12.4.

12.4.3.1 Example of Mixed-Level Modeling with a Complex Sequential Element

This section presents an example which demonstrates how the Trigger and Driver elements can be used to interface an interpreted model of a complex sequential component with an uninterpreted model. In this example, the interpreted model is a microprocessor-based controller and the uninterpreted model is that of a motor control system including a motor controller and a motor. The motor controller periodically asserts the microcontroller's interrupt line. The microcontroller reacts by reading the motor's current speed from a sensor register on the motor controller, calculating the new control information, and writing the control information to the motor controller.

The microcontroller system consists of interpreted models of eight-bit, RISC-like microprocessor, RAM, memory controller, I/O controller, and clock. The memory controller handles read and write requests issued by the processor to the RAM, while the I/O controller handles read and write request issued by the processor to an I/O device. In the system model, the I/O device is the uninterpreted model of a motor controller. A schematic of the model is shown in Figure 12.31.

Three Triggers and two Drivers are used to construct the mixed-level interface for the control system model. One of the Triggers is used to detect when the I/O controller is doing a read or write. The other two Triggers are used to collect auxiliary information about the operation, such as the address on the address bus and data on the data bus. One of the Drivers is used to create a microcontroller interrupt and the other Driver is used to force data onto the data bus when the processor reads from the speed sensor register on the motor controller.

The interrupt Driver's program is listed in Figure 12.32. The program begins by forcing the interrupt line to "Z" and then waiting for a token from the uninterpreted model of the motor controller to arrive. Once a token arrives, the program forces the interrupt line high for 10 clock cycles. This condition is accomplished by using a `for-next` statement with a `wait_on_rclk` as the loop body. After 10 clock cycles, the program jumps to line 10 where the cycle begins again.

The data Driver's program is listed in Figure 12.33. The program begins by also waiting for a token from the uninterpreted model of the motor controller to arrive. If the value on the condition tag field of the token is 1, then "ZZZZZZZZ" is forced onto the data bus. If the condition tag field value is 3, then the value on the `probe_value` tag field of the `in_color_token` input is forced on the data bus. This process is repeated for every token that arrives.

The I/O Trigger's program is listed in Figure 12.34. This Trigger waits until there is a change on the probe. Once there is a change, the program checks to see if the I/O device is being unselected, written to, or read from. If one of the `when` statements matches the probe value, then its corresponding `output` statement is executed. An output of 1 corresponds to the I/O device not being selected. An output of 2 corresponds to the processor writing control information to the motor controller. An output of 3 corresponds to the processor reading the motor's speed from the sensor register on the motor controller.

Figure 12.35 shows the results from the mixed-level model as a plot of the sensor output and the processor's control response. Some random error was introduced to the sensor's output to reflect variations in the motor's load as well as sensor noise. The target speed for the system was 63 ticks per sample time (a measure of the motor's RPM). The system oscillates slightly around the target value because of the randomness introduced into the system.

TABLE 12.4 Trigger and Driver Command Programming Language Constructs

Command	Element	Meaning
– <comment>	Both	Comment—no action
alert_user	Both	Print message in simulation window
delay_for <T>	Both	Delay for <T > time units where the time unit is specified as a generic on the module's symbol
end	Both	End the command program
for <N> <loop body> **next**	Both	Iterate *N* times over the sequence of statement in the loop body
goto <L>	Both	Go to line <L> in the command program
output_sync	Both	Generate a token on the sync output of the module
wait_on_sync	Both	Wait for an occurrence of a token on the sync port of the module
case_probe_is **when** <STD_LOGIC_VAL> <sequence of statements> **when** . . . **end_case**	Trigger	Conditionally execute some sequence of statements depending on the STD_LOGIC value of the probe signal
output <INTEGER_VAL> **after** <T>	Trigger	Generate a token on the Trigger's output with the value of <INTEGER_VAL> on the tag field specified by the generic on the symbol after <T > time units
trigger	Trigger	Must appear as the first statement in the Trigger's command program
wait_on <STD_LOGIC_VAL>	Trigger	Wait until the probe signal takes on the specified STD_LOGIC value
wait_on_probe	Trigger	Wait until there is ANY event on the probe signal
case_token_is **when** <**INTEGER_VAL**> <**sequence of statements**> **when . . .** **end_case**	Driver	Conditionally execute some sequence of statements depending on the integer value of the input token's tag field specified by the generic on the symbol
driver	Driver	Must appear as the first statement in the Driver's command program
dynamic_output_after <T>	Driver	Force the value from the specified tag field of the input token onto the probe after <T> time units
output <STD_LOGIC_VAL> **after** <T>	Driver	Force the specified STD_LOGIC value onto the probe signal after <T> time units
wait_on <INTEGER_VAL>	Driver	Wait until a token with the given integer value on the tag field specified by the generic on the symbol arrives on the in_event_token signal
wait_on_fclk	Driver	Wait until the falling edge of the clock occurs
wait_on_rclk	Driver	Wait until the rising edge of the clock occurs
wait_on_token	Driver	Wait until a token arrives on the in_event_token signal

12.5 Performance and Mixed-Level Modeling Using SystemC

This section describes a performance-modeling environment capable of mixed-level modeling that is based on the SystemC language [50]. The environment is intended to model the system at the Processor Memory Switch level much like the Honeywell PML environment described earlier. The goal of this work was to show how SystemC could be used to construct a mixed-level modeling capability.

In the SystemC-based PBMT (Performance-Based Modeling Tool), the user begins by describing the functions executed by the system as a task graph. A task graph is a representation of the flow of execution through an application. The nodes in a task graph represent computational tasks, and the edges in a task graph represent the flow of control, or the actual transfer of data, between tasks. An example of a task graph for a simple application is shown in Figure 12.36. Note that the topology shown in the figure, the example application has the opportunity for some tasks, such as Task 2, Task 3, and Task 4, to be executed in parallel if the system architecture upon which the application is to be executed, allows for it.

Once the task graph model is constructed, the user then selects a system architecture on which the application will execute. The system architecture is specified by the number of processors in the architecture, and an interconnect topology used to provide communications between them. The available interconnect topologies include a bus (a single shared communications resource), a crossbar switch (a partially shared communications resource), or fully connected (a completely nonshared communication resource). Note that in this high-level architecture model, what actually constitutes a processor in the system is not specified. That is, a processor is simply modeled as a computational resource and may in implementation be a general-purpose processor (of any clock speed), a special purpose processor like a DSP, or custom hardware for a specific task.

Once the system architecture is specified, all that remains is for the user to specify upon which processor each of the tasks is to execute and what the total execution time for that task on the specific processor will be. This delay value may be either fixed, or dependent on the amount of data that is passed into the task by the previous task in the graph. Once this task-to-processor mapping and delay specification is done, the complete SystemC model is constructed and simulated using either the reference simulator, included as part of the SystemC distribution available in Ref. [10], or the commercial Mentor Graphics ModelSim simulator which includes the capability to cosimulate SystemC models along with Verilog or VHDL models.

Figure 12.37 shows the results of executing the task graph of Figure 12.36 on three different system architectures. All of the architectures utilize a single shared bus for communications. The first result is for an architecture with only a single processor. In this case, the obvious result is that all of the tasks execute in sequence on the single processor and the run time is simply the sum of the individual task execution times. The second result is for a three-processor architecture. In this case, after Task 1

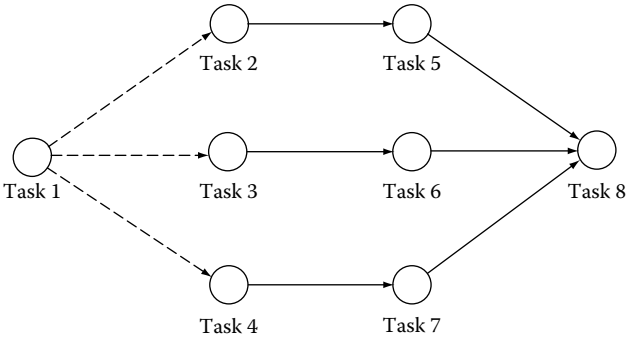

FIGURE 12.36 Example task graph.

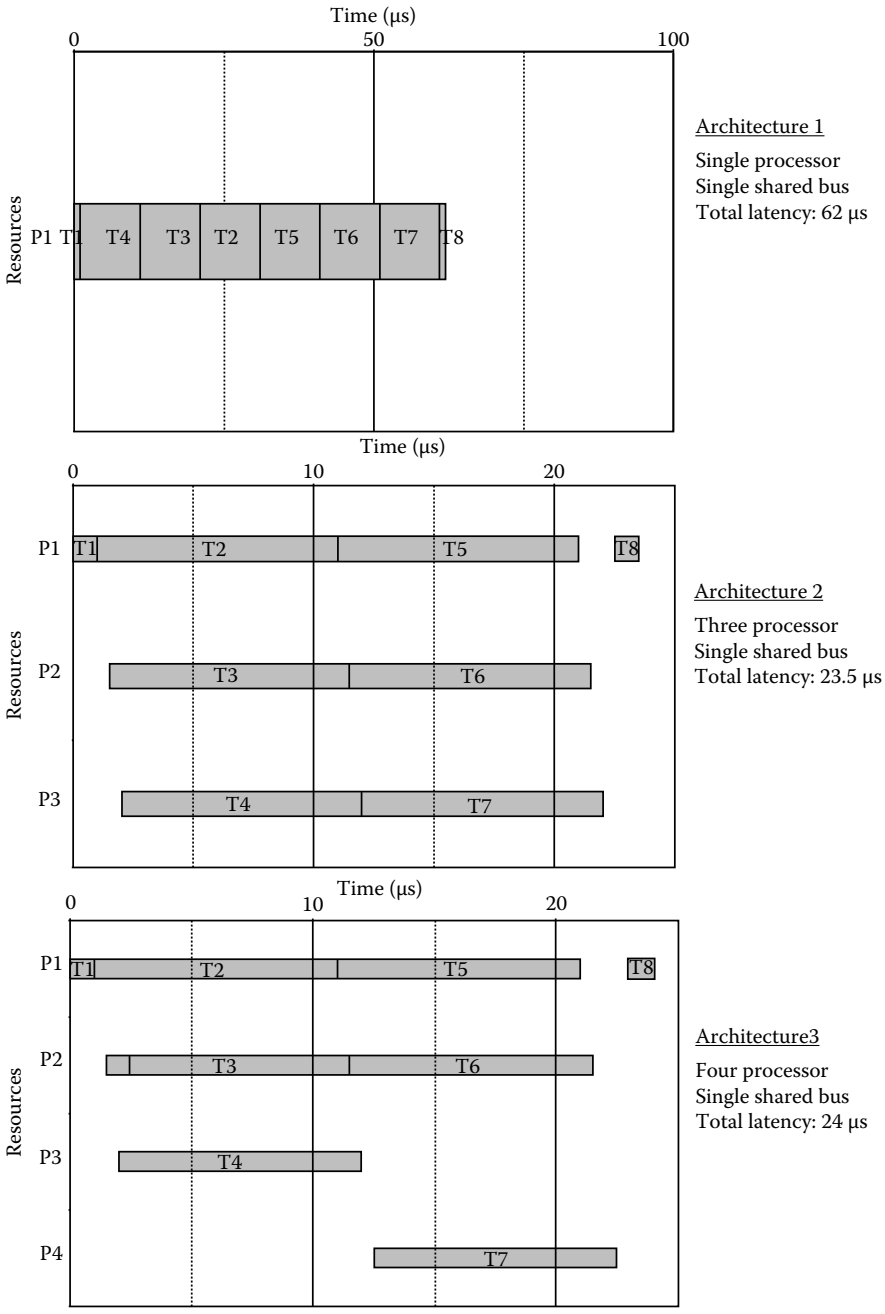

FIGURE 12.37 Parallel example shared bus timelines.

completes, some latency can be seen before Tasks 3 and 4 begin execution. This accounts for the communication time required to send data from the processor that executed Task 1 to the processors that are executing Tasks 3 and 4. In addition, the graph shows that Task 4 begins execution after Task 3 because of the contention for the single shared bus communications resource. Likewise, the latency between the end of execution for Tasks 5–7, and the start of execution for Task 8 accounts for the time required to communicate Tasks 6 and 7's results back to the single processor that is schedule to execute

Task 8. The overall run time for this configuration is much less than the first example because the inherent parallelism in the application is being exploited by the selected architecture. Finally, the third result is for a four-processor architecture. In this simulation, Tasks 1 and 8 are allocated to the fourth processor, separate from the other Tasks 2–7. This results in additional communications time being required using the single bus to transfer all of the data from, and back to, that extra processor. Thus, as can be seen from the graph this architecture actually takes longer than the three processor architecture to execute the application.

12.5.1 SystemC Background

This section describes some of the basic concepts of SystemC and how it is used to model systems at a high level. SystemC is a library extension to C++. Essentially, SystemC uses a set of classes and predefined functions to build a new ''language'' on top of C++. The basic unit of a SystemC model is the `SC_MODULE` class. The `SC_MODULE` is roughly equivalent to an entity in VHDL. It can have input, output, and bidirectional ports. However, it is a C++ class and as such it can, and does, have member functions. Any member function that is declared as public can be accessed just like the member function of any other class. Every `SC_MODULE` must have at least one public member function, its constructor. In the constructor the module is given a SystemC name, and declares if it has any processes, and does anything else necessary to get the model ready for simulation. There are two types of processes in SystemC, the `SC_THREAD` and the `SC_METHOD`. The behavior of a process must first be declared as a member function, then that member function can be declared to be either an `SC_THREAD` or an `SC_METHOD` in the constructor. The primary differences are how they behave when they reach the end of their definition, and when the scheduler activates them.

An `SC_THREAD` will terminate, and never be activated again, if it reaches the end of its description. Typically `SC_THREAD`s are infinite loops with one or more wait statements to break the execution, and wait on some signal change or other event. An `SC_METHOD` will be activated any time something it is sensitive to changes, and will run once through to the end of its description. If something an `SC_METHOD` is sensitive to changes again, it will run again. `SC_THREAD`s do have the ability to use a form of the wait command that is not available to `SC_METHOD`s. They may use a wait command with no parameters which will cause them to be reactivated and continue execution with the line after the wait statement when something in their sensitivity list has an event.

As indicated by the discussion of processes, SystemC uses an event-driven simulation methodology. The library provides basic signal classes that have a notify-update sequence much like VHDL. As mentioned in the Transaction Level Modeling discussion above, SystemC has a concept of channels. A channel is generally some means of moving information. The basic signal classes provided are base channels. A designer could potentially design some new base channel type that has the same interfaces as the existing base channels. However, building a new base channel is rather involved since its implementation must interact directly with the scheduler to implement the notify/update semantics of a signal. Additionally, such a user-designed base channel would still only have a basic interface, and could not have any internal processes, thus would not provide significant abstraction leveraging for the amount of time required to design it. Instead designers should use what is called a hierarchical channel for most modeling needs. A hierarchical channel is a channel that is made up of a number of elements of base classes. A hierarchical channel can have any number of ports, or methods. The methods that a module could use to access the channel, and convey information through it, are called interface methods. For a module to be able to access an interface method the channel needs to have a defined interface that it inherits. The `sc_interface` class is used as a base class to define such an interface. The file in Figure 12.40 shows one such interface class. Once an interface class has been defined and inherited by the channel, then any module with a port of that type can be bound to the channel's interface. In addition to the base channel classes, the SystemC library provides an event object that can be waited upon using the same syntax as a wait for a signal change event. For more details on the syntax, classes, and functions of SystemC the reader may refer to Ref. [10].

At the time of this writing, there are several options for simulating SystemC models. The two most robust SystemC simulators are the reference simulator, available with the SystemC distribution, and the ModelSim simulator as mentioned above. Because of some internal implementation details which differ between the two simulators, there are minor code differences required in the performance models between the two simulators. The differences and the techniques for enabling the models to be compiled and run in either simulators are described in the sections below.

12.5.2 SystemC Performance Models

The performance models described herein take advantage of the C++ foundations of SystemC to provide a highly parameterizable simulation environment that loads most of the parameters at run time. Figure 12.38 shows the class definition for the top level of the simulation model, and the relevant comments. The top-level entity makes use of a pointer to an object of type `SIM`, declared in the header file *generic.h*, to allow the constructor arguments to be read in from the *top_config.txt* file rather than statically specified in the source code. When the simulation is loaded the SystemC constructor (`SC_CTOR` in the code) will be called. The constructor will create a `streambuf` object, a number of processors variable, a connection type variable, as well as a pointer variable to point to an object of type `SIM`. It will then open the *top_config.txt* file and associate it with the `streambuf` variable. Then it will read an unsigned value into the number of processors variable, then read an unsigned value into the connection type variable. Once those values are read in then the constructor uses the ''new'' command to instantiate a new object of type `SIM`. The ''new'' command allows passing variable constructor arguments to the objects constructor, so the new `SIM` object's constructor builds the object with the value of `num_processors` processors, and the value of `connect_type` interconnect number. If the number of processors or interconnect type was specified via a template argument, or a fixed constructor

```
#ifndef MY_MAIN
#define MY_MAIN

#include <systemc.h>
#include "generic.h"

SC_MODULE(main_sim)
{
   SIM *simulation;

   SC_CTOR(main_sim)
   {
      ifstream topFile;
      unsigned num_processors;
      //1 to 9, could be to 10^13 or memory constraints except for modelsim
namebinding
      unsigned connect_type;   //1,2,3 are valid
      topFile.open("top_config.txt");//this doesn't do error check!
      topFile>>num_processors;
      //get info from file & set num_processors,connect_type
      topFile>>connect_type;// read in the interconnect type to use
      simulation = new SIM("simulation",num_processors,connect_type);
      // systemC name,number of processor ,connection class
   };

};
#endif
```

FIGURE 12.38 Top-level class definition.

```
#include <systemc.h>
#include "generic_main.h"
#ifdef MTI_SYSTEMC
SC_MODULE_EXPORT(main_sim);
#else
//for OSCI reference simulator
int sc_main(int ac, char *av[] )
{
    main_sim my_sim("my_sim");
    sc_start(500, SC_NS);
    sc_close_vcd_trace_file(main_trace);
    return 0;
};
#endif
```

FIGURE 12.39 Top-level C++ file.

value (e.g., "`simulation = new SIM("it,9,1);`") in the source code then the simulation would have to be recompiled every time something was changed.

Notice that all the implementation details of the SystemC modules are declared in header files. This is the recommended way of describing models to compile the SystemC code for the ModelSim simulator. The included guards are also a must for any `SC_MODULE` definitions to ensure they are not included multiple times by the ModelSim SystemC compiler, SCCOM. The actual C++ file that is compiled to generate the simulation models is shown in Figure 12.39. The `SC_MODULE_EXPORT(module_class_name)` is the function used to create the ModelSim model for the specified entity. The `MTI_SYSTEMC` compiler definition is defined specifically for compilation using SCCOM, and allows having a single set of code for both the ModelSim and reference simulator. Any ModelSim specific code can be placed inside a `#ifdef MTI_SYSTEMC` compiler directive statement so that the compiler only uses it when compiling for ModelSim. The `#else` statement prevents the ModelSim compiler from trying to compile the reference simulator-specific portions, and the `#endif` closes out the if-else statement.

The *generic.h* header file defines the class `SIM`. It makes use of the shared base class `my_basic_rw_port` to declare a pointer that will allow assignment of an instantiation of any of the three channel types developed for the environment. The `my_basic_rw_port` base class definition is shown in Figure 12.40. Notice the use of the keyword `virtual`. Since the method is declared as virtual, all

```
#ifndef INTERFACE_TYPE
#define INTERFACE_TYPE
include <systemc.h>
/* this header describes the interface type...*/

class my_basic_rw_port
  : public virtual sc_interface
{
public:
  // basic read/write interface
  //virtual bool read(int address, int data) = 0; //not used anymore!
  virtual bool read(int address, int source_address, int data,
                    int dest_task) = 0;
  virtual bool write(const int source, int address, int data,
                     int dest_task) = 0;
  virtual bool non_blk_write(const int dest_address, int source,
                             int data, int dest_task)=0;
}; // end class
#endif
```

FIGURE 12.40 "interface_type.h."

classes that inherit from this class must either provide, or inherit, an implementation for the `read`, `write`, and `non_blk_write` methods. This common interface is also what allows the type compatibility for pointer assignment used in the *generic.h* file. This is described in more detail in Section 12.5.4.

12.5.3 Processor Model

The processor model has a fairly simple structure. There are three methods in this model, the constructor, and two member functions. The first member function describes the performance only behavior of the processor, the second describes the mixed-level behavior. The mixed-level functionality will be described in detail in Section 12.5.9.

In addition to those methods, the processor model has a number of objects that are members of the class. It has three integer variables for passing command arguments to the interface methods, a pointer for a `command_in` object that opens the command file and parses the model execution commands for the processor model, a `command_type` object that is used to return the commands from the `command_in` object, a signal of enumerated type `action_type` to display the current action, an unsigned signal to display the current task number, and a pointer for a refined computation model. Figure 12.41 graphically shows the objects in the processor model. On the far right is the IO port. It is mapped to the interconnect interface. Next on the right are the three integer variables used to pass information to the interconnect calls. Below the variables are boxes representing the two signals that allow the state of the processor to be viewed in the ModelSim waveform window. Then to the left there are the performance and mixed-level descriptions. One of these member functions will be turned into an `SC_THREAD` and will control the model's behavior during simulation. On the top labeled as refined model, is an outlined box representing the pointer to a refined model object. Below is a storage location (labeled command) that the `command_in` object will return values in. In the bottom left is a dashed box representing a pointer to a `command_in` object. In the top left is a box representing the constructor. The IO port and constructor are both on the edge of the processor model because they are the only ones that interact with other objects in the simulation.

The constructor receives a processor number, and creates a `command_in` object with the appropriate processor number for the processor the current instance represents. The `command_in` object creates a string with the proper processor number in the middle, and uses it to open the processor's command file. It is called by the active behavior to read in the next command once the previous one has executed. Its primary function is to remove command parsing from the processor model. Having it as a separate object makes changing how the commands for the processor are read in or generated a simple matter of including a different implementation of the object. Once the `command_in` object is created and initialized, the processor model constructor then instantiates either the performance only or mixed-level implementation, and opens its log file. It does this by registering the proper member function with

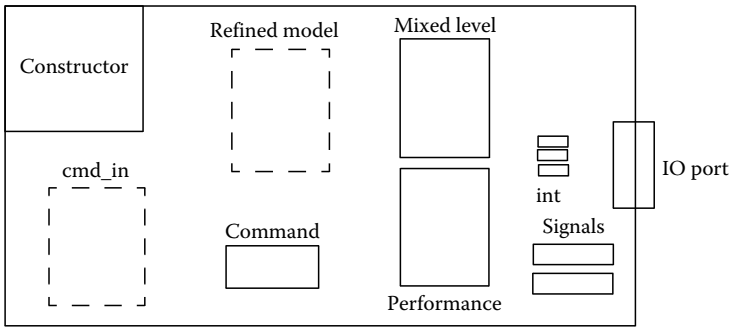

FIGURE 12.41 Graphical representation of processor model.

```
void tlm_behav()
{
   int temp2;
   double temp_time;
   while(1)
   {
      cmd_input->get_command(&this_command);
      switch (this_command.command)
      {
      case 1://ie send
         {...
            break;}
      case 2: //ie receive
         {...
            break;};
      case 0: //ie compute
         {...
            break;};
      case 3: //non_blocking_send
         {...
            break;};
      case 4: //io done
         {...
            break;};
      case 5: //loop/branch
         {...
            break;};
      default: //idle the processor
         {...
            break;};
      };//end of switch
   wait(SC_ZERO_TIME); //to break things up in the text output...
   };//end of infinite while loop
};
```

FIGURE 12.42 Main processor loop.

the simulation kernel as an `SC_THREAD`. During simulation the processor model essentially reads in a command from a file, then uses a case statement to perform whatever command was read in and repeats until it reaches a done command, an end of file, or some command it does not recognize. Figure 12.42 shows the framework of the main processor loop.

Notice in the source code that the processor has a port of the same type as the base type for the interconnect channels `my_basic_rw_ port`. This port is bound to the interface of the channel object. If the command read in from the command file is a send or receive command, then the processor uses the port as a pointer to the interface to the channel object and accesses the appropriate interface method to perform the send or receive operation. In the models here the thread in the processor model actually executes all the code in the blocking send and receive methods, so the processor model is incapable of doing anything else until the blocking io function returns.

12.5.4 Channels

The channels used in these models are considered hierarchical channels. They are not any of the predefined SystemC primitive channel types, they are composed of multiple objects, and they contain a number of threads. To allow for a variable number of processors to connect via the channels they have only an interface and no ports. In SystemC, all ports must be bound to something, be it another port, an interface, or a signal. Interfaces however may exist even if nothing is bound to them. So for maximum

flexibility, channels should provide an interface, and any connected modules should have a port of the type of the interface and have that port bound to the interface on the channel.

Since multiple ports can be bound to a single interface, the channel object can have any number of processors bound to it. However, the crossbar and fully connected channels' behavior is determined in part by the number of processors present, so all channels are passed a constructor argument that tells them how many processors are present in the simulation. The channel models are the most extensive models since their behavior is an abstract representation of all of the characteristics of an interconnect topology. They model the arbitration, data transfer, and blocking/nonblocking characteristics of the interconnect without restricting the designer to a particular implementation. Since nonblocking sends are allowed they also implicitly model a sending queue.

All the channel models are based on the `comm_medium` class. The `comm_medium` class provides a logical connection between processors, with signals for the source processor number, the destination processor number, and transaction type, as well as blocking and nonblocking read and write methods, and an arbitration thread. In addition, the `comm_medium` class provides two threads to allow for nonblocking reads and writes. Figure 12.43 shows the members of the `comm_medium` class. The four signals shown in the top left are signals to show the current state of the logical connection in the waveform window. To the right are the two wait queues, one for write request, and one for read request. New transaction requests received via the interface methods are placed into these queues. The Boolean `no_match` variable maintains whether there is currently a match between read operations and received data, the integers below it are used to store the values of the current processor for the sender and receiver, and to store the location in the queue of the current send request being executed, and the current receive request being executed. Below the integers is a dummy variable whose sole purpose is to fix an existing bug in the implementation of the SystemC simulator. In the bottom left of the figure are the member functions of the object. The functions all the way to the left are the functions intended to be accessed by other objects, the remaining four are intended for internal use only, though they are declared as public and thus visible to other objects. The functions with a star after them are registered with the simulation scheduler as `SC_THREAD`s. The top two events in the bottom right of the figure are used by the read and write methods to notify the arbitrator process that there may be new pairs of requests that could be activated to communicate. The event in the very bottom is used to coordinate the execution of two threads when they communicate. In the top right of the figure are two transaction pointers. These

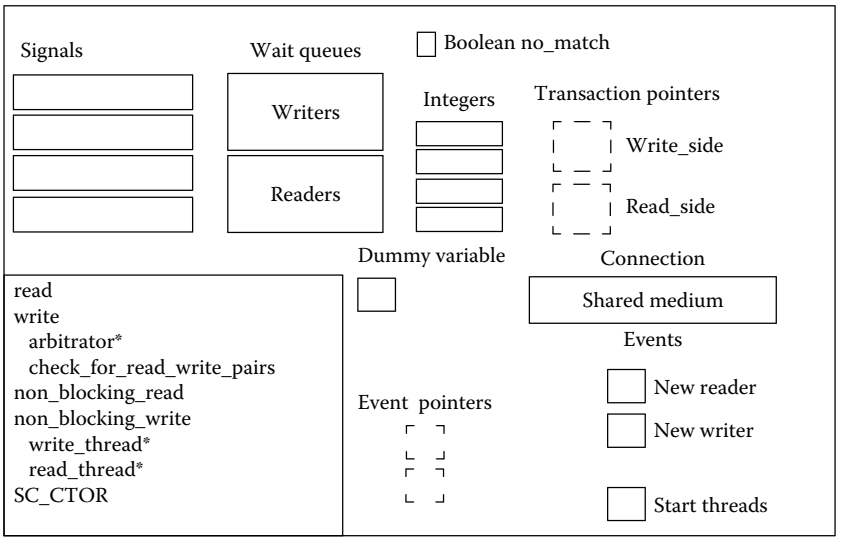

FIGURE 12.43 Graphical representation of ''comm_medium'' class.

pointers are used by the arbitrator to keep track of which two transactions it is dealing with. The event pointers in the bottom center of the figure are also used by the arbitrator. When the arbitrator has selected two transaction requests to communicate it does not actually handle the communication. There is a write thread, and read thread that execute the `transact()` code in each of the two transaction objects. For any blocking transaction objects the calling processor's thread is suspended in the interface call waiting on the transaction to notify it that the transaction is complete. Any nonblocking transaction objects have already had their calling thread return to the processor model code. The arbitrator has no need to check for any potential request pairs until after the two threads have completed their transaction. These two pointers are set to allow the arbitrator to suspend until both threads have completed, rather than wasting simulation resources polling to see if they are done.

While support exists in the `comm_medium` object for nonblocking reads, the channels do not have methods to give access to that functionality to the processor models. This was done on purpose to avoid having to check data dependencies before beginning a computation. This also keeps the simulation simple, and more efficient in terms of simulation time. The functionality was built into the `comm_medium` object because it was easy to do and makes adding nonblocking reads at some future point much easier. The arbitration scheme provided is a longest waiting first scheme. As soon as at least one transaction pair, a matching send and receive, is present the pair with the largest sum of positions in the wait queues is selected to transact next. The crossbar channel uses a variant of the `comm_medium` class. In the crossbar variant there are pointers to the transaction wait queues which allow a single set of queues to be used by all of the logical channels.

The `comm_medium` class also makes use of the class `transaction_wait_queue`, which is a specialized linked list to allow for a large number of waiting transactions without allocating a fixed large amount of memory. The elements of the linked list are of the class transaction_element, which contains all the essential information about a transaction request. The only item of importance from the linked list is the class that actually holds the transaction information. This `transaction_element` class contains all of the information about the transaction request. Figure 12.44 graphically depicts the key elements of the `transaction_element` class.

The integers in the bottom center contain the source processor number, the destination processor number, the destination task's id number, and the size, in nanoseconds, associated with the transaction. The Boolean variables in the top right tell whether the transaction element is a write or read, and whether it is blocking or not. The handshakes object in the upper middle is a set of four events that are used by the transact method to logically ''perform'' the transaction. The complement pointer below the handshakes is a pointer to a `transaction_element` object. To communicate two `transaction_element` objects must be paired up the channel's arbitrator process. It does this pairing by setting a read and a write's compliment pointer to each other. The `activate_me` event in the top left is used by the arbitrator to activate the thread executing the element's side of a transaction.

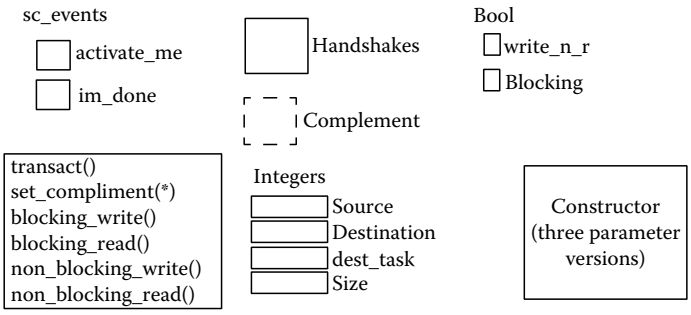

FIGURE 12.44 Graphical representation of ''transaction_element'' class.

While the `im_done` event is used to notify the arbitrator, and in the case of a blocking transaction the requesting processor's thread, that the transaction is complete. The constructor for this object depicted in the bottom left has three different implementations with different parameter lists, the first constructor implementation that sets all of the transaction values is the one used in the current version of the models. The others were left to maintain backward compatibility with previous versions, and may be useful for future versions. The purpose of the methods displayed in the bottom left of the figure are self-explanatory. The `transact` method is what controls the actual behavior of a transaction pair once it has been scheduled. The nondebugging parts are repeated below in Figure 12.45. The blocking and nonblocking versions of the read and write routines are the same in this version of the models.

The nondebugging versions of the blocking read and write methods are shown in Figure 12.46. These methods show how the four-way handshaking is implemented. The use of a full four-way handshaking in the channel model is somewhat arbitrary, but it makes incremental refinement of the channel easier.

```
   void transact() //method for creating thread to call (blocking read
or write)
   {
      wait(activate_me); //wait for arbitration process to activate me
      if (blocking)
      {
         if (write_n_r) //then it's a blocking write
            blocking_write(); //call the blocking write routine
         else //it's a blocking read
            blocking_read();  //call the blocking read routine
      }
      else
      {
         if (write_n_r) //then it's a non-blocking write
            non_blocking_write(); //call the non-blocking write routine
         else //it's a non-blocking read
            non_blocking_read();  //call the non-blocking read routine
      };
      im_done.notify(SC_ZERO_TIME);
      return;
   };
```

       wait (size,SC_NS)
    };
```

FIGURE 12.47 Alternative write and read methods.

However, with the abstract behavior described here a single line for the write method and two for the read method would be sufficient. Figure 12.47 shows how the methods could be implemented in this way.

All of the channel models also read in parameter information from the *channel_param.txt* file located in the directory that the simulation is running in. This file contains two lines. The first line is the bus speed in megabytes per second. The second line is the fixed communication overhead per communication transaction. In the top-level channel models the data size parameter passed to read interface method is run through a `data_to_delay` function that return the delay in nanoseconds that the communication should take based on the specified bandwidth and communication overhead.

12.5.5 Shared Bus Model

The shared bus architecture consists of a single logical communication medium, which is an object of class `comm_medium`. The behavior is encapsulated in the `shared_bus_io` class. This class inherits the virtual interface functions from the `my_basic_rw_port` class, and must provide an implementation for them. The implementation for these functions is shown in Figure 12.48. The

```
   inline bool read(int dest_address, int source_address, int data_size, int
dest_task)
   //blocking read function with writer's address
      //read function takes data to be size of data transmission
   {
      int temp_size;
      temp_size = data_to_delay(data_size);
      shared_bus.read(dest_address, source_address, temp_size, dest_task);
      return 1;
   };
   inline bool write(const int dest_address, int source, int data,
                     int dest_task)
      //blocking write function here
   {
      shared_bus.write(dest_address, source, data, dest_task);
      return 1;
   };
   inline bool non_blk_write(const int dest_address, int source, int data,
                             int dest_task)
   //non-blocking write function here
   {
      shared_bus.non_blocking_write(dest_address,source,data,dest_task);
      return 1;
   };
```

FIGURE 12.48 Implementation of inherited virtual interface functions.

functions essentially map the interface functions to the methods of the `comm_medium` object. The `data_to_delay` function takes the `data_size` passed to the read method, and calculates the required transaction time in nanoseconds based on the bandwidth, and then adds the fixed communication overhead that the channel's constructor reads in from the channel parameter file.

12.5.6 Fully Connected Model

The fully connected architecture is built around the same `comm_medium` object as the Shared Bus model. The fully connected architecture creates a `comm_array` object which contains all the logical connections, and copies the addresses of the `comm_medium` objects into a two-dimensional array that it uses to map a processor's request to the overall communication architecture to the appropriate logical connection. The fully connected architecture passes the number of processors to the `comm_array` object which then instantiates the number of `comm_medium` objects needed to provide a dedicated shared bus between each pair of processors in the simulation.

12.5.7 Crossbar Model

The crossbar architecture is similar to the fully connected architecture except that it only requires four `cross_comm_medium` objects since with nine processors only four concurrent connections are allowed. As mentioned earlier, it uses its own version of the basic `comm_medium` object. This is necessary because the logical connections in the crossbar are not associated with any particular processor, and the communication requests are not associated with any of the logical connections. Just to clarify in the fully connected architecture there is a logical connection between every processor modeled by a `comm_medium` object. The fully connected architecture model simple directed the requests it received to the correct logical connection. In the fully connected architecture there is only one connection that all requests are intended for, but in the crossbar the number of logical connections is equal to the number of processors divided by two, and every request could potentially communicate over any of them.

12.5.8 SystemC Performance Modeling Examples

This section contains a number of examples of performance models constructed using the SystemC modeling modules described above. The examples are presented as a demonstration that the models execute correctly and also that they demonstrate performance of the system they are intended to model. The first example is a trivial example with a set of four tasks all executing on one processor. Since data communication inside a processor is assumed to take no time, the description should take simulation time equal to the sum of the computation time of all the tasks. The second example is the same four tasks allocated to two processors such that each task must send the data over the communication channel to the next task. This second example should take longer, with three 100 byte sends being sent over the communication channel. The third example is the same task graph description with varying bus parameters. The fourth and fifth examples have bus contention, to show that contention is handled properly. Each example lists the simulated latency, and a timeline showing the simulation results.

12.5.8.1 Single Processor

Figure 12.49 shows the simple sequential task graph for the first example. Here all the tasks are allocated to Processor 0. Each task has a compute value of 10 μs, and each edge has a data value of 100 bytes. Since communication within a processor is assumed to take no time, the latency for this description should be the sum of the compute times, which is 40 μs.

In addition to the processing timeline shown previously, the models generate a text output stream that describes the actions each module is taking at a given simulation time. The text output for this simulation

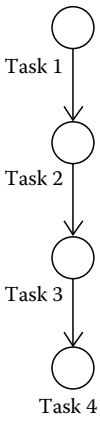

FIGURE 12.49 Single processor example task graph.

is shown below. Note that the final task is completed at 40 μs of simulation time which is exactly as expected.

```
shared bus architecture
0 s proc#0 Task number 1 Computing for 10000 ns
0 μs proc#0 Task number 2 Computing for 10000 ns
20 μs proc#0 Task number 3 Computing for 10000 ns
30 μs proc#0 Task number 4 Computing for 10000 ns
40 μs proc#0 done!
sim done!?
```

12.5.8.2 Dual Processor

The task graph for the second example is shown in Figure 12.50. The graph also shows the allocation of the tasks to two processors. Notice that the sequential tasks are on different processors so the data must be transferred across the communication channels before the computations can begin. Here the communication channel's bandwidth determines how long a communication transaction should take to complete. The length of time is the data size in bytes divided by the bandwidth in megabytes per second. The communication channel can also take into account communication overhead, in nanoseconds, if it is specified. The channel bandwidth and communication overhead are read in from a file. If this file is not present or an item is missing it will take on its default value. The value specified for this example is 100 Mbyte/s for bandwidth and 5 ns for channel overhead.

Since all the communication is of the same size, the expected latency for this example can be determined using the following equation:

$$\text{Computation time} + \text{numtrans} * \left(\frac{\text{Data size (byte)}}{\text{Bandwidth (Mbyte/s)}} + \text{Communication overhead (ns)} \right)$$

which, for this example, evaluates as follows:

$$40\ \mu\text{s} + 3 * \left(\frac{100\ \text{byte}}{10\ \text{Mbyte/s}} + 5\ \text{ns} \right) = 40\ \mu\text{s} + \frac{300}{100 * 10^6}\ \text{s} + 15\ \text{ns} = 40\ \mu\text{s} + \frac{300}{100}\ \mu\text{s} + 15\ \text{ns}$$

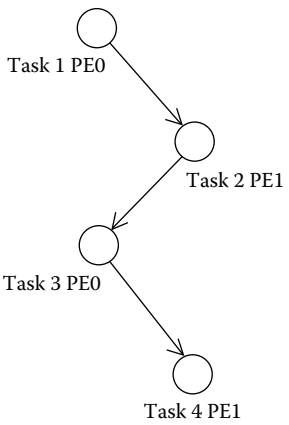

FIGURE 12.50 Dual processor example task graph.

Thus the expected latency is 40 μs for computation plus 3 μs for the actual data transmission, plus 15 ns for communication overhead. That gives a total latency of 43,015 ns. The timeline output for this simulation is shown in Figure 12.51. Note that the final task, Task 4, completes at 43 μs on the graph.

12.5.8.3 Parallel Communications Example

The next example shows the effect of various communications topologies on an application with requirements for simultaneous communications. The task graph for this example is shown in Figure 12.52. Each task (called nodes in this graph) computes for a fixed period of time and then sends data to a second task causing it to begin execution. The tasks are allocated to processors such that after completion of the first set of tasks, all processors attempt to send data to another processor. Because the first tasks all have the same execution time, all the communications become ready to begin at the same time. Thus, if an architecture has parallel

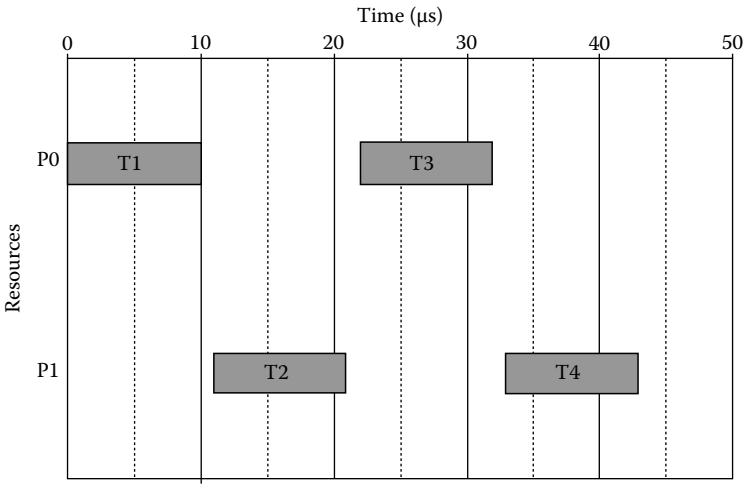

FIGURE 12.51 Dual processor example timeline.

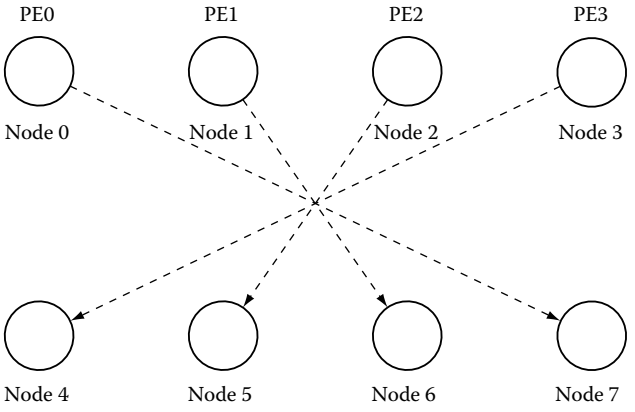

FIGURE 12.52 Bus contention example task graph.

communication paths, this will result in a decrease in the total application run time. The four start tasks (nodes) in this example all compute for 10 μs, then attempt to do a nonblocking send of size 100 byte to a task allocated to another processor. They then move on to start the read required to begin their next task.

For all of the results discussed below, the channel parameters are set to a bus bandwidth of 1 Mbyte/s and a communication overhead of 0 ns.

12.5.8.3.1 Shared Bus Simulation Results

The first set of results is for a system with a single shared bus. On this system Tasks 0–3 all execute in parallel on the four processors. At this point there will be four-way contention for the single system bus. The communications operations will be assigned priority on a first-come-first-serve basis. In the current implementation of SystemC, the task that will get first priority to communicate its data cannot be determined ahead of time, however the tasks will all run in the same order every time the simulation is run.

With a shared bus architecture, the latency is 100 μs for all processors to compute in parallel plus 4*(data size/bandwidth)*1000 (ns), or 400 μs, for each of the four sends to occur in series, plus 100 μs for the last receiver to compute after completing their receive. Thus the overall latency should be 600 μs.

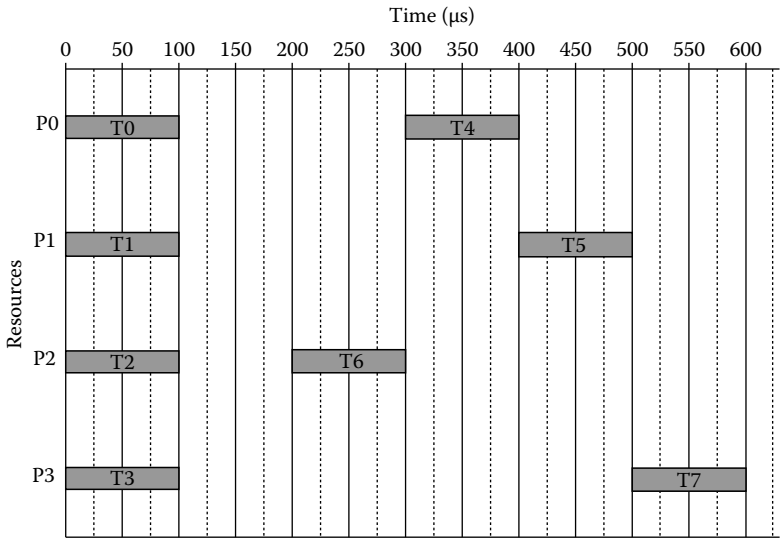

FIGURE 12.53 Shared bus contention example timeline.

The timeline for this example is shown in Figure 12.53. The timeline shows all the tasks beginning their blocking read then having to wait for the arbitrator to select them to communicate across the bus. Once the individual communications have taken place, the destination task, Tasks 4–7, execute. The timeline correctly shows the last task completing execution at 600 μs.

12.5.8.3.2 Fully Connected Simulation Results

In the fully connected architecture there is a dedicated communications channel between each pair of processors. However, in this architecture, it was decided to model a system where a processor cannot both send and receive a message from the same processor at the same time. Because of the connectivity of the task graph for this application, after the first set of tasks execute in parallel, each processor needs to send and receive a message before it can execute the next task. For example, Processor 0 cannot send to Processor 3 and receive from Processor 3 at the same time. Rather it must do one, then the other. Thus, for this example, each channel in the fully connected architecture is effectively a half duplex connection.

During execution the run time is 100 μs for all processors to compute the first four tasks in parallel plus 100 μs for the first set of sends, plus 100 μs for the second set of sends—during which the tasks started by the first set of sends also execute, then finally 100 μs for the last two tasks to compute in parallel. Thus the overall latency for the fully connected architecture should be 400 μs. The timeline for this example is shown in Figure 12.54.

12.5.8.3.3 Crossbar Simulation Results

As mentioned above, the crossbar architecture behaves like a fully connected architecture where the maximum number of connections is limited to the number of processors divided by two. Thus for this four processor example, the crossbar architecture will only allow two communications at a time. This characteristic means that for this example, the crossbar architecture will have the same latency as the fully connected architecture for this example. This result is shown in Figure 12.55.

12.5.8.4 Second Contention Example

This second example expands on the previous example by showing a slightly different set of contention conditions. In the first example, the communication requirements specified by the task graph required

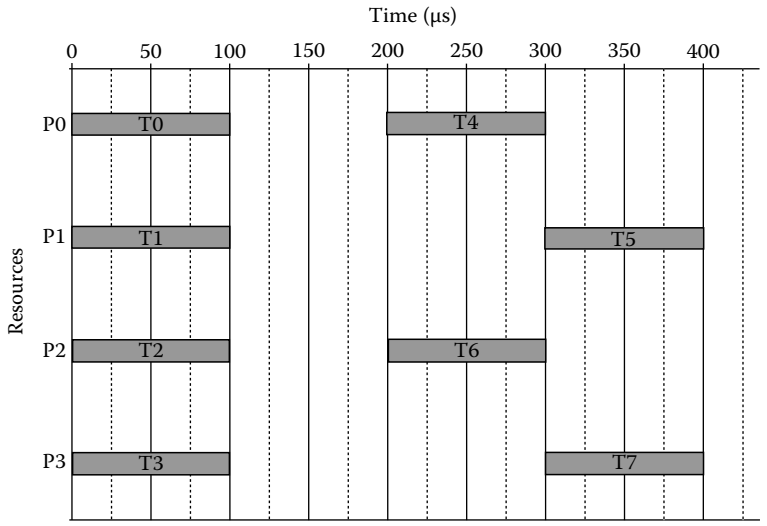

FIGURE 12.54 Fully connected contention example timeline.

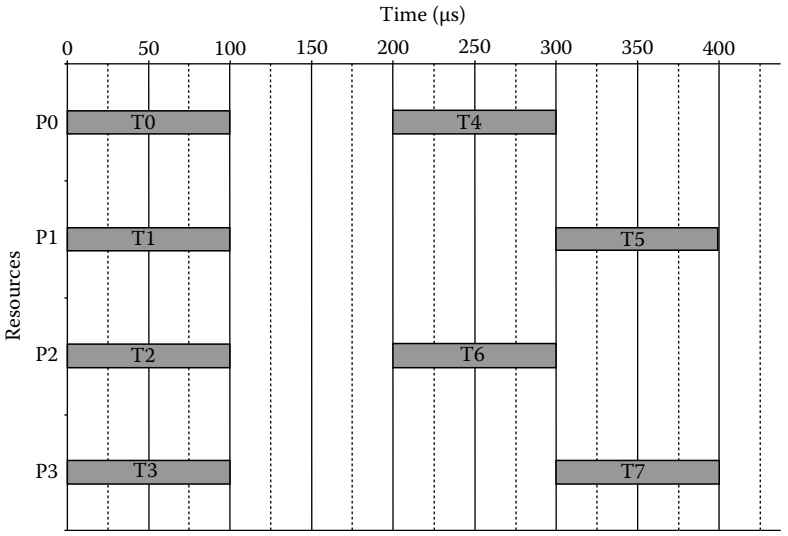

FIGURE 12.55 Crossbar contention example timeline.

the processors to send and receive data from the same processor. This effectively allowed for only two active communication transactions on the fully connected architecture. In this example, as shown in Figure 12.56, the processors will be sending and receiving data from different processors during the communications portion of the application. This set of communication requirements will allow all of the available communication channels to be used concurrently with the fully connected architecture.

Figure 12.57 shows the results for this example for the shared bus, fully connected, and crossbar architectures. Note that in this example, in the fully connected architecture, all of the communication operations occur in parallel which allows the entire application to execute in 300 μs.

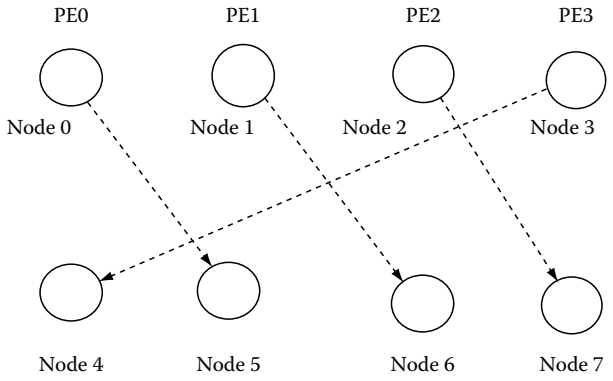

FIGURE 12.56 Second contention example task graph.

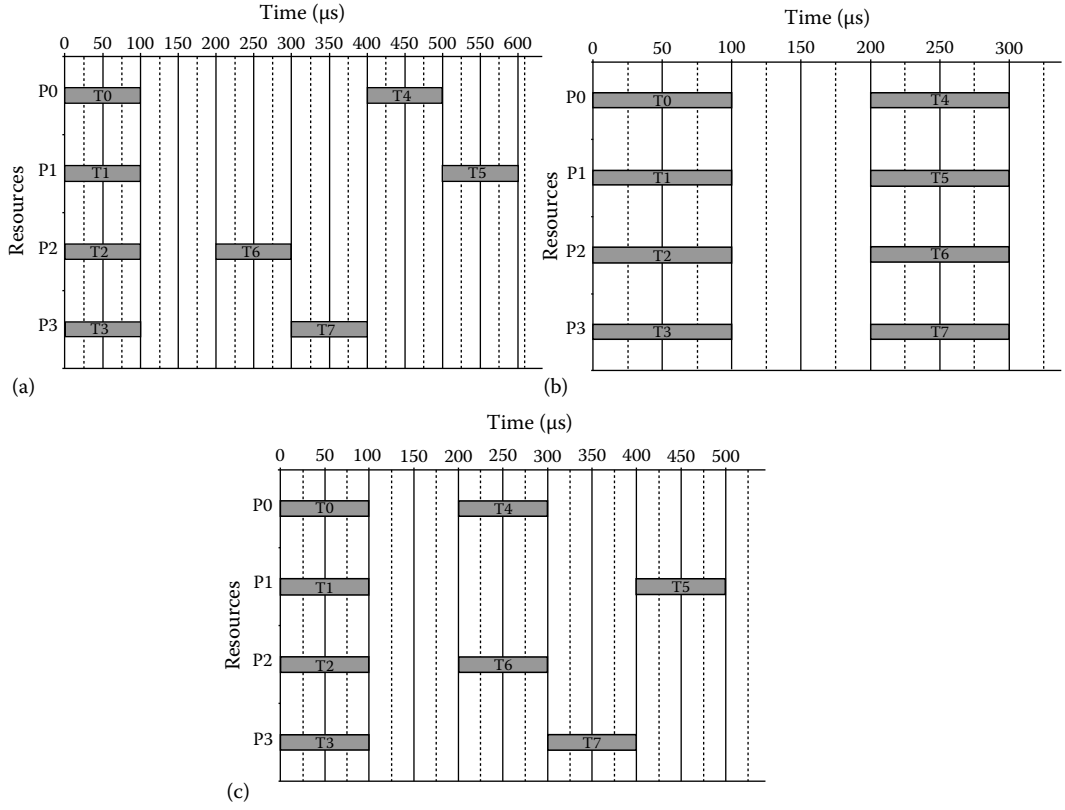

FIGURE 12.57 Second contention example timelines: (a) shared bus, (b) fully connected, and (c) crossbar.

12.5.9 Mixed-Level Processor Model

Although simplistic in nature, the above examples show that the SystemC-based performance modeling methodology can be used to model the execution of different applications on various system architectures. In addition to this capability, as mentioned earlier, the SystemC module for the processor has the

ability to replace the performance only computation delay with a refined computation model that is described in VHDL or Verilog. This mixed-level modeling capability allows the model to be refined to a lower level in a step-wise fashion.

The replacement of an abstract processor model with a refined (RTL or gate-level model) is accomplished by using the ModelSim `SC_FORIEGN_MODULE` syntax. The `SC_FORIEGN_MODULE` provided by ModelSim allows a non-SystemC model that has been compiled for ModelSim to be instantiated by a SystemC model. Incidentally, it also allows an already compiled SystemC module to be loaded in the same manner.

The processor model opens its processor command file and looks at the first line during the execution of its constructor. If the first line is "mixed" then the processor model knows that it should run as a mixed-level model with a refined computation model. If the model is to be a mixed-level one, the constructor of the processor model will then look for a *mixed_processor.txt* text file that specifies the ModelSim path for the refined computation model to use. The relevant part of the constructor that instantiates the refined model is shown in Figure 12.58.

The `refined_computation` object is the one that opens the *mixed_processorX.txt* file, where *X* is the processor number. Once this file is opened, the constructor uses the path contained within it to open the refined model object. In this example, it instantiates an object of class `rng_comp_tb` that is shown in Figure 12.59.

This class is essentially a wrapper for the actual precompiled model VHDL or Verilog model. This class/module definition would map to a VHDL entity definition like the one shown in Figure 12.60. Note that this entity corresponds to what is effectively a test bench for the refined model.

```
        cmd_input = new command_in(proc_num);
        string_temp.assign(cmd_input->get_proc_type());
        if(/*1st_line*/string_temp=="mixed")
        {
           SC_THREAD(mixed_behav);
           //only make the relevant behavior a thread!
           hardware_compute=new
  refined_computation("name",proc_num);
           //may need to add an argument this class...
        }
```

     start : in std_logic;
     done : out std_logic
     );

END rng_comp_tb;
```

FIGURE 12.60 Sample VHDL refined computation entity declaration.

The intent for this interface is for it to be easy to integrate into an existing test bench for the refined model of computation. The start and done signals are active high. So when the start goes high to a logical ''1,'' the refined model should start a ''computation.'' This computation is effectively the test bench applying a set of predefined stimulus waveforms to the refined model. As described below, these stimulus waveforms can be derived for the specific refined model in a number of different ways depending on the objectives for the mixed-level model.

When the refined model has finished its ''computation'' it should raise the done signal. Both signals should be low at the start of the simulation. When the processor model puts the start signal high, the refined model begins its computation. The presumption is that the refined model is something like a test bench, with a model of the actual hardware, or some other more detailed model, instantiated inside of it. The refined model presents any required data to the detailed model, and watches for whatever condition indicates that it has completed the computation. Once the computation is completed, it raises the done signal telling the abstract processor model it is done. The processor model will then lower the start signal, and the refined model will respond by lowering the done signal. Figure 12.61 shows the basic timing diagram for the interface.

Figure 12.62 shows the portion of the processor model that raises and lowers the start signal and waits for the done signal. This code is located in the `refined_computation` object. The `refined_computation` object is instantiated by the processor model's constructor when it reads in from the command file and determines that it should be a mixed-level model.

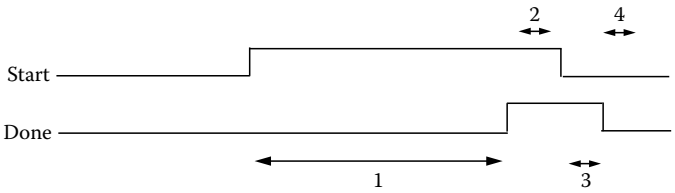

FIGURE 12.61 Refined computation model interface-timing diagram.

```
   bool start_compute()
   {/* basic algorithm is:
      send start signal
      wait for done signal
      return
      */
#ifdef MTI_SYSTEMC
      temp= true; //'1';
      start = temp;
      while (done != temp)  //ie while done != 1
         wait(done.value_changed_event());//wait until event and
loop..
      temp = false;
      start = temp;
#endif
      return 0;
   };
```

```
-------------------------------------------------------------------
-- Process to respond to start and create go and done. JA
-------------------------------------------------------------------
   CompBench: PROCESS (start, tb_done)
   Begin
      if (start='1') then
         if ((tb_done'event) AND (tb_done='1')) then
            go   <= '0';
            done <= '1';
         ELSE
            go   <= '1';
            done <= '0';
         end if;
      end if;
   End process CompBench;
```

FIGURE 12.63 Sample VHDL start/done interface code.

Figure 12.63 shows a portion of sample VHDL test bench that implements the refined computation model's side of the start/done interface. The start signal from the start/done interface activates the process. The process uses the go signal to cause the test bench to perform a computation, and the test bench raises the `tb_done` signal when it is finished with a single computation.

12.5.10 Mixed-Level Examples

The following examples are mixed-level examples where the computation part of the processor is modeled in more detail. Since the rest of the simulation is at a more abstract level and does not have all of the stimuli needed for the refined model, the stimuli need to be created in some way. The following examples focus mainly on different ways of generating the data that the various refined models need to function.

12.5.10.1 Fixed Cycle Length

The first example is one where an abstract processor is replaced with a random number generator. The model for the random number generator is an RTL discrete digital model of a random number generator described in Ref. [51]. The model attempts to describe a number of elements that are extremely sensitive to initial conditions, and thus in reality exhibit more random behavior than can be modeled with a solely digital model. As it is, the model always generates the same nonrepeating sequence of values. For this example, the existing test bench was modified to put the generator through its reset cycle, then through a single random number generation. The only inputs to the refined model are a set of control signals and a clock. When the processor, that it is the refined computation model for, gets a compute command; it will send the start signal to the test bench, which will then go through the reset and generate phases, and signal back with the done signal once a number has been generated. In this particular example the internal signals continue to oscillate between compute commands. Since this model takes a fixed number of cycles using the refined model, and the values generated are not passed elsewhere, this example is less efficient and no more accurate than putting in the actual compute time for the abstract compute command.

12.5.10.2 Variable Cycle Length

The rest of the mixed-level examples presented use an RTL booth multiplier model. The booth multiplier takes a variable number of cycles to complete the binary multiplication. The number of cycles required depends on the numbers being multiplied. The inputs to the model are the two numbers to be multiplied, and a clock, the outputs are the result and a control signal indicating that the multiplication is complete.

There is a slight propagation delay for the result to appear on the output after the done signal appears. If the input clock continues to cycle after the multiplication is complete, then the result will become invalid after a clock cycle. Thus the test bench allows a half cycle to elapse before considering the computation done. Note that the effect of this refined model is that the computational delay is dependent on the data being applied to it for the computation. This delay mechanism is a more accurate representation of how a refined model would be used in, and add additional accuracy to, a system-level performance model. However, as discussed in the section above on VHDL-based mixed-level modeling, the important question is how to generate the data that is input to the refined model in such a way as to accurately represent the performance of the refined component in the real system. Typically, this can be done by either presenting the refined model with random data to develop a statistical representation of average system performance, or presenting the refined model with predefined data. This data can be generated by the designer to represent typical system performance, or to exercise the best-, or worst-case delay scenarios.

12.5.11 Random Data Generation

In this example, the booth multiplier is presented with two random numbers generated by two other entities instantiated in the test bench. Since random number generation is not present in standard VHDL library, ModelSim's mixed language ability is utilized to allow a SystemC random number generator module to be used. The SystemC module uses the C++ `rand()` function to generate a pseudo random number, which is passed back to the VHDL test bench. Since the VHDL test bench is instantiated by the SystemC performance simulation, this is in fact a SystemC–VHDL–SystemC hierarchy. ModelSim's mixed language interface allows the designer to use whatever language is best suited for the task at hand. Here the random number must be passed back to the VHDL test bench as an `sc_logic` vector, which is automatically translated into a VHDL `std_logic_vector` by the simulator. Since both numbers are pseudorandom, the computer will take a variable amount of time to complete. Although it is possible that the use of the `rand()` function will result in repeating sequence of numbers, most simulations will not run long enough for this to be noticeable. If a more random distribution, or a particular type of distribution is desired, a specialized random number generator package can be used in the model. Since most of the computations at the system level, will consist of multiple operations, to make this example more typical, a means of generating a set multiple numbers to be multiplied was needed. While it is possible to generate a fixed size data set this example goes just a little farther and generates a pseudorandom size data set of pseudorandom numbers. The generation of the random size of the data set is done using the same SystemC module that generates the random data itself. A few changes to the test bench needed to be made so that it did not send the done signal back until all of the multiplications were completed. Figure 12.64 shows two waveforms from two different mixed-level simulations, each with two different size sets of random numbers multiplied together.

12.5.11.1 Data Set from File

As described above, when a sample set of data that exercises a specific scenario for the refined model is available, it can be advantageous to use it rather than generating a new set that may or may not be close to the actual data. Using this predefined sample data set ensures accurate performance for that data set, and removes any guesswork as to what a realistic data set might be. Since VHDL has standard file access capabilities that are easy to use, the test bench for this example reads the values directly from the input file, and does not send the done signal until it reaches the end of file. Unfortunately, the current implementation ModelSim used for this example did not allow passing generic information across the language boundary, thus specification of the file to use had to be done in the VHDL code. An extension to this approach would be to read the filename to use from a configuration file similar to what is done to specify the refined model to use in the SystemC performance code. Figure 12.65 shows the waveform of the mixed-level model simulation where the data for the refined component were read in from a file.

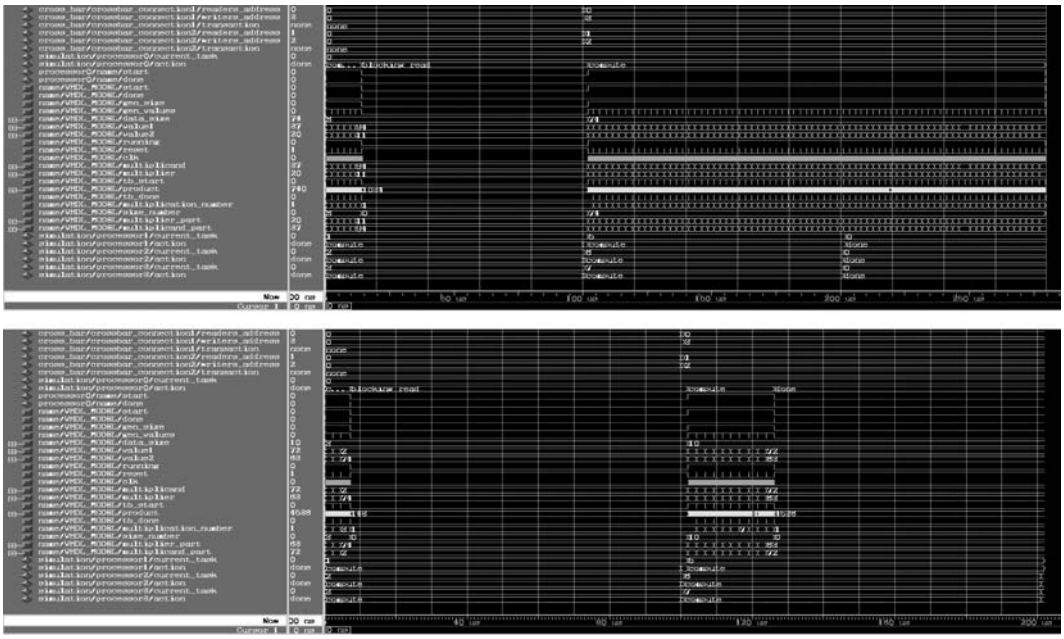

FIGURE 12.64 First- and second-random data set waveforms.

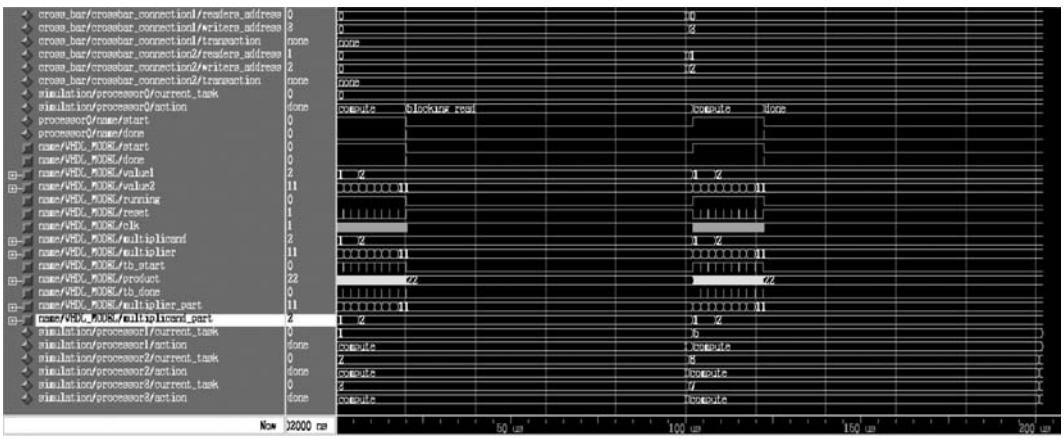

FIGURE 12.65 Data from file example waveform.

12.5.12 Mixed-Level Example Summary

Mixed-level modeling techniques in SystemC-based performance models have been demonstrated. These examples utilized simple pseudorandom data generation, variable size pseudorandom data set generation, reading a data set from single file, and reading multiple data sets from multiple files. Multiple variations and combinations of the above approaches can be used to generate stimuli for a wide variety of refined computation models. Anything from randomly selecting a file from which to read a data set, to using a file to parameterize random data generation is possible depending on whether realistic data are available and on the simulation objective. It is clear to see, in any case, that including refined behavioral

RTL or gate-level components in a performance model in SystemC is fairly easily done and can increase the overall accuracy of the performance model, just as was possible in the VHDL-based performance model.

12.6 Conclusions

Integration of performance modeling into the design process such that it can actually drive the refinement of the design into an implementation has clear advantages in terms of design time and quality. The capability to cosimulate detailed behavioral models and abstract system-level models is vital to the development of a design environment that fully integrates performance modeling into the design process. One methodology and implementation for cosimulating behavioral models of individual components with an abstract performance model of the entire system was presented. This environment results in models that can provide estimates of the performance bounds of a system that converge as the refinement of the overall model increases.

This chapter has only scratched the surface on the possible improvements that performance- or system-level modeling can have on the rapid design of complex VLSI systems. As more and more functionality can be incorporated into the embedded VLSI systems and these systems find their way into safety-critical applications, measures of dependability such as reliability and safety at the system-level are becoming of great interest. Tools and techniques are being developed that can use the performance model from which to derive the desired dependability measures. In addition, behavioral fault simulation and testability analysis are finding their way into the early phases of the design process. In summary, the more attributes of the final implementation that can be determined from the early and often incomplete model, the better the resulting design and shorter the design cycle.

13.1 Introduction

This chapter describes embedded computing systems that make use of microprocessors to implement part of the system's function. It also describes hardware/software codesign, which is the process of designing embedded systems while simultaneously considering the design of its hardware and software elements.

13.2 Uses of Microprocessors

An embedded computing system (or more simply an embedded system) is any system which uses a programmable processor but itself is not a general-purpose computer. Thus, a personal computer is not an embedded computing system (though PCs are often used as platforms for building embedded systems), but a telephone or automobile which includes a CPU is an embedded system. Embedded systems may offer some amount of user programmability—3Com's PalmPilot, for example, allows users to write and download programs even though it is not a general-purpose computer—but embedded systems generally run limited sets of programs. The fact that we know the software that we will run on the hardware allows us to optimize both the software and hardware in ways that are not possible in general-purpose computing systems.

Microprocessors are generally categorized by their word size, since word size is associated both with maximum program size and data resolution. Commercial microprocessors come in many sizes; the term microcontroller is used to denote a microprocessor which comes with some basic on-chip peripheral devices, such as serial input/output (I/O) ports. Four-bit microcontrollers are extremely simple but capable of some basic functions. Eight-bit microcontrollers are workhorse low-end microprocessors.

Sixteen- and 32-bit microprocessors provide significantly more functionality. A 16/32-bit microprocessor may be in the same architectural family as the CPUs used in computer workstations, but microprocessors destined for embedded computing often do not provide memory management hardware. A digital signal processor (DSP) is a microprocessor tuned for signal processing applications. DSPs are often Harvard architectures, meaning that they provide separate data and program memories; Harvard architectures provide higher performance for DSP applications. DSPs may provide integer or floating-point arithmetic.

Microprocessors are used in an incredible variety of products. Furthermore, many products contain multiple microprocessors. Four- and eight-bit microprocessors are often used in appliances: for example, a thermostat may use a microcontroller to provide timed control of room temperature. Automatic cameras often use several eight-bit microprocessors, each responsible for a different aspect of the camera's functionality: exposure, shutter control, etc. High-end microprocessors are used in laser and ink-jet printers to control the rendering of the page. Many printers use two or three microprocessors to handle generation of pixels, control of the print engine, and so forth. Modern automobiles may use close to 100 microprocessors, and even inexpensive automobiles generally contain several. High-end microprocessors are used to control the engine's ignition system—automobiles use sophisticated control algorithms to simultaneously achieve low emissions, high fuel economy, and good performance. Low-end microcontrollers are used in a number of places in the automobile to increase functionality: for example, four-bit microcontrollers are often used to sense whether seat belts are fastened and turn on the seat belt light when necessary.

Microprocessors may replace analog components to provide similar functions, or they may add totally new functionality to a system. They are used in several different ways in embedded systems. One broad application category is signal conditioning, in which the microprocessor or DSP performs some filtering or control function on a digitized input. The conditioned signal may be sent to some other microprocessor for final use. Signal conditioning allows systems to use less-expensive sensors with the application of a relatively inexpensive microprocessor. Beyond signal conditioning, microprocessors may be used for more sophisticated control applications. For example, microprocessors are often used in telephone systems to control signaling functions, such as determining what action to take based on the reception of dial tones, etc. Microprocessors may implement user interfaces; this requires sensing when buttons, knobs, etc. are used, taking appropriate actions, and updating displays. Finally, microprocessors may perform data processing, such as managing the calendar in a personal digital assistant.

There are several reasons why microprocessors make good design components in such a wide variety of application areas. First, digital systems often provide more complex functionality than can be created using analog components. A good example is the user interface of a home audio/video system, which provides more information and is easier use than older, non-microprocessor-controlled systems. Microprocessors also allow related products much more cost-effectively. An entire product family, including models at various price and feature points, can be built around a single microprocessor-based platform. The platform includes both hardware components common to all the family members and software running on the microprocessor to provide functionality. Software elements can easily be turned on or off in various family members. Economies of scale often mean that it is cheaper to put the same hardware in both expensive and cheap models and to turn off features in the inexpensive models rather than to try to optimize the hardware and software configurations of each model separately. Microprocessors also allow design changes to be made much more quickly. Many changes may be possible simply by reprogramming; other features may be made possible by adding memory or other simple hardware changes along with some additional programming. Finally, microprocessors aid in concurrent engineering. After some initial design decisions have been made, hardware and software can be designed in parallel, reducing total design time.

While embedded computing systems traditionally have been fabricated at the board level out of multiple chips, embedded computing systems will play an increasing role in integrated circuit design as well. As VLSI technology moves toward the ability to fabricate chips with billions of transistors, integrated circuits will increasingly incorporate one or several microprocessors executing embedded

software. Using microprocessors as components in integrated circuits increases design productivity, since CPUs can be used as large components which implement a significant part of the system functionality. Single-chip embedded systems can provide much higher performance than board-level equivalents, since chip-to-chip delays are eliminated.

13.3 Embedded System Architectures

Although embedded computing spans a wide range of application areas, from automotive to medical, there are some common principles of design for embedded systems. The application-specific embedded software runs on a hardware platform. An example hardware platform is shown in Figure 13.1. It contains a microprocessor, memory, and I/O devices. When designing on a general-purpose system such as a PC, the hardware platform would be predetermined, but in hardware/software codesign the software and hardware can be designed together to better meet cost and performance requirements.

Depending on the application, various combinations of criteria may be important goals for the system design. Two typical criteria are speed and manufacturing cost. The speed at which computations are made often contributes to the general usability of the system, just as in general-purpose computing. However, performance is also often associated with the satisfaction of deadlines—times at which computations must be completed to ensure the proper operation of the system. If failure to meet a deadline causes a major error, it is termed a hard deadline. And missed deadlines, which result in tolerable but unsatisfactory degradations, are called soft deadlines. Hard deadlines are often (though not always) associated with safety-critical systems. Designing for deadlines is one of the most challenging tasks in embedded system design. Manufacturing cost is often an important criteria for embedded systems. Although the hardware components ultimately determine manufacturing cost, software plays an important role as well. First, the size of the program determines the amount of memory required, and memory is often a significant component of the total component cost. Furthermore, the improper design of software can cause one to require higher-performance, more-expensive hardware components than are really necessary. Efficient utilization of hardware resources requires careful software design. Power consumption is becoming an increasingly important design metric. Power is certainly important in battery-operated devices, but it can be important in wall socket-powered systems as well—lower power consumption means smaller, less-expensive power supplies and cooling and may result in environmental ratings that are advantageous in the marketplace. Once again, power consumption is ultimately determined by the hardware, but software plays a significant role in power characteristics. For example, more efficient use of on-chip caches can reduce the need for off-chip memory access, which consumes much more power than on-chip cache references.

Figure 13.1 shows the hardware architecture of a basic microprocessor system. The system includes the CPU, memory, and some I/O devices, all connected by a bus. This system may consist of multiple chips for high-end microprocessors or a single-chip microcontroller. Typical I/O devices include analog/digital (ADC) and digital/analog (DAC) converters, serial and parallel communication devices, network and bus interfaces, buttons and switches, and various types of display devices. This configuration is a complete, basic, embedded computing hardware platform on which application software can execute.

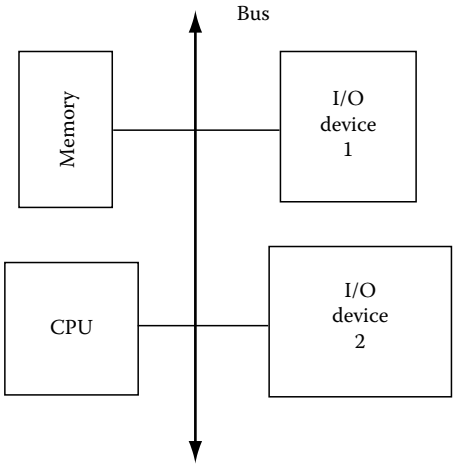

FIGURE 13.1 Hardware structure of a microprocessor system.

The embedded application software includes components for managing I/O devices and for performing the core computational tasks. The basic software techniques for communicating with I/O devices are polling and interrupt-driven. In a polled system, the program checks each device's status register to determine if it is ready to perform I/O. Polling allows the CPU to determine the order in which I/O operations are completed, which may be important for ensuring that certain device requests are satisfied at the proper rate. However, polling also means that a device may not be serviced in time if the CPU's program does not check it frequently enough. Interrupt-driven I/O allows a device to change the flow of control on the CPU and call a device driver to handle the pending I/O operation. An interrupt system may provide both prioritized interrupts to allow some devices to take precedence over others and vectored interrupts to allow devices to specify which driver should handle their request.

Device drivers, whether polled or interrupt-driven, will typically perform basic device-specific functions and hand-off data to the core routines for processing. Those routines may perform relatively simple tasks, such as transducing data from one device to another, or may perform more sophisticated algorithms such as control. Those core routines often will initiate output operations based on their computations on the input operations.

Input and output may occur either periodically or aperiodically. Sampled data is a common example of periodic I/O, while user interfaces provide a common source of aperiodic I/O events. The nature of the I/O transactions affects both the device drivers and the core computational code. Code which operates on periodic data is generally driven by a timer which initiates the code at the start of the period. Periodic operations are often characterized by their periods and the deadline for each period. Aperiodic I/O may be detected either by an interrupt or by polling the devices. Aperiodic operations may have deadlines, which are generally measured from the initiating I/O event. Periodic operations can often be thought of as being executed within an infinite loop. Aperiodic operations tend to use more event-driven code, in which various sections of the program are exercised by different aperiodic events, since there is often more than one aperiodic event which can occur.

Embedded computing systems exhibit a great deal of parallelism which can be used to speed up computation. As a result, they often use multiple microprocessors which communicate with each other to perform the required function. In addition to microprocessors, application-specific ICs (ASICs) may be added to accelerate certain critical functions. CPUs and ASICs in general are called processing elements (PEs). An example multiprocessor system built from several PEs along with I/O devices and memory is shown in Figure 13.2.

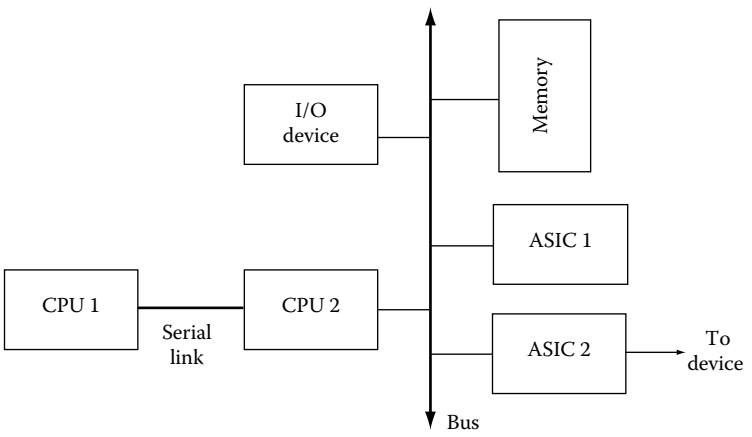

FIGURE 13.2 Heterogeneous embedded multiprocessor.

The choice of several small microprocessors or ASICs rather than one large CPU is primarily determined by cost. Microprocessor cost is a nonlinear function of performance, even within a microprocessor family. Vendors generally supply several versions of a microprocessor which run at different clock rates; chips which run at varying speeds are a natural consequence of the variations in the VLSI manufacturing process. The slowest microprocessors are significantly less expensive than the fastest ones, and the cost increment is larger at the high end of the speed range than at the low end. As a result, it is often cheaper to use several smaller microprocessors to implement a function.

When several microprocessors work together in a system, they may communicate with each other in several different ways. If slow data rates are sufficient, serial data links are commonly used for their low hardware cost. The I^2C bus is a well-known example of a serial bus used to build multi-microprocessor embedded systems; the CAN bus is widely used in automobiles. High-speed serial links can achieve moderately high performance and are often used to link multiple DSPs in high-speed signal processing systems. Parallel data links provide the highest performance thanks to their sheer data width. High-speed busses such as PCI can be used to link several processors.

The software for an embedded multiprocessing system is often built around processes. A process, as in a general-purpose computing system, is an instantiation of a program with its own state. Since problems complex enough to require multiprocessors often run sophisticated algorithms and I/O systems, dividing the system into processes helps manage design complexity. A real-time operating system (RTOS) is an operating system specifically designed for embedded, and specifically real-time applications. The RTOS manages the processes and device drivers in the system, determining when each executes on the CPU. This function is termed scheduling. The partitioning of the software between application code which executes core algorithms and an RTOS which schedules the times to which those core algorithms are executed is a fundamental design principle in computing systems in general and is especially important for real-time operation.

There are a number of techniques which can be used to schedule processes in an embedded system—that is, to determine which process runs next on a particular CPU. Most RTOSs use process priorities in some form to determine the schedule. A process may be in any one of three states: currently executing (there can obviously be only one executing process on each CPU), ready to execute, or waiting. A process may not be able to execute until, for example, its data has arrived. Once its data arrives, it moves from waiting to ready. The scheduler chooses among the ready processes to determine which process runs next. In general, the RTOS's scheduler chooses the highest-priority ready process to run next; variations between scheduling methods depend in large part on the ways in which priorities are determined. Unlike general-purpose operating systems, RTOSs generally allow a process to run until it is preempted by a higher-priority process. General-purpose operating systems often perform time-slicing operations to maintain fair access of all the users on the system, but time-slicing does not allow the control required for meeting deadlines.

A fundamental result in real-time scheduling is known as rate-monotonic scheduling. This technique schedules a set of processes which run independently on a single CPU. Each process has its own period, with the deadline happening at the end of each period. There can be arbitrary relationships between the periods of the processes. It is assumed that data does not in general arrive at the beginning of the period, so there are no assumptions about when a process goes from waiting to ready within a period. This scheduling policy uses static priorities—the priorities for the processes are assigned before execution begins and do not change. It can be shown that the optimal priority assignment is based on period—the shorter the period, the higher the priority. This priority assignment ensures that all processes will meet their deadlines on every period. It can also be shown that at most, 69% of the CPU is used by this scheduling policy. The remaining cycles are spent waiting for activities to happen—since data arrival times are not known, it is not possible to utilize 100% of the CPU cycles.

Another well-known, real-time scheduling technique is earliest deadline first (EDF). This is a dynamic priority scheme—process priorities change during execution. EDF sets priorities based on the impending deadlines, with the process whose deadline is closest in the future having the highest priority.

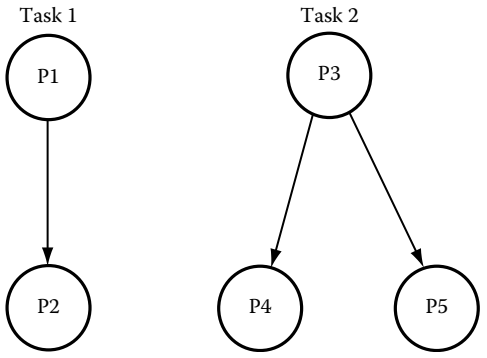

FIGURE 13.3 Task graph with two tasks and data dependencies between processes.

Clearly, the rate of change of process priorities depends on the periods and deadlines. EDF can be shown to be able to utilize 100% of the CPU, but it does not guarantee that all deadlines will be met. Since priorities are dynamic, it is not possible in general to analyze whether the system will be overloaded at some point.

Processes may be specified with data dependencies, as shown in Figure 13.3, to create a task graph. An arc in the data dependency graph specifies that one process feeds data to another. The sink process cannot become ready until all the source processes have delivered their data. Processes which have no data dependency path between them are in separate tasks. Each task can run at its own rate. Data dependencies allow schedulers to make more efficient use of CPU resources. Since the source and sink processes of a data dependency cannot execute simultaneously, we can use that information to eliminate some combinations of processes which may want to run at the same time. Narrowing the scope of process conflicts allows us to more accurately predict how the CPU will be used.

A real-time operating system is often designed to have a small memory footprint, since embedded systems are more cost-sensitive than general-purpose computers. RTOSs are also designed to be more responsive in two different ways. First, they allow greater control over the order of execution of processes, which is critical for ensuring that deadlines are met. Second, they are designed to have lower context-switching overhead, since that overhead eats into the time available for meeting deadlines. The kernel of an RTOS is the basic set of functions that is always resident in memory. A basic RTOS may have an extremely small kernel of only a few hundred instructions. Such microkernels often provide only basic context-switching and scheduling facilities. More complex RTOSs may provide high-end operating system functions such as file systems and network support; many high-end RTOSs are POSIX (a Unix standard) compliant. While running such a high-end operating system requires more hardware resources, the extra features are useful in a number of situations. For example, a controller for a machine on a manufacturing line may use a network interface to talk to other machines on the factory floor or the factory coordination unit; it may also use the file system to access a database for the manufacturing process.

13.4 Hardware/Software Codesign

Hardware/software codesign refers to any methodology which takes into account both hardware and software during the design of an embedded computing system. When the hardware and software are designed together, the designer has more opportunities to optimize the system by making trade-offs between the hardware and software components. Good system designers intuitively perform codesign, but codesign methods are increasingly being embodied in computer-aided design (CAD) tools. We will discuss several aspects of codesign and codesign tools, including models of the design, cosimulation, performance analysis, and various methods for architectural cosynthesis. We will conclude with a look at design methodologies that make use of these phases of codesign.

13.4.1 Models

In designing embedded computing systems, we make use of several different types of models at different points in the design process. We need to model basic functionality. We must also capture nonfunctional requirements: speed, weight, power consumption, manufacturing cost, etc.

In the earliest stages of design, the task graph is an important modeling tool. The task graph does not capture all aspects of functionality, but it does describe the various rates at which computations must be performed and the expected degrees of parallelism available. This level of detail is often enough to make some important architectural decisions. A useful adjunct to the task graph are the technology description tables, which describe how processes can be implemented on the available components. One of the technology description tables describes basic properties of the processing elements, such as cost and basic power dissipation. A separate table describes how the processes may be implemented on the components, giving execution time (and perhaps other function-specific parameters like precise power consumption) on a processing element of that type. The technology description is more complex when ASICs can be used as processing elements, since many different ASICs at differing price/performance points can be designed for a given functionality, but the basic data still applies.

A more detailed description is given by either high-level language code (C, etc.) for software or hardware description language code (VHDL, Verilog, etc.) for software components. These should not be viewed as specifications—they are, in fact, quite detailed implementations. However, they do provide a level of abstraction above assembly language and gates and so can be valuable for analyzing performance, size, etc. The control-data flow graph (CDFG) is a typical representation of a high-level language: a flowchart-like structure describes the program's control, while data flow graphs describe the behavior within expressions and basic blocks.

13.4.2 Cosimulation

Simulation is an important tool for design verification. The simulation of a complete embedded system entails modeling both the underlying hardware platform and the software executing on the CPUs. Some of the hardware must be simulated at a very fine level of detail—for example, busses and I/O devices may require gate-level simulation. On the other hand, the software can and should be executed at a higher level of abstraction. While it would be possible to simulate software execution by running a gate-level simulation of the CPU and modeling the program as residing in the memory of the simulated CPU, this would be unacceptably slow.

We can gain significant performance advantages by running different parts of the simulation at different levels of detail: elements of the hardware can be simulated in great detail, while software execution can be modeled much more directly. Basic functionality aspects of a high-level language program can be simulated by compiling the software on the computer on which the simulation executes, allowing those parts of the program to run at the native computer speed. Aspects of the program which deal with the hardware platform must interface to the section of the simulator which deals with the hardware. Those sections of the program are replaced by stubs which interface to the simulator. This style of simulation is a multirate simulation system, since the hardware and software simulation sections run at different rates: a single instruction in the software simulation will correspond to several clock cycles in the hardware simulation. The main jobs of the simulator are to keep the various sections of the simulation synchronized and to manage communication between the hardware and software components of the simulation.

13.4.3 Performance Analysis

Since performance is an important design goal in most embedded systems, both for overall throughput and for meeting deadlines, the analysis of the system to determine its speed of operation is an important element of any codesign methodology. System performance—the time it takes to execute a particular aspect of the system's functionality—clearly depends both on the software being executed and the underlying hardware platform. While simulation is an important tool for performance analysis, it is not sufficient, since simulation does not determine the worst-case delays. Since the execution times of most programs are data-dependent, it is necessary to give the simulation of the program the proper set

of inputs to observe worst-case delay. The number of possible input combinations makes it unlikely that one will find those worst-case inputs without the sort of analysis that is at the heart of performance analysis.

In general, performance analysis must be done at several different levels of abstraction. Given a single program, one can place an upper bound on the worst-case execution time of the program. However, since many embedded systems consist of multiple processes and device drivers, it is necessary to analyze how these programs interact with each other, a phase which makes use of the results of single-program performance analysis.

Determining the worst-case execution time of a single program can be broken into two subproblems: determining the longest execution path through the program and determining the execution time of that program. Since there is at least a rough correlation between the number of operations and the actual execution time, we can determine the longest execution path without detailed knowledge of the instructions being executed—the longest path depends primarily on the structure of conditionals and loops. One way to find the longest path through the program is to model the program as a control-flow graph and use network flow algorithms to solve the resulting system.

Once the longest path has been found, we need to look at the instructions executed along that path to determine the actual execution time. A simple model of the processor would assume that each instruction has a fixed execution time, independent of other factors such as the data values being operated on, surrounding instructions, or the path of execution. In fact, such simple models do not give adequate results for modern high-speed microprocessors. One problem is that in pipelined processors, the execution time of an instruction may depend on the sequence of instructions executed before it. An even greater cause of performance variations is caching, since the same instruction sequence can have variable execution times, depending on whether the code is in the cache. Since cache miss penalties are often 5X or 10X, the cost of mischaracterizing cache performance is significant. Assuming that the cache is never present gives a conservative estimate of worst-case execution time, but one that is so over-conservative that it distorts the entire design. Since the performance penalty for ignoring the cache is so large, it results in using a much faster, more expensive processor than is really necessary. The effects of caching can be taken into account during the path analysis of the program—path analysis can determine bound how often an instruction present in the cache.

There are two major effects which must be taken into account when analyzing multiple-process systems. The first is the effect of scheduling multiple processes and device drivers on a single CPU. This analysis is performed by a scheduling algorithm, which determines bounds on when programs can execute. Ratemonotonic analysis is the simplest form of scheduling analysis—the utilization factor given by ratemonotonic analysis tells one an upper limit on the amount of active CPU time. However, if data dependencies between processes are known, or some knowledge of the arrival times of data is known, then a more accurate performance estimate can be computed. If the system includes multiple processing elements, more sophisticated scheduling algorithms must be used, since the data arrival time for a process on one processing element may be determined by the time at which that datum is computed on another processing element.

The second effect which must be taken into account is interactions between processes in the cache. When several programs on a CPU share a cache, or when several processing elements share a second-level cache, the cache state depends on the behavior of all the programs. For example, when one process is suspended by the operating system and another process starts running, that process may knock the first program out of the cache. When the first process resumes execution, it will initially run more slowly, an effect which cannot be taken into account by analyzing the programs independently. This analysis clearly depends in part on the system schedule, since the interactions between processes depends on the order in which the processes execute. But the system scheduling analysis must also keep track of the cache state—which parts of which programs are in the cache at the start of execution of each process. Good accuracy can be obtained with a simple model which assumes that a program is either in the cache or out of it,

without considering individual instructions; higher accuracy comes from breaking a process into several subprocesses for analysis, each of which can have its own cache state.

13.4.4 Hardware/Software Cosynthesis

Hardware/software cosynthesis tries to simultaneously design the hardware and software for an embedded computing system, given design requirements such as performance as well as a description of the functionality. Cosynthesis generally concentrates on architectural design rather than detailed component design—it concentrates on determining such major factors as the number and types of processing elements required and the ways in which software processes interact.

The most basic style of cosynthesis is known as hardware/software partitioning. As shown in Figure 13.4, this algorithm maps the given functionality onto a template architecture consisting of a CPU and one or more ASICs communicating via the microprocessor bus. The functionality is usually specified as a single program. The partitioning algorithm breaks that program into pieces and allocates pieces either to the CPU or ASICs for execution. Hardware/software partitioning assumes that total system performance is dominated by a relatively small part of the application, so that implementing a small fraction of the application in the ASIC leads to large performance gains. Less performance-critical sections of the application are relegated to the CPU.

The first problem to be solved is how to break the application program into pieces; common techniques include determining where I/O operations occur and concentrating on the basic blocks of inner loops. Once the application code is partitioned, various allocations of those components must be evaluated. Given an allocation of program components to the CPU or ASICs, performance analysis techniques can be used to determine the total system performance; performance analysis should take into account the time required to transfer necessary data into the ASIC and to extract the results of the computation from the ASIC. Since the total number of allocations is large, heuristics must be used to search the design space. In addition, the cost of the implementation must be determined. Since the CPU's cost is known in advance, that cost is determined by the ASIC cost, which varies as to the amount of hardware required to implement the desired function. High-level synthesis can be used to estimate both the performance and hardware cost of an ASIC which will be synthesized from a portion of the application program.

Basic, cosynthesis heuristics start from extreme initial solutions: We can either put all program components into the CPU, creating an implementation which is minimal cost but probably does not meet performance requirements, or put all program elements in the ASIC, which gives a maximal-performance, maximal-expense implementation. Given this initial solution, heuristics select which program component to move to the other side of the partition to either reduce hardware cost or increase performance, as desired. More sophisticated heuristics try to construct a solution by estimating how critical a component will be to overall system performance and choosing a CPU or ASIC implementation accordingly. Iterative improvement strategies may move components across the partition boundary to improve the design.

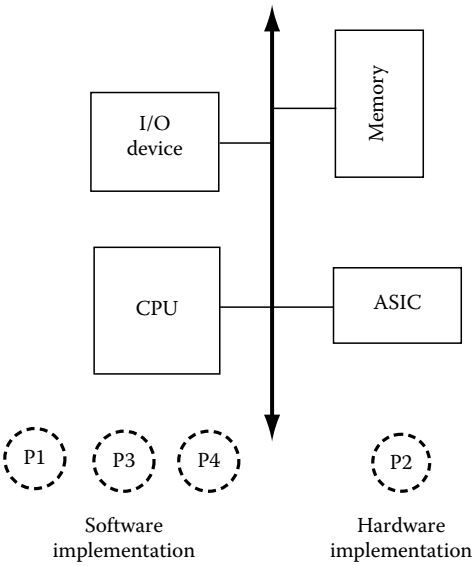

FIGURE 13.4 Hardware/software partitioning.

However, many embedded systems do not strictly follow the one CPU, one bus, *n* ASIC architectural template. These more general architectures are known as distributed embedded systems. Techniques for designing distributed embedded systems rest on the foundations of hardware/software partitioning, but they are generally more complicated, since there are more free variables. For example, since the number and types of CPUs is not known in advance, the cosynthesis algorithm must select them. If the number of busses or other communication links is not known in advance, those must be selected as well. Unfortunately, these decisions are all closely related. For example, the number of CPUs and ASICs required depends on the system schedule. The system schedule, in turn, depends on the execution time of each of the components on the available hardware elements. But those execution times depend on the processing elements available, which is what we are trying to determine in the first place. Cosynthesis algorithms generally try to fix several designs and vary only one or a few, then check the results of a design decision on the other parameters. For example, the algorithm may fix the hardware architecture and try to move processes to other processing elements to make more efficient use of the available hardware. Given that new configuration of processes, it may then try to reduce the cost of the hardware by eliminating unused processing elements or replacing a faster, more expensive processing element with a slower, cheaper one.

Since the memory hierarchy is a significant contributor to overall system performance, the design of the caching system is an important aspect of distributed system cosynthesis. In a board-level system with existing microprocessors, the sizes of second-level caches is under designer control, even if the first-level cache is incorporated on the microprocessor and therefore fixed in size. In a single-chip embedded system, the designer has control over the sizes of all the caches. Cosynthesis can determine hardware elements such as the placement of caches in the hardware architecture and the size of each cache. It can also determine software attributes such as the placement of each program in the cache. The placement of a program in the cache is determined by the addresses used by the program—by relocating the program, the cache behavior of the program can be changed. Memory system design requires calculating the cache state when constructing the system schedule and using the cache state as one of the factors to determine how to modify the design.

13.4.5 Design Methodologies

A codesign methodology tries to take into account aspects of hardware and software during all phases of design. At some point in the design process, the hardware and software components are well-specified and can be designed relatively independently. But it is important to consider the characteristics of both the hardware and software components early in design. It is also important to properly test the system once the hardware and software components are assembled into a complete system.

Cosynthesis can be used as a design planning tool, even if it is not used to generate a complete system architectural design. Because cosynthesis can evaluate a large number of designs very quickly, it can determine the feasibility of a proposed system much faster than a human designer. This allows the designer to experiment with what-if scenarios, such as adding new features or speculating on the effects of lower component costs in the future. Many cosynthesis algorithms can be applied without having a complete program to use as a specification. If the system can be specified to the level of processes with some estimate of the computation time required for each process, then useful information about architectural feasibility can be generated by cosynthesis.

Cosimulation plays a major role once subsystem designs are available. It does not have to wait until all components are complete, since stubs may be created to provide minimal functionality for incomplete components. The ability to simulate the software before completing the hardware is a major boon to software development and can substantially reduce development time.

14.1 Introduction

No invention in the modern age has been as pervasive as the semiconductor and nothing has been more important to its technological advancement than has electronic design automation (EDA). EDA began in the 1960s both for the design of electronic computers and because of them. It was the advent of the computer that made possible the development of specialized programs that perform the complex management, design, and analysis operations associated with electronics and electronic systems. At the same time, it was the design, management, and manufacture of the thousands (now tens of millions) of devices that make up a single electronic assembly that made EDA an absolute requirement to fuel the semiconductor progression. Today, EDA programs are used in electronic packages for all business markets from computers to games, telephones to aerospace guidance systems, and toasters to automobiles. Across these markets, EDA supports many different package types such as integrated circuit (IC) chips, multichip modules (MCMs), printed circuit boards (PCBs), and entire electronic system assemblies.

No electronic circuit package is as challenging to EDA as the IC. The growth in complexity of ICs has placed tremendous demands on EDA. Mainstream EDA applications such as simulation, layout, and test generation have had to improve their speed and capacity characteristics with this ever-increasing growth in the number of circuits to be processed. New types of design and analysis applications, new methodologies, and new design rules have been necessary to keep pace. Yet, even with the technological breakthroughs that have been made in EDA across the past four decades, it is still having difficulty keeping up with the breakthroughs being made in the semiconductor technology progression that it fuels. Decrease in size and spacing of features on the chip is causing the number of design elements per chip to increase at a tremendous rate. The decrease in feature size and spacing coupled with the increase in operating frequency is causing additional levels of complexity to be approximated in the models used by design and analysis programs.

In the period from 1970 to the present semiconductor advances such as the following have had a great impact on EDA technology (Figure 14.1):

- IC integration has grown from tens of transistors on a chip, to beyond tens of millions.
- Feature size on production ICs has shrunk from 10 μm to 90 nm and smaller.
- On-chip clock frequency has increased from a few megahertz to many gigahertz.

Playing an essential part in the advancement of EDA have been advances in computer architectures that run the EDA applications. These advances have included the following:

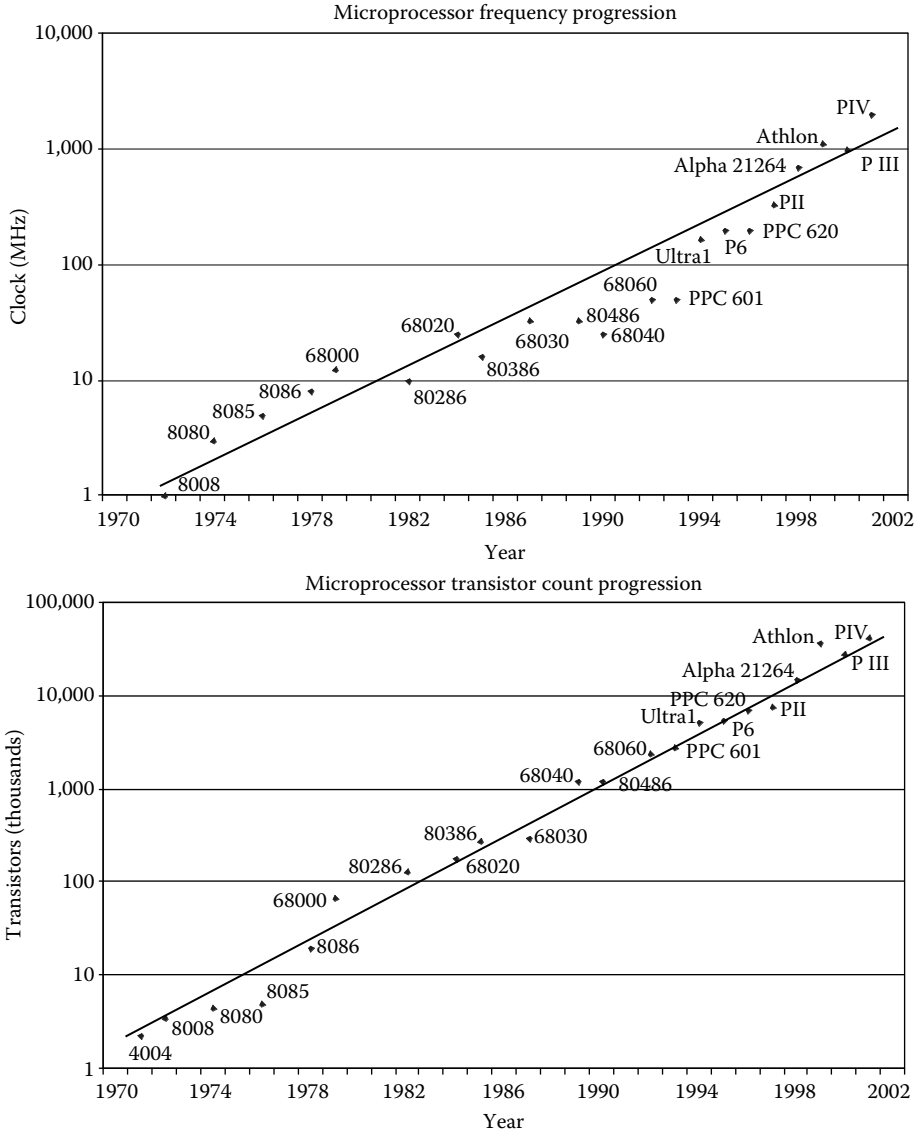

FIGURE 14.1 Microprocessor development.

- Computer CPU speed: from less than a million instructions per second (MIPS) of shared mainframe to hundreds of MIPS on a dedicated workstation
- Computer memory: from <32 KB to >500 GB
- Data archive: from voluminous reels of (rather) slow-speed tape to virtually limitless amounts of high-speed electronic storage

However, these major improvements in computing power alone would not have been sufficient to meet the EDA needs of semiconductor advancement. Major advances have also been made to fundamental EDA algorithms, and entirely new design techniques and design paradigms have been invented and developed to support semiconductor advancement. This chapter will trace the more notable advancements made in EDA across its history for electronics design and discuss important semiconductor technology trends predicted across the next decade along and the impact they will have on EDA for the future. It is important to understand these trends and projections, because if the EDA systems cannot keep pace with the semiconductor projections, then these projections cannot be realized. Although it may be possible to build foundries that can manufacture ultradeep submicron wafers and even to acquire the billions of dollars of capital required for each, without the necessary EDA support these factories will never be fully utilized. SEMATECH reports that chip design productivity has increased at a compounded rate somewhere between 21% and 30%, while Moore's Law predicts the number of transistors on a chip to increase at a compound rate of 56%. This means that at some time, bringing online new foundries that can produce smaller, denser chips may reach a point of diminishing returns, because the ability to design and yield chips with that many transistors may not be possible.

14.2 Design Automation: Historical Perspective

14.2.1 The 1960s: The Beginnings of Design Automation

Early entries into design automation were made in the areas of design (description) records, PCB wiring, and manufacturing test generation. A commercial EDA industry did not exist and developments were made within companies with the need, such as IBM [1] and Bell Labs, on mainframe computers such as the IBM 7090. The 7090 had addressable 36-bit words and a limit of 32,000 words of main storage (magnetic cores). This was far less than the typical 256+ MB of RAM on the average notebook PC, and certainly no match for a high-function workstation with gigabytes of main store. Though computer limitations continue to be an on-going challenge for EDA development, the limitation of the computers of the 1960s was particularly acute.

In retrospect, the limitation of computers in the 1960s was a blessing for the development of design automation. Because of these limitations, design automation developers were forced to invent highly creative algorithms that operated on very compact data structures. Many of the fundamental concepts developed during this period are still in use within commercial EDA systems today. Some notable advances during this period were

- Fundamental "stuck-at" model for manufacturing test and a formal algebra for the generation of tests and diagnosis of faults
- Parallel fault simulation, which provided simulation of many fault conditions in parallel with the good-machine (nonfaulty circuit) to reduce fault-simulation run times
- Three-valued algebra for simulation which yields accurate results using simple delay models, even in the presence of race conditions within the design.
- Development of fundamental algorithms for the placement and wiring of components
- Checking of designs against prescribed electrical design requirements (rules)

Also, there was development of fundamental heuristics for placement and wire routing, and for divide-and-conquer concepts supporting both. One such concept was the hierarchical division of a wiring image

into cells, globally routing between cells, and then performing detailed routing within cells, possibly subdividing them further. Many of these fundamental concepts are still applied today, although the complexities of physical design (PD) of today's large-scale integration (LSI) are vastly more complex.

The 1960s represented the awakening of design automation and provided the proof of its value and need for electronics design. It would not be until the end of this decade when the explosion of the number of circuits designed on a chip would occur and the term LSI would be coined. EDA development in the 1960s was primarily focused on printed circuit assemblies, but the fundamental concepts developed for design entry, test generation, and PD provided the basics for EDA in the LSI era.

14.2.1.1 Design Entry

Before the use of computers in electronics design, the design schematic was a hard-copy drawing. This drawing was a draftsman's rendering of the notes and sketches provided by the circuit designer. The drawings provided the basis for manufacturing and repair operations in the field. As automation developed, it became desirable to store these drawings on storage media usable by computers so that the creation of input to the automated processes could, itself, be automated. So, the need to record the design of electronic products and assemblies in computers was recognized in the late 1950s and early 1960s. In the early days of design automation, the electronics designer would develop the design using paper and pencil and then transcribe it to a form suitable for keyed entry to a computer. Once keyed into the computer, the design could be rendered in a number of different formats to support the manufacturing and field operations. It was soon recognized that these computerized representations of the circuit design drawing could also drive design processes such as the routing of printed circuit traces or the generation of manufacturing test patterns. Finally, from there, it was but a short step to the use of computers to generate data in the form required to drive automated manufacturing and test equipment.

Early design entry methods involved the keying of the design description onto punch cards that were read into the computer and saved on a persistent storage device. This became known as the design's database, and is the start of the design automation system. From the database, schematic diagrams and logic diagrams were rendered for use in engineering, manufacturing, and field support. This was typically a two-step process, whereby the designer drew the schematic by hand and then submitted it to another for conversion to the transcription records, keypunch, and entry to the computer. Once in the computer, the formal automated drawings were generated, printed, and returned to the designer. Although this process seems archaic by today's standards, it did result in a permanent record of the design in computer readable format. This could be used for many forms of records management, engineering change history, and as input to design, analysis, and manufacturing automation that would soon follow.

With the introduction of the alphanumeric terminal, the keypunch was replaced as the window into the computer. With this, new design description languages were developed, and the role of the transcription operator began to move back to the designer. Although these description languages still represented the design at the device or gate level, they were free format and keyword oriented and design engineers were willing to use them. The design engineer now had the tools to enter design descriptions directly into the computer thus eliminating the inherent inefficiencies of the ''middleman.'' Thus, a paradigm shift began to evolve in the method by which design was entered to the EDA system. Introduction of the direct access storage devices (disks) in the late 1960s also improved the entry process as well as the entire design system by providing online, high-speed direct access to the entire design or any portion of it. This was also important to the acceptance of design entry by the designer as the task was still viewed as a necessary overhead rather than a natural part of the design task. It was necessary to get access to the other evolving design automation tools, but typically, the real design thought process took place with pencil and paper techniques. Therefore, any change that made the entry process faster and easier was eagerly accepted.

The next shift occurred in the later part of the 1970s with the introduction of graphics terminals. With these, the designer could enter design into the database in schematic form. This form of design entry was a novelty at first, but not a clear performance improvement. In fact, until the introduction of the

workstation with dedicated graphics support, graphic entry was detrimental to design productivity in many cases. Negative effects such as less than effective transaction speed, time lost in making the schematic esthetically pleasing and the low level of detail all added to less than obvious advances. In contrast, use of the graphics display to view the design and make design changes proved extremely effective and was a great improvement over the red-lined hard-copy prints. For this reason, use of computer graphics represented a major advance and this style of design entry took off with the introduction of the workstation in the 1980s. In fact, the graphic editor's glitz and capability was often a major selling point in the decision to use one EDA system over another. Further, to be considered a commercially viable system, graphics entry was required. Nevertheless, as the density of ICs grew, graphics entry of schematics would begin to yield to the productivity advantages of (alphanumeric) description languages. As EDA design and analysis tool technology advanced, entry of design at the register-transfer level (RTL) would become commonplace and today the design engineer is able to represent his design ideas at many levels of abstraction and throughout the design process. System-level and RTL design languages have been introduced and the designer is able to verify design intent much earlier in the design cycle.

By the 1990s and after the introduction of synthesis automation, design entry using RTL descriptions was the generally accepted approach for entry of design, although schematic entry remained the accepted method for PCB design and many elements of custom ICs. There is no doubt that the introduction of graphics into the design automation system represents a major advance and a major paradigm shift. The use of graphics to visualize design details, wiring congestion, and timing diagrams is of major importance. The use of graphics to perform edit functions is standard operating procedure.

Large system design, often, entails control circuitry, dataflow, and functional modules. Classically, these systems span across several chips and boards and employ several styles of entry for the different physical packages. These may include

- Schematics—graphic
- RTL and behavioral level languages—alphanumeric
- Timing diagrams—graphic
- State diagrams—alphanumeric
- Flowcharts—graphic

Today, these entry techniques can be found in different EDA tools and each is particularly effective for different types of design problems. Schematics are effective for the design of ''glue'' logic that interconnects functional design elements such as modules on a PCB and for custom IC circuitry. Behavioral languages are useful for system-level design, and particularly effective for dataflow behavior. Timing diagrams lend themselves well to describe the functional operations of ''black-box'' components at their I/Os without needing to describe their internal circuitry. State diagrams are a convenient way to express the logical operation of combinational circuits. Flowcharts are effective for describing the operations of control logic, much like use of flowcharts for specification of software program flow. With technology advances, the IC is engulfing more and more of the entire system and all of these forms of design description may be prevalent on a single chip. It is even expected that the design of ''black-box'' functions will be available from multiple sources to be embedded onto the chip similar to the use of modules on a PCB. Thus, it is likely that future EDA systems will support a mixture of design description forms to allow the designer to represent sections of the design in a manner most effective to each. After all, design is described in many forms by the designer outside the design system.

14.2.1.2 Test Generation

Testing of manufactured electronic subassemblies entails the use of special test hardware that can provide stimulus (test signals) to selected (input) pins of the part under test and measure for specified responses on selected (output) pins. If the measured response matches the specified response, then the part under test has passed that test successfully. If some other response is measured, then the part has failed that test

and the presence of a defect is indicated. Manufacturing test is the successive application test patterns that cause some measurable point on the part under test to be sensitized to the presence of a manufacturing defect. That is, some measurable point on the part under test will result in a certain value if the fault is present and a different one if no fault were present. The collection of test patterns causes all (or almost all) possible manufacturing failures to render a different output response than would the nondefective part. For static DC testers, each stimulus is applied and after the part under test settles to a steady state, the specified outputs are measured and compared with the expected results for a nondefective part.

To bound the test generation problem, a model was developed to represent possible defects at the abstract gate level. This model characterizes the effects of defects as stuck-at values. This model is fundamental to most of the development in test generation and is still in use today. It characterizes defects as causing either a stuck-at-one or a stuck-at-zero condition at pins on a logic gate. It assumes hard faults (i.e., if present, a fault remains throughout the test) and that only one fault occurs at a time. Thus, this model became known as the single stuck-at fault model. Stuck-at fault testing assumes that the symptom of any manufacturing defect can be characterized by the presence of a stuck-at fault some place within the circuit and that it can be observed at some point on the unit under test. By testing for the presence of all possible stuck-at faults that can occur, all possible manufacturing hard-defects in the logic devices can thus be tested.

The stuck-at fault models for NAND and NOR gates are shown in Figure 14.2. For the NAND gate, the presence of an input stuck-at-one defect can be sensitized (made detectable) at the gate's output pin by setting the good-machine state for that input to 0, and setting the other input values to 1. If a zero is observed at the gate's output node, then a fault (stuck-at-one) on the input pin set to 0 is detected. A stuck-at-zero condition on any specific input to the NAND gate is not distinguishable from a stuck-at-zero on any other input to the gate, thus is not part of the model. However, a stuck-at-one is modeled for the gate's output to account for such a fault or a stuck-at-one fault on the gate's output circuitry. Similarly, a stuck-at-zero is modeled on the gate's output.

The fault model for the NOR gate is similar except that here input faults are modeled as stuck-at-zero, as the stuck-at-one defect cannot be isolated to a particular input.

Later in time, additional development would attack defects not detectable with this stuck-at fault model; for example, bridging faults where nodes are shorted together, and delay faults where the output response does not occur within the required time. The stuck-at fault model cannot detect these fault types and they became important as the development of CMOS progressed. Significant work was performed in both these areas beginning in the 1970s, but it did not have the impact on test generation development that the stuck-at fault model did.

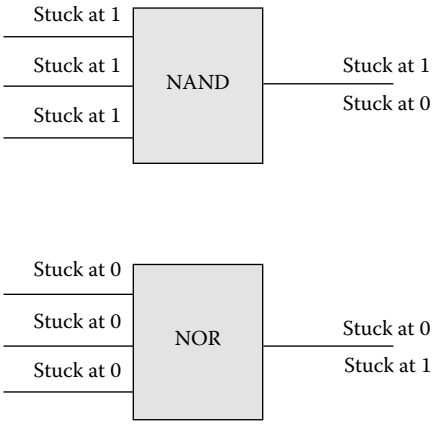

FIGURE 14.2 Stuck-at fault models.

The creation of the fault model was very important to test generation as it established a realistic set of objectives to be met by automated test set generation that could be achieved in a realistic amount of computational time. A formal algebra was developed by Roth [2] called the D-ALG that formalized an approach to test generation and fault diagnosis.

The test generation program could choose a fault based on the instances of gates within the design and the fault models for the gates. It could then trace back from that fault to the input pins of the design and, using the D-ALG calculus, it could find a set of input states that would sensitize the fault. Then, it could trace forward from that fault to the design's output pins, sensitizing the path (causing the good-machine value to be the opposite of the stuck-at fault value along that path) to at least one observable pin (Figure 14.3).

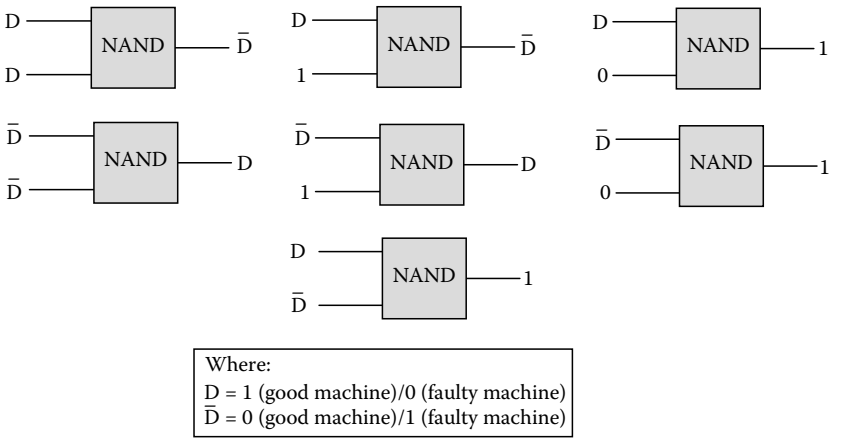

FIGURE 14.3 D-ALG calculus.

The use of functional patterns as the test patterns in lieu of heuristic stuck-at test generation was another approach for manufacturing test. However, this required an extreme number of tests to be applied and provided no measurable objective to be met (i.e., 100% of all possible stuck-at faults) thus, depended on the experience and skill of the designer to create quality tests. The use of fault models and automatic test generation produced a minimum set of tests and greatly reduced intensive manual labor.

The exhaustive method to assure coverage of all the possible detectable defects would be to apply all possible input states to the design under test and compare the measured output states with the simulated good-machine states. For a design with n input pins, however, this may theoretically require the simulation of 2^n input patterns for combinatorial logic and at least 2^{n+m} for sequential logic (where m is the number of independent storage elements). For even a relatively small number of input pins, this amount of simulation would not be possible even on today's computers, and the time to apply this number of patterns at the tester would be grossly prohibitive.

The amount of time that a part resides on the tester is critical in the semiconductor business, as it impacts a number of parts that can be produced in a given amount of time and the capital cost for testers. Thus, the number of test patterns that need to be applied at the tester should be kept to a minimum. Early work in test generation attacked this problem in two ways. First, when a test pattern was generated for a specific fault, it was simulated against all possible faults one at a time. In many cases, the application of a test pattern that is targeted for one specific fault will also detect several other faults at the same time. The presence of a specific fault may be detectable on one output pin, for example, but at the same time additional faults may be observable at the other output pins. The use of fault simulation (discussed in Section 14.2.1.3) detected these cases and provided a mechanism to mark as tested those faults that were "accidentally" covered. This meant that the test generation algorithm did not have to generate a specific test for those faults. Second, schemes were developed to merge test patterns together into a smaller test pattern set to minimize the number of patterns required for detection of all faults. This is possible when two adjacent test patterns require the application of specific values on different input pins, each allowing all the other input pins to be at a do not-care state. In these cases, the multiple test patterns can be merged into one. With successive analysis in this way, all pairs of test patterns (pattern n with $n+1$, or the merger of m and $m+1$ with pattern $m+2$) are analyzed and merged into a reduced set of patterns.

Sequential design elements severely complicate test generation, as they require the analysis of previous states and the application of sequences of patterns. Early work in test generation broke feedback nets, inserted a lumped delay on them, and analyzed the design as a combinatorial problem using a Huffman model. Later work attempted to identify the sequential elements within the design using sophisticated topological analysis and then used a Huffman model to analyze each unique element. State tables for each

unique sequential element were generated and saved for later use as lookup tables in the test generation process. The use of three-value simulation within the analysis reduced the analysis time as well as guaranteed that the results were always accurate. Huffman analysis required 2^x simulations (where x is the number of feedback nets) to determine if critical hazards existed in the sequential elements. Using three-valued simulation [3] (all value transitions go through an X state), this was reduced to a maximum of 2^x simulations.

This lumped delay model did not account for the distribution of delays in the actual design, thus it often caused pessimistic results. Often simulated results yielded do not-know (X-state) conditions when a more accurate model could yield a known state. This made it difficult to generate patterns that would detect all faults in the model. As the level of integration increased, the problems associated with automatic test generation for arbitrary sequential circuits became unwieldy. This necessitated that the designer be called back into the problem of test generation most often to develop tests that would detect those that were missed by the test generation program. New approaches that ranged from random pattern generation to advanced algorithms and heuristics, which use a combination of different approaches, were developed. However, by the mid-1970s the need to design-for-test was becoming evident to many companies.

During the mid-1970s the concept of scan design such as IBM's Level Sensitive Scan Design (LSSD), was developed [4]. Scan design provides the ability to externally control and observe internal state variables of the design. This is accomplished by the use of special scan latches into the design at the points to be controlled and observed. These latches are controllable and can accept one of the two different data inputs depending on an external control setting. One of these data inputs is the node within the IC to be controlled/observed and the other is used as the test input. These latches are connected into a shift register chain that has its stage-0 test input and stage-n output connected to externally accessible pins on the IC. Under normal conditions, signals from within the design are passed through individual latches via the data input/output. Under test conditions, test vectors can be scanned, under clock control, onto the scan register's externally accessible input pin and into the scan latches via their test data input. Once scanned into the register, the test vector is applied to the internal nodes. Similarly, internal state values within the design are captured in individual scan latches and scanned through the register out to its observable output pin.

The development of scan design was important for two reasons. First, LSSD allowed for external control and observability of all sequential elements within the design. With specific design-for-test rules, this reduced the problem of test generation to one of a set of combinatorial circuits. Rigid design rules such as the following assure this, and checking programs and scan chain generation algorithms were implemented to assure that they were adhered to before entering test generation:

- All internal storage elements implemented in hazard-free polarity-hold latches
- Absence of any global feedback loops
- Latches may not be controlled by the same clock that controls the latches feeding them
- Externally accessible clocks control all shift register latches

Second, scan design allowed for external control and observability at otherwise nonprobable points between modules on an MCM or PCB. During the 1980s an industry standard was developed, called Boundary Scan (IEEE 1149.1 Joint Test Action Group) [5], which uses scan design techniques to provide control and observability for all chip or module I/Os from pins of their next level package (MCM or PCD, respectively).

Scan design requires additional real estate in the IC design and has a level of performance overhead. However, with the achievable transistor density levels on today's ICs and the test and diagnosis benefits accrued, these penalties are easily justified in all but the most performance critical designs (Figure 14.4).

During the 1980s, IC density allowed for the design of built-in self-test (BIST) circuitry on the chip itself. Operating at hardware speed, it became feasible to generate complete exhaustive tests and large numbers of random tests never possible with software and stored program testers. BISTs are generated

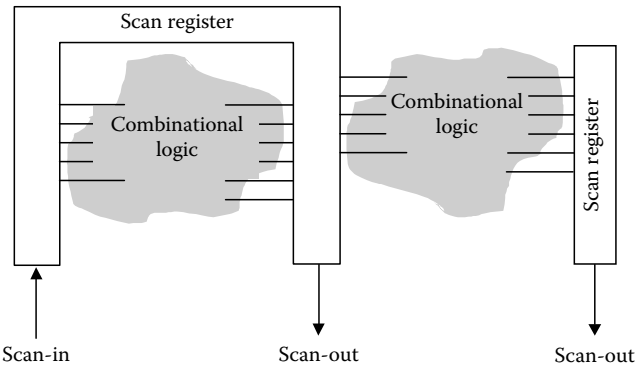

FIGURE 14.4 Scan design.

on the tester by the device under test, reducing the management of data transfer from design to manufacturing. A binary counter is used or linear feedback shift registers (LFSR) are used to generate the patterns for exhaustive or random tests, respectively. In the latter case, a pseudorandom bit sequence is formed by the exclusive-OR of the bits on the LFSR and this result is then fed back into the LFSR input. Thus, a pseudorandom bit sequence whose sequence length is based on the number of LFSR stages and the initial LFSR state can be generated. The design can be simulated to determine the good-machine state conditions for the generated test patterns, and these simulated results are compared with the actual device-under-test results observed at the tester.

BIST techniques have become common for the test of on-chip RAM and ROS. BIST is also used for logic sections of chips either with fault-simulated weighted random test patterns or good machine-simulated exhaustive patterns. In the latter case, logic is partitioned into electrically isolated regions with a smaller number of inputs to reduce the number of test patterns. Partitioning of the design reduces the number of exhaustive tests from 2^n (where n is the total number of inputs) to

$$\sum_{i=1}^{m} 2^{n^i}$$

where

m is the number of partitions

n^i ($n^i < n$) is the number of inputs on each logic partition

Since the use of BIST implies an extremely large number of tests, the simulated data transfer and test measurement time is reduced greatly by the use of a compressed signature to represent the expected and actual test results. Thus, only a comparison of the simulated signatures for each BIST region needs to be made with the signatures derived by the on-chip hardware, rather than the results of each individual test pattern. This is accomplished by feeding the output bit sequence to a single input serial input LFSR after exclusive-OR with the pseudorandom pattern generated by that LFSR. In this way, a unique pattern can be observed for a sequence of test results, which is a function of the good-machine response and a pseudorandom number (Figure 14.5).

Today, testing of ICs typically consists of combinations of different test strategies. These may include stored program stuck-at fault tests, BIST, delay (or at-speed) test (testing for signal arrival times in addition to state), and I_{DDQ} tests (direct drain quiescent current testing checks for CMOS defects that cause excessive current leakage). The latter two test techniques are used to detect defect conditions not identified by stuck-at fault tests such as shorts (bridging faults) between signal nets or gate oxide defects

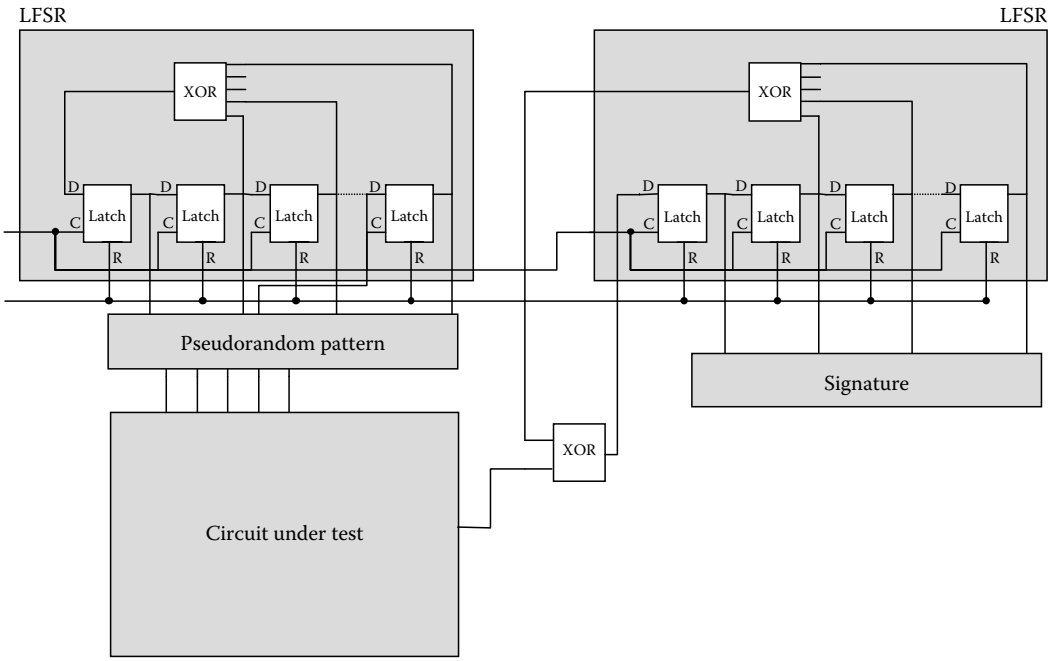

FIGURE 14.5 BIST logic.

that cause incorrect device operation and parametric variability resulting from process variations in the wafer foundry. However, the stuck-at fault model and scan techniques have been and will continue to be fundamental ingredients for the manufacturing test recipe.

14.2.1.3 Fault Simulation

Fault simulation is used to predict the state of a design at observable points when in the presence of a defect. This is used for manufacturing test and for field diagnostic pattern generation. Early work in fault simulation relied on the stuck-at fault model and performed successive simulations of the design with each single fault independent of any other fault; thus, a single stuck-at fault model was assumed. Because even these early designs consisted of thousands of faults, it was too time consuming to simulate each fault serially and it was necessary to create high-speed fault simulation algorithms.

For manufacturing test, fault simulation took advantage of three-valued zero-delay simulation. The simulation model of the design was levelized and compiled into an executable program. Levelization assured that driver gates were simulated before the gates receiving the signals; thus, allowing a state resolution in a single simulation pass. Feedback loops were cut and the *X*-transition of three-valued simulation resolved race conditions. The inherent instruction set of the host computer (e.g., AND, OR, and XOR.) allowed the use of a minimum set of instructions to simulate a gate's function.

The parallel-fault simulation algorithm that allowed many faults to be simulated in parallel was developed during the 1960s. Using the 32-bit word length of the IBM 7090 computer architecture, for example, simulation of 31 faults in a single pass (using the last bit for the good-machine) was possible. For each gate in the design, two host machine words were assigned to represent its good-machine state and the state for 31 single stuck-at faults. The first bit position of the first word was set to 1 or 0 representing the good-machine state for the node, and each of the successive bit position was set to the 1/0 state that would occur if the simulated faults were present (each bit-position representing a single fault). The corresponding bit position in the second word was set to 0 if it was a known state

and one if it was an *X*-state. The entire fault list was divided into *n* partitions of 31 faults and each partition was then simulated against all input patterns. In this way, the run time for simulation is a function of

$$\sum_{i=1}^{n=F/31} Patterns$$

where *F* is the total number of single stuck-at faults in the design.

Specific faults are injected within the word representing their location within the design by the insertion of a mask that is AND'd or OR'd at the appropriate word. For stuck-at-one conditions the mask contains a 1-bit in the position representing the fault (and 0-bit at the others) and it is OR'd to the gate's memory location. For stuck-at-zero faults the mask contains a 0-bit at the positions representing the fault (and 1-bit at the others) and it is AND'd with the gate's memory location.

As the level of integration increased, so did the number of faults. The simulation speed improvement realized from parallel-fault simulation was limited to the number of faults simulated in parallel and because of the algorithm overhead, it did not scale with the increase in faults.

Deductive-fault simulation was developed early in the 1970s and required only one simulation pass per test pattern. This is accomplished by simulating only the good-machine behavior and using deductive techniques to determine each fault that is detectable along the simulated paths. Note here that fault detection became the principal goal and fault isolation (for repair purposes) was ignored, as by now the challenge was to isolate from a wafer bad chips that were not repairable. Because lists of faults detectable at every point along the simulated path need to be kept, this algorithm requires extensive memory, far more than the parallel-fault simulation one. However, with increasing memory on host computers and the inherent increase in fault simulation speed, this technique won the favor of many fault simulators.

Concurrent-fault simulation refined the deductive algorithm by recognizing the fact that paths in the design quickly become insensitive to the presence of most faults, particularly after some initial set of test patterns is simulated (an observation made in the 1970s was that a high percentage of faults is detected in a low percentage of the initial test patterns, even if these patterns are randomly generated). The concurrent-fault simulation algorithm simulates the good machine and concurrently simulates a number of faulty machines. Once it is determined that a particular faulty machine state is the same as the good-machine one, simulation for that fault ceases. Since on logic paths most faults will become insensitive rather close to the point where the fault is located, the amount of simulation for these faulty machines was kept small. This algorithm required even more memory, particularly for the early test patterns; however, host machine architectures of the late 1970s were supporting, what then appeared as, massive amounts of addressable memory.

With the introduction of scan design in which all sequential elements are controllable from the tester, the simulated problem is reduced to that of a combinatorial circuit whose state is deterministic based on any single test pattern, and is not dependent on previous patterns or states. Parallel-pattern fault simulation was developed in the late 1970s to take advantage of this, by simulating multiple test patterns in parallel against a single fault. A performance advantage is achieved because compiled simulation could again be utilized as opposed to the more costly event-based approach. In addition, because faults not detected by the initial test patterns are typically only detectable by a few patterns and for these a sensitized path often disappears within a close proximity to the fault's location, simulation of many patterns does not require a complete pass across the design.

Because of the increasing number of devices on chips, the test generation and fault simulation problem continued to face severe challenges. With the evolution of BIST however, the use of fault simulation was relaxed. With BIST, only the good-machine behavior needs to be simulated and compared with the actual results at the tester.

14.2.1.4 Physical Design

As with test generation, PD has evolved from early work on PCBs. PD automation programs place devices and generate the physical interconnect routing for the nets that connect them into logic paths assuring that electrical and physical constraints are met. The challenge for PD has become ever greater since its early development for PCBs where the goal was simply to place components and route nets typically looking for the shortest path. Any nets that could not be auto-routed were routed (embedded) manually, or as a last resort with nonprinted (yellow) wires. As the problem moved on to the ICs, the ability to use nonprinted wires to finish routing was no more. Now, all interconnects had to be printed circuits and anything less than a 100% solution is unacceptable. Further, as the IC densities increased, so did the number of nets which necessitated the invention of smarter wiring programs and heuristics. Even a small number of incomplete (overflow) routes became too complex of a task for manual solutions.

As IC device sizes shrank and the gate delays decreased, the delay caused by interconnect wiring also became an important factor for a valid solution. No longer was any wiring solution a correct solution. Complexity increased by the need to find wiring solutions that fall within acceptable timing limits. Thus, the wiring lengths and thickness needed to be considered. As IC features become packed closer together cross-coupled capacitance (cross talk) effects between them is also an important consideration and for the future, wiring considerations will expand into a three-dimensional space. PD solutions must consider these complex factors and still achieve a 100% solution that meets the designer-specified timing for IC designs that contain hundreds of millions of nets.

Because of these increasing demands on the PD, major paradigm changes have taken place in the design methodology. In the early days, there was a clear separation of logic design and PD. The logic designer was responsible for creating a netlist that correctly represented the logic behavior desired. Timing was a function of the drive capability of the driving circuit and the number of receivers. Different power levels for drivers could be chosen by the logic designer to match the timing requirements based on the driven circuits. The delay imposed by the time-of-flight along interconnects and owing to the parasitics on the interconnect was insignificant. Therefore, the logic designer could hand off the PD to another, more adept at using the PD programs and manually embedding overflow wires. As the semiconductor technology progressed, however, there needed to be more interactions between the logic designer and the physical designer, as the interconnect delays became a more dominant factor across signal paths. The logic designer had to give certain timing constraints to the physical designer and if these could not be met, the design was often passed back to the logic designer. The logic designer, in turn, then had to choose different driver gates or a different logical architecture to meet his design specification. In many cases, the pair had to become a team or there was a merger of the two previously distinct operations into one ''IC designer.''

This same progression of merging logic design and PD into one operational responsibility has also begun at the EDA system architecture level. In the 1960s and 1970s, front-end (design) programs were separate from back-end (physical) programs. Most often they were developed by different EDA development teams and designs were transferred between them by means of data files. Beginning in the 1980s, the data transferred between the front-end programs and the back-end ones included specific design constraints that must be met by the PD programs—the most common being a specific amount of allowed delay across an interconnect or signal path. Moreover, as the number of constraints that must be met by the PD programs increases so does the challenge to achieve a 100% solution. Nonetheless, many of the fundamental wiring heuristics and algorithms used by PD today spawned from work done in the 1960s for PCBs.

Early placement algorithms were developed to minimize the total length of the interconnect wiring using Steiner trees and Manhattan wiring graphs. In addition, during these early years, algorithms were developed to analyze wiring congestion that would occur as a result of placement choices and minimize it to give routing a chance to succeed. Later work in the 1960s led to algorithms that performed a hierarchical division of the wiring image and performed global wiring between these subdivisions

(then called cells) before routing within the cells [6]. This divide-and-conquer approach simplified the problem and led to quicker and more complete results. Min-cut placement algorithms often used today are a derivative of this divide-and-conquer approach. The image is divided into partitions and the placements of these partitions are swapped to minimize interconnect length between them and possible wiring congestion. Once a global solution for the cells is found, placement is performed within them using the same objectives. Many current placement algorithms are based on these early techniques, although they now need to consider more physical and electrical constraints.

Development of new and more efficient routing algorithms progressed. The Lee algorithm [7] finds a solution by emitting a ''wave'' from both the source and target points to be wired. This wave is actually an ordered identification of available channel positions—where the available positions adjacent to the source or destination are numbered 1, and the available positions adjacent to them are numbered 2, etc. Successive moves and sequential identification is made (out in all directions as would a wave) until the source and destination moves meet (the waves collide). Then a backtrace is performed from the intersecting position in reverse sequential order along the numbered track positions back to the source and destination. At points where a choice is available (i.e., there are two adjacent points with the same order number), the one which does not require a change in direction is chosen.

The Hightower line-probe technique [8], also developed during this period and speeded up routing, by use of emanating lines rather than waves. This algorithm emanated a line from both the source and destination points, toward each other. When either line encounters an obstacle, then another line is emanated from a point just missing the edge of the obstacle on the original line at a right angle to the original line, and toward the target or source. Thus, the process is much like walking blindly in an orthogonal line toward the target and changing direction only after bumping into a wall. This process continues until the lines intersect at which time the path is complete.

In today's ICs, the challenge of completed wiring that meets all constraints is of crucial importance. Unlike test generation, which can be considered successful when a very high percentage of the faults are detected by the test patterns, 100% complete is the only acceptable answer for PD. Further, all of the interconnects must fall within the required electrical and physical constraints. Nothing $<$100% is acceptable! Today these constraints include timing, power consumption, noise, and yield and this list will become more complex as IC feature sizes and spacing are reduced further.

14.2.2 The 1970s: The Awaking of Verification

Before the introduction of large-scale integrated (LSI) circuits in the 1970s, it was common practice to build prototype hardware to verify the design correctness. PCB packages containing discrete components, single gates, and small-scale integrated modules facilitated engineering rework of real hardware within the verification cycle. Prototype PCBs were built and engineering used test stimulus drivers and oscilloscopes to determine whether the correct output conditions resulted from input stimuli. As design errors were detected, they were repaired on the PCB prototype, validated, and recorded for later engineering into the production version of the design. Use of the wrong logic function within the design could easily be repaired by replacing components in error with the correct ones. Incorrect connections could easily be repaired by cutting a printed circuit and replacing it with a discrete wire. Thus, design verification (DV) was a sort of trial-and-error process using real hardware.

The introduction of LSI circuits drastically changed the DV paradigm. Although the use of software simulation to verify system design correctness began during the 1960s, it was not until the advent of the LSI circuits that this concept became widely accepted. With large-scale integration, it became impossible to use prototype hardware or to repair a faulty design after it was manufactured. The 1970s are best represented by a quantum leap into verification before manufacture through the use of software modeling (simulation). This represented a major paradigm shift in electronics design and was a difficult change for some to accept. DV on hardware prototypes resulted in a tangible result that could be touched and held. It was a convenient tangible, which could be shown by management to represent real progress.

Completed DV against a software model did not produce the same level of touch and feel. Further, since the use of computer models was a relatively new concept, it met with the distrust of many. However, the introduction of LSI circuits demanded this change and today, software DV is a commonplace practice used in all levels of electronic components, subassemblies, and systems.

Early simulators simulated gate-level models of the design with two-valued (1 and 0) simulation. Since gates had nearly equal delays and the interconnect delay was insignificant by comparison, the use of a unit of delay for each gate with no delay assigned to interconnects was common. Later simulators exploited the use of three-valued simulation (1, 0, and unknown) to resolve race conditions and identify oscillations within the design more quickly. With the emergence of LSI circuits, however, these simple models had to become more complex and, additionally, simulators had to become more flexible and faster—much faster. In the first half of the 1970s, important advances were made to DV simulators that included

- Use of abstract (with respect to the gate-level) models to improve simulation performance and enable verification throughout the design cycle (not just at the end)
- More accurate representations of gate and interconnect delays to enhance the simulated accuracy

In the latter half of the decade, significant contributions were made to facilitate separation of function verification from timing verification and formal approaches for verification. However, simulation remains a fundamental DV tool and the challenge to make simulators faster and more flexible continues even today.

14.2.2.1 Simulation

Though widely used for DV, simulation has a couple of inherent problems. First, unlike test generation or PD, there is no precise measure of completeness. Test generation has the stuck-at fault model and PD has a finite list of nets that must be routed. However, there is no equivalent metric to determine when verification of the design is complete, or when enough simulation is done. During the 1970s research began to develop a metric for verification completeness, but to this day none has been generally accepted. Use is made of minimum criteria such as all nets must switch in both directions, and statistical models using random patterns. Recent work in formal verification is applying algorithmic approaches to validate coverage of paths and branches within the model. However, the generally accepted goal is to ''do more.''

Second, it is a hard and time-consuming task to create effective simulation vectors to verify a complex design. DV simulators typically support a rich high-level language for the stimulus generation, but still require the thought, experience, and ingenuity of the DV engineer to develop and debug these programs. Therefore, it is desirable to simulate the portion of the design being verified in as much of the total system environment as possible and have the simulation create functional stimulus for the portion to be verified.

Finally, it is tedious to validate the simulated results for correctness, making it desirable to simulate the full system environment where it is easier to validate results. Ideally, the owner of an application-specific integrated circuit (ASIC) chip being designed for a computer could simulate that chip within a model of all of the computer's hardware, the microcode, the operating system, and use example software programs as the ultimate simulation experiment. To even approach this goal, however, simulator technology must continuously strive for rapid and more rapid techniques.

Early DV simulators often used compiled models (where the design is represented directly as a computer program), but this technique gave way to interpretative event-driven simulation. Compiled simulators have the advantage of higher speeds because host machine instructions are compiled in-line to represent the design to be verified and are directly executed with minimum simulator overhead. Event-based simulators require additional overhead to manage the simulation operations, but provide a level of flexibility and generality not possible with the compiled model. This flexibility was necessary to provide for simulation of timing characteristics as well as function, and to handle general sequential designs. Therefore, this approach was generally adopted for DV simulators.

14.2.2.1.1 Event-Based Simulation

There are four main concepts to an event-based simulator:

- Netlist, which provides the list of blocks (gates at first, but any complex function later), connections between blocks, and delay characteristics of the blocks.
- Event time queues, which are lists of events that need to be executed (blocks that need to be simulated) at specific points in (simulation) time. Event queues contain two types of events—update and calculate. Update-events change the specified node to the specified value, then schedule calculate-events for the blocks driven from that node. Calculate-events call the simulation behavior for the specified block and, on return from the behavior routine, schedule update-events to change the states on the output nodes to the new values at the appropriate (simulation) time
- Block Simulation Behavior (the instructions that will compute that block's output(s) states when there is a change to its input(s) state—possibly also scheduling some portion of the block's behavior to be simulated at a later time).
- Value list—the current state of each node in the design.

Simulation begins by scheduling update-events in appropriate time queues for the pattern sequence to be simulated. After the update-events are stored, the first-time event queue is traversed and, one-by-one, each update-event in the queue is executed. Update-events update the node in the value list and, if the value new value is different from the current value (originally set to unknown), schedule calculate-events for blocks driven from the updated node. These calculate-events are saved back in time queues based on delay specifications for later execution—which will be discussed later. After all update-events are executed and removed from the queue, the simulator selects calculate-events in the queue sequentially, interprets its function, and passes control to the appropriate block simulation behavior for calculation.

The execution of a calculate-event causes simulation of a block to take place. This is accomplished by passing control to the simulation behavior of the block with pointers to the current state-values on its inputs (in the value list). When complete, the simulation routine of the block will pass control back to the simulator with the new state condition for its output(s). The simulator then schedules the block output(s) value update by placing an update-event for it in the appropriate time queue. The decision of which time queue the update-events are scheduled within is based on what the delay value is for the block.

Once all calculate-events are executed and removed from the queue, the cycle begins again at the next time queue and the process of executing update-events followed by calculate-events for the current time queue repeats. This cycle repeats until there are no more events or until some specified maximum simulation time. To keep update-events separated from calculate-events within the linked-list queues, it is common to add update-events at the top of the linked-list and calculate-events at the bottom, updating the chain-links accordingly.

Because it is not possible to predetermine how many events will reside in a queue at any time, it is common to create these as linked lists of dynamically allocated memory. Additionally, time queues are linked since the required number of time queues cannot be determined in advance and similar to events, new time queues can be inserted into that chained list as required (Figure 14.6).

A number of techniques have been developed to make queue management fast and efficient as they are the heart of the simulator. Because of its generality, the event-based algorithm was the clear choice for DV. One advantage of event-based simulation over the compiled approach is that it easily supports the simulation of delay. Delays can be simulated for blocks and nets and even early simulators typically supported a very complete delay model, even before sophisticated delay calculators were available to take advantage of it.

Treatment of delay has had to evolve and expand since the beginnings of software DV. Unit delay was the first model used—where each gate in the design is assigned one unit of delay and interconnect delays are zero. This was a crude approximation, but allowed for high-speed simulations because of the

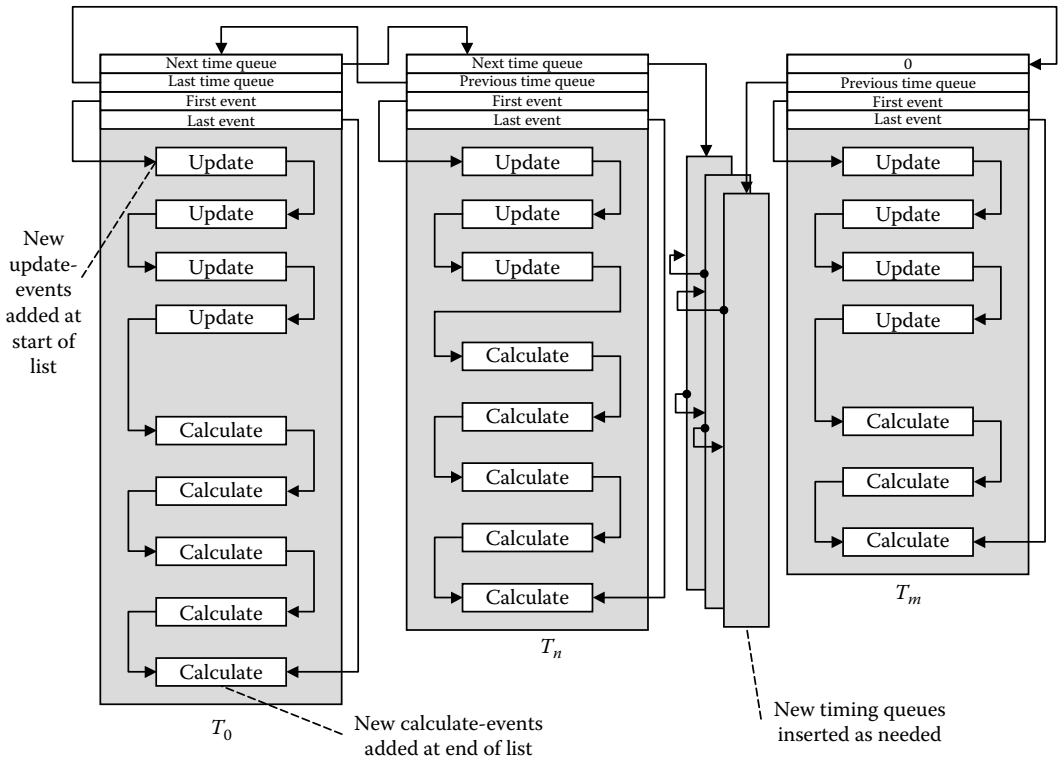

FIGURE 14.6 Event queues.

simplifying assumptions and it worked reasonably well. As the IC evolved, however, the unit delay model was replaced by a lumped delay model in which, each gate could be assigned a unique value for delay—actually, a rise-delay and a fall-delay. This was assigned by the technologist based on some average load assumption. At this time, also, the beginnings of development of delay calculators began. These early calculators used simple equations, adding the number of gates driven by the gate being calculated, and then adding the additional delay to the intrinsic delay values of that gate. As interconnect wiring became a factor in the timing of the circuit the pin-to-pin delay came into use. Though delay values used for simulation in the 1970s was crude by today's norm, the delay model Figure 14.7 was rich and supported specification and simulation for

- Intrinsic block delay (T_{block})—the time required for the block output to change state relative to the time that a controlling input to that block changed state
- Interconnect delay (T_{int})—the time required for a specific receiver pin in a net to change state relative to the time that the driver pin changed state
- Input–output delay (T_{io})—the time required for a specific block output to change state relative to the time the state changed on a specific input to that block

Today's ICs, however, require delay calculation based on very accurate distributed RC models for interconnects, as these delays have become more significant with respect to gate delays. Future ICs will require even more precise modeling for delays, as will be discussed later in this chapter, and consider inductance (L) in addition to the RC parasitics. Additionally, transmission line models will be necessary for the analysis of certain critical global interconnects. However, the delay model defined in the early years of DV and the capabilities of the event-based simulation algorithm stand ready to meet this challenge.

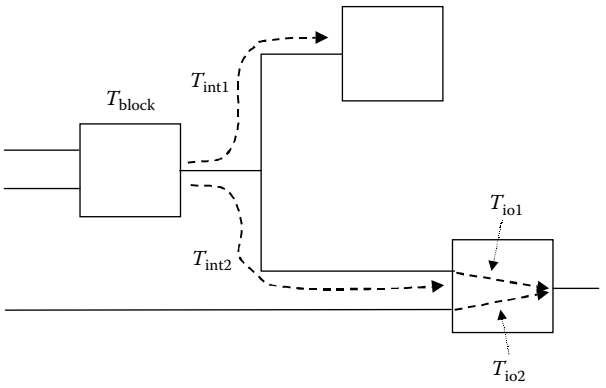

FIGURE 14.7 Simulation delay types.

Another significant advantage of the event-based simulation is that it easily supports simulation of blocks in the netlist at different levels of abstraction. Recall that one of the fundamental components of event simulation is the block simulation behavior. A calculation-event for a block passes control to the subroutine that simulates the behavior using the block's input states. For gate-level simulation, these behavior subroutines are quite simple—AND, OR, NAND, and NOR. However, since the behavior is actually a software program, it can be arbitrarily complex as well. Realizing this, early work took place to develop description languages that could be coded by designers and compiled into block simulation behaviors to represent arbitrary sections of a design as a single (netlist) block. For example, a block simulation behavior might look like the following:

```
  FUNCTION (CNOR);
/* Complimentary output NOR function with 3 inputs. Input delay=2,
   intrinsic delay for true output=10, intrinsic delay for complement
   output=12*/
  INPUT (a,b,c); /*Declare for inputs a, b, c*/
  OUTPUT (x,y);
  DECLARE input1, input2, input3; /*Declare storage for inputs*/
  DECLARE out, cout;              /*Declare storage for outputs*/

  GET a,input1, b,input2, c,input3;

  DELAY 2, Entry1;
    Entry1: out=input1|input2|input3;
    cout=¬out;

    DELAY 10, (x=out); /*Schedule this update-event for 10 time units
                         later */
    DELAY 12 (y=cout); /*Schedule this update-event for 12 time units
                         later */
    END Entry1;

  ENDCNOR;
```

The sophisticated use of these behavioral commands supported the direct representation not only for simple gates, but also for complex functions such as registers, MUXs, RAM, and ROS. In doing so, simulation performance was improved because what was treated before as a complex interconnection of gates could now be simulated as a single block.

By generalizing the simulator system, block simulation routines could be loaded from a library at simulation run time only when required (by the use of a block with that function in the netlist), and dynamically linked with the simulator control program. This meant that the block simulation behaviors could be developed by anyone, compiled independently from the simulator, stored in a library of simulation behavioral models, and used as needed by a simulation program. This is common practice in DV simulators today, but this concept in the early 1970s represented a significant breakthrough and supported a major paradigm shift in design—namely, the concept of top-down design and verification.

With top-down design, the designer no longer had to design the gate-level netlist before verification could take place. High-level (abstract) models could be written to represent the behavior of sections of the design not yet complete in detail, and they could be used in conjunction with gate-level descriptions of the completed parts to perform full system verification. Now, simulation performance could be improved by use of abstracted high-speed behavior models in place of detailed gate-level descriptions for portions of the overall design. Now, concurrent design and verification could take place across design teams. Now, there was a formal method to support design reuse of system elements without the need to expose internal design details for reusable elements. In the extreme case, the system designer could write a single functional model for the entire system and verify it with simulation. The design could then be partitioned into subsystem elements and each could be described with an abstract behavioral model before being handed off for detailed design. During the detailed design phase, individual designers could verify their subsystem in the full system context even before the other subsystems were completed. Also, the behavioral model concept was particularly valuable for generation of the functional patterns to be simulated as they could now be generated by the simulation of the other system components. Thus, verification of the design no longer had to wait until the end, it could now be a continuous process throughout the design.

Throughout the period, improvements were made to DV simulators to improve performance and in the formulation and capability of behavioral description languages. In addition, designers found increasingly novel ways to use behavioral models to describe full systems containing nondigital system elements and peripherals such as I/O devices. Late in the 1970s and during the 1980s two important formal languages for describing system behavior were developed:

- VHDL [9] (very high-speed integrated circuit [VHSIC] high-level description language), sponsored by DARPA
- Verilog [10], a commercially developed RTL description language

These two languages are now accepted industry-standard design description languages.

14.2.2.1.2 Compiled Simulation

Synchronous design such as that used for scan-based design which emerged in the 1970s provides for a clean separation of timing verification and functional verification of combinatorial circuits. Because of this, the use of compiled simulation returned for high-speed verification for designs meeting constraints. A simulation technique called cycle simulation that was developed yielded a major performance advantage over event-based simulation. Cycle-simulation treats the combinational sections of a scan-based design as compiled zero-delay models moving data between them at clock-cycle boundaries. The simulator executes each combinatorial section at each simulated cycle by passing control to the compiled routine for it along with its input states. The resulting state values at the outputs of these sections are assumed to be correctly captured in their respective latch positions. That is, the clock circuitry and path delays are assumed correct, and are not simulated during this phase of verification. The (latched) output values are used as the input states to the combinatorial sections they drive at the next cycle, and the process repeats for each simulated cycle. Each simulation pass across the compiled models represents one cycle of the design's system clock, starting with an input state and resulting in an output state. To assure that only one pass is required, the gates or RTL statements for the combinational sections are levelized

before compilation into the host-machine instructions. This assures that value updates occur before calculations and only one pass across a section of the model is required to achieve the correct state response at the outputs.

Simulation performance was greatly improved with cycle simulation because of the compiled model and because the clock circuitry did not have to be simulated repeatably with each simulated-machine cycle. Cycle simulation did not replace event simulation even for constrained synchronous designs as the clock circuitry needs to be verified; however, it proved to be effective for many large systems and these early developments provided the foundations for modern compiled simulators used today.

14.2.2.1.3 Hardware Simulators

During the 1980s, research and development took place on custom hardware simulators and accelerators. Special-purpose hardware-simulators use massively parallel instruction processors with much customized instruction sets to simulate gates. These provide simulation speeds that are orders of magnitude faster than the software simulation on general-purpose computers. However, they are expensive to build, lack the flexibility of software simulators, and the hardware technology they are built in soon becomes outdated (although general parallel architectures may allow the incremental addition of additional processors). Hardware accelerators use custom hardware to simulate portions of design in conjunction with the software simulator. These are more flexible, but still have the inherent problems that their big brothers have. Nonetheless, use of custom hardware to tackle the simulation performance demands has gained acceptance in many companies and they are commercially available today using both gate-level and hardware description language (HDL) design descriptions.

14.2.2.2 Timing Analysis

The practice of divide and conquer in DV started in the 1970s with the introduction of the behavioral model. Another divide-and-conquer style born in the 1970s, which achieved wide popularity in the 1990s, is to separate verification of the design's function from its timing. With the invention of scan design, it became possible to verify logic as a combinational circuit using high-speed compiled cycle simulators. Development of path tracing algorithms to verify timing resulted in a technique to verify timing without simulation; thus providing a complete solution which is not dependent on completeness of any input stimulus as required by simulation. For this reason alone, this technique coined static timing analysis (STA) was a major contribution to EDA—one that became key to the notion of ''signoff'' to the wafer foundry.

STA is used to analyze projected versus required timing along signal paths from primary inputs to latches, latches to latches, latches to primary outputs, and primary inputs to primary outputs. This is done without the use of simulation, but by summing the min–max delays along each path. At each gate, the STA program computes the min–max time in which that gate will change in state based on the min–max arrival times of its input signals. STA tools do not simulate the gate function, they only add its contribution to the path delay, although the choice of using rise or fall times for the gate is based on whether it has a complementary output, or not. Because the circuitry between the latches is combinational, only one pass needs to be made across the design. The addition can be based on the minimum rise or fall delay for gates or both, providing a min–max analysis. The designer specifies the required arrival times for paths at the latches or primary outputs, and the STA program compares these with the actual arrival times. The difference between the required arrival and the actual arrival is defined as slack. The STA tool computes the slack at the termination of each path, sorts them numerically, and provides a report. The designer then verifies the design correctness by analysis of all negative slacks.

Engineering judgment is applied during the analysis, including the elimination of false-path conditions. A false-path is a signal transition that will never occur in the real operation of the design. Since the STA tool does not simulate the behavior of the circuit, it cannot automatically eliminate all false-paths. Through knowledge of the signal polarity, STA can eliminate false-paths caused by the fan-out and reconvergence of certain signals. However, other forms of false-paths are only identifiable by the designer.

14.2.2.3 Formal Verification

Development of formal methods to verify the equivalence of two different representations of a design began during the 1970s. Boolean verification analyzes a circuit against a known good reference and provides a mathematical proof of equivalence. An RTL model, for example, of the reference circuit is verified using standard simulation techniques. The Boolean verification program then compiles the known-good reference design into a canonical NAND–NOR equivalent circuit. This equivalent circuit is compared with the gate-level hardware design using sophisticated theorem provers to determine equivalence. To reduce processing times, formal verification tools may preprocess the two circuits to create an overlapping set of smaller logic *cones* to be analyzed. These *cones* are simply the set of logic traversed by backtracing across the circuit from an output node (latch positions or primary outputs) to the controlling input nodes (latch positions or primary inputs). User controls specify the nodes that are supposed to be logically equivalent between the two circuits.

Early work in this field explored the use of test generation algorithms to prove equivalence. Two *cones* to be compared can be represented as $F_{\text{cone1}} = f(a, b, c, X, Y, Z, \dots)$ and $F_{\text{cone2}} = f(d, e, f, \dots, X', Y', Z', \dots)$. F_{cone1} and F_{cone2} are user defined output nodes to be compared for equivalence. The terms a, b, c and d, e, f represent the set of input nodes for the function and X, Y, Z are the computational subfunctions. User inputs define the equivalence between a, b, c and d, e, f. If F_{cone1} and F_{cone2} are functionally equivalent, then the value of G must be 0 for all possible input states. If the two cones are equivalent then, use of D-ALG test generation techniques for $G = F_{\text{cone1}}$ XOR F_{cone2} will be unable to derive a test for the stuck-at-zero fault on the output of G. Similarly, the use of random pattern generation and simulation can be applied to prove equivalence between *cones* by observing the value of G for all input states.

Research during the 1980s provided improvements in Boolean equivalence checking techniques and models (such as binary decision diagrams), and modern Boolean equivalence checking programs may employ a number of mathematical and simulation algorithms to optimize the overall processing. However, Boolean equivalence checking methods require the existence of a reference design against which equivalence is proved. This implies there must be a complete validation of the reference design against the design specification. Validating the reference design has typically been a job for simulation and, thus, is vulnerable to the problems of assuring coverage and completeness of the simulation experiment. Consequently, formal methods to validate the correctness of functional-level models have become an important topic in EDA research. Modern design validation tools use a combination of techniques to validate the correctness of a design model. These typically include techniques used in software development to measure completeness of simulation test cases such as

- Checking for coverage of all instructions (in the model)
- Checking to assure that all possible branch conditions (in the model) were exercised

They may also provide more formal approaches to validation such as

- Checking (the model) against designer-asserted conditions (or constraints) that must be met
- Techniques that construct a proof that the intended functions are realized by the design

These concepts and techniques continue to be the subject of research and will gain more importance as the size of IC designs stretches the limits of simulation-based techniques.

14.2.2.4 Verification Methodologies

With the use of structured design techniques, the design to be verified (Figure 14.8) can be treated as a set of combinational designs. With the arsenal of verification concepts that began to emerge during this period, the user had many verification advantages not previously available. Without structured design, delay simulation of the entire design was required. Use of functional models intermixed with gate-level descriptions of subsections of the design provided major improvements, but was still very costly and time consuming. Further, to be safe, the practical designer would always attempt to delay simulate the entire design at the gate level.

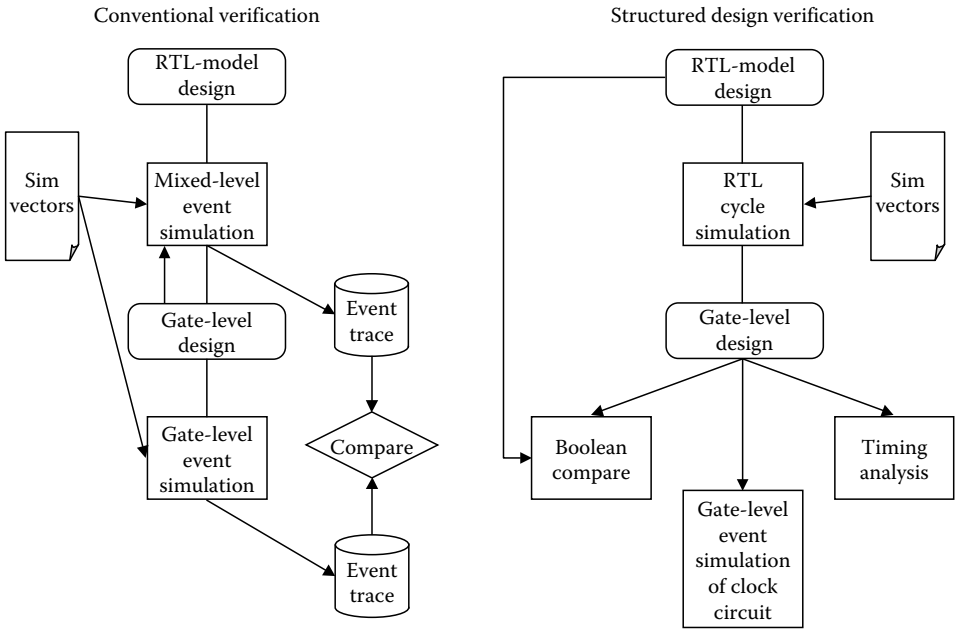

FIGURE 14.8 Verification methodology.

With structured design techniques, the designer could do the massive simulations at the RTL focusing of the logic function only, regardless of the timing. Cycle simulation improved the simulation performance by 1 to 2 orders of magnitude by eliminating repetitive simulations of the clock circuitry and use of compiled (or table lookup) simulation. For some, the use of massively parallel hardware simulators offered even greater simulation speeds—the equivalent of hundreds of millions events per second. Verification of the logic function of the gate-level design could be accomplished by formally proving its equivalence with the simulated RTL model. STA provided the basis to verify the timing of all data paths in a rigorous and methodical manner. Functional and timing verification of the clock circuitry could be accomplished with the standard delay-simulation techniques using event simulation. Collectively, these tools and techniques provided major design productivity improvements. However, the IC area and performance overhead required for these structured design approaches limited the number of designs taking advantage of them. During the 1980s as the commercial EDA business developed, these new verification tools and techniques remained as in-house tools in a few companies. Commercial availability did not emerge until the 1990s when the densities and complexities of ICs began to demand the change.

14.2.3 The 1980s: Birth of the Industry

Up to the 1980s design automation was, for the most part, developed in-house by a small number of large companies for their own proprietary use. Almost all EDA tools operated against large mainframe computers using company-specific interfaces. High-level description languages were unique and most often proprietary, technology rule formats were proprietary, and user interfaces were unique. As semiconductor foundries made their manufacturing lines available for customer-specific chip designs; however, the need for access to EDA tools grew. With the expansion of the ASIC, the need for commercially available EDA tools exploded. Suddenly, a number of commercial EDA companies began to emerge and electronics design companies had the choice of developing tools in-house or

purchasing them from a variety of vendors. The EDA challenge now often became that of integrating tools from multiple suppliers into a homogeneous system. Therefore, one major paradigm shift of the 1980s was the beginnings of EDA standards to provide the means to transfer designs from one EDA design system to another or from a design system to manufacturing. VHDL and Verilog matured to become IEEE industry-standard HDLs. Electronic data interchange format (EDIF) [11] was developed as an industry standard for the exchange of netlist and GDSII (developed in the 1970s at Calma) became a standard interface for transferring mask pattern data. (In 2003, SEMI introduced a new mask pattern exchange standard, OASIS, that compacts mask pattern data to one-tenth or less of the bytes used by GDSII.)

A second paradigm shift of the 1980s was the introduction of the interactive workstation as the platform for EDA tools and systems. Although some may view it as a step backward, the ''arcade'' graphics capabilities of this new hardware and its scalability caught the attention of design managers and made it a clear choice over the mainframe wherever possible. For a time, it appeared that many of the advances made in alphanumeric HDLs were about to yield to the pizzazz of graphical schematic editors. Nevertheless, although the graphics pizzazz may have dictated the purchase of one solution over another, the dedicated processing, and the ability to incrementally add compute power made the move from the mainframe to the workstation inevitable. Early commercial EDA entries such as from Daisy (Logician) and Valid (SCALD) were developed on custom hardware using commercial microprocessors from Intel and Motorola. This soon gave way, however, to commercially available workstations using RISC-based microprocessors, and UNIX became the de facto operating system standard. During the period, there was a rush of redevelopment of many of the fundamental algorithms for EDA onto the workstation. However, with the development of commercial products and with the new power of high-function graphics, these applications were vastly improved along the way. Experience and new learning streamlined many of the fundamental algorithms. The high-function graphic display provided the basis for enhanced user interfaces to the applications and high-performance high-memory workstations allowed application speeds to compete with the mainframe. The commercial ASIC business provided focus on the need for technology libraries from multiple manufacturers. Finally, there was significant exploration into custom EDA hardware such as hardware simulators and accelerators and parallel processing techniques.

From an IC design perspective however, the major paradigm shift of the 1980s was synthesis. With the introduction of synthesis, automation could be used to reduce an HDL description of the design to the final hardware representation. This provided major productivity improvements for ASIC design, as chip designers could work at the HDL level and use automation to create the details. Also, there was a much higher probability that the synthesis-generated design would be correct than for manually created schematics. The transgression from the early days of IC design to the 1980s is similar to what occurred earlier in software. Early computer programming was done at the machine language level. This could provide optimum program performance and efficiency, but at the maximum labor cost. Programming in machine instructions proved too inefficient for the vast majority of software programs, thus the advent of assembly languages. Assembly language programming offers a productivity advantage over machine instructions because the assembler abstracts up several of the complexities of machine language. Thus, the software designer works with less complexity, using the assembler to add the necessary details and build the final machine instructions. The introduction of functional-level program languages (such as FORTRAN then, and C++ now) provided even more productivity improvements by providing a set of programming statements for functions that would otherwise require many machine or assembler instructions to implement. Thus, the level at which the programmer could now work was even higher, allowing him/her to construct programs with far fewer statements. The analog in IC design is the progression of transistor-level design (machine level), to gate-level design (assembler level), to HDL-based design. Synthesis provided the basis for HDL-based design and its inherent productivity improvements, and major changes to IC design methodologies.

14.2.3.1 Synthesis

Fundamentally, synthesis is a three-step process:

- Compile an HDL description of a design into an equivalent NAND–NOR description
- Optimize the NAND–NOR description based on design targets
- Map the resulting NAND–NOR description to the technology building blocks (cells) supported for the wafer foundry (process) to be used

Although work on synthesis techniques has occurred on and off since the beginnings of design automation and back to Transistor–Transistor Logic (TTL)-based designs, it was not until gate array style ICs reached a significant density threshold that it found production use. In the late 1970s and 1980s, considerable research and development in industry and universities took place on the high-speed algorithms and heuristics for synthesis. In the early 1980s, IBM exploited the use of synthesis on the ICs used in the 3090 and AS400 computers. These computers used chips that were designed from qualified sets of predesigned functions interconnected by personalized wiring. These functions (now called cells) represented the basic building blocks for each specific IC family. The computers used a high number of uniquely personalized chip designs so it was advantageous to design at the HDL level and use automation to compile to the equivalent cell-level detail. The result was significant improvements to the overall design productivity.

Today, synthesis is a fundamental cornerstone of the design methodology (Figure 14.9) for ASICs supporting both VHDL and Verilog as the standard input. As the complexities of IC design have increased, so have the challenges for synthesis. Early synthesis had relatively few constraints to be observed in its optimization phase. Based on user controls, the design was optimized for minimum area, minimum fan-out (minimum power), or maximum fan-out (maximum performance). This was accomplished by applying a series of logic reduction algorithms (transforms) that provide different types of reduction and refinement [12]. Cell behavior could also be represented in primitive-logic equivalent form and a topological analysis could find matches between the design gate patterns and equivalent cells.

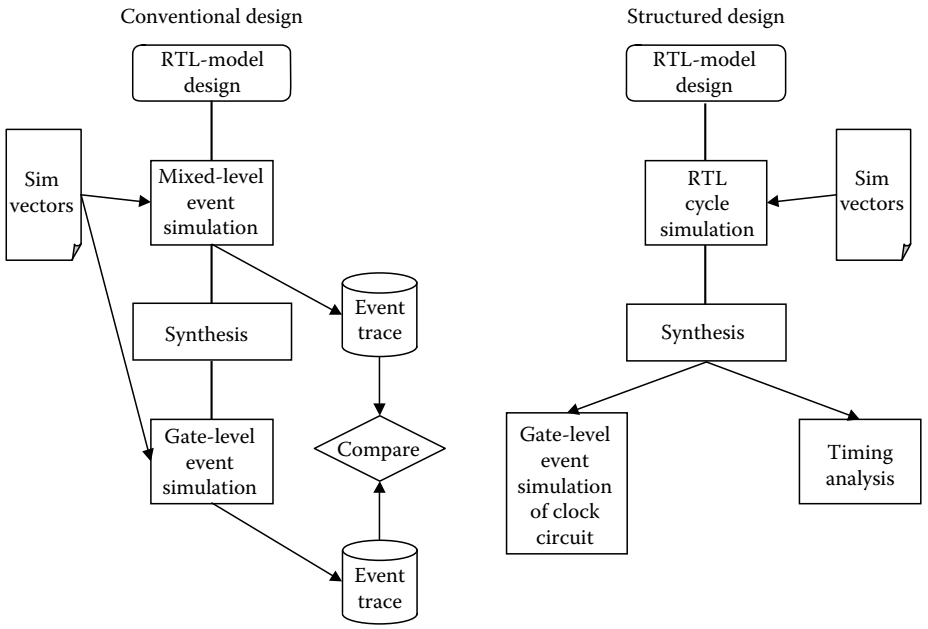

FIGURE 14.9 Synthesis methodology.

The mapping phase would then select the appropriate cells based on function and simple electrical and physical parameters for each cell in the library such as drive strength and area. Previously, synthesis was not overly concerned with signal delays in the generated design nor for other electrical constraints that the design may be required to meet. As IC feature sizes decreased, however, these constraints became critical in synthesis and automation became required to consider them in its solution.

The design input to modern synthesis tools is not the functional HDL design alone, but now includes constraints such as the maximum allowed delay along a path between two points in the design. This complicates the synthesis decision process as it must now generate a solution that meets the required function with a set of cells and interconnections that will fall within the required timing constraints. Therefore, additional trade-offs must be made between the optimization and mapping phases, and the effects of interconnection penalty need to be considered. Additionally, synthesis must now have technology characteristics available to it such as delay for cells and wiring. To determine this delay it is necessary to understand the total load seen by a driver cell as a result of the input capacitance of the cells it drives and the RC parasitics on the interconnect wiring. However, the actual wiring of the completed IC is not yet available (since routing has not taken place) and estimates for interconnect parasitics must be made. These are often based on wire load models that are created from empirical analysis of other chip designs in the technology. These wire load models are tables that provide an estimate of interconnect length and parasitic values based on the fan-out and net density.

As interconnect delay became a more dominant portion of path delay it became necessary to refine the wire load estimations based on more than total net count for the chip. More and more passes through the synthesis-layout design loop became necessary to find a final solution that achieved the required path delays. The need for a new design tool in the flow became apparent as this estimation of interconnect delay was too coarse. The reason is that different regions on a typical chip have different levels of real estate (block and net) congestion. This means that wire load estimates differ across different regions on the chip because the average amount of wiring length for a net with a given pin count differs with the region. Conversely, the actual placement of cells on the chip effect the congestion and therefore, the resulting wire load models. Consequently, a new tool, called floor planning, was inserted in the flow between synthesis and layout.

14.2.3.2 Floor Planning

The purpose of floor planning is to provide a high-level plan for the placement of functions on the chip, which is used to both refine the synthesis delay estimations and direct the final layout. In effect, it inserts the designer into the synthesis-layout loop by providing a number of automation and analysis functions used to effectively partition and place functional elements on the chip. As time progressed, the number of analysis and checking functions integrated into the floor planner grew to a point where today, it is more generally thought of as design planning [13]. The initial purpose of the floor planner was to provide the ability to partition the chip design functions and develop a placement of these partitions that optimized the wiring between them. Optimization of the partitioning and placement may be based on factors such as minimum wiring or minimum timing across a signal path. A typical scenario for the use of a design planner is as follows:

- Run synthesis on the RTL description and map to the cell level.
- Run the design planner against the cell-level design with constraints such as path delays and net priorities.
  - Partition and floor plan the design, either automatically or manually, with the design planner.
  - Create wire load models based on the congestion within the physical partitions and empirical data.
- Rerun synthesis to optimize the design at the cell level using the partitioning, global route, and wire load model data.

User-directed graphics and autoplacement-wiring software algorithms are used to place the partitions and route the interpartition (global) nets. One key to the planner is the tight coupling of partitioning and routing capability with electrical analysis tools such as power analysis, delay calculation, and timing analysis. Checking of the validity of a design change (such as placement) can be made immediately on that portion of the design that changed. Another key is that it needs to be reasonably tightly connected to synthesis, as it is typical to pass through the synthesis-planner-synthesis loop a number of times before reaching a successful plan for the final layout tools.

After a pass in the floor planner, more knowledge is available to synthesis. With this new knowledge, the optimization and mapping phases can be rerun against the previous results to produce a refined solution. The important piece of knowledge now available is the gate density within different functions in the design (or regions on the chip). With this, the synthesis tool can be selective about which wire load table to use and develop a more accurate estimate of the delay resulting from a specific solution choice.

Floor planning has been a significant enhancement to the design process. In addition to floor planning, modern design planners include support for clock tree, design power, bus design, I/O assignment, and a wealth of electrical analysis tools. As will be discussed later, semiconductor technology trends will place even more importance on the design planner and dictate an ever-tightening integration between it with both synthesis and PD. Today, synthesis, design planning, and layout are three discrete steps in the typical design flow. Communication between these steps is accomplished by file-based interchange of the design data and constraints. As designs become more dense and with the growing complexities of electrical analysis required, it will become necessary to integrate these three steps into one tight process as are the functions within the modern design planners.

14.2.4 The 1990s: The Age of Integration

Before EDA tools were commercially available, software architecture standards could be established to assure smooth integration of the tools into complex EDA systems supporting the entire design flow. Choice of languages, database and file exchange formats, host hardware and operating systems, and user interface conventions could be made solely by the developing company. Moreover, the need for comprehensive EDA systems supporting the entire flow through design and manufacturing release in a managed process is of paramount importance. Design of ICs with hundreds of thousands of gates (growing to hundreds of millions) across a design team requires gigabytes of data contained within thousands of files. All these data must be managed and controlled to assure its correctness and consistency with other design components. Design steps must be carried out and completed in a methodical manner to assure correctness of the design before release to manufacturing. The EDA system that encompasses all of this must be efficient, effective, and manageable. This was always a challenge for EDA system integrators, but the use of EDA tools from multiple external vendors compounded the problem. EDA vendors may develop their tools to different user interfaces, database and file formats, computer hardware, and operating systems. In turn, it is the EDA system integrator who must find a way to connect them in a homogeneous flow that is manageable, yet provides the necessary design efficiency across the tools. By the late 1980s it was said that the cost to integrate an EDA tool into the in-house environment was often over twice that of the tool itself. Consequently, the CAD Framework Initiative (CFI) was formed whose charter was to establish software standards for critical interfaces necessary for EDA tool integration. Thus began the era of the EDA Framework.

The EDA Framework [14] is a layer of software function between the EDA tool and the operating system, database, or user. For this software layer CFI defined a set of functional elements, each of which had a standard interface and provided a unique function in support of communication between different tools. The goal was to provide EDA system integrators with the ability to choose EDA tools from different vendors and be able to plug them into a homogeneous system to provide an effective system operation across the entire design flow. The framework components included

- Design information access—a formal description of design elements and a standard set of software functions to access each, called an application program interface (API)
- Design data management—a model and API to provide applications the means to manage concurrent access and configuration of design data
- Intertool communication (ITC)—an API to communicate control information between applications and a standard set of controls (called messages)
- Tool encapsulation specification (TES)—a standard for specifying the necessary information elements required to integrate a tool into a system such as input files and output files
- Extension language (EL)—specification of a high-level language that can be used external to the EDA tools to access information about the design and perform operations on it
- Session management—a standard interface used by EDA tools to initiate and terminate their operation and report errata
- Methodology management—APIs used by tools so that they could be integrated into software systems to aid the design methodology management
- User interface—a set of APIs to provide consistency in the graphical user interface (GUI) across tools

Each of these functional areas needs to be considered for integration of EDA tools and to provide interoperability between them. In its first release, CFI published specifications for design representation (DR) and access, ITC, TES, and EL. Additionally, the use of MOTIF and X-Windows as specified as the GUI toolkit. However, for many practical, business, and human nature reasons, these standards did not achieve widespread adoption across the commercial EDA industry and the ''plug-and-play'' motto of CFI was not realized. However, the early work at CFI did serve to formalize the science of integration and communication, and a number of the information models developed for the necessary components are used today, but often, slightly modified and within a proprietary interface.

As learned, it was not only expensive to change EDA tools to use a different internal interface or data structures, but it was also not considered good business to allow tools to be integrated into commercial system offerings from competitors. For a period, several framework offerings became available, but these quickly became the product end in themselves rather than a means to an end. These products were marketed as a means to bring outside EDA tools into the environment, but few vendors modified their tools to support this by adopting the CFI specifications. Instead, to meet the need for tool integration, the commercial industry focused on data flow only and chose an approach that provides communication between tools by standard data file formats and sequential data translation. Consequently, EDA flows of the 1990s were typically a disparate set of heterogeneous tools stitched together by the industry-standard data files. These files are created from one tool and translated by another tool (within the design flow) to its internal data structures. Many of these formats evolved from proprietary formats developed within commercial companies that were later transferred or licensed for use across the industry. Common EDA file formats that evolved were

- Electronic data interchange format (EDIF)—netlist exchange (EIA → IEC)
- Physical data exchange format (PDEF)—floor plan exchange (Synopsys → IEEE)
- Standard delay file (SDF)—delay data exchange (Cadence Design Systems → IEEE)
- Standard parasitic exchange file (SPEF)—parasitic data exchange (Cadence Design Systems → IEEE)
- Library exchange file (LEF)—physical characteristics information for a circuit family (Cadence → OpenEDA)
- Data exchange format (DEF)—physical data exchange (Cadence → OpenEDA)
- Library data format (.lib)—ASIC cell characterization (Synopsys)
- ASIC library format (ALF)—ASIC cell characterization (Open Verilog International)
- VISIC high-level design language (VHDL)—behavioral design description language (IEEE)
- Verilog—RTL design description language (Cadence Design Systems → IEEE)

These "standard" formats have provided the desired engineering and business autonomy necessary to get adoption and their use across the industry has improved the ability to integrate tools into systems drastically compared with the 1980s. It has proved to be an effective method for the design of today's commodity ICs above 0.25 μm. However, the inherent ambiguities, translation requirements, rapidly increasing file sizes (owing to increasing IC density), and the fundamental nonincremental sequential nature of design flows based on them will soon give way to IC technology advances.

14.3 The Future

It may be said that the semiconductor industry is the most predictable industry on earth. Whether it was an astute prediction or the cause, the prediction of Gordon Moore (now known as Moore's Law) has held steadily over the past two decades. Every 18 months, the number of transistors or bits on an IC doubles. To accomplish this, feature sizes are shrinking, spacing between features is shrinking, and chip die sizes are increasing. In addition, the fundamental physics that govern the electrical properties of these devices and between them has been documented in electrical engineering textbooks for some time. However, there are points within this progression where paradigm shifts occur in the elemental assumptions and models required to characterize these circuits, and where fundamental EDA design and analysis must change. Earlier, we discussed paradigm shifts in DV because of the inability to repair. We also discussed shifts resulting from the number of elements in a design versus the necessary tool performance and designer productivity. Through the past three decades, we have seen shifts in test, verification, design abstraction, and design methodologies. When the 0.25 μm node was passed, another paradigm shift was required. Feature packing, decreased rise times, increased clock frequencies, increased die sizes, and the explosion of the number of switching transistors are all interacting to place new demands of models, tools, and EDA systems. After that and including the present, new challenges came about in design tools, rules, systems, and schools for problematic areas of delay, signal integrity, power, test, and manufacturability.

14.3.1 International Technology Roadmap for Semiconductors

SEMATECH periodically publishes a report called the *International Technology Roadmap for Semiconductors* [15] (ITRS). This report is jointly sponsored by the European Semiconductor Industry Association, Japan Electronics and Information Technology Industries Association, Korea Semiconductor Industry Association, Taiwan Semiconductor Industry Association, and the Semiconductor Industry Association. The objective of the ITRS "is to ensure advancements in the performance of integrated circuits." Thus ITRS characterizes planned semiconductor directions and advances across the next decade and the necessary technology advancements in areas including

- Design and test
- Process integration devices and structures
- Front-end (manufacturing) processes
- Lithography
- Interconnect
- Factory integration
- Assembly and packaging
- Environment, safety, and health
- Defect reduction
- Metrology
- Modeling and simulation

ITRS provides a wealth of information on the semiconductor future as well as the problematic areas that will arise and areas where inventive new technology will be required. Some relevant ITRS-projected

TABLE 14.1 2004 ITRS Microprocessor Roadmap

Characteristic	2001	2004	2007	2010	2013	2016
Transistor gate length (nm)	90	53	35	25	18	13
Chip size (mm^2)	310	310	310	310	310	310
Million transistors/mm^2	0.89	1.78	3.57	7.14	14.27	28.54
Million transistors/chip	276	553	1106	2212	4424	8848
Wire pitch (nm), metal	350	210	152	104	76	54
Clock frequency (GHz) (on-chip)	1.684	4.171	9.285	15.079	22.980	39.683
Supply voltage (V) (low power)	1.1	0.9	0.8	0.7	0.6	0.5
Maximum power (W) (high-performance)	130	158	189	198	198	198

semiconductor advancements for MPU/ASIC ICs are shown in Table 14.1 and compared with previous ITRS numbers for year 2001. The reader is encouraged to study the technology characteristics in the ITRS, as the following is just a summary of certain points for the purpose of illustration.

To understand some of the implications of the ITRS data, it is convenient to review the effects of scaling on a number of electrical parameters [16]. *Gate delay* is a function of the gate capacitance and transistor resistance. The gate capacitance ($C = k\varepsilon_o A/T_{gox}$) is a function of the gate area (A), and the gate-oxide thickness (T_{gox}). Assuming ideal scaling (all features scale down in direct proportion to the change in transistor size), gate capacitance scales in direct proportion to transistor-size scaling (ΔSize) since

$$\Delta C_{gate} \propto \left(\Delta W_{gate} \Delta L_{gate}\right)/\Delta T_{gox}$$

therefore

$$\Delta C_{gate} \propto \Delta\text{Size}$$

The transistor resistance (R_{tr}) is proportional to supply voltage and inversely proportional to current both of which scale down proportionally, so the R_{tr} is constant. Thus, the gate delay (D_{gate}) decreases in direct proportion to ΔSize since

$$D_{gate} = R_{tr} C_{gate},$$

therefore

$$\Delta D_{gate} \propto 1^{*}\Delta\text{Size} = \Delta\text{Size}$$

Thus, gate delays scale down in proportion to feature size. However, the effects of interconnect delay must be considered to understand the impact of scaling on timing. For $R_{int} < R_{tr}$ interconnect effects have little affect on signal path timing. As R_{int} increases, however, delay analysis must also take into account the interconnect parasitics.

Interconnect delay is a function of the *RC*-time constant, which is a result of resistance and distributed capacitance of the interconnect. Assuming ideal scaling, the interconnects' cross-sectional area scales in direct proportion to ΔSize.

Interconnect resistance is proportional to the length and inversely proportional to the cross-sectional area of the interconnect. Since

$$R_{int} \propto L_{int}/(W_{int} H_{int}),$$

therefore

$$\Delta R_{\text{int}} \propto L_{\text{int}}/\Delta\text{Size}^2$$

where, L_{int}, H_{int}, and W_{int} are the length, height, and width of the interconnect, respectively.

The self-capacitance ($C_{\text{self}} = k\varepsilon_o A/t$) of the interconnect is proportional to its plate area ($A = W_{\text{int}}\, L_{\text{int}}$) and inversely proportional to dielectric layer thickness (t). Assuming ideal scaling for t,

$$\Delta C_{\text{self}} \propto \Delta L_{\text{int}}\Delta\text{Size}/\Delta\text{Size}$$

therefore

$$\Delta C_{\text{self}} \propto \Delta L_{\text{int}}$$

The resulting interconnect *RC* constant, therefore, scales as

$$\Delta R_{\text{int}}\Delta C_{\text{self}} \propto \left(\Delta L_{\text{int}}/\Delta\text{Size}^2\right)(\Delta L_{\text{int}}) = \Delta L_{\text{int}}^2/\Delta\text{Size}^2$$

For *local nets* the interconnect length (L_{int}) scales with ΔSize thus, the *RC* constant remains relatively constant

$$\Delta(R_{\text{int}}C_{\text{self}})_{\text{local}} \propto \Delta L_{\text{int}}^2/\Delta\text{Size}^2 = \Delta\text{Size}^2/\Delta\text{Size}^2 = 1$$

Local interconnect delay does not scale down in proportion to gate delay on successive technology generations. Therefore, its relative impact on the overall timing across a signal path is increasing in importance.

For *global nets*, the interconnect length does not scale down with the feature size. Here, the die size (S_{die}) is the more predominant determinant. Therefore, the *RC* constant for global nets scales as

$$\Delta(R_{\text{int}}C_{\text{self}})_{\text{gobal}} \propto \Delta L_{\text{int}}^2/\Delta\text{Size}^2 = 1/\Delta\text{Size}^2$$

Global interconnect delay increases in indirect proportion to gate delay for successive technology generations. Thus, global interconnect routing and delay analysis has become a critically important area for EDA.

For complete analysis on interconnect delay, the cross-coupling effect of closely spaced features on the chip must also be considered. Capacitance results whenever two conducting bodies are charged to different electric potentials and may be viewed as the reluctance of voltage to build or decay quickly in response to injected power. The self-capacitance between the interconnect surfaces and ground is only a part of the overall capacitance to be considered. Another important consideration is the mutual capacitance between interconnects in close proximity. To get an accurate measure of the total capacitance along any interconnect it is necessary to consider all conducting bodies within a sufficiently close proximity. This includes not only the ground plane, but also adjacent interconnects as there is a mutual capacitance between these. This mutual capacitance is a function of interconnect sidewall area, the distance between it and adjacent interconnects, and the dielectric constant of the dielectric separating them.

Figure 14.10 depicts three equally spaced adjacent interconnect wires on a signal plane. An approximate formula for the capacitance [17] of the center wire is

$$C = \text{self-capacitance} + \text{mutual capacitance} = C_{\text{int-ground}} + 2C_{\text{m}}$$

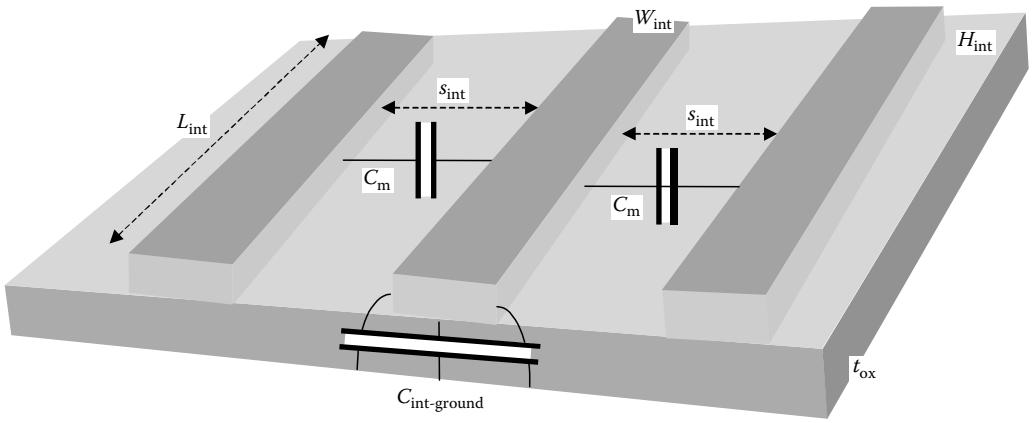

FIGURE 14.10 Mutual capacitance.

The mutual capacitance is a function of the plate area along the sides of the interconnects and the spacing between them and may be simply approximated as

$$C_m = k\varepsilon_o L_{int} H_{int} / S_{int}$$

where S_{int} is the distance between the interconnects.

Therefore (for a constant k-value), the change in mutual capacitance as a function of ideal scaling is given by

$$\Delta C_{m(Local)} \propto \Delta Size^2 / \Delta Size = \Delta Size \quad \text{and} \quad \Delta C_{m(Global)} \propto \Delta Size / \Delta Size = 1$$

Thus, mutual capacitance for local interconnects scales with feature size, while for global interconnects, it does not. Because of increased frequencies, electrical cross talk effects between interconnects must be considered. Further, mutual capacitance between only adjacent interconnects may not be complete. Full analysis may require consideration of all interconnects within a sphere around the interconnect being analyzed or even on wiring layers above or below.

Noise is the introduction of unwanted voltage onto a signal line, and is proportional to mutual capacitance between them and inversely proportional to the rate at which the voltage potential between them changes. Therefore, because the full effect of mutual capacitance is also a function of the voltage potential between interconnects (Miller effect) analysis of the simultaneous signal transitions on each becomes an important consideration for delay. Mutual capacitance injects current into adjacent (victim) signal lines proportional to the rate of change in voltage on the exciting (aggressor) signal line. The amount of induced current can be approximated by the following equation [18]:

$$I_{mC} = C_m \left(dV_{aggressor} / dt \right)$$

The amount of noise induced onto the victim net is proportional to the resistance on the victim net and the mutual capacitance, and inversely proportional to the rise time (τ_r) of the aggressor waveform:

$$V_{mC} = I_m Z_{victim} = C_m \left(\Delta V_{aggressor} / \tau_r \right) R_{victim}$$

Noise can increase or even decrease [19] the signal delay on the victim net. Voltage glitches induced can also give rise to faulty operation in the design (e.g., if the glitch is of sufficient amplitude and duration to cause a latch to go to an unwanted logic state.

Inductance can also cause noise when large current changes occur in very short times according to the following relationship:

$$V_L = L(dI/dt)$$

Sudden changes in large amounts of current can be seen on the power grid resulting from a large number of circuits switching at the same time. The inductance in the power grid and this large current draw over short periods of time (di/dt) results in a self-induced electromagnetic force whose voltage is equal to Ldi/dt. This induced voltage causes the power supply level to drop, resulting in a voltage glitch that is proportional to the switching speed, the number of switching circuits, and the effective inductance in the power grid.

14.3.2 EDA Impact

Scaling effects have impact on EDA beyond delay and timing, and the list of DF*x* (design-for-*x*) topics is increasing beyond design-for-test and design-for-timing (closure). Scaling down V_{dd} decreases power for a transistor, but the massive scaling up of total transistors on the IC dictates extensive analysis of high currents and leakage (design for power). Lithographic limitations (discussed later) now require consideration of diffraction physics (design for manufacturability [DFM]). Further, while the design complexities owing to electrical effects such as these are increasing, the number of circuits on the IC continues to increase. The fundamental challenge for EDA is more analysis on many more circuit elements with no negative effect on design cycle times.

14.3.2.1 EDA System Integration

It is now necessary to use EDA applications with increased accuracy and scope for electrical analysis to assure that designs will meet intended specifications and to integrate EDA design flows in ways that contain design cycle times. EDA systems must now take a data-centric view of the design process as opposed to the tool-centric view of the past. Data must be organized and presented in ways that allow EDA to exploit: abstraction and hierarchy, shared access by design tools, incremental processes (whereby only portions of a design that have changes need be reanalyzed), and concurrent execution of design and analysis tools within the design flow.

EDA systems have evolved or are evolving toward integration and database technology that meets the above requirements to one degree or another. EDA systems have evolved from vendor-specific sets of design and analysis applications supporting data exchange between custom, often proprietary, file formats to systems that support interchange between vendors through industry-standard files. Over the past decade they have moved toward systems of applications communicating through vendor-specific integrated database technology supporting intersystem exchange via the same industry-standard files. Because of the increasing need for new and additional EDA applications companies performing IC design continue to require the ability to use EDA applications from many vendors and develop flows that provide efficient and complete intervendor integration. With increasing feature counts and complexities for successive technology generations, this dictates the need to reduce the overhead and possible data loss caused by file-based interchange (Figure 14.11). In 2000, a multicompany effort under Si2 was initiated to develop an industry-open data model that could be used by commercial EDA companies and for university research and (EDA customer) proprietary EDA development. This effort resulted in the publication of an EDA data model specification, which includes an application program software interface, and development of a production-quality *reference* database that is compliant with that specification. Collectively, this specification and database is called OpenAccess (see www.si2.org) and was made available to the industry in 2003 on a royalty-free basis. OpenAccess has an excellent chance of being the foundation on which the next point of EDA systems' evolution will be founded. At that

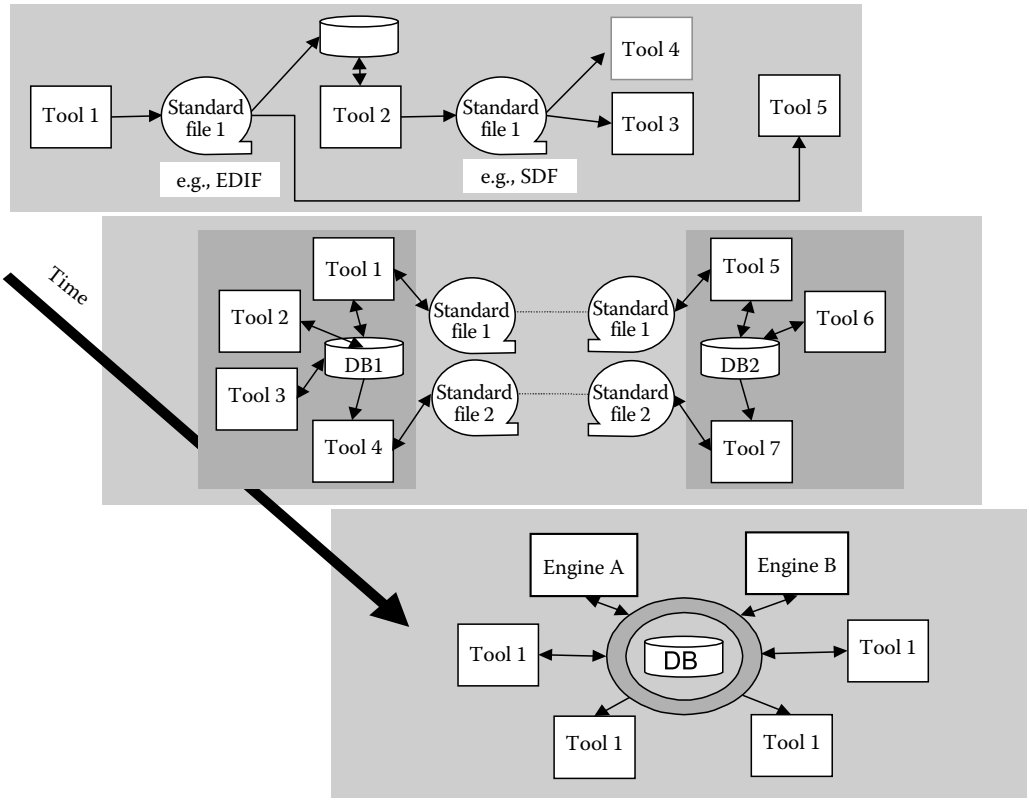

FIGURE 14.11 EDA system architecture progression.

point, highly efficient EDA flows will be built using EDA tools from multiple sources and integrated around a single database meeting the fundamental requirements mentioned above.

14.3.2.2 Delay

Simplifying assumptions and models for delay have provided the foundation for high-speed event-driven delay simulation since its initial use in the 1970s. More accurate waveform simulation such as that provided by SPICE implementations has played a crucial role in the characterization of IC devices during over three decades and continues to do so. SPICE-level simulations are important for characterization and qualification of ASIC cells and custom macros of all levels of complexity. However, the run times required for this level of device modeling are too large to support its use across the entire ICs. SPICE is often used to analyze the most critical signal paths, but SPICE-level simulation on circuits with hundreds of millions of transistors is not practical today. Consequently, simulation and STA at the abstracted gate-level, or higher, is essential for IC timing analysis. However, simplifying models used to characterize delay for discrete-event simulation and STA have become more complex as feature sizes on ICs have shrunk, and the importance of interconnect resistance and cross talk increased. In the future, these models will need to improve even more (Figure 14.12).

When ICs were considerably >1 μm, gate delay was the predominant factor in determination of timing. Very early simulation of TTL used a simple model which assigned a fixed unit of delay to each gate and assumed no delay across the interconnects. Timing was based only on the number of gates through which a signal traversed along its path. As LSI advanced delay was based on a foundry-specified gate delay value (actually a rise delay and a fall delay) that was adjusted based on the capacitive load of

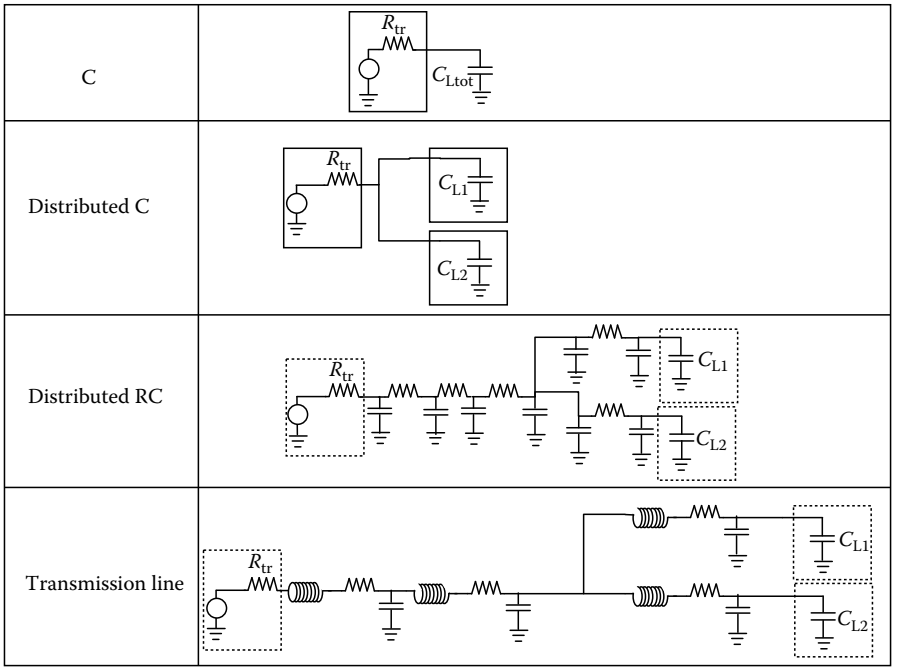

FIGURE 14.12 Delay models.

the gates it fanned out to (receiver gates). At integration levels above 1 μm, the load seen by a gate was dominated by the capacitance of its receivers, so this delay model was sufficiently accurate. As feature sizes crossed below 1 μm, however, the parasitic resistance and capacitance along the interconnects became a significant factor. More precise modeling of the total load effect on gate delay and interconnect delay had to be taken into account. By 0.5 μm the delay attributed to global nets almost equaled that of gates, and by 0.35 μm the delay attributed to short nets equaled the gate delay.

Today, a number of models are used to represent the distributed parasitics along interconnects using lumped-form equations. The well-known π-model, for example, is a popular method to model these distributed RCs. Different degrees of accuracy can be obtained by adding more sections to the equivalent-lumped RC model for interconnect.

As the importance of timing-driven design tools grows, integration of multiply sourced design tools into an EDA flow becomes problematic. As more EDA vendors use custom built-in models for computation of gate and interconnect delays, the calculated values may differ across different design tools. This results in difficult and time-consuming analysis on the designers' part to correlate the different results. In mid-1994, an industry effort began to develop an open architecture supporting common delay-calculation engines [20]. The goal of this effort was to provide a standard language usable by ASIC suppliers to specify the delay calculation models and equations (or table lookups) for their technology families. In this way, the complexities of deciding appropriate models to be used to characterize circuit delay and the resulting calculation expressions could be placed in the hands of the semiconductor supplier rather than across the EDA vendors. These models could then be compiled into a form that could be directly used by any EDA application requiring delay calculation and in a way that would protect the intellectual property contained within them. By allowing the semiconductor supplier to provide a single software engine for the calculation of delay, all applications in the design flow could provide consistency in the computed results. The Delay Calculation Language (DCL) technology, originally developed by IBM Corporation, was contributed to industry as the basis for this. Today,

DCL has been extended to cover power calculation in addition to delay and it has been ratified by the IEEE as an open industry standard (Delay and Power Calculation System [DPCS], IEEE 1481–1999). For a number of technical and business reasons, adoption of this standard has failed to take hold. Although release and adoption of the Synopsys.lib format, used to provide technology parameters used by delay calculation in a standard form, greatly improved this situation, problems with accuracy and consistency of delay calculation remain. To that end, a renewed interest in developing an industry-wide solution came about in 2005 and the Open Modelling Coalition (OMC) has been formed under Si2 to readdress the challenge with industry partners.

At 0.25 μm, cross talk noise resulting from mutual capacitance between signal lines begins to have a significant effect on delay. At this technology generation, it became necessary to consider effects of mutual capacitance between interconnects. Today, sophisticated extraction tools must analyze the proximity of features (including wires, vias, and pads) and properties of dielectrics between them. In addition, EDA design and analysis applications must account for mutual parasitics and cross talk. This is an important element of layout, parasitic extraction, delay calculation, and timing analysis. Further, the development of wafer fabrication techniques such as dielectric air gaps to reduce effective *k*-values will bring further challenges to EDA.

With future technology generations, more sophisticated models that consider inductance may also become necessary. Distributed *RC* models used to characterize delay are very accurate approximations so long as the rise time (t_r) of the signals is much larger than the time-of-flight (t_{of}) across the interconnect wire. As the transistor size scales down, so do the signal rise times. As t_r approaches t_{of}, transmission line analysis may be necessary to accurately model timing. Between these points is a gray area where transmission line analysis may be necessary depending on the criticality of the timing across a particular path. Published papers [21,22] address the question of where this level of analysis is important and the design rules to be considered for time-critical global lines. For future EDA systems, this means more complexities in the design and analysis of circuits. Extraction tools will then need to derive inductance of interconnects so that the effects of the magnetic fields surrounding these lines can be factored into the delay calculations. Effects of mutual inductance also becomes important, particularly along the power lines which will drive large amounts of current in very short times ($e = L\ \mathrm{d}i/\mathrm{d}t$). Design planners and routers will need to be aware of these effects when designing global nets and power bus structures.

14.3.2.3 Test

Manufacturing test of ICs today is becoming a heuristic process involving a number of different strategies in combination to assure coverage and maximize generation costs and throughput at the tester. Today, IC test employs the use of one or more of the following approaches:

- Static stuck-at fault test using stored program testers: The test patterns may be derived algorithmically or from random patterns and the test is based on final steady-state conditions independent of arrival times. The goal of stuck-at fault test is to achieve 100% detection of all stuck-at faults (except for redundancies and certain untestable design situations that can result from the design). Algorithmic test generation for all faults in general sequential circuits is often not possible, but test generation for combinational circuits is. Therefore the use of design-for-test strategies (such as scan design) is becoming more accepted.
- Delay (at-speed) test: Patterns for delay testing may be algorithmically generated or functional patterns derived from DV. The tester measures output pins for the logic state at the specified time after the test pattern is applied.
- BIST: BISTs are generated at the tester by the device under test and output values are captured in scan latches for comparison with simulated good-machine responses. BISTs tests may be exhaustive or random patterns and the expected responses are determined by simulation. BIST requires special circuitry on the device-under-test (LFSR and scan latches) for pattern generation and result

capture. To improve tester times, output responses are typically compressed into a signature and comparison of captured results and simulated results is made only at the end of sequences of tests.

- Quiescent current test (I_{DDQ}): I_{DDQ} measures quiescent current draw (current required to keep transistors at their present state) on the power bus. This form of testing can detect faults not observable by stuck-at fault tests (such as bridging faults) that may cause incorrect system operation.

Complicated semiconductor trends that will affect manufacturing test in the future are the speed at which these future chips operate and the quiescent current required for the large density of transistors on the IC. To perform delay test, for example, the tester must operate at speeds of the device-under-test. That is, if a signal is to be measured at a time n after the application of the test pattern, then the tester must be able to cycle in n units of time. It is possible that the hardware costs required to build testers that operate at frequencies above future IC trends will be prohibitive. I_{DDQ} tests are a very effective means to quickly identify faulty chips as only a small number of patterns are required. Further, these tests find faults not otherwise detected by stuck-at fault test. Electric current measurement techniques are far more precise than voltage measurements. However, the amount of quiescent current draw required for the millions of transistors in future ICs may make it impossible to detect the small amount of excess current resulting from small numbers of faulty transistors. New inventions and techniques may be introduced into the test menu. However, at present it appears that in the future manufacturing test must rely on static stuck-at fault tests and BIST. Therefore, it is expected that more and more application of scan design will be prevalent in future ICs.

14.3.2.4 Design Productivity

The ITRS points out that future ICs will contain hundreds of millions of transistors. Even with the application of the aforementioned architectural features and new and enhanced EDA tools, it is unclear that design productivity (number of good circuits designed per person year) will be able to keep pace with semiconductor technology capability. Designing and managing anything containing over 100,000,000 subelements is almost unthinkable. Doing it right and within the typical 18-month product cycles of today seems impossible. Yet, if this is not accomplished, semiconductor foundries may run at less than full production, and the possibility of obtaining returns against the exorbitant capital expenditures required for new foundries will be low. Ultimately, this could negate the predictions in the ITRS.

Over the history of IC design, a number of paradigm shifts enhanced designer productivity, the most notable being high-level design languages and synthesis. Use of design rules such as LSSD to constrain the problem has also represented productivity advances. Algorithm advances and faster processing computers will necessarily play a crucial role, as the design cycle time is a function of computer resources required. Many of the EDA application algorithms, however, are not linear with respect to design size and processing times can increase as an exponential function of transistors. Therefore exploitation of hierarchy, abstraction, shared, incremental, and concurrent EDA system architectures will play an important role to overall productivity. Even with all of this, there is a major concern that industry will not be able to design a sufficient number of good circuits fast enough. Consequently, there is a major push in the semiconductor industry toward design reuse. There is a major activity in the EDA industry (Virtual Sockets Interface Alliance [VSIA] www.vsia.org) to define the necessary standards, formats, and test rules to make design reuse a reality with ICs.

Design reuse is not new to electronic design or EDA. Early TTL modules were an example of reuse, as are standard cell ASICs and PCB-level MSI modules. With each, the design of the component is done once, then qualified, then reused repeatedly in application-specific designs. Reuse is also common where portions of a previous design are carried forward to a new system or technology node, and where a common logical function used multiple times across the system. However, the ability to embed

semiconductor designs qualified for one process into chips manufactured on another, or for which the logical design was developed by one company to be used by another one results in new and unique challenges. This is the challenge that the VSIA is addressing.

The VSIA has defined the following three different types of reusable property for ICs:

1. Hard macros: These functions have been designed and verified, and have a completed layout. They are characterized by being a technology-fixed design and a mapping of manufacturing processes is required to retarget them to another fabrication line. The most likely business model for hard macros is that they will be available from the semiconductor vendor for use in application-specific designs being committed to that supplier's fabrication line. In other words, hard macros will most likely not be generally portable across foundries except in cases where special business partnerships are established. The complexities of plugging a mask-level design for one process into another process line are a gating factor for further exploitation at present.
2. Firm macros: These can be characterized as reusable parts that have designed down to the cell level through partitioning and floor planning. These are more flexible than hard macros since they are not process dependent and can be retargeted to other technology families for manufacture.
3. Soft macros: These are truly portable design descriptions, but are only completed down through the logical design level. No technology mapping or PD is available.

To achieve reuse at the IC level, it will be necessary to define or otherwise establish a number of standard interfaces for design data. The reason for this is that it will be necessary to integrate design data from other sources into the design and EDA system being used to develop the IC. VSIA was established to determine where standard interfaces or data formats are necessary and choose the right standard. For soft macros these interfaces will need to include behavioral descriptions, simulation models, and timing models. For firm macros the scope will additionally include cell libraries, floor plan information, and global wiring information. For hard macros GDSII may be supplied.

To reuse designs that were developed elsewhere (hereafter called intellectual property [IP] blocks), the first essential requirement is that the functional and electrical characteristics of the available IP blocks be available. Since internal construction of firm and hard IP may be highly sensitive and proprietary, it will become more important to describe the functional and timing characteristics at the I/Os. This will drive the need for high-level description methods such as use of VHDL behavioral models, DCL, I/O Buffer Information Specification (IBIS) models, and dynamic timing diagrams. Further, the need to test these embedded IP blocks will mandate more use of scan-based test techniques such as Joint Test Action Group (JTAG) boundary scan. Standard methods such as these for encapsulating IP blocks will be of paramount importance for broad use across many designs and design systems.

There are risks, however, and reuse of IP will not cover all design needs. Grand schemes for reusable software yielded less than desired results. Extra effort to generalize the IP block design points for broad use, and describe its characteristics in standard formats is compounded by the ability to identify an IP block that fits a particular design need. The design and characterization of reusable IP will need to be robust in timing, power, reliability, and noise in addition to function and cost. Further, the broad distribution of IP information may conflict with business objectives. Moreover, even if broadly successful, use of reusable IP will not negate the fundamental need for major EDA advances in the areas described. First, tools are needed to design the IP. Second, tools are needed to design the millions of circuits that will interconnect IP. Finally, tools and systems will require major advances to accurately design and analyze the electrical interactions between, over, and under IP and application-specific design elements on the IC. Standards are essential, but they are not by themselves sufficient for success. Tools, rules, and systems will be the foundation for future IC design as they have been over the past. Nevertheless, the potential rewards are substantial and there is an absence of any other clear EDA paradigm shift. Consequently, new standards will emerge for design and design systems, and new methods for characterization, distribution, and lookup of IP will become necessary.

14.3.2.5 DFM

14.3.2.5.1 Lithography

Because of the physical properties of diffraction, as printed features shrink, the ability to print them with the required degree of fidelity becomes a challenge for mask making. The scaling effects for lithographic resolution can be generally viewed using the Rayleigh equation for a point light source:

$$\text{Smallest resolvable feature} = K(\lambda/\text{NA})$$

Here

Value of K is a function of the photoresist process used
λ is the wavelength of the coherent light source used for the exposure
NA is the numerical aperture of the lens system

As feature shrink continues, the ITRS projects that design wafer foundry lithographic systems will keep pace by moving to light sources of smaller wavelength, photoresist systems with lower values for K, and immersion lithography. (Immersion lithography increases the maximum achievable numerical aperture ($\text{NA} = I \sin a$) beyond that in air (in air, the refractive index (I) = 1, thus $\text{NA}_{\max} = 1$), because of higher refractive indices for water and other fluids). However, the physics of light diffraction is now affecting the design of photomasks, and this will dramatically increase in importance with future technology generations.

Without attempting to discuss the physics behind them, two complications need to be accounted for in the design of a mask. First, the intensity of the light source passing through the mask and onto the photoresist is nonlinear. That is, the intensity at the edges of small features is less than that in the center. Thus, edges of small features do not print with fidelity. To compensate for this, for example on the corners of lines (which will expose as rounded edges) and line ends (which will be rounded and short), a series of reticle (mask) enhancement techniques are used. These techniques add subresolution features to the pattern data. Some examples are the addition of serifs on corners and hammerheads on line ends to extend as well as square them.

The second complication is the interference of diffracted light between adjacent features. That is, the light used to expose densely packed features may interfere with the exposure of other features in close proximity. This may be corrected for by phase-shift mask techniques or be accounted for by adjusting feature placement (spreading densely packed areas and using scatter bars to fill sparsely packed areas) and biasing feature widths to adjust for the interference.

Though these corrections are necessary for two distinct physical properties, they are generally collectively performed by optical proximity correction (OPC) programs. OPC in today's design systems is generally performed a step after the design is complete and ready for tape-out. The desired design pattern data is topographically analyzed by OPC against a set of rules or models that determine if and what corrections need to be made in the mask pattern to assure wafer fidelity. These corrections result in the incorporation of additional features to be cut into the mask such as serifs, hammerheads, and scatter bars.

With successive technology generations, the number of OPCs for a mask set will increase and cause mask pattern data to increase beyond that of Moore's Law for features. This, in turn, causes increased time (and resulting costs) in capital-intensive mask manufacturing. Therefore, future design systems will need to consider lithography limitations early in the design process (synthesis and PD) rather than at the end, and new OPC methods to optimize the mask pattern volume will be required.

14.3.2.5.2 Yield

Traditionally, wafer yield has been viewed as the responsibility of the wafer foundry alone. Hard defects caused by random particles or incorrect process settings are under control of the foundry manager and defects in feature parametrics were sufficiently bounded by design rules to be insignificant. As features shrink, small variations in print fidelity or process parameters have an increasingly important impact on

feature parasitics and this can be a significant factor in the yield of properly operating chips. Traditionally, parasitic extraction performed on the PD-generated geometry was sufficient to analyze a parasitic effect on, for example, timing. In future, because of lithography limitations, the analysis of parasitics may require extraction based on the simulated geometries that are projected to print on the wafer. Traditionally, EDA design applications can operate within the specific bounds of the design rules to yield good design. Future design applications may require that statistical analysis of their decisions be performed to account for intrachip parametric variations and to provide a design known to be good within a certain degree of probability. The topic of yield will become an important aspect of the next EDA paradigm shift.

Future design system flows will require a closer linkage between the classical EDA flow and Technology Computer Aided Design (TCAD) systems and mask making. In addition, the need for rich models that can be used to accurately predict the impacts of design choices on the results of foundry and mask manufacturing processes will become important. New design tools such as Statistical Static Timing Analysis (SSTA) have become available and are a topic of much discussion. How to incorporate the effects of variability on yield in, for example PD and synthesis will be a topic for future research. High-speed lithographic simulation, capable of full chip analysis, will be an important field for EDA R&D. Finally, database and integration technology to support this increased level of collaboration between IC designers, mask manufacturers, and the fabricating engineers will be critical.

14.4 Summary

Over the past four decades, EDA has become a critical science for electronics design. Where it may have begun as a productivity enhancement, it is now a fundamental requirement for the design and manufacture of electronic components and products. The criticality of EDA for semiconductors is the focus of much attention because of the expanding semiconductor advancements. Fundamental approaches in test, simulation, and PD are being constantly emphasized by these semiconductor advancements. New EDA disciplines are opening up. Fundamental electrical models are becoming more important and at the same time, more complex. New problems in design and IC failure modes will surely surface.

The next decade of EDA will prove to be as challenging and exciting as its past!

K

Kernighan–Lin (K–L)
algorithm, 6-12
graph bisections, 6-10
locked/unlocked vertices, 6-11–6-12
vertex exchanges, 6-11

L

Latin hypercube sampling (LHS) method, 1-9–1-11
Least-square fitting method
basis functions, 1-12
coefficient of determination, 1-12–1-13
definition, 1-11
Lee's algorithm, 6-16–6-18
Levenberg–Marquardt algorithm, 8-27
Linear equations, decompositon methods
backward substitution, 3-14
forward substitution, 3-13
matrix factorization
computation cost, 3-15–3-16
Crout's algorithm, 3-12–3-13
Doolittle's algorithm, 3-12
pivoting, 3-14–3-15

M

Maximally flat quadratic interpolation (MFQI) method, 1-15
Microprocessors
analog components, 13-2
digital signal processor (DSP), 13-2
peripheral devices, 13-1
VLSI technology, 13-2–13-3
Mixed integer-linear programming (MILP), 11-6
Model-building procedures, 1-4–1-5
MOSFET model, 9-6
MOS models
bipolar capacitance models
BJT model, 8-41–8-42
junction diode capacitor, 8-41
overlap, 8-42
DC analysis
Berkeley short-channel IGFET model (BSIM), 8-30–8-31
extraction strategy, 8-31–8-35
SPICE, 8-29–8-30
Multichip modules (MCMs), 11-5
Multi-level modeling approach
advantages, 12-8
architecture design and assessment system (ADAS), 12-7
behavioral and performance models, 12-6
functional models, 12-5
heterogeneous, 12-8–12-9
interpretation, 12-6
Petri nets, 12-6–12-7
Ptolemy project, 12-8
SystemC language
background, 12-44–12-45
C++ foundations, 12-45–12-47
channels, 12-48–12-52
crossbar contention, 12-56–12-58
crossbar model, 12-53
dual processor, 12-54
fixed cycle length, 12-61
fully connected architecture, 12-53
mixed-level processor model, 12-58–12-61
parallel communications, 12-54–12-56
performance-based modeling tool (PBMT), 12-42
performance model, 12-63–12-64
processor model, 12-47–12-48
random data generation, 12-62–12-63
shared bus architecture, 12-52–12-53
single processor, 12-53–12-54

system architecture, 12-42–12-43
task graph model, 12-42–12-44
variable cycle length, 12-61–12-62
transaction-level model (TLM), 12-8
VHDL models, 12-7–12-8

O

OPC, *see* Optical proximity correction
Operational amplifiers (op-amps)
characteristics, 2-14
compacted MNA matrix (CMNAM), 2-14–2-15
components
norator, 2-13
nullator, 2-12–2-13
nullor, 2-13
definition, 2-12
gyrator circuit, 2-15
Optical proximity correction (OPC) programs, 14-37
Optimization algorithms
constrained methods
direction method, 4-6
Lagrange multiplier, 4-5
linear programming, 4-5
others, 4-8
penalty function method, 4-5–4-6
Vaidya's convex programming, 4-6–4-8
definitions
concave function, 4-4
convex function, 4-3–4-4
convex hull, 4-3
convex programming problem, 4-4
convex set, 4-2–4-3
posynomial function, 4-4
multicriterion
design, 4-9
formulation, 4-8
minmax function, 4-10
Pareto critical point, 4-8–4-9
weighted sum function, 4-9–4-10
nonlinear problem, 4-2

P

PCBs, *see* Printed circuit boards (PCBs)
PD, *see* Physical design
Performance modeling and analysis
ADEPT design environment
design flow, 12-17
EDIF netlist, 12-17–12-18
handshaking and token passing mechanism, 12-12–12-16
interpreted and uninterpreted models, 12-9
module categories, 12-16–12-17
revolutionary approach, 12-9
token implementation, 12-10–12-12
VHDL behavioral description, 12-9–12-10
design methodology, 12-4
disadvantages, 12-2
embedded systems, 12-4
engineering/system-level design environments, 12-3
hardware/software system, 12-3–12-4
interfaces, 12-5
mixed-level modeling
behavioral models, 12-25
characteristics, 12-25
complex sequential components, 12-34–12-41
FSMD components, 12-26–12-34
interpreted and uninterpreted models, 12-23–12-24
structure, 12-24
taxonomy, 12-25–12-26
multi-level modeling approach
advantages, 12-8
architecture design and assessment system (ADAS), 12-7
behavioral and performance models, 12-6
functional models, 12-5
heterogeneous, 12-8–12-9
interpretation, 12-6
Petri nets, 12-6–12-7
Ptolemy project, 12-8
transaction-level model (TLM), 12-8
VHDL models, 12-7–12-8
product's development cycle, 12-1–12-2
queue lengths *vs.* simulation time, 12-23
risk driven expanding information models (RDEIMs), 12-4–12-5
SystemC language
background, 12-44–12-45
C++ foundations, 12-45–12-47
channels, 12-48–12-52
crossbar contention, 12-56–12-58
crossbar model, 12-53
dual processor, 12-54
fixed cycle length, 12-61
fully connected architecture, 12-53
mixed-level processor model, 12-58–12-61
parallel communications, 12-54–12-56
performance-based modeling tool (PBMT), 12-42
performance model, 12-63–12-64
processor model, 12-47–12-48
random data generation, 12-62–12-63
shared bus architecture, 12-52–12-53
single processor, 12-53–12-54
system architecture, 12-42–12-43
task graph model, 12-42–12-44
variable cycle length, 12-61–12-62
three-computer system
ADEPT model, 12-19–12-20
Data-Dependent Delay A (DDA) element, 12-20
Fixed Delay (FDA and FDB) modules, 12-19
interconnection, 12-18

weight function (wα), 5-28–5-29

Electrical Engineering

Upon its initial publication, *The Circuits and Filters Handbook* broke new ground. It quickly became **the** resource for comprehensive coverage of issues and practical information that can be put to immediate use. Not content to rest on his laurels, in addition to updating the second edition, editor Wai-Kai Chen divided it into tightly focused texts that made the information easily accessible and digestible. These texts have been revised, updated, and expanded so that they continue to provide solid coverage of standard practices and enlightened perspectives on new and emerging techniques.

Computer Aided Design and Design Automation draws together international contributors who address topics, such as the modeling of circuit performances, symbolic analysis methods, numerical analysis methods, design by optimization, statistical design optimization, and physical design automation. Building on this, they then turn their attention to high performance simulation, formal verification, system-level design, Internet-based microelectronic design automation framework, performance modeling, and embedded computing systems design.

Features

- Addresses the usefulness of symbolic analysis as a computer-aided design tool and its application to integrated circuit design
- Presents an overview of the fundamental concepts of VLSI physical design automation
- Examines the three primary simulation modes: DC, AC, and transient analysis with an overview of numerical techniques used and a discussion of common pitfalls
- Discusses analog circuit simulators and the theory behind them and provides examples that illustrate their use
- Presents a collaborative engineering framework that coordinates distributed design activities through the Internet
- Describes embedded computing systems that make use of microprocessors to implement part of the system's function

This volume will undoubtedly take its place as the engineer's first choice in looking for solutions to problems encountered in computer aided design and design automation.
